To my three marvelous girls Ella, Jess, and Flo for teaching me the importance of life outside work, to my wonderful wife Kay for being my best friend, and to my Dad for inspiring me to follow the medical path.

Mike Thomson

To what's truly important in life, my family especially the boys Karl and Dan, and my coeditors especially JEF, it has been a pleasure to work with you all.

Khalid M. Khan

To my family, who supported me all these years and taught me never to give up. It was worth it!

Holger Till

Preface

This book owes its existence to the families who brought us their babies with the difficult problem of esophageal atresia. Other families have similarly inspired each of the editors and authors of this book in their continuing efforts to treat the many difficult esophageal and gastric disorders which occur in childhood. We acknowledge our feelings of great indebtedness to these patients and families. They offered us the privilege to learn from them.

Originally, the book was only going to be a how-to-do-it surgery book, but it rapidly grew into a multidisciplinary effort. We quickly realized we needed to enlist a number of distinguished pediatric gastroenterologists as well as other pediatric surgeons to provide the necessary information. As the result of everyone's efforts, this book offers a comprehensive and detailed approach to these complex patients. We believe this is an informative and detailed resource which will be of great value for all workers in this field, but we look forward to your judgment.

Of course, the success of this book is dependent on each author's contribution, and we cannot thank them enough for their scholarly chapters and their patience. Moreover, each editor dedicated a great deal of time and energy to review the proofs. Finally, Holger and Mike, sharing the leading editorship equally, created the connections among the articles and shaped it into a unified piece of work. Of course many other peopled supported this process tremendously like Sandra Becker, Mary Merrit and Bharatwaj M.V. We thank you all.

Last but not least we return the love and energy of our families, who shared our enthusiasm and gave us strength to accomplish this work.

On behalf of all authors, editors, families, and friends, we dedicate this book to our patients and the future challenges this field presents.

Yours sincerely,
The Editors

Postscript:
Mike Thomson would like to acknowledge his coeditors in their unstinting energy and application toward the eventual conclusion of this book. He would also like to pay tribute to the patience and understanding of his friends as authors who have contributed to this massive piece of work, without whom this would not have been even remotely a feasible venture. Thank you so much for your patience while this long gestation came about. Lastly he would

like to thank most deeply for their support and, at times, bewildering faith in this project his family – Kay, his lovely friend and wife and partner, Ella, Jess, and Flo, his wildly amazing and fast-growing up daughters.

Introduction

The outlook for pediatric patients should be for 70 or more good years, a timeline which leaps well past the traditional therapeutic mileposts of length of stay (LOS) and even 5- and 10-year outcomes. The subject of this book, *Esophageal and Gastric Disorders of Infancy and Childhood*, includes some of the most serious birth defects as well as such common but potentially severe problems as gastroesophageal reflux (GER). As will be emphasized, these lesions and disorders may also have significant later consequences, and therefore success beyond childhood will likely depend on the effectiveness and durability of the early treatment. Clearly, the specific problems, if not well managed, will stand in the way of realizing 70 or more good years. Although this long-term goal may be difficult to achieve, the recent and continuing advances described in these chapters now make it increasingly possible.

The editors have designed this book *Esophageal and Gastric Disorders in Infants and Children* to be of value to all workers in this area, even the most experienced and knowledgeable. To be sure, this is also a lofty goal, and to accomplish it we have included a wide range of features in this book to broaden its value. First, both medical and surgical chapters are included and equally emphasized. Certainly, more and more information is becoming available in both the medical and surgical fields making it difficult to keep up in one's own specialty much less in other areas. The selection of the best treatment plan, however, requires some understanding of the benefits and consequences of the various options even though they may be outside of one's specialty.

Our experience has also indicated that there is less and less shared understanding between pediatricians and surgeons despite protestations from the "best" centers that this is "not true at our place." Either medical or surgical therapy will likely have benefits, especially initially, but limitations may appear over the long term, increasing the importance of the treatment decision. This book will provide the practitioner with the information on which to base these decisions. The organization of the major sections begins with normal development and function, followed by the biological bases of the disease problems to provide a background for reviewing the benefits and consequences of the therapeutic approaches. The biological features are emphasized throughout the book which we believe will make it easier to interpret the clinical situations encountered.

This book initially was to be limited to pediatric esophageal problems. As we began working with the esophageal topics, however, the stomach kept

intruding whether through the gastroesophageal junction or into the chest itself. Function moves downward while damage usually flows upward. The esophageal and gastric mucosal layers were active, intertwined, could undergo a variety of unsatisfactory changes with inflammation and injury, and were difficult to separate. Clearly, these two organs seemed to belong together from both medical and surgical standpoints.

With the scope of the book determined, the topics were selected to cover the significant biological, medical, and surgical issues of the pediatric esophagus and stomach. The distinguished contributing authors have been chosen for their insight into these problems and treatments. The range and depth provided will not only provide comprehensive current information but also establish a framework on which to build. Knowledge will continue to move ahead and a solid conceptual background will be valuable to adding and understanding future advances.

An insightful presentation of the diseases and treatments is also of real value because a worldwide consensus and uniform approach to these problems often does not currently exist. Despite the efforts of many workers in the field and attempts to provide well-reasoned recommendations, little seems to be settled in the minds of practitioners. Even for common problems such as GER and esophageal strictures, we have found individual conclusions about the severity of the findings and the resulting treatment plans not only vary widely across the world but even within institutions. The assessment and treatment of reflux, for example, is surprisingly varied among pediatricians and surgeons, and not just between them. This is despite the efforts of acknowledged experts to set detailed guidelines. For GER, the methods and difficulties of diagnosis and the judgment of its significance, as well as the evaluation of potential treatments, all pose difficulties. This book, by fully presenting the issues, should improve understanding and lead to more effective therapy.

The goal of 70 years or more also requires the active pursuit of normality. To reach this goal follow-up evaluations and treatments should be continued as necessary to be sure normality remains in sight. What will be needed in follow-up will often depend on an understanding of the longer term effects of both the abnormalities and the treatments, and this may be provided by well-designed prospective studies. At present, while evidence-based decision-making is certainly a worthwhile goal, it is in limited supply. We anticipate that the authors of this book will continue to be leaders in developing well-designed studies. However, in the meantime, practitioners must select and provide treatment based on the information available. The contents of this book will be aimed to aid the practitioner in making these decisions.

The biological underpinning of the clinical situations is of particular importance for pediatric problems. Not only are most congenital defects the result of developmental abnormalities, but there is also an active background of continuing normal development, which increases complexity in management generally. What might seem to be routine treatments with defined consequences in the adult population may be of far greater significance in the infant and child. Of course, there are significant biological factors in the treatment of adult patients but active development has ended, leaving the background reasonably stable.

In children, therapy directed at a disease process will be superimposed on continuing normal development and all are inter-related and may be affected. Whether medical or surgical, any therapy which affects function or anatomy over a long period will likely have several consequences. The commonly used acid suppression treatment of reflux esophagitis, for example, may produce significant effects on the development of the stomach, in particular, the acid-producing cells. Other areas of development may also be affected by the medications and, perhaps, impaired calcification will lead to decreased bone density. Such considerations become greater the longer the planned therapy.

Common surgical operations, such as fundoplication, may also have significant later consequences. A thoracotomy incision which results in the fusion of ribs and/or the loss of innervation of the serratus anterior muscle might produce significant problems including scoliosis. Granted, no current operation is in its final form, but the principles and details that comprise the surgical goals should be accessible and are some of the additional considerations that must be factored in when selecting therapy. Consequently, each surgical writer will present not only the indications for the operations along with the important details that will make for a successful repair but also, as far as possible, the long-term biological consequences and later problems associated with them. These issues are present in virtually all therapeutic choices and have increased importance when carried out against the background of growth and development. Predictably, the longer view will be more and more thrust upon us.

In keeping with the long view in treating these patients, it is recognized that many of these esophageal and gastric disorders may have significant later consequences. Another feature of this book, therefore, has been carrying the information on the disease processes and effects of treatment into early adulthood. For those caring for children, there almost seems to be an assumption that life does not go much beyond age 16, a proposition for which there is little evidence. The teenager is handed off "doing well" to practitioners caring for young adults and, in effect, disappears. The later consequences, however, of GER and the long-term effects of the other types of treatment used in childhood, whether medical or surgical, illustrate the importance of the longer view.

Treatment may require a choice between a relatively easy short-term solution and one that appears more difficult but which has significant long-term advantages. This conflict is most often present in surgical approaches. An operation which produces a desirable short LOS does not necessarily place the child on a path to 70 or more good years. This goal may be an unwelcome burden for the surgeon whose peace of mind as well as reputation depends on a shorter LOS and the occurrence of only "acceptable" complications. Problems which may occur 20 or 30 years later may not even be considered. The spread of information and the inevitable increasing emphasis on long-term results, however, will make these considerations necessary.

The therapy of difficult lesions and diseases may run the risk of setting in motion new problems or the substitution of one disease state for another. Palliative solutions are sometimes necessary but, by definition, bring their own form of chronic problems, and, with time, the deficiencies will become

increasingly apparent. Transplantation, with the need to hold off rejection, provides a clear example of the problems that predictably result from substituting one disease for another. Less obvious are other treatments which significantly alter anatomy and function, such as interposition grafts for esophageal atresia (EA), but the consequences may also be unsatisfactory. Palliation, although accepted and sometimes necessary, should be limited for the best long-term results.

We have emphasized the biological theme of this book, as is well illustrated by the chapters on the recent enlistment of developmental responses to solve some of the most severe problems. The use of growth induction on the small esophageal segments for patients with esophageal atresia (EA), for example, provides a biological solution for the traditionally difficult defect of long-gap esophageal atresia (LG-EA). At the extreme end of the EA spectrum, the entire thoracic esophagus may be missing, making the possibility of using only the esophagus for the repair apparently impossible. The developmental potential, however, is great and even very small (2–3 mm) esophageal primordia have been induced to grow into an outwardly normal lower esophagus. This has been a spectacular example of using a biology-based therapy to solve the problem of a significant congenital defect (Chaps. 22 and 25). Long, recalcitrant esophageal strictures have also been difficult to treat and typically have led to gastric or colon interpositions. A variation on the tension-induced esophageal growth approach has been used to treat the significant problem of long strictures by using staged resections with greatly improved long-term results (Chapter 34). These are the most noteworthy examples of the biological approach but others will follow.

Another strength of this book is the detailed explanations of the surgical treatment of some of the most severe problems. Growth induction provides an excellent solution to LG-EA, but less well known are the technical difficulties in achieving a good growth response. The details helpful in growth induction as well as in the surgical treatment of related problems such as the difficult esophageal anastomosis, tracheomalacia, and re-operative strategies among other procedures are presented. These descriptions will overcome the space and page limitations of journal articles and be valuable to surgeons.

A developmental solution requires that the defect is not primarily genetic in origin and all the information necessary for a catch-up response is present. Although congenital defects are often loosely thought to be genetic in origin, the evidence suggests these problems arise primarily from faulty development. EA, for example, seems to result from the faulty budding of the trachea from the primordial esophageal tube and the creation of a gap between the upper and lower esophageal segments. With the segments separated and the entire esophagus no longer acted on by the tension of the growing spinal column, the gap may increase in length. The outwardly wide EA spectrum predictably begins with a central defect and is determined by the length of the gap and the presence or absence of residual fistulas into the airway.

Despite the apparent complexity of the EA spectrum, development can be effectively restarted. Only the signal is missing which is able to trigger the well-orchestrated three-dimensional growth seen during development. Catch-up growth can be reliably induced in the small and widely separated

esophageal segments by providing the missing signal. The signals themselves have usually proven to be very straightforward biomechanical stimuli, and for the esophagus, axial tension will produce effective growth of the smallest segments. The tension principle of esophageal growth induction, as noted, has also been extended to acquired problems, such as long recalcitrant strictures.

When a principle is basic and effective, it is likely to have other general applications with improved treatment solutions. Although not applicable to every problem, there are other examples of tissue or organ deficiency where it has been used with impressive results. For patients with a hypoplastic cardiac ventricle, induced growth has produced two usable ventricles and has avoided a palliative solution which brings increasing problems over the succeeding years. Currently, an intra-abdominal testis is most commonly treated by dividing the arterial blood supply, losing most, if not all, function. Traction, however, will stimulate catch-up length and an improved result. Deficiencies of skin and abdominal wall are commonly treated with tissue expanders to aid closure. These devices were initially thought to involve only skin stretching, but basic studies have shown a proliferative response to the tension by the many cell types involved. Effective induced lengthening of the remaining intestine in the short gut syndrome would greatly speed the transition from hyper-alimentation and costly elemental solutions to a more normal diet. For all of these problems, as with LG-EA, the traditional treatments have been palliative or otherwise unsatisfactory for the long term. The use of these biological solutions with the induction of normal development has moved the outlook for these patients far closer to normal, with fewer adverse consequences and better long-term results.

When we focus on anatomy, embryology, and function dependent on these abnormalities which are caused by chance, we must remember that medicine has evolved massively over the last 30 years and that approaches which are not just reparative in a surgical sense may be beneficial to the quality of life of an individual affected by such issues. Indeed the advances in medical and pharmaceutical approaches have been enormous in this time span and should be and are, emphasized, within this text. For instance, it was only understood in the early 1990s that *Helicobacter pylori* was the primary cause of peptic ulcer disease and not, as previously thought, an overactive vagal nerve stimulated acid production from the stomach. So went Billroth-type operations and selective vagotomies. Medical approaches recently have therefore challenged surgery to produce reasons for the traditional approaches, and we see the obvious advantages now. Similarly, surgical solutions such as open fundoplication have been supplanted by laparoscopic approaches which, in turn, have been challenged by endoscopic trans-oral approaches – which are receiving a great deal of attention at present and are promising. Long-term anti-acid medical treatments are generally safe and may be attached to less morbidity than surgical solutions, and this area has received considerable attention in this book. So, while medical and surgical approaches are both effective, it must be identified that a joint approach in pediatrics is mandatory if we are to achieve a balanced management strategy for many of these complex conditions. We would never suggest that a pure surgical or medical approach is ideal for an

empyema or a subdural hematoma, for example, and this is equally true in this field involving the upper GI tract. This is what makes this book unique – as, for the first time, surgeons and pediatric gastroenterologists have come together to produce the first text on these complex topics which is of a bilateral genre. Pediatric gastroenterologists and surgeons alike do not live and work in bubbles isolated from one another in the real world but work in superb harmony (in the best centers) and to the advantage of the families and children they serve. Long may this continue and we hope that this text will serve to perfect that partnership as the editorship has also done. When we look to the future, we can see many options and opportunities that involve closer collaboration between medical and surgical GI doctors and teams. They may also involve such specialities as bioengineering, molecular biology, genetics, neuroimmunology, neurogenetics, tissue modeling, etc., but not forgetting the traditional team-orientated approaches involving our colleagues in GI physiology, feeding therapy, psychology, dietetics, GI nursing, stoma therapy, and pharmacology to name only a few. We hope that this multispecialty book will appeal and educate many within our multidisciplinary specialty and conjoin medicine and surgery toward a greater theme which is collaboration and a more effective collateral approach going forward.

As stated at the beginning of the Introduction, the goal in pediatric therapy must be for 70 or more good years, and this is a stringent requirement. The problems encountered in pediatric patients are a unique mixture of developmental and genetic defects, which play out on a continuing background of normal and abnormal development. For these young patients, the often long-range consequences of both diseases and treatments must also be kept in mind. The aim of this book is to clarify as much as possible these complex events and the therapeutic options. Treatments which enlist normal biological responses, we believe, will have particular value and, as this approach becomes better understood and the applications expand in number, the goal of 70 or more good years will come into view for even the most difficult of these problems.

Part I

Introduction

The Biology of Defects, Disease, and Treatments

1

John E. Foker

The origins of this book began with the success in growing the smallest esophageal segments to normal size in patients with esophageal atresia (EA). It had become clear that the growth procedure effectively tapped into the considerable developmental potential of even the most rudimentary blind ends of the esophagus allowing the benefits of a true primary repair to be realized across the full EA spectrum [1]. Although congenital defects are often loosely considered to be primarily genetic mistakes, the evidence suggests that many of these problems arise from faulty development and, therefore, are potentially reversible. A tiny esophageal primordium poses an obvious obstacle to a primary esophageal repair; however, only the signal is required to effectively restart the well-orchestrated and complex three-dimensional organ development. The signal for the growth and development of organs and tissue is often a biomechanical stimulus, and in the case of long gap EA, axial tension provides it [1, 2].

This biological approach also opened up related questions which needed answers. The questions included the quality of the esophagus recently subjected to catch up growth, the characteristics of the gastroesophageal (GE) junction, as well as the universal debates which surround the treatment of GE reflux (GER). Because strictures frequently developed at the anastomotic site, this response also needed improved understanding. All of these issues can be viewed as biological questions, and the answers will be important to designing effective therapy.

What had started as essentially a surgical monograph on EA was greatly expanded to contain chapters about all of the disorders of the esophagus and stomach in childhood. The book now features the wide variety of medical approaches to these problems as well as providing expanded surgical techniques which emphasize the underlying biological principles. As a result of this comprehensive approach, the possible obstacles to unfavorable long-term outcomes may be recognized and overcome. For pediatric caregivers, long-term outcomes leap well beyond the 5- or 10-year results common in the adult world to a goal of 70 good years, making the active pursuit of normalcy necessary.

The editors have designed this book on esophageal and gastric disorders in infants and children to be of value to all workers in this area, even the most experienced and knowledgeable. To be sure, this is a lofty goal, and to accomplish it, we have greatly increased the breadth and depth of this book. Certainly, more and more information is becoming available in each field making it difficult

DOI 10.1007/978-3-642-11202-7_1

to keep up in one's own specialty much less in other areas. The selection of the best treatment plan, however, requires some understanding of the benefits and consequences of the various options even though they may be outside of one's specialty. Our experience has also indicated that there is less and less shared understanding between pediatricians and surgeons despite protestations from the "best" centers that this is "not true at our place". A medical or a surgical therapy will likely have benefits, especially initially, but limitations may appear over the long term, increasing the importance of the treatment decision.

An insightful presentation of diseases and treatments is also of real value because, currently, a world-wide consensus and uniform approach to these problems often does not exist. Even for common problems such as GER and despite the efforts of many workers in the field and attempts to provide well-reasoned recommendations, little seems to be settled in the minds of practitioners. The assessment and treatment of GER is surprisingly varied among pediatricians and surgeons, as well as between them. Esophageal strictures also remain unsettled, and we have found that individual conclusions about the severity of the findings and the resulting treatment plans vary widely not only across the world but even within institutions. The chapters in this book also reveal that disagreements may exist even among those knowledgeable and experienced. Understanding should be improved, however, by fully presenting the issues which will help practitioners achieve more logical treatment plans.

The goal of 70 years requires an active pursuit of normalcy. For the goal to be reached, follow-up evaluations and treatments are often required to be sure normalcy does not slip away. Well-designed clinical studies with longer follow-up will be expected and, eventually, demanded by families as well as practitioners. At present, while evidence-based decision-making is certainly a worthwhile goal, it is in limited supply. We anticipate that the authors of this book will continue to be leaders in developing well-designed studies which will contribute to the evidence base; in the meantime, however, practitioners must select and provide treatment based on the information available. The contents of this book will aid making these decisions.

The biological underpinning of the clinical situations is of particular importance for pediatric problems. The developmental abnormalities of many congenital defects exist against an active background of continuing normal development, which greatly increases the complexity. Whether medical or surgical, any therapy which affects development over a long period will likely have consequences. The commonly used acid suppression treatment of reflux esophagitis, for example, may produce significant effects on the development of the acid-producing cells. Other effects may be more distant, and the proton pump inhibitors, for example, may alter calcium metabolism and slowly lead to decreased bone density. Such considerations become greater the longer the planned therapy. What might seem to be routine treatments with defined consequences in the adult population may be of far greater significance in the developing infant and child.

Surgical treatments may also have significant later consequences. A thoracotomy incision which results in the fusion of ribs and/or the loss of innervation of the serratus anterior muscle predictably leads to significant chest wall problems which may include scoliosis. Certainly, the various interposition grafts for long gap EA often have increasing problems with time, and these should be considered when selecting the initial therapy. Granted, no current operation is in its final form, but the principles and details that comprise the surgical indications and goals as well as the long-term outcomes should be accessible and part of the therapeutic considerations. Because operations in children are carried out against the background of growth and development, the longer view will be more and more thrust upon surgeons.

For those caring for children, there almost seems to be an assumption that life does not go much beyond age 16; a proposition for which there is little evidence. The teenager is handed off "doing well" to practitioners caring for young adults and, in effect, disappears from the pediatric world. The long-term consequences of GER, for example, and the later effects of other therapies used in childhood, whether medical or surgical, illustrate the importance of the longer view.

Treatment unfortunately may require a choice between a relatively easy short-term solution and one that appears more difficult initially but which has significant long-term advantages. This conflict is most often present in surgical approaches. An operation which produces a desirable short length of stay (LOS) does not necessarily place the child on a path to 70 good years. The latter goal may be an unwelcome burden for the surgeon whose peace of mind as well as reputation depends on a shorter LOS and the occurrence of only well-recognized and "acceptable" complications. Currently, problems which may occur 20 or 30 years later might not even be considered. The spread of information and the inevitable increasing emphasis on long-term results, however, will make these considerations necessary.

The therapy of difficult lesions and diseases may also run the risk of setting in motion new problems or the substitution of one disease state for another. Palliative solutions are sometimes necessary but, by definition, bring their own chronic issues, and, with time, the deficiencies will become more important. Transplantation, with the need to hold off rejection, provides a clear example of the problems that predictably result from substituting one chronic disease for another. Interposition grafts for EA, as mentioned, significantly alter anatomy and function and the later consequences are often unsatisfactory. Palliation, although sometimes necessary, will likely be less frequently used.

This book also provides detailed explanations, which are not readily available elsewhere, of the surgical treatment of some of the most severe problems. Growth induction provides a good solution to the difficult problem of LG-EA, but there are technical demands in achieving a good end result. The details helpful in growth induction as well as in the surgical treatment of related problems are presented. As our practice has shown, a number of complications can result even from routine EA/TEF repairs as well as from other esophageal and gastric operations. Consequently, the surgical topics include the difficult esophageal anastomosis, the long stricture, the recurrent TEF, a large diverticulum, the partial intrathoracic stomach, significant tracheomalacia, and various re-operative strategies. Pediatric surgeons will recognize the biological solutions to many of these problems are a departure from current approaches. Because the objectives are more nearly normal anatomy and function, however, they should be considered. The surgical descriptions will overcome the space and page limitations of journal articles and should be helpful.

When a principle is basic and effective, it is likely to have other general applications with improved treatment solutions. Although not applicable to every problem, there are other examples of tissue or organ deficiency where growth induction has been used with impressive results. Deficiencies of skin and abdominal wall are commonly treated with tissue expanders to aid closure. These devices were initially thought to involve only skin stretching, but basic studies have shown a proliferative response to the tension by the many cell types involved [3]. For patients with a hypoplastic cardiac ventricle, increased flow across the AV valves induced growth and produced two usable ventricles [4]. Longitudinal tension has induced growth of the small intestine experimentally [5]. Traction has lengthened intra-abdominal testes and allowed a normal location [5]. For these problems of organ deficiencies, as previously with LG-EA, the traditional treatments have been palliative or otherwise unsatisfactory for the long term. The use of biological solutions and the induction of normal development have moved the outlook for these patients far closer to normal.

Of additional biological interest is that in these applications of growth induction, the stimulus is variable which may be important to a maximum response. Although the biomechanical growth signal is increased at intervals, the strength wanes as growth occurs. The importance of variable signal strength to maximize growth has been more rigorously demonstrated in cell culture experiments [6]. Interestingly enough, this important observation was made first, although not fully recognized in the clinical treatment of LG-EA.

As stated at the beginning of the Introduction, the goal in pediatric therapy must be for 70 or

more good years, and this is a stringent requirement. The problems encountered in pediatric patients are a complex mixture of developmental and genetic defects, which play out with a continuing background of normal and abnormal development. The aim of this book is to clarify as much as possible these complex interactions to guide the therapeutic options. Treatments which enlist normal biological responses, we believe, will have particular value [7]. As this approach becomes better understood and the applications expand in number, the goal of 70 good years will come into view for even the more difficult of these problems.

2 The Genetics and Molecular Biology of Oesophageal Development

Stephen P. Robertson and Spencer W. Beasley

Epidemiology

Incidence

The incidence of EA/TEF has been measured in three large epidemiological studies drawn from populations in Europe and California and from a worldwide collaboration [3–5]. These studies identified a relatively invariant incidence ranging between 2.55 and 2.86 cases per 10,000 births. The proportion of cases defined as isolated EA (in contrast to those with one or more additional congenital malformations) ranged from 38.7 to 57.3 %. All three studies included cases complicated by chromosomal anomalies. It is likely that exclusion of early foetal deaths in the international study, many of which would be associated with multiple additional malformations, has led to an overestimate of the proportion of EA that is truly isolated in nature and accounts for some of the variation in these estimates between the three studies. In all three cohorts, there was a male preponderance of cases ranging from 52 to 62 % of the total sample. Of all infants with EA/TEF, 50 % have associated congenital anomalies. Many represent the presence of a syndrome for which mutations in a single gene of major effect are responsible (see below) or represent instances of a recognised association, the primary mechanistic basis of which has not been defined.

Effect of Parity and Birth Weight

Extremes of parity and low birth weight are both associated with EA/TEF [6]. The malformation is over-represented in prematurely born infants although the explanation for this may partially lie in concomitant obstetric complications (e.g. maternal polyhydramnios) that frequently complicate such pregnancies and can precipitate premature labour.

Twinning

The rate of twinning is increased in association with EA (7 % vs 2.3 % in the Royal Children's Hospital, Melbourne study) [7–9]. Additionally twins are at an elevated risk (2.56-fold; 95 % CI 2.01–3.25) of having EA although such twin pairs will generally be discordant for the malformation (concordance rate 2.5–4 % [6, 9]).

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_2

The interpretation of these data is, as is the case with many congenital anomalies, that twinning itself seems to constitute a risk factor although the biological basis for this phenomenon is poorly understood. In one study [9], mean birth weight, gestational age and survival were lower in twin infants with EA/TEF compared to affected singletons. Similarly, congenital anomalies were also over-represented in this group.

Teratology

Although exposure to certain medications and infections during pregnancy has been proposed as a possible risk factor for the development of EA/TEF, no external factor has been consistently linked to its development [10]. Candidate teratogens that may result in EA/TEF include mycophenolate mofetil [11], methimazole [12] and related agents such as carbimazole [13] that may lead to a specific embryopathy which includes EA/TEF [14, 15]. It is noteworthy that carbimazole exposure is also associated with choanal atresia and colobomata – both major criteria for a diagnosis of CHARGE syndrome, a monogenic disorder that is also associated with EA/TEF [16, 17]. This observation would be consistent with a mechanistic basis for the teratogenic effect of these antithyroid drugs that involves the gene mutated in CHARGE syndrome, *CHD7* (see below) and/or cellular components that relate directly to its function as a chromatin-modifying protein.

Despite the lack of clear causal links with environmental agents in humans, the successful development of a mammalian model for EA using the administration of Adriamycin to pregnant rats raises the possibility that EA/TEF could result from teratogenic exposure in humans.

The Genetics of Oesophageal Atresia

It is convenient to divide EA/TEF into two groups: those presenting with EA/TEF as part of a syndrome, the so-called syndromic esophageal atresia (SEA), and those individuals in whom EA/TEF is an isolated abnormality and not part of any syndrome – isolated esophageal atresia (IEA). It must be acknowledged that although this categorisation may be useful for epidemiological purposes, SEA can initially present as IEA in a family due to the wide clinical variability associated with some of the syndromic entities that include EA/TEF as a phenotypic component.

Recurrence Risk

For individuals with isolated EA/TEF without a clear aetiology, the recurrence risk for sibs for the same malformation is less that 1 % [1, 18, 19]. No comparative data for recurrence risks for isolated versus non-isolated EA/TEF are available, although the relevant recurrence risk for some aetiologies (e.g. aneuploidy, monogenic syndromes) is well established. This fact underscores the importance of seeking as precise a diagnosis as possible for all infants with syndromic or non-isolated EA/TEF and the limitations of treating these designations as a homogeneous group. Due to several decades of improving surgical and postoperative management of infants with EA/TEF, figures are becoming available that estimate the risk to offspring of individuals with TEF. In this instance, the recurrence risk is, like the sibling recurrence risk, also in the region of 1 % [18], providing further evidence that genetic factors do not play a substantial role in the cause of EA/TEF.

Although the recurrence of EA/TEF itself is low, there is evidence that first-degree relatives of individuals are at an elevated risk of associated anomalies. For individuals with EA/TEF without a clearly defined aetiology, the recurrence risk to first-degree relatives for EA/TEF or for a wide spectrum of malformations that fall within the VACTERL group of anomalies (see below) is elevated twofold over the general population risk figure [19, 20]. These estimates apply to offspring of individuals with both isolated and non-isolated EA/TEF but importantly exclude those with a clear chromosomal or Mendelian aetiology.

Genetic Syndromes

An identifiable syndrome underlies the presentation of EA/TEF in approximately 50 % of cases. These genetic entities include Mendelian syndromic disorders, segmental chromosomal aneuploid states and trisomy for several chromosomes. For several of these Mendelian disorders, a causative gene has been identified and a substantial amount is known of the developmental pathways in which some of these operate (see below). Tellingly, however, no genetic factors have been identified that contribute to isolated, non-syndromic EA/TEF, reflecting the epidemiological evidence that genetic factors are not predominant in the causation of non-syndromic forms of this malformation.

The study of syndromic EA/TEF with a confirmed genetic aetiology in conjunction with experiments in animal models has done the most to advance understanding of the biology of EA/TEF over the last 20 years. For example, in those instances of EA/TEF where an underlying genetic aetiology has been defined, no confirmed association has been identified between these genetic etiological categories and the five subtypes of EA/TEF (A–E) [1] defined on anatomical grounds. This suggests that these subtypes represent a disruption at various stages on a continuum to which multiple genetic and environmental factors contribute.

Chromosomal Disorders Associated with EA/TEF

In complete surveys of fetuses and infants with EA, 6–10 % of cases will have a chromosomal anomaly that is visible on G-banded karyotypic analysis [3–5]. The commonest aneuploid states that are associated with EA include trisomy 18 and trisomy 21 [21–24]. In terms of absolute risk, the incidence of EA complicating trisomy 18 is greater (~25 % of all individuals with trisomy 18) than that in trisomy 21 (~0.5–1.0 % of individuals affected with trisomy 21) [21–24]. EA has been reported as a much less frequent accompaniment of trisomy 13 and trisomy 8 mosaicism.

Segmental Chromosomal Imbalance

Segmental chromosomal aneuploidy refers to a group of conditions that are characterised by chromosomal imbalance (either a duplication or deletion) that is less than an entire chromosome in extent. The identification of such imbalances as correlated with certain specific malformations can serve as a useful first approximation of the whereabouts of single genes that lead to the same phenotypic effect when disrupted. Several loci characterised by recurrent imbalance that is frequently (but not always invariably) associated with EA/TEF have been identified. The non-random occurrence of these associations indicates the existence of specific genes that when mutated will lead to EA/TEF in a proportion of individuals – although the phenotypic result, as noted above, tends to be a syndromic presentation of EA/TEF rather than isolated disease [21].

The most frequently observed segments of chromosomal imbalance that have been observed in association with EA/TEF are:

- Deletions of 2q37.2-qter [25], 3q27-ter, 4q35-qter, 5p15-pter, 6q13-q15, 12q24-ter [26], 13q34-qter, 14q32.3-qter, 17q22-q23 [27, 28] and 22q11 [29, 30]
- Duplications of 3p25-pter and 5q34-qter

Additionally other chromosomal anomalies have been reported that may also give some indication to the location of genes predisposing to the development of EA/TEF:

- Patients with deletions on 13q present with anomalies resembling the VACTERL association within which EA/TEF is represented.
- A chr 6;15 reciprocal translocation disrupting the *BPAG* gene has been studied in a single patient with neurodevelopmental disability and EA [31].

Genetic Syndromes with a Defined Monogenic Aetiology

The definition of chromosomal regions and aneuploid states can give a broad indication that genetic factors play a role in the etiopathogenesis of oesophageal atresia. However, defining exactly what genes and pathways play a direct role in

humans has been difficult, at least until the relatively recent description of the genetic basis of several Mendelian disorders that feature EA/TEF as a prominent phenotypic component. Several genes involved in syndromic forms of EA/TEF that are inherited in an autosomal dominant fashion have been identified recently (*N-MYC*, *SOX2* and *CHD7*). Only one recessively inherited entity (Fanconi anaemia) demonstrates EA/TEF as a recurrent (albeit still infrequent) component of its presentation. Two X-linked disorders also have EA/TEF as a presenting feature and indicate that their underlying genes play a role in the partitioning and canalisation of the upper aerodigestive tract.

Autosomal Dominant Syndromic EA/TEF (Table 2.1)

Anophthalmia-Esophageal-Genital (AEG) Syndrome (MIM 206900)

AEG syndrome is an autosomal dominant multiple malformation syndrome characterised by anophthalmia/microphthalmia, EA/TEF and anomalies of the urogenital tract (cryptorchidism, hypospadias and hypogentialism). Mutations in *SOX2* are responsible [32]. Patients with point mutations in *SOX2* can also manifest hearing loss and variable degrees of psychomotor retardation. Chromosomal anomalies encompassing this locus, as well as point mutations and intragenic deletions, indicate that the mode of action of these mutations is via haploinsufficiency for the SOX2 protein. SOX2 is a transcription factor that has established roles in organogenesis, most notably in the eye [33], in the hypothalamic-pituitary axis and in the differentiation of epithelium in the developing aerodigestive tract. Murine expression of *Sox2* is highest in the developing foregut endoderm which develops to form the future oesophagus and stomach. Mice whose *Sox2* has been selectively deleted from the anterior epithelial field of the developing anterior foregut have defective epithelial-mesenchymal interactions and tracheal branching in addition to EA/TEF [34, 35].

CHARGE Syndrome (MIM 214800) [36, 37]

This multiple malformation syndrome is clinically defined by the presence of major and minor criteria. The major criteria for diagnosis include the presence of colobomata of the eye, heart anomalies, atresia of the choanae, retardation of mental and somatic development, genital hypoplasia and ear abnormalities and/or hearing loss. Although not a major criterion, EA/TEF is present in approximately 10 % of cases [36, 38]. CHARGE syndrome usually presents as a sporadic disorder in families, but occasional parent-child transmissions have been recorded. The genetic basis of nearly all cases of the condition is mutation in the chromodomain-helicase DNA-binding domain-containing protein, *CHD7*. Mutation types include point mutations, intragenic deletions and whole-gene deletions [1, 36, 37, 39]. The function of *CHD7* is to regulate the transcriptional activity of broad arrays of genes in a reversible

Table 2.1 Autosomal dominant syndromes with assigned genes associated with EA/TEF

Syndrome	Gene	Locus	Clinical manifestations
Anophthalmia-oesophageal-genital syndrome	*SOX2*	3q26.3	Anophthalmia/microphthalmia, EA/TEF urogenital tract anomalies
CHARGE syndrome	*CHD7*	8q12.1	Ocular colobomata, cardiac anomalies, choanal atresia, mental and growth retardation, genital anomalies, auditory anomalies
Feingold syndrome	*MYCN*	2p24.1	Oesophageal and duodenal atresia, microcephaly digital anomalies, cardiac defects

manner during development through epigenetic modification of heterochromatin [40]. Upon the description of *CHD7* as the underlying causative gene in CHARGE syndrome, it was anticipated that understanding the targets that are regulated by this protein would indicate genes and pathways that are subverted to lead to the multiple malformations in diverse organ systems in this condition. At this time, few such targets have been defined [40].

Feingold Syndrome (MIM 164280)

This autosomal dominant condition is characterised by variable combinations of gastrointestinal tract atresia, the two principal forms being oesophageal and duodenal atresia. Anorectal malformations have also been described [41]. The syndrome also features microcephaly, learning disabilities, digital anomalies and cardiac defects [42]. The digital anomalies, although seldom incapacitating, can be characteristic and in conjunction with EA/TEF are highly suggestive of the diagnosis. These anomalies include brachydactyly due primarily to shortening of the middle phalanges of digits 2 and 5. Clinodactyly of the same digits together with syndactyly of the toes also occurs. Individuals with Feingold syndrome are heterozygous for mutations and deletions of *N-MYCN* [43]. *N-MYC* is a regulator of the hedgehog signalling pathway, a set of genes that are activated widely throughout multiple organ systems in development including the brain, heart and developing limb in addition to the foregut. The discovery that mutations in this gene lead to EA was therefore congruent with the findings in the rat that hedgehog signalling is dysregulated in drug-induced EA (see below). Notably, point mutations in *N-MYC* were only observed in exons incorporated in full-length *NMYC* transcripts [44], indicating that domain-specific functions were at the heart of the pathogenesis of this condition. A knockout mouse model of the gene orthologous to human *N-MYC* produced multiple malformations, but not EA as is seen in the Feingold syndrome [45].

Oesophageal Atresia/ Tracheoesophageal Fistula in Recessively Inherited Syndrome

Fanconi Anaemia (Table 2.2)

Fanconi anaemia is characterised by bone marrow failure, short stature, skin pigmentary anomalies, hearing loss, developmental delay and a wide variety of congenital malformations that can include radial ray, eye, renal, cardiac and central nervous system anomalies. Gastrointestinal anomalies, including EA/TEF, are observed frequently. Due to their close similarity in clinical presentation, it is not uncommon for sporadic presentations of Fanconi anaemia to be misdiagnosed as the VACTERL association. It is essential that Fanconi anaemia is definitively excluded in infants who appear to have the VACTERL association because of its markedly different natural history and recurrence risk [46].

Mutations in all but one of the genes implicated in the causation of Fanconi anaemia are associated with autosomal recessive inheritance. The exception is the *FANCB* locus which is located on the X chromosome. An X-linked subtype of VACTERL association has been described that incorporates hydrocephalus as a clinical manifestation and is caused by mutations in the *FANCB* gene [47].

X-Linked Syndromic EA/TEF (Table 2.3)

Opitz syndrome is characterised by midline abnormalities including cleft lip, heart defects, hypospadias, agenesis of the corpus callosum and laryngeal clefts. Occasionally EA/TEF is observed, although laryngotracheal clefts are the most commonly occurring malformations in the tracheoesophageal complex [48]. Mutations in *MID1* lead to the syndrome [49]. The pathophysiological connection between *MID1* and other pathways implicated in EA may lie with its role in asymmetrically distributing Gli transcription factors in the early developing embryo [50, 51].

VACTERL association with hydrocephalus (VACTERL-H) is characterised by vertebral anomalies, anorectal malformations, cardiac malformations, EA/TEF, renal and limb anomalies

Table 2.2 Autosomal recessive syndromes with assigned genes associated with EA/TEF

Syndrome	Genes	Clinical findings
Fanconi anaemia	*FANCA*, *FANCB*,*FANCC*, *FANCD2*,*FANCE*, *FANCF*,*FANCG*, *FANC*,*BRIP1*, *FANCL*,*FANCM*, *PALB2*	Bone marrow failure, predisposition to malignancy, short stature, abnormal skin pigmentation, radial ray limb anomalies, renal and cardiac defects; developmental delay gastrointestinal anomalies including EA/TEF

Table 2.3 X-linked syndromes with assigned genes associated with EA/TEF

Syndrome	Gene	Locus	Clinical findings
Opitz syndrome	*MID1*	Xp22	Cleft lip, laryngeal clefts, heart defects, hypospadias, EA/TEF (rare)
VACTERL-H	*FANCB*	Xp22.31	Vertebral anomalies; anal atresia; EA/TEF; renal, cardiac and limb anomalies; hydrocephalus

and hydrocephalus. Mutations in the *FANCB* have been associated with this phenotype [47].

Genetic Syndromes with an Undefined Genetic Aetiology

Several other syndromes currently defined by their clinical presentation have had EA/TEF reported as a phenotypic component in a variable number of instances:

- A syndrome incorporating supernumerary nostrils, EA and persistent ductus arteriosus [52]
- A syndrome incorporating EA, hypoplasia of the zygomatic arch complex, mental retardation, congenital heart defects and microcephaly [53]
- Martinez-Frias syndrome (multiple gastrointestinal tract atresias; MIM 601346)
- Bartsocas-Papas syndrome (lethal multiple pterygium syndrome; MIM 263650)

Fryns syndrome (diaphragmatic hernia, coarse facies, digital anomalies; MIM 229850)

Associations

An association is a non-random co-occurrence of clinical features without evidence for them being collectively caused by a defined single etiological factor. Associations differ from syndromes in that the co-occurrence of clinical manifestations in syndromes is due to an identifiable shared cause that can be either environmental or genetic or a combination of both.

VATER/VACTERL Association (OMIM 192350)

This is defined as the non-random association of *v*ertebral, *a*nal, *c*ardiac, *t*racheoesophageal fistula, *r*enal and *l*imb defects. It was initially described as the VATER association, but subsequent, more rigorous attempts to define which malformations are genuinely associated with each other (as opposed to representing artefacts of ascertainment) led to extending the association to include cardiac and limb defects. Approximately 10% of infants with EA/TEF have at least two of the other defects included in the VACTERL spectrum and can be said to have VACTERL association if a specific syndromic diagnosis cannot be reached [54]. Nearly one half of individuals with EA/TEF will have malformations in the VACTERL spectrum of anomalies [19], a fact ascribable to the considerable overlap between the forms of malformation that co-occur in defined syndromes and those also found as a component of the VATER/VACTERL spectrum. Although the sibling recurrence risk for VACTERL is low and familial occurrences rare,

first-degree relatives of individuals with EA are at elevated risk of having malformations within the VACTERL spectrum, an observation that is consistent with ill-understood genetic determinants contributing to the VACTERL spectrum of anomalies [19, 20]. Moreover, mice with mutations in genes within the Shh and Gli pathways demonstrate malformations within the spectrum of VACTERL anomalies, hinting that signalling by these genes is involved in the pathogenesis of these malformations.

Schisis Association

This condition represents a non-random association of neural tube defects with exomphalos (omphalocele), oral clefts and posterolateral diaphragmatic hernia [55]. An elevated incidence of oesophageal atresia has been noted in association with neural tube defects in experimental animals, but whether EA/TEF is also over-represented in similar instances in humans remains to be established.

Molecular Biology of Oesophageal Atresia

Until recently, embryologists have largely concerned themselves with detailed description of the changes that occur in the morphology of the growing embryo, and the vocabulary of embryogenesis has been that of cell differentiation, differential cell growth, body layers folding, fusion and division. With advances in genetics and molecular biology, interest has increasingly focused on the processes that occur at a cellular level and gene patterns of expression and elucidating gene signalling pathways. The following pages are devoted to some recent observations that have contributed to our understanding of the molecular biology of the embryogenesis of the foregut and its derivatives at the molecular level.

Early Development of the Foregut

Following gastrulation, the definitive endoderm becomes the primitive gut tube, of which the most cranial (anterior) region is known as the foregut. Its early morphogenesis is determined by transcription factor genes such as *Foxa 1*, *Foxa 2*, *Gata 4* and *Gata 6* that are expressed in the endoderm [56–58]. Their local expression along the anteroposterior (AP) axis of the foregut endoderm marks organ-specific domains (specifically thyroid, thymus, trachea, lung, liver and pancreas). For example, the homeodomain protein gene *Nkx2.1* (*also known as Titf1 or T/EBP*) is expressed in the thyroid and respiratory fields [59].

At critical times, the primitive foregut also receives diffusible signals from adjacent structures whose proximity changes according to changes in the shape and relationships of the embryo, and this too influences endodermal cell specification [60, 61]. Fibroblast growth factor 4 (Fgf 4), bone morphogenetic protein 2 (Bmp2) and retinoic acid (RA) are among the signals that confer AP identity to the early endoderm and enable it to respond to signals from both adjacent mesoderm and nearby structures [56, 62].

The early development of the respiration system and its separation from the gut and the genes that control the processes are summarised in Table 2.4.

Primary Lung Bud Morphogenesis

In mice, lung buds form at E9.5 (25 somite stage) in a process initiated by the local expression of a Fgf ligand (*branchless*) where the budding will occur, followed by activation of a Fgf receptor (*breathless*) that induces budding [64]. In mammals, signalling by Fgf10 and Ffgr2b is crucial for lung bud formation [56], and deletion of either results in lung agenesis. Fgfr2b is the major receptor for Fgf10.

Tracheoesophageal Separation

Embryologists have long recognised that clarification of the processes that surround normal tracheoesophageal separation was critical to a better understanding of the abnormal separation of the trachea from the oesophagus that leads to EA/

Table 2.4 Stages in the development of the respiratory system from the primitive foregut

1. Two endodermal lung buds (precursors of the left and right bronchi) are induced from the ventral-lateral aspect of the single foregut tube [56]
Nkx2.1-expressing endodermal cells are the first respiratory progenitors to appear
Lung budding initiated by expression of signalling molecules, such as Fgfs and local transcription factors
In mammals, signalling by Fgf10 and Fgfr2b crucial for lung bud formation
Likely additional roles for RA, Gli2, Gli3, Tbx2, Tbx3 and Tbx4
2. Ventral tracheal primordium separates from the dorsal aspect of the foregut (precursor of the oesophagus) by apoptosis
Influenced by *Shh* and *Nkx2.1* (and probably *Foxf1*, *Tbx4*, *RA*)
3. Secondary budding of lung buds into specific bronchi and into separate lobes to form the respiratory tree
Nkx2.1 required for expression of several lung markers, including *Sftpc* [63]
Fgf10 triggers secondary and subsequent budding
Local downregulation of the Sry-like HMG box transcription factor *Sox2* may be required for lung budding
BMP4 prevents distal epithelial cells assuming a proximal phenotype

TEF. Many theories of the pathophysiology of EA/TEF have been proposed but even the two theories that have held most sway have recently been challenged [65]. One theory, the "tap water" theory [66–68] states that the respiratory bud forms from the primitive pharyngeal wall and descends in a way similar to that of a tap being turned on: first the trachea develops after which the bronchi appear and develop. The second theory, the "tracheoesophageal septum" theory [69, 70], describes how fusion of two lateral tracheoesophageal ridges separates the trachea from the oesophagus. These ridges form a septum that ascends to the pharynx to complete the process of separation, leaving the trachea ventrally and oesophagus dorsally.

Whilst these theories do not accommodate all observations, they do reflect several aspects of early tracheoesophageal separation and have served as useful models. In the mouse and rat, there is now clear evidence that the bronchi develop as "lung buds" before tracheoesophageal separation occurs (Fig. 2.1), a process probably driven by Fgf10 expressed in the mesenchyme overlying the tips of the primary buds [71]. The "tap water" theory assumes that the trachea develops first as an out-pouching from the foregut tube, which then elongates caudally and later divides into lung buds. As it does so, it and the later developing lung buds appear to descend from the primitive pharyngeal floor. This interpretation may not be exactly accurate but is based on the correct observation that the distance between the point of tracheoesophageal separation and the pharynx alters little during the period of development. Progressive caudo-cranial apoptosis on the lateral walls of the foregut maintains the point of separation, the same absolute distance from the pharynx despite ongoing growth of both the fetus and the foregut (Fig. 2.2), [65]. Although the point of tracheoesophageal separation commences immediately cranial to the future gastro-oesophageal junction, apoptosis in the lateral walls of the foregut causes it to remain the same distance from the pharynx throughout its relative ascent to the sagittal laryngeal lamina during this critical phase of development.

What controls this process of tracheoesophageal separation? Bmp4 is expressed in the ventral mesoderm in the region which will subsequently become the trachea, whereas noggin is expressed in the dorsal endoderm of the foregut in the region that later becomes the oesophagus. The noggin protein may protect the dorsal endoderm from the action of Bmp4 [72].

Patterns of Apoptosis During Tracheoesophageal Separation

There are three processes that determine morphology during early embryogenesis:

1. Differential rates of cell division, i.e. the relative rate of increase in the numbers of specific cells and the space they occupy influences morphology

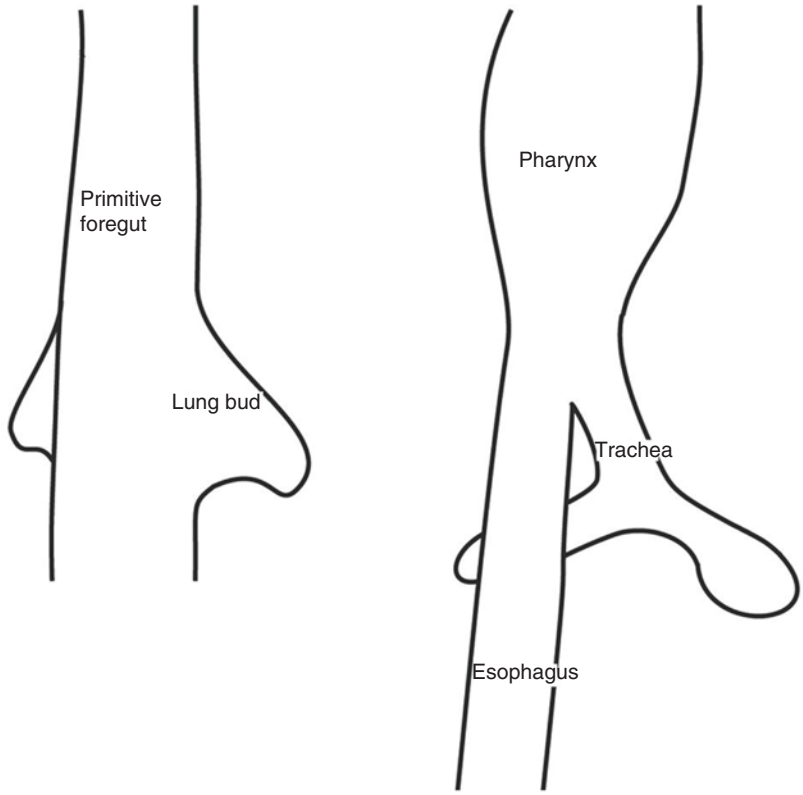

Fig. 2.1 In the rat (and mouse), the bronchi develop as "lung buds" before tracheoesophageal separation occurs and before the lung itself develops. The figure shows the changes that occur during lung bud development in the rat between gestational day 11.5 and day 12

2. Cell differentiation – the type of cell
3. Apoptosis (programmed cell death) where cells that have been present, but are no longer required, disappear

Apoptosis is tightly controlled and occurs at a specific time and at a specific location, i.e. it has strict temporo-spatial characteristics. Anything that alters its timing or location markedly changes the ultimate morphology of the affected organ.

Apoptosis appears to be critical in ensuring appropriate tracheoesophageal separation. In the primitive foregut of the normal rat, apoptosis occurs in the lateral walls at the point of tracheoesophageal separation on day 12 (Fig. 2.3), but in the Adriamycin-exposed rat that is developing oesophageal atresia, it fails to occur at this time [72]. The foregut remains a single tube in that region and has features more in keeping with a trachea, with connections to the lungs. Ultimately, an upper oesophageal pouch develops from the posterior wall of the pharynx (see below). The normal pattern of apoptosis is disturbed in the Adriamycin-exposed rat model of oesophageal atresia [73] as well as in the Shh and Nkx2.1 mouse models of foregut malformations [74].

Subsequent Branching of Lung Buds

Branching of the respiratory tree is controlled by a complex exchange of signals between the buds themselves and the surrounding mesenchyme. These determine the size and shape of the bud during branching [56].

Fgfr2b activity and *Fgf10* expression are controlled by the sprouty (Spry) and Shh

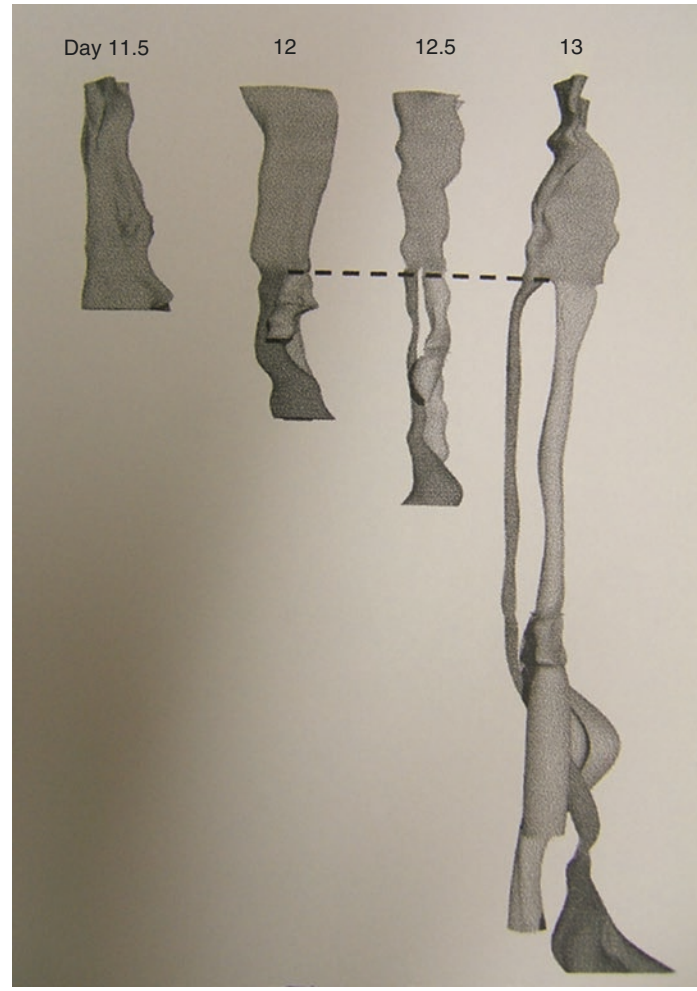

Fig. 2.2 During tracheoesophageal separation in the rat, there is progressive caudo-cranial apoptosis on the lateral walls of the foregut which maintains the proximal point of separation of the trachea and oesophagus, the same absolute distance from the pharynx – despite ongoing growth of both the fetus and the foregut

pathways, respectively. Fgf10 diffuses locally to bind to Fgfr2b, which is expressed throughout the lung epithelium, and activates induction of a further bud. Fgfr2b signalling induces expression of *Spry2* and *Bmp4* which have an inhibiting effect.

Shh signalling in the disal mesenchyme inhibits *Fgf10* expression but via Gli3 also controls availability of Foxf1, a positive regulator of *Fgf10* [56]. By induction of *Hhip* expression, Shh also inhibits its own signalling to allow *fgf10* expression. Low Shh levels in the more proximal bud regions allow *fgf10* expression in adjacent mesenchyme, enabling later induction of the lateral buds [56].

A number of other genes have been implicated in lung branching as well, but their exact role remains unclear. Bmp4 probably works through its ability to influence Fgf10-mediated bud outgrowth [56]. The role of Wnt signalling is controversial: several Wnt ligands, frizzled receptors and components of the Wnt pathway (e.g. β-catenin and Tcf/Lef transcription factors) are present in the developing lung [75]. Tgfb1, Tgfb2 and Tgfb3, members of the Tgfb subfamily, also affect lung branching [56], and exogenous Tgfb1 inhibits branching [76].

Expression of the transcription factor Foxf1 in the foregut mesoderm is partly regulated by Shh signalling through Gli3 [77]. It appears to be upregulated by Shh protein and inhibited by Bmp4 [78]. Heterozygous *Foxf1* embryos have a narrow oesophagus abnormally connected to an irregular and very abnormal trachea [72].

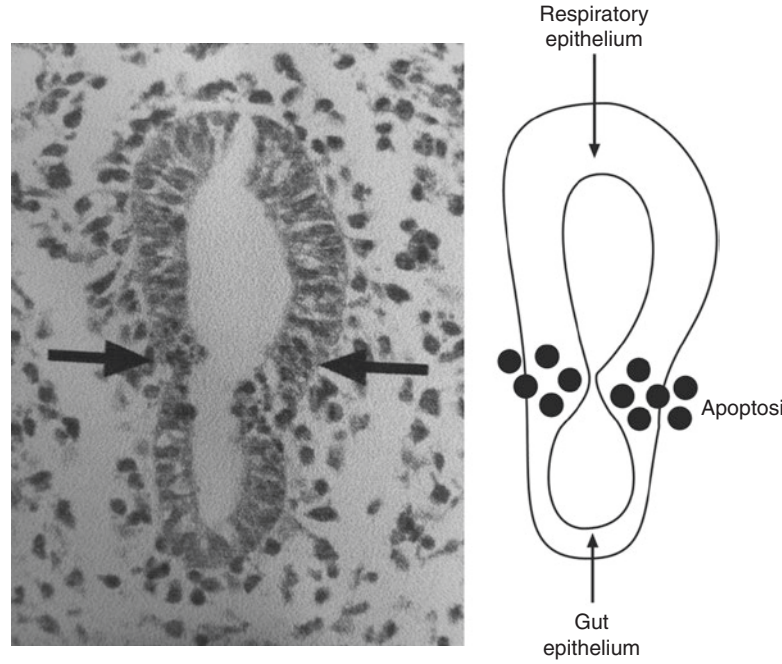

Fig. 2.3 In the normal rat, apoptosis occurs in the lateral walls at the point of tracheoesophageal separation on day 12 (unlike in the Adriamycin-exposed rat that is developing oesophageal atresia where it fails to occur at this time, and the primitive foregut remains a single tube). During normal development, apoptosis of the lateral walls of the primitive foregut effectively splits the tube into an anterior respiratory tube (which becomes the trachea) and a posterior tube (which becomes the oesophagus)

The Proximal Oesophageal Pouch

The development of the proximal oesophageal pouch in oesophageal atresia has never been well understood. The appearance of the upper oesophageal segment does not fit comfortably with many theories of embryogenesis of oesophageal atresia. Moreover, differences in its cellular properties [79] and in its innervation and intrinsic nerve supply [79, 80] have not always been easy to explain. Finally the proximal oesophageal pouch appears to elongate after birth, further fuelling the debate [81]. Recent research indicates that apoptosis plays a role in the development of the proximal oesophageal pouch, at least in the rat [82]. Apoptosis in the dorsal wall of the pharynx is the first indication of upper pouch development, and this is followed by proliferation of the cells immediately dorsal to this point. Proliferation and extension of the proximal oesophageal pouch continues until day 16 of gestation [82].

In the human, the proximal oesophageal pouch in oesophageal atresia is usually relatively long when there is a distal tracheoesophageal fistula. In contrast, the proximal oesophagus in rats with oesophageal atresia elongates and grows caudally from day 15, but for how long this growth occurs in late gestation and after birth is uncertain. It is conceivable that in the human with oesophageal atresia, growth of the upper oesophagus may continue to occur during the remaining 30 weeks of gestation and even after birth. This would be consistent with the clinical observation that the proximal oesophageal pouch appears to elongate significantly after birth, irrespective of whether bougienage is performed [81].

Development of the Notochord in Oesophageal Atresia

The notochord acts as a primary organiser in normal embryogenesis [83] and is involved in directing the formation of the neural tube, sclerotome and myotome [84]. It runs along the embryonal axis between the endoderm and ectoderm from the third week of gestation. Later it degenerates, except for those parts that persist as the intervertebral discs. Abnormal development of the notochord produces abnormalities of the vertebral column, ribs, limbs and neuroenteric canal

remnants. The notochord of rat embryos exposed to Adriamycin [85, 86] or *Nog* null mutants [72] becomes malpositioned. The vertebral bodies fail to develop properly, resulting in hemivertebrae. In these embryos, the notochord often has an extremely bizarre and abnormal branching pattern and may be split [85–88]. In rats developing oesophageal atresia, the notochord often becomes abnormally adherent to the foregut and assumes a grossly abnormal and distorted shape with branching (Fig. 2.4) [85, 89]. The more the notochord is abnormal, the more disturbed is subsequent foregut development, and the more likely there will be abnormalities of the vertebral column, including hemivertebrae [90].

In Adriamycin-exposed rats developing oesophageal atresia, *Shh* is expressed profusely in the abnormal ventral branches of the distorted notochord, including where it is abnormally adherent to the foregut (normally it has no direct contact with the foregut). The notochord has been shown to be a major source of signalling activity influencing the development of cell populations in the tissues that surround it. For a molecular messenger, which acts in a dose dependent and diffusible manner in organising

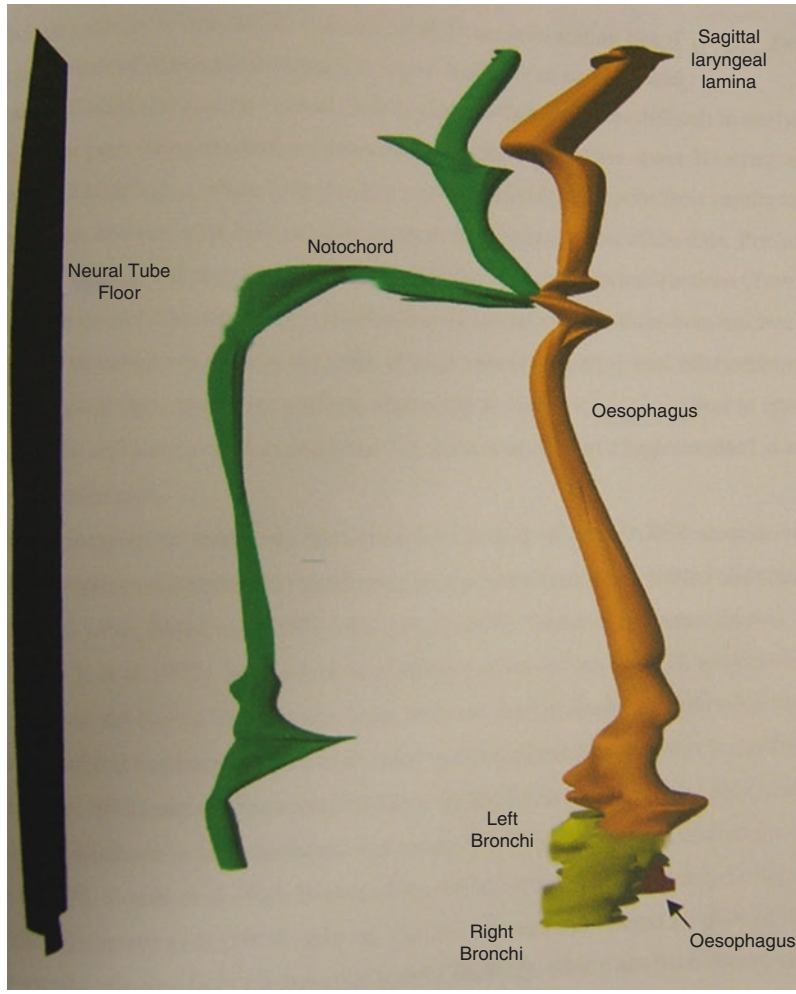

Fig. 2.4 In rats developing oesophageal atresia, the notochord often becomes displaced well anterior to its usual position and in one or more parts can become abnormally adherent to the foregut. Overall, it assumes a grossly abnormal and distorted shape and often has an abnormal branching pattern (Modified from Williams et al. [85])

patterns of early development, it is likely that the ectopic expression of *Shh* (in relation to the primitive foregut) and its actual distance from the target tissue may lead to interference with normal development [91].

The temporal and spatial characteristics of expression of *Shh* gene in the foregut are different between the normal embryo and those embryos that are developing oesophageal atresia [91] (Fig. 2.5). Normally, the *Shh* gene is expressed strongly in those parts of the foregut that eventually become the trachea (the anterior aspect of the primitive foregut), whereas the expression in those parts of the foregut epithelium that later become oesophagus (the posterior aspect) is either absent or comparatively low. In Adriamycin-exposed rats that appear to be developing oesophageal atresia, the usual pattern of dorsal-ventral *Shh* expression is lost [91] and those with abnormal diffuse expression are likely to develop structural abnormalities [92]. In short, expression of *Shh* in the foregut is abnormal when the position of the notochord is abnormal. A possible consequence of the abnormal proximity of the notochord to the foregut is that the foregut expression of *Shh* may be repressed by excessive signals from the notochord.

It is noteworthy that the notochord of *Nog* null mutants that are developing EA/TEF is also grossly abnormal, whereas the small proportion of Nog null mutants that do not develop EA/TEF have a normal notochord [72]. It is likely that Noggin normally functions by restricting the level of the Bmp4 signalling in the dorsal foregut region; thus, the notochordal abnormalities observed may reflect the requirement for correct levels of Bmp signalling during separation of the notochord from the endoderm. Reducing the dose of *Bmp4* markedly reduces the risk of EA/TEF in *Noggin* null mutants [72].

Further research is required to confirm whether Shh from the notochord promotes *Nog* expression in the dorsal foregut endoderm. If this were so, the EA/TEF seen in Shh null mutants (as also occurs after exposure of rat embryos to Adriamycin) may be due to an imbalance in Bmp4 signalling [72], at least in part.

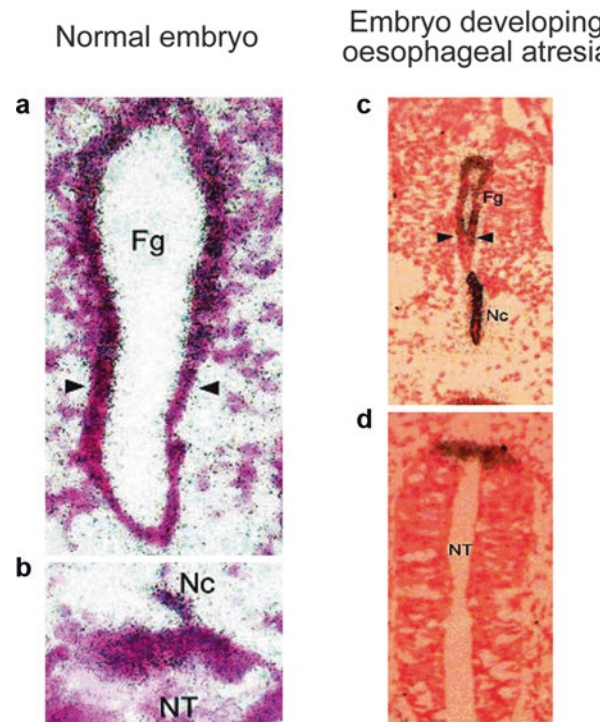

Fig. 2.5 The temporo-spatial characteristics of *Shh* expression in the foregut are tightly controlled. The black dots identify the location of Shh expression in the normal rat embryo (**a**, **b**) and in the rat embryo developing oesophageal atresia (**c**, **d**). Note also the anterior displacement and abnormal attachment of the notochord to the foregut in the Adriamycin-exposed embryo in which oesophageal atresia is occurring

Sonic Hedgehog in Organogenesis

Normal expression of *Shh* begins just after the establishment of the digestive tube [93, 94] and continues throughout the development of the gut. *Shh* exhibits its regulation in a concentration-dependent manner. *Shh* expression is first present during early development when it maintains the epithelium. Later in gut development, it is involved in the region-specific differentiation of epithelium and mesenchyme [95–97], and this is reflected in its specific timing and location of expression [74]. Levels of *Shh* gene and protein during normal development of the foregut in rat embryos are different from those that are developing oesophageal atresia [98]. Normally, Shh protein is expressed in the rat foregut throughout embryogenesis, and its level declines as the embryo approaches birth. In Adriamycin-exposed rats that are developing oesophageal atresia, the level of Shh protein expression is much lower than normal and varies little with time [98] (Fig. 2.6), providing further evidence that disruption of the Shh signalling pathway leads to abnormal development of the foregut.

The overall importance of Shh in organogenesis is highlighted by the observation that disruption of normal *Shh* expression during critical periods of development is associated with not just abnormalities of the foregut and hindgut but holoprosencephaly (HPE) and the VACTERL association as well. An autosomal form of HPE has been shown to be associated with mutations in human *Shh* coding sequences [99]. This observation in the human applies also to the *Shh* −/− mouse.

Hedgehog proteins are secreted as inactive precursor proteins that undergo post-translational modification. One part (the N-terminal) remains associated with the surface of the cells, whereas the other (the C-terminal peptide is freely diffusible [100]. This enables *Shh* to direct long-range effects (such as sclerotome differentiation – the precursor of vertebrae and ribs) as well as short-range effects (neural tube development) [99]. Patched (*Ptc*) is the receptor for *Shh*. In the absence of hedgehog, Ptc receptors block the

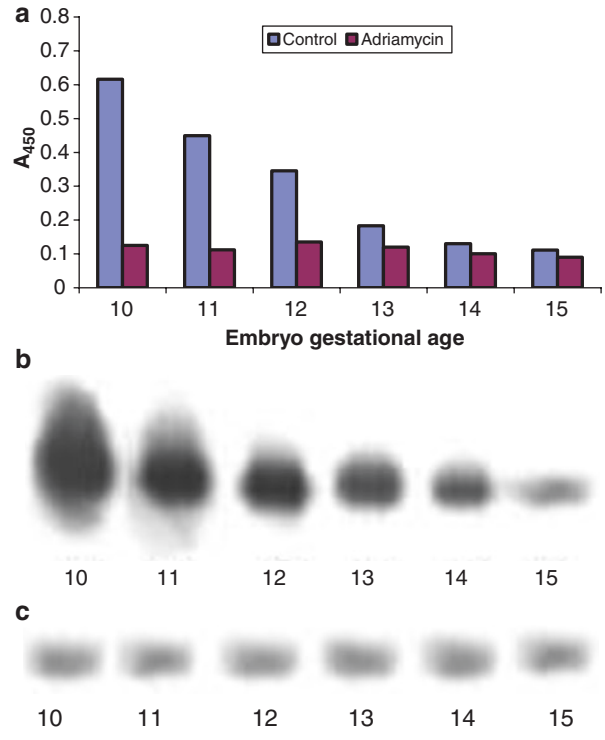

Fig. 2.6 Levels of Shh protein during normal development of the foregut in rat embryos are different from those that are developing oesophageal atresia. (**a**) ELIZA test confirms the presence of Shh protein (Santa Cruz antibody) in foregut homogenates and shows that its level decreases significantly over time, whilst Adriamycin exposure results in a diminished level of Shh protein without time-dependent changes. Immunoblot demonstrates that cleaved amino-terminal Shh signal protein in both the normal rat embryo (**b**) and the rat in whom oesophageal atresia is developing as a result of Adriamycin exposure (**c**) between the critical gestational days 10 and 15 (Modified from Arsic et al. [98])

function of another protein, Smoothened (Smo), and inhibit signalling. When the hedgehog is bound to Ptc, Smo becomes active and initiates a signalling cascade that results in the activation of three Gli transcription factors, Gli1, Gli2 and Gli3 [101]. In turn, the Gli transcription factors are responsible for the activation and repression of several hedgehog target genes, including tumour growth factor (TGF-β), cyclins, p21, β-catenin, bone morphogenetic protein (BMP) and fibroblast growth factor family (FGF) (Fig. 2.7). In the absence of *Shh*, Gli proteins translocate to the nucleus where they act as the main transcriptional repressors of the target genes.

Evidence from the Shh, Nog and Nkx2.1 Null Mutant Mouse Models

In the wild-type mouse embryo, the trachea begins to separate from the oesophagus by a "tracheoesophageal septum", whereas this septum does not appear in the *Shh* $^{-/-}$ mutant embryos, implicating *Shh* in the separation of the respiratory tube from the digestive tube in this model [95, 102].

Knockout mutant mice (for Gli1, Gli2, Gli3) have been produced to elucidate the role of the various Gli genes in sonic hedgehog signalling [51]. Gli $3^{-/-}$ mutant mice have many abnormalities, including central nervous system and lung defects, and limb polydactyly [101]. Aspects of these phenotypes are similar to *sonic hedgehog* gain of function. Gli $2^{-/-}$ mutant mice die at birth with severe skeletal and neural defects. The normal mouse lung develops with four right lobes and one left lobe, whereas the right lung in the Gli $2^{+/-}$ mutant has only one lobe. The size of the lung in Gli 2 $^{-/-}$ is significantly reduced, the oesophagus does not develop smooth muscle and the oesophageal lumen is small. Gli 2/Gli 3 double-mutant mice have been used to demonstrate the overlapping functions of Gli 2 and Gli 3 in foregut development. Gli $2^{+/-}$ Gli $3^{+/-}$ mutant mice are viable without obvious foregut defects, whereas Gli $2^{-/-}$ Gli $3^{+/-}$ mutants have oesophageal atresia with a tracheoesophageal fistula. In these mutants, the single foregut tube does not

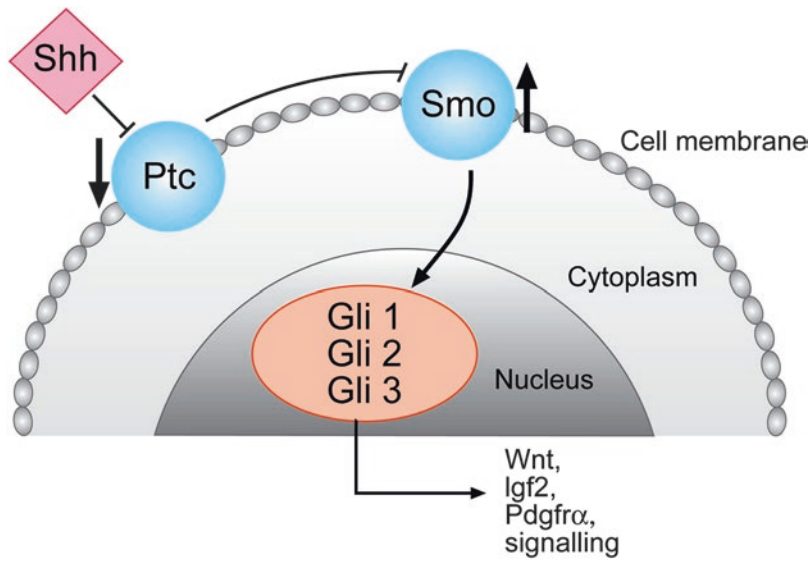

Fig. 2.7 The *Shh*-Gli pathway. Sonic hedgehog (*Shh*) acts on the membrane receptor complex consisting of Patched (Ptd) and Smoothened (*Smo*) to inhibit the repression of Smo by Ptc. Smo signals the cell causing the GLI proteins in the nucleus to regulate target genes, including tumour growth factor (TGF-β), cyclins, p21, β-catenin, bone morphogenetic protein (BMP) and fibroblast growth factor family (FGF) In the absence of *Shh*, Ptc receptors block the function of another protein, Smoothened (*Smo*), and inhibit signalling

separate normally into the trachea and oesophagus [51]. Interestingly, Gli 1 functions as dispensable in mice if both copies of the Gli 2 gene are present [101]. These findings are consistent with the observation that mice with a targeted deletion of *Shh* and *Gli* mutants develop oesophageal atresia and related abnormalities because of breakdown of the *Shh* signalling pathways [103].

In the mouse at E9.5, the homeodomain transcription factor *Nkx2.1* is expressed in the ventral foregut endoderm in the region where the trachea and lungs will develop [104]. This is controlled by Ffgs (and probably other factors such as RA as well). Null mutations in Nkx2.1 compromise tracheoesophageal separation [104], although in the absence of an oesophageal pouch, normal dorsoventral patterns of Nkx2.1 and Sox2 expression have been observed in Adriamycin-exposed mouse embryos who have defective foregut separation [74].

Deletion of the human chromosomal region containing the NOGGIN gene can produce EA/TEF [28]. More recent work confirms that *Nog* null mutants also have EA and TEF. The close functional interrelationship of these genes is evident in that *Nog* encodes a polypeptide of Bmps. Also, *Nog* and *Bmp4* are reciprocally expressed in distinct and specific dorsal and ventral domains in the foregut [74].

In summary, *Nog* mutants resemble *Shh* and compound *Gli* mutants (and embryonic exposure to Adriamycin) in producing EA/TEF and its variants [74].

Future Directions

The enormous advances that have occurred in recent years in both clinical genetics and molecular biology have given researchers tools that will continue to provide new insights into the complex processes and effects of gene expression on morphology. A better understanding of normal processes will assist us in identifying how and why aberrations of normal development occur – aberrations that sometimes lead to oesophageal atresia and its related abnormalities. One might hope that eventually this knowledge will be applied to the prevention of these conditions.

Swallowing and the Upper Esophageal Sphincter

3

Robert E. Kramer

Introduction

Swallowing is a complex physiologic process, requiring integration of both voluntary and involuntary motor complexes within both the respiratory and digestive systems. Alterations in this process may present with a wide variety of clinical manifestations, including aspiration, chronic cough, choking, dysphagia, feeding problems, vomiting/retching, oral aversion, and failure to thrive. Evaluation of swallowing disorders can be challenging and difficult to differentiate from respiratory, neurologic, allergic, developmental, or other gastrointestinal disorders. In many patients there may be two or more of these processes occurring simultaneously, making it difficult to ascertain the primary pathology or the relative contribution of each. This challenge is made more difficult in infants and toddlers who are unable to communicate details about their symptoms that can help pinpoint the root of the problems. Furthermore, the dynamic transition in diet that occurs during the first year of life, in terms of taste, consistency, and mode of feeding, is yet another layer of complexity which may obfuscate swallowing and behavioral feeding disorders. Addressing these patients, therefore, often requires a multidisciplinary approach, with input from gastroenterologists, occupational or speech therapists, dietitians, radiologists, and other pediatric specialists, such as pulmonologists and otolaryngologists. In order to understand the myriad ways that this process can go awry, a thorough understanding of the normal process of swallowing is essential.

Normal Swallowing

The purpose of swallowing is to propel the contents of the oral cavity, including secretions, liquids, and solids, through the oropharynx and hypopharynx, past the upper esophageal sphincter (UES) into the esophagus and ultimately into the stomach for digestion. Swallowing can be functionally divided into an oral phase and a pharyngeal phase.

Oral Phase

In the oral phase, initiation of swallowing occurs following appropriate mastication (for solids) and bolus control by the tongue. This is a voluntary process controlled by the central nervous system. The tongue accommodates bolus size and prepares the bolus for swallowing by

DOI 10.1007/978-3-642-11202-7_3

approximating the posterior portion of the tongue to the soft palate, effectively separating the bolus from the hypopharynx and airway. This bolus activates receptors within the oropharynx, which provide sensory information to the swallowing center by virtue of afferent nerve fibers coursing through branches of the trigeminal, glossopharyngeal, and vagus nerves. The swallowing center integrates this information to determine that the bolus is appropriate for swallowing. Swallowing is then voluntarily initiated in conjunction with cessation of respiration, opening of the UES, and peristalsis in the striated portion of the upper esophagus.

In the first specific step in this process, the mouth is closed, the tip of the tongue is pressed against the hard palate, and the lateral aspect of the tongue is pressed against the alveolar ridges, forming a seal. A wave of contraction then occurs from the tip through the body of the tongue, propelling the food bolus from the oral cavity into the oropharynx, completing the oral phase of swallowing [1].

Pharyngeal Phase

Within the pharyngeal phase of swallowing, several events occur in a near simultaneous fashion. The base of the tongue pushes bolus posteriorly, while the oropharynx is elevated and pushed open. Meanwhile, the extrinsic muscles, comprised of the levator veli palatini, tensor veli palatini, palatoglossus, and palatopharyngeus muscles, close the nasopharynx off from the food bolus by elevating the soft palate and uvula. Other extrinsic muscles such as the stylohyoid, styloglossus, stylopharyngeus, and digastric posterior raise the larynx while the geniohyoid, mylohyoid, digastric anterior, and thyrohyoid pull the larynx and pharynx forward, helping to open the UES. The intrinsic muscles, comprised of the superior, middle, and inferior pharyngeal constrictors, are responsible for creating negative pressure in front of the bolus, while it is pushed from behind by the action of the tongue, resulting in advancement of the bolus into the esophagus. The inferior pharyngeal constrictor is comprised of two parts, the thyropharyngeus and the cricopharyngeus, which forms part of the UES. At this point, the bolus is intersecting the airway, and measures must be taken to protect it. Therefore, the thyroarytenoid, aryepiglottic, and the oblique arytenoid close the larynx to block off the trachea.

The primary peristaltic wave is initiated in the pharynx and extends through the cervical portion of the esophagus. Liquids progress primarily by gravity in the upright position and typically reach a closed lower esophageal sphincter (LES) before the peristaltic wave. Solid boluses travel by virtue of gravity as well as peristalsis, which opens the LES and permits passage into the gastric lumen. Secondary peristaltic waves may occur locally, by virtue of the enteric nervous system, in response to distention from residual food content within the esophagus [1]. Between swallows, the UES and the LES remain tonically contracted to minimize gastroesophageal and esophagopharyngeal reflux, respectively.

Neurologic Control of Swallowing

Coordination of the complex steps involved in normal swallowing, as outlined above, requires the integration of sensory data from the periphery to modulate motor control. This control is mediated through the parasympathetic, sympathetic, and enteric nervous systems. Integration and control of the parasympathetic system occurs primarily within the swallowing center, located in the dorsal vagal complex. The dorsal vagal complex sits within the dorsomedial hindbrain medulla and encompasses two nuclei, the nucleus tractus solitarius and the dorsal motor nucleus. Vagal afferents, carrying sensory information from the pharynx, esophagus, and stomach synapse within the nucleus tractus solitarius. This information is then projected to the nucleus ambiguous to coordinate the process of deglutition and to the dorsal motor nucleus of the vagus, which sends motor output to the esophagus. The rostral and caudal portions of the dorsal motor nucleus each provide opposing influences on lower esophageal sphincter pressure, with the

rostral portion causing contraction and the caudal causing relaxation. Thus, the resulting tone of the LES is the balance of these two influences.

The sympathetic control of swallowing function arises in the intermediolateral columns of the thoracic spinal cord, at the level of T1 through T10. The majority of the preganglionic fibers pass through the greater splanchnic nerves to terminate in the celiac ganglia. Postganglionic neurons then travel to the esophagus via perivascular fibers to synapse in the myenteric and submucosal plexi of the esophagus.

Local innervation of the esophagus via the enteric nervous system arises within the complex network of submucosal (Meissner's) and myenteric (Auerbach's) plexi. Though this system receives input from and provides feedback to the central nervous system, it is capable of producing secondary peristalsis even with complete dissociation from the CNS [2]. Its effects are modulated by release of nitric oxide, as well as other neuropeptides from nerve endings, which are differentially expressed along the length of the esophagus [3]. In the circular muscle layer, the concentration of nitrous oxide (NO)-containing neurons decreases along the length of the esophagus, with the lowest amount found at the level of the LES. In the longitudinal muscle layer, this pattern is reversed, with greatest concentration of NO-containing neurons at the LES. This pattern suggests that peristalsis in the esophagus is modulated by the release of inhibitory neuropeptides and NO along its length [4].

Upper Esophageal Sphincter

The UES is a functional zone of high pressure demarking the entrance to the esophagus. It has two primary functions. The first is relaxation, to accommodate passage of a solid or liquid bolus into the esophagus following deglutition or to allow expulsion of gas during belching. The second is contraction, to prevent entry of air into the esophagus during inspiration and passage of refluxate into the pharynx. This zone of high pressure is variable in length, extending up to 4 cm in adults and exhibiting radial asymmetry, with greatest pressures in the anterior and posterior aspects. The muscles responsible for UES opening are the thyrohyoid and the geniohyoid, while those responsible for closure are primarily the cricopharyngeus and to a lesser extent the thyropharyngeus and cervical esophagus. The UES at rest is retained in a state of tonic contraction, due to continuous firing of medullary neurons, running through the vagal trunks. Cessation of firing leads to UES relaxation, while rate of firing determines the resting pressure. The range of normal resting pressure for the UES is difficult to establish due to variability in testing methods, the radial asymmetry of UES pressure, and the stimulatory effect of recording instruments. In adults the normal range is estimated to be between 40 and 100 mmHg.

The deglutition process, described above, leads to almost immediate UES relaxation to a pressure level equivalent to that of the pharynx, though cessation of neural input from the brainstem. This relaxation in pressure alone, however, is not sufficient to allow opening of the UES. It is accompanied by elevation and forward displacement of the larynx, which serves to pull open the UES. This relaxation immediately precedes pharyngeal contraction, facilitating the transport of the food bolus from the hypopharynx into the upper esophagus. This brief relaxation lasts less than 1 s.

A number of factors can alter resting UES tone, in accordance with the primary functions it performs. To prevent or minimize entrance of air into the esophagus during respiration, tone increases during inspiration, while thoracic and esophageal pressures decrease. To minimize pharyngeal passage of refluxate, acid exposure in the proximal esophagus increases UES tone as well. Similarly, balloon distention in the proximal esophagus, modeling liquid refluxate, also results in increased tone. Exposure of the mucosa to water or neutral liquids does not produce as pronounced of an increase as does acid. Conversely, balloon distention modeling passage of gas results in a decrease in UES tone, to accommodate belching. This relaxation is paired with glottis closure to further protect the airway. The mechanisms used to discriminate gaseous versus

liquid distention are not well characterized. Animal data suggest that the response to acid exposure is modulated via vagal afferents in the recurrent laryngeal nerves. This pathway only seems to be responsible for a portion of the response to esophageal distention, however. Patients with peptic esophagitis do not appear to have any alteration or impairment of this normal pathway. Emotional stress seems to increase UES tone, which may be involved in globus sensation. During deep sleep, UES tone decreases, which may be a factor in nocturnal gastroesophageal reflux. Anesthesia virtually eliminates UES tone, increasing the risk for aspiration of gastric contents during procedures in patients with an unprotected airway.

The cricothyroid muscle is responsible for the majority of UES tone, and impaired relaxation results in a high-pressure bar across this region. This is clinically defined as cricopharyngeal achalasia. In cricopharyngeal achalasia, there is also impaired distensibility of the cricopharyngeus, which forms the appearance of a "bar" from its indentation during a barium swallow. The impaired ability to open the UES during deglutition results in increased bolus pressure in the hypopharynx, which can lead to a Zenker's diverticulum. This is a false diverticulum created at an area of pharyngeal weakness between the oblique fibers of the inferior pharyngeal constrictors and the cricopharyngeus muscle itself. Diverticulae may also occur at the junction of the middle and inferior constrictors. These diverticulae may result in trapped food content, a sensation of dysphagia and risk for aspiration. In contrast, paralysis of the suprahyoid pharyngeal constrictors results in paralytic achalasia due to failure of UES opening (Table 3.1).

Table 3.1 Factors affecting resting upper esophageal sphincter tone

Increased tone	Decreased tone
Inspiration	Deep sleep
Emotional stress	Deglutition
Distention from liquids	Belching/distention from air
Acid exposure	Emesis

Oropharyngeal Dysphagia

Assessment

Dysphagia is defined as "difficulty swallowing" and is contained within the broader category of feeding disorders. Feeding disorders in general are relatively common in the pediatric age group, estimated to occur in up to 45 % of children with normal development and 80 % in those with developmental disabilities [5]. With the improved survival of premature infants over the last few decades, the resultant incidence of children with developmental deficits has increased and with it the incidence of feeding/swallowing disorders.

Identification of children who warrant a formal evaluation by a feeding team can be challenging from the primary care perspective. Arvedson has developed a panel of questions which can aid the caregiver in determining whether a given patient has reached that threshold (see Table 3.2) [6]. These patients require a multidisciplinary approach to successfully discriminate the organic and nonorganic components, which are often inextricably entwined. Commonly, underlying feeding or swallowing disorders result in compensatory measures or strategies in parents which may become maladaptive and cause oral aversion. This has led to a proposed set of criteria for the formal diagnosis of "feeding disorder between parent and child" which recognizes this issue [7].

Paramount in importance during the evaluation of these children is an accurate assessment of the risk of continued oral feedings and implementation of appropriate measures to provide for safe delivery of adequate nutrition. In the primary assessment period, anatomic and obstructive lesions must first be excluded. A comprehensive medical history must be obtained, as virtually any primary neurologic disorder or muscular disease involving the oropharynx can result in dysphagia. Deficits in either afferent or efferent innervation of the oropharynx can result in dysfunction by interfering with the intricate timing of the swallowing processes outlined above. Potential points where dysfunction can occur

Table 3.2 Screening assessment for feeding team referral

Question	Assessment
How long does it take the child to feed?	More than 25–30 min points to a problem
Is the child totally dependent on others for feeding?	Children unable to self-feed in an age-appropriate manner are at increased risk for feeding problems and silent aspiration
Does the child refuse food?	Food refusal may be an indication of disordered parent-child interaction, sensorimotor deficits, or underlying organic disease
Are mealtimes stressful?	Increased parental stress with meals can lead to forced feedings and subsequent oral aversion in the child
Has the child slowed or stopped growing in the previous 2–3 months?	Growth delay points to significant impairment of the ability to provide adequate nutrition in the face of the observed feeding problems
Are there signs of respiratory distress?	Increase suspicion of aspiration
Does the child vomit regularly?	Points to underlying organic pathology, such as reflux, obstruction, impaired motility, or others. In some cases, children may vomit purposefully as a method of food refusal
Does the child become irritable or lethargic during meals?	Fussiness with feeds may indicate underlying inflammation or irritation within the upper GI tract, as well as airway issues. Lethargy my indicate fatigue from inefficient or difficult feeding

include tongue loading, bolus propulsion, nasopharyngeal closure, laryngeal closure, UES opening, and pharyngeal clearance. Regardless of the underlying cause or mechanism, dysphagia in infants and children is significantly correlated to the risk of aspiration pneumonia [8].

Etiology

The potential etiologies for feeding problems and dysphagia in infants and children are numerous and often interrelated. Anticipatory guidance must be given for patients with known risk factors for feeding disorders so that appropriate feeding strategies can be implemented and nutrition can be delivered in a safe fashion. Though certainly not exhaustive, the potential etiologies outlined below constitute some of the most common causes seen in the pediatric age group.

Prematurity

The premature infant faces a number of challenges that may result in feeding difficulties and dysphagia. First and foremost, among these is the developmental readiness necessary to coordinate sucking, swallowing, and respiration. Although the prenatal fetus is capable of deglutition of amniotic fluid by 16 weeks gestation, it is not generally until 34 weeks post-conceptional age that suckling capability is acquired. Even at this point, preterm infants may have difficulty coordinating swallowing and breathing, which may result in aspiration with oral feeds. These problems may be compounded by other common comorbid conditions encountered in the preterm infant, such as bronchopulmonary dysplasia [9], necrotizing enterocolitis [10], and gastroesophageal reflux [11]. Prolonged use of oxygen therapy for lung disease in preterm infants may further impair development of nonnutritive suckling (NNS), due to decreased positive stimulation and increased perioral noxious stimuli from intubation and taping [12, 13]. As a result, introduction of oral feeds may be significantly delayed in these patients, causing them to miss a critical period of oral stimulation. Subsequent development of normal oral feeding may be interrupted and difficult to reestablish. Prophylactic implementation of nonnutritive suckling during gavage feeds may help avoid these pitfalls [14] and seems to result in decreased hospital stay and improved transition from tube feeds to bottle feeds [15].

Cerebral Palsy (CP)

Neurological dysphagia can be related to a number of conditions, but cerebral palsy is by far the most common [16]. The mechanism for dysphagia in these patients may be related to

hypertonicity, hypotonicity, abnormal suckling and rooting reflexes, and sensory changes to oral stimuli [17]. Swallowing disorders in these children can be grouped into three primary categories [18]. In the first, there are significant oromotor difficulties, such as tongue thrusting and poor lip closure, resulting in impaired control of the food or liquid bolus within the oropharynx. In the second, there are the same oromotor issues, with the addition of delayed initiation of the pharyngeal phase of swallowing. This pattern seems to be the most commonly encountered in patients with cerebral palsy. In the third, both the oromotor problems and the delayed pharyngeal swallowing are accompanied by inefficient pharyngeal clearance following the swallow. Impaired opening of the UES and cricopharyngeal dysfunction are uncommon in CP patients, so that aspiration *during* the swallow is unusual. Aspiration, if present, typically occurs *before* the swallow due to poor oromotor control or *after* the swallow due to poor pharyngeal clearance of the food bolus.

Genetic Syndromes

Congenital birth defects and genetic syndromes are commonly associated with feeding and swallowing disorders. In these conditions the dysphagia can be related to one or more problems impacting feeding. Central nervous system dysfunction causing generalized hypotonia is a common element in many of these congenital disorders which result in impaired feeding. Anatomic abnormalities of the nasopharynx, such as submucosal cleft, macroglossia, cleft lip/palate, and micrognathia, can disrupt normal suckling and latching in the feeding infant. Neurological compromise can result in dysfunctional swallowing by interrupting the timing or efficiency of the normal swallowing process. A list of some of the more common genetic conditions associated with feeding and swallowing disorders is presented in Table 3.3 [19].

Neuromuscular Disease

Essentially any neuromuscular disease which involves the swallowing musculature can result in dysphagia. Myotonic dystrophy is a characteristic example, in which there is impaired relaxation of affected muscle. Pharyngeal and esophageal abnormalities are near universal in these patients, resulting in weakened pharyngeal contraction and decreased or absent peristalsis within the esophagus. These patients are at risk for aspiration, as difficulty in passing the food bolus through the cricopharyngeus results in overflow of the pyriform sinuses which may cause retained contents to fall into the opened airway after the swallow [18]. Spinal muscular atrophy type II results in oromotor problems with retained food in the valleculae, as well as swallowing dysfunction [20]. Recent data suggests that feeding function in these patients may be improved if the head is tilted forward during feeding [21].

Postsurgery/Congenital Heart Defects

Vagal nerve injury following surgery can result in hemiparesis of the soft palate and pharyngeal constrictors, leading to possible nasopharyngeal reflux and interrupting symmetrical sweeping of the pharynx following the swallow. The recurrent laryngeal nerve can be injured during any surgery involving the thyroid or mediastinum. The left recurrent laryngeal nerve is more vulnerable than the right, as it creates a larger loop within the chest. Injury to the nerve may result in unilateral vocal cord paralysis, leaving the airway vulnerable to aspiration. This increased risk has been studied in patients who have undergone surgical correction of congenital cardiovascular defects, where subsequent vocal cord dysfunction was found in 1.7 % [22]. The risk was greatest in those patients undergoing aortic reconstruction, and more than half required gastrostomy placement to manage their long-term feeding difficulties. Clement et al. found PDA ligation to be associated with a greater than 50 % incidence of vocal cord paralysis, with increased risk in extremely low birth weight infants, and associated with increased requirements for tube feeding and ventilator support [23].

Other associated conditions leading to oropharyngeal dysphagia include tracheostomy, due to decreased elevation of the larynx [24], medullary tumors such as medulloblastoma [25], and

Table 3.3 Genetic syndromes commonly associated with feeding/swallowing disorders

Syndrome	Characteristic feeding issues
Angelman syndrome	Frequent feeding problems but not severe
Apert syndrome	Related to cleft palate feeding issues
Arthrogryposis	Aversion to solids, swallowing problems
ATR-X syndrome	Hypotonia, poor suck
Beckwith-Wiedemann syndrome	Macroglossia with feeding problems
CHARGE syndrome	Pharyngeal incoordination, abnormal laryngeal and pharyngeal anatomy
Cornelia De Lange syndrome	Poor oral coordination, small mouth and jaw
Costello syndrome	Poor suck with severe feeding problems
Deletion 22q13 syndrome	Mild problems, secondary to hypotonia
Down syndrome	Tongue hypotonia, small oral cavity, poor suck
Fragile X syndrome	Feeding problems common but no dysphagia
Holoprosencephaly	Significant problems, poor suck, possible aspiration, may have cleft lip/palate
Kabuki syndrome	Feeding problems in up to 70 %, poor coordination of suck and swallow
Myotonic dystrophy type 1	Weakness of facial and pharyngeal muscles
Noonan syndrome	Poor suck, prolonged feeding time
Prader-Willi syndrome	Infantile hypotonia, leading to poor suck
Rett syndrome	Delayed pharyngeal swallow
Robin sequence	Difficulty maintaining airway while feeding
Rubinstein-Taybi syndrome	Hypotonia, feeding problems in 80 %
Smith-Lemli-Opitz syndrome	Hypotonia and poor suck commonly lead to feeding problems commonly
Smith-Magenis syndrome	Infantile hypotonia, poor suck and swallow, oral sensorimotor dysfunction
Soto syndrome	Failure to suck, poor coordination of swallowing
Treacher Collins syndrome	Craniofacial malformations/cleft lip/palate
Trisomy 18, Trisomy 13	Poor suck and swallow
Turner syndrome	Difficulty latching to breast and suckling
Velocardiofacial syndrome	Nasal regurgitation due to hypoplastic soft palate with large nasopharynx, poor esophageal peristalsis, risk of aspiration
Williams syndrome	Severe feeding problems in 70 %, sensory aversion to solids, tongue thrust, abnormal position of jaw and neck
Wolf-Hirschhorn (4p-) syndrome	Central hypotonia, orofacial clefts, results in poor suck

traumatic brain injury, with dysphagia prevalence as high as 76 % [26].

Evaluation

Feeding Observation

Despite the numerous radiologic, endoscopic, and functional diagnostic tests available for feeding evaluation, there is nothing that replaces careful observation of the affected child during an actual feed. This is usually performed by a speech-language pathologist or occupational therapist. Before the formal evaluation occurs, the astute observer should take care to assess the patient at rest, before feeding actually begins. Careful attention should be paid to facial symmetry, presence of dysmorphic features, size and position of the tongue, and appearance of the lip and palate. In the infant, observation of nonnutritive sucking ability may give early clues as to the proficiency of nipple feeds. If the NNS does not appear vigorous and rhythmic, the infant may have difficulty coordinating suck, swallowing, and breathing with sufficient ease to provide adequate nutrition. After the global assessment is complete, the true feeding observation can take place but should be performed in a venue that most closely approximates the usual home feeding environment. It is important that the observa-

tional period is of sufficient duration to determine that a representative sample is witnessed and that late feeding fatigue or disorganization is not missed. Usual feeding should not require more than 30 min to complete.

Feeding characteristics observed during the assessment may give important clues to underlying dysfunction. Cranial nerve abnormalities may be suspected on the basis of these observations. Cranial nerves V, VII, IX, X, and XII are all involved in feeding and swallowing function, and impairment of these cranial nerves (CN) causes distinctive feeding abnormalities [6]. For example, CN V dysfunction results in inability to form a food bolus, while CN VII problems may result in poor lip seal and movement. CN IX and X dysfunction results in delayed initiation of the pharyngeal swallow after food is loaded in the posterior oropharynx. Typically this action should be initiated within 2 s of the bolus being moved posteriorly within the oropharynx. CN XII abnormality results in poor tongue elevation and excessive thrusting. Another important clue is the need for multiple swallows to completely clear the pharynx, indicating impaired function of the pharyngeal constrictors. Abnormal movements during feeding, such as jaw thrust, tonic bite reflex, and jaw clenching, should be noted. Close observation of the parent-child interaction during feeds is critical as well. Children should be challenged with foods of varying texture. The most critical assessment that must be made at the conclusion of the feeding observation period is whether the child can safely tolerate oral feeds. Presence of a wet, coarse voice or cry following feeding should alert the clinician that aspiration may be occurring. Secondarily, the assessment may address whether modifications can be made to diet composition, timing of feeds, position, or posture to improve feeding tolerance.

Upper GI

The role of an upper GI series or esophagram is primarily focused on assessment of upper gastrointestinal anatomy. It may be helpful to determine if there are any structural anomalies which may be manifesting as feeding difficulties or dysphagia. This would include esophageal strictures and webs, vascular rings and slings, tracheoesophageal fistula, achalasia, hiatal hernia, pyloric stenosis, malrotation, and more. Though upper GI series is often requested as part of the assessment of gastroesophageal reflux, it is neither a sensitive or specific screening test for reflux [27]. It also does not adequately assess swallowing function as obtained by a true videofluoroscopic study.

Ultrasound

Ultrasound examination of the tongue, floor of the mouth, and pharynx during feeding can give a dynamic picture of the movement of these structures to help identify sites of pathology [28]. Though acoustic shadowing from bones in the neck may limit visualization, lack of radiation exposure offers an advantage over traditional fluoroscopic evaluation.

Nuclear Scintigraphy

Technitium-99m is used as a tracer to label ingested food or liquid during the study, in an effort to measure transit time or the presence of aspiration with feeds [29]. The tracer is not absorbed by the gut mucosa and will not stick to the mucosal surface. Sensitivity for detecting aspiration has generally been reported as poor, but it does have less radiation exposure than the fluoroscopic studies.

Videofluoroscopic Swallow Study

The videofluoroscopic study or modified barium swallow is the primary assessment tool for evaluation for dysphagia and feeding problems. It is especially helpful in differentiating oropharyngeal from esophageal dysfunction. It is typically performed with the patient upright and from the lateral position, with feeding administered by a speech-language pathologist. Oropharyngeal dysfunction can be broadly divided into four major categories on the videofluoroscopic exam: delayed initiation of pharyngeal swallowing, aspiration, nasopharyngeal regurgitation, and incomplete bolus clearance from the pharynx following swallowing. These studies are used extensively to determine the presence of aspiration with feeds, though the clinical significance of

small amounts of aspiration remains controversial. If aspiration is observed, careful note must be made of whether this aspiration occurs before, during, or after deglutition. Other specific findings can help identify corresponding swallowing disorders. For example, greater than three sucks per swallow suggests decreased suck strength or coordination. Decreased opening of the UES can be suspected on the basis of nasopharyngeal reflux, residue in the pyriform sinuses and pharyngeal pouches, or slow bolus passage through UES. The type and consistency of feeds can be altered to assess whether these "modifications" result in improved safety of oral feeding.

Fiberoptic Endoscopic Evaluation of Swallowing (FEES)

Conventional endoscopic evaluation has a limited role in the evaluation of dysphagia and feeding disorders. While it can be helpful in excluding esophageal conditions such as eosinophilic esophagitis, reflux esophagitis, and esophageal webs/strictures, it is not able to reliably assess swallowing function or motility disorders. In contrast, fiberoptic endoscopic evaluation of swallowing (FEES) allows for real-time direct visualization of swallowing function [30]. Though initially developed for adults, it has been used successfully in even premature infants [31], and does not require specialized endoscopic skills. There is, however, a standardized protocol for the tasks and assessments that should be performed as part of a formal FEES examination [32]. A laryngoscope is passed transnasally after topical anesthetic has been applied to the nares. Examination of the anatomy of the patient's nasopharynx and larynx, as well as their basic function, constitutes the initial portion of the examination. Included with this is an assessment of the symmetry and movement of these structures during a dry swallow, normal respiration, and phonation of specific words or sounds (if the patient is old enough to cooperate). The subsequent portion of the examination involves direct examination of these structures during delivery of liquids and solids of varying textures and bolus sizes. From this information, the examiner should be able to assess the underlying physiology of any identified swallowing problems and potentially offer guidance for manipulating feedings to improve the safety of oral intake.

Management

Cricopharyngeal Myotomy

For patients with isolated cricopharyngeal achalasia, with or without Zenker's diverticulum, myotomy may be considered as a potential therapy [33]. Response rates to myotomy are decreased when patient selection is generalized to include those with other or additional etiologies for their dysphagia. Ideally the candidate for myotomy should have cricopharyngeal dysfunction as the primary cause for their dysphagia, the ability to propel a bolus through the oropharynx to the level of the UES, and the ability to close the airway during deglutition. Given these parameters, response rates are quite good, though published data in children is scarce due to the relatively low incidence of this condition in the pediatric population [34, 35].

Enteral Access Device

If oral feeding is ultimately deemed unsafe or if the limitations in oral feedings result in an inability to take in sufficient volume to provide adequate nutrition, consideration must be given to placement of an enteral feeding device. In the pediatric setting, this decision can initially be a daunting subject for parents and caregivers to address. In each case the risk-benefit balance of each type of device must be carefully weighed to come to the best option for that child. For initial delivery of enteral nutrition in a relatively noninvasive fashion, nasogastric or nasoduodenal feeding tubes are often the best option. These tubes have the disadvantage, however, of potentially causing further disruption of the normal feeding/swallowing mechanism and perhaps hastening the development of oral aversion. Careful consideration must therefore be given to the anticipated duration that enteral support will be needed, and, if prolonged access will be required, discussion of the more durable devices, which bypass the nasopharynx, should occur. For the child felt to have treatable oropharyngeal dysphagia, the ability to

deliver appropriate nutrition while parents engage in the long process of feeding therapy enables the child to progress at their own pace [36]. Without access, there may be substantial pressure on the parents and the child to take sufficient caloric intake, which may be counterproductive to their therapy and encourage development of maladaptive feeding strategies [37].

Diet alteration

Comprehensive treatment of feeding and swallowing disorders typically involves intervention from a multidisciplinary team, often including a dietitian, behavioral psychologist, a speech-language pathologist, and an occupational therapist. There are numerous strategies available to alter the diet to address current feeding limitations and encourage the development of feeding skills [38]. For the infant, adjusting the nipples used for feeds can change flow rate and allow for improved function [39]. Modifying the thickness can decrease aspiration risk for patients with dysphagia to thin liquids, as determined from videofluoroscopy. For patients with sensory integration disorders leading to feeding problems, changing texture of solids may enhance palatability and acceptance.

Positioning/Timing of Feedings

For patients with specific disorders, changing position or posture with feedings may allow improved function by accentuating the portions of their swallowing mechanism that work well. For those patients with unilateral weakness of pharyngeal constrictors, turning the head to the side may improve swallowing efficiency and decrease risk of aspiration. Additional exercises to strengthen muscles of the face, tongue, lips, and palate can be prescribed for the parents to implement in the home [38]. Adjusting the pace of feeding to allow more time for swallowing may be necessary and is sometimes aided by the use of smaller utensils.

Esophageal Motility

4

Hayat M. Mousa and Rodrigo Machado

General Background

The esophagus is a hollow viscous constituted of four layers: mucosa, submucosa, muscle layer, and adventitia. The esophageal mucosa is formed by three layers: nonkeratinizing stratified squamous epithelium, the lamina propria (with mucous glands), and the muscularis mucosa. Mucus-producing tubular glands (submucosal or esophageal glands) extending into the submucosa are scattered throughout the esophagus [1]. The submucosa is composed by loose connective tissue containing arteriolar plexus, elastic fibers, and nerve cell bodies of Meissner's plexus.

The esophageal muscle layer presents unique features, as it is composed by striated muscle in the first quarter and smooth muscle in its distal half. The second quarter is mixed, with striated and smooth (involuntary) fibers. In the internal layer, the muscle fibers are circular, while the external layer presents longitudinal fibers. The myenteric ganglia (Auerbach's) are located between these layers. These ganglia, together with those of Meissner's plexus, play an important role in the coordination of esophageal motility. The last layer, adventitia, is composed of loose connective tissue, allowing movement of the organ during swallows. Physiologically, three parts are distinguishable: the upper esophageal sphincter, the esophageal body (EB), and the lower esophageal sphincter.

Upper Esophageal Sphincter (UES)

The pharyngoesophageal junction locates at C5–6 intervertebral space and at the inferior border of the cricoid cartilage. The UES consists of the three muscles (cervical esophagus, cricopharyngeus, and inferior pharyngeal constrictor) and the surface of the cricoid cartilage [2]. Its role is to prevent air from entering the digestive tract during inspiration and to protect the airways from aspiration by preventing esophageal contents refluxing into the hypopharynx [3].

The cricopharyngeus is the most important muscle in the sphincter, and it attaches to the dorsolateral aspect of the lower part of the cricoid cartilage, forming a horizontal band, like a c-clamp. The muscle presents unique features for maintaining constant basal tone and for relaxing rapidly when required, including presence of both slow-twitch and fast-twitch muscle fibers, absence of a spindle or median raphe, and a large amount of connective tissue [3]. However, most

DOI 10.1007/978-3-642-11202-7_4

of the high-pressure zone corresponding to the UES is related to the projections of the cricoid cartilage and arytenoid cartilages [3].

Physiology

The cricopharyngeus is innervated by the pharyngeal plexus, which is supplied by three major nerves: vagus nerve branches, including the pharyngeal branch, the glossopharyngeal nerve, and sympathetic nerve fibers from the superior cervical ganglion [4]. Acetylcholine is the principal neurotransmitter for efferent innervation, acting via skeletal muscle nicotinic receptors.

The pressure profile of the UES shows axial asymmetry with a sharp ascent in its upper part and a more gradual decline, as well as marked radial asymmetry [3]. The cricopharyngeus corresponds to the distal part. The resting pressure ranges from 30 to 110 mmHg, but the UES basal tone is lower in full-term neonates as compared to adults, although they present similar deglutitive relaxation [3, 5]. Resting UES tone also varies with head position, phonation (increase), higher pitch notes (increase), and inspiration (increase).

Swallow

During swallow, the continuous spike activity of the cricopharyngeus ceases, due to a transient chloride-dependent inhibition of active lower motor neurons in the brainstem innervating the UES [3]. Anterior motion of the hyoid during its superior excursion, by contraction of the suprahyoid muscle, is also required to abolish the residual pressure and open the sphincter [3]. Next, the relaxed and open UES actively contracts as the deglutitive pharyngeal peristaltic wave reaches the sphincter, reaching twice the resting pressure. The UES opening can be independently modulated by bolus volume and viscosity.

Reflexes

Relaxation follows an abrupt distention of the esophagus, as in belching. The relaxation differs from that associated with swallows as it may be partial and lasts more and the associated hyoid movement exhibits less amplitude [3, 6].

Relaxation of UES also follows most (79%) transient lower esophageal sphincter relaxation (tLESR), but contraction happens in 8% [6]. It may happen before or after the tLESR, and it is more variable in completeness than that observed in swallows. It is generally associated with depressurization of the EB (suggesting air venting) and presents higher median pressure, longer duration, higher incidence of incomplete relaxation, and lower maximal after-contraction amplitude [6].

UES pressure may increase with gagging and slow esophageal distension. It is controversial if acidic content of the bolus enhances UES relaxation [6]. Pharyngeal stimuli, such as infusion of water and air, may also generate UES contraction in adults. On the other hand, in newborns, such stimuli generate pharyngeal swallows rather than UES contraction, possibly as a defense reaction against aspiration [7].

Esophageal Body

The esophagus is a flattened muscular tube that is collapsed between swallows, but can distend to 2 cm in the anterior-posterior dimension and 3 cm laterally to accommodate an ingested bolus [8]. The organ is topographically divided in three parts: cervical, thoracic, and abdominal.

The cervical esophagus extends from the pharyngoesophageal junction to the suprasternal fossa [8]. At this level, the esophagus is bordered anteriorly by the larynx and trachea, posteriorly by the vertebral column, and laterally by the carotid sheaths and the thyroid gland. The thoracic esophagus extends from the level of T1–T10 or T11, lying posterior to the trachea and the pericardium; anterior to the vertebral column and aorta; and sided by the mediastinal pleura [1]. The abdominal esophagus extends from the diaphragmatic hiatus to the cardia, lying in the esophageal groove on the posterior surface of the left lobe of the liver, on the right of the gastric fundus, being posterior to the left vagal trunk and anterior to the diaphragmatic crura and the aorta.

Esophageal arterial supply is segmental, coming mostly from the inferior thyroid artery (UES

and cervical esophagus), esophageal branches of the aorta (thoracic esophagus), the left gastric artery (LES and distal esophagus), and the splenic artery (distal esophagus) [1]. Venous drainage of the proximal two-thirds drains to systemic veins; the distal third drains to the portal system, but there are plenty of connections between the two systems [1]. Proximal third lymphatic vessels drain into the deep cervical lymph nodes, while middle third lymphatic vessels drain into the superior and posterior mediastinal nodes, and distal third lymphatic vessels follow the left gastric artery to the gastric and celiac lymph nodes [8].

Sensory innervation comes from vagus and spinal nerves. Spinal afferents have their cell bodies in the dorsal root ganglia and terminate in the spinal column and in the nucleus gracilis and cuneatus in the brainstem [9, 10]. Motor innervation is predominantly vagal.

Physiology

Esophageal muscle is phasic, without resting tone. However, some authors have identified a tone that is inhibited during abrupt distention of esophageal lumen and helps preventing reflux episodes [11]. There are intramural inhibitory (nitric oxide) and excitatory (acetylcholine) neurons, which receive inputs from preganglionic neurons located in the dorsal motor nucleus of vagus. Cholinergic excitatory innervation is most marked in the proximal esophagus and decreases gradually in the distal part, while inhibitory (nonadrenergic noncholinergic) increases distally. Vagally activated inhibitory neurons generate the latency of peristalsis.

Primary Peristalsis

Primary peristaltic waves are associated with swallows and can be triggered at will or by reflex. They assist the gravity to propel the bolus through the esophagus and participate in the clearance of reflux episodes [12]. The striated muscle peristalsis depends on sequential activation of motor neurons in the nucleus ambiguous, without any triggering peripheral mechanism [13].

The spread of peristalsis to the smooth muscle depends on coordination of the central and neural peripheral circuitry and myogenic properties. The smooth muscle segment presents cholinergic (excitatory) and nonadrenergic noncholinergic (inhibitory) effector neurons. Also, muscle cells interact and operate as a functional unit, while the interstitial cells of Cajal modulate the muscle nerve interaction [14]. There is a latency period between the onset of a swallow and contraction of esophageal circular smooth muscle. Early in this period, intramural neurons release nitric oxide that causes initial hyperpolarization and inhibition of esophageal muscle. Latency duration increases from proximal to distal esophagus, and this gradient is the basis for esophageal peristalsis [15].

Esophageal contractions are limited by two inhibitory phenomena: initial inhibition and refractoriness [16]. Initial inhibition is the inhibition of any activity in the esophagus that may be occurring at the time of vagal stimulation, and its degree increases with increasing frequency of stimulation. Refractoriness is the inhibition of any evoked contraction that may tend to occur during and soon after the ongoing esophageal response to a previous stimulus. As a consequence, repetitive swallowing at short intervals produces an esophageal response characterized by quiescence until the last of the swallows, which is then followed by an esophageal contraction [16].

Primary peristalsis has been observed in the fetus as early as 32 weeks of post-menstrual age (PMA) [17]. The mean maximum peristaltic wave amplitude increases from 33 to 39 PMA in the proximal esophagus, both in primary and secondary peristalsis, but not in the distal esophagus [18]. Newborns present lower amplitude, slower velocity of propagation, and greater duration of the contraction than adults [5]. The amplitude of peristaltic wave in the distal esophagus was found to increase with age, peaking in the 50s [19]. Elderly patients frequently present abnormal esophageal contractions, possibly due to reduction in the number of ganglion cells with age and inflammation of Auerbach's plexus [20].

Secondary Peristalsis

Secondary peristalsis is a response to esophageal distension triggered by afferent and efferent

innervation through vagus. The secondary peristalsis depends on peripheral mechanisms and also involves inhibition followed by excitation. It is uncertain if the chemical content of the bolus (acidic or not) influences the threshold to initiate the peristalsis [11]. The secondary peristalsis is a clearance mechanism, after primary peristalsis and reflux episodes [11]. The mean maximum peristaltic waveform amplitude is lower in the distal esophagus but not in the proximal [18].

Clearance mechanisms are present in preterm infants, and they present similar latency period to trigger them and similar volume-dependent increase in the UES pressure following infusion of liquid in the esophageal lumen [21]. The presence of secondary peristalsis has been observed in the fetus as early as 32 weeks of post-menstrual age [17]. On the other hand, preterm babies (33 weeks) present lower volume threshold for mechano- and chemostimulation to evoke secondary peristalsis [21]. In response to acidic content, the main clearance mechanism is primary peristalsis in 33-week infants, but secondary peristalsis in 36-week infants [21].

Lower Esophageal Sphincter (LES)

The gastroesophageal junction is a dynamic structure composed by the LES, the crural diaphragm, and components of the gastric muscle (Fig. 4.1) [12]. Its function is to avoid gastroesophageal reflux, without impair swallowing and appropriate reflux of gaseous contents. There is a thickening of the esophageal circular muscle layer in the LES, which may be located above, at the level or below the esophageal hiatus. This thickened region is limited by a fascia, forming a discrete muscular ring [22]. Crura circle the proximal 2–4 cm of the LES and determine inspiratory spikelike increases in LES pressure as measured by esophageal manometry [23].

Resting

Resting tone is believed to be predominantly due to intrinsic muscle activity because the resting LES tone persists even after surgical or pharmacologic destruction of all neural input [24]. LES muscle fibers present unique features, as differentiated composition of contractile proteins and continuous electrical spike activity, that play a role in keeping the tone by myogenic properties [13]. Also the diaphragmatic crura contribute to the LES pressure, contracting during inspiratory effort [25].

Motor innervation depends on vagus, which provides both excitatory (cholinergic) and inhibitory (nitrergic) innervations to the LES, but they influence the resting tone only when stimulated. Neurohormones modulate basal LES tone (figure) [12, 13].

In preterm babies younger than 29 weeks PMA, LES presents lower basal pressure (3.8–5 mmHg) as compared to full-term infants (18.1–23 mmHg) [12, 26].

Reflexes

Excitatory stimuli from vagus are related to acetylcholine and substance P neurotransmitter, while the inhibitory stimuli depend mainly on nitric oxide [13]. Deglutitive transient LES relaxation (dTLESR) begins within less than 2 s of a swallow and is mediated by vagal inhibitory pathway and the postganglionic myenteric neurons that act by releasing nitric oxide [13]. The relaxation usually lasts 8–10 s and is followed by a contraction, continuation of esophageal peristalsis, in the proximal part of the LES that lasts 7–10 s.

Pharyngeal tactile stimuli elicit LES contraction through a reflex that follows the same pathway and can be abolished by bilateral vagal nerve section or cooling. Esophageal distention by a bolus of liquid or food triggers relaxation of the LES through motor fibers originating in the dorsal motor nucleus of the vagus and the compact portion of the nucleus ambiguous when the distention happens in the striated part of the esophagus [12]. On the other hand, distention in the smooth muscle zone seems to result in a reflex relaxation from intramural neurons [27].

tLESR is not associated with swallowing, and it helps to regulate gastric distension, by allowing belching and vomiting. tLESRs are a vagovagal reflex that involves only the inhibitory pathway [13]. Sensory fibers from infradiaphragmatic receptors, such as fundic mechanoreceptors, ter-

REDUCE LES PRESSURE
- Nicotine
- Beta adrenergic antagonists
- Cholecystokinin
- Secretin
- Vasoactive intestinal polypeptide (VIP)
- Calcitonin gene-related peptide
- Adenosine
- Prostaglandin E
- Nitric oxide donors (i.e nitrate)
- Glucagon
- Atropine
- Gastric inhibitory peptide
- Calcium channel blockers
- Morphine
- Inhibitors of phosphodiesterase-5
- Decreased ventilatory drive (apnea)

INCREASE LES PRESSURE
- M2 and M3 receptor agonists
- Alfa adrenergic agonists
- Motilin
- Pancreatic polypeptide
- Bombesin
- Angiotensin II
- Metoclopramide
- Cisapride
- Gastrin
- Substance P
- Prostaglandin F2alpha
- Hypoxia

minate in the caudal brainstem (nucleus tractus solitarius), from which downstream motor nuclei such as the dorsal motor nucleus of the vagus and nucleus ambiguus are activated. These nuclei then send afferent input to the LES, esophageal wall, pharynx, and crural diaphragm and activate tLESRs [12]. tLESR combines cessation of tonic cholinergic excitation and active inhibition of muscle contraction through nonadrenergic noncholinergic pathways [12]. The most important noncholinergic, nonadrenergic mediators involved are NO and VIP [12]. Deep inspiration may also trigger tLESR [12]. Different from dLESR, tLESR is associated with concurrent inhibition of diaphragmatic crural activity. Also, the relaxation is longer (more than 10 s) and more variable, ending with an unpredictable pattern of terminating motor event in the esophagus, either primary peristalsis or spontaneous contractions, which seems to be more frequent [28]. tLESR triggering is enhanced by phosphodiesterase-5 inhibitors and inhibited by GABA-B agonists. Finally, cholecystokinin (CCK) receptors may play a role, and CCK released on food entering the duodenum may enhance tLESRs triggering [29].

Tests to Detect Esophageal Contraction Abnormalities

Indications

Esophageal manometry is considered the gold standard for assessing esophageal motor activity, especially diagnosing nonstructural dysphagia [30]. Both normal and abnormal esophageal

contractions and bolus movement can be detected without the use of radiation [31]. However, the diagnostic tool should be used only after a careful history and endoscopic and fluoroscopic examinations have ruled out any organic pathology or cardiopulmonary involvement [30]. Following these considerations, esophageal manometry can successfully evaluate upper and lower esophageal sphincter (UES and LES) pressure, esophageal body contraction amplitude, and peristaltic sequence [32, 33]. Causes of unexplained or noncardiac chest pain, systemic collagenosis, and symptoms related to gastroesophageal reflux disease (GERD) [30, 32] may also be identified. Although esophageal manometry does not diagnose GERD, it may be used to evaluate a patient prior to antireflux surgery [30, 34] to rule out scleroderma esophagus and achalasia and to adequately access esophageal length [32].

However, both standard manometry and HRM are not definitive diagnostics when it comes to achalasia. Both tests fail to detect brief periods of EGJ relaxation, which affects peristalsis and pressure within the distal esophagus. While this data has not yet been fully refined, it may prove significant to accurate achalasia diagnosis. HRM may prove beneficial in subclassifying achalasia into classic, spastic, and combined with esophageal compression [35].

Esophageal manometry is contraindicated in cases of pharyngeal or upper esophageal obstructions, severe coagulopathy, cardiac conditions in which the patient is intolerant of vagal stimulation, and patient noncompliance [30].

Methods and Equipments

To ensure an accurate diagnosis, it is necessary to thoroughly understand the many technical issues of esophageal manometry [36], use proper instrumentation [30], and maintain a standard in technique and evaluation among laboratories [32]. Differences in practice, measurement, and interpretation may hinder an accurate diagnosis [32, 37].

Equipment

Two types of solid-state intraluminal microtransducers have replaced the earlier water-infused manometry systems, ensuring accurate qualitative and quantitative esophageal pressure recordings [32, 38]. Unidirectional transducers measure pressures in one direction, while circumferential transducers measure pressures in 360°, and corresponding software automatically averages the results. Standard catheters are now equipped with up to four unidirectional or proximal transducers and one circumferential transducer, each transducer placed 5 cm apart [38]. Measurements are similar when using either a unidirectional or single circumference transducer [38].

Successful manometry requires a three-channel, triple-lumen catheter and a pneumo-hydraulic capillary infusion system with deltaP/deltaT >150–200 mmHg/s [30]. To study the esophageal body and LES, data should be recorded at a rate of ≥8 Hz, noting LES tonic (pressure) and phasic (relaxation) activities in addition to the esophageal body amplitude and peristaltic activity [30].

Evaluations and Recordings

Ideally, the manometry catheter is placed from the pharynx to the stomach, with sensors in and around the sphincters [37]. The catheter is initially placed in the stomach and then rotated in 0.5-cm increments [38]. The study can be successfully completed with the catheter in one position and the patient swallowing 10.5-mL swallows, spaced 20–30 s apart [32]. Systematically evaluating the LES, smooth muscle of the esophagus, and if needed, the proximal esophagus and upper sphincter enables evaluation of LES pressure, length, and residual pressure; distal esophageal body strength and function; and if needed, proximal esophagus and UES studies [32]. All recordings are automatically interpreted by embedded software, but it is important to review the readings independently and provide a written impression [32].

Table 4.1 Normal parameters for esophageal motility studies

	Normal values
Esophageal manometry	Pressures:
Stationary	LES during H_2O swallow [34]: <5 mmHg[a]
24 h	LES resting mid-resp. [38]: 15–45 mmHg
	LES resting length [38]: 2–5 mmHg
Ambulatory	Contraction amplitude at 5 and 10 cm [31]: ≥30 mmHg
	Resting pressures [33][b]:
	UES: 116 ± 9.6 mmHg
	LES: 24.0 ± 2.0 mmHg
	Contraction amplitude [33][b,c]:
	Upper: 60.7 ± 9.5 mmHg
	Lower: 924.0 ± 3.3 mmHg
	Contraction duration [33][b,c]:
	Upper: 2.7 ± 0.2 s
	Lower: 3.5 ± 0.1 s
Stationary	Swallows [33][c]:
Pediatric numbers—because this is one of few studies, not meant to be used as a gold standard/ authors	Upper: 100 %
	Lower: 3.5 ± 0.1 s
	Resting pressures [39][b]:
	UES: 62.5 ± 19.4 mmHg
	LES: 24.0 ± 7.6 mmHg
High resolution	Intraluminal esophageal pressures [39][b]:
	17.6 ± 4.7 mmHg before wet swallows
	↑ 43.1 % ± 47.5 % after swallows
	Per Chicago Classification [40]:
	<3 cm defect in 30-mmHg isobaric contour
	IBP <15 mmHg
	DCI <5,000 mmHg s^{-1} cm^{-1}

GEJ gastroesophageal junction
[a]Values are often lower in the sitting than supine position
[b]Values presented as mean ± SD
[c]Upper, lower refers to location in the esophagus
[d]Measured from cricopharyngeal sphincter to the GEJ [41]

Normal Values

For accurate recordings, pressure data are obtained from at least three sites, each spaced 5 cm apart. The most distal pressure transducer should be located no more than 3 cm distal to the pH sensor. Data are recorded on an electronic data logger and analyzed by software. Manual tracings of pressure and pH will help locate abnormal readings and correlate them to pain periods. A normal LES reading relaxes below 5 mmHg during water swallowing [34]. Normal values for esophageal motility testing are provided in the Table 4.1.

Esophageal motor functions vary throughout the day, with more activity noted during meals, as propulsion forces solids down the esophagus, creating longer, higher amplitude contractions [33, 42]. Values are often lower in the sitting than supine position, possibly because intra-abdominal pressure during sitting increases intrinsic muscle tone [38]. There may also be a

connection between esophageal motor activity in the supine position and rapid eye movement during sleep [33]. The normal mid-respiratory LES resting pressure has been noted at 15–45 mmHg, and the corresponding normal LES resting length is 2–5 mmHg [38]. Values may also be affected by age and gender. A study of adults by van Herwaarden et al. determined that females have higher resting pressures than males. They also determined that UES resting pressures and UES relaxation interval and rate show an inverse correlation with age, while UES residual pressure increases. This results from a loss of basal tone and a decrease of UES compliance [43].

Stationary Esophageal Manometry

Stationary esophageal manometry, often performed with the patient in the supine position, is used to evaluate the UES and pharynx and to determine the upper margin of the lower esophageal sphincter (LES) prior to ambulatory manometry. Although solid-state manometry is capable of recording in the upright position, normal values for that position have yet to be determined, and the position affords more ineffective contractions [32].

Ambulatory 24-h Esophageal Manometry

Limited studies have been done on normal readings during a 24-h ambulatory esophageal function, and ambulatory studies have been criticized because of the individual variables involved, although the variables may not be different than those of stationary manometry [42]. Ambulatory 24-h esophageal manometry is beneficial to diagnose esophageal spasm because pain symptoms often correlate with abnormal motility or acid reflux, neither of which may be diagnosed during stationary manometry. Using a solid-state combined manometry and pH probe, the probe's pH sensor is positioned 5 cm above the upper margin of the LES. Routine treatments, such as a proton pump inhibitor, are continued during the study [44].

High-Resolution Esophageal Manometry

Conventional manometry details the esophageal pressure profile, but it does not provide information on bolus transit or esophageal emptying [37]. As a result, diagnosis based on manometry is somewhat subjective [37]. Given that there is poor association between conventional manometry and symptoms, high-resolution esophageal manometry (HRM) is a natural evolution [44, 45]. Technical advances have led to the development of powerful computerized acquisition systems, high-fidelity multichannel perfusion pumps, and manometric catheters, thereby enabling a higher resolution of measurements [39]. Pressure data are then transformed into a topographic colored data sheet of continuous esophageal pressure [37, 39, 45].

Algorithms expand the data into pressure topography plots, which characterize the spatial limits, vigor, and integrity of contractile segments along the esophagus in addition to distinguishing between pressure and contractions. Studying 400 patients and 75 controls, Kahrilas et al. formulated the Chicago Classification system to reclassify esophageal motility to coincide with the new colored plots. This system essentially refines diagnosis and essentially eliminates nonspecific esophageal motor disorder [40] because all manometry findings are nonspecific, and there is always more than one diagnosis associated with each noted pattern. Since its development, the Chicago system has been subtly modified by research groups around the world, and most likely, the system will continue to evolve for many years [35].

The HRM catheter can be positioned to record pressures just above the UES and also below the LES, thereby recording normal esophageal motor function in addition to dysfunction [39]. Pressure sensors on the HRM catheters are spaced 1–2 cm apart, rather than 5 cm as in conventional or solid-state manometry, and HRM catheters may have as many as 36 sensors [35, 39, 44]. Multiple sensors eliminate movement-related artifact [35, 40] and the dependency on correct sensor positioning [37], both problems with conventional manometry.

While unidirectional and circumferential HRM catheters are available, they do not appear to provide significant benefit [37].

While the correlation between conventional manometry and HRM is high, HRM offers numerous advantages:

- Presents pressure data in pattern recognition and real time, allowing objective measures and standardized interpretation [35, 37]
- Provides intuitive and easy to learn technology, offering reproducible studies [35, 37]
- Allows quicker and easier high-quality studies, without need for catheter pull-through and sensor positioning [35]
- Reveals complex functional anatomy of esophageal peristalsis and esophagogastric junction, thereby improving ability to predict success or failure of bolus movement through esophagus [37, 44, 45]
- Detects reflux events and distinguishes components of antireflux barrier, allowing study of their interaction [44]
- Increases diagnostic accuracy of achalasia and its subclassifications, functional dysphagia, and esophageal spasm [37, 44]
- Defines, with combined impedance, intraluminal pressure gradients within the esophagus and across sphincters [45]

HRM is useful in pediatrics and allows the clinician to differentiate between aperistalses due to ineffective motility or due to achalasia [46]. Recommendations for HRM in pediatrics include [46]:

- Avoid sedation, if at all possible.
- Identify LES using standard manometry.
- Run baseline of LES pressure once patient is relaxed.
- Aim for maximum tolerated volume in ten wet swallows: 5 mL if >5 years, 2 mL <5 years, and 0.5–1.0 mL for infants.
- Study solid swallows if patient has symptoms following solid food.

Despite the advantages of HRM, there is the basic issue of how to apply the advanced technology to evaluate patients. Most likely, a new language may need to be developed [35, 45]. There are limitations to this new technology, and studies are needed on cost-effectiveness compared to conventional manometry and on the benefit of HRM in all applications [44]. While HRM indirectly estimates bolus transit, it can determine and localize bolus transit failure [37]. Accurate readings require a skilled clinician who has been trained in manometric recordings and interpretations. The clinician should also be cautioned against misinterpretation, which could lead to unnecessary or ineffective treatment [44]. In addition, current classification of esophageal motility, developed for conventional manometry, may need to be reconsidered [35].

High-Resolution Impedance

Intraluminal impedance provides information on bolus transit and avoids the radiation exposure of fluoroscopy. Combined manometry and impedance provide information on both bolus transit and motor function, thereby allowing tighter categorization of esophageal dysfunction and treatment. Combined HRM and impedance take accurate diagnosis one step further by refining the diagnosis and management of achalasia, functional obstruction, and rumination. Together, they also distinguish pressure values for abnormal bolus transit [37].

Impedance detects the type of acid (liquid, gas, or mixed) and the proximal extent of reflux, regardless of its acidity. However, the ability to detect small amounts of reflux have yet to be determined, suggesting that combined impedance and pH monitoring may be required to fully evaluated reflux [45].

High-Definition HRM

Technologies will continue to evolve, and high-definition HRM catheters, with more pressure sensors, closer together, are being developed. This newer development will offer enhanced spatial resolution and radial pressure detail, thereby allowing detailed study of the CD component of EGJ pressure and the intragastric component of EGJ [45].

Tests to Evaluate Esophageal Bolus Transit and Clearance

Videocineroentgenography

Videocineroentgenography, also known as videofluorography (VFG) [47], provides a highly sensitive morphodynamic study of swallowing, including vocal cord and soft palate motility, oral and pharyngeal phases of swallowing, and pooling of contrast agent in the sinuses, and is a valid study of the overall esophagus [47]. The test helps identify esophageal motor alterations, such as clearing deficit and dilatation, GERD, and hiatus hernia, and may be successfully used as an indicator of the progression of systemic sclerosis [47]. Early stages of esophagitis, however, must be identified by endoscopy [47].

Initially, the pharyngeal function is dynamically evaluated by recording the ingestion of barium. Barium is ingested voluntarily, but it may also be instilled with a syringe into the cheek pouch [48]. Possible abnormalities include abnormal tongue movement, pharyngeal muscle dysfunction, laryngeal penetration, and aspiration [49]. Then, high-density barium is swallowed in upright position in order to coat the mucosa with a thin layer of contrast, for double-contrast frames, which are useful to evaluate the esophageal mucosa [50]. Next, low-density barium is ingested in the prone position (right anterior oblique position) to evaluate esophageal motility. Five swallows with at least 20-s interval are required in this part [50]. Finally, more low-density barium is ingested to distend the lumen and detect strictures [49]. Children need to be immobilized, and the use of an Octostop device (Octostop, Laval, Quebec, Canada) or special car seat is beneficial for children under 3 years and may reduce a child's fear [48]. Barium, which is generally instilled during voluntary swallowing, can be made more palatable with flavoring packets or mixed in milk [48]. Timed barium esophagogram follows a different protocol to evaluate the esophageal emptying, with three radiograph exposures (1, 2, and 5 min) after ingestion of 250 mL of low-density barium [51].

Abnormal motility is defined by abnormal peristalsis observed in two or more discrete swallows [49]. Achalasia features a flaccid and dilated esophagus, with a beak-like narrowing at the gastroesophageal junction. Diffuse esophageal spasm is characterized by intermittently absent peristalsis with lumen obliterating nonperistaltic contractions, producing a typical corkscrew appearance [49]. Finally, double-contrast examination may suggest diagnosis of esophagitis (peptic, infectious, and eosinophilic) and strictures.

Although radiology cannot provide a definitive diagnosis, it is a useful screening test in patients with dysphagia, as it may suggest motility abnormalities and rule out strictures. Overall, radiology is 80 % sensitive and 79–95 % specific for diagnosing esophageal motility disorders [50, 52]. The sensitivity of the study depends on the number of swallowing studies performed in both the upright and supine positions. A higher sensitivity may be noted with the patient in the prone position, although more abnormal contractions are detected in the upright position. The reason for this remains unclear [52].

A major disadvantage of the method is the exposure to radiation, which can be diminished by optimizing the X-ray beam and using beam filtration, additional layers of aluminum and copper filtration, low-dose pulsed fluoroscopy, minimized fluoroscopy time, and tight collimation [48]. Also, the total number of higher dose spot film-type exposures can be reduced by using fluoroscopy capture technology or frame grab. The use of analog or digital recording may allow for recording of a limited number of swallows.

Esophageal Transit Scintigraphy

Esophageal scintigraphy allows evaluating the esophageal emptying, the bolus transit through its segments, and the presence of reflux in all evaluated segments [53].

After ingesting radiolabeled bolus, images are acquired at four to ten frames per second for 60 s (or 0.5 s for 40 s) [54]. The test is performed with a large field gamma-camera that views the entire

organ. Anterior and posterior views can be used, being anterior preferred when oral and pharyngeal phases are being evaluated and posterior preferred when the interest rely on the esophagus. The Exam can be performed with ^{99m}Tc-sulfur colloid, ^{99m}Tc-nanocolloid, ^{99m}Tc-diethylenetriaminepentaacetic acid (DTPA), or any other nonabsorbed radiopharmaceutical, mixed with water or juice. The minimum dose is 7–11 MBq. A semisolid bolus may be used but it is not as standardized as liquid bolus [53]. Although an upright position is more physiological, the supine position is better to evaluate clearance as this position removes the effect of gravity.

The clearance is indicated by retained radioactivity in the esophagus. In adults, the mean residual radioactivity at 20 s is 6.4 ± 1.8 %, and values over 10 % (mean + 2 standard deviations) are abnormal [54]. Based on one wet swallow (15 mL, 11 mBq) and three successive dry swallows (5 s interval), a fraction >19.8 % in the posterior view (or 13.1 % in the anterior) at the fourth swallow is considered abnormal in the supine position [55].

Scintigraphy may suggest motility abnormalities, such as achalasia, by detecting delayed esophageal emptying with 91 % sensitivity and 98 % sensitivity [53]. Also, it can be used to evaluate the esophageal function after endoscopic treatment of achalasia [56]. Advantages of the method include the compression of the exam to a single image and the better accuracy to evaluate emptying rate as compared to conventional radiology. Its interpretation relies on objective and quantifiable measures, depending less on the interpreter [54]. On the other hand, it requires equipment not widely available and does not evaluate the esophageal anatomy well. Also, the test is not properly standardized, and protocols vary significantly between centers.

Impedance and Ambulatory Esophageal Impedance and pH Monitoring

Impedance is the resistance to electrical flow in an electric alternating current (AC) circuit. In this test, an AC is passed between electrodes, and each pair of two electrodes forms an impedance channel between them. The baseline impedance is a measure of impedance in the esophageal mucosa, as the lumen is collapsed and the mucosa is in contact with the electrodes. Although there is no normal value for baseline, it is lower in inflamed mucosa, in the proximal esophagus, in Barrett's esophagus, and in dilated esophageal lumen and when liquid stasis is present [57]. Changes in the impedance reading are related to the passage of substances presenting impedance that is different from the esophageal mucosa: a liquid bolus diminishes the impedance (presenting lower resistance to the electrical current); and a gaseous bolus increases the impedance (more resistance). At the distal end of the catheter is placed a pH sensor that allows determining the chemical content of the bolus. Combined ambulatory esophageal impedance and pH monitoring allows evaluating not only the bolus transit and clearance but also the clearance of refluxate bolus and the chemical clearance of the esophageal lumen after a reflux episode.

The exam employs a polyvinyl catheter (2.13-mm diameter) with six impedance sensors and a distal pH probe that is located to 13 % the distance between LES and the nostrils. Specific catheters are available for infants, children, and adults.

The impedance test for esophageal transit time is performed with a protocol similar to that of esophageal manometry, with ten discrete liquid swallows and ten discrete viscous swallows. Bolus entry in a channel is defined by a drop of 50 % of baseline and exit by return to that point. Impedance has been validated, with a 97 % concordance with fluoroscopy in detecting normal bolus transit [58]. Total transit time is the interval elapsed between entry in the first channel and exit in the last distal channel. Frequently a small amount of air is observed in front of the bolus. This leads to a brief increase in the impedence that is not accounted for in the bolus transit. The standard impedance criteria for determining transit passage do not predict reliably bolus transit in the hypopharynx, the UES, and the proximal esophagus. Szczesniak et al. (2008) proposed different

cutoffs for impedance in these locations [59]. According to them, a drop to 71% of baseline would define bolus entry in hypopharynx, 72% in UES, and 80% in proximal esophagus, while clearance could be defined by 0% recovery (nadir) in the hypopharynx, 5% in UES, and 19% in the proximal esophagus. With these criteria, the agreement between fluoroscopy and impedance would improve, but would still remain fair to moderate, because impedance is not good at evaluating bolus transit before esophagus, because pharynx is not a collapsed organ [59].

The main parameter evaluated is the proportion of swallows that present complete bolus transit. Complete bolus transit is achieved in 93% of normal individuals for at least 80% liquid swallows and 70% viscous swallows [60–62]. An abnormal bolus transit can signify stasis, if there is a fail in demonstrating bolus exit or if the impedance falls after transient recovery, or retrograde escape, defined by the return of the bolus to an area previously cleared [58]. This last event happens generally after a new swallow before 30 s.

The bolus velocity, bolus transit time, chemical clearance, and distal baseline after liquid and viscous swallows can also be evaluated. Bolus velocity is slower for viscous bolus (2.56 cm/s± 0.24) than for liquid bolus (water, 3.81 cm/s±0.31) [63]. Distal impedance after liquid swallow and after viscous swallow is abnormally low in patients with scleroderma, achalasia, and ineffective esophageal motility compared to healthy volunteers and normal patients [57].

Impedance as a test for evaluating bolus transit is mainly indicated in patients with nonobstructive dysphagia and before an antireflux surgery. Impedance cannot replace fluoroscopy, because it cannot evaluate swallows of solid bolus. Also, it does not provide any information on the anatomy of the organ, although it does provide useful information on mucosal integrity [64]. Impedance is the only test that evaluates bolus transit without radioactivity exposure, making it suitable for pregnant women and children, as well as repeated tests are needed. However, the impedance is not useful for diagnosing achalasia. In these patients, a low baseline may be found, due to stasis and inflammation. Also, air trapping makes the exam technically difficult [65]. The exam has not been tested in the follow-up of these patients posttreatment.

Prolonged combined impedance-pH monitoring is useful in evaluating gastroesophageal reflux, mainly when atypical symptoms are thought to be related to reflux episodes. The test is better than prolonged pH monitoring in finding a significative symptom association with reflux episodes. Also, it is useful to evaluate GERD refractory to therapy [64]. Esophageal impedance monitoring with simultaneous gastric pressure evaluation identifies patients with rumination better than esophageal pH monitoring, as rumination generally involves nonacid bolus. Gastric manometry demonstrates increase in the intragastric pressure that initiate the event, and impedance identifies the consequent reflux event. Finally, supragastric belching can also be identified through impedance, as it shows air rapidly entering and being expelled in the oral direction, different from gastric belching, when it is possible to observe the oral direction of the air [66].

Esophageal Function Testing

Esophageal function testing (EFT) combines esophageal manometry and multichannel intraluminal impedance monitoring, using a specific catheter with solid-state pressure transducers in the center of impedance channels and a distal pressure transducer. Then, the catheter is passed into the stomach through the nostrils. Intragastric pressure is set as baseline pressure [67]. Next, the LES is identified using the pull-through technique, and the last distal pressure transducer is located at it. In order to evaluate peristalsis and bolus clearance, the patient receives in supine position ten liquid and ten viscous discrete swallows, 5 mL each, 20–30 s apart [60]. Swallows initiated within 10–15 s of a primary swallow are excluded from analysis.

There are three different catheters. A catheter with 11 impedance channels (2 cm each, 2.5-mm diameter) and 4 manometric channels (6 cm

apart) disposed between impedance channels 1 and 2 (proximal to distal), 4 and 5, 7 and 8, and 10 and 11. Another one contains four impedance channels (5 cm each), with one pressure transducer in the middle of each channel (10, 15, 20, and 25 cm from the tip) and a distal pressure transducer located 5 cm from the tip. Recently, a high-resolution catheter is available with 36 pressure sensors (1 cm apart) and 12 impedance channels (2 cm apart, except for a 4-cm gap in the proximal segment) [68].

Esophageal function testing provides information previously obtained in esophageal manometry and fluoroscopy in only one exam. It allows monitoring bolus transit patterns, estimating bolus transit parameters and monitoring swallow associated events (aerophagia, air trapping) [69]. It is indicated for evaluating nonobstructive dysphagia, unexplained chest pain, suspicion of generalized gastrointestinal motility disorder, and preoperative evaluation before antireflux surgery [62]. Its use for primary diagnosis is generally made after endoscopy and fluoroscopy yielding negative. It may be useful to assess longitudinal change and therapeutic interventions. After fundoplication, the EFT is useful in evaluating dysphagia, and incomplete bolus transit is more common in symptomatic patients and in patients with abnormal anatomy after the surgery [70].

Esophageal function testing identifies abnormalities in patients with nonobstructive dysphagia in which manometry would have been normal or unspecific, such as in patients with ineffective esophageal motility and distal esophageal spasm [67]. However, there are no data to evaluate the impact of this information in the management. Also, interestingly, in adult patients with distal esophageal spasm, patients presenting with chest pain presented more frequently complete bolus transit, while those presenting with dysphagia, incomplete bolus transit [31]. EFT has no advantage in diagnosing achalasia, although it may be useful in monitoring the treatment. However, in these patients the exam may be technically challenging, due to air and food trapped in the esophageal lumen. In adult patients with worsening dysphagia after fundoplication, preoperative esophageal function testing shows longer liquid bolus transit time [71].

Pediatric experience with esophageal function test has not been published at this time.

Esophageal contractions are said to be normal (contraction amplitude at 5 and 10 cm above LES of at least 30 mmHg and onset velocity in the distal esophagus less than 8 cm/s), simultaneous (onset velocity greater than 8 cm/s or retrograde onset and an amplitude >30 mmHg at 5 and 10 cm above LES), or ineffective (amplitude less than 30 mmHg). Complete bolus transit is bolus exit in all three distal channels, and incomplete bolus transit is defined by absence of bolus exit in any of the channels, and normally at least 80% liquid swallows and 70% viscous swallows are associated with complete bolus transit [67]. Based on the EFT findings, esophageal motility abnormalities can be divided in two groups: abnormal manometry and transit (achalasia, scleroderma, ineffective esophageal motility, and distal esophageal spasm) and abnormal manometry with normal transit (nutcracker esophagus, hypertensive LES, hypotensive LES, and poorly relaxing LES) [60]. In addition, other impedance parameters can be estimated, such as bolus transit time (time between bolus entry in the proximal channel and exit in the distal channel), velocity, and baseline impedance during resting. Normal values for total bolus transit time (time between bolus entry in the proximal channel and bolus exit in the distal channel) have been proposed for adults, as 5.2–11.9 s (percentiles 5th and 95th) for liquid boluses and 5.9–12.4 s to viscous boluses [61]. Normal values for bolus head advance time (time between bolus entry in the proximal channel and bolus entry in the distal channel) also were proposed for adults, being 0.5–5 s for liquid bolus and 2.8–7.4 for viscous bolus, values that correspond to a speed of 3–30 cm/s and 2.02–5.3 cm/s, respectively [72]. The bolus transit is delayed in patients with ineffective esophageal motility and accelerated in patients with nutcracker esophagus [73]. Recently, EFT with high-resolution manometry has been used with impedance, and an isobaric contour break longer than 3 cm in the isobaric contour of 30 mmHg was associated with incomplete bolus transit [68].

Pathophysiologic Aspects of Esophageal Motility

Pharyngoesophageal swallowing disorders occur with a high prevalence of concomitant disease, often neuromuscular in origin. The disorders are often chronic, with alarming, yet nonspecific symptoms [74]. They may severely affect a patient's quality of life, especially newborns and young children who are easily susceptible to poor nutrition and failure to thrive [75]. Although esophageal motility disorders have been recognized for centuries, there is a lack of large population studies. As a result, disorder prevalence and economic impact are not well characterized, and many treatments have not been standardized [74].

Motility disorders of the esophagus can be classified as primary or secondary disorders. In primary disorders—such as achalasia, diffuse esophageal spasm (DES), or nonspecific esophageal motor disorder (NEMD)—only the esophagus is primarily affected. Secondary disorders, such as reflux esophagitis, are primarily systemic diseases due to physical or chemical injury that affect the esophagus [50]. The pathophysiology of the most common esophageal motility disorders is described below.

Cricopharyngeal Achalasia

Etiology and Symptoms

Normal swallowing occurs when the cricopharyngeus muscle, a sphincter of the upper esophagus, relaxes, thereby allowing a bolus of food or drink to pass the UES into the esophagus. Primary cricopharyngeal achalasia occurs when the muscle, normally in a constant state of contraction, fails to fully relax and enable swallowing (Fig. 4.2) [76–78]. Problems with PES opening may be due to pharyngeal weakness, possibly due to systemic or neurologic processes. However, many cases of cricopharyngeal achalasia are idiopathic [78].

It occurs most often in middle-aged or elderly patients, but is rare in newborns [77]. While most cases of achalasia occur in the presence of organic disease, other motor abnormalities are generally absent in cricopharyngeal achalasia. Symptoms include dysphagia, choking, cyanosis, salivation, and nasal reflux during feeding [76, 79].

Diagnosis

It is difficult to diagnosis primary cricopharyngeal achalasia, which is most commonly seen in neonates, and confirmed diagnosis is often delayed and sometimes even overlooked [75, 76]. Despite the fact that many cases of cricopharyngeal achalasia are idiopathic [78], anatomic (tracheoesophageal fistula) and functional (esophagus atresia and GER) obstructions must be identified or ruled out with a chest X-ray, barium swallow, and manometry [76]. Neurologic defects should be ruled out by brain ultrasound or computed tomography [77].

A diagnosis of cricopharyngeal achalasia is confirmed following an esophagoscopy that reveals a slight shelf at the level of the UES [75, 76] or cineradiography with lateral views [77]. Radiography shows a persistent prominence of the muscle and an associated narrowing of the PES throughout the entire swallowing [78]. Botulinum toxin injections into the cricopharyngeus muscle have also been used as a diagnostic test in adults to determine the degree of dysphagia related to the muscle [80]. However, following Botox, some patients may develop an inflamed gastroesophageal junction, making myotomy more difficult [81].

Treatment

Achalasia in the premature infant may be self-resolving and best handled with a feeding or gastrostomy tube. Primary cricopharyngeal achalasia requires further treatment, albeit the options are limited: dilatation of the upper esophagus, surgical myotomy of the cricopharyngeus muscle, or drug therapy. Because the disorder is rare and more studies are needed, the efficacy of these options is uncertain [76, 77].

Dilatation, a safe and effective procedure, is more effective in patients with mild dysphagia [79]. The procedure may need to be repeated several times before healthy swallowing is restored. Cricopharyngeal myotomy is not always effective

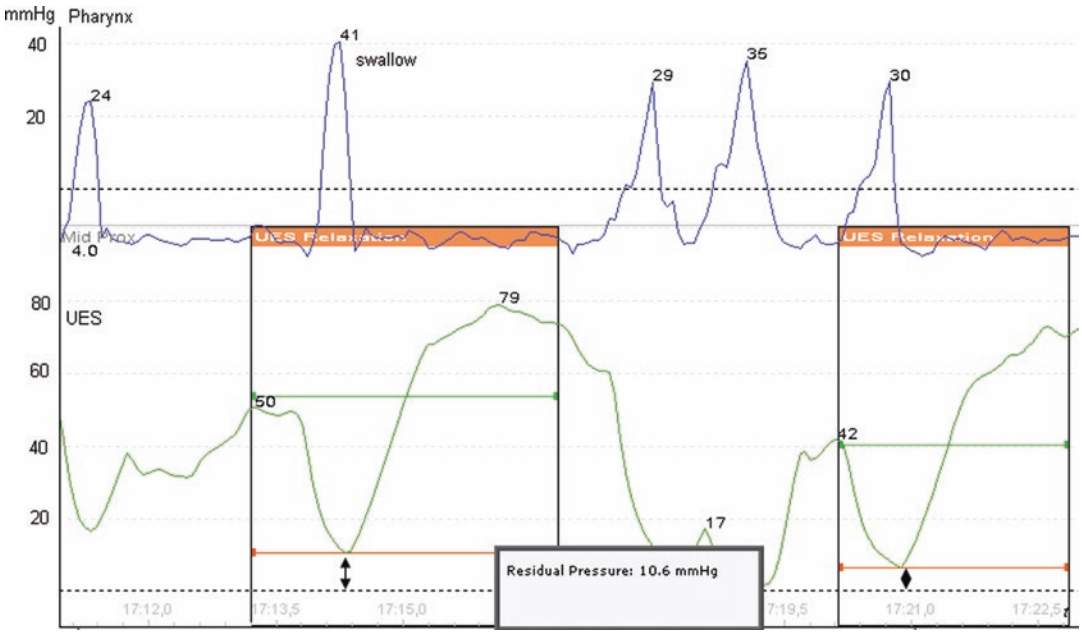

Fig. 4.2 Esophageal manometry in a patient with cricopharyngeal achalasia. Note the swallow followed by incomplete relaxation of UES (*double arrows*), with a resting pressure of 10.6 mmHg. UES: lower esophageal sphincter

and may introduce postoperative complications such as infection and recurrent laryngeal nerve damage. Given the potential complications, some feel that this option should be reserved for patients with residual dysphagia following nonsurgical treatment [75, 76] or patients without other esophageal abnormalities or associated diseases [77]. However, others argue that surgical correction with a complete myotomy provides immediate resolution or a noticeable decrease in symptoms [79]. Myotomy success in reducing the PES narrowing can be measured by a videofluorographic swallow study [78].

Early intervention allows the patient to learn how to swallow during the appropriate development stage [79]. Drug therapy with nifedipine and nitrates may also be beneficial in reducing the muscle tone of the esophageal smooth muscle [77]. But data on their benefits remains scarce, and side effects, such as hypotension, headache, or flushing, have been noted [77]. Injections of botulinum toxin into the cricopharyngeal muscle have been effective in the diagnosis and therapy of adults [80], although it has noted side effects and has yet to be tried in children [76].

Achalasia

Etiology and Symptoms

Achalasia, a rare condition in children, occurs when the LES fails to relax properly, resulting in progressive aperistalsis in the distal two-thirds of the esophagus body (Fig. 4.3). Consequently, the esophagus fails to empty, and material accumulates until enough pressure accumulates and the bolus passes [74]. Although the cause is unknown, most likely, smooth muscle denervation plays a significant role [65, 82, 83]. A primary inflammatory process may be involved, supporting the theory that achalasia is immune mediated [84]. Achalasia is also strongly associated with Chagas' disease, which is caused by the homoflagellate protozoan *Trypanosoma cruzi* and tends to occur in the young [83, 85]. The disorder may be progressive, causing pronounced morbidity [83]. Achalasia may also be associated with the Allgrove syndrome (alacrima, achalasia, and adrenocorticoid deficiency) [86].

Older children with achalasia often have progressive dysphagia to solids and liquids that lasts from several months to several years [65, 82]. Other symptoms include regurgitation (most

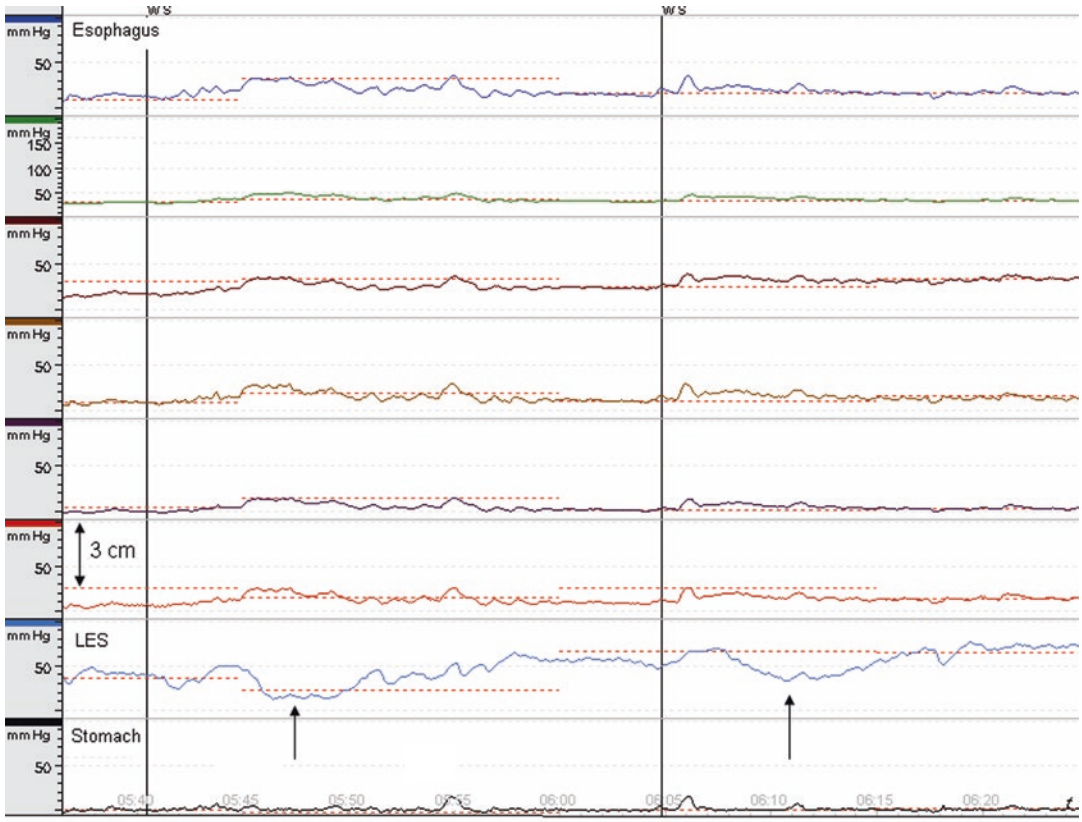

Fig. 4.3 Esophageal manometry in a patient with achalasia. Note the incomplete relaxation of LES (*arrows*) and the absence of primary peristalsis. *WS* wet swallows, *LES* lower esophageal sphincter

often in supine position) [65, 86, 87], chest pain, heartburn often due to stasis of food [88], weight loss [74], coughing (mainly nocturnal), vomiting in children under 5 years of age, and recurrent pneumonia secondary to aspiration [82].

More than one-quarter of children with achalasia may have coexisting conditions including asthma [82]. Pseudoachalasia, which is caused by a tumor at the esophagogastric junction, mimics classic achalasia. Diagnosis is dependent on a surgical biopsy [82]. Patients with achalasia are at increased risk for developing squamous carcinoma [83] and adenocarcinoma and should be followed with routine endoscopy following treatment [87].

Achalasia Subtypes

A study by Pandolfino et al. suggests that there are three subtypes of achalasia, as determined by high-resolution manometry (HRM) [37, 89]:

- Type I or classic achalasia is characterized by a high percentage of failed peristalsis. Patients in this group respond best to Heller myotomy.
- Type II achalasia, which comprises many females, is characterized by pan-esophageal pressurization. Patients in this category respond well to most interventions (Botox, pneumatic dilation, or Heller myotomy).
- Type III patients often have a negative treatment response. Patients in this group have a higher percentage of spastic contraction and chest pain.

Types I and II may represent the natural disease progress, while type III, noted for esophageal spasm, may represent a variant of the disorder. Classifying patients into these subtypes may well determine treatment efficacy [89].

Diagnosis

Prior to diagnosis, it is important to rule out any neurologic involvement in addition to other pathologies or obstructions with an upper endoscopy [82, 87, 90]. Achalasia is most often diagnosed by barium esophagogram, which evaluates both morphology and caliber of the esophagogastric channel [91], thereby identifying the typical "bird beak" or narrowing at the gastroesophageal junction [87, 92]. The esophagus becomes very dilated and tortuous as the disease evolves [92]. However, in the early stages of the disease, the esophagus may have a normal diameter, and a barium esophagogram may not show any abnormalities [51]. Another diagnostic, timed barium esophagogram, provides more dynamic information on esophageal emptying and may objectively assess patient response to pneumatic dilatation and surgery [51].

Although some researchers feel that esophageal manometry may not be necessary if radiographic findings decidedly indicate a diagnosis of achalasia [51], others feel that manometry is the gold standard [87, 90], especially high-resolution manometry (HRM) [93]. HRM is over 98 % sensitive in detecting achalasia compared to conventional manometry, with a sensitivity of 52 % [93]. HRM allows better evaluation of esophageal motor function, including spatial and temporal characteristics, and disordered motor function. This enables an indirect assessment of intestinal wall movements and transit of food contents [39]. Most patients with achalasia also experience more esophageal shortening upon swallowing compared with healthy subjects, although it is unclear if this shortening alters intraesophageal volume [39].

When combined multichannel intraluminal impedance and esophageal manometry (MII-EM) is used as a diagnostic tool, patients with achalasia present with low MII values, which identifies chronic fluid retention, low baseline impedance, elevated intraesophageal and LES residual pressure, and normal [90] or elevated LES pressure [82, 87, 88]. A diagnosis of achalasia can be confirmed by HRM showing aperistalsis of the smooth esophageal muscle and poor or incomplete relaxation of the LES during swallowing. Failed peristalsis is represented on the data scans by a vertical band of color extending from the UES to the LES [39].

Results of esophageal transit scintigraphy correlate with LES pressure and achalasia symptom score, and some researchers use the barium esophagography and scintigraphy to confirm achalasia diagnosis. Scintigraphy can be used to evaluate esophageal emptying and to measure the efficacy of treatment [91].

In one study, functional magnetic resonance imaging (fMRI) was used with success to diagnose achalasia (Table 4.2). The disease morpho-functional alterations were identified and in agreement with findings of conventional videofluoroscopy [41]. fMRI is fast, easy to reproduce, and noninvasive. It also provides images in different spatial planes, the possibility of targeting contrast material, and the elimination of ionizing radiation. There are also disadvantages: low spatial resolution renders study of wall profile more difficult, a temporal resolution below those obtained by radiology, and a restriction to the clinostatic position [41].

Treatment

Because normal motor function cannot be restored, treatments are considered palliative [82] and are aimed at improving LES relaxation and reducing LES pressure [88, 93]. Current treatments comprise medical therapy, endoscopic therapy, and surgery [74], although minimally invasive surgery is now the treatment of choice [81]. Pharmaceuticals, such as calcium channel blockers, nitrates, and botulinum toxin injections, have been used in adults with limited benefits and are eventually replaced with other therapies [74, 81]. Calcium channel blockers and Botox have been used infrequently in the pediatric population [82], and the SSAT Patient Care Committee recommends using Botox only for patients who are poor surgical or dilation candidates [83, 87].

Pneumatic dilation, which reduces the pressure by tearing the muscle fibers and weakening the LES, is routinely used in adults, but carries the risk of perforation [74]. The procedure is the initial treatment preferred to myotomy [91], even though it has a success rate of 70–80 % [88].

Table 4.2 Diagnostic criteria for esophageal dysmotility (values)

Esophageal dysmotility	Diagnostic tests	Diagnostic criteria
Cricopharyngeal achalasia	Esophageal manometry stationary/24-h ambulatory	R/O obstruction [76]
Achalasia	Esophageal manometry with impedance monitoring [82, 87]	Chronic fluid retention
		Baseline impedance ↓
		Intraesophageal pressure ↑
		LES residual pressure ↑
		LES pressure ↑ or normal
		Abnormal bolus transit [37]
		Impaired EGJ relaxation [45]
	HRM	Pressures [39]:
		UES normal or ↑
		LES resting ↑
		Max. esophageal pressures [39]:
		Normal before wet swallows
		↑ Significantly after
		During multiple rapid swallows [46]:
		Aperistalsis
		Lack of EGJ relaxation
		Chicago Classification of classic achalasia [40]:
		Aperistalsis
		Mean IRP ≥15 mmHg
		Colored data [39]:
		Failed peristalsis: vertical band of color from UES to LES
		Failed LES resting: little change in color
	Functional MRI [41]	Morphological findings:
		Narrowing of distal esophagus (>10 mm)
		Dilation of segments above
		Poor relaxation of EGJ
		Inefficient peristalsis
		↑ Bolus transit time to 20
		Advanced disease:
		Marked distension to 60 mm
		Tertiary peristalsis
		Failure to empty organ
	Barium esophagogram	Esophagus appearance:
		"Bird beak" narrowing at GEJ [51, 87, 88]
		Flaccid and dilated above junction [94]
		Early disease: may appear normal [51]
		Advanced disease: grossly dilated and tortuous [92]

Table 4.2 (continued)

Esophageal dysmotility	Diagnostic tests	Diagnostic criteria
DES/NE	Esophageal manometry	Contractions [83]:
	Stationary/24-h ambulatory	20 to >30 % abnormal, simultaneous [61]
		Frequent, repetitive DES: ≥3 peaks; NE: >2 peaks
		Prolonged (>6 s)
		Amplitudes [95][a]:
		Primary DES: 73.4 ± 23.2 mmHg
		Primary DES: ≥180 mmHg [83]
		Primary NE: 219.8 ± 38.3 mmHg
		Pressures [81, 83]:
		UES normal
		LES normal to ↑
		May or may not have abnormal bolus transit [37]
		Abnormal reflux [81][b]:
		Reflux score: 49 ± 38
		Reference score: ≤14.7
		Chicago classification [40]:
		CFV ≥8 cm s^{-1}
	HRM	Chicago classification of NE [40]:
		CFV ≥8 cm s^{-1}
	Functional MRI	DES [41]:
		Intermittent progression of bolus
		Tertiary peristalsis
		↑ Transit time
		Corkscrew appearance

[c]Values are often lower in the sitting than supine position

Esophagography is useful for evaluating the degree of gastroesophageal junction opening after endoscopic treatment of achalasia [91]. Several years following dilation or bougienage with rubber dilators, patients often require other therapies [74] for residual achalasia or persistence of clinical symptoms [82]. GERD may occur in 25–35 % of patients following dilatation [88]. Dilatation is rarely effective in adolescents and younger patients [87].

Surgical myotomy, such as laparoscopic modified Heller's transthoracic esophagomyotomy and/or partial fundoplication, is currently the definitive treatment of choice [87, 88, 93]. Heller's myotomy offers relief of symptoms in 85–100 % of patients [87]. Laparoscopic Heller's and now robotic myotomy have reduced the rate of perforations [93]. When combined with a partial fundoplication, the myotomy significantly reduces chances of resultant reflux [74, 81, 82, 87]. However, resultant scarring or incomplete initial myotomy can cause recurrent dysphagia many years later [83]. It is uncommon to treat achalasia with esophagectomy. This treatment should be reserved for advanced cases in which myotomy offers no relief [87].

Diffuse Esophageal Spasm and Esophageal Nutcracker

Etiology and Symptoms

Both diffuse esophageal spasm (DES) and nutcracker esophagus (NE) or hypertensive peristalsis [93] are rare, benign, and nonprogressive disorders with unknown etiologies (Fig. 4.4) [61]. They account for approximately 3–7 % of manometric abnormalities [98]. The disorders are classified as primary esophageal motility disorders (PEMDs) if GERD is not present [95]. However, research has shown that two out of three patients with DES or NE have GERD, even though symptoms may not correlate with reflux [95]. GERD may also play a role in triggering spasm [83, 93]. While the correlation is still unclear, treatment for

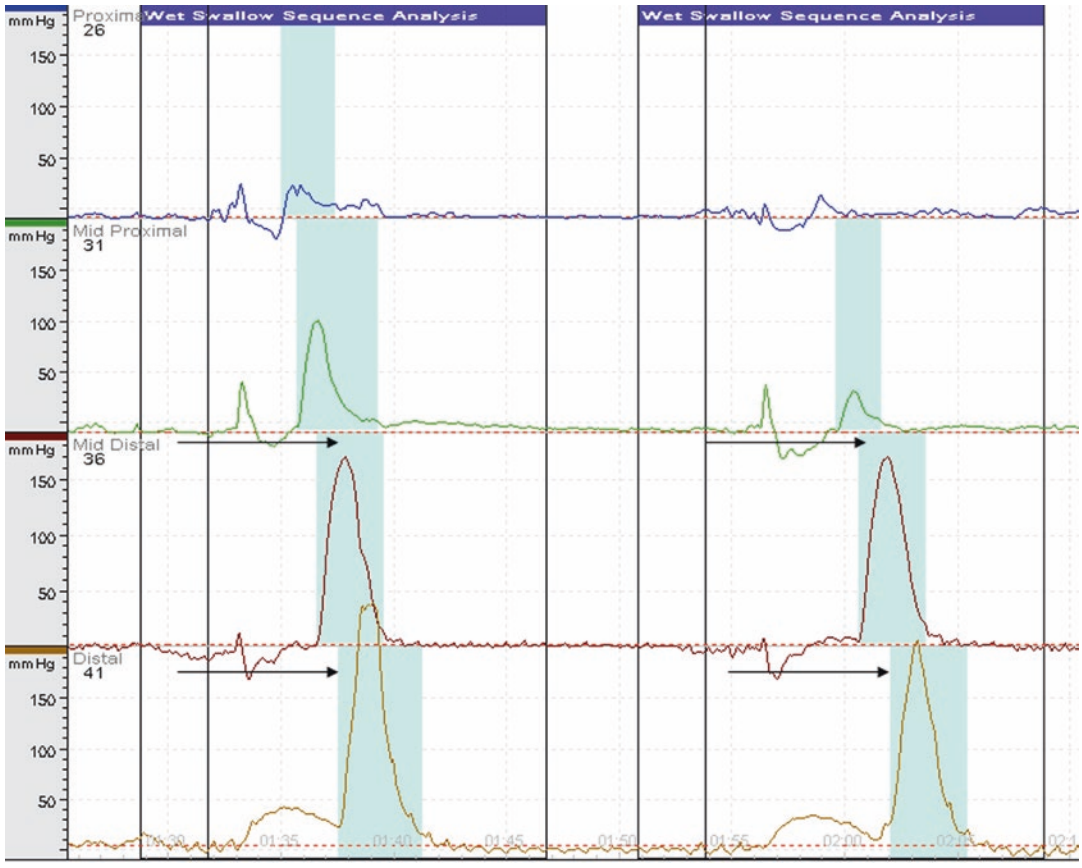

Fig. 4.4 Nutcracker esophagus. Note the mean amplitude in the distal channels (*arrows*) above 180 mmHg

reflux has reduced painful symptoms in a number of patients diagnosed with NE [83].

Manometry findings have shown that DES contractions are restricted almost exclusively to the lower third of the esophagus, which comprises smooth muscle controlled by autonomic nonadrenergic, noncholinergic neural pathways dependent on nitric oxide control. As a result, some researchers are renaming the acronym DES to distal esophageal spasm [31, 61]. Although the pathogenesis of both DES and NE is unclear, nitric oxide has been shown to be a major factor in maintaining distal esophageal peristalsis [61, 98] by mediating LES and esophageal body relaxation. This may account for the positive response in some patients to nitroglycerin and recombinant hemoglobin infusions (see "Treatment") [61]. While some researchers define DES into two types, low amplitude with less chest pain and high amplitude with more chest pain [99], others have found no distinct differences [61].

Symptoms of DES and NE are intermittent and include radiating chest pain with or without swallowing and dysphagia [50, 61, 83, 96]. Chest pain may be caused by spasms or increased contraction amplitudes during a normal bolus transit [31]. It may also be due to visceral hypersensitivity and reduce esophageal compliance [97]. Dysphagia may be due to a lower amplitude, resulting in an impaired transit [31]. Symptoms of spasm most often occur when eating or drinking, especially foods that are very hot or very cold. Pain varies in severity, ranging from mild to severe, and may last from a few seconds to several minutes [61, 83]. The intermittent, nonprogressive symptoms distinguish these disorders from achalasia and esophageal cancer [83]. NE is defined by normal peristalsis and very high intraluminal pressures [81]. Nutcracker is found more frequently in obese patients [93].

Diagnosis

Both diagnosis and treatment of DES and NE are not well defined [81], and literature recommendations vary [96]. Esophageal spasm is diagnosed using clinical symptoms and manometry, while the diagnosis of nutcracker esophagus is based only on manometry [83]. In both disorders, pH monitoring is necessary to distinguish primary motility disorder from GERD, which ensures appropriate and directed treatment [95], and an upper endoscopy will appear normal except for the presence of GERD [83]. Because healthy people often have similar symptoms and manometry readings, there is sometimes confusion regarding the diagnosis [83]. DES is marked with either high or low contraction amplitudes, while NE has high-amplitude peristaltic waves like normal peristalsis [90]. There is no presence of a corkscrew esophagus [92].

Patients with DES may have abnormal esophageal contractions in 20% [31, 95] to more than 30% [83] of wet swallows tested, although half of all patients with DES have normal bolus transit [31]. Positive manometry shows long (>6 s) frequent and repetitive esophageal contractions (≥3 peaks) [83]. Distal esophageal amplitudes can range from 73.4 ± 23.2 mmHg [95] or even exceed 180 mmHg [83]. The UES and LES usually have normal baseline pressure, although the LES pressure can be high [83], ranging from 15.7 ± 8.7 mmHg in primary DES [95]. Patients with low simultaneous and peristaltic amplitudes most likely do not have DES [99].

Patients with primary NE present with a high distal esophageal amplitude (>180 mmHg [83, 100]), even averaging up to 219.8 ± 38.3 mmHg [95]. The amplitude is slightly higher for NE in the presence of GERD (225.2 ± 52.2 mmHg) [95]. LES pressure can range from 22.7 ± 11.2 mmHg in primary NE [95].

fMRI, used in one study to diagnose DES, identified classic determinates similar to manometric and radiologic findings [41]. Other diagnostic tests, such as the barium swallow and endoscopic ultrasonography, have proven unreliable. While a barium swallow shows a "corkscrew" appearance during a contraction in patients with spasm, there is normal activity in the upper one-third of the esophagus and abnormal activity in the region of the spasm [83]. Patients with often have normal barium swallows, thereby confirming the need for manometry. Although esophageal motor disorders are associated with thickening of the esophageal muscle wall, as detected by endoscopic ultrasonography, it is unclear whether this occurs in DES [83, 96]. The thickening may

actually result from increased resistance to the bolus passage [96].

Treatment

It is not easy to treat spasm [98]. Medical and surgical approaches are palliative [82] and should be based on both bolus transit and manometric information [31]. Muscle relaxants, such as nitrates, calcium channel blockers, and Botox, have been used for esophageal spasm because they improve manometric findings and chest discomfort [74]. Calcium channel blockers, such as oral diltiazem, decrease LES pressure and inhibit peristaltic amplitude and duration [101], but pharmaceutical agents, especially nifedipine [96], may also worsen esophageal dysfunction [99] by relaxing the LES [95]. The use of these agents for DES has yet to be studied in a blinded, placebo-controlled trial [74, 98, 101].

If GERD is present, DES or NE may be considered a secondary problem, and antireflux medications are often given early in the course of treatment [83, 95]. There may be a tendency to treat symptoms with proton pump inhibitors without obtaining a pH reading. However, the result may be costly and delay appropriate treatment [95]. Anxiety and depression occur more often in patients with DES [96], and anxiolytics might be beneficial [83].

Although pneumatic dilation provides some relief, it is difficult to dilate the balloon in an effective position, rendering some dilatations ineffective. Esophageal myotomy is usually reserved for patients in whom medical therapy is ineffective because the surgery decreases the intensity but not the frequency of contractions, and it may result in dysphagia [83]. Patients who complain of dysphagia and who have a hypertensive sphincter may benefit from surgery [81]. Controlled studies on these procedures have not been done [83]. A laparoscopic Heller myotomy is the primary treatment for DES, although results of myotomy on NE are poor [81].

Nonspecific Esophageal Motility Disorders

Etiology and Symptoms

Nonspecific esophageal motility disorders (NEMDs), also known as ineffective esophageal motility (IEM) [93], are benign and nonprogressive disorders [83]. They are characterized by poor peristalsis [93] and do not appear to fit into other diagnostic categories [83, 95]. Patients may experience dysphagia and/or chest pain and have abnormal esophageal motility tracings and incomplete LES relaxation [83]. Except for abnormal contractions on manometry, patients diagnosed with NEMD often appear to have symptoms of esophageal spasm or nutcracker esophagus.

Nearly one-quarter to one-half of all patients with NEMD also have GERD, and in some studies, NEMD is a marker for GERD, especially when linked with esophagitis. This connection may be triggered by a reduced acetylcholine release from excitatory myenteric neurons to circular smooth muscle. Chronic inflammation may permanently alter neuromotor function, although acute esophagitis can be reversed [97].

The longer the segment of affected esophagus, the greater the likelihood of impaired bolus transit [97].

Diagnosis

Manometry is used to make a definitive diagnosis (Fig. 4.5) [97] and to determine the appropriate treatment for symptomatic relief [83]. In NEMDs, the bolus movement is ineffective due to low-amplitude distal esophageal contractions of <30 mmHg. The patient may also have nontransmitted proximal contractions in >30 % of wet swallows [96].

Treatment

Nonstandardized treatment is aimed at symptomatic relief, as determined by esophageal manometry [83].

Gastroesophageal Reflux Disease (GERD)

Etiology and Symptoms

GER is a very common problem in infants, although most children outgrow it by 9 months. Symptoms range from eructation to vomiting [48], and belching is common [45]. Some children have

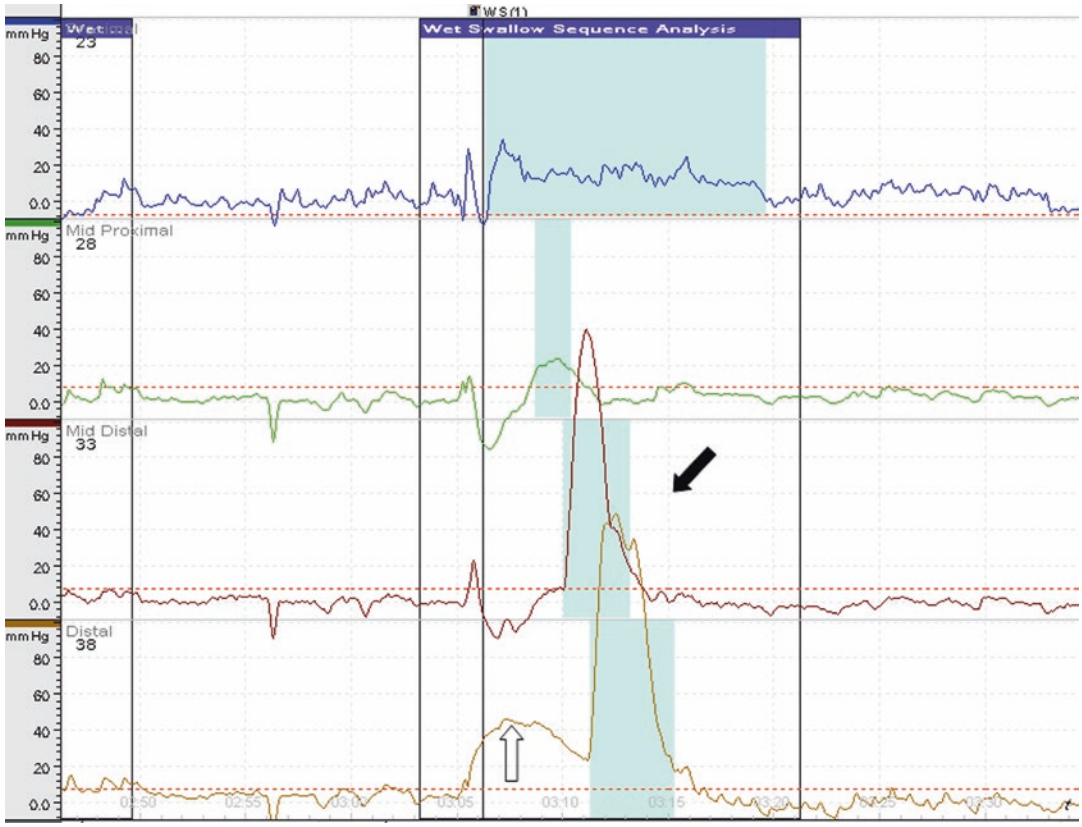

Fig. 4.5 Nonspecific abnormalities. Note the increased intrabolus pressure (*open arrow*) and the double-peaked contraction in the distal channel (*closed arrow*). *WS* wet swallow

weight loss or respiratory symptoms such as hoarseness and bronchospasm [48]. Pathologic GER is more frequently seen in children with trisomy 21, cystic fibrosis, and cerebral palsy. The majority of symptomatic reflux incidences are acidic, and 15 % are weakly acidic [45].

Diagnosis

When diagnosing GERD, it is important to coordinate reported symptoms with the analysis of reflux events. This is done by comparing the symptom index (SI) and symptom association probability (SAP) index, although controlled studies are still needed [45]. An upper GI is often done to confirm anatomic detail and exclude obstruction, such as pyloric stenosis. The upper GI also confirms a normally positioned duodenal-jejunal junction. Radionuclide studies are used to estimate reflux volume [48]. Barium esophagogram is used to determine the morphology of reflux including reflux esophagitis, peptic strictures, and carcinoma [92] (Table 4.2). Impedance-pH monitoring helps determine acid and nonacid reflux events, the extent of refluxate, and refluxate composition [45].

Fluoroscopy can be used as the only test, thereby eliminating a pH probe, if high-grade spontaneous reflux is identified [48]. The results of ultrasound correlate with pH monitoring, and the test is used to measure the length of the intra-abdominal esophagus. The shorter the esophagus, the more severe the disease [48]. During esophageal shortening, the LES is positioned above the diaphragm, thereby opposing intragastric pressure and facilitating LES opening after relaxation [45].

Patients with GERD present lower number of contractions during GER episodes, but not in the whole period [102]. HRM studies show that patients with GERD vacillate between type I

(superimposed CD and LES) and type II (CD and LES separated), with reflux usually occurring during type II [45]. However, no significant differences were found between patients with GERD and controls at stationary manometry [102].

Treatment

Initially, symptomatic GER is treated with thickened feedings. If symptoms do not improve, medications are started [48]. If symptoms persist, open or laparoscopic reflux surgery is an effective treatment [48]. The most common procedure is the laparoscopic Nissen wrap fundoplication [93], followed by the Thal and Toupet surgeries [48]. The Nissen may present complications such as a loosened wrap, which may slide down over the body of the esophagus, or a wrap that is too tight, leading to esophageal obstruction or reflux symptoms [48]. While fundoplication reduces both acid and weakly acid liquid reflux, gas reflux is reduced to a lesser extent [45].

Secondary Esophageal Motility Disorders and Others

A variety of etiologies are responsible for secondary esophageal motility disorders [49]. These include:

- Collagen vascular disease including scleroderma or systemic sclerosis
- Neuromuscular disorders
- Metabolic and endocrine disorders such as diabetes and alcoholism
- Chagas' disease, an infectious disease caused by the protozoan *Trypanosoma cruzi*

Systemic Sclerosis

Although linear scleroderma is common in children, systemic sclerosis is quite rare in this age group [103]. It is characterized by idiopathic fibrosis, which affects the esophagus in 75 % [50] to 90 % [47] of patients. Fibrosis of the smooth muscle causes atrophy in the distal two-thirds of the esophagus, resulting in esophageal dilation and an incompetent LES. Changes in the esophagus are considered a reliable indicator of disease progression [47].

The esophagus typically presents low-amplitude contraction waves and atony in the distal two-thirds [104]. Hypotonic LES is also frequent [103]. Esophageal compromise is also evident in the videofluorography, which shows the typical hypotonic esophageal dyskinesia, but also may show corkscrew esophagus, tertiary contractions, atony, dilation, and intraluminal pooling [47]. Although esophageal scintigraphy is not useful as a primary diagnostic tool, or even as a screening test, monitoring the bolus time may be useful to follow the progression of the disease [105]. The treatment of esophageal dysmotility with prokinetic agents, such as cisapride and domperidone and tegaserod, may be useful in the early stage of systemic sclerosis [106].

Progressive fibrosis of the organ may lead to shortening and, consequently, hiatal herniation. As a result, GERD is present in 90 % [47], and it may lead to reflux esophagitis, peptic strictures, Barrett esophagus, and associated esophageal adenocarcinoma [47, 50]. Dysphagia, caused by abnormal esophageal peristalsis or peptic strictures [50], chronic gastritis, and retrosternal pyrosis are common, and diagnosis may be difficult because clinical symptoms do not always coincide with the results of manometry, pH monitoring, or endoscopy [47].

Neurological and Neuromuscular Disorders

Children with cerebral palsy present decreased amplitude of peristaltic waves, lower basal pressure of LES, as well as increased frequency of simultaneous was compared to controls [107].

Patients with myotonic dystrophy may present complete contractions and normal LES relaxation, but with lower amplitude of contraction and lower UES basal tone [108]. Nonperistaltic waves after liquid swallows and simultaneous waves are common [109]. Also, the duration of the deglutitive LES relaxation is longer than in healthy subjects [110].

However, in children with progressive muscular dystrophy, UES and LES resting pressure was not different from controls, as well as contraction wave amplitude in the distal esophagus, while the lower contraction wave amplitude was found in

the proximal esophagus in children with myotonic dystrophy [111]. However, abnormalities may affect the lower esophagus, with simultaneous nonperistaltic waves [112].

Down's Syndrome

The condition is associated with disorders of the enteric nervous system, like Hirschsprung's disease and achalasia [113]. However, Down's syndrome patients also present significant more retention of radionuclide in the esophagus when compared to controls, as well as frequently abnormal manometric study, with aperistalsis, hypotonic LES, and EB dysmotility [114].

Eosinophilic Esophagitis

Dysphagia is the main symptom associated with eosinophilic esophagitis in adults and teenagers, and it may result from strictures (Schatzki's ring and stricture) and mucosal inflammation leading to mucosal thickening or dysmotility. A range of abnormalities have been reported in eosinophilic esophagitis, such as ineffective peristalsis, simultaneous high-amplitude contractions, aperistalsis, tertiary contractions, and achalasia [115]. Episodes of dysphagia are frequently associated with nonpropagated contractions and high-amplitude (>180 mmHg) contractions in children evaluated with prolonged manometry [116]. Although most pediatric patients present normal esophageal stationary manometry, abnormal stationary esophageal manometry is more frequent in patients with eosinophilic esophagitis than in patients with GERD [115, 116]. In adults, abnormalities may include all categories of manometric findings, such as aperistalsis, lower-amplitude nonpropagating contraction waves, nutcracker esophagus, and hypotensive LES [117]. Initially, the motility is normal, then hyperperistalsis develops, and it eventually evolves to low-amplitude simultaneous contractions [115].

Esophageal Injuries

After sclerotherapy for treating esophageal varices, nonpropagating contractions and simultaneous contractions can be observed in the distal third, and it may justify thoracic pain after treatment when it is not related to ulcers. LES is not affected by sclerotherapy or variceal ligation [118]. Esophageal banding ligation causes less often simultaneous contraction, while amplitude, duration, and speed of peristaltic waves are normal [118].

Caustic injuries of the esophagus may also be associated with aperistalsis and lower amplitude of contractions, but without compromising UES and LES function [119]. Abnormalities begin soon after the accident and are long lasting [120].

Congenital Disorders

Gastroschisis is associated with abnormal esophageal motility, including lower frequency of propagation of contractions, and less frequent esophageal reflexes related to infusion of bolus in the lumen. These abnormalities may play a role in the development of GERD [121].

Esophageal atresia is associated with esophageal dysmotility, although the mechanism behind is not clear. Preoperatively, normal motility has been reported, with adequate LES basal pressure, LES relaxation, and progression of contractions between proximal and distal esophagus, in spite of not being connected [122]. However, postoperatively, the anastomosis region presents no motility, while the proximal segment presents normal motility. It suggests that the coordination between the proximal and the distal esophagus is intact in not treated esophageal atresia. On the other hand, study in animal model of esophageal atresia showed that the distal atresic presents impaired smooth muscle reactivity [123]. Also, the animal model of esophageal atresia presents abnormal branching of the vagus nerve in the distal atresic segment [124]. Probably, abnormal motility in esophageal atresia results from neurological damage during surgical correction of the atresia and abnormal smooth muscle functioning. The subset of patients without vagal nerve surgical injury may present better prognosis, but further studies on motility coordination in animal model are warranted. Recently, two groups of patients have been identified: those with normal contractions in the distal part and those with aperistalsis of the distal esophagus. The last

group presents high frequency of GERD, while the first group presents better prognosis [125]. Typically, UES and LES function are normal in patients with esophageal atresia [126].

Other Diseases

Chagas' disease may be difficult to diagnose initially because manometry and radiography results mimic achalasia. *Diabetes and alcoholism*, a connective tissue disease [47], may cause decreased primary peristalsis, increased tertiary contractions, and mild esophageal dilatation [50].

5 Vascular, Neurological and Functional Development of the Oesophagus

Udo Rolle and Alan J. Burns

The functional development of the oesophagus is closely related to the development of the oesophageal innervation and blood supply. The following chapter summarises the current knowledge in this field.

Gross Histology

The histology of the oesophageal wall shows major similarities with that of the rest of the gastrointestinal tract. There are only slight differences, i.e. only a patchy serosal layer and the lack of a mesentery. The oesophageal wall is composed of four layers: the tunica mucosa, the tunica submucosa, the tunica muscularis and the tunica adventitia.

The mucosal layer is located on the innermost side and consists of the epithelium, the lamina propria and the muscularis mucosae. The second layer is the submucosal layer, which is mainly a layer of connective tissue. This layer also contains part of the enteric nervous system (ENS), the submucosal plexus (Auerbach's plexus) as well as blood vessels. The third layer is the muscle layer, which contains the inner circular muscle and the outer longitudinal muscle. The second major component of the ENS, the myenteric plexus (Meissner's plexus), is situated between the two muscle layers. The outermost layer of the oesophagus is the adventitia, which consists of connective tissue.

Along the length of the oesophagus, there is a transition between striated muscle and smooth muscle: in the upper third of the oesophagus, the muscle is entirely striated. The second third is composed of both striated and smooth muscles, whereas in the lower third of the oesophagus, only smooth muscle is present.

Blood Supply

The blood supply of the oesophagus starts developing at the seventh week of gestation.

The arterial oesophageal blood supply can be divided into the cervical, thoracic and abdominal components [4]. These arteries are interconnected by numerous anastomoses.

The upper oesophagus (pharyngo-oesophageal transition and cervical oesophagus) is supplied by the lower thyroid artery (a branch of the thyrocervical trunk) and additional small branches of several other arteries (subclavian, common carotid, vertebral, superior thyroid, costocervical trunk).

The thoracic oesophageal blood supply is provided by branches of the aorta (paired arteries),

DOI 10.1007/978-3-642-11202-7_5

the bronchial arteries and the right intercostal arteries. At the level of the tracheal bifurcation, the main blood supply comes from branches of the bronchial arteries, whereas the oesophageal branches of the aorta supply the oesophagus below the bifurcation.

The abdominal oesophagus is supplied by the oesophageal branches of the left gastric and left lower phrenic arteries. Additional blood supply may be provided by branches of the aorta, the splenic artery, the celiac trunk and the left aberrant artery [2].

The well-developed subepithelial capillary network is supplied by a distinct submucosal arterial plexus. This plexus is composed of longitudinally oriented arteries with lateral anastomosis and is formed by penetrating branches arising from a minor extrinsic plexus in the adventitia [2].

The copious blood supply and network of potentially anastomotic vessels may explain the rarity of oesophageal infarction.

The dense submucosal venous plexus of the upper oesophagus drains into the superior vena cava. The veins of the proximal and distal oesophagus drain into the azygos system. Collaterals of the left gastric vein, a branch of the portal vein, receive venous drainage from the mid-oesophagus. The submucosal connections between the portal and systemic venous systems in the distal oesophagus form oesophageal varices in cases of portal hypertension.

Lymphatic Drainage

Most of the lymphatic fluid of the oesophagus drains directly to the juxta-oesophageal lymph nodes. Additional lymphatic drainage is provided by the lung lymph nodes and the diaphragmatic lymph nodes.

Innervation

The oesophagus is dually innervated; that is, it is innervated by both intrinsic and extrinsic nerves. This specific innervation pattern is responsible for the oesophageal peristalsis.

Like other parts of the gastrointestinal system, the oesophagus is governed by the autonomic nervous system (enteric nervous system, ENS). In addition to this intrinsic nervous system, an additional extrinsic nervous system is present. Both systems are relevant for swallowing and oesophageal peristalsis.

The Oesophageal ENS

The enteric nervous system (ENS) starts from the most oral part of the oesophagus and extends along its complete length down to the stomach. There are notable differences between the oesophageal ENS and the ENS of the remaining gastrointestinal system (GI).

In general, the oesophageal ENS, particularly the submucosal plexus, seems less developed than the ENS in the rest of the gastrointestinal tract [13].

The proportion of nitrergic myenteric neurons seems to be much higher within the oesophageal ENS. Nitrergic myenteric neurons comprise up to 55 % of all myenteric oesophageal neurons in humans [10], with the greatest number of these neurons within the abdominal segment of the oesophagus. Another specific finding is the remarkable coexistence of nNOS with other neuropeptides (vasoactive intestinal peptide, galanin and neuropeptide Y) in the human oesophagus [10].

Previous investigations have clearly demonstrated region-dependent overall neuronal loss of 22–62 % in the human oesophagus during ageing [8]. This neuronal loss is more pronounced in the upper oesophagus.

Development of the Oesophageal ENS in Humans [3, 12]

Vagal (hindbrain) neural crest cells migrate into the oesophagus at gestational week 4. These cells migrate in an oral-to-anal direction, reaching the distal stomach at week 5 and colonising the entire length of the GI tract by week 7.

Neural and glial differentiation can be detected at week 7 within the foregut using PGP9.5 and

S-100 staining, respectively. These neurons and glial cells are present in the presumptive myenteric plexus close to the serosal layer. The first neuronal and glial cells are found within the submucosal layer at week 9. From weeks 9 to 12, the submucosal plexus of the foregut increases in size.

At week 7, the myenteric plexus consists of a few closely packed neurons and glia. The myenteric plexus increases in size, and the respective neurons and glial cells become less packed from week 12 to 20.

Development of the Foregut ENS [12]

Week 4	Neural crest cells (NCCs) scattered within the dorsal foregut mesenchyme
Week 5	NCCs within the dorsal foregut start to coalesce and form chains
Week 6	Numerous NCCs within the stomach
Week 7	Numerous NCCs external to the oesophageal circular muscle organised into distinct ganglia (Fig. 5.1)
Week 8	Ganglia present external to the oesophageal circular muscle
Week 8	NCCs at the internal aspect of the oesophageal circular muscle

The activity of the oesophageal ENS is modified by sympathetic and parasympathetic innervation.

Sympathetic Innervation

Preganglionic sympathetic nerves arise from the anterior mediolateral cell columns of the T1 to T10 spinal cord segments. Sympathetic innervation of the oesophagus is provided by postganglionic fibres, which are sympathetic nerve fibres originating from the cervico-thoracic ganglion (ganglion stellatum) of the thoracic celiac and the cranial thoracic ganglia (ganglia thoracica II–V). These postganglionic fibres reach the oesophageal wall and synapse with submucosal and myenteric neurons of the ENS.

Activation of sympathetic innervation leads to inhibition of oesophageal peristalsis and inhibition of the secretory activity of oesophageal glands.

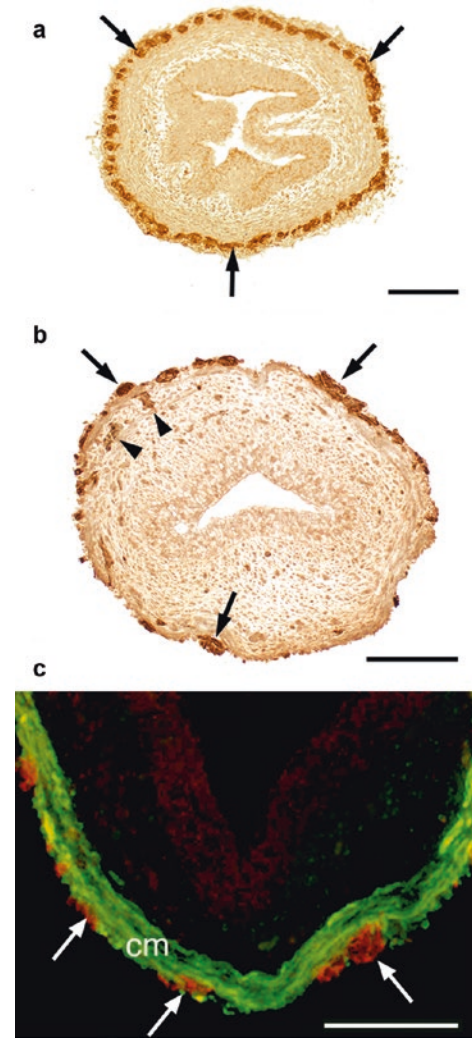

Fig. 5.1 Development of neural crest-derived enteric nervous system (ENS) and smooth muscle in the human oesophagus. (**a**) At week 7 of development, neural crest cells, as shown by p75NTR-immunostaining (*brown*), were present external to the circular muscle layer (*arrows*) in the region corresponding to the presumptive myenteric plexus. (**b**) At week 8, neural crest cells were distributed around the periphery of the gut wall (*arrows*), external to the circular muscle layers. Occasional immunopositive cells were also present internal to the circular muscle (*arrowheads*) in the region corresponding to the presumptive submucosal plexus. (**c**) At week 8, the circular muscle layer (*cm*) was well developed, and a dense band of cells was strongly immunopositive for alpha smooth muscle actin (*green*). p75NTR-positive neural crest cells (*red*) were grouped into presumptive ganglia (*arrows*), external to the circular muscle. Scale bar = 100 um (**a**, **b**) and 50 um (**c**) (Reproduced with kind permission from Springer Science+Business Media B.V. from original article by Wallace and Burns [12] (Modified from Figs. 3, 4, and 6))

Parasympathetic Innervation

Preganglionic parasympathetic neurons originate from the dorsal vagal complex located in the dorsomedial hindbrain medulla. The dorsal vagal complex consists of two nuclei, the nucleus tractus solitarius and the dorsal motor nucleus of the vagus.

The parasympathetic innervation of the upper oesophagus is from the recurrent laryngeal nerve, while in the lower oesophagus parasympathetic innervation is from the vagus nerve. Below the tracheal bifurcation, the trunks of the left and right vagal nerves form the oesophageal plexus within the adventitial layer.

The axons of the preganglionic parasympathetic neurons are carried via the vagus nerve and synapse on postganglionic neurons within the enteric nervous plexus.

Functional Considerations/ Oesophageal Peristalsis [9]

Peristalsis within the skeletal muscle of the oesophagus results from sequential activation of the neurons by the vagal centres (nucleus ambiguous), whereas peristalsis of the smooth muscle part of the oesophagus is mediated by the vagal dorsomotor nucleus and the intrinsic myenteric plexus [5]. The phasic smooth muscle of the oesophagus receives intramural inhibitory innervation (i.e. by nitric oxide) and excitatory innervation (mediated by acetylcholine). The mechanism of peristalsis within the oesophagus appears to be complicated and is not completely understood. It has been shown that the oesophagus, in contrast to the remaining intestine, is able to generate a primary peristalsis. Generally, one assumes that peristalsis within the striated and smooth muscle parts of the oesophagus is due to sequential activation of cholinergic excitatory nerves. Furthermore, it has been shown that a gradient of the contraction wave exists due to the latency of the contraction along the oesophagus. This latency gradient might be related to nitric oxide-mediated inhibitory innervation [1]. It has been demonstrated that inhibitory innervation seems to be denser within the lower oesophagus than in the upper oesophagus.

Furthermore, it has been shown that an increase in cholinergic stimulation delays the latency of contraction in the proximal oesophagus, which is under greater cholinergic control than the distal oesophagus. This phenomenon results in a loss of peristalsis [6]. Peristalsis in the longitudinal muscle layers seems to be mediated at the level of the dorsomotor nucleus of the vagus nerve [7, 11].

Part III

Esophageal Atresia Spectrum

The Spectrum of Esophageal Atresia

6

John E. Foker

The spectrum of esophageal atresia (EA) is commonly portrayed as comprising four basic types [1] (Fig. 6.1). This general classification satisfactorily illustrates the main configurations of EA lesions that may be encountered in affected babies. It does not convey, however, the many variations that may occur within the types nor the treatment complexities that may arise from them.

Defects Found in the EA Spectrum

The Primary Defect

An atresia of part of the esophagus is, of course, the primary and necessary defect in the EA spectrum. The site of the atresia predictably occurs at the level of the lower trachea, although there is considerable variation in how much esophagus is missing. The absent portion of esophagus creates upper and lower esophageal segments separated by a variable gap. The gap may range from negligible when the upper and lower segments are fused, to very long when the lower segment is only a primordial nubbin on the wall of the stomach at the site where the esophagus originates.

Gap length is the most important practical consequence of EA. The ease of achieving a successful primary esophageal anastomosis and, in turn, a good long-term outcome is primarily determined by the relative gap length [3, 4]. The significance of the gap length will be in the eye of the beholder; nevertheless, as it increases from 2 to 3 cm and beyond, an initial primary anastomosis will be increasingly difficult. From the literature, a 3 cm gap is generally considered long, and a primary anastomosis will have a greater likelihood of complications including leaks and later strictures [3–5]. Certainly, gap length guidelines are only relative, and a 3 cm gap in a 3-year-old does not have the same significance as one in a small newborn. The use of esophageal growth induction, moreover, has provided great flexibility and allowed this length and even longer gaps to be reliably repaired [6]. A reliable repair, nevertheless, always requires careful construction of the anastomosis to ensure a good result [7].

When EA is the only significant lesion and there is no associated tracheoesophageal fistula (TEF), it leaves blind upper and lower esophageal pouches, and this configuration, type A, begins the classification (Fig. 6.1).

DOI 10.1007/978-3-642-11202-7_6

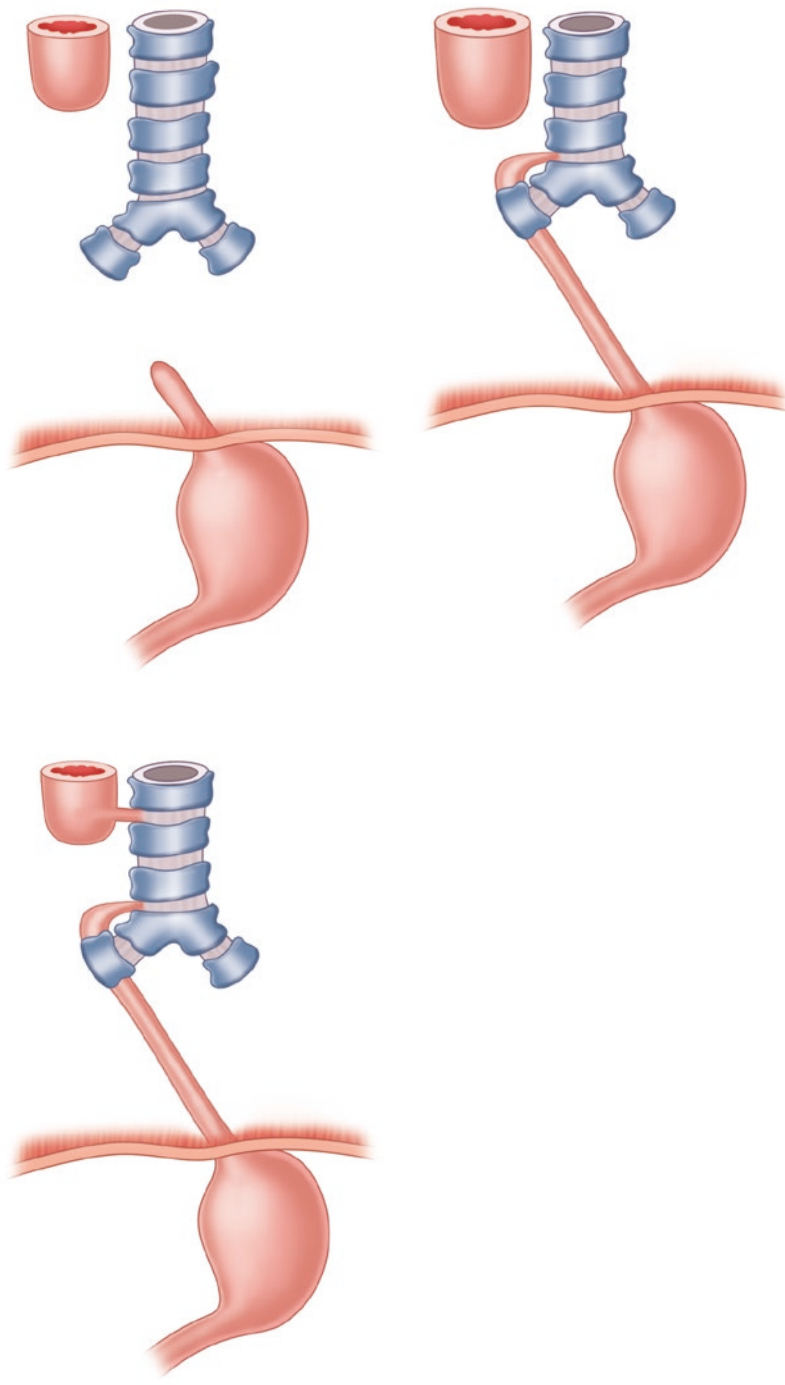

Fig. 6.1 This classification of EA is commonly, but not universally, used. Gross [1] proposed this grouping based on the earlier work of Vogt [2] and others. The necessary defect is atresia of the esophagus and with this alone is type A EA. In the next three types, the occurrence of a tracheoesophageal fistula (TEF) into the upper, lower, or both esophageal segments completes the groupings

The Major Secondary Defect

A tracheoesophageal fistula (TEF) is the next most important defect, and this occurs in most cases of EA. When present, its location broadens and fills out the spectrum, also often adding complexity for surgeons and interventionists. A TEF may be into the upper, lower, or both esophageal

segments and creates the other major types (B, C, and D), respectively, within the EA spectrum [1].

An upper pouch TEF produces type B EA, and it is usually located relatively high into the upper thoracic trachea, while the lower segment is unattached as in type A. This, in turn, means the unattached lower esophagus may vary greatly in length with an inversely resulting gap length.

The most common EA lesion by far, however, has a lower segment which ends as a fistula into the trachea and together with a blind upper pouch is the configuration of type C EA. A fistula into both the upper and the lower segments rounds out the general classification with the rare configuration (type D) (Fig. 6.1).

Tertiary Defects

The major groups are not uniform, however, and a variety of other less important lesions add to the considerable variety and complexity found in the EA spectrum. Some of these additional lesions may make a primary repair more difficult, while others may make it easier.

The additional lesions include double atresias; multiple TEFs; cords between the lower segment and the upper segment, the airway, or the mediastinum; and other rare variations [8]. In general, tertiary lesions which increase the effective gap length will make an anastomosis more difficult, while those that shorten it will make a primary repair easier. Often they may not affect gap length as in a double TEF and require only a slightly more involved repair. A missed TEF, however, may produce significant continuing symptoms and subsequently may be difficult to diagnosis and repair.

The goal of this chapter will be to describe the EA spectrum in more detail and include the implications for the ease of accomplishing a primary anastomosis.

Previous Recognition of the EA Spectrum

Our understanding of the EA spectrum has been shaped by a long antecedent history. A description of the EA malformation appeared at least as early as 1670 with the report by William Durston of a blind upper pouch in a baby that succumbed shortly after birth [9]. In 1697, Gibson described the common form of EA (type C) in greater detail and later published the case [10]. Unfortunately, these lesions could not be successfully repaired for almost another three centuries.

The first collection of EA cases published in 1905 by Kreuter began to indicate the breadth of the EA spectrum [11]. The more systematic description by Vogt in 1929 was helpful to Gross in constructing the classification described that is still commonly used today (Fig. 6.1) [1, 2].

More variations continued to be reported in case reports and small series, and in 1976 they were compiled into an Atlas of Esophageal Atresia by Kluth [8]. The atlas diagrammatically illustrated the 54 variations that had appeared in the literature and put them into categories which provided an increased understanding of the breadth of the EA spectrum. The categories in the Atlas, although logical, do not correspond to the current classification; for example, both type I and type II would now be considered type A. The atlas, nevertheless, is very interesting and useful for the clear diagrams of the many unusual lesions that had been found and described by that time.

The classification proposed by Gross [1] also included two additional groups that were without EA: one for an isolated tracheoesophageal fistula (TEF) and another for esophageal stenosis [1]. The TEF in the former group is typically located relatively high near the junction of the cervical and thoracic trachea and considered an H- or N-type TEF.

The isolated stenosis is usually found at about the junction of the middle and lower thirds of the esophagus and may be produced by one of several mechanisms: a simple web, aberrant rests of bronchial or pancreatic tissue or from an isolated, thick knot of dysplastic, fibromuscular tissue.

The lesions of these two additional, and seemingly unrelated, groups have a fairly predictable location which suggests they may also result

from a relatively constant developmental error or, much less likely, because of a secondary genetic influence. Atresia is not part of these otherwise very different groups, and they will not be included in this discussion of the EA spectrum.

Variation Within the Main Types of the EA Spectrum

For all infants with EA, the reparative goal is to establish continuity with the stomach. Continuity can be accomplished in one of several ways; however, the emphasis at the University of Minnesota has been on a true primary esophageal repair. We have defined a true primary repair as an esophageal anastomosis leaving the gastroesophageal (GE) junction below the diaphragm, where it belongs, and without doing esophageal myotomies to increase length bur which disrupt the integrity of the esophageal wall and may lead to a diverticulum [6].

An initial true primary repair may be difficult in some cases; however, the ability to induce esophageal growth makes an anastomosis eventually possible in virtually all patients. Rather than using the fallback approach of a replacement or interposition graft, the small, blind segments of esophagus can be reliably grown and a true primary repair carried out. Before or, at least, during the initial operation, the recognition of the anatomic details of an unusual and difficult EA defect will increase the likelihood of developing a successful surgical plan. A true primary repair should always be the goal, how it is accomplished, of course, will be influenced by the EA variations encountered.

This chapter, therefore, will present the EA spectrum in greater detail beginning with the classification proposed by Gross [1] and identify the characteristics which may affect the ability to accomplish a primary repair (Fig. 6.1). This information should make the difficult case more understandable and less daunting, which will increase the likelihood of achieving a good and durable outcome.

Type A EA (Fig. 6.2)

EA with a blind upper and lower esophageal pouch (type A) is conceptually the most straightforward and begins the classification. The atretic site typically occurs in the mid-esophagus; however, when the patient is born, the upper and lower segments may be of substantially different sizes. A blind upper pouch tends to be enlarged by the attempts at swallowing saliva in utero, while the size of lower esophagus may be quite variable and will mainly determine the gap length. The repair, therefore, may differ substantially in ease of accomplishment. These lesions

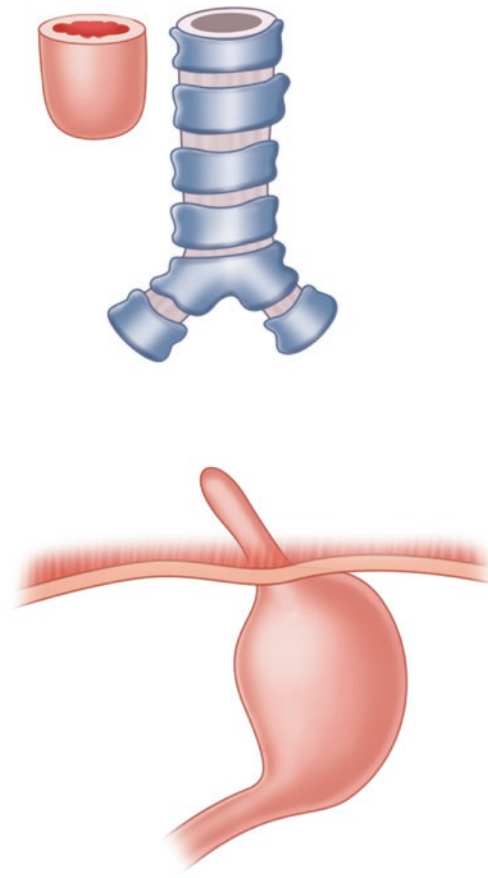

Fig. 6.2 Type A is the first group and consists of EA without other significant lesions. As will be discussed, the lower segments vary greatly in size and make this outwardly simple group quite variable in configuration and clinical difficulties

vary from the easiest to the most difficult defects in which to accomplish a primary esophageal anastomosis while maintaining the GE junction below the diaphragm.

Variations Which Increase Gap Length in Type A EA

Small Lower Segments

Lower segment size is the most important determinant of gap length. Growth usually lags when the lower segment is not attached in some way, even with a cord, to either the upper esophagus or the airway. If the lower segment is unattached, the axial tension provided by the growing spinal column (which provides the biomechanical growth signal) will not be effectively transmitted, and the distal esophagus may remain small. Although it is often unclear what constitutes effective attachment, the wide variation found in lower segment size is illustrated by expanding the type A defects pictured within the classification. The subtypes A_1, A_2, and A_3 attempt to convey the range in size and morphology of the lower esophageal segments in these defects (Fig. 6.3). This variation, in turn, will determine the difficulty in accomplishing an esophageal anastomosis.

The lower segment size range, however, is even greater than shown. The smallest will be a primordium barely discernible on the northwest quadrant of the surface of the stomach, while the largest lower segment will abut the upper pouch. Between these extremes will be a continuum of sizes and difficulties in repair. For examples of the spectrum and the corresponding methods of repair.

Second Atresias

A second atresia in either the upper or lower pouch effectively lengthens the gap because the true lumen stops well short of the apparent end of the segment. An unrecognized second atresia was present in one case in the Minnesota experience in which the upper pouch was put on axial tension (traction) in the usual fashion to induce growth. Unfortunately, more growth occurred in the distal portion of the upper pouch which did not have a satisfactory lumen. When this was discovered, the distal portion was trimmed away, and the shorter true upper segment was put on traction. After sufficient upper pouch growth occurred, a successful true primary repair was carried out.

Variations Which Decrease Gap Length

An Atretic Cord

The lower segment may have an atretic cord arising from the end and reaching higher in the posterior mediastinum or even to the airway or upper pouch [8]. As the spinal column lengthens, the cord may transmit tension to the lower segment in utero enhancing its growth. An atretic cord can be helpful during the initial thoracotomy when it is found in the posterior mediastinum, deep to the vagus nerve. The cord should be grasped and divided, and by pulling up the inferior end, the lower esophageal segment can be delivered upward and dissected free down to the esophageal hiatus. When a cord is present, the lower segment will typically be at least 2–3 cm in length and not a tiny primordium. Granted, a 2–3 cm long lower segment would be very unsuitable for an initial true primary repair; however, it will be quite satisfactory for placement of traction sutures.

Fusion of the Esophageal Segments

Occasionally the upper and lower esophageal segments are fused to some degree, although there is no luminal continuity. This configuration eliminates concerns about the gap and makes a primary repair much easier.

Type B EA

Type B EA has a TEF from the upper pouch into the high thoracic trachea and a blind lower segment (Fig. 6.4). Very rarely, there may be two upper pouch fistulas [8]. The upper pouch fistula, in turn, tends to drain the saliva and reduces the tendency for a large upper segment. The fistulas are relatively

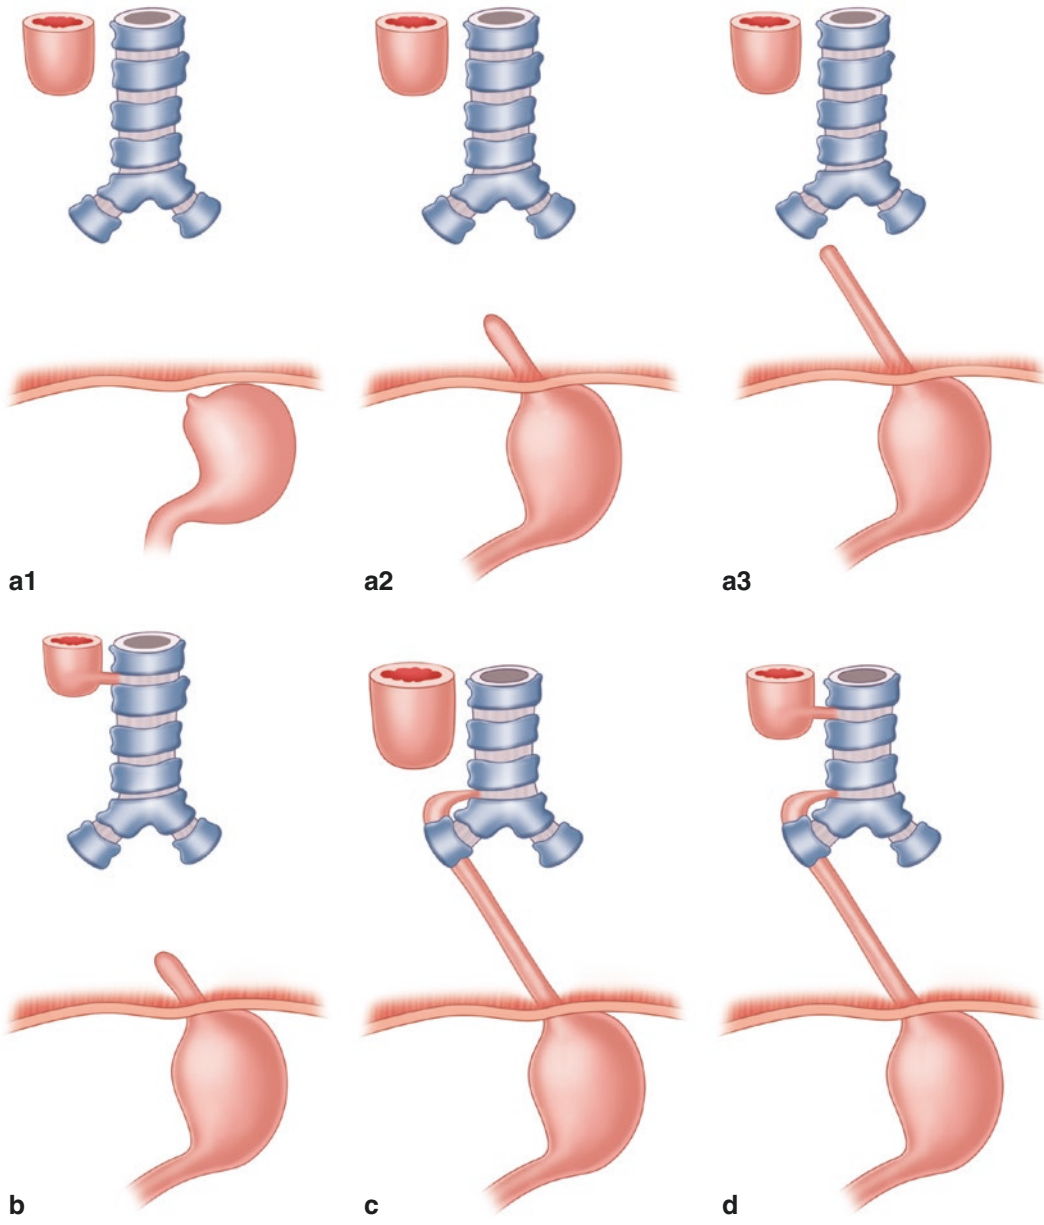

Fig. 6.3 This expanded classification portrays a range of lower segment size in type A EA. The segments pictured range from an esophageal primordium ($\mathbf{A_1}$) to a relatively long lower esophagus ($\mathbf{A_3}$). In reality, however, the range is even wider with a lower segment not discernible on preoperative studies or one abutting the upper esophageal pouch

small; nevertheless, the upper pouches are usually smaller than expected.

Of importance, the lower segment size should be highly variable and resemble the type A lesions. Although only a few examples have been described in any detail, lower segment size will be a consequence of effective attachment to spinal column growth; therefore, their length should vary consid-

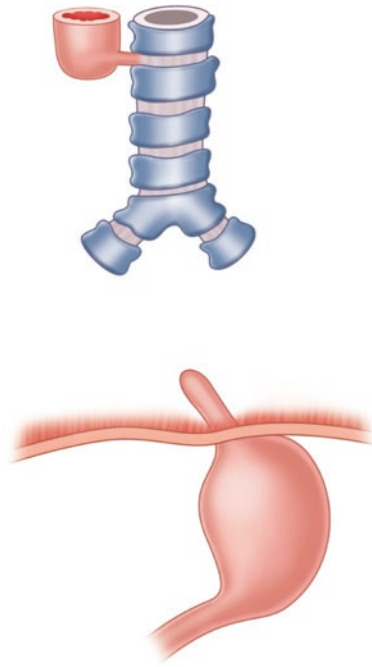

Fig. 6.4 Type B EA. The upper pouch has a TEF and may be relatively small. The lower segment is unattached and therefore should vary widely in size

erably. A portrayal of lower segment size that resembles the type A EA lesions has been created (Fig. 6.5).

Variations Which Increase Gap Length

Upper Pouch TEF

The upper fistula drains saliva into the trachea, and the pouch tends to be smaller than in the type A and type C lesions. A smaller upper pouch will increase the gap length.

More than one upper pouch TEF could increase drainage and further hinder upper pouch growth. Although small series of this unusual lesion have been reported, the upper pouch size was not given [9, 10].

Unattached Lower Segment

When the lower pouch is not attached to either the airway or the upper esophageal segment, it is not reliably subjected to the axial tension supplied by spinal column growth. If the investing fibers around the lower segment are relatively loose and do not effectively transmit the axial tension to the lower segment, it will remain small and the gap will be long.

Variations Which Decrease Gap Length

Larger Upper Pouch

The upper pouch TEF may be very small, however, and therefore saliva swallowed in utero may effectively enlarge the upper pouch and make it as large as in type C EA [9, 10].

Attachments to Lower Segment

Attachments (e.g., a cord) to the upper esophagus or trachea from the lower segment would provide tension as the spinal column lengthens and stimulate pouch growth and reduce gap length. The few reports of type B EA, however, have not described this variation nor the anastomotic consequences.

Type C EA (Fig. 6.6)

Type C EA with a blind upper pouch and a TEF from the lower segment to the trachea is by far the most common form encountered and makes up 70–85 % of the EA cases in most series.

For pediatric surgeons, this is a favorite congenital defect to repair. Because the lower segment usually reaches the lower trachea, most type C defects are initially primarily repairable; nevertheless, keeping the GE junction below the diaphragm may occasionally pose difficulties.

Variations Which Increase Gap Length

Lower Insertion of TEF

The principal variation which increases gap length is a low insertion of the distal esophageal segment into the airway. Usually, the TEF inserts directly into the lower thoracic trachea and provides adequate length for an initial true primary repair. If the insertion is into the undersurface of the carina or into the right or even left main stem bronchus,

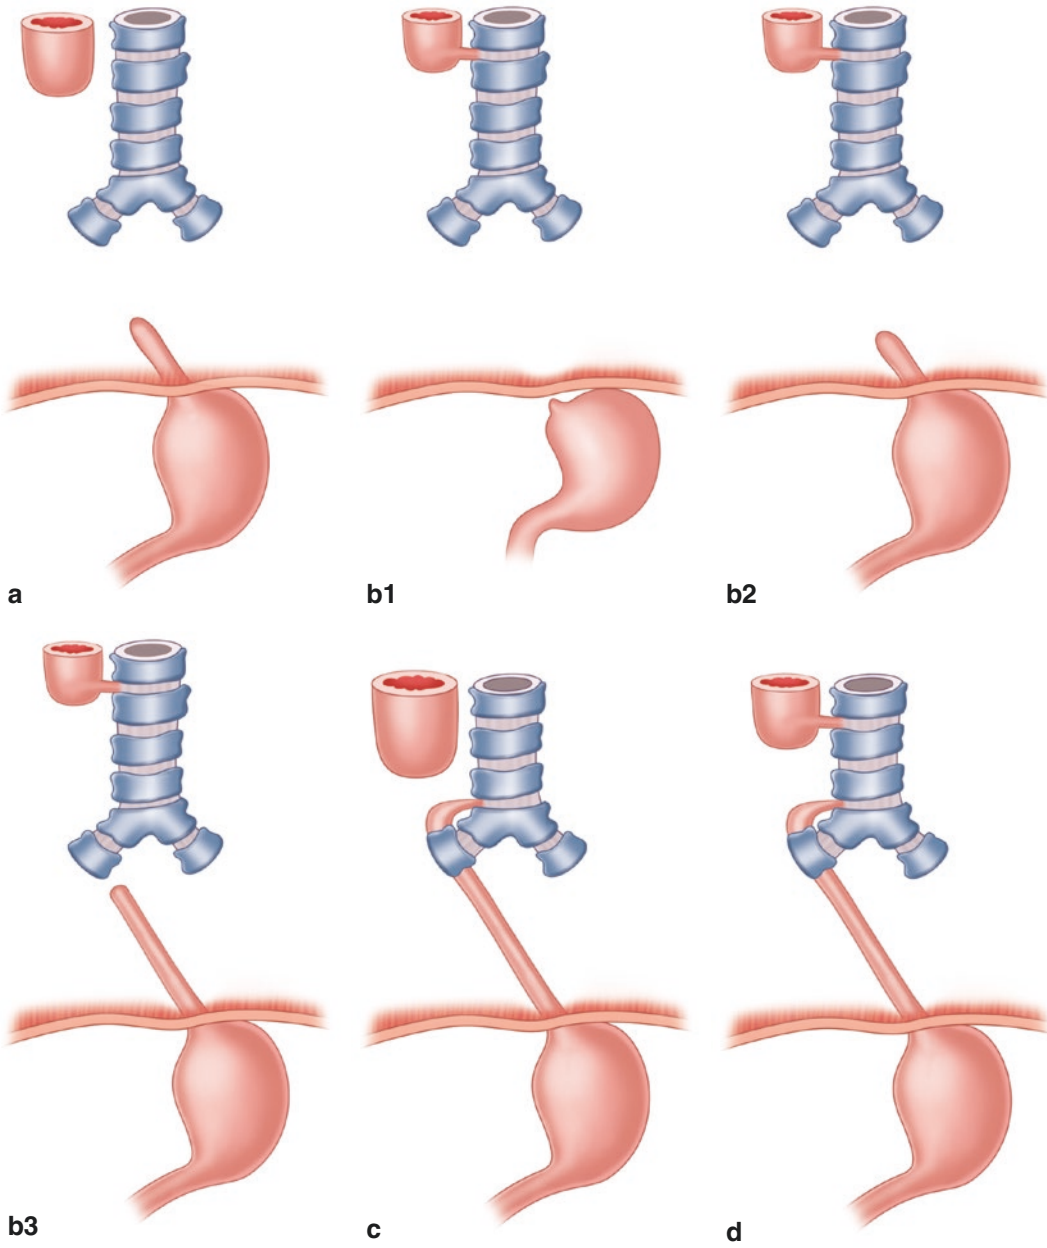

Fig. 6.5 The usually unattached lower segment in type B EA leads to a variety of possible sizes as shown by the B_1, B_2, and B_3 configurations

however, the gap between the divided TEF and the upper pouch will be increased. Even though the upper pouch is undrained by a TEF and is typically large in type C lesions, a low insertion of the TEF may provide difficulties for a primary repair.

If the gap length raises uncertainties for the surgeon, the lower segment fistula should be divided, closed, and placed, along with the upper pouch, on a period of internal traction to stimulate growth. Each end should be anchored into

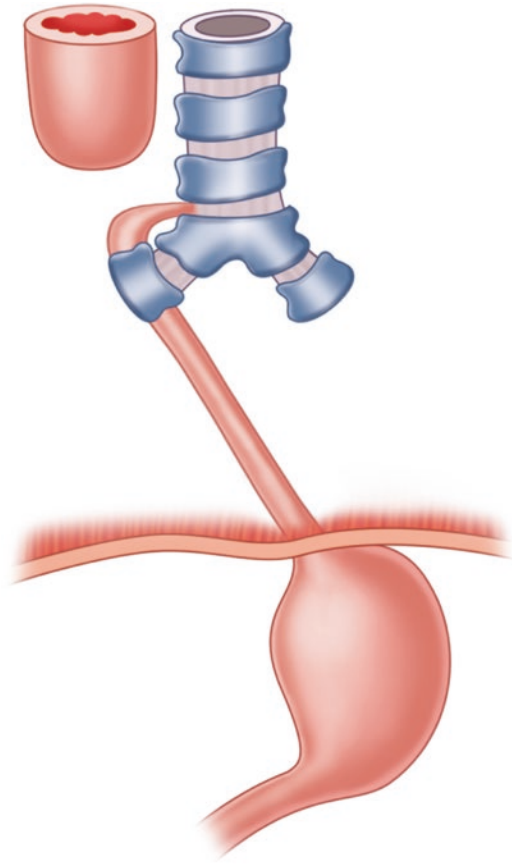

Fig. 6.6 Type C EA. Type C EA is, by far, the most common configuration. The upper pouch is relatively large, and the lower segment usually enters the trachea making a configuration usually suitable to an initial true primary repair

the prevertebral fascia under tension which will provide the biomechanical signal. A period of growth will allow a better anastomosis to be created without resorting to myotomies or a partial gastric pull up.

Aortic Arch Anomalies (Aberrant Subclavian Artery, Vascular Ring, and Right Aortic Arch)

Anomalies of the aortic arch will often be associated with increased gap length and could occur with any of the EA types. The reports, however, are predictably with the much more common type C EA lesions. An aberrant right subclavian artery from a left aortic arch will lie between the upper and lower segments and may be associated with a longer gap. One series reported several cases and this anatomy made the repair more difficult but still possible. Although the aberrant vessel may appear to be influencing the gap, it is unlikely to be directly increasing gap length because this vascular anomaly occurs more commonly with an intact normal esophagus. A similar, albeit more unusual, circumstance could exist in the presence of a right aortic arch, an aberrant left subclavian artery and EA.

Complete vascular rings are the most difficult form of these arterial anomalies to treat. The aortic ring may be completely produced by the double aorta or one composed of the ascending aorta, a retroesophageal transverse arch, and a left descending aorta in which the ring is completed by the ductus arteriosus. The ring must be divided, and, whatever its configuration, the anterior component must be moved forward to relieve tracheal compression. After the mobilization is completed, the esophageal ends are either placed on traction or an esophageal the anastomosis carried out.

A right aortic arch will make the esophageal repair more difficult through a right thoracotomy incision. The difficulty in repair comes more from the presence of the descending aorta in front of the anastomotic site rather than an increased gap length, although this can also occur. Surgeons vary as what approach they would use. The author would choose a left thoracotomy in order to make the very important esophageal anastomosis as straightforward as possible.

Variations Which Decrease Gap Length

High Insertion of a Large TEF

If the lower segment remains large virtually up to the trachea and inserts higher than usual, the conditions will be more favorable for a primary repair. These variations are not discussed in reports, however, and are only accepted with gratitude.

Fusion Between Upper and Lower Pouches

Occasionally, the upper and the lower pouches are touching or even fused. Gap length would not be a problem; however, the openings should be generous to reduce the likelihood of a later stricture.

Type D Esophageal Atresia (Fig. 6.7)

The rare type D lesions have two TEFs, one from the upper pouch into the posterior aspect of the trachea and one from the lower esophageal segment lower into the airway. This is a rare lesion, infrequently reported and probably comprising only 1 % of the EA spectrum.

The factors which increase or decrease the gap length will resemble those for the upper pouch in type B lesions and for the lower segment in type C EA. For the potential effects on the gap lengths, see also the discussions of the type B and C EA lesions. The actual occurrence and consequences of anatomic variations which will affect gap length, however, have not been reported but can be predicted.

Variations Which Increase Gap Length

A large TEF will more effectively decompress the upper pouch, and it will remain smaller and higher, increasing the gap.

If the lower fistula inserts into the underside of carina or a mainstem bronchus as opposed to the trachea as commonly occurs in type C lesions, the gap would be increased.

Variations Which Decrease Gap Length

A small upper segment fistula will impede drainage, leading to a larger pouch. Similarly, a lower TEF which is larger and inserted higher will improve the configuration for a primary anastomosis.

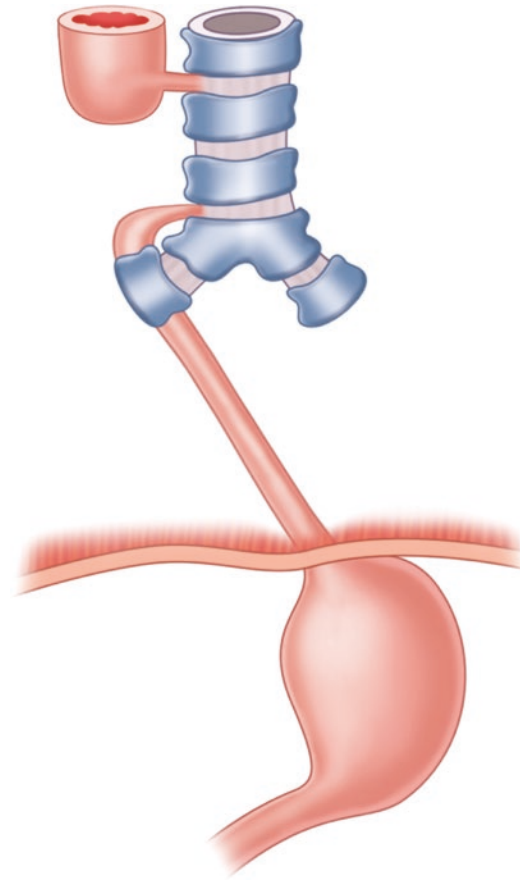

Fig. 6.7 Type D EA. A very rare lesion in which both the upper and lower esophageal segments are connected to the air way, usually the trachea as shown, but the proximal portion of a mainstem bronchus may be the terminus for the lower esophagus

Summary

As experienced pediatric surgeons know, the variety in EA will be even greater than illustrated in this chapter. Within the EA groups will be a continuum of lesions that range from more easily repairable to those defects that are essentially impossible to initially repair primarily. The success of an EA repair will largely be determined by the length of the gap between the upper and lower segments; however, other variations in the anatomy of the EA defect may also influence the outcome.

The recognition of the favorable or unfavorable characteristics of these defects should aid an understanding of the implications for repair. EA repair is certainly not in its final form now, and this chapter should stimulate further thinking about EA and lead to improved outcomes. Finally, consideration of the EA spectrum reveals the developmental

variety produced by Nature, which enriches the surgeon and those who care for these infants.

7 Esophageal Atresia and Tracheoesophageal Fistula: The Clinical Spectrum, Diagnosis, and Evaluation

Justin D. Klein and Russell W. Jennings

Introduction

The embryologic formation of the esophagus is complete following recanalization around the tenth week of fetal life. Any irregularity in the developmental process may result in a variety of malformations, including but not limited to esophageal atresia with or without a tracheoesophageal fistula. Knowledge of the anatomic and clinical spectrum of esophageal malformations, as well as the relationship with other organ systems, is essential for the surgeon to assess and diagnose these lesions. This chapter reviews the spectrum of disease, associated anomalies, and diagnostic evaluation which begins with prenatal evaluation.

Anatomic Spectrum

Interruption in the normal development of the esophagus and trachea may result in a wide variety of esophageal malformations. These congenital anomalies range from pure esophageal atresia, to esophageal atresia with tracheoesophageal fistula (either proximal or distal), to an isolated tracheoesophageal fistula. Before the development of successful surgical repair of esophageal atresia and tracheoesophageal fistula, affected infants died from bronchopneumonia and dehydration within the first weeks of life [1]. Improvement in surgical skills and knowledge, the advent and availability of antibiotics, and superior intensive care skills have led to greater success taking care of the neonate. Today, virtually all infants with esophageal atresia without severe associated anomalies survive infancy.

Accounts of esophageal atresia date back to 1670 with William Durston's report "A Narrative of a Monstrous Birth in Plymouth" in which a blind-ending upper esophageal pouch was described in the right-sided infant of female thoracopagus conjoined twins [2]. The next report of an infant with esophageal atresia and tracheoesophageal fistula can be found in the 6th edition of *The Anatomy of Human Bodies Epitomized*. Thomas Gibson described both the clinical and anatomic features of the most common type of esophageal atresia in 1697 where he explained the infant's attempts at feeding resulted in convulsive choking [3]. Confirmatory postmortem findings included a blind upper pouch with a distal tracheoesophageal fistula. After this time, numerous references appeared in the literature, but there were no reported survivors for the next 250 years.

Throughout the 1800s case reports of esophageal atresia and tracheoesophageal fistula emerged,

including one with an infant afflicted with esophageal atresia, tracheoesophageal fistula, and associated rectal agenesis with rectourinary fistula [4]. Harald Hirschsprung published four cases of his own in Copenhagen and collected ten cases of esophageal atresia and distal tracheoesophageal fistula from the literature in 1861 [5]. Years later Morell McKenzie reported 57 cases of congenital esophageal malformations with 37 examples of tracheal or bronchial esophageal fistula in 1880 and suspected these lesions were not extremely rare. He also discussed at length the embryology, pathology, and clinical diagnosis of these anomalies, including a description of associated anomalies such as spina bifida, horseshoe kidney, and imperforate anus [6]. Reports in the literature up to 1919 accounted for 136 verifiable cases of esophageal atresia, 92 of which had associated tracheoesophageal fistula [7].

The history of the approach to classification of esophageal atresia reflects differences in the terminology but not in the types of anomalies encountered. The first proposal to gain acceptance was that of Vogt in 1929 that recognized four main categories [8]. Type 1 was total agenesis of the esophagus, admittedly rare. The second referred to esophageal atresia without accompanying tracheoesophageal fistula. Type 3 described esophageal atresia accompanied by tracheoesophageal fistula and was further subdivided to describe the location of the fistula. Type 3a referred to esophageal atresia with a proximal tracheoesophageal fistula, type 3b was used to describe esophageal atresia with a distal tracheoesophageal fistula, and type 3c was esophageal atresia with tracheoesophageal fistula between both esophageal segments and the trachea. The last, type 4 described a tracheoesophageal fistula with an intact esophagus.

With the accumulation of operative experience, many other anatomic classifications of esophageal atresia were proposed. In 1944 Ladd emphasized that atresia of the esophagus occurs more frequently than previously considered, and he introduced a numeric form of classification that consisted of five types of esophageal atresia denoted by Roman numerals [9]. Gross subsequently changed the numeric system in 1953 to an alphabetical one that is still widely used [10] (Fig. 7.1). Type A refers to esophageal atresia alone and accounts for 7.8 % of anomalies. Type B occurs in 0.8 % of patients and includes esophageal atresia with an upper pouch fistula. Esophageal atresia with lower pouch fistula is denoted by the letter C and is the most common with 85.8 % of cases. Type D is the least common at 1.4 % and is esophageal atresia with both upper and lower fistulas. A tracheoesophageal fistula without atresia accounts for 4.2 % of anomalies and is denoted by type E. The last, type F, is not commonly grouped with atresias and describes esophageal stenosis [11]. Subsequent classification schemes based on prevalence did not gain widespread acceptance, and neither did Swenson's proposal to return to a numeric classification using Arabic numerals instead of Roman numerals [12, 13].

Using a large number of case descriptions from 1673 to 1973, in 1976 Kluth classified tracheoesophageal defects into 10 types and 88 subtypes [14]. Kluth's classification suggests that any imaginable configuration of esophageal atresia and tracheoesophageal fistula has happened or may happen. Kluth's findings may be summarized as follows: among lesions of the middle esophagus, atresia is more common than stenosis; tracheal fistula accompanies most atresias; and the fistula is usually from the lower esophageal segment in the presence of an atresia, but from the cervical esophagus when no atresia is present.

More recently, classification schemes have faded with the recognition that the critical surgical features are omitted from most of them. One of the most important pieces of information for the surgeon is the length of the gap between segments. The common form of blind upper pouch and lower fistula may be technically difficult to put together when the ends are far apart, or very straightforward when close together. The distance between esophageal segments can range from negligible, as is the case when the segments are separated by only a membrane, to ultra-long gap, where a distance of 3 cm or more is found [15–18]. One should also be suspicious of the possibility of an additional upper fistula no matter the initial classification. A full description of the important anatomic details of the malformation is more desirable than fitting it into a classification scheme. Classification attempts are also

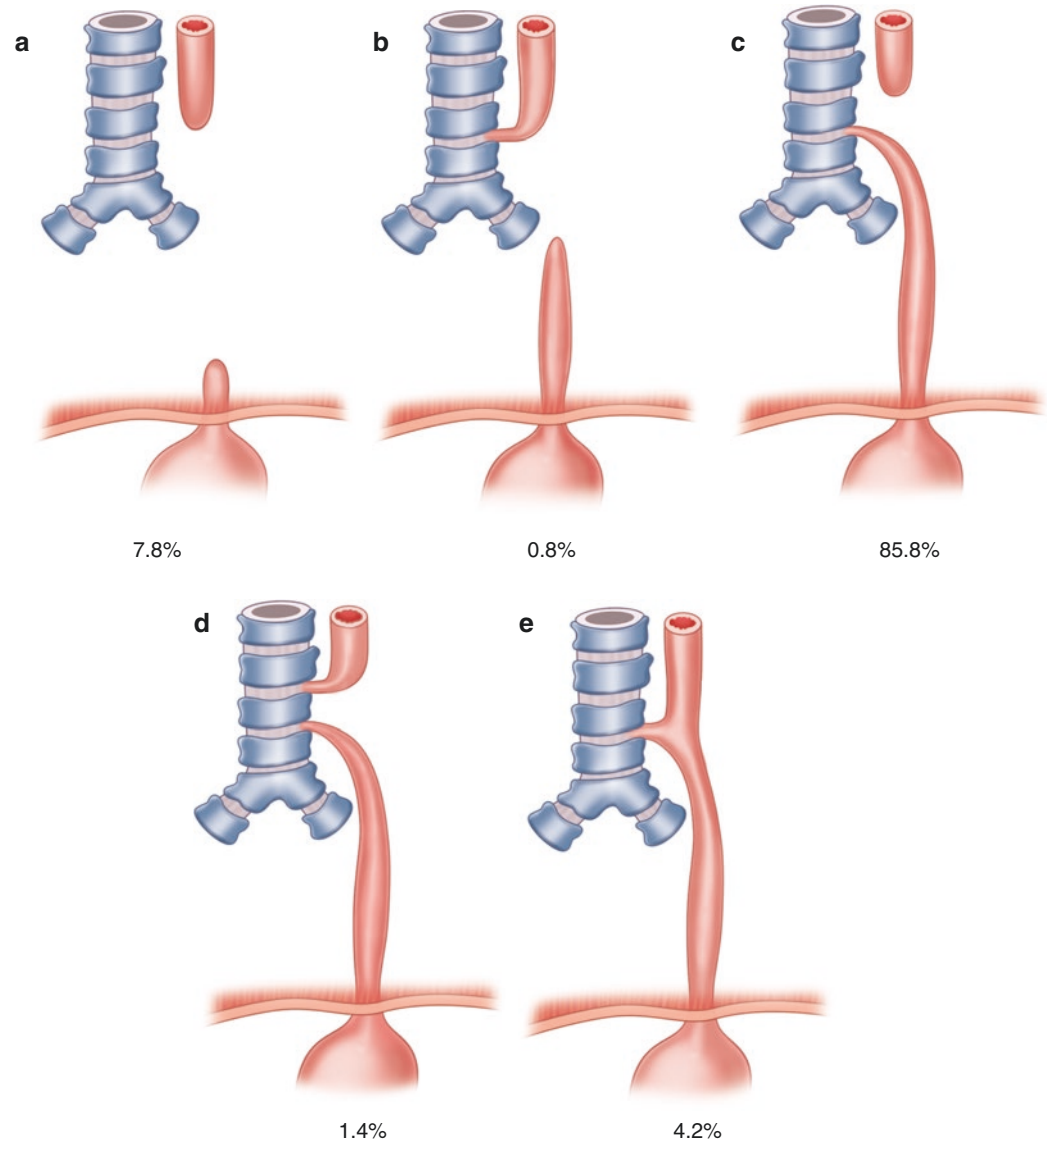

Fig. 7.1 Gross classification of anatomic patterns of esophageal atresia. (**a**) Esophageal atresia without a tracheoesophageal fistula. (**b**) Atresia with a proximal tracheoesophageal fistula. (**c**) Esophageal atresia with a distal tracheoesophageal fistula. (**d**) Esophageal atresia with both a proximal and distal fistula. (**e**) Tracheoesophageal fistula without atresia (From Gross [10])

incomplete because of the numerous anatomic variations of esophageal atresia. Although some types could be grouped together and a few were esophageal duplications rather than atresias, it is apparent that the esophageal atresia spectrum is wide ranging. In spite of the above statements, the surgeon must keep in mind that variations, even among the most common type, may require that changes in procedure be adopted for each particular patient.

Clinical Spectrum

In contrast to anatomic classifications, a classification scheme based on the infant's clinical condition was proposed by Waterston in 1962 (Table 7.1). It has proven useful to predict survival among infants with EA. This risk stratification allowed comparison of case outcomes over time and between hospitals [19]. Infants were grouped by birth weight, severity of pneumonias

Table 7.1 Waterston risk groups

Group	Survival (%)	Waterston classification
A	100	Birth weight >2,500 g and otherwise healthy
B	85	Birth weight 2,000–2,500 g and well or higher weight with moderated associated anomalies (noncardiac anomalies plus patent ductus arteriosus, ventricular septal defect, and atrial septal defect)
C	65	Birth weight <2,000 g or higher with severe associated cardiac anomalies

Table 7.2 Spitz classification

Group	Survival (%)
I. Birth weight >1,500 g without major congenital heart disease	97
II. Birth weight <1,500 g or major congenital heart disease	59
III. Birth weight <1,500 g and major congenital heart disease	22

if present, and associated congenital anomalies. Not surprisingly, survival was found to be very good for large (>2,500 g), healthy babies (group A), but remained poor for premature infants weighing less than 1,800 g (group C). Classification into the intermediate group was based on either an intermediate weight of 1,800–2,500 g, moderately severe pneumonia, or a significant anomaly that meant a larger baby would be at greater risk. Significant birth defects or severe pneumonia would also move a larger baby into group C. Today, severe associated cardiac anomalies and preoperative ventilator dependence, rather than pneumonia, are the major preoperative determinants of mortality and may well define a more current group C [20, 21].

Attempts to improve survival in Waterston group C infants have to some extent mirrored the surgical techniques of the pre-survival era. Division of the stomach was proposed for some group C infants when thoracotomy was considered too risky. This approach allows control of the tracheoesophageal fistula and provided a gastrostomy without producing reflux and without incurring the risks of a thoracotomy [22, 23]. Perhaps a better solution is the simpler and more effective technique of transthoracic fistula ligation, which has been successfully used on many occasions in low-birth-weight, critically ill infants [24, 25]. Currently, infants at high risk are nourished by hyperalimentation and decompressed by gastrostomy. If ventilation is compromised or alimental nutrition is desired, the fistula is ligated so the infants can be maintained until they are in suitable condition for repair of the esophageal atresia.

The Waterston classification is routinely used to compare results between centers caring for affected infants; however, many investigators have questioned its current validity [20, 26, 27]. Increased numbers of low-birth-weight infants are surviving, neonatal critical care continues to improve, and more treatment options are available for infants with multiple congenital anomalies. Because of these advances, several new classification systems have been proposed. One of the first was suggested around the fiftieth anniversary of the first successful primary anastomosis for esophageal atresia with tracheoesophageal fistula. It suggested refining Waterston's classification based on the overall physiologic status of the infant with esophageal atresia without regard to weight, gestation, or pulmonary condition. More frequent and earlier primary repairs were performed while maintaining excellent survival rates compared with infants previously managed using Waterston's criteria [26].

One of the most commonly used systems resulted from a review of 357 cases of esophageal atresia over 12 years. Spitz discovered that birth weight and major cardiac disease are the most important predictors of survival [28] (Table 7.2). Other prognostic classifications have been proposed, including one suggesting only severe pulmonary dysfunction with preoperative mechanical ventilation requirement, and severe associated anomalies were independent predictors of survival. It also reflected the more favorable outcome of low-birth-weight neonates [20]. The measured length of the esophageal gap also provides a method of classification to predict morbidity, long-term outcome, and costs associated with esophageal atresia and tracheoesophageal fistula surgery [29].

Despite the advances in surgical technique and repair of esophageal atresia with or without tracheoesophageal fistula, survival of the infant depends more on improved methods of caring for neonates in the intensive care unit. Survival of the infant depends on efficiently minimizing airway contamination by oral and gastric secretions and facilitating enteral nutrition. This is evidenced by the newer prognostic classifications proposed, reviewing variables that are independent predictors of survival. Effective repair continues to aim to control the upper pouch and eliminate any fistula present to prevent aspiration while the stomach is accessed for ongoing enteral nutrition.

Incidence

There is sizable variation in the frequency at which esophageal atresia and tracheoesophageal fistula have been reported over the years. Combined, these anomalies occur at an incidence of approximately 1 in 3,000 to 1 in 4,500 births [30–34]. Over the years, studies have documented a slight male predominance for esophageal atresia. This has been statistically quantified with a male-to-female ratio of 1.26, whereas the normal population sex ratio is 1.06 [35]. There is also an increased risk for esophageal atresia with a first pregnancy and there is a slight increasing trend in the rate of esophageal atresia with advanced maternal age [34, 35]. There has been no evidence for a difference in the incidence of esophageal atresia with pregnancies induced by in vitro fertilization [36].

Multiple reports of affected siblings in the same family, as well as one of a father having two children affected by esophageal atresia by different wives, have been published [6, 37–39]. Esophageal atresia with tracheoesophageal fistula has also been noted in a parent and child, as well as cases spread over multiple generations [40–42]. Children with successful repair of these defects have now reached reproductive age and will be interesting to observe their effect on population studies. Twinning among infants with esophageal atresia has been frequently reported and rates are higher, ranging from 6 to 9 % of cases compared with 1 % of twinning in the general population [35, 38, 39, 43, 44].

Early observations regarding familial esophageal atresia and tracheoesophageal fistula were presented with the belief of a developmental rather than genetic origin [30]. However, chromosomal anomalies are also relatively frequent, occurring in 6.6 % of infants with esophageal atresia. Anomalies include trisomy 13, trisomy 18, the VACTERL association, Pierre Robin sequence, Holt-Oram syndrome, and DiGeorge syndrome [35, 45]. Multiple studies have also described transverse and vertical familial cases of each variety of esophageal atresia [40, 45–48].

It has been postulated that the development of esophageal atresia is not a genetic phenomenon, but a developmental environmental incident because identical twins originate within 2 weeks of fertilization, and the trachea and esophagus develop 2 weeks later [49]. Various environmental agents have been implicated as teratogens in the pathogenesis of esophageal atresia. Esophageal atresia has occurred in children born to mothers with prolonged exposure to estrogen and progesterone during pregnancy as well as prolonged exposure to contraceptive pills [50, 51]. Additionally, esophageal atresia has been reported in some infants of diabetic mothers, after intrauterine exposure to thalidomide, and in the setting of infectious hepatitis [49, 52].

All things considered, esophageal atresia is usually sporadic and appears to have multiple heterogeneous and complex causes. Evaluation of the risk statistics reported in the literature to date suggests a 0.5–2 % recurrent risk among parents of one affected child. This number increases to 20 % if more than one sibling is affected. The empiric risk of an affected child born to an affected parent is 3–4 % [45]. Evidence to date suggests both developmental environmental and genetic causation. Sporadically, a fistula without esophageal atresia escapes detection in the neonatal period. Several such cases have been reported in children and even more remarkable are those which remain undiscovered until adulthood [53–55].

Table 7.3 Incidence of associated anomalies

Anomaly	Incidence (%)
Cardiovascular	~35
Genitourinary	~24
Gastrointestinal	~24
Neurologic	~12
Musculoskeletal	~20
VACTERL association	~20
Overall incidence	50–70

Associated Anomalies

The clustering of anomalies in esophageal atresia infants has long been recognized (Table 7.3). The associated anomaly often alters treatment and affects survival – especially cardiovascular anomalies and when multiple anomalies are present and frequently the infant weighs less than 2 kg [56, 57]. The widely used VATER association acronym was created to incorporate vertebral defects, anorectal malformations, tracheoesophageal lesions, and renal or radial anomalies that tend to occur together [58–60]. The most common of all associated defects are hemivertebrae, which along with the less frequent rib and sternal anomalies are associated with longer esophageal gaps [61]. The term association was introduced to include a nonrandom occurrence of a number of malformations, suggesting that several organ systems are similarly susceptible to a disruption of normal mesodermal induction and development [58].

Cardiovascular complications are commonly present in infants with associated anomalies and also the principal cause of death in the majority of these children [57]. To include this important group of lesions, the mnemonic has been altered to the VACTERL association by the addition of cardiac and limb defects [62–64]. A proposed reorganization to ARTICLE (anal, renal, tracheoesophageal, intestinal, cardiac, limb, etc.) had been suggested as an easier acronym to remember, but has not been generally accepted [65]. The appearance of any of the characteristic VACTERL defects should stimulate a search for other such defects. Esophageal atresia is also often found in conjunction with the CHARGE association (coloboma, heart defects, atresia choanae, developmental retardation, genital hypoplasia, and ear abnormalities) [66, 67].

Other less well-described and infrequent conditions connected with esophageal atresia include the Schisis association (omphalocele, neural tube defects, cleft lip and palate, and genital hypoplasia), unilateral pulmonary agenesis, cleft lip and palate, deafness, microcephaly, omphalocele, and multiple other syndromes [45, 64, 68–74]. Online Mendelian Inheritance in Man lists 23 entries involving esophageal atresia.

Prenatal Diagnosis

Prenatal diagnosis of structural congenital anomalies permits prompt neonatal management and may avoid potential hazards associated with diagnostic delays. It also prepares parents for the birth and intensive postnatal management of their baby [75, 76]. The first sign of esophageal atresia in the fetus may be polyhydramnios, which occurs with approximately 33 % of mothers with fetuses with esophageal atresia and distal tracheoesophageal fistula and with virtually 100 % of mothers with fetuses with esophageal atresia without fistula. Polyhydramnios can result from the inability of the fetus to swallow and thus absorb amniotic fluid. This mechanism has been demonstrated in fetuses with esophageal atresia by injecting saccharine into the amniotic sac and failing to recover it in the maternal urine [77].

Obstetrical ultrasound findings of a subjectively small or absent stomach bubble with polyhydramnios are suggestive of esophageal atresia and tracheoesophageal fistula [78–80].

The finding of only a small or absent stomach bubble is known to have a high false-positive rate [80, 81]. Healthcare providers should be alerted by this finding to search further for other ultrasound features of anomalies associated with esophageal atresia and tracheoesophageal fistula such as those of the VACTERL association and CHARGE syndrome discussed earlier [82–84]. Prenatal detection rates on ultrasound are around 45 % when esophageal atresia is an isolated anomaly.

However, interpretation of findings suspicious of esophageal atresia and tracheoesophageal fistula must be done cautiously, especially when other anomalies are noted at the same time [85].

An "upper pouch sign" was first visualized by ultrasonography and reported in two cases with polyhydramnios and absence of the stomach bubble in 1983 [86]. Subsequently, several investigators have used ultrasound to visualize the blind-ending upper esophageal segment in the neck and mediastinum during fetal swallowing [79, 84, 87–91]. The ultrasonographic finding of an anechoic area in the middle of the fetal neck in association with polyhydramnios and a small stomach may increase the accuracy of prenatal diagnosis of esophageal atresia, but is an inconsistent finding.

Magnetic resonance imaging (MRI) has been used to confirm prenatal ultrasound findings and assist in the identification of fetal thoracic lesions [92, 93]. Reports have varying results based on the MRI criterion for diagnosis of esophageal atresia and tracheoesophageal fistula. If non-visualization of the esophagus alone was used as criterion, there would be an unusually high proportion of false-positive results [94]. Others require the distinction of an absent stomach bubble, but employ the MRI scan as a complement to the sonographic evaluation [93–95].

Postnatal Diagnosis

Postnatal suspicion of esophageal atresia and tracheoesophageal fistula is frequently prompted by the observation of excessive salivation in the first few hours of life. The addition of coughing, choking, and/or cyanotic spells when the first feedings are initiated and inability to pass a tube through the mouth or nose into the stomach should also raise suspicion and prompt further evaluation. Clinically, infants with tracheoesophageal defects present with well-differentiated symptoms depending on the type of defect encountered.

In the case of esophageal atresia without tracheoesophageal fistula, the diagnosis of esophageal atresia should be suspected when unswallowed saliva is noted in the infant's mouth and nostrils at birth. If enteral feeds are attempted, the milk will be regurgitated and not coagulated, having never reached the stomach. Coughing and choking are usually less consistent than when a proximal fistula is present and cyanosis is less severe. Failure to pass a suction catheter through each nostril or mouth into the stomach almost confirms the diagnosis and should be documented with a chest radiograph. There will be no gas visualized in the bowel with pure esophageal atresia (Fig. 7.2). Aspiration of saliva and feeds will result in pneumonitis, and there will be no lanugo (swallowed hair and skin cells) in the meconium.

The presence of a proximal fistula to esophageal atresia alters the presentation to include more severe choking and coughing spells, as saliva and any feedings given have direct access to the tracheobronchial tree. The infant may have periods of cyanosis resulting from intermittent laryngeal

Fig. 7.2 Coiled nasogastric tube in the proximal esophagus with absence of intestinal air suggests isolated esophageal atresia without a tracheoesophageal fistula

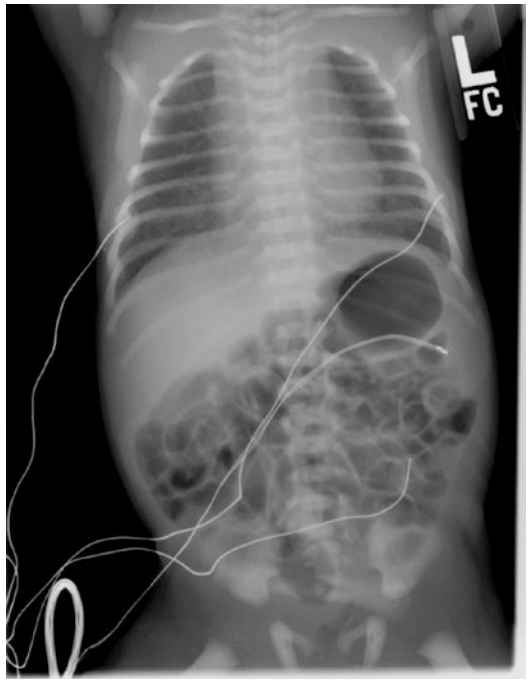

Fig. 7.3 Coiled nasogastric tube in the proximal esophagus with the presence of intestinal air suggests esophageal atresia with a tracheoesophageal fistula

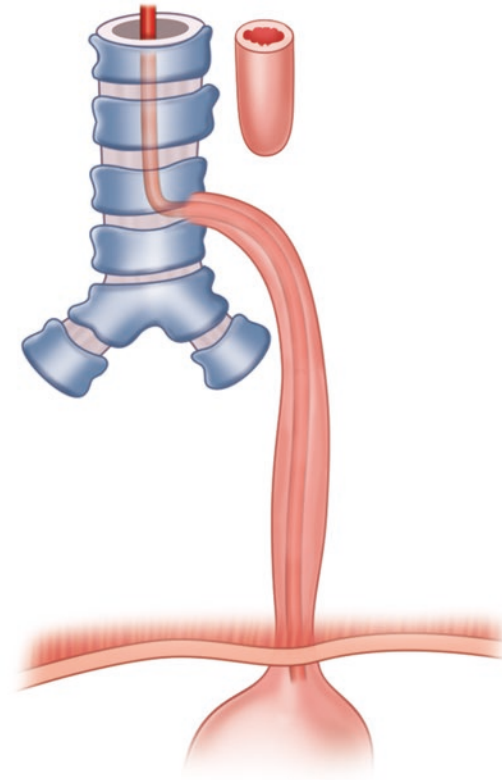

Fig. 7.4 Catheter passing through the tracheobronchial tree and entering the distal tracheoesophageal fistula

spasm. A nasal catheter may be passed via the fistula into the airways, but radiographically will be confirmed to not be below the diaphragm. There will similarly be no air noted in the gastrointestinal tract. Severe pulmonary compromise may ensue if this type is not recognized quickly.

Esophageal atresia with isolated distal tracheoesophageal fistula may present similarly to the infant discussed above with esophageal atresia without tracheoesophageal fistula. However, radiographs will demonstrate air within the gastrointestinal tract (Fig. 7.3). Another consideration will be GER through the distal esophageal fistula into the airways and gastric distension resulting in inability to ventilate. Additional considerations in the immediate neonatal period result from abdominal distention as the latter will be accentuated if bagging the infant at the time of birth is necessary. Pulmonary compromise can be significant as gastric fluid passes retrograde through the distal fistula and enters into the trachea and lungs, producing a chemical pneumonitis. A distended abdomen also elevates the diaphragm, placing pressure on the lungs, reducing compliance, and worsening pulmonary function. The aforementioned aspiration of saliva from the upper pouch into the trachea further exacerbates pulmonary compromise.

Infants with esophageal atresia and both proximal and distal fistulas present similarly to those with only a proximal fistula, resulting in respiratory distress and symptoms primarily from the fistula of the upper segment. Additionally, the distal segment can lead to more severe pneumonitis as the gastric contents have access to the trachea from retrograde flow as previously discussed. A nasal catheter may end up in the tracheobronchial tree and radiographs will demonstrate air in the bowel as well with this type of fistula [96] (Fig. 7.4). In theory, the catheter may also pass directly from the proximal fistula into the distal fistula and end up in the stomach providing a false sense of security or suggesting the presence of an H-type fistula (Fig. 7.5).

The presence of symptoms and their severity among the H-type fistula are governed by the size of the fistula. Widely patent fistulas may allow

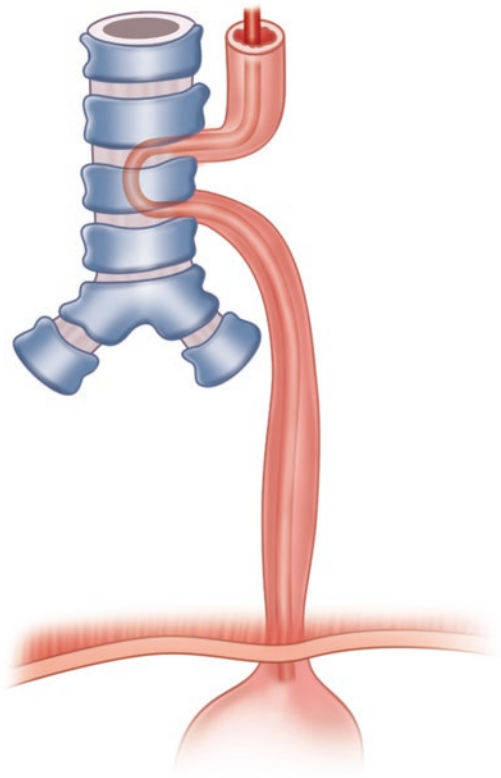

Fig. 7.5 Catheter passing through both the proximal and distal fistulas

enough esophageal contents to enter the trachea and these infants will present similarly to those with esophageal atresia and a proximal fistula. Smaller communications may result in repeated bouts of pneumonitis and/or pneumonia as well as a persistent cough. This type of fistula must be kept in mind when assessing older children and adults with chronic respiratory complaints, especially bronchiectasis of unknown etiology [97]. When evaluating a neonate for recurrent pneumonia, the differential diagnosis should include diseases like agammaglobulinemia, cystic fibrosis, and neurogenic dysfunction of the esophagus. Additionally, mechanical complications related to esophageal stenosis, congenital hiatal hernia, or tracheal compression by vascular rings must be ruled out.

Finally, isolated esophageal stenosis without tracheoesophageal fistula is often clinically insignificant. Symptoms depend on the diameter of the stenotic segment. Regurgitation of feeds and failure to thrive are the most common presenting symptoms and may be exacerbated by the introduction of solid food. As undiagnosed children become older, dysphagia becomes the primary presenting complaint. If the stenotic segment produces significant proximal dilation, tracheal compression may occur. Although pulmonary symptoms are uncommon, aspiration pneumonitis is always a danger if frequent vomiting develops. It has been suggested that an etiologic factor of esophageal stenosis is failure of epithelialization, based on the denuded mucosal linings of stenotic segments [98]. However, embryologically the earliest manifestation of the esophagus is an epithelial tube, and the absence of epithelialization must have only been acquired secondarily [99].

Diagnosis and Evaluation of the Esophagus in Infants

A clinical diagnosis may be confirmed by esophageal catheterization, x-ray examination with or without contrast media, and esophagoscopy or bronchoscopy. Esophageal catheterization is easily accomplished with a soft #10 French catheter. Failure to pass the catheter beyond 12 cm or having the catheter return out the nose or mouth suggests a proximal atresia. A chest x-ray at this time will support the diagnosis by demonstrating the radiopaque tube curled in the proximal segment or the tip of the catheter resting in the superior thorax (Figs. 7.2 and 7.3). Chest radiographs may confirm the presence of pneumonitis and suggest the length of the upper pouch by the location of the curled catheter tip. In rare circumstances with a double fistula, the catheter may pass down the trachea into the distal fistula ending up in the stomach. This situation may lead to a delay in diagnosis and be dangerously misleading.

Esophageal perforation after a traumatic intubation may mimic esophageal atresia [100–103]. Attempts to pass a catheter into the stomach fail due to an extra esophageal pouch or because swelling has closed off the esophagus. Esophageal injury may mimic esophageal atresia on esophagogram either as a pseudodiverticulum secondary to a contained cervical perforation or as esophageal

obstruction from compression of the lumen by the mass effect created by a false passage [104, 105].

Radiographs of infants with the existence of a distal fistula usually reveal a distended, air-filled stomach and intestines. Typically the location of the fistula will be just above the carina but may enter either of the mainstem bronchi, thus lengthening the gap. Often, there is associated atelectasis from upward pressure on the diaphragm. The absence of gastrointestinal gas suggests a pure atresia or an atresia with an associated proximal fistula. There is also at least one case report of a gasless abdomen resulting from an obstructed distal tracheoesophageal fistula [106]. Other information gleaned from evaluating chest and abdominal radiographs includes heart size, pulmonary vascularity, abdominal gas patterns, the presence of pneumonia, and evidence of vertebral and rib anomalies. Rarely necessary, computed tomography (CT) and magnetic resonance imaging (MRI) have been used if the esophageal segments could not otherwise be identified.

Contrast medium may be added to better assess the length of the upper pouch and determine if an upper fistula is also present. Even with a seemingly normal esophagus, the presence of a small fistula, particularly an H type, cannot be ruled out. Upper fistula findings are often subtle, and in one series the diagnosis was made with equal frequency before, during, and after repair of the esophageal atresia [107].

Air contrast will assist in visualizing the anatomy and contrast agents will also help distinguish between a stenotic segment and achalasia with cardiac stricture as the cause of the regurgitation. While the use of contrast agents should be generally avoided, when needed, a small amount of dilute barium, 1–2 cc, administered under fluoroscopy is usually adequate for diagnostic purposes, and the contrast should be aspirated from the existing catheter at the completion of the study (Fig. 7.6). Barium is well tolerated in the airway, while water-soluble agents with an osmolality greater than 240 are contraindicated due to the high osmotic load which causes severe pneumonitis if it enters the tracheobronchial tree.

Radiographs and contrast studies may suggest the diagnosis of esophageal atresia with tracheoesophageal fistula, but bronchoscopy and/or esophagoscopy is often required to confirm the diagnosis. Bronchoscopy has been helpful in demonstrating proximal tracheoesophageal fistulas, as well as discovering the presence of unusual lesions or determining tracheobronchitis and tracheomalacia [108] (Fig. 7.7). Esophagoscopy and bronchoscopy may add to the amount of preoperative information and provide the simplest method of excluding the presence of a proximal fistula, if adequate skill levels are present in the anesthesia and surgical teams.

In the diagnostic evaluation for esophageal atresia, associated recognizable defects must be excluded which could influence the choice and timing of operative repair. The diagnosis of ano-

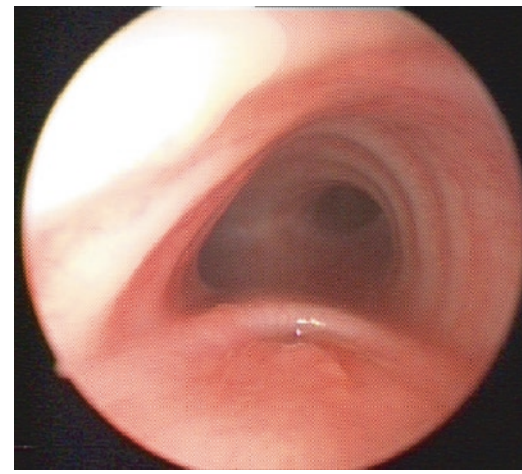

Fig. 7.7 Bronchoscopy demonstrating a posterior tracheal wall fistula just proximal to the carina

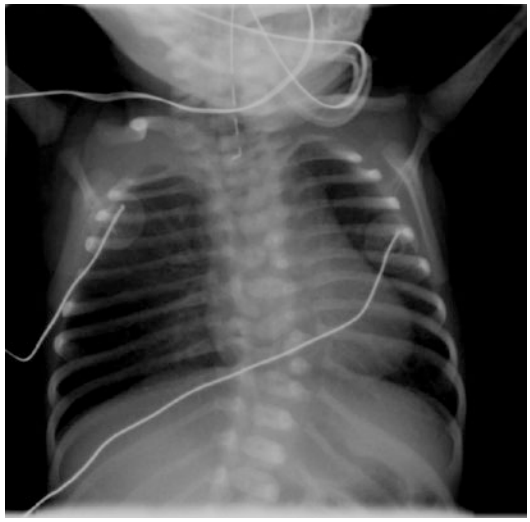

Fig. 7.8 Vertebral body malformations

rectal malformations often precedes the clinical signs and symptoms of esophageal atresia and/or tracheoesophageal fistula. In addition to physical examination, additional testing usually includes echocardiography, renal ultrasonography, spine/limb radiographs, and chromosomal analysis (Fig. 7.8).

Echocardiography, in addition to evaluating underlying cardiac defects, is used to aid in lateralizing the aortic arch which influences the surgical approach. A right-sided arch is present in 5–10 % of infants, and the esophagus and trachea are sometimes best approached on the side opposite the aortic arch [109–112]. Even at experienced centers, localization with echocardiography is only successful in two-thirds of patients [113]. Other methods to aid in the diagnosis include chest radiographs with high peak kilovoltage and air-gap magnification and localization of the descending aorta from the position of umbilical artery catheters [111, 114–116]. When a left-sided descending aorta is coupled with a right-sided arch, there is more likely an associated vascular ring completed by the ductus arteriosus [115, 117, 118]. A left thoracotomy in this circumstance allows for division of the ring, freeing the trachea, and primary esophageal repair.

More recent techniques to determine the side of the arch include computed tomography angiography (CTA) and magnetic resonance angiography (MRA). CTA permits exceptional visualization of the vascular anatomy and has the added benefit of three-dimensional reconstruction [119]. MRA offers similar cross-sectional imaging advantages to CTA, but without the risk of ionizing radiation [120]. Due to technical demands, transport requirements, and anesthesia, it is unlikely to routinely employ these methods in the clinical setting. The most satisfactory method continues to be echocardiography, which can be performed at the bedside without radiation exposure and also evaluate for significant cardiac defects.

Conclusion

Abnormal development of the esophagus and trachea may result in a wide variety of esophageal malformations ranging from pure atresia to esophageal atresia with or without tracheoesophageal fistula. There are multiple classification schemes to address both anatomic details and the infant's clinical condition. An understanding of esophageal embryology and anatomy, clinical presentation, and diagnostic approaches is essential. This knowledge will facilitate the timely arrival at the correct diagnosis, reduce associated morbidity, and allow for definitive treatment which is discussed elsewhere.

Oesophageal Atresia Associations

8

Lewis Spitz

Approximately 50 % of infants born with an oesophageal atresia have at least one associated anomaly. It is important to perform an echocardiogram prior to surgery to correct the oesophageal anomaly in order to exclude or define the possibility of a cardiac defect. The presence of a major cardiac malformation is an important determinant of the prognosis [22]. In addition, an ultrasound scan of the kidneys will determine the presence of a renal defect.

The following table lists the incidence of associated anomalies in a single-centre (Great Ormond Street Hospital, London) [2] experience with oesophageal atresia compared with a combined analysis of almost 3,000 patients in a number of large series in the literature [4, 5, 7]:

	G.O.S.	Series
Total	47 %	47 %
No. of cases	253	2,956
Cardiovascular	29 %	22 %
Genitourinary	14 %	15 %
Gastrointestinal	27 %	21 %
Vertebral/skeletal	10 %	13 %
Respiratory	6 %	–
Genetic	4 %	4.7 %
Other	11 %	15.8 %

Cardiovascular Anomalies [2, 7, 8]

Congenital heart anomalies are the most common associated abnormalities with oesophageal atresia and are responsible for the majority of deaths. Ventricular and atrial septal defects and patent ductus arteriosus are the most frequent cardiac defects, but tetralogy of Fallot and other complex malformations are associated with the highest mortality. Other anomalies include right-sided and double aortic arch, pulmonary stenosis, coarctation of the aorta and dextroposition.

Genitourinary Anomalies

The majority of urinary tract abnormalities are incidental findings of no clinical significance such as ureteric duplication, unilateral agenesis and horseshoe kidney. Bilateral renal agenesis (Potter's syndrome) should be excluded on ultrasound scan in an infant who fails to pass urine as treatment of the oesophageal atresia is futile. Vesico-ureterictic reflux is the most common urinary anomaly which may or may not require active treatment.

Gastrointestinal Anomalies

Anorectal malformations account for the majority of the gastrointestinal defects with equal distribution between high and low anomalies. Other

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_8

frequent anomalies include duodenal atresia, malrotation and pyloric stenosis.

Vertebral/Skeletal Anomalies

Vertebral defects are present in around 10 % of cases and require careful long-term follow-up and management of possible scoliosis. Absent and hypoplastic radial defects, congenital dislocation of the hip and talipes equinovarus as well as rib anomalies are commonly encountered.

Genetic Defects [6]

Genetic defects account for 4 % of anomalies and include mainly trisomy 21 (Down syndrome), trisomy 18 (Edward syndrome) and trisomy13 (Patau syndrome).

Syndromes Associated with Oesophageal Atresia

VACTERL Association [9, 10, 14, 18, 25, 26]

The original VATER association was first highlighted by Quan and Smith in 1973 and expanded later to include cardiac defects in the VACTERL association – vertebral, anorectal, tracheo-oesophageal, renal and radial anomalies and limb defects. The tracheo-oesophageal component is present in 20–67 % of patients with the association, while 5–23 % of infants with oesophageal atresia have two or more components of the VACTERL association.

The incidence of the various components of the VACTERL association is as follows: vertebral/rib anomalies 67 %, anorectal defects 41 %, cardiovascular abnormalities 66 %, renal 35 % and limb defects 33 %.

The mortality for infants with oesophageal atresia within the VACTERL association is 25 %, most of which are due to complex cardiac defects.

CHARGE Association [1, 12, 13, 17, 24]

The components of the CHARGE association comprise coloboma (85 %), heart defects, choanal atresia, retarded growth and development, genital hypoplasia (almost all boys) and ear deformities. Around 2 % of infants with oesophageal atresia have this association, while of infants with the CHARGE association, 16 % have oesophageal atresia. The most frequent physical abnormalities are retarded growth (48 %) and affect the ears (90 %), eyes (90 %), heart (60 %), genitals (38 %) and choanae (35 %). Two thirds of patients are visually impaired or blind, and three quarters have hearing loss. Forty percent are on the autistic spectrum, and over 80 % are developmentally delayed, although only 10–15 % are severely retarded. A characteristic facial appearance (unusually shaped ears, unilateral facial palsy, square face, malar flattening (pinched nostrils)) is commonly observed. Semicircular canal agenesis is the major diagnostic criterion for the diagnosis of CHARGE syndrome. The mortality in this group is high, reaching up to 70 %, mostly due to major cardiac abnormalities of which the most common are tetralogy of Fallot, ventricular septal defects and right aortic arch. Mutations in CHD7, which plays a role in chromatin organisation, are responsible for this condition [28].

Potter's Syndrome

Potter's syndrome comprises renal agenesis, pulmonary hypoplasia and typical facial dysmorphia. Three quarters of infants are male. As a consequence of the renal agenesis, there is oligohydramnios and intrauterine growth retardation. The syndrome can be recognised soon after birth by the typical Potter's facies – large low set ears, prominent epicanthic folds and a flattened nose together with postural limb defects – large floppy hands and feet and deformities of the wrist and ankle joints.

Opitz G/BBB Syndrome/Schisis Association [3]

Oesophageal atresia occasionally occurs in association with omphalocele, cleft lip and/or palate and genital hypoplasia. In addition there may be hypertelorism, laryngotracheal cleft and cardiac defects with mental retardation and agenesis of the corpus callosum.

The combination of *cleft lip and palate* with oesophageal atresia has been noted to be associated with an adverse outcome. Cleft lip and palate is present in 2–3 % of cases and is associated with a mortality of 54 %, due to severe cardiac anomalies or the presence of multiple associated anomalies. Two modes of inheritance have been described in Opitz G syndrome. Mutations in the MID1 gene are responsible for the X-linked form, while the autosomal dominant form has been mapped to chromosome 22q11.2 deletion [19].

Syndromes and Associations in Which Oesophageal Atresia Sporadically Occurs

Pierre Robin Syndrome This syndrome comprises mandibular hypoplasia and glossoptosis and occasional mental retardation.

Down's Syndrome (Trisomy 21, 1 in 600–700) Recognition is based on upward slant of the eyes, prominent epicanthic folds, Brushfield spots on the iris, a flat nasal bridge, protruding tongue, short neck and flat occiput and short broad hands, single transverse palmar creases and a sandal gap between the first and second toes. Congenital cardiac defects are present in 40 % of cases.

Patau Syndrome (Trisomy 13, 1 in 7,000) These infants rarely survive 1 year. They have a small triangular head with a sloping forehead. The eyes are small with colobomata of the iris. Bilateral cleft lip and palate, cardiac defects in 80 % of cases, polydactyly and overlapping fingers and rocker-bottom feet are frequently present.

Edward Syndrome (Trisomy 18, 1 in 5,000) These infants have a prominent occiput and a disproportionately long head and small chin. The ears are low set and malformed. The mouth opening is small, and there is ptosis and wide epicanthic folds. The second finger overlaps the third. The majority have cardiac defects. Mental retardation is severe and only 10 % survive the first year.

Feingold Syndrome [14] Feingold syndrome is characterised by autosomal dominant inheritance of microcephaly and limb malformations, notably hypoplastic thumbs and clinodactyly of second and fifth fingers. Syndactyly frequently involves the second and third as well as the fourth and fifth toes. Approximately one in three Feingold syndrome patients has oesophageal or duodenal atresia or both. Anal atresia has been reported in a single case. At least 79 patients in 25 families have been reported. The syndrome has autosomal dominant inheritance with full penetrance and variable expressivity. Vertebral anomalies, cardiac malformations and deafness have been noted in a minority of patients. The syndrome is caused by mutations of the third exon of the MYCN gene [27].

DiGeorge Syndrome [11] This is a consequence of deletion of 22q11.2 and results in abnormal development of third and fourth pharyngeal pouches. Absent or hypoplastic parathyroid glands cause refractory hypocalcaemic tetany in the neonatal period. Abnormal aortic arch (right sided or double) and complex cardiac defects. Absence of thymus prevents normal differentiation of T lymphocytes resulting in neonatal sepsis. These children have characteristic facies – small chin, down-slanting palpebral fissures, protuberant ears and broad forehead. Calcium metabolism eventually corrects spontaneously and T lymphocytes mature. Prognosis depends on severity of the cardiac abnormality.

Fanconi Syndrome Hypoplastic thumb (80 %) and/or radial hypoplasia or complete absence of the radial bone, pigmented skin lesions, small

penis mental retardation in some and pancytopaenia and lymphoreticular malignancy. Genetic defects have been found in 3q, 9q or 16q locus. The pancytopaenia is characterised by hypoplasia of the erythropoietic, myeloid and megakaryocytic elements of the bone marrow and typically becomes manifest at around 8 years of age. Fourteen percent of patients with the Fanconi anaemia have gastrointestinal atresias.

Goldenhar Syndrome Preauricular skin tags and small and deformed ears, asymmetric facial hypoplasia and macrostomia, cervical vertebral defects, cardiac defects and epibulbar dermoid are the diagnostic criteria.

Smith-Lemli-Opitz Syndrome Described by Smith in 1964, this condition is characterised by microcephaly, growth and mental retardation which is generally severe, soft tissue syndactyly of the second and third toes and genital abnormality. Males predominate.

Holt-Oram Syndrome Hypoplastic thumbs (characteristically triphalangeal) and/or hypoplasia of the radius and secundum ASD/VSD. Also abnormalities of the upper limbs and shoulder girdle. Growth and development are normal.

Rogers/AEG Syndrome/Anophthalmia [15, 29] The association of anophthalmia/microphthalmia and oesophageal atresia was first described by Schenk in 1976 in a 28 mm human embryo. Since then at least 17 cases of this association have been reported. Patients with anophthalmia are usually affected bilaterally and have more severe associated anomalies of the central nervous system, craniofacial, urogenital, cardiovascular and skeletal defects. Patients with microphthalmia are generally unilaterally affected and have less severe associated anomalies. Different genes have been implicated in this syndrome including Sonic Hedgehog (shh), Pax 2 and SOX 2.

Duodenal Atresia [20, 21] Oesophageal atresia associated with duodenal atresia or more commonly with duodenal and anorectal atresia poses a specific management dilemma. The surgical decision is based on which defect is the most life-threatening. Elimination of the danger of reflux aspiration through the tracheo-oesophageal fistula would appear to be the most urgent consideration. If the infant is stable following ligation and division of the fistula, the operative procedure can continue through oesophageal anastomosis to correction of the duodenal atresia to treatment of the anorectal malformation.

Cleft Lip and Palate [16, 23] Cleft lip and palate in association with oesophageal atresia occur in 2–3 % of cases. These infants have a high incidence of associated anomalies particularly cardiac defects which account for the high mortality rate. There is also a high incidence of chromosomal anomalies such as trisomies and CHARGE syndrome. In one series, the mortality rate was over 50 %.

Congenital Esophageal Stenosis Associated with Esophageal Atresia

9

Ashraf H.M. Ibrahim and Talal A. Al Malki

Introduction

CES is suspected by a fixed intrinsic narrowing of the esophagus present at birth and associated with congenital malformation of the esophageal wall architecture [1]. Excluding the membranous type (MD), the diagnosis of CES is only confirmed by the histologic picture [2]. The histopathologic picture may show fibromuscular disease (FMD) or tracheobronchial remnants (TBR). The latter involves ciliated pseudostratified columnar epithelium, seromucous glands, or cartilage alone or in combination [3]. The association of CES and esophageal atresia (EA) and/or tracheoesophageal fistula (TEF) ranges from 0.4 % [1] to 14 % [4–6]. The authors believe that this association is common and that many cases are over looked. CES has been most frequently associated with EA with distal TEF (64 %), followed by isolated TEF (20 %) and isolated EA (16 %) [7]. In the authors experience, the incidence of CES being associated with pure atresia is higher than in EA and distal TEF (50 % vs 11.3 %) [6].

The first case of CES associated with an EA was reported from the Montreal Children Hospital by Dunbar in 1958 [8]. This was followed by 34 reports in the literature till 2008 [1, 4–7, 9–37]. Reviewing the histologic structure and the etiology of esophageal dysmotility in this association is mandatory for understanding this topic.

Histology of the Atretic Esophagus

Few reports are available in the literature regarding the histology of the atretic esophagus. Hokama et al. in 1986 [3] examined six autopsy unoperated cases of EA and TEF and also two surgical specimens. They defined the lower segment of the esophagus as that part where the wall is arranged into four normal layers: mucosa, submucosa, muscularis externa with myenteric plexus, and adventitia. The fistula was defined as that portion between the tracheal/bronchial connection and the transition to esophagus with normal layers. Tracheobronchial elements were defined as ciliated pseudostratified columnar epithelium, seromucous glands (as opposed to normal esophageal mucus glands), or cartilage, alone or in combination. Hokama et al. found a high incidence of TBR in the lower esophagus (five autopsy cases out of six and in the two surgical specimens). They concluded that TBR may be very common in EA/TEF that may lead to stenosis and abnormal motility after successful

anastomosis. They also proposed that lack of a normal muscle coat at the fistulous end may cause esophageal dysmotility. They questioned the feasibility of including the fistula in the anastomosis should this correlation be confirmed.

In 1997, Merei et al. [38] from Australia carried out a histologic study of EA and TEF in an adriamycin animal model. They found that all the fistulae were lined with ciliated respiratory epithelium extending to a variable distances from the origin and in some instances as far as the stomach. Cartilage was occasionally seen in the wall. Transition from ciliated epithelium to stratified squamous epithelium occurred either by partial or abrupt replacement. The muscle layer was absent at the fistulous origin. Later, it was composed of irregular smooth muscle fibers that were not properly arranged into normal esophageal layers. After transition to normal esophageal epithelium, it became regular.

Dutta et al. in 2000 [39] reported a histological study of EA/TEF in 65 cases. The lining epithelium was stratified squamous in 36 cases, pseudostratified squamous in 2, and not seen in 27 cases. The mucous glands were abnormally high in number in 23 cases and with abnormal mucin secretion (typical of respiratory glands) in 23 cases. The ducts were dilated in six cases but with increased number in four. Cartilage was seen in eight cases with large number of mucous and seromucous glands also with abnormal mucin secretion. The muscularis propria was poorly oriented in 17 cases, well developed in 17, and disorganized in 13. Out of the studied cases, one autopsy case showed cartilage with mucous and seromucous glands. In another autopsy case, only mucous and seromucous glands were seen without cartilage. Both autopsy cases showed abnormal mucin secretion. The authors proposed that the TBR in the repaired esophagus as well as a disorganized muscle coat may be part of the transition from the fistula to a normal esophagus. The extent of this TBR is variable, and it may be premature to suggest this as a cause for esophageal dysmotility in each case. The authors stressed the point that loss of normal esophageal function may be due to abnormal numbers of glands and ducts and presence of abnormal mucin production. TBR may present with esophageal stricture refractory to dilatations but have dramatic response to resection. They claimed that these strictures are present only in the lower esophagus away from the area of anastomosis. However, this statement has been challenged. CES should be considered in the etiology of anastomotic stricture [6]. In our series, surgical specimens for histopathologic studies were obtained from the tip of the lower esophageal pouch during primary repair of EA/TEF cases [6]. Up to date, 10 patients out of 65 (15.4%) had histologic pictures suggestive of CES. None of the patients studied had absent muscle layers. This excludes using the fistula in the anastomosis. Two cases had fibromuscular disease (FMD), five with tracheobronchial remnants (TBR) without cartilage, and three with cartilage. The epithelium for these ten patients was normal in seven patients and pseudostratified columnar ciliated in three. These three cases showed increased numbers of mixed respiratory glands, ducts, and cartilage that extended from the submucosa to the adventitia causing muscle distortion (Fig. 9.1). One case with pure EA and gastric pull up showed TBR involving the whole lower esophageal pouch down to the cardia. Five patients showed mixed respiratory glands without cartilage that extended from the submucosa to the adventitia causing muscle distortion (Fig. 9.2). The glands were considered abnormal if they are seromucous or mucous glands that are increased in number and/or abnormally located outside the submucosa. The remaining two cases showed muscular hypertrophy and extensive fibrosis consistent with FMD (Figs. 9.3 and 9.4).

Etiology of Esophageal Motility Disorders in Esophageal Atresia

The etiology of esophageal dysfunction in cases of CES after repair of EA is not understood. It may be due to either CES or EA alone or in combination. *An acquired origin* for esophageal dysmotility is proposed. Extensive mobilization and denervation of the esophageal segments could aggravate reflux and motility disorders [40]. Normal peristaltic activity was documented preoperatively in the proximal esophagus in two patients who had EA without a fistula. One patient examined postoperatively showed a disturbed motility pattern [41]. Vagal damage may be the cause of motility dysfunction [42]. Extensive pouch mobilization is associated with severe motor disability [43].

A congenital origin for esophageal motility disorders after EA repair was proposed. Romeo et al. in 1987 [44] has documented disturbed motility preoperatively in patients with EA. Furthermore, motility disorder has been documented in patients having isolated TEF without EA [45]. Transection and anastomosis of the esophagus did not cause motility disorders [46]. Few histological studies have been conducted in the literature to document the congenital origin of esophageal dysmotility after successful repair of EA. Most of these studies have been done on autopsy patients [3, 47] or animal models [38, 48, 49]. Abnormal Auerbach's plexus was found in the esophagus and stomach in five autopsy patients with EA and TEF. The plexus was looser than normal in the distal esophagus and to a lesser extent in the proximal esophagus and stomach fundus. The ganglia were larger than normal. The smooth muscle layers were documented to be normal [47]. In other studies [3, 6, 38, 39], tracheobronchial elements, namely, ciliated pseudostratified columnar epithelium and seromucous glands with or without cartilage together with irregular smooth muscle fibers, were seen in sections of the distal esophagus. Seromucous glands were seen among muscle bundles of the lower esophageal pouch. Abnormal mucus glands causing muscle distortion were also documented. The transition from the fistula

(**b**) Photo from videofluoroscopy with major dysmotility after 1 month with failure of passage of the contrast distally for more than 5 min. (**c**) Barium swallow and meal after fundoplication and lower esophageal myectomy showing improvement of motility

to normal esophageal histology takes place at a variable distance from the origin of the fistula and may extend down to the cardiac end [3, 6, 38]. Surgical specimen from the tip of the lower pouch also showed a histologic picture consistent with FMD [6].

Singarm et al. in 1995 [50] examined the histological and immunohistochemical features of CES of the FMD in two adults. In comparison to three controls, CES esophagi showed infiltration of neutrophils in the myenteric plane without any increase in collagen. NADPH diaphorase histochemistry showed a significant reduction of myenteric nitrinergic neurons and fibers of the circular muscle. The specific total lack of nitric oxide (NO) inhibitory innervation may be an important mechanism in the pathogenesis of stenosis and aperistalsis of the esophagus in this disorder.

Neuropeptides are abnormal in the atretic esophagus in the Adriamycin fetal rat model [48, 49] and in humans [51–53]. The density of the nerve plexus, ganglia, and number of cell bodies per ganglia immunostained by neuron-specific enolase (NSE), vasoactive intestinal peptide (VIP), or substance P (SP) was significantly reduced in EA/TEF fetuses. So, there are significant abnormalities of the intramural nervous components of the esophagus in EA/TEF fetal rats, involving both the excitatory (SP-labeled) and inhibitory (VIP-labeled) intramural nerves which may be the cause of esophageal dysmotility in EA/TEF [49].

The circumferential neuronal distribution in the myenteric plexus in the atretic esophagus of the rat model was reduced by 50%. The near-complete ring of nerve tissue along the plane of the myenteric plexus was replaced by clusters of nerve tissue in the atretic esophagus. This abnormal distribution of nerve tissue in the atretic esophagus may be contributing factor in the esophageal dysmotility seen in EA [54]. Qi et al. using the same model showed that the vagus nerve gave rise to fewer branches in the esophagus and assumed abnormal route at the level of the lower esophagus [55]. Boleken et al. examined the distal end of the proximal esophageal atretic segment of neonates undergoing EA/TEF repair for intrinsic neuronal innervation. They found that the distribution of ganglion cells and some nerve fibers is deficient. The inadequate and abnormal neuronal innervation of the esophagus could be related to esophageal dysmotility in EA. Deficient expression of glial cell line-derived neurotrophic factor (GDNF) could have an important role in the defective and/or abnor-

mal neuronal innervation of the atretic esophageal segment [51]. Similarly, Li Kai et al. in 2007 investigated the structural characteristics and the expression of a group of neuropeptides in the specimens obtained from the fistulous end of the lower esophagus of patients with EA/TEF. They found imbalance of neurotransmitters excretion in nerve vesicles, abnormal intrinsic dysplasia of nerve plexus, and increased expression of certain neuropeptides, e.g., VIP and nitric oxide synthase (NOS) were the main characteristics of the esophagus with abnormal intrinsic innervation, which may be responsible for postoperative esophageal dysfunction [52]. Most recently, Pederiva et al. examined the intrinsic esophageal innervation in children with isolated EA using specimens from the proximal and distal esophageal segments. There were denser fibrilar network and larger ganglia than controls [53].

Kawahara et al. in 2003 [56] investigated the motor function in four cases with isolated CES. Esophagogram showed stasis of contrast proximal to esophageal narrowing in two cases with FMD and one case with TBR. Three patients showed pathologic acid exposure by pH monitoring despite absence of evidence of esophagitis by endoscopy. Manometry showed synchronous esophageal contractions in FMD and TBR cases. LES pressure was at least 20 mmHg. Swallow-induced LES relaxation was incomplete in these cases. The authors concluded that gastroesophageal reflux (GER) and impaired esophageal motility are common in CES with FMD and TBR. Synchronous contractions seen in patients with FMD and TBR could be related to abnormal innervation of NO. The manometric data in CES in children reported by the Pittsburgh group showed segmental aperistaltic zone at the level of stenosis with local decreased pliability. The superior and inferior sphincters responded normally to swallowing [57]. A manometric study in 12 cases of CES showed another high-pressure zone (HPZ) in addition to the lower esophageal sphincter (LES) found in nine of the patients. This additional pressure zone disappeared after treatment [58]. Cheng in 2004 reported a case of achalasia-like esophageal dysmotility in a 14-year-old boy after successful repair of EA/TEF in the neonatal period. This was proved by clinical, radiological, and manometric study. The manometric features were a cardiac sphincter of 2 cm in length with a high pressure above 40 mmHg with aperistalsis in the esophageal body and failure of the cardiac sphincter to relax after a swallow. The condition responded well to Heller myotomy [59].

Kawahara in 2004 [60] reported the usefulness of videomanometry for studying pediatric esophageal motor disease in four postoperative cases of EA/TEF and one case of isolated distal CES due to TBR. These cases frequently showed impaired esophageal transit during defective esophageal peristaltic contractions. Videofluoroscopic image in cases of EA showed marked stasis of contrast in the esophageal body. Manometry showed absent contractions in the middle esophagus. The distal esophagus showed low-amplitude peristaltic contractions in two cases, low-amplitude synchronous contractions in one case, and no contractions in one case. The authors concluded that impaired esophageal transit was caused by defective luminal closure especially in the middle esophagus during deglutition, but not by LES malfunction. Videofluoroscopy of the case of CES showed stasis of the contrast in the distal dilated esophagus associated with narrowing at the end of the esophagus mimicking achalasia. Manometry showed swallow-induced LES relaxation and low-amplitude synchronous contractions in the whole esophageal body.

Types of Congenital Esophageal Stenosis

Fekete et al. [1] defined CES as intrinsic stenosis caused by congenital malformation of the esophageal wall. It involves a type with TBR, another with segmental hypertrophy of the muscularis and diffuse fibrosis of the submucosa (FMD), and a third type with a membranous diaphragm (MD). The most common type of CES was that of the TBR variety (75 %) followed by the FMD (25 %) [4, 6]. These percentages might not be correct. The FMD responds better to balloon dilatation. If dilatation is successful, no specimen is available. So, a definitive subtype cannot be

determined. Also the percentage of each type that will respond to dilatation is not known [34]. The MD type is rarely reported in association with EA/TEF [9, 32, 61]. It is possible that CES can be multiple [62]. The stenotic area may involve the perianastomotic area or even may extend distally to a variable distance [4, 6]. For this reason, we disagree with the statement that CES does not involve the anastomotic site and is always separate from it [1, 35]. However, a distal isolated area of CES separate from the anastomotic site may be present [4, 5, 7, 15]. All the 11 cases reported by Kawahara in 2001 were found to have narrowing between the anastomosis and the gastroesophageal junction: in the mid-esophagus in two and in the lower esophagus in nine patients [4]. In our experience with ten cases, only one of them had distal esophageal stricture due to FMD that required resection. So, in our series, CES is more common at the perianastomotic area (Tables 9.1, 9.2, and 9.3).

Diagnosis

A high index of suspicion should be raised in all cases of EA. CES is an intrinsic stenosis that may be present at birth but not necessarily symptomatic [7]. The diagnosis of CES is suspected in a neonate with EA if a size 8 French nasogastric tube cannot be passed into the stomach [4, 7]. However, passage of the tube down to the stomach does not rule out CES [7]. The diagnosis of CES before or during primary repair of EA is possible; however, simultaneous repair of the stenosis by doing a double esophageal anastomosis is a controversial approach [4, 32]. An esophagogram demonstrating a narrow segment above the cardia is radiologically diagnostic for CES when found in the neonatal period [7, 63]. Minor esophageal dysmotility as detected by barium is defined as aperistalsis, antiperistalsis, and simultaneous or uncoordinated contractions. The dysmotility is considered major if the transit time for

the bolus to go to the stomach is greater than 5 min [6]. The problem of major dysmotility is that it develops late and can be fatal or amenable to major complications.

Taking a surgical specimen routinely from the tip of the lower pouch during primary repair of EA may show a histological picture consistent with FMD or TBR [6]. This mandates close observation. The latest case in our series (case 10) showed TBR with cartilage (Fig. 9.1). The initial esophagogram was normal. A repeat fluoroscopic esophagogram 1 month later showed major esophageal dysmotility due to aperistalsis in the perianastomotic area. The patient required a feeding gastrostomy, anterior partial fundoplication, and lower esophageal anterior myectomy. The major esophageal dysmotility as seen at fluoroscopy improved, and partial oral feeding was allowed. The histology of the myectomy was normal. We learn from this case that the histologic picture confirmed the site and type of CES. The forthcoming scenario was anticipated. Dysphagia which developed after 1 month was not due to introduction of solid food but was due to pure dysmotility which preceded mechanical stricture. The lower esophageal myectomy helped to improve major dysmotility probably due to a decrease in the pressure of the lower high-pressure zone.

The late-onset diagnosis is suspected by the clinical triad of recurrent aspiration, dysphagia, and FTT together with the aid of an esophago-

gram [64]. Patients may present with distal esophageal foreign bodies [7]. A barium study is the diagnostic and follow-up tool. Full cooperation between the radiologist and the surgeon is required.

The presence of GER in cases of EA with CES is said to be unlikely [27]. However, others believe that it is common [4–6]. Esophagoscopy and biopsy, pH monitoring, and possibly manometry may be required [58]. However, even with these investigations, it may be difficult to differentiate between CES and stricture due to GER [7]. Errors in diagnosis are common as most of these patients are diagnosed and managed as peptic stricture [5, 7].

Precise preoperative diagnosis of CES is important. The type of stenosis determines the modality of treatment. Without the preliminary histologic picture, the preoperative differentiation between FMD and TBR with cartilage is difficult. In a review of the literature for 59 cases with TBR with cartilage up to 2004, a correct preoperative diagnosis of the underlying etiology of stenosis was not reached in most cases. The majority were diagnosed as achalasia or peptic stricture [64]. Esophagoscopy and biopsy may fail to show deep-seated ectopic tissue [1, 65]. Fluoroscopy may show abrupt narrowing in cases of TBR, while that of the FMD may show more gradual, regular, and well-centered narrowing. However, fluoroscopy does not always show these typical findings [35]. During balloon dilatation, the presence of a short, sharp waist-like impression which suddenly disappears with increased pressure means the presence of cartilaginous rings [7, 34]. Endoscopic ultrasonography is said to be useful to distinguish TBR with cartilage from FMD [35, 66, 67]. Intraoperative palpation and the use of the flexible esophagoscopy may be of help [35, 65]. The author like others [58] found that intraoperative palpation of the lesion is not always easy. However, these modali-

ties suspect but not confirm the presence and the type of CES. The diagnosis is only confirmed by the histologic picture.

Treatment

Cases of EA diagnosed or suspected to have associated CES in the neonatal period should have utmost attention. A normal early fluoroscopic barium swallow and meal does not exclude CES and must be repeated at 4–6 weeks. The development of the triad of esophageal dysmotility, GER, and stricture should be managed as early as possible. By doing this, the consequences of malnutrition, recurrent aspiration, and even mortality can be avoided. Full antireflux measures and balloon dilatation for stricture should be initiated. If the dysmotility is major, a partial anterior wrap together with a feeding gastrostomy is indicated. During the procedure, a myectomy as long as possible of the lengthened lower esophagus is taken and sent for histopathologic and possibly histochemical examination.

For those cases discovered late, proper chest treatment, antireflux measures, and nutritional support should be started. Antireflux measures together with balloon dilatation should be the initial treatment of all forms of CES associated with EA [7, 34].

Most cases with TBR without cartilage respond well to medical antireflux measures together with balloon dilatations. Three out of four patients in our series showed excellent long-term clinical outcome despite the persistence of radiological minor dysmotility. Only one patient required surgical resection after failed balloon dilatations. Histopathology of the resected specimen showed glands without cartilage.

Cases with TBR with cartilage will require a limited surgical resection and primary anastomosis if balloon dilatations failed on three occasions [4, 5, 7, 35]. Surgical resection will also be indicated if initial sufficient dilatation is not achieved or symptoms recur very soon after dilatation [58]. Unnecessary prolonged trials of balloon dilatations should be avoided because the trials will be unsuccessful [64]. Some authors experienced severe complications with repeated dilatations [4, 68, 69]. The extent of TBR into the distal esophagus should be accurately assessed during surgery. A frozen section biopsy may be required. A fundoplication is recommended after resection if it disturbs the gastroesophageal junction and to avoid the possible postoperative complications of GER and hiatus hernia [1, 7, 33]. Circular myectomy was performed successfully for the treatment of CES due to TBR [70, 71]. Thoracoscopic resection of a distal CES and esophageal end to end anastomosis was successfully performed [72]. Very recently, a laparoscopic lower esophageal stricturoplasty with anterior fundoplication for CES due to TBR was also successful [73]. Surgical resection may be complicated by recurrent anastomotic stricture that may require few postoperative dilatations.

Cases with FMD usually respond to balloon dilatations [4, 7, 35]. Longitudinal myotomy with Nissen fundoplication may be curative [4, 35]. A limited surgical resection may be required if the above measures fail [4, 35, 58].

Cases of MD and multiple stenoses can be treated with esophageal dilatations alone. Endoscopic partial resection of the membrane can be done at the time of dilatation [35].

Choanal Atresia, Esophageal Atresia, Facial Anomalies, and Dysautonomia

10

Francesco Cozzi and Denis A. Cozzi

Introduction

The old concept that during the neonatal period bilateral choanal atresia causes life-threatening apnea whereas unilateral choanal atresia causes only a unilateral nasal discharge is still well accepted. The cause of life-threatening apnea is considered the inability to open the mouth. The ensuing cyanosis stimulates crying, which is a method to induce mouth breathing, thus relieving the obstructive apnea. As the relief comes, the infant ceases to cry and closes his or her mouth. After a few seconds, the respiratory problems come again [1]. The constant repetition of this cycle is yet described as the main clinical manifestation of bilateral choanal atresia, whereas a persistent nasal mucoid discharge from the affected side is described as the main clinical manifestation of unilateral choanal atresia [54].

In 1977, the senior author reported clinical observations and respiratory studies suggesting that the life-threatening apnea of infants with choanal atresia or choanal stenosis was not due to an inability to switch from nasal to oral ventilation, but it was due to an inability to sustain an adequate oral ventilation. The pathogenic mechanism of oropharyngeal airway obstruction appeared quite similar to that described as glossoptosis by Pierre Robin in infants with micrognathia or in infants with hypertrophied adenoids, that is, a posterior displacement of the tongue obstructing the upper airways [3]. In the senior author's paper, it was also speculated that glossoptotic upper airway obstruction could play a role into the pathogenesis of apparent life-threatening episode (ALTE) observed in some infants with esophageal atresia and into the pathogenesis of asphyxial death in some victims of sudden infant death syndrome (SIDS) [10].

With an increasing number of clinical observations, it became clear that infants with either bilateral or unilateral choanal atresia/stenosis (CA) or with esophageal atresia (EA) present also a common clinical picture [14, 35, 37]. Actually, the respiratory problems, referred to a development delay of respiratory control, were often associated with other clinical manifestations of autonomic disorders. A possible explanation of these findings was that the face, the esophagus, and the autonomic nervous system have a common origin from the cephalic neural crest. Therefore, a cephalic neurocristopathy, that is a maldevelopment of cephalic neural crest derivatives [9], may explain why both CA and EA can be associated with symptoms and signs of autonomic dysfunctions. Support to this theory comes from the presence in infants with CA or EA of similar facial dysmorphisms, which are considered markers of a cephalic neurocristopathy [39].

DOI 10.1007/978-3-642-11202-7_10

This is a review of our main contributions to the literature during more than three decades regarding the clinical and pathophysiological manifestations that the infants with EA share with those with CA.

Pathophysiology

Early respiratory studies in infants with bilateral choanal atresia suggested that the main pathogenic factor of upper airway obstruction was a backward aspiration of the tongue. Flow signals were obtained from a pneumotachograph connected to tight-fitting mask. Esophageal pressure, as an index of intrapleural pressure, was measured with a water-filled polyethylene catheter passed through the mouth into the lower esophagus and connected to a pressure transducer. Infants with CA were breathing through an oropharyngeal cannula without respiratory distress. When the oropharyngeal cannula was removed, increasing esophageal pressure swings with very negative values, and a complete absence of airflow occurred (obstructive apnea, equivalent of Muller's maneuver). The conclusion was that the strong negative pressure generated by the inspiratory efforts was responsible for the aspiration of the tongue and the consequent oropharyngeal obstruction [10]. Therefore, we proposed the term vacuum-glossoptosis to indicate that falling back of the tongue was not due to a simple mechanical consequence of a short mandible, as proposed by Pierre Robin [3], but was mainly due to aspiration of the tongue and its sealing to the palate [25].

Subsequent clinical observations showed that some infants with EA or CA [37], as well as some infants with Pierre Robin syndrome without micrognathia, or some infants with unilateral choanal atresia, or some infants with a nasal obstruction caused by a simple rhinitis [14] may present recurrent episodes of glossoptosis-apnea. The absence of correlation between the severity of symptoms and the degree of anatomical or inflammatory upper airway obstruction suggested that also the muscular activity of the genioglossus plays an important role in maintaining the patency of the upper airways [14]. The tongue and the soft palate act as a dynamic flap valve that may easily obstruct the oropharyngeal airway when the negative inspiratory pressure overcomes the genioglossus forces, which tend to protrude and depress the tongue [24].

During normal breathing, there is an activation of genioglossus and of other upper airway-dilating muscles prior the activation of the diaphragm and of other inspiratory muscles [27, 29]. This pre-activation serves to counteract the negative intrathoracic pressure generated by the inspiratory muscles, thus avoiding the aspiration of the tongue and the collapse of the musculomembranous walls of the pharynx. During loaded breathing, animal experiments have demonstrated the presence of a powerful reflex mechanism to protect pharyngeal patency. Any increase in resistance in the upper airway is followed by an increase in negative pressure during inspiration, resulting in stimulation of laryngeal mechanoreceptors. This afferent feedback to central pattern generator in the brainstem determines respiratory stimuli to activate the genioglossus [27, 29].

The concept that glossoptosis-apnea was the result of an abnormal control of respiration was further supported by the frequent presence in infants with both CA and EA of obstructive and central hypopneas/apneas [37]. Obstructive apnea implies an inspiratory effort not associated with pre-activation of upper airway-dilating muscles. Central hypopnea/apnea implies a decreased or absent stimulus from the respiratory centers to the inspiratory muscles (Fig. 10.1). In addition, in some patients with glossoptosis-apnea syndrome, many symptoms were not relieved by the surgical removal of the anatomic obstruction, suggesting persistence of a dysfunction of upper airway-dilating muscles [35]. A similar persistence of some clinical manifestations following adenoidectomy was long before noticed and called "adenoidism without adenoids" or "glossoptism" [3, 4]. The persistent symptoms disappeared spontaneously at long-term follow-up, thus indicating that they were not caused by an anatomical obstruction

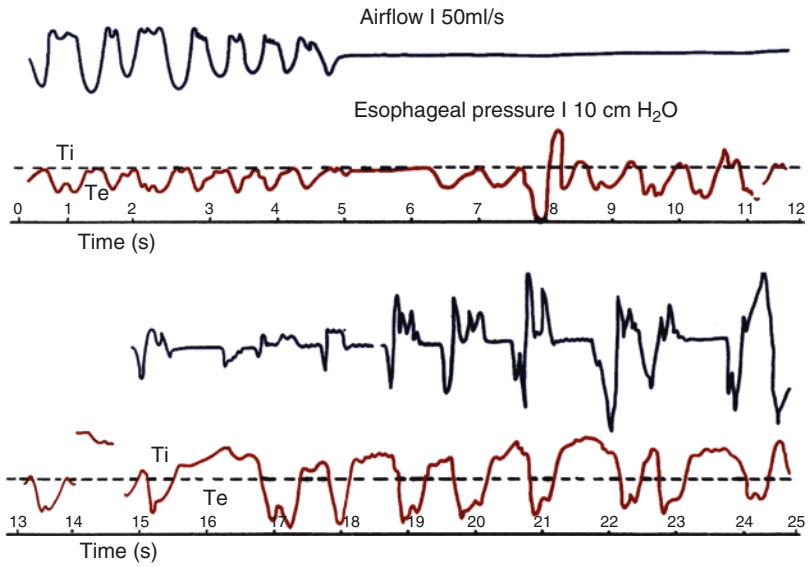

Fig. 10.1 Central hypopnea/apnea followed by obstructive apnea in an infant with esophageal atresia and distal tracheoesophageal fistula. Note: (1) parallel reduction followed by complete absence of airflow and esophageal pressure, that is central hypopnea/apnea (0–6 s); (2) inspiratory effort without airflow, that is obstructive apnea (6–13 s); (3) grunting expiration, characterized by prolonged expiratory time, interrupted expiratory flow despite positive expiratory pressure, and progressive increase of retarded expiratory flow (*arrows*) (14–3 s). Ti and Te are inspiratory and expiratory time, respectively

but were related to a "maturational dysautonomia" [35].

The main conclusion was that various types of upper airway anatomical obstructions, including CA, EA, congenital micrognathia, or even a simple upper respiratory tract infection, become symptomatic if associated with an impaired reflex activation of upper airway-dilating muscles. The infant who is not able to counterbalance the increased inspiratory pressure brought about by the anatomical or inflammatory obstruction presents recurrent episodes of functional upper airway obstruction [35, 37].

Clinical and radiologic studies in infants with various types of obstructions of the nasal airway showed that the respiratory distress is characterized by signs of an obstruction of both inspiration and expiration [2, 6, 22, 26]. In infants with CA, the mechanism of the obstruction in expiration is considered the anatomical obstruction of nasal airway due to choanal atresia associated with the functional obstruction of oral airway due to the sealing of the soft palate to the base of the tongue [6, 22]. In infants with EA, expiratory airway obstruction is conventionally attributed to tracheomalacia. However, our studies of pulmonary mechanics and breathing patterns during glossoptosis in infants with CA or in infants with EA have shown that the expiratory obstruction is characterized by an absent flow despite a positive expiratory pressure and a retarded expiratory flow pattern (Fig. 10.1) [42]. The obstructed expiratory efforts (equivalent of the Valsalva maneuver) and the retarded expiratory flow were associated with an audible grunting, which was loudest over the neck. Therefore, the expiratory airways obstruction may be referred, at least in part, to active braking of the expiratory flow, that is, an active closure of the glottis associated with a positive expiratory pressure. This expiratory flow pattern is frequently found in babies with hyaline membranes [17] or even in normal babies with a subclinical grunting [19]. Forced expiration is a breathing strategy that serves to defend lung volume and lower airway patency by forcing gas retrogradely into the peripheral airways during expiration.

In conclusion, infants with various types of upper airway obstruction present respiratory problems if the anatomical or inflammatory obstruction is associated with an upper airway instability responsible for a functional glossoptotic pharyngeal obstruction. Recurrent episodes of functional upper airway obstruction may bring about a low lung volume, that is, a lower airway instability. In this condition, active braking of the expiratory flow is a useful breathing strategy to avoid collapse of widespread areas of the lung and the consequent intrapulmonary right-to-left shunt. This breathing strategy is particularly useful in infancy since large intrapulmonary right-to- left shunt seems to play an important role into the pathogenesis of ALTE and SIDS [14, 35–37, 39, 41, 46].

Table 10.1 Prevalence of main clinical features in infants with choanal atresia/stenosis and infants with esophageal atresia

	Esophageal atresia (%)	Choanal atresia (%)
Respiratory problems		
Inspiratory dyspnea	88.7	98.2
Expiratory dyspnea	43.7	49.2
ALTE	35.0	29.8
Sudden death	3.7	3.5
Feeding problems		
Oropharyngeal dysphagia	62.7	57.8
Vomiting/GER	60.4	52.6
Failure to thrive	45.0	40.0
Bradycardia	25.0	12.2
Hyperthermia	16.2	21.0
Sialorrhea	18.6	17.5
Hyperhydrosis	34.8	22.8

Clinical Features

Nearly all symptomatic infants with CA or EA have one or more clinical manifestations of dysautonomia [35, 37, 39] (Table 10.1).

The most frequent clinical manifestation is the presence of respiratory symptoms and signs, usually observed during the first months of life. These problems are triggered by any respiratory load including upper respiratory tract infections, crying, exercise, supine position, and flexion of the neck. The respiratory problems are also precipitated by those factors which decrease the activity of upper airway-dilating muscles including sleeping, sedatives, and anesthesia.

The clinical manifestations of respiratory problems have been described in details both in infants with EA [5, 15, 37, 39] and in infants with CA [14, 35]. All patients with respiratory distress have one or more signs of inspiratory obstruction, including snoring; sniffing; stridor; head retraction; open mouth breathing; glossoptosis; retrognathia; indrawing of the cheeks, lip, and soft tissues of the neck; indrawing of the sternum (paradox respiration); and reduced or absent air entry. Open mouth breathing is a maneuver adopted to bring the tongue forward, thus preventing glossoptotic pharyngeal obstruction [3, 23]. Similarly, head extension (opisthotonous) is a protective maneuver to prevent glossoptotic pharyngeal obstruction by increasing the pharyngeal dimensions [30, 38].

The signs of inspiratory obstruction do not reflect an increased alveolar resistance due to a lung disease, because most often no lung lesions are detected on chest-films. In addition, the inspiratory dyspnea may not be attributed to tracheomalacia because the negative intrathoracic pressure during inspiration increases the diameter of the malacic intrathoracic trachea. Furthermore, compression of the thoracic trachea or an increased alveolar resistance causes retraction of soft parts of the thorax, but not the soft parts of the neck. Actually, the inspiratory retractions of soft part of the neck and suprasternal retractions should be considered a red flag sign of an obstruction of extrathoracic airways, which causes a strong negative pressure inside the cervical trachea.

One of the main characteristics of the respiratory problems due to a dysautonomic control of dilating upper airway muscles is that the inspiratory dyspnea, during the most severe phases, is associated with signs of expiratory

obstruction. The signs of expiratory dyspnea, which is usually transient, include expiratory ballooning of soft tissues of the neck, grunting, and contraction of abdominal wall muscles during expiration. Grunting may be easily distinguished from wheezing because with a stethoscope, it is possible to ascertain that the sound of grunting is loudest over the neck, whereas wheezing is loudest over the thorax. Most likely, the peak flow at the end of expiration (Fig. 10.1) is responsible for the expiratory ballooning of soft part of the neck, as well as of the "puffing" of cheeks [42].

The active expiration may become detrimental when the lung volume reaches a critical low volume. In this situation, any additional expiratory efforts, that is, crying, coughing, etc., may cause a sudden and massive collapse of widespread areas of the lung. The result will be a large right-to-left intrapulmonary shunt and hypoxemia that may cause ALTE. If the protective mechanisms to reverse ALTE are not efficient, a sudden asphyxial death may supervene [36]. Actually, about 3 % of infants with esophageal atresia or choanal atresia are found dead in their crib, and asphyxia seems the most reasonable cause of death.

About half of the infants with EA or with CA present feeding problems. In some infants with EA or CA feeding problems may be the only clinical manifestation. Sucking difficulties usually result in an unusually long feeding time. Pharyngeal dysphagia causes nasal regurgitation and/or laryngeal penetration. More than half of the patients present vomiting and/or gastroesophageal reflux. In infants with dysautonomia, feeding problems are considered the cause of a body weight in the lower centiles. However, clinical experience indicates that sometimes increasing the caloric support through a gastrostomy does not reverse failure to thrive, supporting the concept that in infants with dysautonomia, the metabolic cost of the increased work of breathing contributes to failure to thrive. Furthermore, many of these infants present a constitutionally low body weight [53]. The frequent association between respiratory and feeding problems may be explained with the consideration that the upper airway-dilating muscles are involved not only in the respiratory function but also in the functions of sucking and swallowing.

The concept that feeding and respiratory problems are mainly due to an anomalous autonomic regulation is supported by the frequent association with clinical manifestations of other autonomic dysfunctions. Bradycardia may be present even before birth during the last weeks of gestation and may be so severe to require an emergency caesarean section [37]. After birth, about 10–25 % of infants with CA or EA present episodes of bradycardia not associated with apneic spell and/or hypoxemia. Sometimes, bradycardia follows pharyngeal or tracheal suctioning; however, most often the mechanism triggering bradycardia is not identified. In one infant, during the course of esophageal repair, bradycardia was followed by cardiac arrest requiring cardiac message. This episode was probably the result of vagus nerve manipulation. Subsequently, this infant had two additional episodes of bradycardic arrest during esophageal dilatations under general anesthesia [37].

About one-third of the infants with EA or CA present profuse sweating during feeding or during sleeping. Sweating should be considered pathologic if the patient clothes became wet from dripping sweat. In one infant with EA, sweating associated with flushing was localized only on one side of the face and the body [37]. In infants with choanal atresia, this peculiar sign, that is unilateral sweating, was first reported by Richardson [1].

Additional dysautonomic features include sialorrhea, which should be considered significant if numerous daily replacements of wet bibs are required. Finally we considered as due to an anomalous regulation of body temperature the recurrent episodes of high body temperature without clinical or laboratory evidence of infection. These episodes of high temperature, previously observed in an infant with tracheal compression by an anomalous subclavian artery [16], usually last for few hours or days; however, they can be so severe to require parenteral rehydratation. One infant with CA

died during an episode of uncontrolled hyperthermia [35].

Associated Facial Anomalies

How to explain that infants with CA or EA present with a quite similar clinical features, enabling a common syndrome to be recognized?

As the autonomic nervous system develops from the neural crest cells, it has been postulated that these autonomic disturbances may be a manifestation of a neurocristopathy [13, 33]. This term was introduced by Bollande to describe a category of diseases arising from a maldevelopment of neural crest cells [9].

The number of neurocristopathies increased when Le Douarin and her colleagues with elegant animal experiments made fundamental acquisitions on the role of cephalic neural crest cells in the embryogenesis of cervicofacial region [11]. Accordingly, CA and the associated defects known as "CHARGE" association were considered the consequence of an abnormal contribution of cephalic neural crest cells to the development of nasofrontal bud [31]. As abnormalities in the migration of cephalic neural crest cells have profound effects on the embryogenesis of branchial arches [12], Pierre Robin syndrome [34] and DiGeorge syndrome were considered neurocristopathies of the first and second branchial arches, respectively [28].

To make sense out of the associations between CA, EA, and dysautonomia, we speculated that EA, CA, and dysautonomia may be related to an abnormal neural crest involvement. As facial anomalies are considered markers of a cephalic neurocristopathy [12], to test our hypothesis we studied the prevalence of facial anomalies in a series of infants with EA or CA, evaluated at a special follow-up clinic [39]. The association between CA and asymmetry of the face has been noticed since the first descriptions of clinical features of choanal atresia considered the result of "the same fetal condition that produces the choanal deformity" [1].

The facial anomalies were classified as follows: (1) anomalies of frontonasal process derivatives, (2) ear anomalies, and (3) asymmetric anomalies of branchial arches derivatives. Anomalies of frontonasal process derivatives included defects with a deficiency of ethmoid bone (flat nasal bridge, epicanthal folds, broad nasal bridge, and antiverted nares) or of other structures embryologically related to the frontonasal process (hypoplastic philtrum and/or upper lip, anomalies of maxillary incisors) (Fig. 10.2). Anomalies of the ears included one ear smaller than the ether, lop ears, deafness, structural anomalies of the pinna, low set ears, and preauricular tags or pits. Asymmetric anomalies of branchial arch derivatives included facial asymmetry (Fig. 10.3), unilateral facial paresis, and other unilateral facial dysmorphisms.

Overall, more than 90 % of infants with either CA or EA had one or more facial anomalies. About two-thirds of infants with choanal atresia and about one-third of infants with EA showed anomalies related to frontonasal process deriva-

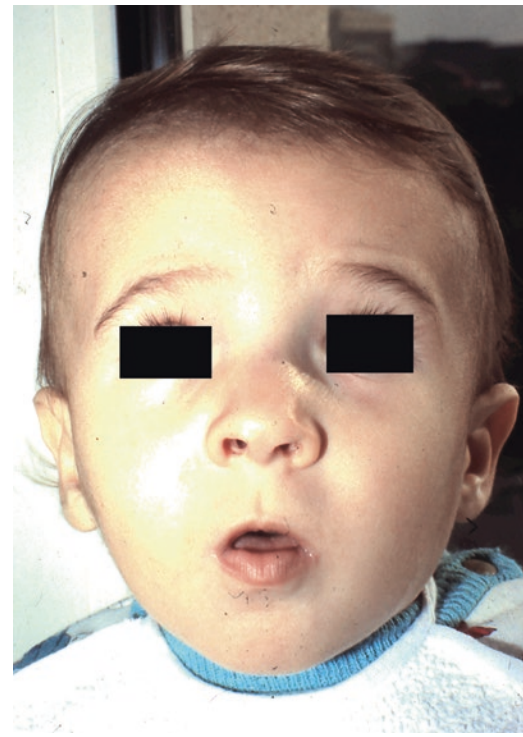

Fig. 10.2 Broad nasal bridge, hypoplastic nasal philtrum, hypoplastic upper lip, and antiverted nares in an infant with bilateral choanal atresia

tives. More than two-thirds of infants with EA and more than one-third of infants with CA showed asymmetrical facial defects. These two differences between EA and CA were statistically significant ($p=0.01$) [39].

Minor facial anomalies occur in about 40 % of normal infants with no major malformations and about 60 % of infants with major malformation [32]. Therefore, in infants with CA or EA, the overall prevalence of facial anomalies is significantly higher. In addition, the significant higher prevalence of facial anomalies related to branchial arch derivatives suggests that EA should be considered a branchial arch neurocristopathy. The striking pattern of neural crest-related cardiovascular anomalies (aortic arch anomalies, conotruncal defects, and superior vena cava malformation) associated with EA supports the concept that EA may be related to an abnormal contribution from the caudal portion of cephalic neural crest cells, which migrate into the fourth and sixth arches [45].

The main difference between facial anomalies associated is the higher prevalence of frontonasal process defects in infants with CA. This finding supports the concept that CA should be considered a frontonasal process neurocristopathy (ethmoidal syndrome) [31]. Finally, the association between of either CA or EA with a maturational dysautonomia may be explained with the contribution of cephalic neural crest not only to the cervicofacial structure but also to the autonomic nervous system [39].

The clinical implication of our observations is that the prevalence of facial dysmorphisms should alert the suspicion of a subclinical dysautonomia. Many facial anomalies are subtle and may pass unnoticed. However, minor facial anomalies should be evaluated and used as markers of other associated major anomalies as well as of an associated dysautonomia. As maturational dysautonomia may be involved in the pathogenic mechanism of SIDS, further studies should be designed to investigate if facial dysmorphisms may also serve to identify those infants at greater risk of SIDS [43].

Relief of Vacuum-Glossoptosis-Apnea

In clinical practice various methods have been found valid for the prevention of asphyxial death related to recurrent episodes of partial or complete glossoptotic pharyngeal obstruction. In 1923, New reported that, in an infant with a "congenital flaccid tongue and palate" obstructing the pharynx, dyspnea and cyanosis during sleep were relieved by the insertion of a catheter into the pharynx through the mouth [2]. A similar observation was made by Hough in an infant with bilateral choanal atresia. In his view, the passage of a nasogastric tube through the mouth serves to break the seal on inspiration between palate and tongue [6]. Even in infants with "fatal respiratory distress" brought about by a rhinitis, a simple "mouth-tube" relieved the respiratory problems allowing respiration through and around the tube [8]. Similarly, relief of respiratory distress may be obtained by thumb-sucking in infants with micrognathia [4] or CA [20]. Another simple device, invented by the parents of an infant with bilateral choanal atresia, was a nipple with enlarged holes to assure efficient mouth breathing [7].

We observed that even a simple dummy may prevent cyanotic attacks in infants with bilateral choanal atresia (Fig. 10.4). Swift and Emery first observed that infants sucking dummies do not respond to induced nasal obstruction with signs of pharyngeal obstruction because they manage to keep the oral airway open [21]. Based on this observation, in 1979 we speculated that the use of a dummy may prevent some deaths in infants with sudden infant death syndrome (SIDS) [25]. Mitchell et al. tested our hypothesis with a case-control study and found that SIDS victims used a dummy during the last sleep very much less frequently than the infants of the control group [40]. Similar case-control studies were carried out in many countries around the world. A meta-analysis of these studies showed that the use of a dummy significantly reduces the risk of SIDS [49]. Based on these data, the American Academy of Pediatrics of North America recommends offering a dummy to infants at bedtime [48].

Fig. 10.4 Baby with bilateral choanal atresia is able to breathe through the mouth around a pacifier without respiratory distress

The role of glossoptosis-apnea in the pathogenic mechanism of SIDS was apparently disproved by the discovery that prone sleep position increases the risk of SIDS. In infants with Pierre Robin syndrome, prone position is traditionally considered a method to prevent glossoptosis-apnea because the force of gravity tends to bring the tongue forward. However, in infants with Pierre Robin syndrome, to avoid an obstruction of the upper airways in the prone position, the face is turned to one side, or the head is supported in a foam mattress in which a hole has been cut for the patient's face [34, 44]. An alternative method to avoid obstruction of the face and the nose in the prone position is a ventral suspension of the head by a stockinette cap.

International campaigns advocating a supine sleep position have resulted in a reduction of SIDS prevalence by more than 50 % [50]. The most accepted explanation is that prone sleeping position blocks the nose and the mouth and causes asphyxia, which seems to play an important role in many sudden deaths historically attributed to SIDS [51]. Therefore, sleeping in a prone position and the consequent potential upper airway obstruction are currently considered the most important extrinsic risk factors that may trigger SIDS [18].

In addition to the extrinsic factors, current evidence suggests that also intrinsic factors increase the risk for SIDS. Researches on the brain stem of SIDS victims suggest that the most important intrinsic risk factor is a dysfunction of the serotonergic system deputed to the modulation and integration of diverse autonomic functions [18, 52]. The regions of brain stem involved in SIDS victims are those deputed to the regulation of upper airway control, respiration, temperature, and other autonomic functions [18].

These data taken altogether strongly suggest that the old hypothesis that glossoptosis-apnea syndrome provides a model of sudden infant death that may be related to SIDS remains feasible [10, 25, 35, 47].

Acknowledgments We wish to thank Prof A Schiavetti and Dr S Frediani for their help and comments in the preparation of this chapter.

Skeletal Anomalies Associated with Esophageal Atresia

11

Jonathan Nubla Sembrano, Walter H. Truong, Charles Gerald Tan Ledonio, and David Wayne Polly Jr.

Introduction

Associated anomalies, including those of the skeletal system, are commonly present in the setting of esophageal atresia (EA) or tracheoesophageal fistula (TEF). One of the more common scenarios for disruption of the esophagus and trachea is the VACTERL association. VACTERL is a mnemonic that stands for vertebral, anal, cardiac, tracheal, esophageal, renal, and limb anomalies.

The purpose of this chapter is to determine the incidence of musculoskeletal anomalies associated with esophageal atresia/tracheoesophageal atresia, the spectrum of skeletal anomaly involvement (upper limb, lower limb and spine), and the natural history, prognosis, and recommended treatment of these.

Search Strategy

A Pubmed search was performed in October 2009 as follows: First, various permutations and combinations of the term "esophageal atresia" and "tracheoesophageal atresia" were searched and combined (union). There were a total of 3,558 hits (A). Second, a search was conducted using the terms "musculoskeletal anomaly," "musculoskeletal deformity," "skeletal anomaly," "skeletal deformity," "vertebral anomaly," "vertebral deformity," "spinal anomaly," "spinal deformity," "limb anomaly," "limb deformity," and "congenital scoliosis." These searches were then combined (union); there were a total of 48,276 hits (B). Third, the intersection of A and B was obtained using the "AND" function. There were 295 hits (C). Fourth, a search was made on "VATER" and "VACTERL." There were 620 hits (D). Fifth, using the "OR" function, the union of C and D was obtained; there were 772 hits (E). These 772 titles were reviewed to ascertain relevance to the topic of skeletal anomalies; 80 titles were deemed appropriate for review (F). The abstracts of these 80 articles were then reviewed; 58 abstracts were deemed appropriate for review. The full-text articles of these 58 articles were then obtained and individually reviewed (WHT and JNS). Of these 58 articles, 53 were chosen for inclusion to this chapter.

There were 19 retrospective cohort studies of patients with esophageal atresia, tracheoesophageal fistula, or VATER/VACTERL association and looking at the incidence of skeletal anomalies (e.g., limb and spine). There were 25 case reports or small case series ($n<10$) describing rare or previously unreported skeletal anomalies

associated with esophageal atresia. There were seven papers on the incidence of scoliosis or chest wall deformity as a consequence of thoracotomy for esophageal repair. There were two animal (rat) studies, one of which also had a clinical series described in the same paper. The other described a method for producing VACTERL-type malformations in rats by injecting Adriamycin during gestation [1]. Finally, one case control family study looked at the risk of associated anomalies in relatives of patients with esophageal atresia [2].

Occurrence of Skeletal Anomalies with Esophageal Atresia

Reported rates of musculoskeletal anomalies in patients with esophageal atresia range from 1.6 to 55 % [3–9] (Table 11.1).

The incidence of skeletal anomalies seems to rise when other atresias are also present. A 1976 paper by Gruchalski reported a 13.2 % incidence of skeletal involvement with esophageal atresia; this rose to 28.8 % and 40 % when there are anorectal atresia and anorectal + duodenal atresia, respectively [32].

In a retrospective comparative study, van Heurn et al. compared the incidence of skeletal involvement with EA between Asians and Europeans. They found no difference in rates (Asian 17 % vs. European 21 %) [8].

In a case control family study, Brown et al. found that associated skeletal malformations within the VACTERL association occur more frequently in relatives of individual with EA/TEF [2].

In an animal study by Abu-Hijleii et al., the researchers were able to produce skeletal anomalies in rat fetuses by injecting Adriamycin during the early gestational period. The authors theorized that vascular disruption of the mesoderm led to malformations and that the presence of the avascular mesenchymal interzone allowed for normal synovial joint development.

Limb Anomalies

The incidence of limb anomalies for the most part is not clearly delineated from that of general skeletal involvement in most published studies. In those that separated limb from spinal involvement, the incidence of limb anomalies in EA or VACTERL ranged from 8.9 to 42.7 % [9, 33, 34]. The most common form of limb anomaly is preaxial (radial) defect or deficiency, with an incidence of up to 35 % in VACTERL patients [33]. In a study utilizing pooled data from 11 birth defect registries, Rosano et al. found that the odds of having a preaxial defect is 4.3 times higher in those with esophageal atresia than those without [35].

Fernbach and Glass specifically looked at limb anomalies other than preaxial abnormality in 24 VATER patients. They described an expanded spectrum of limb anomalies, including Sprengel deformity, humerus hypoplasia, radioulnar synostosis, midline hand anomaly, clinodactyly, and syndactyly [36].

Lower extremity involvement includes tibial field defect, hip dysplasia, clubfoot, and other foot deformities [7, 11, 20, 21, 33, 34, 36, 37]. In a literature review by Castori et al., they found that among 24 VACTERL patients with lower extremity malformation, the most common type was that of tibial field defect (hypo-/aplasia) [11].

Spine Anomalies

Reported incidence of spinal anomalies in EA ranges from 6.9 % to 75 % [5, 9, 32, 34, 38–41]. These include vertebral hyper- or hyposegmentation, abnormal number of ribs, hemivertebra and wedge or butterfly vertebra, unsegmented bar, and congenital rib fusion (Fig. 11.1a–c).

Incidence of spinal anomalies in patients with the VATER/VACTERL association is much higher, with reported rates ranging from 66.4 to 100 % [33, 37, 42].

The occurrence of tethered spinal cord (TSC) appears to be higher when esophageal atresia is associated with an imperforate anus or any urogenital anomaly [43].

Mortality

Lower birth weight has been reported to be associated with higher incidence of associated anomalies, and the number of systems involved correlates directly with mortality. Isolated esophageal atresia had 0 % mortality; one other system involved had 3.2 % mortality, and two or more systems involved had 40 % mortality.

On the other hand, Keckler et al. in 2007 reviewed 112 EA cases and found that 63 % have associated VACTERL anomalies. They, however, concluded that although VACTERL anomalies are common, these have little impact on overall survival, which was 92.9 %.

Mortality also, however, is influenced by the time period of study, as technological advances in medical care allow for better survival. Okada et al. compared survival rates of EA patients among three time periods (1957–1967 vs. 1968–1980 vs. 1981–1995) and found improving survival: 27.8 % vs. 51.7 % and 80.4 %.

In a comparison of mortality rates between those with spinal involvement and those without, Bond-Taylor did not find significant difference

(with spine involvement 33 % vs. without spine involvement 24 %).

Atypical Presentations and Associations

Case reports of unusual presentations involving EA/TEF and skeletal malformation include reports of VACTERL with prune-belly syndrome [10], upper limb amelia [12], progressive torticollis [13], hydrocephalus (aka VACTERL-H) [17, 19], cleft hand [18], congenital absence of the long head of the biceps brachii [22], spondyloarthropathy-like presentation [23], bilateral tibial aplasia [24], partial hemihypoplasia [25], laryngeal stenosis [27], vertebral hypersegmentation [28], congenital absence of scaphoid [29], spinal dysraphism and tethered spinal cord [30], and CNS malformation requiring surgical intervention [31].

Other conditions or syndromes (non-VACTERL) that have also been reported to present with EA/TEF and skeletal anomalies include TAR (thrombocytopenia + absent radii) syndrome [14], Feingold (oculo-digito-esophago-duodenal or ODED) syndrome [15, 44], Gollop-Wolfgang complex (unilateral bifid femur with ectrodactyly) [16], sirenomelia [45], and tracheal agenesis [26].

Scoliosis Associated with Thoracotomy

The reported incidence of scoliosis after thoracotomy for esophageal atresia repair ranges from 19 % to 50 % [46–48]. Other sequelae described

include chest wall deformity, rib fusion with or without scoliosis, and breast disfigurement [44, 49] (Table 11.2).

Gilsanz et al. showed that the incidence of post-thoracotomy scoliosis is much higher among patients who develop dehiscence of their esophageal anastomosis than those who did not (57% vs. 0%) [51]. It was postulated by the authors that the mechanism of scoliosis development involved pleural scarring and rib fusion caused by disruption of the esophageal repair and subsequent leakage of contents.

Scoliosis after thoracotomy may either be concave or convex toward the side of approach. In the series of Westfelt and Nordwall, 75% (15/20) of cases were convex to the side of skin incision [48]. The authors hypothesize that pleural scarring on the side of approach causes concave scoliosis, whereas disruption of the costotransverse joints and intercostal and paraspinal muscles causes convex scoliosis.

Because of the high incidence of post-thoracotomy scoliosis, it is recommended that patients who undergo esophageal atresia repair through a thoracotomy approach be followed until skeletal maturity with regular scoliosis screening [50, 52]. In addition, Jaureguizar et al. concluded that alternative approaches to performing esophageal repair should be considered, in order to minimize the long-term sequelae associated with thoracotomy [44].

Treatment

Treatment of skeletal anomalies in the setting of EA/TEF requires a thorough assessment and good understanding of associated anomalies and overall prognosis. As a general rule, skeletal deformities are not as life-threatening as involvement of other organs; thus, treatment may be delayed until other conditions have been worked up and addressed. Once it has been established that the life expectancy and overall prognosis in regard to the nonskeletal anomalies are good, then the principles of treatment of the skeletal anomalies are the same as those in isolated cases (i.e., those not associated with EA/TEF) (Table 11.3).

Limb Anomalies

The goals in the treatment of limb anomalies mainly are preservation/optimization of function and cosmesis. For the upper extremity, motion, proprioception, and the ability to grasp are very important in achieving good function. For the lower extremities, equalization of leg lengths and correction of foot deformity to allow a plantigrade (foot flat on ground) stance are desirable goals, particularly in patients who are or are expected to be ambulatory.

Modalities used in treatment of limb deformities include surgery either in the form of amputation or reconstruction of the deformity; the use of casts, splints, prostheses, orthoses, and/or walking aids (crutches, walker, or wheelchair); physical and occupational therapies; and constant reevaluation.

Because limb deformities do change with growth, it is recommended that patients be followed until skeletal maturity.

Spine Anomalies

Scoliosis associated with EA/TEF may either be congenital or iatrogenic (post-thoracotomy). In either case, the focus of treatment in early-onset scoliosis (onset before 7 years old) is to allow growth of the chest cavity and maximize lung development.

Once a deformity is detected, patients should be evaluated regularly for progression of the deformity. In majority of cases, the scoliosis does not progress to the point of requiring fusion surgery. And in general, fusion is best delayed as reasonably possible, in order to allow as much growth of the spine as possible to occur.

Bracing may be instituted in an effort to halt curve progression. However, this requires careful consideration of patients' associated conditions, as a circumferential brace may be restrict breathing and limit access to the chest and/or abdomen.

Non-fusion surgical options that may find applicability in early-onset scoliosis include growth modulation via hemi-epiphysiodesis, vertebral stapling, and placement of conventional growing rods or a VEPTR (vertical expandable

prosthetic titanium rib) device. All of these are aimed at halting curve correction (with some curve correction) while still allowing spinal growth.

In patients with focal deformity (e.g., a single hemivertebra), short-segment fusion (with or without hemivertebrectomy) is preferable to a long-fusion construct.

Long-Term Results

Because of the very wide spectrum of presentation, as well as the relatively rare occurrence of the condition, there have been no high evidence level studies looking specifically at the effect of treatment of associated skeletal anomalies in patients with tracheoesophageal abnormality on long-term function.

It can be said, however, that long-term functional and cosmetic results of treatment of these skeletal anomalies are mainly dependent on the degree of the initial or underlying malformation, as well as the severity of associated abnormalities related to other organ systems. Patients who have minimal problems or limitations secondary to nonskeletal abnormalities may be expected to have the same functional results with treatment as those with similar but isolated skeletal anomalies.

Table 11.1 Case reports or small case series describing rare or new presentations of skeletal anomalies associated with esophageal atresia

Article	Country, years	N (male, female)	Spine anomalies	UE anomalies	Pelvis/LE anomalies	Misc
Ely et al. [10] Case report	USA (WV) 2008	1 (0, 1) VACTERL with pseudo-prune-belly syndrome	Scoliosis, decreased no. of ribs		Foot polydactyly	
Castori et al. [11] Case report	Italy	1 (1, 0) VACTERL with tibial developmental field defect	Hypoplastic ribs, hemi- and "butterfly" vertebrae	Clubhand (absent radius, thumb, and distal phalanx of the index finger); hypoplasia of the left scapula	Left tibia agenesis, clubfoot, hallucal deficiency, preaxial polydactyly	Lit review: 24 pts LE malformation: 68 % tibial hypoplasia/aplasia, 20 % fibular field defects
Pelluard-Nehme et al. [12] Case report	France	1 (1, 0) VACTERL with unilateral upper limb amelia	Butterfly vertebra, hemivertebrae, fused cervical vertebrae	Upper limb amelia, dysplastic scapula		Medically terminated at 22 wks gestation. Trisomy 18
Al Kaissi et al. [13] Case report	Austria	1 (0, 1) VATER with progressive congenital torticollis	9/f, with progressive torticollis treated with occiput-C1 fusion			Authors postulate that torticollis developed 2′ to congenital fusion between the atlas and occiput
Eren et al. [14] Case report	Turkey	1 (0, 1) TAR syndrome (thrombocytopenia + absent radii) with EA		Bilateral absent radii and thumbs		(+) family hx of consanguinity
Kellermayer et al. [15] Case report	Hungary	1 (1, 0) Feingold (oculo-digito-esophago-duodenal or ODED) syndrome with vertebral defects	Prominent sacral pit, anterosuperior ossification defects at L1, L2	Clinodactyly index and small fingers	Brachydactyly of toes, absent middle phalanges of all toes	
Erickson [16] Case report	USA (AZ)	1 (1, 0) variant of Gollop-Wolfgang complex (unilat bifid femur with ectrodactyly)			Bilateral clubfeet, right bifurcated femur, absent right tibia, absent left hallux	
Herman and Siegel (2004) Case report	USA (MO)	1 Feingold syndrome or MMT (microcephaly, mesobrachyphalangy, tracheoesophageal fistula)		Shortening of the index and small middle phalanges	Shortening of all middle phalanges	
Vatansever et al. [17] Case report	Turkey	1 (0, 1) VACTERL-H (VACTERL + hydrocephalus)	Fused L4–5	Right triphalangeal thumb		

(continued)

Table 11.1 (continued)

Endoh et al. [18] Case report	Japan	1 VACTERL with cleft hand	13 pairs of ribs, lumbosacral fusion abnormalities	Right cleft hand: preaxial syndactyly; absent middle and distal phalanges, short prox. phalanx of long finger		
Balci et al. [19] Case report	Turkey	1 (1, 0) VACTERL-H (VACTERL + hydrocephalus)	Multiple hemivertebrae	Bilateral triphalangeal thumbs		
Spoon [20] Case report	USA (MO)	1 (1, 0) VATER case study	Sacral fusion anomaly, 13 pairs of ribs	Bilateral shortened forearms, left radial clubhand, with 2 digits	Bilateral posterior hip subluxations	
Spruijt et al. [21] Case reports ($n=2$)	Belgium, Netherlands	2 (2, 0) VACTERL with tibial aplasia		#1 – Left radial ray defect and brachydactyly; right index-long cutaneous syndactyly, small finger clinodactyly	#1 – Absent left fibula, aplastic tibia #2 – Absent right tibia, cutaneous syndactyly of the left toes 2–3, 4–5	
Smith et al. [22] Case report	USA (HI)	1 (1, 0) VATER with absence of long head of biceps brachii	Tethered cord	Right rudimentary duplicate thumb, absent long head of biceps, hypoplastic superior labrum		
Erkan et al. [23] Case report	USA (NY)	1 (1, 0) VATER mimicking spondyloarthopathy	Fusion L1–L5, block vertebrae, butterfly T11			
Sozubir et al. 2000 Case report	Turkey	1 (0, 1) EA with sirenomelia	Caudal regression, vertebral anomalies		Sirenomelia (mermaid syndrome) – fused soft tissue of the lower extremities, normal bony hips, femurs, tib/fibs, feet	VATER may be a less severe form of sirenomelia, which is not compatible with life

Article	Country, years	N (male, female)	Spine anomalies	UE anomalies	Pelvis/LE anomalies	Misc
Basel and Goldblatt [24] Case report	South Africa	1 (1, 0) VACTERL with bilateral tibial aplasia	11 rib pairs, T6 hemivertebra	Right rudimentary (triphalangeal) thumb, absent 1st metacarpal, camptodactyly of the index finger, single palmar crease	Bilateral absent tibia, bilateral dislocated talus, absent great toes	
Chen et al. [25] Case report	Taiwan	1 (1, 0) VACTERL with partial hemihypoplasia	Right rib hypoplasia, scoliosis, multiple vertebral segmentation defects cervical and thoracic	Right hemihypoplasia: hypoplastic pectoralis, absent humerus and radius, short ulna, 3 metacarpals, 2 fingers		
Evans et al. [26] Case series ($n=5$)	Canada, Hungary	5 (3, 1, 1 NS) tracheal agenesis (TA); analysis of 100 cases pooled from literature	Vertebral anomalies 14 %	Radial ray defects 11 %	Lower limb deficiencies 3 %	Skeletal anomalies 38.1 %
Corsello et al. [27] Case series ($n=9$)	Italy	9 VATER/VACTERL	5 hemivertebrae; 1 additional congenital scoliosis	2 radial aplasias, 2 thumb hypo-/aplasias, 2 thumb duplication		Prefer VACTERL to VATER; "L" may refer to either the limb or larynx (1/9 had laryngeal stenosis)
Wulfsberg et al. [28] Case report	USA (MD) 1991	1 (1, 0) VATER with vertebral hypersegmentation	Hypersegmented vertebrae: 13 thoracic, 13 pairs of ribs, 7 lumbar		Bilateral hip dislocation, dorsiflexed feet	Propose that some malformations are 2′ to excessive flexion 2′ to vertebral hypersegmentation

(continued)

Table 11.1 (continued)

Treble [29] Case report	England	1 (0, 1) VATER with congenital absence of scaphoid	6 lumbar vertebrae, sacral agenesis	Absent scaphoid and radial styloid; hypoplastic 1st metacarpal and trapezium		
Chestnut et al. [30] Case series ($n=6$)	USA (CA) 1992	6 (1, 3, 2 NS) VATER with spinal dysraphism and tethered spinal cord (TSC)	#1: hemivertebra T9 to the sacrum; TSC 2′ to lipoma #2: vertebral defects; TSC 2′ to thickened filum with adipose tissue #3: vertebral defects; TSC 2′ to lipoma #4: hemivertebrae, TSC 2′ to lipoma #5: vertebral defects, TSC 2′ to lipoma #6: TSC 2′ to lipoma	#5: radial anomalies	#1: mild bilateral cavus feet #2: R foot deformity	Spinal dysraphism may have increased incidence in VATER Can diagnose TSC lipoma with ultrasound if less than 10–12 months of age
Raffel et al. [31] Case series ($n=4$)	USA (CA)	4 (3, 1) VATER with CNS malformation requiring neurosurgical intervention	#1: Severe kyphosis, segmental agenesis of the spinal cord at the level of T12 #2: L2–3 hemivert #3: T12-L1 hemivert, L3 spina bifida #4: severe cervical kyphosis with stenosis at 2 years old; quadriparesis at 3 years old after a fall	#3: bilateral radial agenesis, bilateral abducted thumbs	#1: R club foot #3: bilateral club feet	Suggest that all VATER patients be evaluated for neurosurgical malformations

Table 11.2 Articles describing development of scoliosis/chest wall defects after thoracotomy for repair of esophageal atresia

Article	Country, years	N (male, female)	Spine anomalies	UE anomalies	Pelvis/LE anomalies	Misc
Wong-Chung et al. [50] Case report	USA (NY)	1 (0, 1) scoliosis 2′ to rib fusion after thoracotomy for EA repair during infancy	9/F with scoliosis (47°, concave toward thoracotomy); 6th–10th rib fusion; treated with rib fusion mass resection			Patients who had thoracotomy for EA repair should be followed up to skeletal maturity for scoliosis screening
Westfelt and Nordwall [48] Retrospective cohort	Sweden 1972–1978, f/u in 1988	61 (33, 28) EA patients who underwent lateral thoracotomy for EA repair in childhood Looked at the development of scoliosis Mean age at thoracotomy 7 years, mean age at f/u 20 years	20/61 (33 %) developed scoliosis (24 % in boys, 43 % in girls) 15/20 convex to the side of incision Only two >20 deg curve; none underwent surgery for scoliosis			Hypotheses Pleural scarring causes curve concave to incision Disruption of costotransverse joints and muscles cause curve convex to incision
Chetcuti et al. [46] Retrospective cohort	Australia 1948–1985, f/u 1986–1987.	302/538 EA/TEF patients were interviewed/examined for long-term follow-up for the development of spinal deformity	58/302 (19 %) developed spinal deformity 51/302 (17 %) had congenital vertebral anomaly, but only 47 % developed clinical deformity 34/251 (14 %) without anomaly developed scoliosis			Scoliosis associated with mixed vertebral anomalies in lower thoracic spine had worst prognosis in terms of curve progression. Recommend careful follow-up of patients with vertebral anomalies

(continued)

Table 11.2 (continued)

Chetcuti et al. [46] Retrospective cohort	Australia	285 EA/TEF patients who had thoracotomy for repair and with long-term follow-up for the development of chest wall deformity (CWD)	99/285 (35%) developed CWD 22/53 (41%) of those with congenital vertebral anomaly developed CWD 77/232 (33%) of those w/o congenital vertebral anomaly developed CWD, and 20/232 (13%) developed scoliosis 2/3 of scoliosis were concave toward the side of incision			Anterior chest wall deformity more common in patients > 25 years old Breast surgery to minimize inequality was required in three patients
Gilsanz et al. [51] Retrospective cohort	USA (CA) 1966–1980	82 thoracotomy for EA, w/o vertebral malformation Looked at the development of scoliosis, follow-up 2–17 years	8/14 who had dehiscence of esophageal anastomosis developed scoliosis ≥20°, concave toward incision 0/54 w/o dehiscence developed scoliosis			Scoliosis after EA repair seen only in those with disruption of surgical anastomosis, leading to subsequent pleural scarring and rib fusion
Durning et al. [47] Retrospective cohort	USA (OH) 1960–1970	18 (8, 10) thoracotomy for EA/TEF Looked at the development of scoliosis, follow-up ≥10 years	9/18 developed scoliosis 8/9 concave toward incision 5/9 >20°. 2/9 >40°, 1 underwent spinal fusion			Curves that develop before puberty are more likely to progress. Early childhood thoracotomy needs careful observation for scoliosis development
Jaureguizar et al. [44] Retrospective cohort	Spain 1965–1981	89 thoracotomy for TEF with long-term follow-up (3–16 years) Looked at the sequela of thoracotomy	18 (20%) thoracic wall asymmetry 9 (10%) rib fusion 7 (7.8%) severe thoracic scoliosis 3 (3.3%) breast disfigurement	21 (23.8%) "winged" scapula 2 (2.2%) shoulder LOM 2′ to cicatrix		Dorsolateral thoracotomy may lead to significant musculoskeletal complications, should consider alternative approach
Dunlay et al. [52] Case report	USA (IA)	1 (0, 1) scoliosis 2′ to rib fusion s/p thoracotomy for TEF	22/f, 50° left convex T1–T8 curve. Fused right ribs 3–4, 4–5			Treated with PSF T2–L1. Recommend scoliosis screening post-thoracotomy

Table 11.3 Retrospective cohort studies of patients with EA/TEF/VATER/VACTERL looking at the incidence of skeletal/limb/spinal anomalies

Article	Country, years	N (male, female)	Spine anomalies	UE anomalies	Pelvis/LE anomalies	Misc
Eghbalian et al. [3] Retrospective cohort	Iran, 2002–2008	63 (25, 38) EA. Looked at associated anomalies		1 absent radius		1/63 (1/6 %) skeletal involvement
De Jong et al. [42] Retrospective cohort	Netherlands 1988–2006	90 (58, 32) with ≥2 VACTERL defects, normal karyotype Looked at non-VACTERL-type anomalies	62 (68.9 %) vertebrae/ribs: 50 vertebrae, 37 ribs	29 (32.2 %): 16 radial, 18 thumbs, 6 preaxial polydactyly		70 % had non-VACTERL anomalies, e.g., single umbilical artery (20 %), genital defects (23 %)
Kuo et al. [43] Prospective observational	Taiwan 2001–2004	9 (4, 5) VACTERL w/ imperforate anus Looked at tethered spinal cord (TSC)	7/9 had TSC; 6/7 of those with urogenital anomalies had TSC			Recommend MRI for all VACTERL w/ imperforate anus or urogenital anomaly
Keckler et al. [34] Retrospective cohort	USA (MO) 1985–2005	112 (62, 50) esophageal atresia Looked at VACTERL anomalies	24.1 % vertebral anomalies (4.4 % tethered cord, 3.5 % butterfly vertebra, 4.4 % fused vertebra, 4.4 % hemivertebra, 1.8 % additional vertebra, 5.3 % additional or absent ribs)	8.9 % upper limb anomalies (3.5 % absent radius, 6.2 % digital anomaly) If (+) vertebral anomaly, 28.6 % chance of limb abnormality	0.8 % hip dysplasia	Only 37 % have isolated TEF VACTERL anomalies common but have little impact on overall survival (92.9 %)
van Heurn et al. (2001) Retrospective comparative study	China, Netherlands 1982–1998	European 34 (20, 14); Asian 48 (25, 23) EA Looked at associated anomalies	Asian – 1 vertebral European – 6 vertebral	Asian vs European: polydactyly 2 vs 2; syndactyly 2 vs 1; other 3 vs 2		Musculoskeltal involvement similar, Asian 17 % vs European 21 %

Part IV

Repair of Shorter Gap EA

History of the Treatment of Esophageal Atresia

12

John E. Foker

Introduction

The story of esophageal atresia (EA) is as fascinating and varied as the lesions themselves. EA comprises a wide spectrum of defects, ranging from an absent or atretic segment commonly referred to as pure EA through lesions which have one or more associated tracheoesophageal fistulae (TEF) [1]. The first understanding of EA comes early but only much later and after many different surgical attempts to correct these lesions is anything like reasonable success achieved. Most early efforts dealt with the common form of a blind upper esophageal pouch and lower tracheoesophageal fistula (about 80–85 % of the total) but the other types also contribute to the story [2]. The history can only be recounted from what has been published; nevertheless, the thinking about and struggling with these babies and even the poignancy of repeated failures come through clearly.

Pre-repair History

The first accurate portrayal of both the clinical and anatomic features of an infant with esophageal atresia and tracheoesophageal fistula was by Thomas Gibson in 1697 [1]. The infant's greedy attempts at feeding, followed by convulsive choking and later by death, were subsequently explained by the postmortem findings of a blind upper pouch with a distal tracheoesophageal fistula.

Probably because of the futility of attempting to treat the lesion, the story seems to unfold slowly. When traced through the literature, over a century passed without the birth defect again being mentioned. Even well into the 1800s, only a few cases are added to the world's apparent experience. Hirschsprung (1861) described four cases collected over a 7-month period from his then small city of Copenhagen and added these to ten others that had been reported [3]. The scattered reports and presumably by word of mouth led Mackenzie (1880) to suspect that these lesions were not extremely rare [4]. Presumably the lesions were occurring at an incidence of approximately 1 in 2,500–3,500 births, but the result was always the same – death [5–7].

The few case reports in the nineteenth century which both described the clinical and pathological picture indicated there was an appreciation of the lesions themselves. These cases must also have stimulated thinking about a possible repair

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_12

and although success would come much later, it was recognized early that a primary repair of esophageal atresia would be the preferable treatment. In the *Surgical Management of Children's Diseases*, Holmes (1869) suggested that the esophageal ends could be joined together when a fistula was not present [8]. A gastrostomy was the first surgical treatment recorded, however, and was based on the obvious need for hydration and nutrition. It was recognized that a gastrostomy would not solve the entire problem and, in a baby with EA/TEF, could make matters worse. SP Steele (1888) was apparently the first to place a gastrostomy in one of these infants with the hope that only a rupturable membrane existed between the esophageal segments. Unfortunately, that was not the case [9].

The early reports recognizing the defect and the long, heartfelt discussions on the attempts at treatment have been more extensively recounted by Ashcroft and Holder and, especially, Myers [6, 10]. The reader is directed to these articles to provide a more complete picture of this fascinating journey. It seems certain, however, that the discussions of possible modes of therapy and the recognition of the determinants of success and failure by individuals must have far exceeded those appearing in the literature.

The surgeon who might have moved the treatment of EA/TEF substantially ahead was Richter, who recognized in 1913 both the desirability and impracticality then of a primary repair [11]. He also knew that gastrostomy alone would fail and so used positive pressure anesthesia, probably for the first time in an infant, to ligate the fistula intrathoracically. Unfortunately, the patient did not live long enough to address the problem of the blind upper pouch. Richter accurately described the problems one encounters when trying to surgically control the fistula and might have succeeded had he operated on additional infants. His approach would prove useful decades later as the staged repair in unusually premature or sick infants [12].

Both gastrostomy placement and fistula ligation were considered necessary after Richter's report, but Smith noted that gastrostomy alone was still being tried repeatedly without success [11, 13]. Vogt, for example, described six cases, five of which were treated and were unsuccessful [14]. Even jejunostomy would not solve the problem because gastric secretions stimulated by feeding could still enter the trachea. Because the ligation of the TEF could not be carried out with hope of success, it proved an insurmountable problem for nearly two more decades.

Even as the era of survival approached, recognition of EA was one thing and effective treatment was quite another. Gage and Ochsner (1936) reported being unsuccessful in treating six infants over 15 months [15]. At that time, the consequences of the EA/TEF spectrum were so damaging to the infant that a reliably successful repair would depend more on the development of better methods of caring for the critically ill infant and less on new surgical techniques.

The early accounts of the surgical attempts to treat the EA spectrum graphically revealed what would be the necessary components of success. Effective treatment would require control of the upper pouch to prevent aspiration and ligation, or division, of the fistula to eliminate reflux into the trachea. Both of these consequences had predictably led to fatal pneumonias in the pre-antibiotic era. Control of the TEF, however, made it necessary to be able to adequately ventilate the infant when the chest was open. If aspiration and reflux could be controlled, gastrostomies were available and quickly became important for hydration and nutrition to allow survival of more than a day or two. Much had to be in place before the technical details of a primary esophageal repair came into play.

The initial survivors were isolated and relatively unusual cases of the spectrum which did little to advance the treatment of infants with EA or affect the struggle for reliable treatment. Their survival was almost fortuitous as they made it through the potential early problems so that repair could come much later. The first survivor was born in 1931 with a TEF and no EA, but did not undergo repair until 1935 [16]. Repair was done through a transtracheal incision, and a residual fistula was closed a short time later. The first survivor of pure esophageal atresia was born in 1936 and maintained with gastrostomy

feedings until reconstruction was carried out much later by a jejunal interposition [17]. These two anomalies were at the opposite ends of the spectrum. More importantly, they were single problems with a favorable situation, and the repair could be begun later without a thoracotomy incision.

The far more common combination of a blind upper pouch and a lower TEF located in the midthorax proved much more difficult to treat. The accounts of Lanman and Haight were particularly poignant [18, 19]. Deaths following these operations were commonly due to pneumonia or mediastinitis, and effective antibiotics were unavailable. Even fluid management was poorly understood, and the infant who might have become the first survivor of a primary repair apparently died from overhydration produced by excessive continuous intravenous fluids. Lethal dehydration, however, was equally likely to occur in the preoperative period [20].

Although the early surgical attempts to treat EA with a TEF showed an understanding of the necessary components of a reliable repair, the methods tried varied widely and generally failed to solve the problems. The 32-patient series recounted by Lanman described the varied surgical approaches taken by a number of famous surgeons to solve the problems of EA/TEF [18]. Either right or left posterior incisions were made with wide extrapleural approaches to avoid entering the pleura because of the uncertainties of positive pressure ventilation. After dividing the musculature, four to six ribs were sectioned and the center two removed to provide generous access. Attempts to deal with the proximal and distal esophageal ends were hindered by poor airway control or the problems imposed by the need for positive pressure ventilation if the pleural space was entered. Several surgeons divided the fistula and brought the distal end out the back, which controlled the reflux and provided a site for feedings, but the ends tended to slough and retract, and mediastinitis raged [18].

Because an abdominal incision might be better tolerated, the fistula was ligated near the stomach and a gastrostomy placed, but spillover of the lower esophageal secretions into the trachea still occurred. This concept was carried further by dividing the stomach with the proximal end brought out to drain the lower esophagus and a gastrostomy placed in the distal half. Spillage into the trachea, however, still occurred and the ventilatory capacity suffered with large fistulae [21]. Division of the lower esophageal segment, with the upper end oversewn and the distal end brought out to serve as a feeding gastrostomy, fared no better [22].

All attempts at treatment of esophageal atresia prior to the late 1930s were unsuccessful. Preoperative preparation was ineffective, and the infants usually went to surgery in critical condition. Rehydration, treatment of existing pneumonias, and control of the upper pouch were not satisfactory. The condition prior to surgery could not readily be reversed, and the operation did not halt the deterioration.

Even when the first survivals occurred, whether following staged procedure or a primary repair, the reasons for success were not apparent, and the case descriptions were similar to previous discussions of failure. Success came twice, 1 day apart, in 1939. Leven at the University of Minnesota and Ladd at the Children's Hospital of Boston placed gastrostomies in two infants with esophageal atresia and tracheoesophageal fistula [23, 24]. Despite the presence of a fistula, small feedings in these two instances did not prove fatal, and the fistulae were not ligated until 5 weeks and 4 months later, respectively. Cervical esophagostomies were performed much later, and more years elapsed before Leven provided continuity with a jejunal interposition and Ladd completed construction of an antethoracic skin tube [24, 25]. Although the firsts, both patients had survived having a TEF for many weeks and did not resemble the usual circumstances.

The First Primary Repairs

The first successful primary repair, by Haight in 1941, broke another long spell of failures [26]. A primary repair had been attempted but without survival at least 11 times by several surgeons beginning as far back as 1923, including twice by

Haight himself and twice by Alexander at their institution [27, 28]. This was clearly a milestone but the reason for success this time was not apparent. The successful anastomosis was begun under local anesthesia, but the esophageal ends could not be brought together without quieting the infant by open drop ether anesthesia. The primary repair was accomplished, but survival in this case occurred despite such overhydration as to produce sclerema. In addition, there was an anastomotic leak with presumed mediastinitis, and the patient was not discharged from the hospital until she was 20 months of age. Nevertheless, this breakthrough broke the spell; success began to come more frequently, and by 1944, a third of these infants survived primary repair [29].

Over the next two decades, the advances which occurred rapidly on all fronts – preoperative preparation, antibiotic therapy, and intraoperative and postoperative management – allowed primary repair in favorable circumstances to become reliably successful. As has often been the story when new surgical fields have been opened, the operative capabilities were present before overall care was sufficient to help the patient withstand the stresses of the operation. During the late 1940s, the reliability of primary repair improved, and in one series, remarkable for the time, short-term survival was 80% [30]. Nevertheless, results in the 1940s and 1950s varied widely as centers struggled to improve care and surgeons wrestled with operative details [31]. Not all EA/TEF patients were in the same condition for an operation, and the classification of Waterston proved valuable in where to direct efforts [32].

Further Refinements and Continuing Issues

The emergence of antibiotic therapy was perhaps the single most important reason for the new success, but almost as significant were the rapid advances in anesthesiology, postoperative management, and the emergence of newborn intensive care units. During this period, there was also a great deal of surgical innovation. Anastomotic leaks were a serious problem from the first cases on, and a variety of techniques were tried to avoid them. Although the first successful primary repair was made with a single-layer anastomosis, the common problem of leaks led to two-layer repairs. After the inner row of muscular sutures was placed, the muscular wall of the upper pouch was pulled down over the first layer and anchored lower down on the esophagus to cover the anastomotic line [17, 19]. These two-layer techniques provided more security against leak, but the trade-off was a greater tendency to stricture formation from the turn-in of the tissue. As is well recognized, the problem of anastomotic leak has only been reduced in incidence and not entirely eliminated. Anastomotic strictures and gastroesophageal reflux also remain problems. Because strictures and GER remain significant, they are taken up in much more detail in separate chapters within this book.

The commonness of postoperative strictures and the persisting dysmotility of the lower segment found after primary repair led to the development of an end-to-side anastomotic technique [5, 33, 34]. The rationale was that limiting the dissection of the lower esophagus to just beyond the fistula might better preserve the blood supply and the vagus nerve and, with them, esophageal function. A large opening could be made in the lower esophagus which did reduce stricture formation, but leaks remained a problem. Unfortunately, recurrent fistulization occurred too frequently even if the mucosa was stripped from the fistula before tying. Dilation of a stricture after this repair ran the additional risk of reopening the fistula. Dysmotility, moreover, was similar to other repairs because the contraction wave passes through the muscular layer and is interrupted with any anastomosis. With exceptions, this operative approach is not generally used [35].

Primary repair is made most difficult by a long gap between esophageal segments, and even today this remains an important surgical problem. Early on, it was recognized that the consequence of a gap between the ends meant anastomotic tension. Several strategies were proposed to reduce the tension that would jeopardize

a primary anastomosis. Suture techniques to lessen tension varied from placement of elaborate mattress sutures that overlapped the anastomosis to the use of traction sutures anchored in the paravertebral tissue [24, 29, 36]. Other methods, such as upward traction on a catheter anchored at the stomach entrance, were tried in order to reduce tension [37]. These and related techniques have never become popular because of the problems they produced or the limited applicability. The problem of long-gap atresia was reliably first solved by interposition grafts; however, as will be discussed in other chapters, they bring their own consequences. More recently, a variety of techniques including the use of circular myotomy have been used and increased the incidence of primary repair when the gap is not overly long [38]. Despite these many efforts, the problem of long-gap EA remains today and is the subject of other chapters in this book under: The Repair of Long-Gap EA; The Growth Procedure for Long-Gap EA, and Interposition Procedures to Establish Continuity.

All these operative variations reflected the increasing emphasis placed on technique as surgeons attempted to solve the variety of problems encountered in the esophageal atresia spectrum. The discouragement of failure after failure was left behind, and the emphasis shifted to refining the techniques and care so that smaller and sicker infants could be included in this success. Primary repair of esophageal atresia became the epitome of pediatric surgery, which it remains to this day. It is frequently the pediatric surgeon's favorite operation and programs are often judged by the yearly number of EA/TEF cases [6, 39].

Preoperative Evaluation

13

H. Till

The detection of a polyhydramnion during a prenatal ultrasound investigation raises the suspicion of an EA/TEF. Also a paucity of fluid in the upper oesophageal portion or the failure to detect a gastric bubble could point towards an impaired gastrointestinal passage in the fetus [1]. However, neither of these parameters nor their combination has a significant predictive value [2]. On the other hand, these findings are of major clinical importance, because those children should be delivered in centres with considerable experience in treating children with EA/TEF.

Most infants with EA/TEF become symptomatic soon after birth with excessive salivation (drooling), choking or coughing. In newborns with type C EA, the gastrointestinal tract may be continuously insufflated via the lower TEF. Thus abdominal distension and impaired diaphragmatic movements contribute to an increasing respiratory insufficiency. Such neonates should be kept "nothing per os" (NPO) and investigated immediately by passing a 12-French nasogastric tube gently into the oesophagus. If there is any resistance and if it fails to reach the stomach, an EA must be ruled out. The 12-French tube could be exchanged for a Replogle suction tube, and further studies are initiated to confirm and classify the malformation.

A regular X-ray film of the chest including the neck and upper quadrants of the abdomen usually reveals most of the important features of any EA, which are (a) the type of atresia, (b) the gap between the oesophageal remnants and (c) the presence of anatomical or genetic malformations.

The presence versus absence of gas below the diaphragm determines the classification: If the abdomen is filled with gas, a lower TEF (type C) must be present (Fig. 13.1), and vice versa if the abdomen is gasless, a pure EA (type A) must be anticipated (Fig. 13.2). Assuming that a pure EA is most likely associated with a considerable gap between the oesophageal remnants, most paediatric surgeons would refrain from a primary repair immediately after birth and place a gastrostomy instead, for early enteral feeding and later evaluation of the lower pouch (see below).

In children with type C, the distance between the upper pouch and the TEF is assessed primarily, because the surgical management depends on the length of the gap. That is what this textbook is all about!

Before taking a chest X-ray, a nasogastric tube is advanced maximally into the upper pouch and thus marks its deepest point (Fig. 13.1). A contrast medium may be used only in unclear situations and with extreme care, because the pouch easily fills with just a few millilitres, and laryngeal

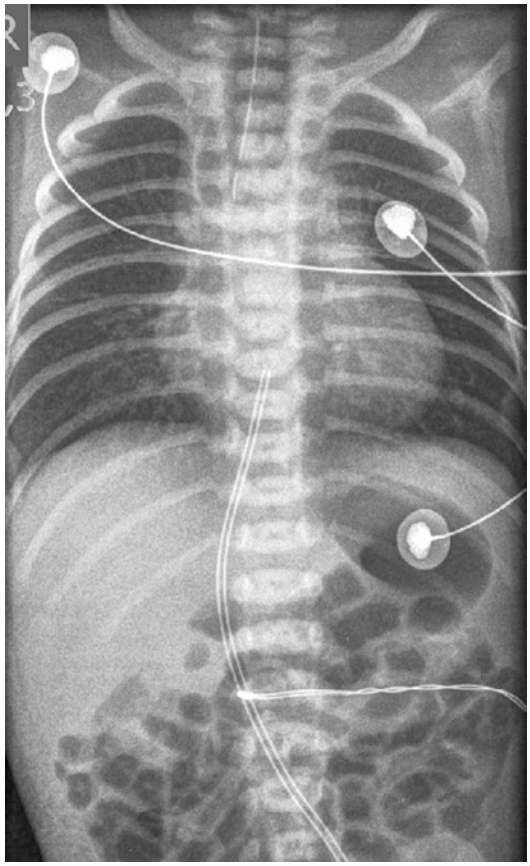

Fig. 13.1 X-ray of a newborn baby with an EA/TEF (type C). The tip of the Replogle tube marks the lowest point of the upper pouch. The TEF allows for gas passing into the gastrointestinal tract

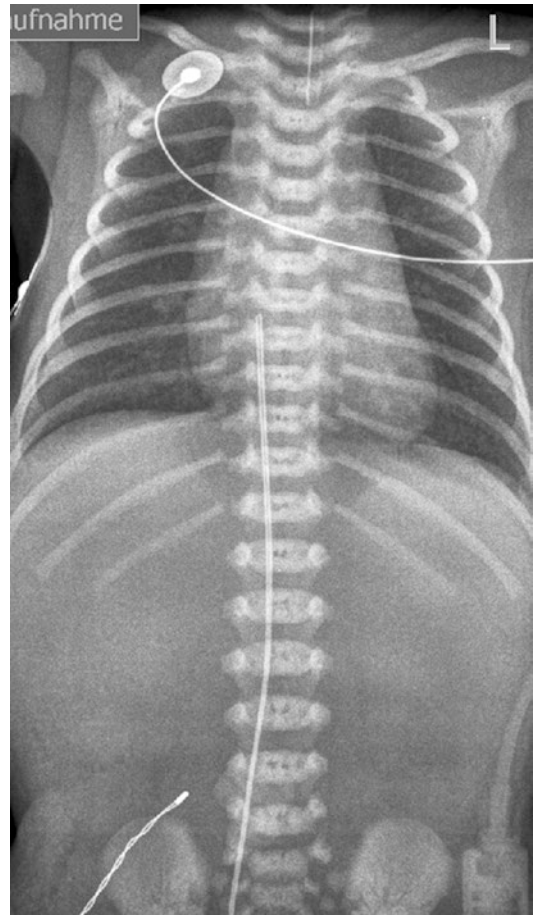

Fig. 13.2 X-ray of a newborn baby with a pure EA (type A). The tip of the Replogle tube marks the lowest point of the upper pouch at approximately the level of the clavicles. No gas is passing into the gastrointestinal tract

overspill could cause aspiration and pneumonia. However, when an upper TEF must be ruled out, this investigation is useful. Recently, K. Bax investigated his children with pure EA and found an incidence of a proximal fistula of more than 50 % [3]. Alternatively, such anatomical questions can also be answered during a preoperative tracheobronchoscopy. Even rare forms of trachea-bronchial malformations, such as laryngotracheal clefts, must be kept in mind.

Concerning the lower oesophageal remnant, a plain chest X-ray is only sufficient in the presence of a TEF. Usually, the TEF originates from the membranous portion of the trachea close to the bifurcation. Thus the gap between both oesophageal remnants can be estimated by measuring the distance between the lowest point of the upper pouch and the bifurcation of the trachea [4]. Per definition, we consider a distance of more than 3 cm or three vertebral bodies as long-gap oesophageal atresia (LGEA).

In cases of pure EA, the distal oesophageal remnant can be easily assessed once the gastrostomy has healed. Retrograde filling of the stomach with contrast medium and simultaneous fluoroscopy outline the endoluminal anatomy (Fig. 13.3). However, this investigation may be false negative, if there is no adequate influx into the distal pouch, e.g. due to a competent lower oesophageal sphincter. Consequently, a direct investigation by fibre-optic endoscopy and simultaneous fluoroscopy (Fig. 13.4) may be

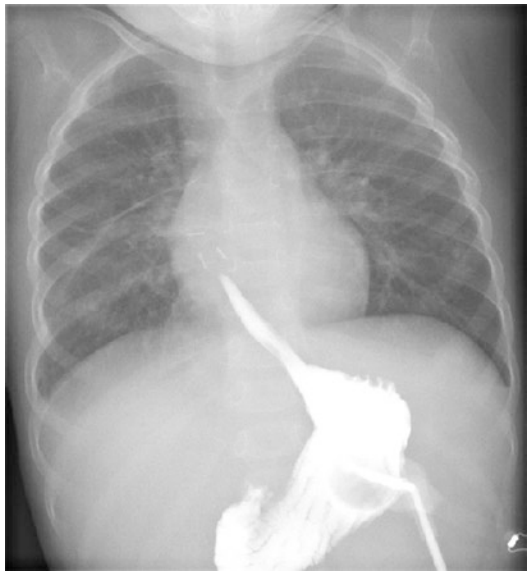

Fig. 13.3 Radiographic investigation of the lower oesophageal remnant in a 1-year-old child with LGEA. He had treated by traction sutures (the metal clips are marking the extraluminal end of the pouch. Contrast medium has been installed via the gastrostomy into the stomach and is delineating the length and the lumen of the lower pouch

Fig. 13.4 Direct investigation of the lower pouch (during "Foker elongation" with clips on both pouches) by fibre-optic endoscopy and simultaneous fluoroscopy

more accurate [5]. In very small infants, when even the smallest endoscope does not fit through the gastrostomy, a 10-French nasogastric tube with a radiopaque guide wire could be used instead.

Besides the type of EA and the length of the gap, every child with EA must be investigated for associated malformations. As mentioned in Chap. 8, an EA can occur as an isolated form (without further malformations), as an associated form (e.g. with VACTERL malformations) or as a syndromic type (e.g. trisomies 13 or 18 or 21). Besides a careful clinical investigation for visible anomalies, a cardiologic assessment including an echocardiography is essential. Cardiac and aortic anomalies like a right-sided descending aortic or a double aortic arch may be identified preoperatively [6]. However, it should be noted that the sensitivity of the echocardiography in detecting abnormalities of the aortic arch is limited and that intraoperative "surprises" must be encountered anyhow [7]. We will deal with the adequate strategies and surgical manoeuvres in Chap. 14. An ultrasound investigation of the abdomen and kidneys (see Chaps. 8, 9, and 10) supplies additional information.

Finally, in cardiorespiratory stable neonates with an EA/TEF, the repair is usually performed within the first 24 h of life. In the meantime the Replogle tube is kept under continuous suction. An endotracheal intubation should be avoided until the child is positioned on the operating table, because the tube may not seal the TEF adequately and any ventilation would thus inflate the stomach. Gastric perforation is a well-recognised complication of EA/TEF and is usually associated with extreme prematurity and requirement for assisted ventilation [8]. Thus babies with a respiratory insufficiency and gross gastric distension must be considered as an emergency. Before finally positioning the child on the operating table on its left side, it is advisable to perform a tracheobronchoscopy [9] to define the origin of the lower TEF in relation to the bifurcation and to exclude an upper TEF. Furthermore, it facilitates positioning the tip of the tube just distal of the TEF and enables intraoperative reassessment of its location in the vent of a cardiorespiratory instability [10]. This completes the preoperative evaluation.

Thoracotomy Incisions

14

John E. Foker and Adrian Bianchi

Introduction

Almost as many different thoracotomy incisions have been described as the number of esophageal repairs that have been proposed. For much of the history of esophageal atresia (EA) repair, the only question in making these incisions was how to obtain the best exposure without considering the functional or cosmetic consequences. While exposure is of major importance, more recently, much more consideration has been given to the incisions themselves as the longer-term consequences have become more apparent [1–6]. The purpose of this chapter, therefore, is to present the principles behind incisions that will provide very adequate exposure while minimizing the late consequences. With these principles in mind, we will present in more detail the incisional approaches which fulfill these criteria best.

The Standard Incision

The incision itself should be placed along the skin lines in order to minimize scarring and keloid formation. If the skin orientation cannot be determined by inspection, or by gently pinching the skin, Langer's lines are diagrammed in most anatomy textbooks. In general, these lines circle the patient's trunk; therefore, transverse incisions are preferable.

The site of the incision itself should be governed by two factors: the location of the organ to be repaired and the structures overlying the chest wall which will be damaged by the incision. In addition, the old justification that "wounds heal from side to side not end to end" does not acknowledge the fact that the longer the incision, the more likely that important structures will be injured and that other longer-term problems will emerge with time.

The patient is positioned in a straight lateral position with the arm bent over the head. The down leg is bent to reduce the rolling tendency. The patient is taped as shown. The tape along the undersurface of the upper arm adds stability and tends to increase the opening. The tape across the hip ensures stability (Fig. 14.1). In general, weighted (sand) bags provide little help in

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_14

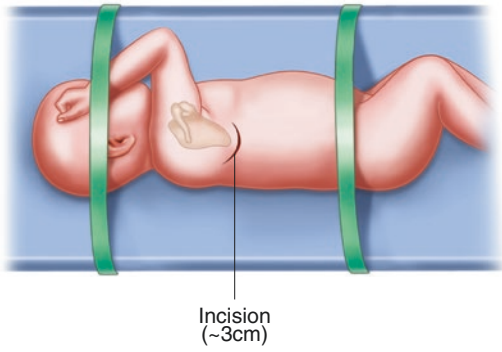

Fig. 14.1 In a straight lateral or slightly tipped forward position, with the lower leg bent to reduce rolling, tapes are applied as shown. The patient will remain fixed and stable. By applying one piece of tape along the undersurface of the upper arm and anchoring it superiorly, it will tend to "open" the chest wall. Padding should be placed between the legs. Sandbags are cumbersome and do not provide stability of the right chest wall which is the point of entry for reaching the esophagus. A 3 cm posterior lateral incision will be ample for EA repair in newborns. For older children, a 4 cm or slightly longer incision should be adequate. To reduce the consequences of the thoracotomy incision, the serratus anterior muscle should be spared in its entirety, and, posteriorly, the incision should not divide any peri-spinal ligaments and muscles. To gain access to a high upper pouch, it will be useful go through the fourth or even third interspace instead of the commonly used fifth (fourth) interspace. In this case, a second intercostal opening will usually be required to reach the lower esophageal segment

stabilizing infants and may impede access by pushing posterior and anterior chest tissue upwards and collapsing the opening. Sandbags, nevertheless, are almost an article of faith in some operating rooms.

The standard thoracotomy incision for EA repair begins with a transverse skin incision about 1 cm posterior and about 1.5 cm inferior to the tip of the scapula and carried posteriorly until the paraspinal muscle group beneath it is reached (Fig. 14.1). In a 3–3.5-kg newborn, this incision need only be 3 cm in length to provide adequate access for the surgeon. For the assistant, and others at the operating room table, however, the view will be very limited. Once the chest is opened, a thoracoscopic telescope can be placed through another rib interspace which will provide good visualization for all in the room.

At the next layer, the serratus anterior muscle is not incised at all, and the long thoracic nerve and vascular bundle carefully preserved as will be the mechanics of the shoulder girdle. The latissimus dorsi muscle is opened a bit longer than the skin incision. Posteriorly, the paraspinal ligaments should be preserved completely to limit the likelihood of scoliosis.

The interspace opening should be longer than the skin incision to allow an adequate opening. The interspace is easily opened by inserting and pushing with the tip of a slightly opened Metzenbaum scissors (a push cut). The scissors are inserted into the intercostal muscle about 2 mm above the upper margin of the lower rib. The vascular bundle within the lower margin of the upper rib is not damaged, and the lower rib is not denuded, which lessens rib fusion and the development of scoliosis. The intercostal incision itself should be made closer to the upper edge of the lower rib to avoid the neurovascular bundle in the rib above. A chest retractor is inserted and gradually opened at intervals to increase the opening. After a little time and successive increases in the spread of the retractor, a large opening can be made without breaking the ribs.

For the standard EA with lower tracheoesophageal fistula (TEF), the interspace at or just above the incision provides very adequate access to the upper and lower esophageal segments and the fistula itself. The choice of the intercostal opening, however, can easily be varied using this same skin incision. If the upper pouch is unusually high, the intercostal incision should be at least one interspace higher. An important point to remember is that if one finds the intercostal incision either too low or too high, another intercostal opening can be made through the same skin incision. For a very small lower esophageal segment that does not reach the diaphragmatic hiatus, a second intercostal (not skin) incision two interspaces lower will provide better access to it. Making the intercostal opening lower than the sixth interspace will not be helpful and, moreover, may place part of the incision into the diaphragm.

With pure esophageal atresia and a long gap, therefore, the standard skin incision would be made, but two intercostal incisions will be used; one through the third and another through the sixth interspace. The two intercostal incisions will provide direct access to the upper and lower

esophageal segments through a single skin incision. The skin incision in infants and children, moreover, is quite flexible. This flexibility together with the ability to change the intercostal entrance into the pleural space means that the skin incision does not have to be long and the important thoracic muscles and ligaments can be spared.

The Axillary Incision

An axillary incision has been used and perfected by one of the authors (AB). The cosmetic advantages are obvious, as are the preservation of thoracic muscles and shoulder mechanics. Consequently, there is much to recommend this incisional approach advocated by a superior surgeon. For those able to gradually gain familiarity with this unconventional approach, it should be used. The only disadvantage that will likely cause difficulty, in the opinion of the other author (JEF), is carrying out the location and mobilization of a very small (diminutive) lower esophageal segment.

The lung will be retracted medially and superiorly revealing the parietal pleura overlying the esophagus.

The Intrathoracic Component

The question of whether to use an extrapleural or intrapleural approach has been long debated although most surgeons choose an extrapleural approach for the repair of a straightforward EA/TEF. The extrapleural approach allows the mobilized pleura to drape over and seal the anastomosis; however, it has not convincingly diminished the incidents of leaks or other problems. When a leak or disruption occurs, this approach provides no advantage and may make repair of the problem more difficult. The combination of a leak and subsequent stricture which requires an esophageal resection is made much more difficult with an adherent pleura. The planes become difficult to identify, and important structures such as the aorta may be included in the resulting scarring.

For a growth procedure, with traction sutures on the esophageal segments, an intrapleural approach is necessary. The smooth intrapleural surfaces allow the esophageal segments to move easily with growth. If the segments are retropleural, however, the pleura drapes over them and becomes adherent, quickly halting progress.

Another point of discussion is whether or not to ligate and divide the azygos vein as it turns toward the superior vena cava where it will be in close proximity to the esophageal repair. If a second operation is needed and the azygos vein is left behind, it may be adherent to the back of the esophagus, where it can be injured. If the azygos vein is very large, however, it may be the result of an inferior vena cava interruption, and the vein must be preserved and the anatomy understood.

Over the years, a number of other incisions have been used by surgeons in order to gain adequate exposure for the dissection and repair of the EA spectrum. These have ranged from a long vertical posterior incision requiring the division of a number of ribs to a long transverse incision in which the serratus anterior and other chest wall muscles are divided. When compared to the incisions discussed above, they have many detrimental consequences and should not be used.

Thoracoscopic (Minimally Invasive) Approach

More recently, spurred on by the realization that long incisions would likely produce significant chest wall deformities as the child grew, as well as their virtual absence when minimally invasive surgical (MIS) procedures are used, thoracoscopic repairs have been more frequently used. With this experience, the MIS results have also improved.

Conclusions

At the present time, a trade-off exists between the short incisions for an open repair and the lesser incisional consequences of an MIS thoracoscopic approach. Currently, the thoracoscopic approach with its attendant larger needles and sutures which can be only placed and tied one at a time and the loss of dexterity ("touch") by the use of long instruments makes this approach a reasonable choice only for the straightforward type C (blind upper

pouch and tracheal fistula to the lower pouch) lesions with a short gap between the two segments. With a longer gap, the inability to use multiple back row sutures to gradually bring the ends together and tie each suture off tension makes MIS a less satisfactory choice. After all, it is the avoidance of a serious complication such as partial disruption of the anastomosis and the quality of the repair itself that will be very important to the infant's quality of life from that time forward.

Although it must be acknowledged that as the gap length increases and, with it, the anastomotic tension, the likelihood of a significant postoperative stricture and the presence of GE reflux also increases. These problems, however, are quite treatable, and, if corrected in infancy, these children can enjoy the ability to eat normally and have outwardly normal esophageal function. The goal, again, is 70+ good years.

The Current Repair Techniques of Short-Gap EA/TEF

15

H. Till and M. Hoellwarth

Introduction

With the advances in neonatal minimal invasive surgery (MIS) and successes in elaborate reconstructive procedures, such as the repair of esophageal atresia [1], a neonate with an EA/TEF in contemporary times has the option to be approached either by thoracotomy or by thoracoscopy [2]. Irrespective of the access route preferred, the basic operative steps remain identical between the two approaches and comprise the closure of the TEF and a primary anastomosis of the esophageal ends. Since the minimal invasive technique will be described in detail in the following chapter, this article focuses on the open, "traditional" access only.

Surgical Techniques

Most pediatric surgeons approach a short-gap EA/TEF from the right side [3]. Even EA/TEF cases with a right-sided aortic arch have been suggested for this approach by several authors [4–6]. Concerning a detailed preoperative workup, we refer to Chap. 12. If a preoperative bronchoscopy is planned, which we recommend to exclude an upper pouch fistula and to determine the position of the TEF, it should be performed before positioning the child for a posterolateral thoracotomy. Thereafter, the child is placed on his/her left side, and the chest is raised with a soft towel to widen the intercostal spaces. The right arm should be placed anteriorly over a padded face and flexed in the elbow to prevent injury to the brachial plexus (Fig. 15.1).

Most surgeons prefer a horizontal or slightly curved skin incision located just at the tip of the scapula. A vertical incision in the midaxillary line or a high axillary skin crease incision has also been advocated [7]. In order to minimize surgical trauma, the intercostal spaces are approached by a muscle sparing and atraumatic dissection of the latissimus dorsi muscle and the serratus anterior muscle [8]. When entering the fourth (or fifth) intercostal space, the operation progresses with an extrapleural mobilization. The main objective for this strategy is to minimize the risk of an empyema in case of an anastomotic leak. With the general acceptance of a thoracoscopic approach, this dogma has been challenged. The present literature reveals no obvious benefits, when the two approaches, trans- or retropleural, are compared [9]. For such an extrapleural preparation, the parietal pleura is bluntly peeled off the thoracic wall down toward the dorsal mediastinum using a wet swab. The azygos vein represents a major landmark in any

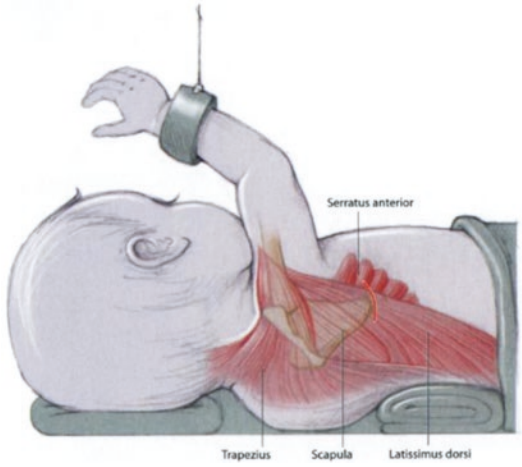

Fig. 15.1 (Drawing from Prof. Höllwarth): Positioning of a child with EA/TEF for a right-sided posterolateral thoracotomy

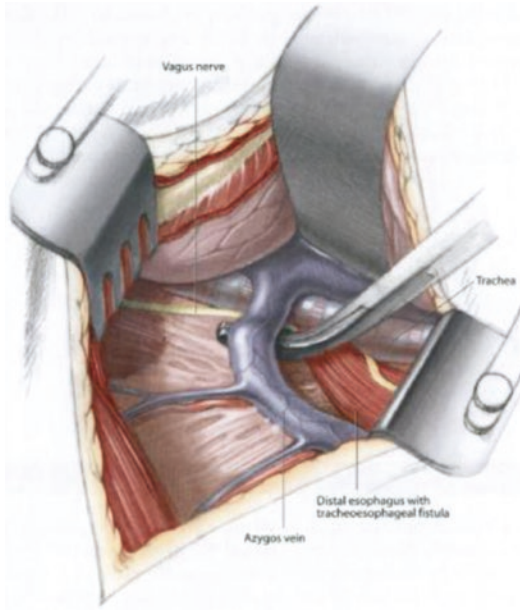

Fig. 15.2 (Drawing from Prof. Höllwarth): The azygos vein represents a major landmark of any EA/TEF operation. Its dissection is not necessary, but usually quite helpful to identify the TEF

TEF repair (Fig. 15.2). Dissection of the vein may not be necessary, but it certainly facilitates an easier identification of the TEF. Next, the vagal nerve fibers should be identified as they converge to the distal esophagus. The distal esophagus is encircled with a vessel loop to permit an atraumatic mobilization (Fig. 15.3). Usually, it is more hypoplastic than the upper pouch, and extensive dissection is not recommended in order to preserve the blood supply and vagal innervation. Instead the TEF is mobilized straightforward to its junction with the trachea. Especially, in preterm babies, this preparation should be performed with great care to avoid damaging the membranous portion of the trachea. The TEF should be divided close to the tracheal wall, leaving a small cuff of approximately 1 mm (Fig. 15.4). This cuff is closed with interrupted 5-0 sutures. It seems worth mentioning that some experts postpone this maneuver until they have assessed the length of the upper pouch and have made a decision about the feasibility of a primary repair.

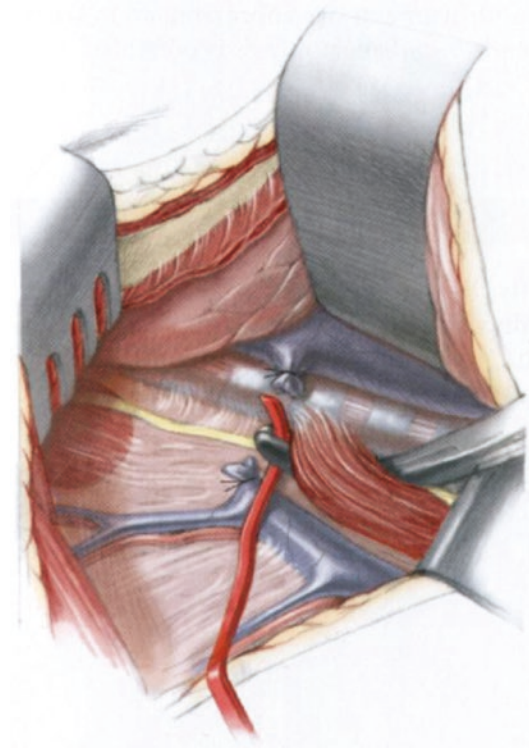

Fig. 15.3 The TEF has been encircled with a vessel loop to allow for an atraumatic preparation. Vagal nerve fibers have been preserved

In order to facilitate identification of the lowest portion of the upper pouch, a Replogle suction tube or a larger nasogastric tube placed in

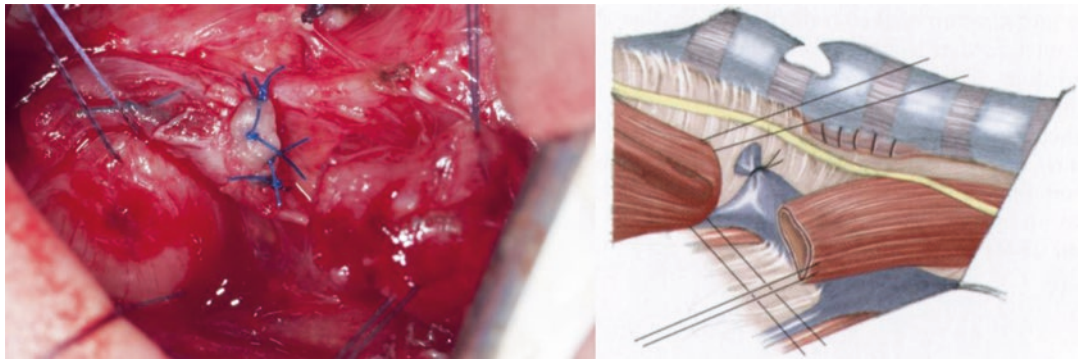

Fig. 15.4 Short-gap EA/TEF in a neonate weighing 2,000 g with duodenal atresia. The TEF has already been dissected and closed with interrupted 5-0 Prolene sutures. Two 5-0 Vicryl sutures are marking the upper pouch (still closed) and lower TEF (same anatomical situation as a diagram on the left)

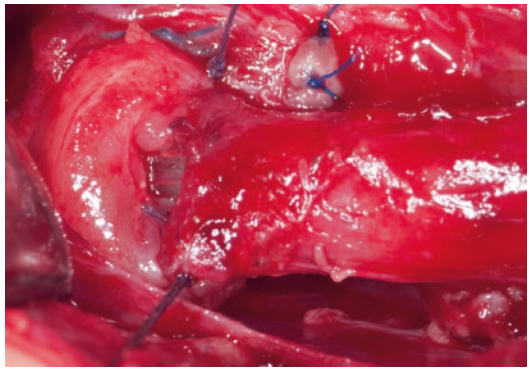

Fig. 15.5 Same case as in Fig. 15.4. The posterior part of the anastomosis has already been fashioned. A transanastomotic drain (8-French feeding tube) has been passed down into the stomach

the upper pouch is gently pushed by the anesthesiologist. Traction sutures are placed on either side of the tip. Since the upper pouch often shares a common wall with the membranous portion of the trachea, special care is essential during the mobilization. We prefer a sharp dissection as it minimizes a collateral damage to the trachea or recurrent laryngeal nerve. Once the pouch has been mobilized completely and the decision for a primary repair has been made by approximation of both segments, the tip is incised. Pushing the Replogle tube may help to define the lowest point. It seems important to mention that the opening of the mucosa must be sufficient large to avoid stenosis later.

Several techniques of an end-to-end anastomosis in EA/TEF have been reported [10, 11]. Techniques worth debating would be single versus double layer, interrupted versus continuous suturing, absorbable versus nonabsorbable material, and of course inverted versus everted knotting. However, there is no evidence in the present literature that any of these parameters offer advantages to their counterpart. In most cases, a single-layer reconstruction with interrupted sutures seems straightforward. We prefer to place the corner stitches in an outside-in and inside-out fashion, always taking "a good bite" of the muscular wall including the mucosa (Fig. 15.5). However, the remaining stitches of the posterior wall do not necessarily have to be on the outside, if tying would stress or twist the anastomosis. If some tension is anticipated, it may be advisable to place all posterior sutures first without tying them right away. Instead, the sutures are then crossed one by one to gradually advance the esophageal ends. This maneuver can be repeated until the esophageal remnants have approximated and the sutures can be tied. Once the posterior suture line has been finished, we pass an 8-French feeding tube into the stomach for stenting of the anastomosis (Fig. 15.5), for postoperative gastric decompression, and for enteral feeding on the first postoperative day. However, the placement of a transanastomotic tube is not supported by a large body of evidence in the literature [12]. Finally, the anterior aspect of the anastomosis is

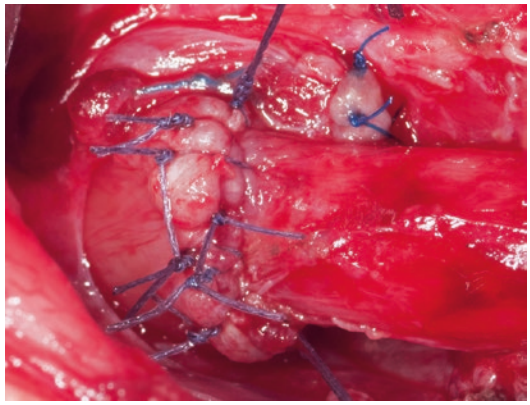

Fig. 15.6 Final aspect of the anastomosis with interrupted sutures and extraluminal knots

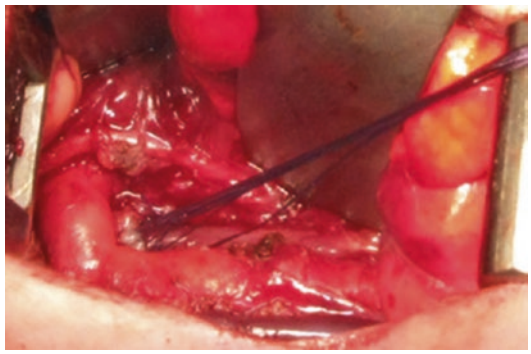

Fig. 15.7 A child with an EA/TEF and a right-descending aorta. For the primary esophageal repair the child has been approached from the right. Thus the aortic arch crosses the upper pouch and the anastomosis lies just distal and underneath it

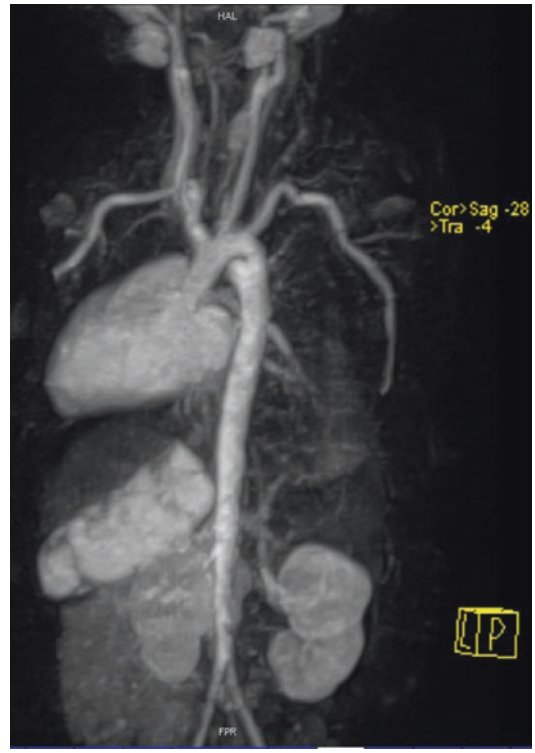

Fig. 15.8 MR angiogram of a child with EA/TEF and an incomplete double aortic arch (diverticulum of Kommerell)

completed with interrupted sutures and extraluminal knots (Fig. 15.6).

Even cases with an EA/TEF and a right-descending aorta can be corrected in the same fashion. Figure 15.7 demonstrates such a situation. In case of a double aortic arch, however, a left-sided approach should be discussed. Figures 15.8, 15.9, and 15.10 depict a child with an incomplete double aortic arch (diverticulum of Kommerell, [13, 14]), which had been approached from the left side to perform a primary repair.

If the primary anastomosis is under too much tension or tears have already happened, several techniques are available before aborting the primary repair. Myotomie, flaps and partial gastric pull-ups will be dealt with elsewhere. Before resorting to such techniques without adequate personal expertise, one may consider mobilizing the distal esophagus further down to the diaphragm. Moreover, a fine management of the sutures as described earlier may be helpful to gain extra length.

If the anastomosis must be aborted, the further management remains a matter of vivid discussion and certainly depends on several factors like the individual anatomy and associated malformations, the setting within the hospital, and the socioeconomic situation of the family. The lower segment should be closed with interrupted sutures and may be fixed to the vertebral column to avoid retraction. The upper segment may be closed completely as well or everted as a spit fistula.

Before closing the chest, some colleagues install an extrapleural chest drain in case the anastomosis leaks. Others place a chest tube only

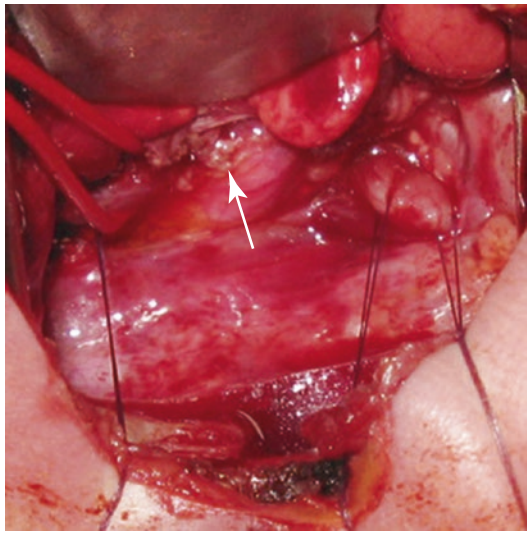

Fig. 15.9 The same child as in Fig. 15.8, approached from the left side (the anatomical aspect is mirrored). The TEF (at 9 o'clock) has been encircled with a vessel loop close to its junction to the trachea. A bulb of (pulsating) tissue crosses and encircle(s) the trachea, which is the incomplete double aortic arch. The upper pouch has been marked with two stitches

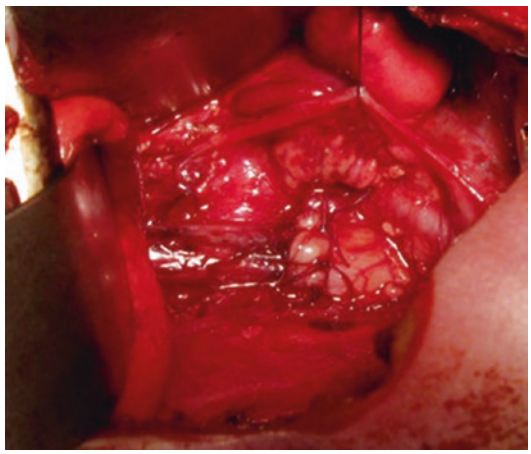

Fig. 15.10 Final anastomosis of this child

in "problematic cases" [15]. In neonates with a short-gap EA/TEF, we stopped doing so for three reasons. Firstly, the rate of anastomotic leaks is so small that many children would be drained in vain. Secondly, such a drain must be left in situ until the anastomosis has been investigated for patency, which usually takes place several days postoperatively. Finally, this drain may not necessarily reach a leak adequately, if it happens. Instead, we only close the muscles in several layers and refrain from suturing the intercostal space in order to avoid rib fusions.

Results, Issues, and Discussions of a Primary Repair

Many issues contribute to the postoperative course of any case with EA/TEF. Certainly, there are numerous nonsurgical factors like birth weight and age, delayed diagnosis, cardiac defects, associated malformations (e.g., VATER), and presence of genetic defects. On the other hand, specific operative details and complications influence the long-term sequelae significantly. Since this chapter focuses on technical aspects of a primary repair, we will focus the discussion on surgical issues and results. Theoretically, the postoperative complications may be divided into "form versus function," meaning "form" includes anastomotic leaks, strictures, and recurrent TEFs, while "function" comprises motility disorders, gastrointestinal reflux, and tracheomalacia. Some of these findings will influence the long-term quality of life of our patients significantly.

The rate of anastomotic leaks varies considerably in the literature. Just recently, Borruto et al. [3] published a meta-analysis about the outcome of thoracoscopy versus thoracotomy for EA/TEF repair. Their manuscript supplies an excellent overview of the present data and concludes that the rate of anastomotic leaks and strictures did not differ significantly between the two techniques (odds ratio of 0.56 in favor of the conventional open approach). But again we refer to Chap. 15 for a detailed discussion about this specific approach. Clinically, an anastomotic leak may occur in 5–25 % of cases [16]. Usually, it becomes apparent with signs of a systemic infection increase, saliva appearing in the chest tube, or the development of an emphysema. A radiological study of the anastomosis demarcates the defect [17]. Most minor leaks may be treated conservatively [16]. Drainage (Replogle suction

tube plus transanastomotic tube) and antibiotics contribute to a spontaneous healing within weeks. If major leaks occur, the adequate strategy should be considered with great care. An immediate operation should be driven by the essential question: What can we do better next time in order to avoid another leak? If tension and ischemia played a major role in the previous operation, there may be some doubt that these conditions have improved significantly. Furthermore, saliva and infectious material may have already damaged the esophageal tissue somehow. So an immediate intervention must always include a "plan B," i.e., the abortion of the primary repair as mentioned above.

Anastomotic strictures are quite common and multifactorial. At least 30% of the EA/TEF patients and up to 50% with pure EA require esophageal dilatations for anastomotic strictures [8]. Extensive mobilization and devascularization, an anastomosis under tension, postoperative leaks, and a significant gastrointestinal reflux may be surgical contributors [16]. Most strictures respond to bouginage or dilatation. Interestingly, there is no clear evidence in the literature, as to which procedure is more effective despite the frequency of stricture treatment [18]. We will deal with these issues in Chap. 15 again. In future, topical agents like mitomycin [19] may increase the efficacy of stricture treatment (see Chap. 33).

Compared to normal children, the incidence of a gastroesophageal reflux (GER) is considerably higher in children with an EA/TEF [20] and may necessitate a fundoplication in 32–30% of all cases [8]. Consequently, all patients should be investigated for a GER eventually (see Chaps. 36 and 37). Some of the causes for the GER may be attributed to the initial repair technique. It is well known that children with EA/TEF have an impaired esophageal motor function [21]. On the other hand, an extensive mobilization of the lower segment down to the diaphragm may weaken the intra-abdominal fixation of the GE junction or even cause a transposition the GE junction above the diaphragm. Furthermore, such extensive mobilization may compromise the vagal nerve fibers converging along the distal esophagus and could contribute to a motility disorder [22]. We will deal with the adequate management of GER in the next chapter.

Moreover, it should be mentioned that every case of EA/TEF may be associated with a certain degree of tracheomalacia. During the immediate postoperative phase, the spontaneous breathing may be impaired, especially when the child is fed orally, and the wide upper portion bulges into the membranous portion of the trachea. A stenosis or stricture of the anastomosis worsens this effect. Later in life, children with EA/TEF may present with a barking cough and inspiratory stridor. Cases of severe tracheomalacia must be investigated by tracheobronchoscopy. This investigation must be performed without a tracheal tube (stenting of the malacia) and during spontaneous breathing (negative pressure in the chest during inspiration provokes the tracheal collapse). Usually, significant tracheomalacia improves over time and up to 1 year. Hence, only severe cases with acute life-threatening events (ALTE) should be considered for aortopexy under bronchoscopic control [23]. Stenting should be the "last resort" option due to long-term consequences; for further information, we refer also to Chaps. 40, 41, and 42.

Finally, it must be noted that a contemporary study reported that no musculoskeletal sequelae were directly attributable to thoracotomy for EA/TEF repair [24]. So the open approach may not be out-fashioned yet? The long-term observation of Sistonen [25], who investigated the respiratory morbidity and pulmonary function of adults after repaired esophageal atresia as newborns, raises a major concern. He found that thoracotomy-induced rib fusions and gastroesophageal reflux were the strongest risk factors for restrictive ventilator defects [25].

In conclusion, we believe that a precise and experienced technique of a primary repair makes all the difference for patients with an EA/TEF concerning the postoperative complications and long-term quality of life.

Thoracoscopic Repair of Esophageal Atresia and Tracheoesophageal Fistula

16

George W. Holcomb III

Introduction

The topic of esophageal atresia (EA), with or without tracheoesophageal fistula (TEF), will be covered in several chapters in this book. Therefore, this chapter will not reiterate information about etiology, classification, the open repair via thoracotomy, postoperative management or management of postoperative complications such as recurrent TEF, gastroesophageal reflux, or indications for aortopexy.

The primary focus of this chapter is to describe the thoracoscopic repair and to provide information regarding this approach. In addition, our institution is a training center for pediatric surgeons. As such, some of the issues that will be discussed relate to similar centers and may or may not be applicable in the private practice setting.

In 1999 during the IPEG Congress in Berlin, Drs. Thom Lobe and Steve Rothenberg (in concert with other surgeons) performed a thoracoscopic repair of a 3-month-old infant with isolated EA [1]. This infant recovered nicely, but did require several esophageal dilations. At the 2000 IPEG meeting, Dr. Rothenberg described the first thoracoscopic repair of an infant with EA/TEF [2]. This patient has continued to recover well without any significant complications. We performed our first thoracoscopic repair of an infant with EA/TEF on Memorial Day (late May), 2002. The operation also proceeded very nicely, and the patient recovered uneventfully without the need for dilation or fundoplication. Since that time, five of the six pediatric general surgeons in our group have either performed this operation or supervised this operation being performed by one of the pediatric surgical residents. Thus, at our institution, the thoracoscopic approach has become the favored approach for most babies with EA/TEF who do not have significant associated diseases.

Preoperative Evaluation

The preoperative evaluation for a baby undergoing a thoracoscopic repair is similar to the baby undergoing the traditional open approach. An evaluation for congenital cardiac anomalies is important, as is a sonographic study to evaluate the location of the aortic arch. Further radiographic evaluation for the VACTERL (vertebral, anorectal, cardiac, tracheoesophageal, renal, limb) anomalies is similarly needed as for the open operation.

The baby who is less than 2.5 kg is a challenge for the thoracoscopic approach. That is not to say

G.W. Holcomb III, MD, MBA

e-mail: gholcomb@cmh.edu

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_16

that this baby should be excluded from undergoing a thoracoscopic repair by an experienced surgeon. However, what makes the operation easier in some babies, as compared to others, is the baby's weight (3 kg or greater), the lack of associated abnormalities, and, most importantly, a close proximity of the two esophageal segments. Therefore, it is my preference to pay close attention to the chest radiograph to see how caudal the upper pouch appears to extend. In addition, it is also my preference to perform bronchoscopy at the time of the thoracoscopic repair to identify the location of the TEF (Fig. 16.1). If the fistula is entering at the carina, the esophageal segments will be further apart than if the fistula enters the middle or lower trachea. Thus, the location of the TEF is helpful for anticipating where the fistula will be found in the chest at the time of the thoracoscopic repair.

This operation is not an emergency. It can be scheduled 2–3 days following birth in order to allow adequate time to perform the operation. In general, this is not an operation that should be performed beginning at 4 o'clock in the afternoon, but rather it is best performed starting earlier in the morning with one's regular operating crew. While awaiting operation, the baby should be turned onto his/her side to allow the oral secretions to drain out of the mouth rather than allow them to accumulate in the posterior pharynx and become aspirated. Also, it is important to have the Intensive Care nurses suction the baby's oropharynx at least every 2 h and more frequently if needed. The baby does not need to be intubated preoperatively unless the baby has respiratory symptoms. Management of the baby in respiratory distress is beyond the purview of this chapter and can be found in other literature reports [3–6].

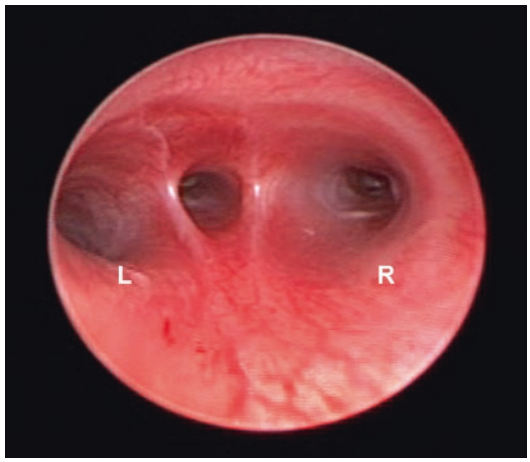

Fig. 16.1 Preoperative bronchoscopy allows the surgeon to confirm the diagnosis of esophageal atresia and tracheoesophageal fistula and also to better understand the expected gap length between the two esophageal segments. As seen in this baby, the fistula enters the carina which indicates that the surgeon should expect a relatively large gap between the two esophageal segments. A fistula that enters the mid-trachea would indicate that the two esophageal segments are likely closer together. (*R* right mainstem bronchus, *L* left mainstem bronchus)

Thoracoscopic Technique

The baby is transported to the operating room, and appropriate intravenous and, in some instances, intra-arterial access are established. As mentioned earlier, it is my preference to perform a preoperative bronchoscopy to identify the site of insertion of the distal TEF. Tracheal intubation, rather than left mainstem intubation, is generally utilized by most pediatric surgeons as the positive pressure pneumothorax will collapse the ipsilateral lung. Also, it can be difficult to perform left mainstem intubation in a small baby. If so desired, a variety of techniques are available to occlude the right mainstem bronchus such as tracheal intubation and placement of a bronchial blocker into the right mainstem bronchus.

In our early experience, we performed the operations with tracheal intubation and conventional mechanical ventilation. However, because of our status as a pediatric surgery teaching institution, we are also an anesthesia resident teaching center as well. As such, we have been dissatisfied with the use of conventional mechanical ventilation provided by the anesthesia residents. Therefore, we now prefer to perform these operations using tracheal intubation and the oscillating ventilator which will be discussed later.

Following intubation and initiation of appropriate ventilation, the baby is turned onto his/her left side (assuming a left aortic arch). The baby is turned more prone than lateral as the esophagus is a posterior mediastinal structure (Fig. 16.2).

Positioning the baby more prone allows the lung to fall forward and out of the area of visualization and dissection. The surgeon and camera holder stand at the front of the baby, and the scrub nurse is best positioned at the baby's back (Fig. 16.3). Following adequate prepping and draping, it is my preference to place an initial 5-mm port at approximately the eighth or ninth intercostal space in the posterior axillary line. It is through this port that a 45° or 70° 4 or 5 mm telescope is introduced. Following insertion of this cannula using a cut-down technique, a pneumothorax with carbon dioxide insufflation (1 L/min) to a pressure of 4–6 torr is created. There can be some initial desaturation as right-to-left shunting may occur. However, after a few minutes, this usually stabilizes. Our preference is to introduce the working instruments using the stab incision technique in the fourth and sixth intercostal spaces in the posterior axillary line just beneath the scapula. These are the two working ports for the surgeon. In our experience, and certainly with conventional ventilation, a fourth port instrument is often needed to help retract the lung. This fourth instrument is often inserted in the 10th or 11th intercostal space near the spine (see Fig. 16.2). A second assistant is sometimes needed to retract the lung using this instrument.

Following creation of an adequate pneumothorax and introduction of the instruments, the field of view is amazing, especially if this is the first time one is performing the operation thoracoscopically. Initially, our preference was to identify the proximal esophagus into which a red rubber catheter has been placed per os. If it is difficult to identify the proximal esophagus, the anesthesiologist is asked to manipulate the catheter and the proximal esophageal pouch can usually be identified. Usually, it is not as easy to identify the distal esophagus as in an open operation because the

Fig. 16.2 As the esophagus is a posterior mediastinal structure, the baby should be turned more prone than lateral to allow the lung to fall forward and away from the area of visualization and dissection. On this newborn, the site for introduction for the initial 5 mm cannula is marked with a black arrow. Above it are two dots marking the stab incisions through which instruments will be inserted for use by the surgeon. On the left side, a final port is sometimes needed (*white arrow*) for lung retraction. With the use of the oscillating ventilator, this port is now often not needed. The lower border of the scapula has also been marked

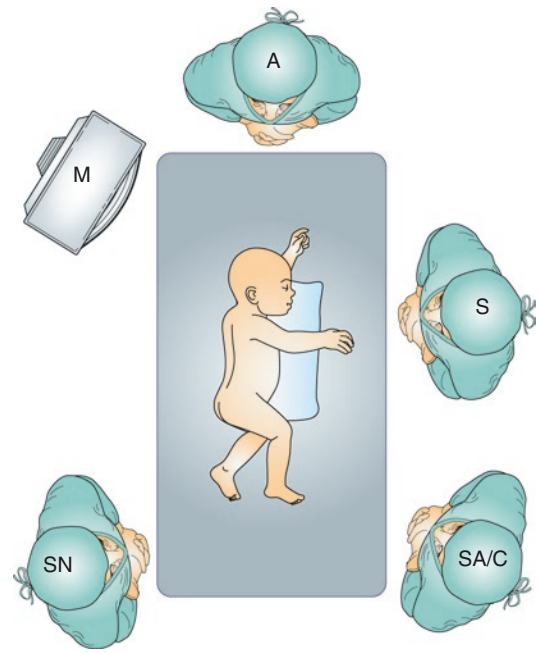

Fig. 16.3 The surgeon (*S*) stands at the front of the baby with the surgical assistant/camera holder (*SA/C*) to his/her left. The scrub nurse (*SN*) is usually opposite the surgeon at the level of the camera operator. The monitor (*M*) is situated opposite the surgeon for optimal viewing (*A* anesthesiologist) (From Holcomb et al. [7]. Reprinted with permission)

positive pressure pneumothorax often prevents ventilation through the fistula. As one's experience increases, it becomes easier to understand where the distal esophagus lies.

Our preference is to divide the azygos vein as the fistula is usually coursing just underneath it. If it is clear that the fistula enters the trachea cephalad to this vein, it may not be necessary to divide it. Assuming ligation and division of the vein is needed, this can be performed using the cautery, ultrasonic scalpel, or LigaSure (Covidien, Mansfield, MA), depending on one's preference. Initially, we utilized the LigaSure but now divide the azygos vein with cautery.

After the proximal esophagus is identified, attention is directed toward the distal esophagus. Blunt dissection initially begins at the level where the distal esophagus enters the trachea. Usually, there is no significant bleeding and hemostasis can be controlled with cautery. Our preference is to perform this dissection using the Maryland dissecting instrument, although other surgeons may prefer other instruments. Once the fistula is identified and mobilized, we next proceed to expose the proximal esophagus, again using a combination of blunt dissection with hemostasis controlled with cautery. It is important to remember that the wall of the proximal esophagus is quite sturdy as this structure has been obstructed for 7–8 months in utero. Sometimes little dissection of the proximal esophagus is needed, and sometimes more dissection is required, depending on the gap between the two esophageal segments. Assuming that a thoracoscopic repair is feasible, the distal TEF is then ligated using a variety of techniques. Initially, we utilized endoscopic stainless steel clips to ligate the fistula at the junction of the esophagus and the trachea (Fig. 16.4). The fistula is then divided distal to the second clip. Now, my preference is to use a Weck clip (Hem-o-lok, Teleflex Medical Inc., Research Triangle Park) as the stainless steel clips can erode through the fistula and may have contributed to a recurrent TEF in one case. (Others may not feel this is a concern.) Another possibility is to divide the esophagus at the level of the trachea with scissors and suture to close the resulting tracheal defect with interrupted 5-0 suture. Either absorbable suture or silk can be used for this purpose. We have utilized all of these techniques and found them satisfactory. If suture closure of the trachea is desired, either intracorporeal or extracorporeal knot tying can be utilized.

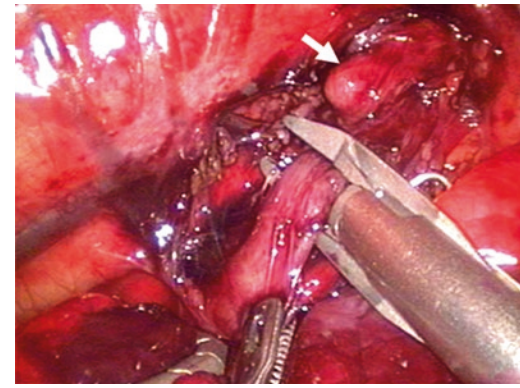

Fig. 16.4 This operative photograph depicts ligation of the fistula with stainless steel clips at the junction of the distal esophagus and trachea. A red rubber catheter is noted in the proximal esophagus (*arrow*)

After the distal esophagus has been disconnected from the trachea, the esophageal anastomosis is performed with 4-0 or 5-0 suture. Either absorbable (polyglactin or polydioxanone) or nonabsorbable (silk) sutures can be used. In a 2007 report from our institution, we looked at 99 patients and found that there was no difference in the incidence of anastomotic leaks or stricture with absorbable or nonabsorbable suture [8]. Initially, as there is usually some tension on the anastomosis, it may be helpful to secure the first two or three sutures using extracorporeal knot tying. As occurs with the traditional open operation, the back row of sutures is usually tied inside the lumen and the front row is tied with the knots on the outside. Prior to complete closure on the front side, our preference is to place a small (6–8 Fr.) Silastic tube through the baby's nose, through the anastomosis, and into the stomach (Fig. 16.5). This tube can be used for feeding purposes if desired in the postoperative period. Following introduction of this Silastic tube, the anterior row of sutures are then placed. If the surgeon does not feel that a good anastomosis has been performed, then conversion to an open operation is suggested.

Following completion of the esophageal anastomosis, the esophageal suture line and the

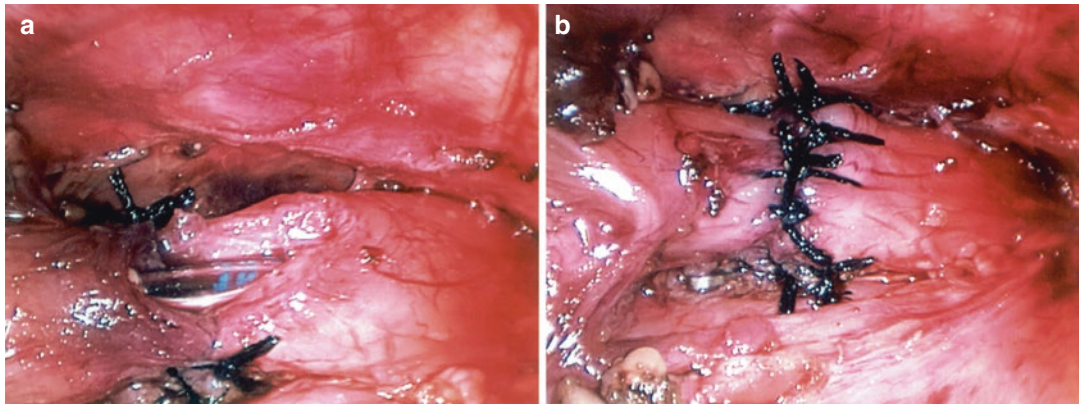

Fig. 16.5 *On the left* (**a**), after completing the posterior anastomosis, a soft 6-French tube is introduced through the infant's nares and is seen coursing through the esophageal anastomosis into the stomach. This is often helpful in the postoperative period for feeding. *On the right* (**b**), the anterior portion of the anastomosis has been completed with interrupted silk sutures which were tied intracorporeally (From Holcomb et al. [7]. Reprinted with permission)

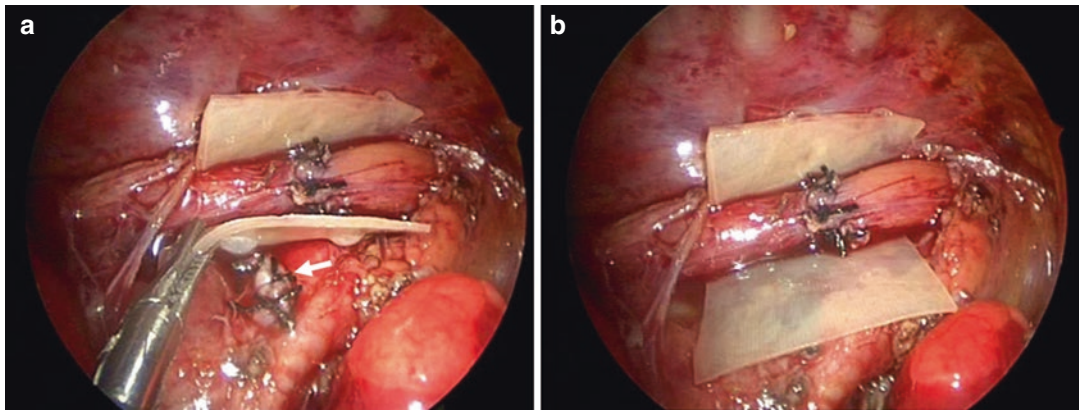

Fig. 16.6 After completing the esophageal anastomosis, it is important to try to separate the esophageal suture line from the fistula closure on the trachea (*white arrow*, **a**), if possible. Often these two sites align next to each other. We now interpose a piece of Surgisis between the two suture lines to separate them (**a**, **b**). We have not had a recurrent fistula develop after instituting this maneuver several years ago (From St. Peter et al. [9]. Reprinted with permission)

tracheal closure are often abutting each other. Our group reported a technique using Surgisis (Cook Inc., Bloomington, IN) which is positioned between these two suture lines to help prevent the development of a recurrent tracheoesophageal fistula (Fig. 16.6) [9]. With the open operation, it is sometimes possible to interpose either pleura or other soft tissue between the two suture closures. However, this can be quite difficult thoracoscopically and is the reason we often place Surgisis between the two suture closures.

The instruments are removed, and a soft Silastic drain is tunneled through one of the caudal incision sites and situated near the anastomosis. The lung is allowed to expand and the small incisions are closed with absorbable suture. Steri-Strips (3 M Corp., St. Paul, MN) are then placed, and the baby is transported to the neonatal unit.

The postoperative course for a thoracoscopic operation is no different than for the open approach. An esophagram is usually performed 5–7 days of the operation. If there is no evidence of leak, then oral feedings are initiated. If a leak is identified, it is managed as similarly described in other chapters. The remainder of the postoperative course is also described in other chapters.

Literature Report

There are a number of literature reports describing large experiences with the open operation for repair of EA/TEF [10–13]. Most of these reports are from the 1980s and early 1990s. The largest series of patients undergoing a thoracoscopic EA/TEF repair was reported at the 2005 meeting of the American Surgical Association [14]. This was a six-center report from three institutions in the United States and three institutions from three other continents. Management and outcomes in 104 babies were described. These patients had the usual associated VACTERL conditions with ten having greater than two VACTERL anomalies. In this series, an anastomotic stricture (defined as a stricture on the initial esophagram) was found in four babies (3.8 %). An anastomotic leak was seen on the initial esophagram in seven babies (6.7 %). The operation was converted in five babies for the following reasons: right aortic arch (1), intraoperative desaturations and a long gap between esophageal segments (3), and too small in size, i.e., 1.2 kg (1).

Regarding associated conditions, ten babies had imperforate anus and four had duodenal atresia. Five babies required cardiac repairs other than a VSD or ASD closure. Twenty-six babies (25 %) needed fundoplication and seven required an aortopexy of which six were performed thoracoscopically. Two recurrent TEFs developed. One occurred at 3 months postoperatively, and one developed at 8 months following the initial operation. Three babies died, but none of these were related to the operative approach. One baby died at 7 months following an episode of necrotizing enterocolitis which was attributed to drinking herbal tea; one baby had undergone successful thoracoscopic EA/TEF repair, but died of congenital heart disease prior to cardiac repair; and one baby was recovering nicely, but died at 20 days of life when the esophagus was inadvertently intubated and the anastomosis was disrupted. This baby died within 24 h of this event. Comparison of the results from this thoracoscopic report and a number of large series of open operations from the United States is seen in Table 16.1.

Modifications in the Approach

As mentioned, our group has described interposing Surgisis between the esophageal and tracheal closures to help prevent a recurrent fistula [9]. Also, over the past 3 years, our group has begun to utilize the oscillating ventilator as the primary mode of ventilation in these babies (Fig. 16.7) [16]. This has evolved for two reasons. First, as mentioned, it takes the oxygenation and ventilation out of the hands of a resident anesthesiologist. Also, there is no longer concern for hypercarbia. The babies are intubated in the operating room and placed on the oscillating ventilator which is controlled and managed by one of our respiratory therapists. Assuming a 3–3.5 kg healthy baby, the standard settings are a mean airway pressure of 13–15 and an FiO_2 of 70 %. The FiO2 can usually be weaned after 10–15 min. If the baby is shaking too much, the Hertz can be reduced from the initial 11–13 setting to 8–9. The use of the oscillator is advantageous in a surgical residency training program because the operative time is not as important. Early in our experience, it became evident that the operation needed to be performed in 2–2.5 h due to the development of hypercarbia and inflation of the lung. Now, the need to perform the operation expeditiously is not as important with the use of the oscillator. This has markedly improved the ability of our residents to participate significantly in these cases.

The main limitation in the use of the oscillator is the shaking of the baby. However, after 5–10 min, the surgeon becomes accustomed to this movement. In our experience and in discussion with our residents, the baby's shaking is not felt to be a significant limitation in performing the operation.

Fig. 16.7 Over the past 3 years, our group has begun to utilize the oscillating ventilator for ventilation in these babies. This photograph shows the baby turned on her left side and the endotracheal tube connected to the oscillating ventilator

Getting Started

One of the main limitations in the use of this approach is a surgeon's reluctance to begin an operation thoracoscopically with the fear of not being able to complete it. The best advice is to pick the first patients well. The optimal first or second baby should have a weight greater than 3 kg, no other associated anomalies, a left aortic arch, and a relatively low-lying proximal esophageal pouch (Fig. 16.8). Assuming that one can perform advanced laparoscopic operations (especially fundoplication as this involves intracorporeal suturing), the surgeon should discuss the thoracoscopic approach thoroughly and honestly with the parents. The surgeon should be encouraged to begin the operation thoracoscopically and proceed as far as he/she feels comfortable. If one is able to accomplish ligation of the fistula, but feels uncomfortable with the anastomosis, then conversion to an open procedure is very reasonable. However, one should believe in the benefits of the operation and not be concerned if conversion is necessary, as conversion implies good operative judgment rather than a failure in technique. Also, after the two esophageal segments have been mobilized, if the gap is too long, then conversion to an open operation is recommended in order to achieve a good outcome.

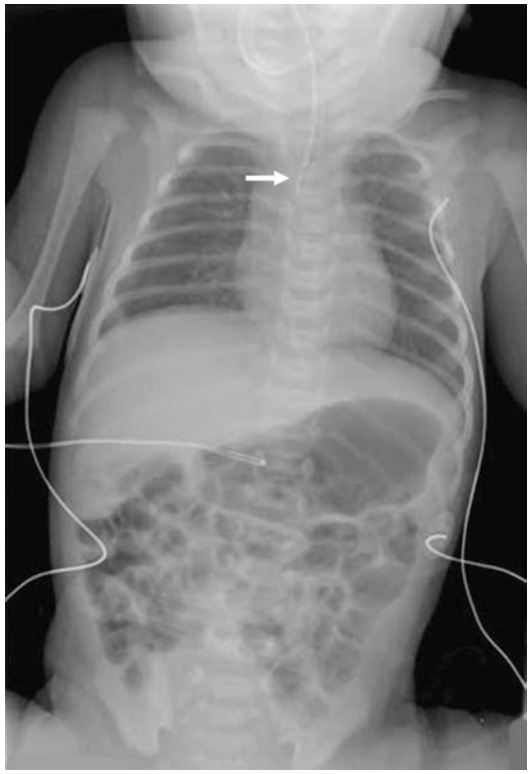

Fig. 16.8 This chest radiograph shows a baby with esophageal atresia and tracheoesophageal fistula. Note the relatively low-lying proximal esophageal pouch (*arrow*). This location of the proximal esophagus would be favorable for attempting thoracoscopic repair

Why Thoracoscopy?

The thoracoscopic approach for EA/TEF repair represents a natural evolution in the development of minimally invasive surgery in babies and children. This was certainly the last of the major pediatric surgery operations to be performed using a minimally invasive approach. In a number of surgeons' hands, this is a very reasonable approach and the outcomes are as good as with the open operation. The primary advantage is a reduction in musculoskeletal sequelae. In a 1985 report, a number of musculoskeletal problems were found in patients who had undergone an open thoracotomy for repair of esophageal atresia and fistula [17]. Similar reports in that decade and in the 1990s have confirmed the fact that musculoskeletal sequelae definitely occur following thoracotomy in infants [15, 18–20]. Advocates of the "muscle-sparing" open approach believe that the incidence of these subsequent problems is minimal [21]. However, although conceptually it certainly appears that this is true, there is a paucity of support in the literature.

Shawn D. St. Peter

Esophageal Duplications

Esophageal duplication cysts are unknown lesions, with an approximate incidence of 1 in 10,000 [1]. They account for about 20 % of all gastrointestinal duplications [2]. Because of the reported association of esophageal duplications and esophageal atresia (EA) [3, 4], some authors have sought a possible commonality in the embryogenesis of these defects. When rats were given Adriamycin to develop EA and tracheoesophageal fistula (TEF), 25 % also developed esophageal duplications [5]. This finding implies that esophageal duplications arise from the foregut, and failure of the esophagus to normally separate from the notochord may contribute to their development. It has also been postulated that esophageal duplications and bronchogenic cysts share a common origin [6]. However, esophageal duplications are histologically distinct from bronchogenic cysts by having layers of smooth muscle and being lined by gastrointestinal epithelium. Most duplications are cystic and do not share a common wall with the esophagus.

While many of these lesions are detected in childhood, up to one-third are found after age 12 [7]. The majority of these lesions are located near the esophagus or trachea [6, 8]. Chest or back pain, respiratory symptoms, or dysphagia are the more common presenting symptoms. Most patients present in infancy or early childhood [9]. The presentation may be more dramatic if the lesion becomes infected, including one report of an esophageal duplication masquerading as empyema [10]. Prenatal diagnosis by ultrasound (US) has also been reported [9, 11].

Esophageal duplications can usually be seen on plain films of the chest [6]. Computed tomography with IV contrast or magnetic resonance imaging (MRI) should be obtained preoperatively to delineate the three-dimensional position of the lesion relative to the trachea, esophagus, and vascular structures in the mediastinum (Fig. 17.1). Usually, the preoperative imaging will not be able to differentiate a bronchogenic cyst from a foregut duplication, but imaging studies may suggest a neurenteric cyst. The abdomen should be imaged as well as these neurogenic cysts can extend into the abdomen or be associated with a concomitant abdominal lesion [2, 8]. In a patient with spinal dysraphism and a newly identified mediastinal lesion, a neurenteric cyst should be considered [6]. In these cases, or when there is concern about a posterior mediastinal lesion, an MRI is recommended to evaluate for communication to the spinal column [12]. Endoscopic US has been described in adults for diagnosis by identifying several muscle layers in

DOI 10.1007/978-3-642-11202-7_17

Fig. 17.1 This CT scan in an 8-year-old shows a foregut duplication cyst (*asterisk*) adjacent to the esophagus. The lesion measured 2×1.5 cm. The patient subsequently underwent right thoracoscopy with resection of the lesion (From Holcomb et al. [56]. Reprinted with permission)

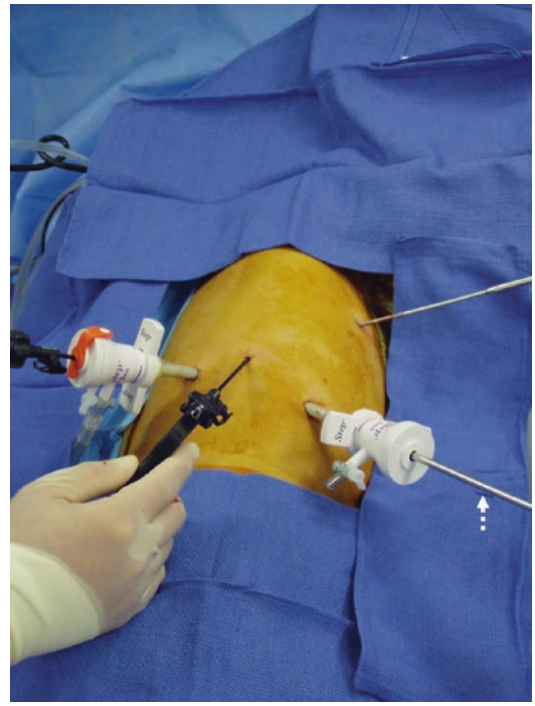

Fig. 17.2 The location of the ports for a right thoracoscopy and resection of the duplication cyst that is seen in Fig. 17.1 are depicted. As is evident, two 5 mm ports and two stab incisions are used. The uppermost stab incision is used for insertion of a diamond-shaped retractor. The *dotted arrow* identifies the camera port (From Holcomb et al. [56]. Reprinted with permission)

the cyst wall [13]. However, not all esophageal duplications possess a muscular wall. Endoscopic US may also identify the presence of esophageal communication, but this imaging modality is not available in many pediatric centers.

Ladd initially proposed cyst marsupialization and mucosal obliteration, but there is a substantial recurrence rate from this approach [6, 14, 15]. Also, although successful cyst aspiration has been described [13], recurrence after aspiration should be expected because of the epithelial lining [16]. Thus, optimal treatment of these lesions is complete resection.

There is debate in the literature about the role of observation in asymptomatic lesions in older patients. Some authors have suggested that observation is appropriate when the diagnosis is confirmed by aspiration in the asymptomatic patient [17, 18]. The cyst aspirate may be yellow colored, and/or clear, or turbid with leukocytes, macrophages, high sodium and chloride levels, and a low protein level [17–19]. Malignant degeneration in the forms of squamous cell carcinoma, adenocarcinoma, and rhabdomyosarcoma have been reported [20–26]. The relatively impressive number of reports of malignancy should be given heavy consideration, especially since there are a small number of esophageal duplications which have been followed long term. Additionally, these lesions can become infected, erode into surrounding structures, ulcerate which leads to hemorrhage, or become densely adherent within the mediastinum, all complicating subsequent resection [6, 10]. More serious complications have been documented in older patients, further arguing for resection as the preferred management strategy [6]. Therefore, most authors, including our group, recommend complete resection of all lesions at diagnosis [6–8, 12, 24].

Thoracoscopy is the preferred approach for resecting most foregut duplications. The instrument and personnel setup and operative plan must be tailored to the size and location of the lesion (Figs. 17.2 and 17.3). While posterior mediastinal lesions may benefit from a modified decubitus position and turning the patient more anteriorly (as is done for thoracoscopic repair of

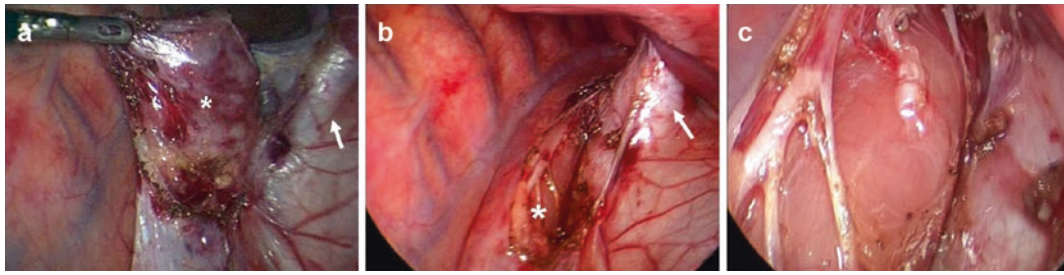

Fig. 17.3 Excision of an esophageal duplication cyst adjacent to the lower esophagus is depicted. (**a**) The cyst (*asterisk*) is being retracted away from the posterior lying esophagus. (**b**) The esophagus is identified (*asterisk*) after the cyst has been excised. In (**a**, **b**), the inferior pulmonary vein is marked with an *arrow*. (**c**) The wall of the esophagus is inspected, and the branches of the vagus nerve are seen as they course along the lateral wall of the esophagus. Histologic examination of the specimen revealed it to be an esophageal duplication cyst (From Holcomb et al. [56]. Reprinted with permission)

EA/TEF) [27], when the lesions are adjacent to large vessels, ready access by emergent thoracotomy must be considered. Additionally, duplications abutting the esophagus should be approached with adequate triangulation to repair an opening in the esophagus that might occur due to dense adherence of the cyst and the esophagus. Placement of a bougie in the esophagus can aid in palpating and identifying the esophagus. Also, it is helpful to locate the vagus and phrenic nerves early in the operation. Sometimes, decompressing the cyst can help to expose the planes of dissection [12]. Even lesions that are resected intact will often need to be decompressed to allow for extraction [28]. We have found that leaving the cyst intact is useful early in the operation to orient the surgeon as to the location of the relevant structures, followed by cyst decompression to complete the dissection around the sides and back of the lesion, which may otherwise be difficult to expose. Some authors have argued against a thoracoscopic approach when the cyst produces mediastinal shift [29]. However, we feel these lesions can be decompressed preoperatively or during the operation to allow for thoracoscopic resection. Lesions along the inferior esophagus may be easier to expose and resect from a laparoscopic approach if they invade the esophageal hiatus or have intra-abdominal extension (Fig. 17.4). The general setup and operative plan utilized for laparoscopic fundoplication or esophagomyotomy procedures provide an excellent view of this area in these cases.

If there are signs of infection preoperatively, it may be prudent to manage these lesions in a staged sequence with either needle aspiration or thoracoscopic decompression followed by interval resection after a course of antibiotics [8, 30]. Although there are no clear recommendations for the timing of definitive surgery, we have used a 2-month interval for infected cysts with good success.

Congenital Esophageal Stenosis

Congenital esophageal stenosis (CES) is a rare lesion manifesting as a discrete, intrinsic, segmental stenosis causing obstruction of the normal aboral propulsion within the esophagus. These unusual lesions occur in 1 in 25,000–50,000 live births [31]. There are three generally accepted types of stenoses: fibromuscular stenosis, mucosal membranes or webs, and tracheobronchial remnants. Tracheobronchial remnants appear to be the most common form, representing about three-fourths of cases with the fibromuscular type compromising most of the remainder [32, 33].

Symptoms usually begin early in life. In a review of the published literature, the mean age of documented symptomatology was 3.2 ± 4.5 months [34]. However, the mean age at treatment was 2.6 ± 3.0 years which underscores the difficulty in identifying these lesions as the source of symptoms. Initial barium swallow studies may not show the lesion in the neonatal

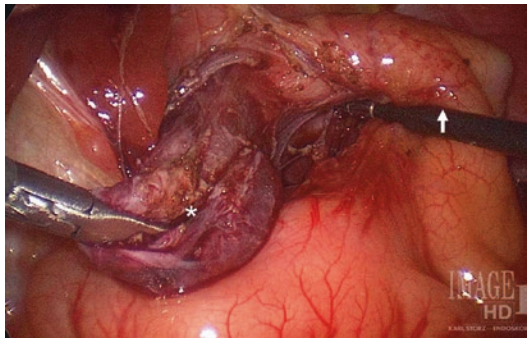

Fig. 17.4 This intraoperative photograph shows an esophageal duplication cyst (*asterisk*) being excised from the lower mediastinum utilizing a laparoscopic transhiatal approach. Notice the intra-abdominal esophagus (*arrow*) being retracted laterally

Fig. 17.5 This child presented with significant dysphagia and weight loss. An esophagram revealed marked narrowing of the mid-esophagus (*arrow*) due to congenital esophageal stenosis. This child underwent resection of the stenosis and primary repair of the esophagus (From Holcomb and Murphy [55]. Reprinted with permission)

period [35]. Symptoms include regurgitation, dysphagia, failure to thrive, hypersalivation, recurrent aspiration or respiratory tract infections, and food or foreign body impaction. There is an association between CES and EA that has been long recognized [36–40]. A review of 25 patients with CES and another congenital anomaly documented 15 of these patients also had EA [34]. When considering newborns known to have EA, the estimated incidence of a concomitant CES has been found to be as low as 0.4 % and as high as nearly 10 % [36–38], making these lesions an important consideration in babies with swallowing difficulties after EA repair. One group found that biopsy of the tip of the distal esophagus may help in the diagnosis as histologic abnormalities in the esophageal wall might be consistent with congenital stenosis [37]. The incidence of CES has been found to be higher with pure EA than with EA/TEF [37].

The diagnosis is often initially suspected on a contrast swallow study which is the primary diagnostic tool (Fig. 17.5). With rare exception, the lesion will be identified in the distal portion of the esophagus [34]. The stenosis on the esophagram may either be abrupt or tapered [33]. While it has been postulated that an abrupt stenosis more likely represents tracheobronchial remnants and a tapered stenosis indicates the fibromuscular type, these relationships are not consistent [41]. The precise etiology of the stenosis can rarely be made prior to histologic evaluation after resection. In a majority of published cases, the preoperative diagnosis was not CES, but achalasia or peptic stricture [34]. Cartilaginous tissue can be seen on endoscopic US which may be a promising future adjunct in separating tracheobronchial remnants from fibromuscular disease [42, 43].

Endoscopic dilation has become the standard management for mucosal webs, and some authors have found it to be successful with the fibromuscular type as well [35, 38, 42]. Others continue to recommend excision with end-to-end anastomosis when the tracheobronchial remnant form is present as this type is often refractory to dilation [34, 41]. Moreover, there may be a higher rate of esophageal perforation with dilation in these patients [34, 44]. Unfortunately, a selective approach based on the type of stenosis is currently not feasible due to the inability to reliably diagnose the type of lesion prior to histologic confirmation. Therefore, fluoroscopically guided balloon dilation has been recommended as the initial therapeutic maneuver in all patients with CES

by several authors [33, 37, 41]. The threshold for proceeding with resection varies among series with several authors recommending resection when symptoms persist after three dilations [35, 38, 40, 42]. Longitudinal myotomy with fundoplication has been reported for distal fibromuscular lesions [38, 42]. Perhaps endoscopic US may facilitate decision-making by identifying cartilage in the stricture as this imaging modality becomes more common in the pediatric population.

The role of gastroesophageal reflux and the potential need for an anti-reflux procedure in patients requiring resection of CES should be considered. An anti-reflux operation is recommended when the gastroesophageal junction is involved in the resection and repair [45–47]. In patients with EA, some authors have recommended the routine performance of an anti-reflux operation at the time of the initial dilation of CES [35, 37, 48]. When fundoplication is considered, some authors prefer partial wrap may be appropriate due to the concern about esophageal dysmotility [37].

Anastomotic Strictures

The most common complication after repair of EA is the development of a stricture at the anastomosis. A large consecutive series has documented the need for at least one dilation in 40 % of the patients [49]. The type and size of suture utilized in the esophageal repair have not been shown to be a factor on the stricture rate [49]. The degree of tension is linearly related to the risk of stricture and is the most powerful patient variable influencing this complication. The presence of a postoperative anastomotic leak substantially increases the risk of stricture formation. Gastroesophageal reflux has also been implicated as a risk factor.

Endoscopic dilation is the initial therapy and is often all that is required. The mean number of dilations required in EA patients who require a dilation is approximately three dilations per patient [49]. There are little comparative data to definitively delineate the best mode of dilation. We currently use radial balloon dilation under

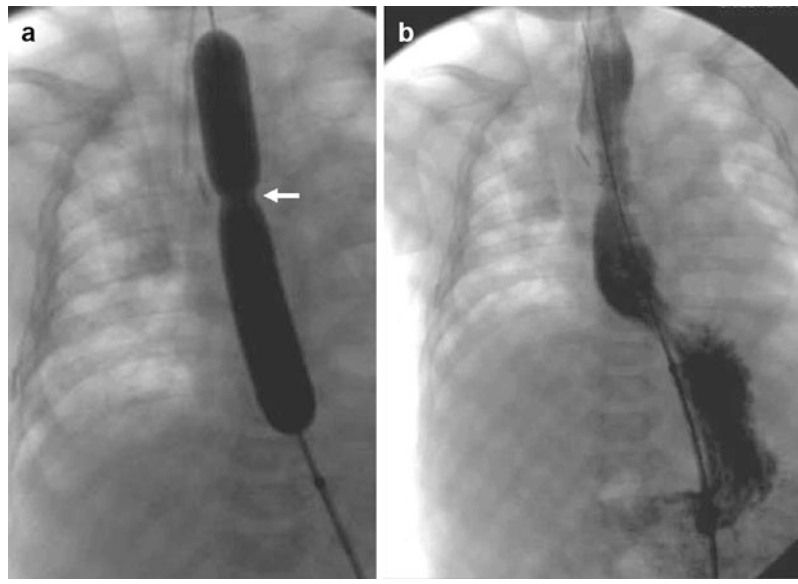

Fig. 17.6 On the *left* (**a**), this fluoroscopic image of a baby undergoing radial balloon dilation of an esophageal stricture following thoracoscopic repair of EA/TEF shows a waist (*arrow*) which identifies the most significant part of the stricture. On the *right* (**b**), an on-table esophagram was performed following radial balloon dilation of the esophageal stricture by injecting contrast material through a red rubber catheter with the patient positioned in reverse Trendelenburg. This study was performed in the patient depicted in (**a**). An esophagram in the operating room allows for assessment of the degree of esophageal dilation and assurance that esophageal perforation did not occur during the dilation

fluoroscopic guidance which offers the ability to clearly see the length of the stricture as well as the degree of narrowing prior to fully deploying the balloon (Fig. 17.6a). The responsiveness of the stricture to sequential dilation also offers some insight as to its stiffness. This author utilizes the fluoroscopy to perform an on-table esophagram after dilation and prior to leaving the operating room to evaluate for an iatrogenic perforation and to gauge the immediate success of dilation. This on-table study is performed by injecting contrast through a red rubber tube with the patient positioned in reverse Trendelenburg (Fig. 17.6b).

Recalcitrant EA strictures pose substantial challenges to the pediatric surgeon as there are no clear guidelines for the number of dilations that should be attempted prior to considering stricture resection or esophageal replacement. Topical mitomycin C has been employed in an attempt to reduce collagen synthesis and deposition after dilation [50, 51]. Similarly, injection or application of corticosteroid has been tried to prevent recurrent scarring after dilation [52–54].

Once the stricture is felt to be unsalvageable with dilation, considerable thought should be given to whether the patient is more likely to have success with focal stricture resection or with esophageal replacement.

18 Evaluation and Repair of Laryngotracheoesophageal Clefts

Katherine K. Hamming and Frank L. Rimell

Introduction

A laryngotracheoesophageal cleft (LTEC) is a fissure between the laryngotracheal and pharyngoesophageal systems. The incidence is currently estimated to be 1:10,000 to 1:20,000 births and is increasing as less severe clefts are more often recognized [18]. Laryngeal clefts are more common in male children, with a male to female ratio of 5:3. Sixty percent are associated with other congenital abnormalities, most commonly tracheoesophageal fistula and tracheomalacia [12].

While severe clefts present with early significant pulmonary compromise and gross aspiration, a high index of suspicion is necessary to diagnose less severe clefts and prevent chronic pulmonary aspiration. Early diagnosis decreases morbidity and mortality. Laryngeal clefts are often associated with tracheoesophageal fistulas and esophageal atresia. Clefts can be associated with syndromes, such as Opitz-Frias and VACTERL [15].

Embryology

There are several theories of esophageal and tracheal embryogenesis. In the classic theory, the larynx develops from the endoderm of the foregut and the mesenchymal elements from the fourth and sixth branchial pouches. Lateral ridges form on the lateral walls of the foregut and fuse in the midline in a caudal to cranial direction. This fusion forms the tracheoesophageal septum. Arrest in this fusion causes a laryngeal cleft, and the earlier the arrest, the more severe the cleft. However, this theory does not explain the origin of more common anomalies, such as tracheoesophageal fistula.

A second theory suggests that development of the trachea and esophagus occurs with a size reduction of the foregut that results in a system of folds of the foregut. A caudal fold develops in a cranial direction, and two cranial folds develop in a caudal direction. This theory is complemented by the idea that the trachea evolves as an outpouching of the ventral foregut.

In a third theory, the mesenchyme located between the digestive and respiratory systems (tracheoesophageal septum) is present initially, and the trachea descends from this tissue. Apoptotic epithelial cells have been found at the tracheoesophageal separation point, supporting an apoptotic phenomenon as part of the development of the trachea and esophagus.

Furthermore, several theories have been proposed to explain the development of tracheoesophageal abnormalities. One is intraembryonic pressure. The curvature of the cervical spine and

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_18

development of the heart cause a displacement of the esophagus under tension. The second theory is epithelial occlusion. During development, there is a solid esophageal stage. If recanalization stops, anomalies persist. The third theory is vascular occlusion, leading to vascular insufficiency of some tissue. The fourth theory is differential cell growth, in which developmental cells dysfunction, causing anomalies [12].

Anatomy/Normal Function

The larynx is a complex, multifunctional organ which, when operating correctly, directs air in and out of the trachea and food into the esophagus. This structure allows for the complex functions of breathing, swallowing, and voicing. The trachea and esophagus are separated by the tracheoesophageal septum, which superiorly includes the posterior lamina of the cricoid cartilage and the paired arytenoids cartilages. For breathing, the arytenoids cartilages abduct, allowing the vocal cords to open and air to flow through. For eating, the arytenoids cartilages adduct, closing the vocal cords to protect the trachea from food or liquid. Normally, there is approximately 3 mm of tissue in the interarytenoid area superior to the level of the true vocal cords. However, in the case of a LTEC, the interarytenoid area or posterior larynx and trachea are deficient, and the depth of this cleft determines the severity of symptoms.

Classification

The most commonly used classification system is the Benjamin and Inglis system [1], which describes four severities of cleft, types 1–4. In a type 1 cleft, a supraglottic interarytenoid cleft extends to the level of the true vocal cords. A type 2 cleft extends below the vocal cords into the upper cricoid cartilage. A type 3 cleft extends through the cricoid cartilage and possibly into the cervical trachea, and a type 4 cleft extends into the thoracic trachea and extends variably toward the carina [1]. A modification of this classification system has been published by Rutter and includes five severities, with a type 5 that extends to or beyond the carina [15]. Sandu and Monnier have subdivided the Benjamin and Inglis system in the following way: type 3a is a total cricoid cleft, type 3b is a total cricoid cleft with extension into the posterior tracheal wall to but not beyond the sternal notch, type 4a extends to the carina, and type 4b involves one of the mainstem bronchi [16].

Presentation

The presentation of laryngotracheoesophageal clefts is variable and is dependent on the severity of the cleft. Children with mild type 1 clefts may be asymptomatic, whereas children with type 4 clefts present with severe respiratory distress at birth due to direct spillage of esophageal contents into the trachea and lungs.

Some patients with type 1 laryngeal cleft are asymptomatic and do not require treatment. Others may present with stridor, hoarse cry, or recurrent pneumonia. The child may have swallowing difficulty as evidenced by cough, dyspnea, or cyanosis during feeding. Aspiration is reported in 59–90 % of type 1 laryngeal clefts. A high index of suspicion is required for diagnosing a type 1 laryngeal cleft, and the differential diagnosis includes tracheoesophageal fistula, laryngomalacia, laryngeal mobility disorder, gastroesophageal reflux, and central neurogenic swallowing disorders.

One hundred percent of types 2, 3, and 4 laryngeal clefts have aspiration due to the communication between the esophagus and trachea. Type 2 clefts will present with symptoms of aspiration and recurrent pneumonia, typically more pronounced than type 1 clefts [11]. Types 3 and 4 laryngeal clefts present with early severe respiratory distress with bronchial flooding and difficulty maintaining ventilation.

Associated Syndromes and Malformations

Laryngotracheoesophageal clefts are associated with other congenital abnormalities in 58–75 % of cases [12, 13, 17]. The majority of these are

gastrointestinal anomalies and include esophageal atresia, tracheoesophageal fistula, imperforate anus, false rotation or failure of intestinal rotation, meconium ileus, and microgastria.

In a study of 74 patients with type 1 or 2 laryngeal clefts, Rahbar found multiple congenital anomalies in three patients. The diagnoses included fetal alcohol syndrome, trisomy 21, and CHARGE [14].

Kawaguchi et al. [9] studied nine patients with clefts involving the entire trachea or extending into the mainstem bronchi. They found that all nine had severe gastroesophageal reflux, six of nine had microgastria, two of nine had Meckel's diverticulum, two of nine had intestinal malrotation, and two of nine had abnormally enlarged left lobe of the liver.

Patients with LTEC can also have genitourinary anomalies, including hypospadias, kidney malformation, inguinal hernia, or testicular ectopia. Cardiac anomalies include coarctation of the aorta, transposition of the great vessels, patent ductus arteriosus, and ventricular septal defect. Reported craniofacial anomalies are cleft lip and palate, choanal atresia, micrognathia, glossoptosis, hypertelorism, dysmorphia, and anomalies of the external ear. And tracheal, bronchial, and pulmonary anomalies include short trachea, bronchial or tracheal stenosis, and abnormal lung separation or hypoplasia.

These associated anomalies are sometimes part of an associated syndrome. Syndromes associated with LTEC include G syndrome or Opitz-Frias syndrome, Pallister-Hall syndrome, VACTERL association, and CHARGE syndrome.

Patient Evaluation

In a patient with breathing or swallowing difficulties, initial workup may involve chest radiograph, speech therapy, swallow evaluation, or swallow study. A chest x-ray may show evidence of aspiration pneumonia. A contrast video swallow study will show immediate passage of barium into the trachea, but tracheoesophageal fistula and LTEC can be difficult to distinguish.

The diagnosis of laryngeal cleft is made with microlaryngoscopy and rigid bronchoscopy. The vocal cords, supraglottis, and trachea are topically anesthetized with lidocaine. A rigid telescope or bronchoscope is advanced through the larynx through the vocal cords and into the trachea to examine for other anomalies. Suspension laryngoscopy can be performed for better visualization and measurement of the cleft. The presence of a laryngeal cleft is examined by palpation of the interarytenoid space with a laryngeal probe or end of the bronchoscope. Instruments for measurement of the depth of the cleft are available [2]. It is important to perform a full airway evaluation, due to the high rate of synchronous anomalies in 50–60 % of cases [12].

Further, once a laryngeal cleft is diagnosed, systematic workup of other associated anomalies is necessary, including genetics consultation, cardiac ultrasound, renal ultrasound, and spine radiographs [5]. Given the frequency of multiple anomalies in children with LTEC, a multidisciplinary approach is necessary.

Treatment

Treatment of most laryngeal clefts is surgical. However, in a mild type 1 laryngeal cleft, medical management should first be optimized, including treatment of reflux and thickening feeds. If the patient is not aspirating with thickened feeds and is gaining weight appropriately, medical management may suffice.

Many patients with laryngeal cleft present with some degree of airway compromise due to aspiration of gastric secretions. A tracheostomy is necessary for most severe laryngeal clefts. A G-tube is also often necessary, as the baby will not be able to be fed orally for some time. Oral stimulation is important during the period of G-tube feeding to help minimize oral aversion once the patient can eat.

Many children with LTEC have congenital syndromes or associated comorbidities. These should be worked up and prioritized with a multidisciplinary approach.

Surgical repair of laryngeal clefts is performed through either an endoscopic or open approach. Endoscopic repair is indicated for type 1 and some type 2 clefts. There have been reports of

endoscopic repair of type 3 clefts [3, 13]. Described techniques include incision with cold steel or CO2 laser in the interarytenoid area, development of anterior and posterior tissue flaps, and placement of sutures to create a few millimeters of tissue in the interarytenoid area above the true vocal cord level.

A more recent technique for type 1 laryngeal clefts is injection laryngoplasty. Various materials have been used, including Gelfoam, Radiesse Voice Gel, and Cymetra [4, 6, 8]. The material is injected into the apex of the interarytenoid notch until fullness and blunting of the interarytenoid notch is seen [6]. Some advocate use of this technique is to determine which patients with mild clefts will benefit from surgical repair [10].

Open approaches are appropriate for type 3 or type 4 clefts, any cleft that cannot be accessed endoscopically, or any cleft that has failed endoscopic repair. These are performed through either a cervical or cervicothoracic approach. Three cervical approaches have been described: lateral approach with lateral pharyngotomy, lateral approach with posterior pharyngotomy, and anterior translaryngotracheal approach, which is the most commonly used.

The anterior laryngotracheal approach provides excellent exposure of the cleft, minimal neck dissection, and no risk to the recurrent laryngeal nerve. A horizontal neck incision is made, preferably in a skin crease, at the level of the cricothyroid membrane. Tissues are divided in the midline, the thyroid gland is identified and divided, and the anterior airway is exposed. A standard laryngofissure is performed, the length of which is determined by the length of the cleft. The cricoid and first two tracheal rings are divided in the midline. Midline can be confirmed endoscopically with simultaneous bronchoscopy. The thyroid cartilage is then divided, taking particular care to exact midline at the anterior commissure. Sutures may be placed at the anterior commissure to the thyroid cartilage to assure exact reapproximation.

Severe LTECs are life-threatening anomalies with high incidence of failed surgery due to the presence of respiratory and gastric secretions bathing the wound and due to directly opposing suture lines. Some sources advocate the use of vascularized tissue such as sternocleidomastoid flap [9] or tibial periosteum [7] as interposition between the esophageal and tracheal layers, whether at initial repair or for repair of a subsequent fistula. These patients can have refractory gastroesophageal reflux disease (GERD), which can be treated by gastric transection if necessary. Finally, they can also have significant tracheomalacia that may require a bifurcated tracheostomy tube [9].

Outcomes

The outcome of laryngotracheoesophageal cleft repair is highly dependent on the severity of the cleft. Grade 1 clefts can be present without the need for surgical intervention. The incidence of this is unknown. Grade 1 and some grade 2 clefts can be repaired endoscopically with good success. Grade 3 and 4 clefts require open repair, may require cardiac bypass or extracorporeal membrane oxygenation support, and have an associated mortality. The presence of congenital syndromes or comorbidities decreases the success rate for all types of LTECs.

Rahbar reported overall postoperative improvement following endoscopic repair in grade 1 and grade 2 clefts in children with no comorbidities of 80 % and 72 %, respectively. In children with comorbidities, outcomes were worse with improvement in 70 % and 60 %, respectively [14].

Cohen has published on injection laryngoplasty [6]. In a study of 16 patients with type 1 laryngeal clefts, the mean duration of symptom improvement was 3.3 months (Gelfoam 2.3 months, Radiesse Voice Gel 3.7 months). Five patients went on to have definitive surgical repair.

The largest published experience with severe LTECs is from Great Ormond Street Hospital [9]. Over a 10-year period, they treated nine patients with grade 3 or 4 clefts. The group included seven boys and two girls. The mean age at operative repair was 119 days. All nine survived the immediate postoperative period, and five were alive at time of publication at ages 9–21 years.

These patients had a significant number of comorbidities. The most common disorders were

gastrointestinal – all type 4 and one type 3 had microgastria; nine out of nine had documented severe GERD; two out of nine had Meckel's diverticulum; two out of nine had intestinal malrotation; two out of nine had enlarged left lobe of the liver. Other anomalies present in the patients with severe clefts included the following: two out of nine had cleft palate; one out of nine had left congenital diaphragmatic hernia and grade III pulmonary atresia; and one out of nine had left lower lobe pulmonary sequestration. Five of the nine patients had significant hearing loss [9].

Conclusion

Laryngotracheoesophageal clefts are an interesting embryologic anomaly with a wide variety of severity. Severe clefts present immediately at birth with severe respiratory compromise due to bronchial flooding with gastric secretions. These patients typically require tracheostomy, G-tube, and early surgical repair. The symptoms of less severe clefts can range from asymptomatic, to aspiration, to respiratory compromise. Type 1 laryngeal clefts require a high index of suspicion for diagnosis and is diagnosed by microlaryngoscopy and bronchoscopy. LTEC is often associated with comorbidities or syndromes, so workup and care should be coordinated.

19 Postoperative Management of Routine Esophageal Atresia Cases

Christopher G. Turner and Russell W. Jennings

Introduction

Postoperative care is a critical component of complete surgical management. Compared to the relatively short preoperative preparation and the procedure itself, it is the longest stage in the sequence from diagnosis to therapy to return of health. Success of the operation and recovery of the patient depend heavily on the level and quality of the postoperative care. Operations on increasingly complex congenital diseases in both term and preterm infants have resulted from refinements in operative technique and, more importantly, advances in the surgical and anesthetic management of newborn infants and the coordination of this care in neonatal intensive care unit (NICU).

In reviewing the routine postoperative management of patients with esophageal atresia, recovery will be divided into three phases: (1) the immediate postoperative phase involving stabilization and recovery from anesthesia, (2) an early postoperative period involving the remainder of the hospitalization, and (3) a late phase after hospitalization. Care during the first two phases is directed at maintenance of homeostasis, treatment of pain, and the prevention and early detection of complications. Many principles of postoperative care in the esophageal atresia population are common to other areas of surgery. This chapter, therefore, will focus on operations on the esophagus and trachea including respiratory care, chest tube management, and the initiation of enteral nutrition. Complications will be reviewed in detail in other chapters but routine postoperative screening will be included here. It is important to note that many details of postoperative care in these patients are not standardized across institutions and a significant variation exists.

Immediate Postoperative Period

The major factors leading to early complications and death after esophageal atresia repair include prematurity, associated congenital heart disease, pulmonary complications, and anastomotic leaks with sepsis. The NICU has both the specially trained staff and equipment for early detection and treatment of these problems. The patient should be directly transported to the NICU and should be accompanied en route by a physician and other qualified attendants. The anesthesiology team generally has primary immediate responsibility for cardiopulmonary function, while the surgical team is responsible for the

surgical wound and the other components not directly related to anesthesia. Transition of care to the intensive care unit is critical.

Postoperative Orders

Detailed treatment orders are required to direct postoperative care, and all members of the team must be aware of the important elements. The transfer of the patient from the operating room to the NICU is a tenuous period with the possibility for miscommunications as well as critical disturbances in the patient's condition. Patient care orders should describe for the nursing staff the diagnosis, the operation performed, and the patient's condition. All monitoring and therapeutic measures should be carefully detailed. Unusual or important orders should also be communicated to the nursing staff orally. Errors in postoperative orders, including medication errors and omission of important orders, are diminished by electronic order entry systems that contain postoperative order sets. Studies have shown that surgical checklists that involve team communication improve outcomes [1, 2].

Monitoring

The successful management of any critically ill infant requires the ability to measure and adjust appropriately the major physiological parameters. Infants are exquisitely sensitive to small changes in these parameters and, due to their size, possess the smallest reserve capacities of any group of patients in the hospital. As a result, invasive and noninvasive monitoring is an important element in management during the postoperative period. By necessity, the NICU has a host of technologies that should be used consistently and intelligently. Minimum requirements should include continuously recorded EKG, rectal temperature, blood pressure, respiratory rate, and hourly urine output. In those patients with compromised cardiorespiratory function, more invasive respiratory and hemodynamic monitoring may be necessary, including transcutaneous blood gas monitoring and interval blood gas measurements.

Temperature Management

Heat loss must balance with heat production in order to maintain a normal body temperature. Due to a large body surface to body weight ratio, the neonate is susceptible to heat loss and temperature imbalance. Mechanisms of heat loss include conduction from direct contact with cold surfaces, convection by the cooling effects of air currents on exposed skin, radiation to nearby objects such as the incubator wall, and evaporation of fluid from the skin and respiratory tract. As poikilotherms, preterm infants will not defend their body temperature and are particularly vulnerable. Cold injury can cause acidosis, hypoglycemia, increased oxygen consumption, and weight loss. In the postoperative period, the patient must be protected from heat loss. Conductive and convective heat loss can be reduced with the use of an incubator with an internal temperature of 32–36 °C, while radiation can be reduced with double-glazed incubators and evaporation can be reduced with humidification. Radiant warmer beds are less effective in protecting against heat loss but provide better access to the infant.

Neurologic Considerations

Newborns do experience pain after surgical procedures and should receive adequate analgesia [3, 4]. In the ventilated patient, options include morphine at a dose of 20–40 μg/kg/h by continuous intravenous infusion or fentanyl at a dose of 5–10 μg/kg/h.

Cardiac Considerations

Due to a relatively immature myocardium, newborns have a limited capacity to increase stroke volume, and their cardiac output is mainly rate dependant. When hypovolemia causes low

output, a reduction in elevated heart is the best guide to the adequacy of volume replacement, rather than blood pressure, which can be maintained at the expense of increasing heart rate and vasoconstriction.

The initial management to the infant with a low cardiac output indicated by tachycardia, vasoconstriction, oliguria, and hypotension is to increase preload by volume expansion with 10–20 ml/kg of plasma or albumin and then to reassess. Central venous pressure measurements may be useful in this context. Failure to raise output by increasing preload is an indication to attempt to decrease afterload or increase contractility by the use of vasoactive drugs.

Due to the common association with congenital cardiac anomalies, many of these patients will have complicated cardiac physiology requiring additional medical and surgical management.

Pulmonary Considerations

Unless there is a contraindication such as a congenital abnormality or injury to the nasal area, infants should be managed with nasotracheal tubes rather than oral tubes. Nasotracheal tubes are more comfortable and secure with attachment to the face and upper lip. The distal tip of the tube should reach only to the manubrium on the chest film in order to avoid entry into a main bronchus and single lung ventilation. The proximal end of the tube should be clear of the nose in order to avoid excoriation of the skin and erosion of cartilage, which can occur rapidly with pressure. The size of the tube should be adequate to avoid a significant leak under positive pressure but create a complete seal. Small tubes which leak at too low a pressure make positive pressure ventilation difficult, while large tubes with high leak pressure can cause airway pressure necrosis leading to subglottic stenosis, tracheal stenosis, and vocal cord granulomas, which may necessitate tracheostomy. Depending on the size of the child, 3–4 mm tubes may be used for newborns. Smaller tubes may be used for premature infants but are more susceptible to blockage from secretions.

Assiduous oral and pulmonary toilet is extremely important in the postoperative period in order to minimize the volume of swallowed saliva, maintain patency of the endotracheal tube, and prevent atelectasis. Infants should be kept in a semi-upright position. To avoid hypoxia and bradycardia, all patients should be inflated with 100 % oxygen by manual hyperventilation before suctioning. The catheter should not be large enough to occlude the lumen of the tube, which would create negative pressures and atelectasis. End-hole catheters are preferred to side-hole catheters that can injure the respiratory mucosa. Suction should be applied no longer than 10 s and only while the catheter is being withdrawn. Sterile technique with surgical gloves and a sterile catheter is important to avoid introduction of pathogens deep in the bronchial tree. Bradycardia is almost always caused by hypoxemia and should be an immediate indication to stop suction and begin manual ventilation. Precautions should be taken to protect the fresh esophageal anastomosis and fresh tracheal closure from the potential trauma of suction catheters. A sign posted at the bedside should display the distance to the esophageal anastomosis and the distance to the end of the endotracheal tube. Suction catheters should be directly measured and marked before use in order to avoid insertion to the depth of the esophageal anastomosis or the tracheal closure.

Humidification of the inspired air is a useful adjunct to pulmonary care. Too little humidification can cause dry secretions to block the endotracheal tube. Too much humidification, however, can cause condensation and the absorption of considerable amounts of water. The goal of optimal humidity is to provide fully saturated humidified gases (44 mg/L H_2O) at a temperature of 37 °C at the endotracheal tube. The temperature of the heated water bath type humidifier must be raised above the goal, to approximately 40 °C, to deliver the appropriate temperature at the endotracheal tube. Heated electric coils inside the inspiratory line can reduce heat loss as well as condensation.

The goal of ventilator management is to maintain normal gases with the lowest possible inspired oxygen and airway pressures. Generally,

infants with esophageal atresia have normal respiratory compliance and airway resistance. With a pressure-preset ventilator, set parameters include a PIP of 10–20 cm H_2O, a PEEP of 4–5 cm H_2O, a tidal volume of 6–8 mL/kg, a rate of 30–40 per minute, a FiO_2 of 0.25–0.35, and an inspiratory to expiratory ratio of 1:2 or 1:3. The adequacy of gas exchange must be confirmed with arterial blood gas samples. Adequate ventilation may compete with the infant's own efforts to breath. In the absence of pain, hypoxia, or acidosis, ventilation may be improved with muscle relaxants.

Chest tubes are used to manage fluid and liquid that accumulates in the chest, and may be used to monitor and control esophageal leaks.

Gastrointestinal Considerations

In the immediate postoperative period, the child should strictly have nothing by mouth. The stomach should be decompressed by continuous drainage of a nasogastric or gastrostomy tube. In the case of a nasogastric tube, the surgeon should place it in the operating room under direct vision to avoid the risk of injuring the fresh esophageal anastomosis. A nasogastric tube should never be passed blindly postoperatively.

Because of tension on the lower esophagus, infants after esophageal atresia repair are at increased risk of gastroesophageal reflux. The esophageal anastomosis will be more likely to stricture if irritated by acidic gastric contents. Patients, therefore, should be treated empirically with medications such as H1 acid blockade and possibly promotility agents.

Fluid Management

Restorative operations can cause significant disturbances in fluid and electrolyte status. Maintenance of normal balance is further complicated by the newborns immature renal system. Glomerular filtration rates are lower in the preterm compared to the term infant. Fluid balance depends on the balance between intake and fluid loss from the skin, urine, and stool. Full maintenance fluid requirements with dextrose/saline solution for the non-ventilated patient start at 60 ml/kg/day in the first day of life and increase to 100–150 ml/kg/day by 1 week of life. Due to humidification of the respiratory tract, it is common practice to give an infant on a respirator 70 % of the calculated maintenance requirement. Losses due to nasogastric suction should be replaced with normal saline. Normal electrolyte requirements are 2–3 mmol/kg/day of sodium and 3–4 mmol/kg/day of potassium. A urine output of more than 1 ml/kg/h is considered adequate following surgical procedures in the newborn.

Antibiotics

Broad-spectrum antibiotics should be continued during the perioperative period. Antibiotics should be adequate to cover both oral and skin flora as both are exposed to the wound during surgery.

Early Postoperative Period

After the initial stabilization and avoidance of acute critical care complications, the focus turns to complete recovery and independence from the many medical supports of the intensive care unit. In the esophageal atresia patient, this requires extubation, removal of all drains, and commencement of oral feeds. During this period of time, there are specific complications to monitor and prevent, specifically esophageal anastomotic leaks, esophageal strictures, and recurrent tracheoesophageal fistulas.

Ventilator Management

The use of long-term paralysis and mechanical ventilation while maintaining neck flexion has been advocated by some to minimize the risk for anastomotic disruption when there is severe tension [5–8]. The rationale is to prevent disruptive force at the anastomotic site by flexion of the

neck and paralysis of the striated muscles in the proximal part of the esophagus [6, 9]. However, in our experience, the ventilator should be weaned as quickly as possible to minimize trauma from positive ventilator pressure or direct contact with the endotracheal tube. Caution should be taken with the actual extubation. Replacement of the endotracheal tube may damage or rupture the trachea at the site of the fistula closure. Ideally, the infant should be able to breathe spontaneously on the ventilator. Furthermore, the need for narcotics to control pain should be low to avoid depressed respiratory drive and apnea. In the unavoidable event of reintubation, an experienced operator should place the tip of the endotracheal tube just beyond the vocal cords. Passage down the esophagus could result in anastomotic disruption, while passage too far into the trachea could result in tracheal laceration.

Drain Management

The drain in the chest should be maintained until a barium swallow demonstrates the integrity of the esophageal anastomosis. A fistula may be identified directly on the barium swallow or may be inferred from the appearance of saliva in the chest tube. Alternately, an extrapleural effusion on chest radiographs may be associated with anastomotic leakage. In order to protect the anastomosis, the chest tube should remain if a significant fistula appears. The vast majority of esophageal leaks controlled by chest tube drainage should spontaneously seal with time.

Diet Advance

In some centers, feeds are started a day or two after the surgery in patients with a gastrostomy tube. Alternately, feeds are started through a nasogastric feeding tube that was placed at the time of the operation. During feedings, all patients should be flat with the head of the bed elevated and monitored closely because of the high prevalence of gastroesophageal reflux. Oral feedings are then initiated only after a normal barium swallow conducted 5–7 days after the operation.

In our center, nutrition is provided parenterally for the first 7–10 days. Feeds via nasogastric tube are initiated on postoperative day 1 at 1 cc/h and increased as tolerated. If there are no signs of a leak clinically during the first 7–10 days, the child is fed orally. A postoperative esophagram to rule out leaks or gastroesophageal reflux is obtained prior to the first oral feeding only if indicated. Feedings are advanced as tolerated and the patient is discharged home when they are at goal.

Because the suck reflex is not adequate until 34–36 weeks gestation, the nasogastric tube should be removed only after oral feedings are established for infants younger than 36 weeks gestation. The presence of a transesophageal feeding tube exacerbates the reflux of gastric contents and justifies keeping the patient in an intensive care unit.

Management of Associated Anomalies

A second anomaly occurs in nearly half of babies with tracheoesophageal anomalies. Many organ systems may be involved: most notably the complex of vertebral, anorectal, tracheoesophageal, radial limb, and renal. It is beyond the scope of this chapter to review the diagnosis and management of these complicating congenital defects. It is, however, important to note that they may occupy much of the management time and effort in the early postoperative period.

Anastomotic Leaks

There are several specific signs of an anastomotic leak such as saliva in the chest tube and gas bubbles in the mediastinum. There are also several nonspecific signs such as fever, elevated white blood cell count, pneumothorax, and shock. There is a general correlation between the time of onset of the leak and its seriousness. Earlier

leaks, occurring in the first 3 days, are more significant. Most of these can be treated nonoperatively, but some surgeons may resort to a cervical esophagostomy. Later leaks, occurring between 3 and 10 days from the operation, are less significant and can usually be treated by chest tube drainage, antibiotics, and hyperalimentation. Later in the hospital course, it is important to note that leaks make an anastomotic stricture more likely, probably as a result of the local inflammation and scarring.

Esophageal Strictures

Anastomotic strictures are the most common postoperative problem in most series. Anastomosis of a large upper esophageal pouch to a tapered thin-walled lower esophageal segment under tension predisposes to stricture formation. Swallowing by the infant may dilate the narrow anastomotic site and diminish the size discrepancy. Some surgeons prefer prophylactic dilations in the postoperative period, while others dilate only when needed. Overall, 20–35 % of patients require several dilations regardless of whether one or two prophylactic dilations were done. In some programs, the infant returns at 6 weeks and 3 month after the operation for dilation with rubber dilators in the clinic. Additional dilations are performed as needed, and if more than three are required, the infants may be considered to have a recalcitrant stricture. In the absence of reflux, these dilations are usually successful. However, when reflux is present, fundoplication may restore their efficacy [10, 11].

Recurrent or Unsuspected Congenital Tracheoesophageal Fistulae

In the early postoperative period, tracheoesophageal fistulae may be identified either because they have recently developed or they were not previously diagnosed. Symptoms that suggest a tracheoesophageal fistula are the same as those in the preoperative period, and include wheezing, coughing, choking, cyanosis, apnea, and recurrent pneumonias. These symptoms overlap with other possible complication of stricture, gastroesophageal reflux disease, and tracheomalacia. As a result, suspicion should be high, and a child with a history of repaired esophageal atresia and these nonspecific symptoms should have a complete evaluation to rule out a tracheoesophageal fistula [12].

A missed congenital upper-pouch tracheoesophageal fistula will be revealed with the initiation of postoperative feeds and be associated with coughing, choking, and signs of aspiration without signs of mediastinal infection and inflammation. A recurrent fistula, on the other hand, may appear years after the operation, when perhaps a small chronic abscess develops from a leak or erosion of sutures between the esophageal and tracheal repairs. The severity of the inflammatory process determines the presence of fever, elevated white blood cell count, and/or mediastinal air.

Evaluation should include a contrast study and endoscopy to discover a recurrent fistula at the anastomotic level or a missed congenital fistula at a higher level. If a fistula is identified, surgical repair is warranted. No delay is necessary unless there are additional medical problems that need to be stabilized. After separation and ligation of the tracheoesophageal fistula, a flap of tissue can be inserted between the trachea and the esophagus to reduce the chance of recurrence. An approach through the old incision allows for only one scar, provides direct access to the problem, and does not introduce the potential for infection into the other side of the chest. An approach through the neck is often preferable for missed congenital upper-pouch tracheoesophageal fistula.

Late Postoperative Period

After discharge from the hospital, the major complications that need to be monitored involve the esophagus and the trachea. Here we will review gastroesophageal reflux, tracheomalacia, and associated lower esophageal stenosis.

Gastroesophageal Reflux

Gastroesophageal reflux disease (GERD) commonly occurs in the postoperative esophageal atresia patient as a result of the combination of lower esophageal dysmotility, tension on the gastroesophageal junction, and chalasia of newborns. GERD is problematic because it stimulates anastomotic stricture formation and esophagitis, as well as producing pulmonary problems and apneic episodes with aspiration of gastric contents [13–16]. Evaluation is appropriate either with repair of a long gap (>2 cm) due to greater tension on the gastroesophageal junction, when signs of a stricture appear, or when a stricture recurs promptly after dilation. A contrast study should be the primary evaluation, but, if negative, pH monitoring and radio-labeled technetium swallow studies may be indicated.

Infants with GERD are initially treated medically with prone positioning, elevated head of bed, and thickening of feeds [17]. The reflux should improve with the passage of time [18]. If medical treatment does fail, a Nissen fundoplication or other anti-reflux procedures should be considered. However, results are not uniformly beneficial because the reflux can recur and the dysphagia, which is intrinsic to the atresia repair, can be aggravated [19, 20]. Persistence of Barrett's esophagus after anti-reflux surgery suggests that this particular problem should be addressed early and followed closely for life [21].

Tracheomalacia

Some degree of tracheomalacia is usually present in patients with esophageal atresia and is more common when a tracheoesophageal fistula is also present [22–24]. Mild forms cause occasional noisy breathing with the characteristic barky cough (TOF cough), while more severe forms can cause life-threatening apneic and bradycardic spells. More severe grades may also prevent the infant from being weaned from the ventilator or may lead to recurrent pneumonia [25].

Diagnostic studies include lateral airway fluoroscopy, cine CT of the airways, and dynamic bronchoscopy. The presence of the innominate artery will produce characteristic anteroposterior narrowing just above the carina. The spectrum of tracheal involvement may include a localized region or be more generalized. With severe forms, the anterior and posterior tracheal walls will collapse and occlude the airway during expiration or coughing [26].

As with GERD, symptoms generally improve over time. However, with severe apnea or failure to wean the ventilator, surgical therapy may be necessary. The initial operative approach is typically an aortopexy with elevation of the ascending aorta artery, which will place tension on the trachea and reduce the risk of collapse. In severe cases, this can be a critical therapeutic maneuver [25, 27–29].

Associated Lower Esophageal Stenosis

Lower esophageal stenosis is a rare association that may not be discovered until 6–12 months of age because the symptoms are attributed to common feeding problems, anastomotic problems, or lower esophageal dysmotility. If the condition is suspected at the time of repair on account of an unusually large lower esophageal segment, a contrast study should be performed when appropriate. Obstruction in the distal portion of a dyskinetic esophagus increases proximal esophageal dilation and results in further dysfunction. If the obstruction tapers and results from fibromuscular hyperplasia, conventional dilation should be adequate. If the obstruction is discrete and results from tracheobronchial remnants or a fibromuscular shelf, resection with reanastomosis should be performed to prevent further increases in esophageal expansion and dysfunction.

Conclusion

Postoperative management is critical in the successful recovery of patients with esophageal atresia. This care includes the immediate acute care through to the chronic complications later in life.

Part V

Repair of Long-Gap EA: The Difficult End of the Spectrum

The Long-Gap Esophageal Atresia Problem

20

John E. Foker

Introduction

The repair of the most common form of esophageal atresia (EA) with a tracheoesophageal fistula (TEF) from the lower esophageal segment to the trachea is often a pediatric surgeon's favorite operation. Beginning with a fatal lesion if untreated, the repair requires skill and judgment, and, as an added bonus, the long-term outlook may be essentially normal. For the majority of EA/TEF infants, the operative result is entirely satisfactory and pleases both the families and the surgeon.

The EA spectrum, however, is broad in terms of the severity of the lesions and leads to treatment approaches which are equally wide. For the surgeon, the difficulty with the repair arises in rough proportion to the length of the gap between the esophageal ends. As the gap increases, the likelihood of a prompt and satisfactory primary esophageal repair decreases and often puts the patient on a complicated and difficult road.

A long gap may also be acquired. When an initial repair of an EA/TEF defect has failed, a considerable space may be left between the esophageal segments, particularly if the upper pouch is converted to a cervical ("spit") fistula. These patients now have the residual difficulties of an unsatisfactory initial operation added to the considerable distance between the esophageal ends.

It has long been recognized, however, that an esophagus-only repair is best [1, 2]. This realization has been the driving force to achieve a primary repair despite the problems long gaps pose for surgeons. The value of a true primary repair lies in its much closer approximation of normal with the likelihood of improved short-term and longer-term results. The important consequence of a long gap between segments, either initially or secondarily, however, is that a true primary repair becomes very difficult or, often, impossible. As a result of the problems and treatment difficulties created, long gap (LG) EA has received a great deal of attention.

Definition

The definition of a long gap is not settled, although it has been proposed that it begins at a preoperative gap over 2 cm [3–5]. The definition will remain elusive, however, because it is subjective in nature. When planning an EA repair, what will be considered to be a long gap is

affected by many factors not easily quantified. The patient's size and condition, the anatomical variations present, the perceived tissue quality, and, very importantly, the experience of the surgeon will affect the judgment. All of these will weigh on any surgical decision; consequently, it does not seem helpful to try and define "long" any more precisely than a gap which may prevent a primary esophageal repair. Any definition, moreover, will only be the roughest of guides because in the operating room, the gap length will be in the eye of the beholder [6].

Even though what constitutes a long gap remains unsettled, the term ultra-long gap has also been used. An ultra-long gap has been proposed to be at least 3.5 cm long, at least in part to define a gap that is beyond a primary repair, a length generally considered too long for a true primary repair [7, 8].

What gap length may prevent a primary repair has also changed with the increasing realization that some degree of tension may not preclude a satisfactory anastomosis. Although what is considered a repairable gap length may have increased, experience still suggests that repairs are not completely reliable much beyond 3.0 cm. Certainly, whatever length might be considered repairable, it would not extend to the far end of the 3.5–6 cm range for which it has been claimed that pediatric surgeons "would almost always perform a primary anastomosis…" [9]. And even only "in some cases" would "gaps greater than 6 cm…not be amendable to primary repair" [9]. These statements are very misleading because that author still considered it a primary repair if the stomach was pulled part way up into the chest so the esophageal segments could be joined together (Coran AG (1996), Personal communication).

We believe, however, that a true primary repair, defined as an esophageal repair without myotomies and with the stomach left below the diaphragm where it belongs, should be the goal [10]. These requirements will provide the configuration to allow an outwardly normal long-term outcome to be realized. The partially intrathoracic stomach, however, is quite unsatisfactory for both the short and long term, principally because of obligatory gastroesophageal reflux (GER) and its predictable consequences. A true primary repair, in contrast, may have GER and/or strictures, but these can be treated and not compromise the long-term results.

The Formation of Long-Gap EA

What determines the gap length when EA occurs is not well understood, although there are biomechanical factors that logically help explain it. The most important factor affecting the gap length is whether or not the original maldevelopment results in the lower esophageal segment being attached to the airway. This is the most common form of EA (type C), and it typically has a shorter gap because the lower segment will necessarily lengthen as the fetus grows (Fig. 20.1). As a result, the common form of EA with a lower TEF is usually amendable to initial primary repair. Occasionally, however, there are structural differences in EA/TEF which may affect the surgeon's impression about the ease of repair. If the lower esophageal segment enters the right or left main stem bronchus or even straight into the carina rather than up along the back of the trachea, the gap may seem too long [11]. A fistula from the upper segment to the trachea (type B) has the opposite effect of a lower TEF, because it decompresses the upper pouch reducing the growth signal, so it is smaller, and higher, and the gap is longer (Fig. 20.1). These variations in anatomy may affect the judgment about the gap length and the suitability for a true primary repair. The surgeon, of course, should be circumspect about true primary repairs when the anatomy is not entirely suitable.

In "pure" EA without a lower TEF (type A), a gap is usually present between the upper and lower esophageal segments rather than the atretic segment being a solid cord (Fig. 20.1). When the lower segment is not attached to the airway, its growth in the fetus is quite variable and the eventual gap may be very long. Occasionally, a cord is present from the end of the lower segment to the airway or up into the posterior mediastinum which usually to encourages growth of the lower

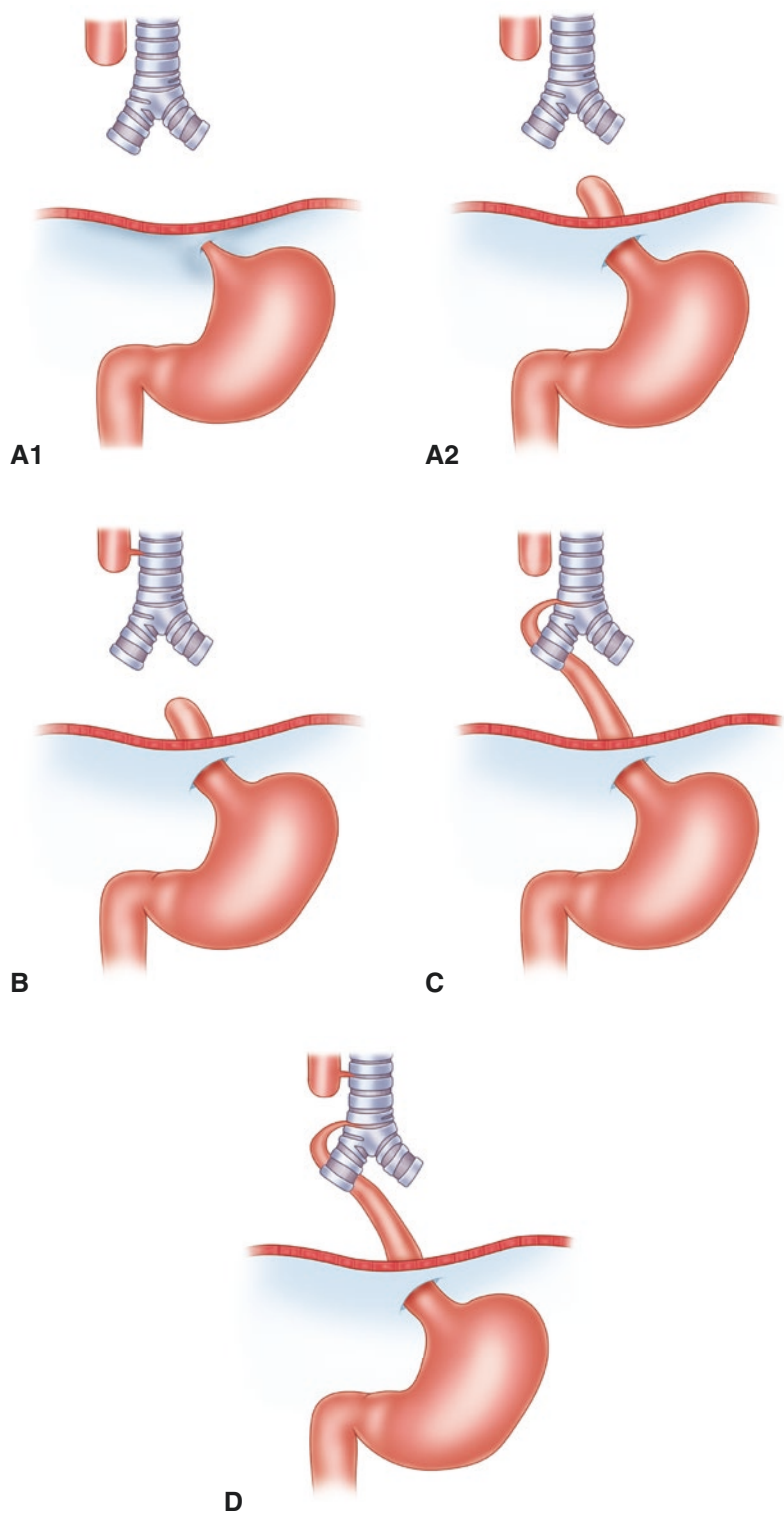

Fig. 20.1 The pathological spectrum of esophageal atresia (EA). Panels (**A**–**D**) illustrate the major subdivisions within the virtually continuous EA spectrum. Depicted are the upper and lower esophageal segments, diaphragm, stomach (not to scale), and proximal tracheobronchial tree. For repair of EA, the major consideration is the length of the gap between the upper and lower segments. Considerable variation exists within the types, as depicted in type A, where the lower segment may not be discernable (A_1) or may reach above the diaphragm (A_2). Decompression through a fistula into the trachea seems to result in a smaller upper pouch and may increase the gap in type B. The most common form (~75%) has a tracheal fistula from the lower segment, and this connection results in adequate length and a shorter gap (type C). A tracheal fistula from both segments adds complexity, but the gaps are not long (type D). A fistula-only form has no atretic segment and is not shown

esophagus. Even when there is not a cord, the lower end may be relatively long and reach well above the diaphragm (type A_3); however, in other cases, only a tiny 3–4 mm-long primordium may be present and located well below the diaphragm, leaving a very long gap (type A_1) (Fig. 20.1). Why these differences in gap length occur is not always clear but presumably is related to greater or lesser biomechanical forces which stimulate growth of the lower segment [12].

The prime mover in the growing of the esophagus is the spinal column with its growth plates which provide the tension through the varying attachments to the esophageal segments. Tension is translated into intracellular signals producing growth. A large body of basic studies have provided an understanding of the many molecular mechanisms involved in cell growth stimulated by these biomechanical factors [12]. The importance of axial tension in producing esophageal growth was confirmed by inducing growth with traction sutures to solve the long-gap problem [10, 13].

There are also several associations found in LG-EA which may contribute to the gap length. EA associated with an aortic arch anomaly including an aberrant origin of the subclavian artery, either right or left, often has a long gap [14]. The aberrant arteries course between the upper and lower segments and seem to provide a reason, if not a mechanism, for the longer gap. A preoperative cardiac evaluation, including echocardiography, in EA newborns, should reveal the presence of an aberrant subclavian artery and alert the surgeon to the possibility of a long gap.

Other developmental anomalies have been found in apparent association with a longer gap. An absence of the azygos vein with LG-EA has been described, but the relationship is more difficult to understand [15]. Because the presence of this anomaly would not be determined preoperatively, the value of this finding is limited. These authors also disputed the value of 13 ribs in predicting a LG-EA which had been previously proposed [15, 16]. These and other associations are presumably the result of alterations in the usually carefully orchestrated biomechanical forces in the area.

Preoperative Evaluation of Gap Length

Given the variability of the EA spectrum and consequently of gap length, a preoperative evaluation is very valuable. The question of gap length quickly arises for babies with a blind upper pouch and a gasless abdomen which suggests a pure atresia (type A) or a presumed blind lower segment with an upper pouch TEF (type B). With a presumed blind lower pouch, a gastrostomy tube (G-tube) is usually placed to allow feeding and to enable the distance between the blind segments to be determined. Although the measurement of gap length will raise questions about its reliability and its significance, it will help in preoperative planning and is what will be needed to achieve a true primary esophageal repair.

There are two commonly used methods of measurement, each with advantages and disadvantages. Any gapogram, moreover, is a two-dimensional representation of what is a three-dimensional problem, and the real distance may be longer.

The method we favor is the injection of contrast material into the G-tube to outline the lower esophageal segment and a radiopaque catheter or other contrast agent to determine the length of the upper pouch. Evaluating the two segments together will provide an unstressed "gapogram" and an estimate of a gap length. A disadvantage of the unstressed measurement is that it does not estimate the gap length after dissection nor the effect of moderate traction pulling the ends together. Nevertheless, this estimate of nonstressed gap length will provide adequate information to formulate an operative approach. The lower segment is usually the determining factor in the long gap and whether it resembles A_1, A_2, or A_3 will help understand what lies ahead (Fig. 20.1)

The other measurement method places an instrument such as an endoscope or a Hegar dilator into the upper and lower segments in order to push them together. Many pediatric surgeons use this method, but it has several drawbacks. First, the configuration of the lumen will not be defined at either end. More importantly, pushing against

newborn tissues with dilators may cause the gap to largely disappear and give the false conclusion that a relatively short gap exists. We have even seen examples where the dilators pushed the stomach and diaphragm well up into the chest and appeared to almost close the gap when virtually no lower segment was present. This considerable distortion may make the reality of what one finds in the operating room very daunting and cause the predicted primary repair to be quickly abandoned.

Because the commonly used methods to determine gap length preoperatively have drawbacks, the surgical approach must be flexible [13]. In the operating room after dissection and a trial of pulling the ends together, the last centimeter or two of gap may be very difficult to close. At this point, the decision should be made. Once open, the esophageal ends must be put together; otherwise, it will be necessary to create a spit fistula and close over the lower segment, maneuvers which may end the hope of a primary repair (see Chap. 25: Esophageal Growth Induction and a Flexible Approach to Long-Gap Esophageal Atresia Repair, Foker).

Traditional Long-Gap Treatment Methods

The wide spectrum of LGs exists largely because of the variability in the size of the lower segment which may reach the level of the carina or only be a primordial nubbin (Fig. 20.1). For the more favorable end of the LG spectrum, the lure of a primary repair has long been present. In an early report, however, an initial primary repair of LG-EA patients produced very unsatisfactory results ranging from a major, persistent leak to disruption of the anastomosis [17]. At the time, these bad results were considered predictable, and it was widely advocated that an anastomosis should be essentially tension free or another treatment method be chosen. Although there is evidence that a well-constructed anastomosis will withstand tension, it seems much wiser to select an intermediate approach that will relatively quickly produce sufficient growth for a more straightforward true primary repair [7, 10, 13] (see also: Chap. 19: Delayed Primary Anastomosis in the Management of LG-EA; Chap. 25: The Flexible Approach for Primary Repair of Long Gaps).

The spectrum of LG-EA has led to a variety of methods to treat these patients and these fall into one of three approaches. A more complete presentation of the methods will be found in the succeeding chapters in this section on Repair of Long-Gap EA.

For a mild to moderately long gap (about 3–5 cm), a period of waiting, with or without bougienage, has been used with the hope that growth stimulated by some combination of swallowing, gravity, G-tube feeds, intermittent pressure by bougienage, or even the force of electromagnets may close the gap sufficiently to make a primary repair possible [18–22]. Although in our experience catch-up growth does not occur, nevertheless for some patients, this has been a satisfactory approach and is explained more fully in the chapter titled, Delayed Primary Anastomosis in the Management of Long-Gap Esophageal Atresia.

For moderate gaps, surgeons have attempted to increase the length of the segments by such methods as upper segment myotomies or flaps to lengthen the upper pouch and allow a primary repair [22–26]. Some have even placed a suture through the segments to develop a fistulous tract between them which can later be dilated [27]. These methods may have predictable potential problems such as significant strictures or a diverticulum from an unsupported esophageal wall after a myotomy. A diverticulum will interfere with transit down the esophagus and, on occasion, has become quite large and even life-threatening [28, 29].

The creation of a flap to lengthen the upper pouch may be useful, although it will produce an ornate suture line. There is limited reported experience with the flap techniques, but if the wall remains full-thickness and the resulting stricture manageable, the result should be satisfactory [25, 26].

An intermediate approach consists of either widening the opening to allow the gastroesophageal (GE) junction to be brought up through the

esophageal hiatus or lengthening the stomach to facilitate the partial pull-up [9, 31] (Coran AG. Personal communication, 1996.). Patients with an intrathoracic GE junction, however, have obligatory reflux which may lead to very unsatisfactory consequences. Effective treatment will require the GE junction to be brought back below the diaphragm, and, depending on the amount of stomach above the diaphragm, it may not be easily accomplished. The alternative method of using a Collis gastroplasty, ostensibly to lengthen the esophagus, leaves a tube of stomach and the real GE junction within the chest which does not seem to be a satisfactory choice for a child hoping to realize 70 good years.

It has been stated that unless the lower segment ends above the diaphragm, a "primary repair" of any type is not possible [31]. Although we disagree with this conclusion, in most cases, it will lead the surgeon to a staged repair – the third general approach to LG-EA. Whether from the original gapogram or by surgical exploration, if a primary repair is judged not possible initially or in the near future, an initial cervical fistula and a G-tube will usually be placed. These allow the patient to grow until a later interposition graft can be used to establish continuity. A staged approach may also be used after a failure of the initial EA/TEF primary repair when the upper esophagus is converted into a spit fistula and the lower esophagus oversewn. For these LG-EA patients, a primary esophageal repair no longer seems possible, and the future typically holds an interposition graft, almost always either the stomach or colon [32–34]. Moving either of these organs into the chest, however, may lead to adverse consequences resulting in a state of chronic disease.

The Flexible Approach to LG-EA

Given the uncertainties and problems described with longer gaps, the surgeon should have a flexible approach for any defect beyond the routine EA/TEF repair. Traditionally, as noted, there has been wide variation in the repairs used to solve the long-gap problem. The variation in the operations indicates both the width of the EA spectrum and the elusiveness of satisfactory outcomes. What has changed more recently is the ability to reliably and rather rapidly induce growth in the atretic segments, making possible the desirable goal of a true primary esophageal repair across the EA spectrum [10]. The ability to induce growth has been so effective it has closed gap lengths of up to 16.5 cm and produced an outwardly normal esophagus beginning with lower segments only 3–4 mm long and located far below the diaphragm. Several techniques to provide axial tension and induce growth have been devised to meet the different configurations of the esophageal segments. The spectrum of operative approaches is described more fully in the chapter titled, Growth Induction and The Flexible Approach for Primary Repair of Long-Gap EA.

The long-term consequences of the surgical approaches to LG-EA should be considered because, to achieve the goal of 70 good years, the treatments must not set in motion significant new problems. The several current approaches to LG-EA also raise the conflict of a relatively easy solution, e.g., a spit fistula and G-tube and later interposition, with one that may take more time initially such as a growth procedure. The staged approach can be performed, usually at relatively low risk and with reasonable length of stay; however, they bring short- and long-term problems of their own, creating new types of chronic disease.

Because the spectrum of EA is so broad, it is important that the surgeon treating the severe forms be well acquainted with the lesions and the various repairs needed to achieve a satisfactory end result. Repairs using growth induction have the capability to achieve a true primary repair with virtually any initial LG-EA lesion; however, worldwide experience has shown the procedures become increasingly more difficult toward the severe end of the spectrum. It would seem logical, therefore, that a very difficult initial EA lesion be referred to a place of greater experience, so the infant will ultimately enjoy the benefits of a true primary esophageal repair, and this plea has been made [35].

Delayed Primary Anastomosis in the Management of Long-Gap Esophageal Atresia

21

Prem Puri and Florian Friedmacher

Introduction

Esophageal atresia is a complex congenital malformation of unknown etiology with a frequency of 1 in 3,500 live births [1, 2]. Pure esophageal atresia without tracheoesophageal fistula is an uncommon anomaly, comprising 8 % of all patients with esophageal atresia, with an expected incidence of 1 in 40,000 live births [3]. Despite improvements in prenatal diagnosis [4, 5], esophageal atresia is still life-threatening, and without any surgery, it is fatal. The first survivors of a staged repair with a primary gastrostomy and a delayed esophageal reconstruction were reported by William Ladd in 1939 [6]. Cameron Haight was the first to perform a successful primary repair of esophageal atresia in 1941 [7]. From then on, advances in surgery, pediatric anesthesia, neonatal intensive care, and parenteral nutrition have increased the survival rate following reconstruction from universally fatal to approximately 95 % [8]. Today, even newborns with very low birth weight and severe cardiac malformations survive [9]. Nevertheless, the high incidence of prematurity, additional anomalies, and long-gap esophageal atresia complicate the care of these patients [10, 11] and may preclude an immediate primary repair. Thus, surgical management of patients with long-gap esophageal atresia represents a major challenge to most pediatric surgeons [12, 13], especially when a primary end-to-end anastomosis is not possible. The distance between the upper and lower esophageal segment and the presence of a tracheoesophageal fistula will determine the operative management. There is a consensus among most pediatric surgeons that every effort should be made to conserve the native esophagus, as no other conduit can replace its function in transporting food from the oral cavity to the stomach [14]. Over the last 70 years, there have been considerable changes in the operative treatment of long-gap esophageal atresia, and it is widely accepted that a delayed primary anastomosis of the esophagus is not only achievable but also the preferred option in the majority of such cases.

History

Over the last four decades, various techniques have been described to reduce the distance between the two esophageal ends to achieve a delayed primary anastomosis. In 1965, Howard and Meyers [15] were the first to advocate periodic manual bougienage of the upper esophageal segment, producing elongation of the pouch,

followed by a subsequent primary anastomosis 5–8 weeks later. Bougienage of the distal esophageal pouch in addition to the proximal pouch was reported first by Lafer and Boley [16] in 1966. Rehbein and Schweder [17] used a temporary silver prosthesis to create a fistula between the two esophageal segments. In 1972, Thomasson [18] described an elongation of the upper esophageal pouch by mercury-filled bags, and Livaditis et al. [19] introduced circular myotomy of the esophagus to enable a primary anastomosis. The use of silk sutures for esophageal auto-anastomosis by producing a mucosa-lined fistula was demonstrated first by Shafer and David [20] in 1974. Hendren and Hale [21] reported their experience with electromagnetic stretching of the two esophageal segments in 1976.

In 1981, Puri et al. [22] published their observations in newborns with pure esophageal atresia that spontaneous growth and hypertrophy of the two esophageal segments occur at a rate faster than overall somatic growth in the absence of any form of mechanical stretching. The maximal natural growth of the esophageal segments occurs in the first 8–12 weeks of life [22]. The stimuli to such natural growth are the swallowing reflex and the reflux of gastric contents into the lower esophageal pouch [23]. Therefore, Puri et al. [22, 23] recommended initial gastrostomy and continuous suction of the upper esophageal pouch followed by delayed primary anastomosis as an ideal procedure for the management of newborns with long-gap esophageal atresia. In 1994, Boyle et al. [24] confirmed that even in cases of ultralong-gap (>3.5 cm) esophageal atresia, a delayed primary anastomosis is achievable. Foker et al. [25] showed in 1997 that esophageal growth is rapid if continuous traction sutures are applied in the esophageal segments, producing significant lengthening within days.

Initial Preoperative Management

Once the diagnosis of esophageal atresia is established, the next step is to perform a preliminary feeding gastrostomy to provide adequate nutritional support (Fig. 21.1). Furthermore, a 10-F Replogle sump-suction catheter should be placed into the upper esophageal pouch and is kept under continuous suction to prevent aspiration pneumonia. The patient is maintained in a head-down position (as far as possible) for efficient suction of the upper esophageal pouch and to allow reflux of gastric juice contents into the lower esophageal segment. The gastrostomy is kept plugged between feedings to encourage gastroesophageal reflux and distension of the lower esophageal pouch. An important factor responsible for hypertrophy of the lower esophageal pouch is the reflux of gastric contents owing to the incompetent gastroesophageal junction of young infants.

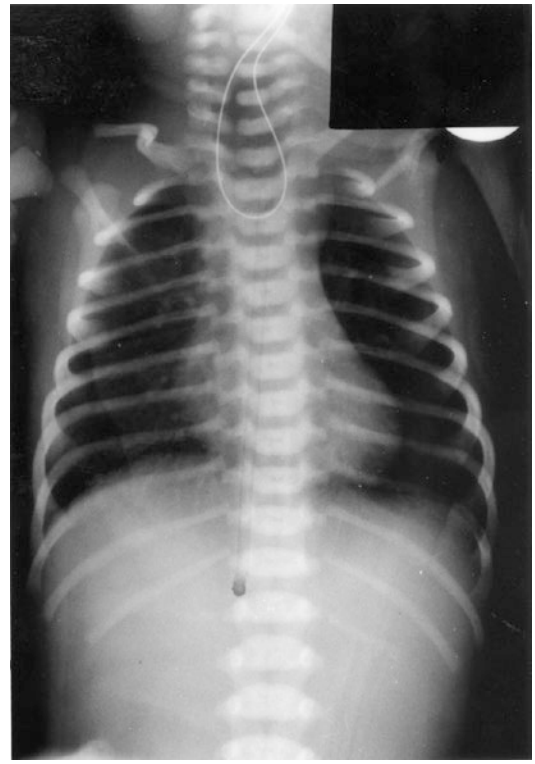

Fig. 21.1 Chest radiograph of a newborn with long-gap esophageal atresia

A variety of techniques for monitoring the elongation of the esophageal pouches have been described. Injection of water-soluble contrast via the gastrostomy tube may be the simplest and oldest technique performed to evaluate the lower esophageal pouch. Most authors favor radiological

assessment of the intervening gap by insertion of a rigid metal dilator in both the upper and lower esophageal pouches [26, 27]. The distance between the two ends can be quantified either by placing the patient on a ruler with radiopaque markings or by counting the number of vertebral bodies between the two segments (one vertebral body is equal to roughly 1 cm). It is important not to apply excessive force to the dilator while measuring the gap between the segments because it can produce errors in estimation of the distance between the two segments [28]. Caffarena et al. [29] first described placing an endoscope in both the upper and lower esophageal pouches for measurement of long-gap esophageal atresia. Chan and Saing [30] combined flexible endoscopy and fluoroscopy in the assessment of the gap between the two esophageal pouches. Gross et al. [31] demonstrated how fiberoptic endoscopy enables measurement of the gap in esophageal atresia. Other investigators used computer tomography scanning for evaluation of neonates with esophageal atresia [32, 33]. Measurement of the gap between the esophageal segments is initially made approximately 2 weeks after gastrostomy and is repeated at 3-week intervals (Fig. 21.2).

Although some centers have allowed these patients to return home for a few weeks on nasopharyngeal suction and gastrostomy feedings [3, 34], generally the patients are kept in the hospital until primary esophageal anastomosis is performed [22, 23, 35, 36].

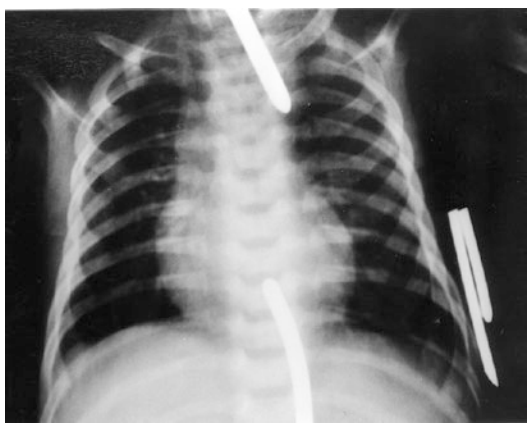

Fig. 21.2 First measurement of the gap between the upper and lower esophageal segment by using radiopaque bougies at 3 weeks of age. The gap is approximately five vertebral bodies long. Care must be taken to not exert excessive pressure on the bougies

Delayed Primary Anastomosis

Puri et al. [22] have shown that the maximal spontaneous growth of the two esophageal segments occurs in most patients by 8–12 weeks of age, and this correlates with doubling of birth weight. By this age, the gap between the two esophageal pouches usually is less than 2 cm (Fig. 21.3) [23, 36, 37]. Therefore, it is recommended to perform delayed primary anastomosis when the patient is 3–4 months old. Successful primary anastomosis with delays of up to 12 months [34] and initial gaps of up to 7 cm [38] or eight vertebral bodies [39] has been reported.

The surgical approach for delayed primary anastomosis of the esophagus in long-gap esophageal atresia is similar to that of repair of esophageal atresia with tracheoesophageal fistula. Lobe et al. [40] also have described thoracoscopic repair of esophageal atresia. A standard right posterolateral thoracotomy is performed via the fourth intercostal space using the extrapleural approach. The advantage of the extrapleural approach is that a postoperative anastomotic leak does not contaminate the pleural cavity, allowing prolonged chest-tube drainage. At the time of the operation, the esophageal pouches appear thickened and hypertrophied [28]. Dissection and mobilization of the upper esophageal pouch usually will facilitate approximating the esophageal segments with minimal tension. Several investigators have reported using circular myotomy to obtain additional length for the upper pouch [22, 34–36, 38, 41–46]. Postoperatively, the patient is nursed in the neonatal intensive care unit. The chest drain is left on water seal, intravenous fluids are administered, and antibiotic prophylaxis is continued. If the esophageal anastomosis has been performed under significant tension, the patient is electively paralyzed and mechanically ventilated for five postoperative days. At 7–10 days post surgery, a water-soluble contrast study should be carried out (Fig. 21.4). If no leak

Fig. 21.3 Significant reduced esophageal gap in the same patient at 14 weeks of age

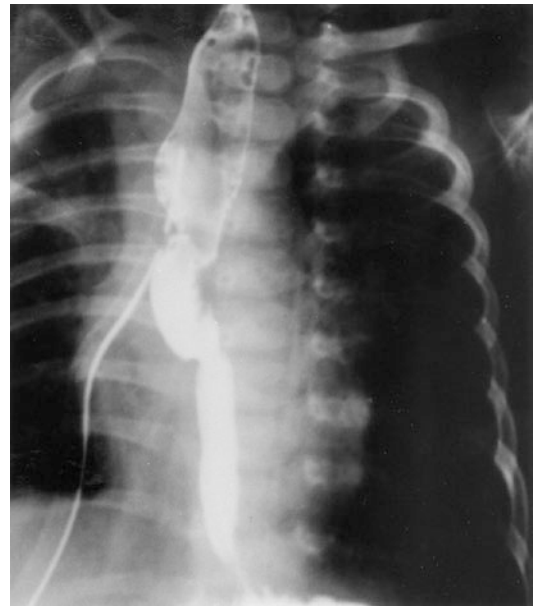

Fig. 21.4 Contrast study on the tenth postoperative day after delayed primary repair showing an intact anastomosis

is present, the chest drain is removed, antibiotics are discontinued, and the patient is allowed to take feedings orally. Furthermore, regular chest physiotherapy is recommended to avoid respiratory infections.

Complications

In most studies, the survival rate for patients with esophageal atresia after delayed primary anastomosis is reportedly greater than 90 % [23, 29, 34, 38, 41, 44,46–54]. The early complications after delayed primary anastomosis are leaks, which occur in up to 50 % of patients [22, 23, 34, 35, 37, 41, 43, 44, 46–48, 50, 51, 55–58]. Most anastomotic leaks are minor and subside spontaneously on total parenteral nutrition without the need for surgical intervention. However, some investigators have reported major disruption and failure of conservative management with need for drainage or reoperation in up to 15 % of their patients [46, 57]. Anastomotic strictures occurred in some studies in up to 80 % of cases [23, 35, 43]. The presence of a previous anastomotic leak has been found out to be the most important factor in stricture formation [28]. Most esophageal strictures respond to periodic dilatations, while some patients finally needed resection and reanastomosis [22, 23, 35, 36, 43, 48, 50, 51, 58, 59]. Persistent esophageal strictures occur mainly in association with gastroesophageal reflux [60]. Gastroesophageal reflux that is present after delayed primary anastomosis usually requires a more aggressive approach to treatment. According to most authors [22, 29, 34–38, 41, 43–50, 53, 55–59, 61], up to 30 % of their patients, treated by delayed primary anastomosis, require fundoplication in the first year after surgical repair of their esophageal atresia due to either symptomatic gastroesophageal reflux or persistent strictures. Severe esophagitis caused by gastroesophageal reflux occurs only occasionally after delayed primary anastomosis and usually can be resolved by fundoplication [45, 48, 55].

Long-Term Results

The majority of patients who have undergone delayed primary esophageal anastomosis are able to eat normally without dysphagia (Fig. 21.5). The reported incidence of swallowing difficulties is low [23, 41, 42, 58, 61]. Patients with dysphagia usually are found to have gastroesophageal reflux or reflux-associated strictures on contrast studies. Recurrent aspiration pneumonia is uncommon in patients who had delayed primary anastomosis but is reported by some authors [37, 42, 45, 61]. Failure to achieve a satisfactory delayed primary anastomosis of the esophagus with need for esophageal replacement is relatively rare and only necessary in a few patients [34, 35, 46, 58]. Long-term follow-up studies have shown that the majority of patients have normal growth and development curves after delayed primary anastomosis [36, 43, 56, 59]. However, the potential risk of Barrett's metaplasia highlights the need for continued long-term follow-up [36, 48].

Fig. 21.5 Contrast study in the same patient showing a patent esophagus at 16 years of age

Conclusion

Delayed primary anastomosis provides an excellent postoperative outcome with good long-term functional results. The high incidence of gastroesophageal reflux and associated morbidities requires early intervention to prevent ongoing feeding problems due to strictures and esophagitis. Long-term follow-up is recommended because of the potential risk of Barrett's metaplasia.

The disadvantages of waiting for the esophageal segments to grow and hypertrophy are prolonged hospital stay and constant threat of aspiration pneumonia, which require continuous skilled nursing supervision. It may also be argued that the initial prolonged hospitalization is expensive. These factors must be balanced against reduced long-term morbidity in a child who should have a normal life expectancy and against the disadvantages of esophageal replacement. There is no "good" substitute for a child's own esophagus.

22 Surgical Methods to Increase Esophageal Length in Long (Wide)-Gap Esophageal Atresia with and Without Tracheoesophageal Fistula

Sigmund H. Ein

Introduction and Philosophy

The long (wide)-gap esophageal atresia (EA) continues to be a problem for the pediatric surgeon; however, ingenious and interesting surgical attempts to bridge the gap continue to come forth. These new ideas are probably for 10–20 % of newborns/infants with EA who are not immediately suitable for primary anastomosis (15 % without a tracheoesophageal fistula (TEF), 5 % with a TEF).

In the 1950s through to the 2000s, several methods to elongate and eventually bring together both esophageal segments to overcome a wider than usual atretic gap have been employed with limited success; however, elimination of anastomotic tension, significant complications, morbidity, and prolonged hospitalization have not resulted [55]. "Many techniques have been proposed to obtain esophageal elongation; although all the procedures give acceptable results, none of them has been unanimously accepted by pediatric surgeons" [2]. "I think (they) got a raw deal, but that's often the fate of pioneers and innovators" [57].

In the following examples, most lengthening procedures focused on the usually bigger and better developed upper esophageal pouch; some on both esophageal segments and a few on the always small and poorly developed lower esophagus. As time passed from the first of these innovations in the 1950s, many of these authors and others used a combination of older and previously described novel techniques and/or their own newer procedure [6, 8, 24, 26, 50, 51]. All of these wide-gap EA patients, with or without a TEF, require some sort of surgery either to make the diagnosis of a wide gap and/or division of the TEF (right thoracotomy), esophagostomy, and always a feeding gastrostomy. Following this degree of stabilization came a succession of thought-provoking ideas, procedures, and options to bring about a primary (albeit delayed) esophageal anastomosis rather than an esophageal interposition, replacement, or substitution. The management of this relatively rare and difficult variation of EA will continue to demand an individualized approach and consideration of all of the various techniques that have been described.

Generally speaking, all of these procedures have the usual postoperative complications seen with the standard primary anastomosis, with, as in most large and complicated operative procedures, a significant learning curve [5]. In spite of the above trials and tribulations, the end results were fairly

similar to the common esophageal repair, that is, a fairly reasonable, but not perfect, swallowing tube.

All of the authors seem to be in agreement with the philosophy that "…the best tissue for oesophageal reconstruction is oesophageal tissue" [5]. Otherwise, they wouldn't have gone through the effort of trying out their new ideas on "bridging the gap." However, it is interesting to note that, with few exceptions, most of these innovative procedures were seldom tried by the silent majority of pediatric surgeons and/or if they were seldom reported in the literature. Rehbein [38] concluded that "…it may not always be technically possible to achieve this but …it is a worthy goal at which to aim."

The hopes and aspirations of all of these innovative pediatric surgeons were best represented by Rehbein's words in 1971: "With children, the essential requirement is to establish a condition that will continue reliably trouble-free for decades. Direct uniting of the (esophageal) segments would appear to us to provide a better guarantee than a transplant. It well could be, however, that transplants in cases of esophageal atresia could become superfluous" [38]. It is interesting to review the writings of the above authors and see their ingenious ideas which they have published on these and other pediatric surgical problems.

Once again, these novel ideas enforce the teaching that the infant or child's own esophagus is almost always better than any substitute that can be made for it; so the search goes on.

This chapter reviews innovative attempts to join the two pieces of wide-gap EA together in three novel approaches:

1. Lengthen upper pouch
2. Pull/push upper and lower pouches together
3. Lengthen lower pouch

Upper Esophageal Segment Anterior Flap

Ten Kate [49] in 1952 first reported the ingenious use of an anterior flap of muscularis used to wrap around the esophageal mucosa to mucosa anastomosis. In his four cases, tearing of the upper-pouch mucosa gave trouble, which led him to suggest a muscle flap be used.

In 1981, this approach was modified by Gough [15] to bridge a wide gap between two EA segments that could not be connected by a primary anastomosis. His rationale was that the wide gap between the two esophageal segments can be reduced if, instead of opening the larger upper pouch at its most distal end, an anterior full-thickness flap could be fashioned and turned down (as an extension of the back wall of the upper segment) to be sewn without tension to the narrower back wall of the lower segment (Fig. 22.1). Then the wider upper esophagus could be closed anteriorly (without compromising its lumen) and sewn to the equally small lower esophagus (Fig. 22.2). The only drawback to this type of anastomosis is that it is three cornered. None of Gough's patients leaked but they all required dilatation.

Davenport [5] concluded that "…the flap will provide sufficient tissue to bridge longer defects at least equivalent to the height of up to four vertebral bodies." However, he did admit "Our less than acceptable complication rate in the first part of the series would lead us to advise care and caution in learning and applying a new technique." This flap technique has not produced many papers since its inception.

Circular and Spiral Myotomy

In 1969, Livaditis et al. [32] introduced the operation of circular myotomy as an effective means of bridging a particularly wide gap in EA to enable a primary anastomosis.

In laboratory studies, he showed that esophageal peristalsis is normal up to and beyond the circular myotomy and the myotomy causes no functional impairment of swallowing [33]. The myotomy site heals with a thin layer of fibrous tissue rich in elastin, and the mucosa at the level of the myotomy distends in response to increased intraluminal pressure. The myotomy does not cause stricture of the mucosa, nor ischemic necrosis and fibrosis of the esophagus distal to the myotomy [33].

An interesting addition to the circular myotomy is the possibility of doing more than one myotomy on a longer than usual upper pouch, a circular myotomy on a longer than usual lower pouch [9, 14], and/or myotomies on both segments [30]. In

the case of an upper pouch that is too short to have a myotomy made with ease, the upper pouch can be brought out the right neck, the myotomy done, and then the upper pouch replaced into the mediastinum for the anastomosis [22, 27]. Each myotomy adds 1–1.5 cm (equal to 1 vertebral body) to the length of the esophageal segment [42, 55].

There is almost always seen an outpouching of the mucosa at the myotomy site, but this rarely created a clinical problem [22]. However, there has been a report of two patients who had a subsequent history of impaction of solid food particles in the upper esophageal segment at the age of 13 months and 2 years. Whether this was due to the dilated and dysfunctional upper esophagus at the circular myotomy site or the more common holdup at the anastomosis is open to speculation. The authors of this report suggested that "the possibility that the circular myotomy contributed to this increased incidence of impaction is raised" [47]. Of course, there is always a risk of making a hole in the mucosa, but as long as it is recognized and repaired at the same time, it seldom causes a problem. This lengthening procedure adds no increased morbidity to the usual list of primary EA repair complications.

As with each new idea, someone comes up with an equally novel approach to change the new idea. Therefore, in 1976, Eraklis et al. [7] modified this technique by having the anesthesiologist insert a balloon catheter down the esophagus to facilitate the myotomy and decrease the risk of entering the lumen.

In 1983, Schwartz [42] suggested that the myotomy was easier to do over an inflated No. 8 French Foley catheter, which the surgeon passed through a purse-string suture placed at the tip of the proximal esophagus (Fig. 22.3).

In 1987, to this innovation, Kimura et al. [26, 27] added a spiral myotomy which he said was mandatory to do over the inflated Foley catheter and was done by twisting the esophagus two and one half revolutions, deflating the Foley balloon, stretching the spiraled myotomy with moderate tension, and then sewing the muscle edges together (Fig. 22.4). The spiral myotomy gives an elongation of 2 cm and the sutured edges prevent a mucosal tear.

In a similar fashion with all the other innovative ideas and procedures, only a few series of circular myotomies have been reported, but each series had only a handful of cases [27, 42, 45–47]. "The circular or spiral myotomy is still the most commonly used technique to lengthen the esophagus in the repair of long gap atresias" [2].

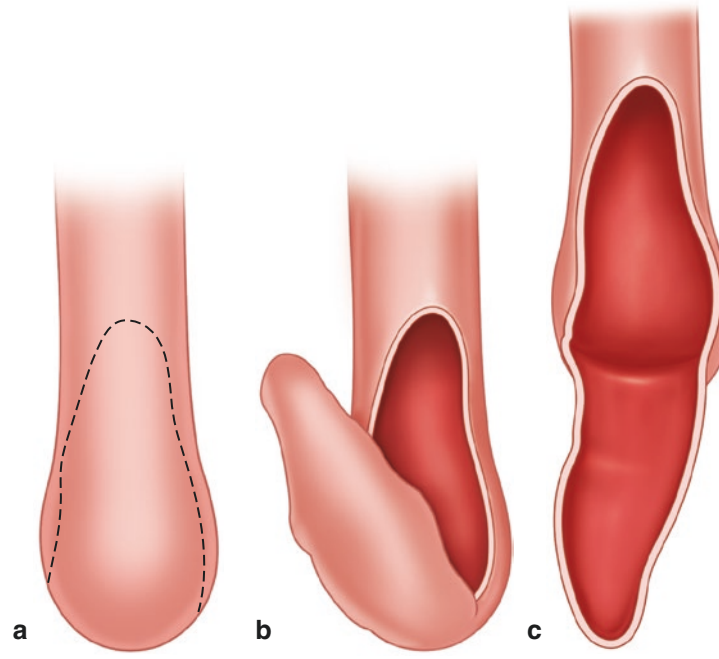

Fig. 22.1 Long, wide, full-thickness posterolateral esophageal pedicle flap 1-3 cm long from the dilated upper pouch (**a**) The posterior flap is mobilized (**b**) until it reaches downward without tension (**c**) (With permission from Dr. Adrian Bianchi (*Pediatr Surg Int*) (Ref. [5]))

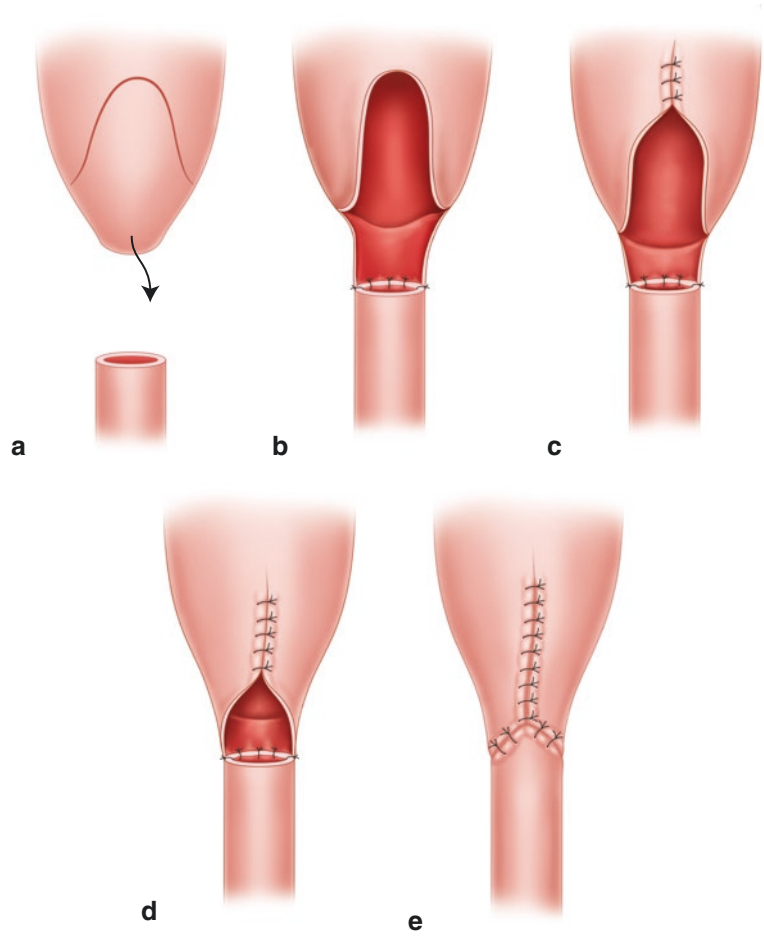

Fig. 22.2 The line of the incision for the anterior wall flap from the upper esophageal pouch is marked (**a**), and the *arrow* shows the downward direction of the flap, which is sutured to posterior wall of the lower esophageal segment (**b**). The anterior wall defect of the upper pouch (from the flap) is repaired (**c**) down to the lower esophagus (**d**), which is then closed in the usual transverse fashion (**e**) (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [15]))

Suture Fistula

In 1971, Rehbein and Schweder [38] apparently initially proposed the idea of pulling (after bougienage had failed in some patients) two widely spaced EA ends (proximal and distal) together in the anticipation of creating a fistula between the two ends. This fistula, it was hoped, would be able to be dilated either directly from above or via a string passed from the nose down through the now patent esophagus and out a feeding gastrostomy. At a later date, if this stricture cannot be maintained open and wide enough to tolerate normal fluid and solids, it could be resected.

Rehbein and Schweder [38] did the above in three stages:

1. The gap was bridged by introducing a silver prosthesis to which both segments were attached. In about 2 weeks the gap was overgrown by fibrous tissue, the prosthesis had become sufficiently detached to enable to be withdrawn through the gastrostomy (Fig. 22.5).
2. A nylon thread was introduced into each segment with the ends emerging through the nose and gastrostomy. The two esophageal segments were approximated as far as possible by three sutures. Four weeks later, using the thread, two silver olives were introduced both from above and pushed up from the gastrostomy and pressed together crushing the two blind ends of the esophagus between them. Thirty-six hours later a channel (between the two segments) was created (Fig. 22.6).
3. A thread was passed through both esophageal segments which were approximated as far as possible by three sutures (Fig. 22.7).

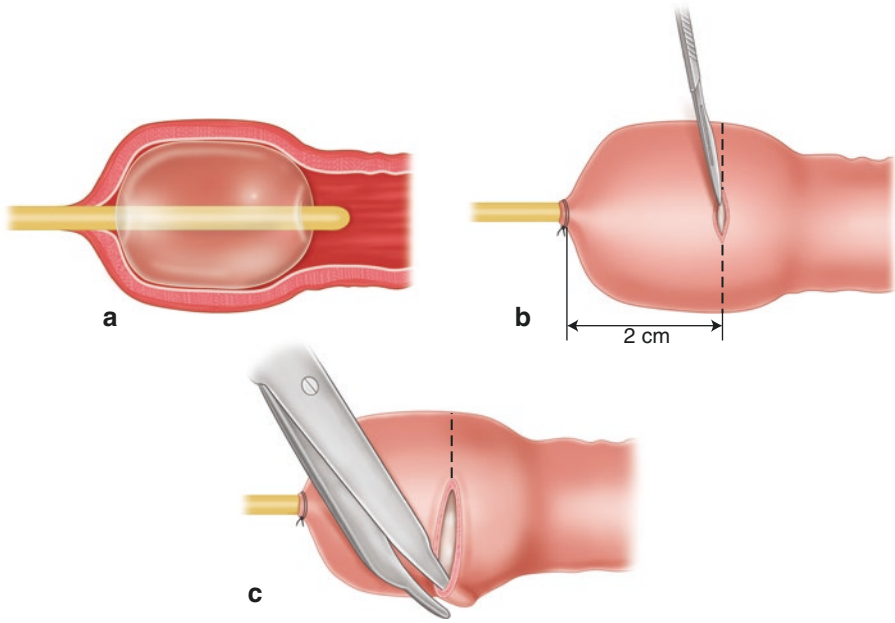

Fig. 22.3 The Foley balloon is passed into the end of the esophageal segment and the balloon is inflated (**a**). The myotomy is begun with a scalpel 2 cm from the end (**b**), and the esophageal muscle is divided with scissors (**c**), after a plane of dissection between the muscle and submucosa is identified. The completed myotomy yields 1–1.5 cm of extra length (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [42]))

It was Rehbein's conclusion that "even major (2 cm) esophageal defects are actually bridged along a prosthesis that is introduced temporarily. The fibrous canal, which develops around such a prosthesis or around a perlon (nylon) thread, shrinks in a longitudinal direction and draws the segments toward each other. At the same time, this shrinkage causes constriction and makes subsequent bougienage necessary. If the constriction does not yield, it will have to be resected at a later date" [38].

In 1974, Shafer and David [43] tried the same suture fistula technique as Rehbein, in which he used silk instead of nylon. He claimed: "Rehbein's technique should be attempted when the two ends can be almost but not quite approximated." Very few papers have been published on this technique.

Electromagnetic Bougienage

The original idea for bougienage was described in 1965 by both Howard and Myers [21] and Johnson [23] who introduced manual bougienage for the upper pouch to elongate it and accomplish a delayed primary anastomosis.

As with all of the other innovations, in 1975 Hendren and Hale [18] modified Howard's simple technique, this time using a surgical approach. He reported two cases of wide-gap EA in which "intermittent electromagnetic force was used to pull together metal bougies ("bullets") placed in each esophageal end and electromagnetic field was then used to pull the bullets together. This method elongated and enlarged the esophageal segments enough to accomplish their anastomosis later" [18].

Hendren's first two successful cases were reported in 1975 [18] and in 1976 he reported two more after "certain refinements in the method were developed" (Fig. 22.8) [19].

1. The sump suction tube attached to the upper-pouch bullet was brought out through a lateral pharyngotomy instead of the nose.
2. The stem of the lower-pouch bullet was brought through a small separate stab incision in the midline to direct it straight upward into the lower esophagus. When it was previously brought through the same opening as the gastrostomy tube site, there was troublesome leakage.

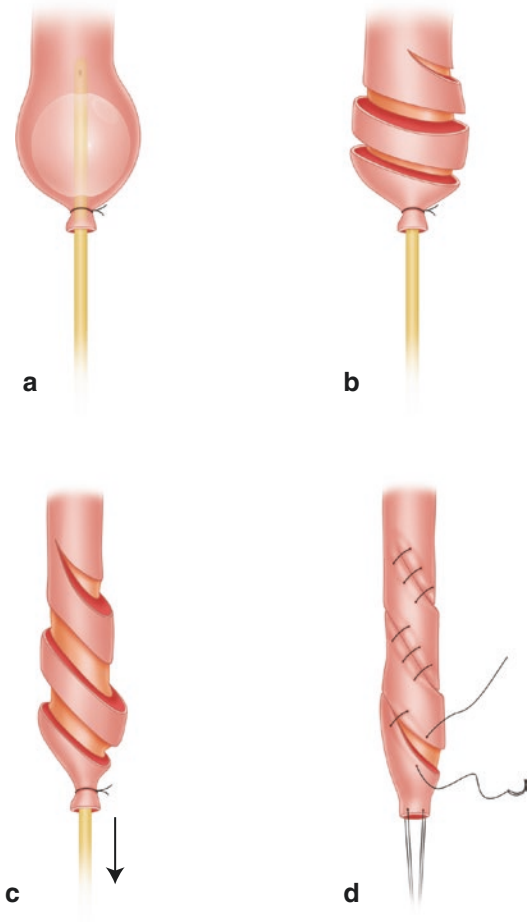

Fig. 22.4 An eight French Foley catheter is passed through the end of the esophageal segment and the balloon inflated (**a**). A spiral myotomy is made over two and one half revolutions (**b**), the balloon is deflated, and the esophagus is twisted and stretched with moderate tension (**c**). The muscle edges are then sutured (**d**) (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [26]))

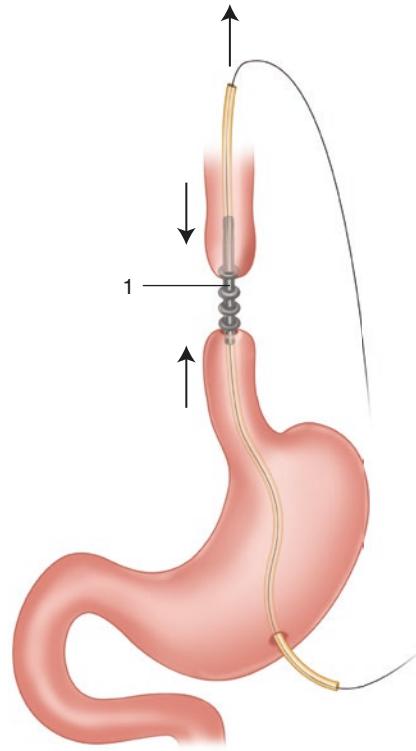

Fig. 22.5 The gap between the two esophageal segments is bridged by a silver prosthesis and the two segments connected with the prosthesis via a string passed down through the nose and out the gastrostomy (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [38]))

3. The lower-pouch bullet was placed "by feel" into the distal esophagus without requiring anesthesia.
4. The lower-pouch bullet, which has a flexible steel stem, was placed by sliding a rigid metal tube over the flexible cable, using this as a handle to direct the bullet up into the lower esophagus [19].

Bougienage consisted of alternating magnetic force (on for 60 s and off for 60 s) with the force building for 15 s and maintained at full force for 45 s, followed by a 15 s decrease and 45 s off. The bougienage continues at a rate of 30 times per hr. The force of pull is adjusted to be less than what seems to cause the baby discomfort by observation. These babies were prone to respiratory difficulties during the first few weeks of life, so its use was deferred until 1–2 months of age, when gastrostomy feeds are well underway. Furthermore, Hendren raised several questions: (1) cost of the electromagnetic machine, prolonged hospitalization, and close nursing supervision; (2) in communities where machine bougienage is not possible, upper and possibly lower-pouch stretching can be attempted for a few minutes several times daily, although it does not duplicate the hundreds of daily stretchings that are possible using the machine; and (3) the risk of whether magnetism may have an adverse effect on the baby. There was no evidence of untoward reaction to

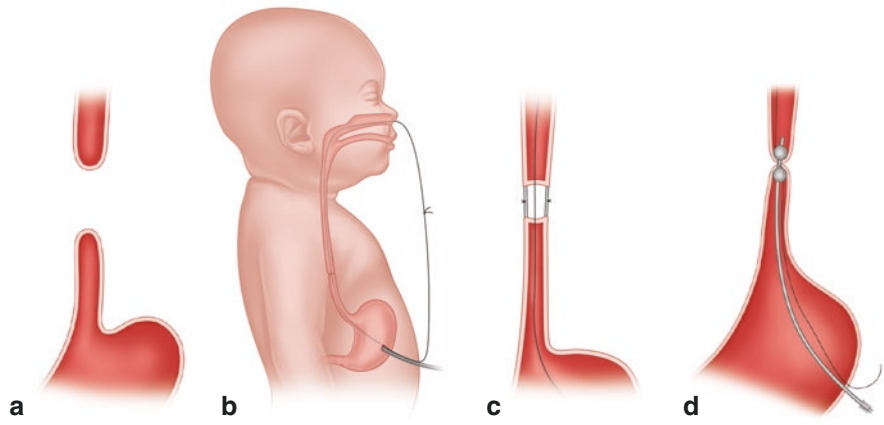

Fig. 22.6 Schematic picture of a long gap esophageal atresia with a long gap (**a**). A nylon thread is introduced into each closed esophageal segment, the ends emerging through the nose and gastrostomy (**b**). The two esophageal segments are approximated as far as possible (**c**) Four weeks later, a silver olive is introduced into each segment (**d**) and pushed together until the two blind ends are crushing (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [38]))

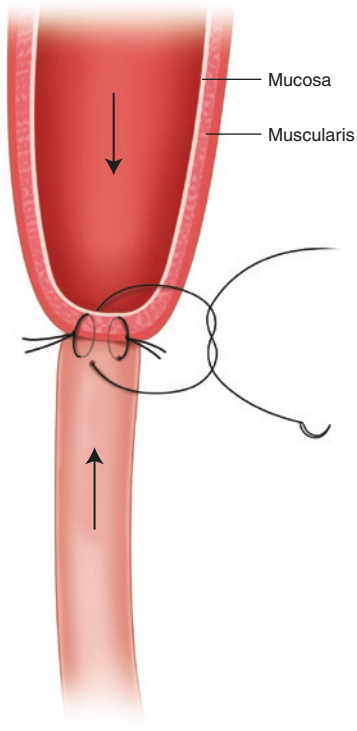

Fig. 22.7 Approximation of unopened upper esophageal pouch to the lower esophageal segment after division and closure of the distal TEF. The central silk suture penetrates the lumen of the upper pouch (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [43]))

magnetism in Hendren's four EA patients [19]. Bougienage in his four cases lasted between 30 and 60 days. It was observed that bougienage not only lengthens the two esophageal segments but induces considerable hypertrophy and a secondarily increased blood supply, thus permitting extensive mobilization with hypovascularity. There was also noted considerable inflammatory reaction in the mediastinum. As in other techniques, Hendren also suggested trimming the two esophageal ends, if possible, at the time of the anastomosis.

To this date, no other reports of electromagnetic bougienage for wide-gap EA have been reported. It is interesting, however, that there is a recent report of the use of magnets to repair pectus excavatum [16, 17] and to create a bowel anastomosis [36].

Staged Esophageal Lengthening with Internal and External Traction Sutures (Foker Growth Procedure)

Between 1984 and 2004, Foker et al. [12] treated 38 patients who presented with the longest gap EA with internal and external traction sutures which quickly and successfully produced esophageal growth for a primary repair (Fig. 22.9) [11, 13].

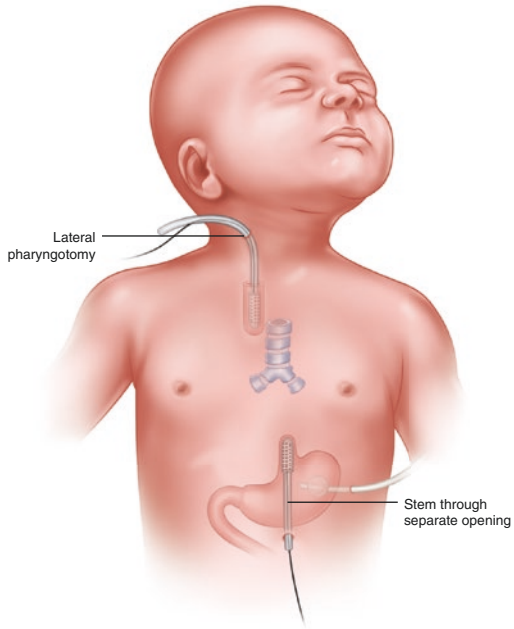

Fig. 22.8 1976 modifications to electromagnetic bougienage. Sump suction tube attached to the upper-pouch bullet is brought out through a lateral pharyngotomy instead of the nose; the stem of the lower-pouch bullet is brought through a small separate gastrostomy (instead of beside the tube gastrostomy) in the midline. It is placed by sliding a rigid metal tube over the flexible cable, using this as a handle to direct it straight upward into the lower esophagus "by feel" (With permission of Elsevier Publishing (*J Pediatr Surg*) (Ref. [19]))

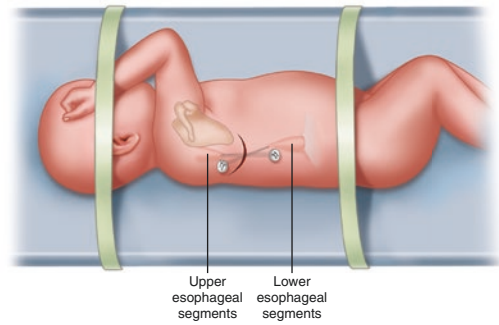

Fig. 22.9 A smaller than normal (3 cm) EA repair 3 cm right fourth to fifth intercostal space thoracotomy incision is made sparing the serratus anterior muscle. Two intercostal entries are made between the fourth and seventh interspaces. A transpleural approach is made. Four pledgeted traction sutures (deep bites, but not into the lumen) are placed into each esophageal segment, and these sutures are brought out posteriorly onto the chest wall; the upper segment sutures exit below the thoracotomy incision and the lower segment sutures above. Traction is placed on the segments by threading the sutures through silastic buttons on the skin surface (With permission from Elsevier Publishing (*Semin Pediatr Surg*) (Ref. [12]))

Throughout the 25 years since this novel technique was first proposed by Foker, there has been continuing doubt about the feasibility and actual results of this double suture traction approach. Following his 1997 presentation, one pediatric surgeon said: "We pediatric surgeons have learned that a primary anastomosis of the esophagus must not be tried when the gap is greater than 2.5 cm, dictated by trial and error and 'common sense'. Dr. Foker and his colleagues have challenged our common sense gap length that has been achieved during our experience for the last 50 to 60 years" [11]. Another Pediatric Surgeon said: "I must say I enjoyed Dr. Foker's presentation, and I think that during the years I have learned not to be skeptical of individuals who do things differently from accepted methodologies" [11].

In a 2009 survey of 88 pediatric surgeons about "The Surgical Approach to Esophageal Atresia Repair and The Management of Long-Gap Atresia," the authors concluded that "Even among experts, there is little consensus on the definition of or the optimum technique for repair of long-gap EA" [39]. Having said that, the same survey revealed that "gastric interposition is the most preferred technique for long-gap EA when primary anastomosis is not possible with 94 % of those surgeons who use the technique are satisfied with it. Growth of the esophageal ends by traction is the other major technique used, but only 76 % of surgeons who use it are satisfied with it" [39]. Suffice it to say, of all the bright, new, novel, ingenious ideas to bridge the long-gap EA and create a successful anastomosis (with as many postoperative problems as other easier primary anastomoses and/or esophageal replacements), the Foker Growth Procedure, after years of disbelief and criticism, seems to be the one technique that more pediatric surgeons are trying (and successfully so) than all of the others put together [34]. As Foker said, when he ended the

question and answer period after his 1997 presentation: "The esophagus serves the child well, much better than the alternatives" [11]. As expected, this is now being done by thoracoscopic means [53].

Extra-thoracic Esophageal Elongation Procedure

In 1994, Kimura and Soper [25] developed a scheme of multiple extra-thoracic esophageal elongation procedures for managing patients with long-gap EA by staged translocations of the proximal esophagostomy stoma down the anterior chest wall gaining 2–3 cm each time. Each elongation can be staged at any time but is usually done at 2–3 months intervals with one to five elongations over time. The definitive esophageal reconstruction has been done as late as 24 months of age.

The esophagostomy is best made on the right side just above the clavicle and tunneled subcutaneously over the clavicle and down the anterior chest wall (Fig. 22.10). Each elongation procedure has an eight French Foley catheter placed into the esophagus through the stoma, its balloon inflated and the esophagostomy closed around the catheter by a purse-string suture. The skin overlying the subcutaneous esophagus is opened in a zig-zag fashion to avoid scar contracture when it is permanently closed. The stoma and proximal esophagus are mobilized all the way up to the cricoid cartilage using the electrocautery minimally. The mobilized proximal esophagus is then passed subcutaneously distally for a few cm, fixing the distal portion of the elongated esophagus to the anterior chest wall fascia to take tension off the new stoma. The continuous movement of the infant/child's neck contributes to further elongation of the proximal esophagus. The elongated esophagus has its muscular continuity preserved, which may be advantageous for its motility. Even though the blood supply in the proximal esophagus originates proximally and travels in its submucosa, and vascular maturation can be expected while the esophagus is embedded in the subcutaneous tunnel, the distal portion of the elongated esophagus still tends to become somewhat ischemic, scarred and usually requires resection of a few cm before anastomosis. Saliva and the sham-fed liquids captured in the esophagostomy appliance can be re-fed into the gastrostomy tube. Finally, esophageal reconstruction is indicated when both ends of the unattached esophagus are at the same vertebral level on a lateral chest x-ray. This is usually seen when the subcutaneous proximal esophagus is at the xiphoid process [27]. This long, somewhat complicated procedure has rarely been reported in any series since its original presentation [48].

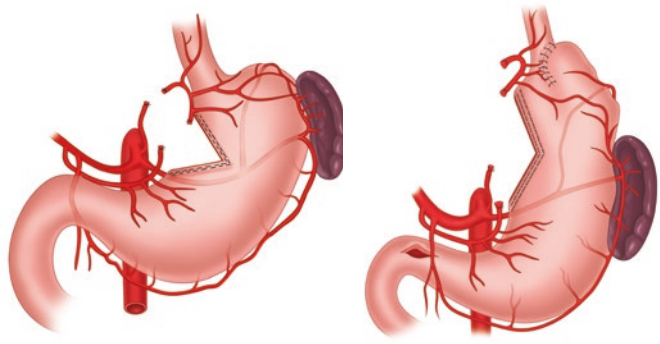

Fig. 22.10 Ligation of the left gastric artery is followed by division of the lesser curvature of the stomach using a GI stapler. The length of the incision on the lesser curvature provides a twofold lengthening of the cardia and distal esophagus. Fundoplication (partial wrap) restores the angle of Hisand prevents GER. Pyloromyotomy or pyloroplastyimproves gastric emptying (With permission from Springer Publishing (*Pediatr Surg Int*) (Ref. [41]))

Elongation of the Distal Esophagus with a Gastric Tube

In 1968, Burrington and Stephens [3] reported a 2.5-month-old baby with a wide-gap pure EA who had her atretic lower esophagus replaced with a so-called partial gastric tube (GT) (a true esophageal interposition) which was distally based (antiperistaltic) on the greater curvature of the stomach and then passed up through the esophageal hiatus. Since only the lower half of the esophagus is missing and needs replacement, half the usual length of GT is required, involving only half of the greater curvature. Frequently, there is a small atretic but still useable distal esophagus which can be part of an isoperistaltic GT. This entire procedure involves an Ivor-Lewis abdominal and right thoracic approach. The small distal esophagus can be anastomosed to the proximal esophagus with more ease than the GT; however, it is often somewhat devascularized because its blood supply comes up from the stomach. GER also comes up from the stomach, and this can cause distal esophagitis leading occasionally to a Barrett's esophagus [31, 44]. Stomach, [41] colon [37], and jejunum [1, 40] have also been similarly used as an esophageal interposition (as above) with equally good results.

Elongation of the Lesser Curvature

In 1992, Schärli [41] published a new means for the preservation of the distal esophagus and cardia, because mobilization of the distal esophagus alone is possible only to a limited extent, due to the fixation of the lesser curvature of the stomach and the left gastric artery. He showed that ligation of the left gastric artery and transverse diagonal division of the lesser curvature with a stapler permits mobilization of 6–8 cm of distal esophagus with preservation of the cardia, ensuring that primary anastomosis of the two esophageal ends is possible (Fig. 22.11). An incision of 3 cm in the lesser curvature provides a gain of 6 cm in length. The esophageal anastomoses were intrathoracic and cervical, and the retrosternal space was also used. In all of his five patients, a semi-fundoplication was performed as well as a pyloroplasty.

Further reports of this procedure (other than Schärli) are not easy to find, although Schärli's

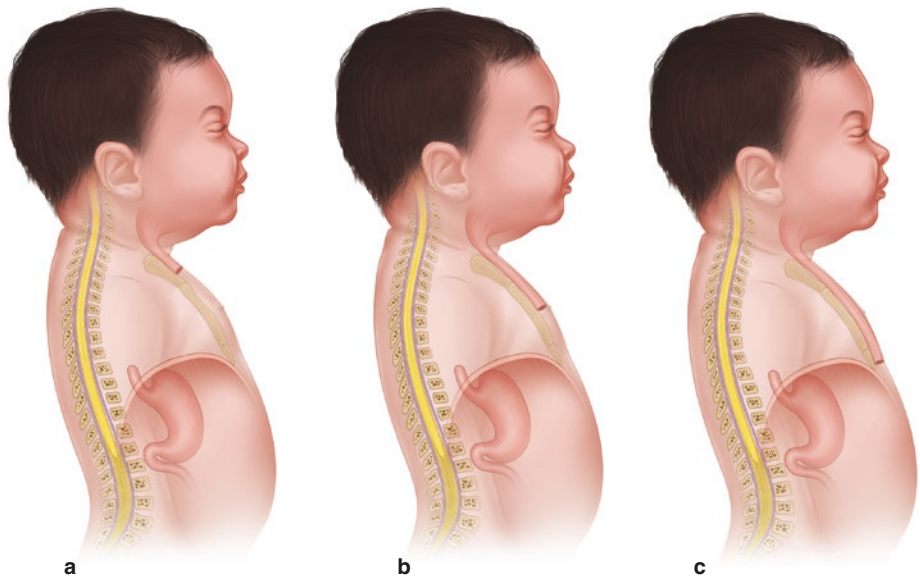

Fig. 22.11 The esophagostomy is best made on the right side just above the clavicle and tunneled subcutaneously over the clavicle and down the anterior chest wall. Each stage (usually 1–5) usually gains 2–3 cm each time (With permission from Elsevier Publishing (J Pediatr Surg) (Ref. [25]))

five patients did well. Once again, a novel approach remains hardly used or copied [10, 54].

Application of Collis Gastroplasty to the Management of Wide-Gap Esophageal Atresia

In 1995, Evans [8] described the use of the Collis gastroplasty as an esophageal lengthening technique for the distal esophagus. This procedure creates a gastric tubular segment from the lesser curve of the stomach (Fig. 22.12). It was felt that this procedure at least doubles the length of the lower esophagus. It is also suggested that an antireflux procedure and pyloroplasty both be added to the Collis gastroplasty to eliminate (or minimize) the GER that is associated with at least 85 % of EA patients [24, 35]. The usual and similar postoperative complications occur with this lengthening procedure as with the others, except the antireflux procedure often causes a partial obstruction at the hiatal area [24]. Therefore, a loose fundoplication may be better for avoiding swallowing difficulties. Furthermore, the influence of the gastric juice secreted from the new tubular gastric segment on the esophageal mucosa above it cannot be ignored [24].

As with the other surgical alternatives, the results of this distal esophageal lengthening procedure, done in wide-gap EA babies in other series, have occasionally been reported by others [4, 24]. Therefore, it must be assumed that it has not been used very often.

Elongation of the Distal Esophagus by Stretching

It appears that Lafer and Boley [29] was the first to report a technique for elongation of the distal EA in 1966. This was, again, an expansion of the previously published papers by Howard and Myers [21] and Johnson [23] both in 1965, in which the upper pouch was elongated, eventually enabling a primary anastomosis of the two pieces of atretic esophagus. Initially, Lafer and Boley [29] removed the feeding gastrostomy and a Hegar sound was passed under x-ray control into the distal esophageal pouch. Intermittent pressure was then applied for 5–10 min, the sound removed, and the gastrostomy tube reinserted. This procedure was continued three times weekly, initially with x-ray control, but eventually at the bedside with minimal obvious trauma to the infant, and with surprising ease. While the proximal pouch was also stretched at the same inter-

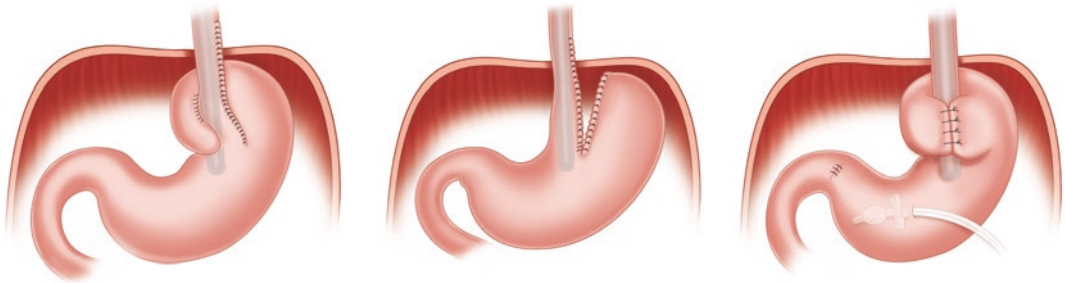

Fig. 22.12 Standard Collis(-Nissen) procedure. Vertical gastroplasty is created with staplers parallel to the lesser curve of the stomach with a bougie in the esophagus. The fundoplication (Nissen) is wrapped loosely 360° around the tubular gastric neo-esophagus. Heineke-Mikulicz pyloroplasty is added for increased gastric emptying to minimize GER and also if vagal nerve damage is a possibility. The tube gastrostomy remains (With permission from Dr. Hisayoshi Kawahara (*World J Surg*) (Ref. [24]))

vals with a mercury bougie, most of the length was obtained in the distal pouch.

As with other previously described innovative surgical techniques in this chapter, clever modifications continued to arise in attempt to make the dilatation of the distal atretic pouch easier. In 1989, Kleinman et al. [28] showed that distal esophageal pouch growth could be achieved by producing intermittent hydrostatic stretches. This was done infusing dilute isotonic contrast into the distal esophageal pouch under fluoroscopy, after an angiographic balloon catheter was inserted through the gastrostomy to temporarily occlude the GE junction.

In 1989, Todd et al. [52] closed the GE junction with Teflon strips in an unstable, very low birth weight premature baby with EA and a distal TEF to prevent reflux into the trachea. This produced a patulous distal esophagus. On the other hand, it has been known for a long time that the small stomach of a pure EA baby can be dilated up (for an eventual GT replacement) by bolus gastrostomy feeds which, because of the known GER that is present in most EA, will also dilate up the atretic distal esophageal pouch.

In 2003, Hikida et al. [20] also reported elongation of this distal esophageal pouch by mechanical bougienage. Yet another novel idea to achieve the same result was published in 2006 by Vogel et al. [56]. A balloon catheter was placed beside the gastrostomy and its tip was positioned in the distal esophageal pouch (Fig. 22.13). The balloon was inflated and an elastic vessel loop was doubly wrapped around the gastroesophageal (GE) junction to secure the catheter in the distal esophageal pouch; the vessel loop was exteriorized through a separate abdominal stab incision. The authors "pressurized" the distal esophageal pouch for 1–2 h two to three times daily, but the original balloon catheter and vessel loop were soon dislodged and only the balloon catheter was replaced and inflated. Routine infant formula boluses were then administered retrogradely through the balloon catheter into the distal esophageal pouch to promote hydrostatic stretching. This routine was successful after just 2 weeks.

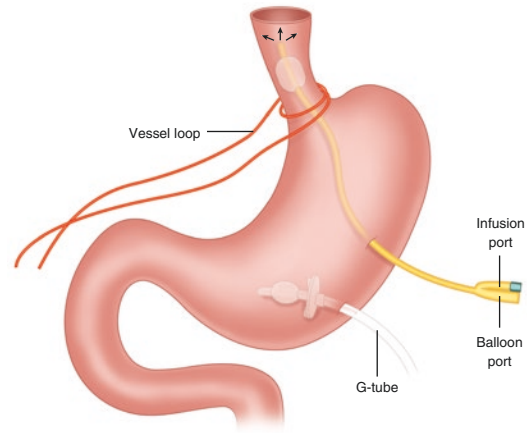

Fig. 22.13 The balloon catheter is placed beside the gastrostomy and its tip is positioned in the distal esophagus. The balloon is inflated and held in place by an elastic vessel loop doubly wrapped around the gastroesophageal junction. The distal esophageal pouch was then pressurized with a simple hydrostatic column of saline (With permission from Elsevier Publishing (*J Pediatr Surg*) (Ref. [56]))

The more one looks at all these variations of the same process, the simpler one seems easier and better, going right back to the original procedure by Lafer in 1966 [29].

Thoracoscopic Repair of Pure Esophageal Atresia

23

Benjamin E. Padilla and Marcelo Martinez-Ferro

Introduction

Esophageal atresia (EA) is a congenital condition characterized by discontinuity of the esophagus. EA is a spectrum of anomalies. The vast majority of EA communicate with the tracheobronchial tree through a tracheoesophageal fistula (TEF). Pure EA without TEF requires special consideration because unlike other forms of EA/TEF, the long distance between the esophageal pouches often precludes primary anastomosis.

The incidence of EA is approximately one in 4,000 live births, with one third of cases occurring in premature infants. While overall survival for infants with EA/TEF exceeds 90 %, most deaths occur in babies with severe associated congenital anomalies. According to the "Rule of Halves," half of patients with EA have associated anomalies and half of these anomalies are congenital cardiopathies. Among patients with associated malformations, half have more than one malformation, mainly anorectal, urogenital, and skeletal. Additionally, malformative associations such as VACTERL (Vertebral defects, Anal atresia, Cardiac anomalies, TracheoEsophageal abnormalities, Renal and Limb disorders) and CHARGE (Coloboma, Heart defects, Atresia of the choanae, developmental Retardation, Genital hypoplasia, and Ear deformities) as well as trisomy 18 and 13 are relatively frequent. Therefore, genetic evaluation may be important at the time of deciding the surgical procedure in such cases [1].

The exact etiology of EA is unknown. Separation between the trachea and the esophagus is complete by gestational day 36. It is in this early gestational period that tracheoesophageal malformations develop. There is speculation that the etiology of EA/TEF in the absence of additional malformations is different from EA/TEF when associated with other malformations. Furthermore, while there are reports of EA in siblings, monozygotic twins, and in the offspring of individuals with EA/TEF, no clear pattern of inheritance has been identified [2, 3].

EA/TEF should be suspected in any newborn with choking or excessive drooling. Babies with EA swallow normally when fed, but gag and cough as the fluid refluxes through the nose and mouth. Over time, respiratory distress develops

as a result of repeated aspiration. When EA is suspected, an orogastric tube is gently passed into the esophagus. The tube should pass into the stomach without any resistance and return gastric contents. If resistance is encountered or there is any doubt as to the position of the tube, a plain radiograph should be obtained (Fig. 23.1). There are case reports of perforation of the retropharynx or esophagus that were misdiagnosed as EA because the tube was lodged in the posterior mediastinum and could not be advanced [4].

The diagnosis of EA can be corroborated with a barium esophagram that shows contrast in a blind-ended esophageal pouch and no contrast in the stomach. Hyperosmotic water-soluble contrast should be avoided because of the concern for aspiration pneumonitis.

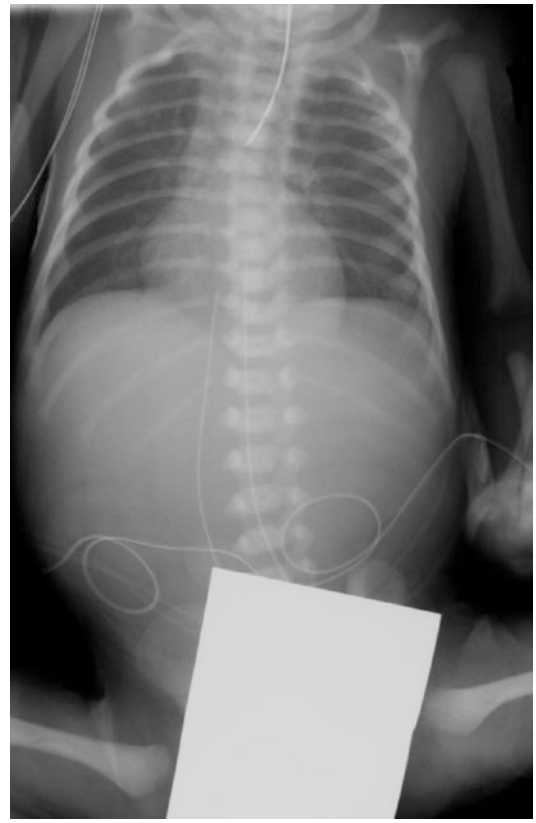

Fig. 23.1 This newborn has the classic radiograph for isolated esophageal atresia. Note the esophageal tube cannot be passed further than the proximal esophagus and there is no air in the abdomen

Isolated Esophageal Atresia

Isolated EA without TEF is the second most common type of EA, accounting for 5–7% of all patients with EA. Due to the long distance between the two blind-ending esophageal pouches relative to other types of EA, isolated EA is often referred to as "long-gap" EA. The terms "isolated," "pure," "type A," and "long-gap" EA are used interchangeably in the literature and refer to the same clinical entity. Strictly speaking, "long gap" should refer to any EA in which the distance between the atretic esophageal ends prevents a primary anastomosis [5]. As such, types B, C, D, and E can be considered "long gap" provided the distance between esophageal segments precludes a primary end-to-end esophago-esophagostomy. The exact distance that constitutes a "long gap" is controversial because of variation in the methods used to determine the gap length [6].

Unlike other types, the diagnosis of pure EA is often made during pregnancy. The characteristic prenatal sonographic findings are a small or absent fetal gastric chamber and associated maternal polyhydramnios. In contrast, fetuses with EA and distal TEF usually have a normal prenatal sonogram because the TEF prevents the formation of marked polyhydramnios. When EA is suspected, genetic testing should be performed to exclude chromosomal abnormalities, and fetal echocardiography is used to identify associated cardiopathies.

Typically, the newborn with isolated EA has an excavated abdomen because air cannot pass into the gastrointestinal tract. In the delivery room, the diagnosis of EA is confirmed by placing a radiopaque catheter in the esophagus until resistance is encountered. Plain radiographs show the tip of the catheter in the upper esophageal pouch. In cases of isolated EA, there is a complete absence of gas in the upper gastrointestinal track (see Fig. 23.1), while EA with distal TEF has gas in the stomach and bowel due to the fistula connecting the airway to the distal esophageal pouch. If the diagnosis is unclear, the surgeon can instill 2–3 cc of barium into the catheter and perform an esophagogram under fluoroscopy, taking care to aspirate the contrast material after the study to prevent

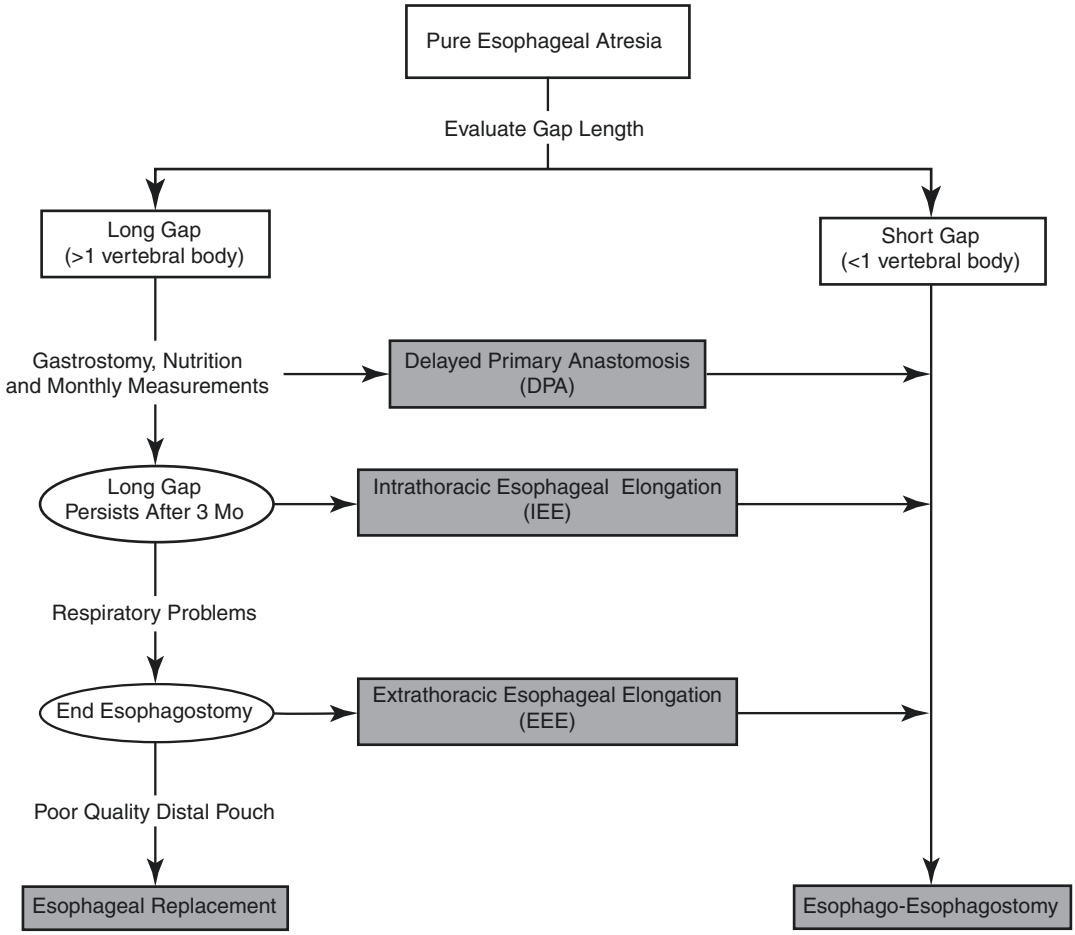

Fig. 23.2 Algorithm for the management of the baby with isolated esophageal atresia

aspiration pneumonia. Contrast esophagography often fails to demonstrate a TEF to the proximal esophageal pouch when it is present and never shows a distal TEF. Therefore, preoperative bronchoscopy is routinely performed to look for a TEF. Vascular rings and other causes of extrinsic compression should be sought to determine the most appropriate operative approach.

Management Options

The ideal treatment for EA remains controversial. Given the rarity of isolated EA, there is little consensus as to the best operative approach because individual and institutional experience in treating the disease is limited. Nevertheless, most surgeons agree that the native esophagus is the best conduit for esophageal function. Based on this principle, several techniques have been developed to elongate one or both ends of the atretic esophagus by means of an internally or externally applied traction device. Irrespective of the timing of operation and the mechanism of esophageal elongation, at the Fundación Hospitalaria Private Children's Hospital, we prefer the thoracoscopic approach when repairing EA and have shown it to be safe and effective. Furthermore, the thoracoscopic approach decreases postoperative pain, shortens hospital stay, and improves the cosmetic appearance [6, 7].

We propose a treatment algorithm based on the patient's anatomy and available surgical

options (Fig. 23.2) [8]. There are three principle considerations regarding the patient's anatomy: (i) What is the length of the esophageal gap? (ii) Is the long gap due to a short proximal pouch, a short distal pouch, or both? (iii) Does the patient have an esophagostomy? Surgical options include (i) delayed primary anastomosis (DPA), (ii) intrathoracic esophageal elongation (IEE), (iii) extrathoracic esophageal elongation (EEE), and (iv) esophageal replacement (ER).

According to the proposed algorithm, an isolated EA with a relatively short distance between proximal and distal pouches (i.e., <1 vertebral body length) should undergo attempted thoracoscopic primary end-to-end anastomosis. On the other hand, if there is a "long gap" measuring more than one vertebral body, enteral nutrition is initiated in anticipation that the gap will narrow spontaneously as the two esophageal pouches grow. After 3 months, if the gap has not narrowed sufficiently (i.e., less than one vertebral body) to allow a tension-free DPA, IEE is attempted. However, occasionally patients require an esophagostomy to control secretions, making the proximal pouch unsuitable for IEE. Patients with an esophagostomy and a well-developed distal pouch are ideal candidates EEE (aka Kimura technique). EEE attempts to progressively elongate the proximal esophageal pouch by repeatedly repositioning the esophagostomy. Therefore, it is important to consider EEE as a reconstructive option early so that the esophagostomy can be properly positioned. ER is reserved for patients who require an esophagostomy and have a poor quality distal pouch or in patients in whom esophageal reconstruction has failed. While the best conduit for ER is controversial, laparoscopic gastric transposition is our preferred choice [9].

Delayed Primary Anastomosis

Successful DPA relies on adequate preoperative nutrition and the ability to create a tension-free esophago-esophagostomy. Therefore, we create a gastrostomy as soon as feasible and start enteral feedings early. This plan of care is followed by a variable waiting period of up to 3 months to allow the gap between the pouches to decrease. Continuous suction is applied to the upper pouch and the distance between the upper and lower esophageal segments is assessed periodically with contrast radiographs. If the distal pouch does not fill adequately to assess its length, a metallic dilator can be gently introduced into the esophagus via the gastrostomy using fluoroscopy. The two ends of the esophagus should meet or slightly overlap to ensure a tension-free DPA. In about 75 % of cases, the esophageal gap narrows sufficiently to allow DPA. On the other hand, if after 3 months, a long esophageal gap persists, further waiting is not productive and esophageal lengthening with traction should be considered.

Operative Technique

Three hours before induction of general anesthesia, gastrostomy feedings are stopped, and the upper esophageal pouch is continuously aspirated until the patient arrives in the operating room. The suction catheter in the upper pouch is replaced with a flexible bougie, being careful to keep the bougie separate from the endotracheal tube. While still supine, a radio-opaque semirigid bougie is inserted into the gastrostomy and positioned in the lower esophageal pouch under fluoroscopy. The end of the bougie is positioned such that it can be manipulated though the drapes during the operation. The bougies are indispensable in identifying the ends of the esophageal pouches during the operation [10].

The operation is performed via right thoracoscopy. The patient is placed in left lateral decubitus position and rotated anteriorly into a three-quarter prone position with the right arm reaching toward the head. The surgeon and assistant surgeon stand on the left side of the table facing the monitor located opposite them near the head of the table. The anesthesiologist stands at the head of the table and the scrub nurse at the foot (Fig. 23.3).

In general, special equipment is not needed for thoracoscopic repair of pure EA. While the dissection can be carried out with monopolar electrocautery, a 5 mm LigaSure (Covidien, Mansfield, MA) is useful for ligating the azygos vein. Intraoperative fluoroscopy helps identify

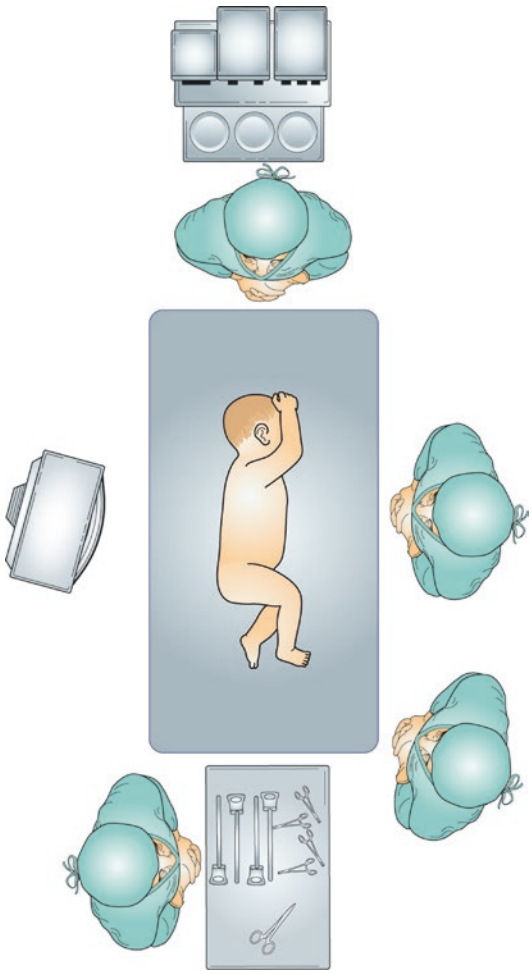

Fig. 23.3 Operating room setup for EA repair. The patient is in the left lateral decubitus position and rotated anteriorly to provide access to the posterior mediastinum

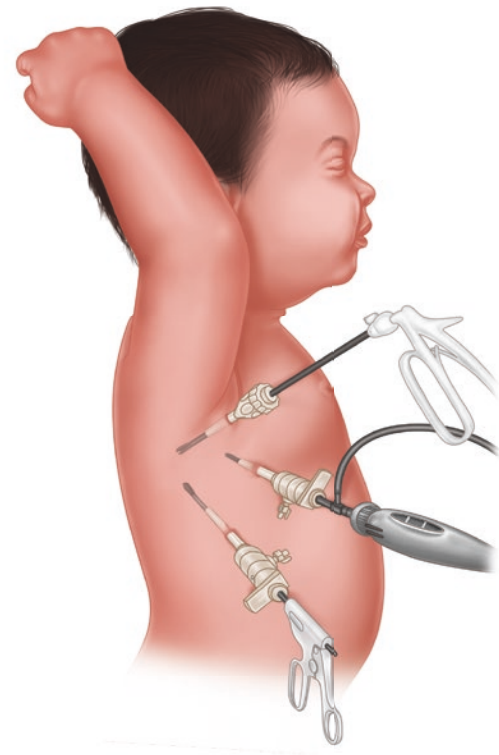

Fig. 23.4 Three ports are routinely used for the dissection and intracorporeal anastomosis: 3 mm camera port in the sixth intercostal space, 5 mm working port in the third intercostal space, and 3 mm working port in the ninth or tenth intercostal space

the esophageal pouches, but is not essential. For the anastomosis, we use 5-0 polydioxanone suture on a CV1 needle.

Three cannulas are positioned as shown in Fig. 23.4. A 3 mm port is inserted in the sixth intercostal space at the midaxillary line and serves as the camera port. We recommend using a short (18 cm) 3 mm telescope with a 30° wide-angle lens because it provides better visibility in the infant's small thoracic cavity. Rather than using single-lung ventilation, CO_2 is insufflated to create a pneumothorax. A pressure of 5 mmHg provides excellent lung collapse without compromising cardiopulmonary physiology. The second cannula is 5 mm and is inserted in the third intercostal space at the midaxillary line. This cannula is larger than the others because it is the primary working port and is used for introducing suture into the thoracic cavity. We recommend using a 3 mm reducer cap to prevent CO_2 leak through the cannula. Finally, a 3 mm port is inserted in ninth or tenth intercostal space at the posterior axillary line. All the cannulas are fixed using the Shah-Neto technique for stabilization which also helps prevent CO_2 subcutaneous emphysema [11].

The first step in DPA is identifying and mobilizing the proximal and distal esophageal pouches. We start by transecting the azygos vein with either monopolar electrocautery or the LigaSure. With the azygos vein divided, we locate the distal esophageal pouch by gently moving the rigid bougie that was inserted through the gastrostomy. The

distal esophageal pouch is dissected from the surrounding tissues by a combination of hook electrocautery, Maryland dissector, and scissors. Great care should be taken with this portion of the dissection as the distal esophageal pouch is thin-walled and easily injured. Next, the proximal esophageal pouch is similarly identified and mobilized. Generally, mobilizing the proximal esophageal pouch off the trachea is the most difficult part of the dissection because it requires dissection up into the neck. The dissection is complete when the proximal and distal pouches slightly overlap with minimal tension. In theory, esophageal mobilization should be limited to what is needed to create a tension-free anastomosis, thereby preserving the segmental blood supply to the esophagus. However, in practice, both esophageal pouches are fully mobilized to reduce tension at the anastomosis.

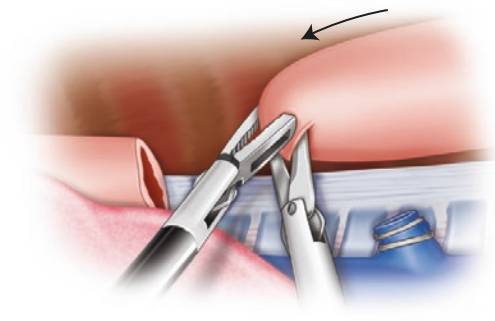

Fig. 23.5 After the proximal and distal pouches are fully mobilized, a transverse esophagotomy is made at the end of the proximal pouch. The distal esophagotomy has already been created

Once the esophageal pouches are adequately mobilized, transverse esophagostomies are made in the ends (Fig. 23.5). Placing tension on the bougies helps identify the very distal part of the esophageal segments and maximizes esophageal length. A primary, single layer end-to-end anastomosis is then performed. The first stitch is placed at the midportion of the posterior wall and knotted in the lumen of the esophagus (Fig. 23.6a). Roeder knots are tied extracorporeally and slid into place using a needle driver, thereby allowing the surgeon approximate the ends of the esophagus despite the tension (Fig. 23.7). Once the posterior wall is approximated, a silastic nasojejunal feeding tube is introduced across the anastomosis to prevent including the posterior wall of the esophagus in the anterior wall closure. As the surgeon transitions to working on the anterior wall of the anastomosis, the knots are tied outside the esophagus. A total of six to eight interrupted stitches are usually needed (Fig. 23.6b). At the end of the operation, an 8–12 Fr. chest tube is left.

We have developed maneuvers to help overcome the technical challenges of thoracoscopic

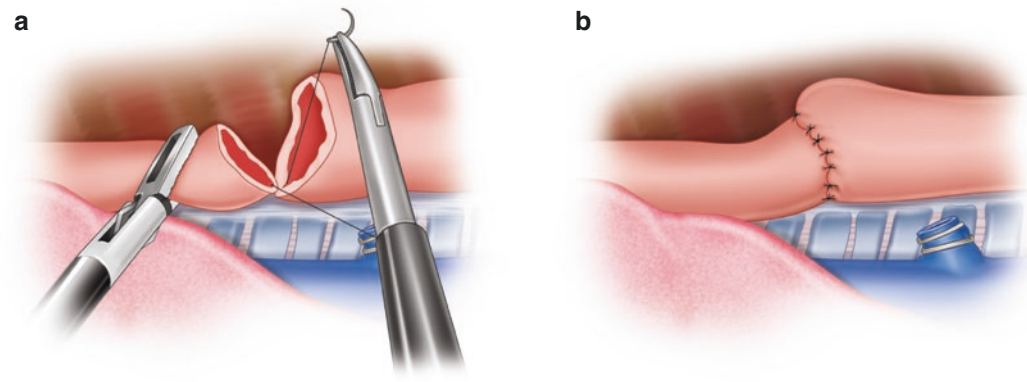

Fig. 23.6 The first stitch is placed in the middle of the posterior wall and the knot is tied on the luminal side of the anastomosis (**a**). The esophago-esophagostomy is complete with six to eight stitches. Note that the knots on the anterior wall are extraluminal (**b**)

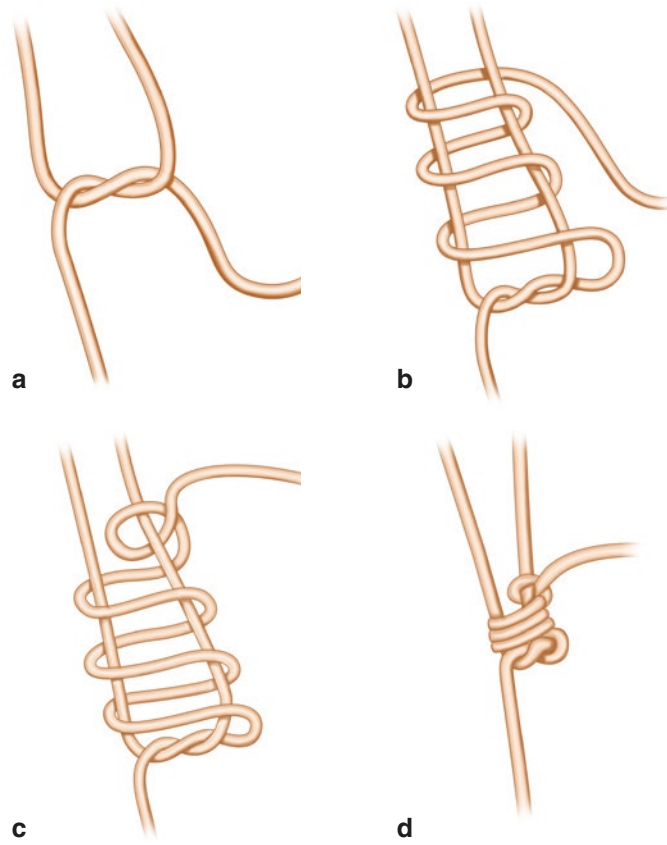

Fig. 23.7 Roeder knots are used because the anastomosis is often under considerable tension. (**a**) A simple knot is tied extracorporally. (**b**) An end of the suture is wound around the suture leading to the knot. (**c**) Next, a half hitch is tied. (**d**) The tension on the knot can be adjusted by pushing the knot down with a needle driver

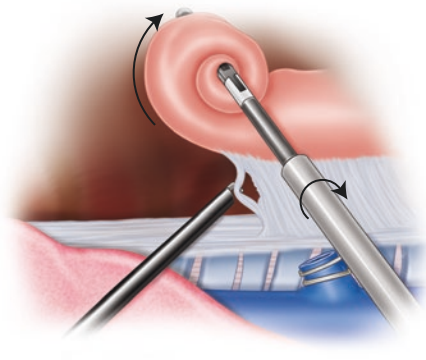

Fig. 23.8 The "spaghetti maneuver" facilitates dissection of the plane between the proximal pouch and the trachea by providing constant tissue traction as the dissection progresses into the neck

repair of EA. As mentioned previously, dissection between the posterior membranous portion of the trachea and the anterior wall of the upper esophagus can be difficult. The "spaghetti maneuver" aids in this portion of the dissection (Fig. 23.8). First, the distal end of the esophageal pouch is mobilized, and the end of the pouch is firmly held with grasping forceps. As the dissection continues proximally, the esophageal pouch is rolled onto the grasping forceps (like spaghetti on a fork) creating constant tissue traction while keeping the mobilized portion of the esophagus out of visualization [6, 7]. In this way, the dissection is continued well into the neck in order to minimize tension at the anastomosis. Because the anastomosis is often under tension despite extensive mobilization of the esophagus, the "twin traction suture" was developed (Fig. 23.9). To distribute the tension evenly, two stitches are placed in the posterior wall of the esophagus and tied simultaneously with Roeder knots. Alternately, tightening the knots gently approximates the tissue and prevents placing all the force on a single stitch [6, 7].

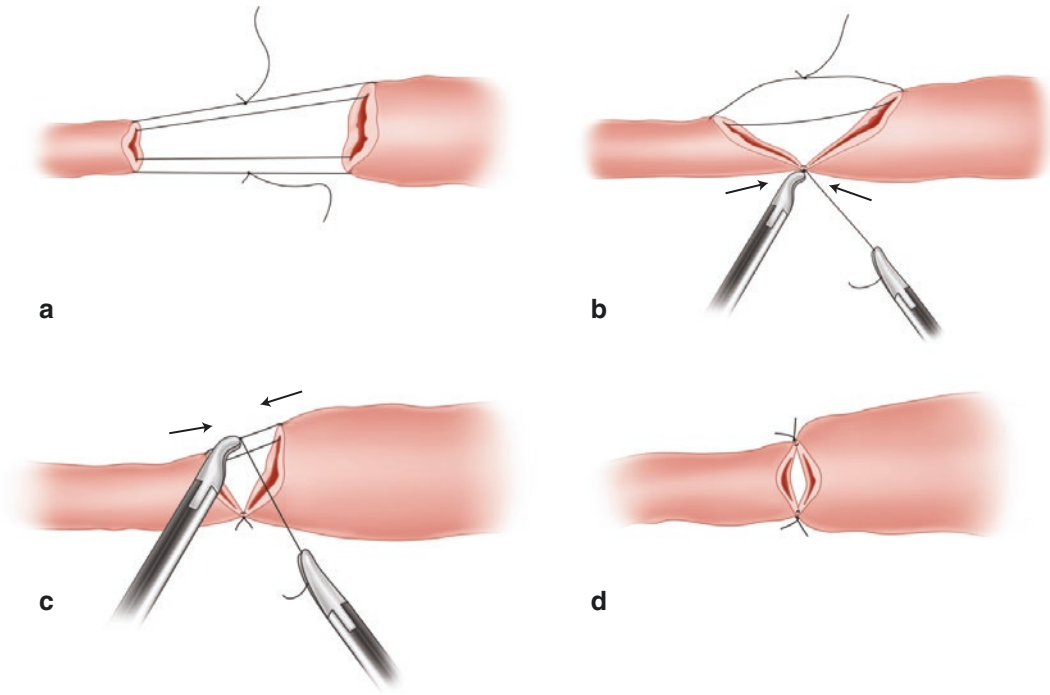

Fig. 23.9 The "twin traction" technique helps approximate the proximal and distal pouches when they are under significant tension (**a**). Two Roeder knots are alternately tightened (**b**–**d**), thus distributing the tensile force and avoiding tears in the esophagus

All patients with high-tension esophageal anastomosis receive full muscle relaxation and are mechanically ventilated for at least 48 h. While muscle relaxation has not been shown to prevent anastomotic problems, we feel it is important to prevent neck extension and excessive swallowing in the early postoperative period. The gastrostomy is vented for 48–72 h and nasojejunal feedings are started on postoperative day 3. A barium esophagogram is performed on postoperative day 5. If the anastomosis is patent and without leak, oral feedings are started and the chest tube is removed. The gastrostomy is left until it is no longer needed.

Intrathoracic Esophageal Elongation (IEE)

IEE is the best alternative for esophageal lengthening if the esophageal gap is greater than one vertebral body height after 3 months of nonoperative management. While various methods for IEE are described, all of the techniques require a relatively well-developed distal pouch and cannot be used in patients with an esophagostomy. In 1971, Rehbein and Schweder were the first to use silver olives as a traction elongation device [12]. An olive is placed in the lumen of each pouch. A nylon suture bridges the esophageal gap and connects the two silver olives. The tension on the nylon suture is adjusted periodically, placing traction on the esophagus and drawing the two ends together. Traction is applied until the two olives are in direct contact and a fistula forms between the two esophageal segments, eliminating the need for an anastomosis. Another group described an innovative thoracoscopic approach to IEE using a magnetic traction device [13].

Our preferred method of IEE is called the "stainless steel spheres technique" (Fig. 23.10) [6, 7]. A stainless steel sphere is placed in both the proximal and distal esophageal pouches. Traction on the two spheres is periodically adjusted by

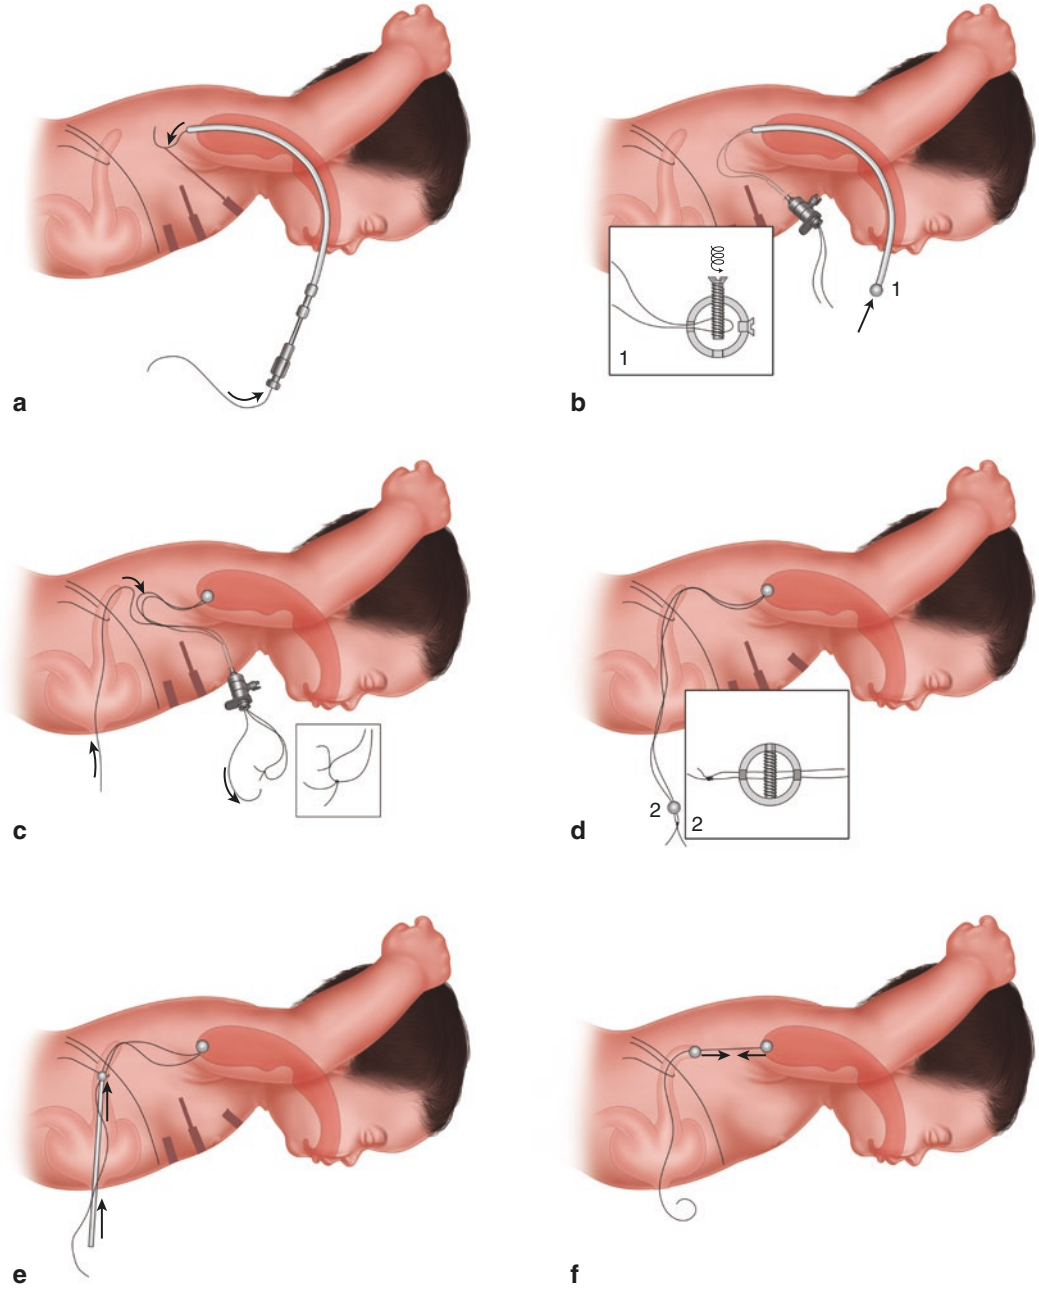

Fig. 23.10 The "stainless steel spheres technique" is depicted. (**a**) A 6-0 Prolene suture is introduced into the thorax and withdrawn from the axillary port. (**b**) The 6-0 Prolene is pulled back and exchanged for a loop of 5-0 Prolene. The 5-0 suture is then attached to a sphere with a removable axis. (**c**) The sphere is pulled into the proximal pouch and a 6-0 Prolene suture is passed through the distal pouch. (**d**) The 6-0 suture pulls the loose ends of the 5-0 suture out the esophagostomy, and the 5-0 suture is attached to the sphere with a fixed axis. (**e**) The 5-0 suture is tied with a Roeder knot and the knot is pushed into the distal pouch. (**f**) The Roeder knot is tightened weekly to maintain traction on the esophagus

tightening the traction suture that is accessed via the gastrostomy stoma. In addition to standard thoracoscopic equipment, IEE requires specialized instruments and devices including the following: two 14 Fr. semirigid, radio-opaque dilators with a hollow central channel, one transurethral injection needle (33 cm long with 23-gauge needle available from Bard, Inc.), one stainless steel traction sphere with a removable axis, and one stainless steel traction sphere with a fixed axis. Intraoperative fluoroscopy is important to ensure proper positioning of the dilators and spheres.

Tube feedings are held 3 h prior to the operation and the patient is placed under general anesthesia. Single-lung ventilation is not required. With the patient supine, a 14 Fr. dilator is passed under fluoroscopy through the gastrostomy and into the distal esophageal pouch. Similarly, a 14 Fr. dilator is passed through the mouth and into the proximal pouch. The dilators are included in the operative field as the surgeon will need access to the dilators during the operation. Next, the proximal and distal esophageal pouches are mobilized thoracoscopically in the same way as for DPA. Special care must be taken to avoid injuring the esophageal pouches because the subsequent repair is at high risk for leaking due to the traction that is placed on the esophageal segments.

Once the esophageal pouches are fully mobilized via thoracoscopy, a traction suture is passed from the upper pouch to the lower pouch. This is accomplished with the transurethral needle and a series of sutures exchanges. First, the transurethral needle is inserted into the hollow channel of the upper dilator and pierces the proximal esophageal pouch. A 6-0 monofilament suture is advanced through the transurethral needle, into the posterior mediastinum, and exteriorized via the axillary port. The proximal dilator and transurethral needle are then removed. The exteriorized end of the 6-0 suture is tied to the middle of the traction suture (5-0 Prolene) and the 6-0 suture is pulled back out of the mouth. In doing so, a loop of the traction suture is brought through the proximal pouch and out the mouth, with the two free ends of the traction suture dangling from the axillary port. The next objective is to pull the two free ends of the traction suture through the distal pouch and out the gastrostomy site. To do this, the transurethral needle is inserted through the dilator that was positioned in the distal esophageal pouch via the gastrostomy stoma. The needle punctures the end of the distal esophageal pouch, and a 6-0 suture is passed through the needle into the mediastinum and exteriorized via the axillary port. The exteriorized 6-0 suture is tied to the two free ends of the traction suture. The 6-0 suture is then pulled back from the gastrostomy site, bringing the free ends of the traction suture through the distal esophageal pouch and out the gastrostomy site. The end result is a single traction suture that forms a loop at the mouth, bridges the esophageal gap, and has two free ends exiting the gastrostomy site.

With the 5-0 traction suture in position, the steel sphere with the removable axis is secured to the loop of suture that exits the mouth. Under fluoroscopy, the surgeon pulls on the free ends of the traction suture, thereby pulling the sphere through the mouth and into the proximal esophageal pouch. Similarly, the ends of the traction suture are threaded through the steel sphere with the fixed axis and pushed through the gastrostomy stoma and into the distal esophageal pouch. The traction suture is tied extracorporally with a Roeder knot and the knot is tightened within the distal esophageal pouch with a knot pusher until there is traction on the esophageal pouches. Note the knot pusher passes over the traction suture, through the gastrostomy site, and into the distal esophageal pouch. A 12 Fr. chest tube is inserted and a chest radiograph is obtained to determine the position of the spheres. Each week, the Roeder knot is tightened through the gastrostomy stoma, using fluoroscopy to gauge the esophageal gap. After 3–4 weeks of traction, the esophageal gap is narrowed, and thoracoscopic DPA is performed.

An alternative to the stainless steel spheres technique is to use sutures to approximate the two ends of the esophagus. The proximal and distal pouches are fully mobilized thoracoscopically as previously described. Next, two or three 5-0 monofilament stitches are placed between the upper and lower pouches and exteriorized out the

axillary port. The stitches are tied with Roeder knots and tightened with a knot pusher. Each week, the patient returns to the operating room and the knots are tightened to increase traction on the esophageal segments. DPA is performed when the esophageal pouches are approximated without tension. The main disadvantages of this technique are: (1) the tensile forces are focused on two or three discrete points, and (2) the patient must undergo general anesthesia each time the knots are tightened.

Extrathoracic Esophageal Elongation (EEE)

The EEE was originally described by Kimura et al. [14] and has proven to be a valid means of esophageal reconstruction when the proximal pouch has been used for esophagostomy or damaged by prior attempts at esophageal reconstruction [15–17]. It is important to remember that, at best, EEE will lengthen the proximal pouch 3–4 cm. Thus, the success of an EEE is predicated on two factors: (1) a good quality distal pouch that at least reaches the level of the carina and (2) not injuring the proximal pouch with each lengthening procedure. While the primary objective of EEE is to preserve the esophagus as the conduit in the chest, an added benefit is that patients can eat while awaiting definitive repair because they have esophagostomies. Though there is no nutritional benefit to eating, these so-called sham feedings are thought to prevent the development of food aversion.

EEE is performed in two stages: (1) esophageal lengthening and (2) establishing esophageal continuity. Esophageal lengthening is achieved by creating a series of esophagostomies that put the proximal pouch under tension, thus progressively elongating the pouch. It is crucial that the surgeon has a clear strategy for executing an EEE when performing the initial esophagostomy; otherwise, the proximal esophageal pouch may be rendered useless. We prefer positioning the esophagostomy on the right side because it simplifies the final operation which requires access to both the esophagostomy and right chest. To create the esophagostomy, an incision is made in the neck just anterior to the right sternocleidomastoid muscle and the dissection is carried down to the esophagus. It may be necessary to transect the anterior scalene muscle to adequately expose the esophagus at this level. Once the esophagus is encircled, the thoracic portion of the proximal pouch is easily mobilized with blunt dissection through the cervical incision. The proximal esophageal pouch is delivered out the neck incision, and a subcutaneous tunnel is made from the neck incision onto the chest. An exit incision is made on the chest, the pouch is passed through the tunnel, and an end esophagostomy is created. The tunnel should be long enough that the esophagostomy is under tension. Two weeks later, the entire proximal pouch is mobilized again, the subcutaneous tunnel is lengthened, and a new esophagostomy is created further down on the chest wall. Counter incisions along the length of the tunnel may be needed to prevent injuring the esophagus during dissection and mobilization. This procedure is repeated every 2 weeks, progressively lengthening the pouch with each esophagostomy (Fig. 23.11).

Once the proximal pouch is of adequate length for a tension-free anastomosis, esophageal continuity is established. The right hemithorax and right arm are fully scrubbed and the arm is wrapped in gauze to allow the patient to be repositioned between the cervical and thoracoscopic portions of the operation. Stay sutures placed at the end of the extrathoracic esophageal pouch serve as a handle for manipulating the esophagus. The pouch is bluntly mobilized from the surrounding soft tissue and may require counter incisions over the neck and chest to avoid injuring the esophagus (Fig. 23.12a). Once the proximal esophageal pouch is mobilized, the distal esophageal pouch is thoracoscopically mobilized as described for DPA. Next, the surgeon bluntly develops a tunnel in the prevertebral space from the right neck into the right thorax. The thoracic portion of the dissection is performed using thoracoscopy. The proximal esophageal pouch is then pulled through the tunnel by the stay sutures using a 3 mm grasper (Fig. 23.12b). The surgeon

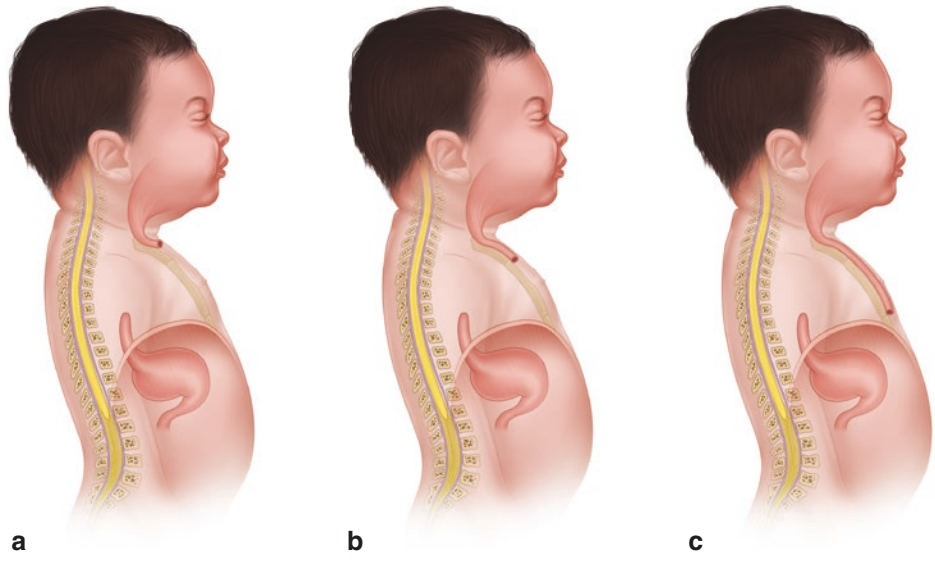

Fig. 23.11 With the extrathoracic esophageal elongation technique, the proximal esophageal pouch is lengthened by serially repositioning the end esophagostomy to maintain traction on the pouch (**a**–**c**)

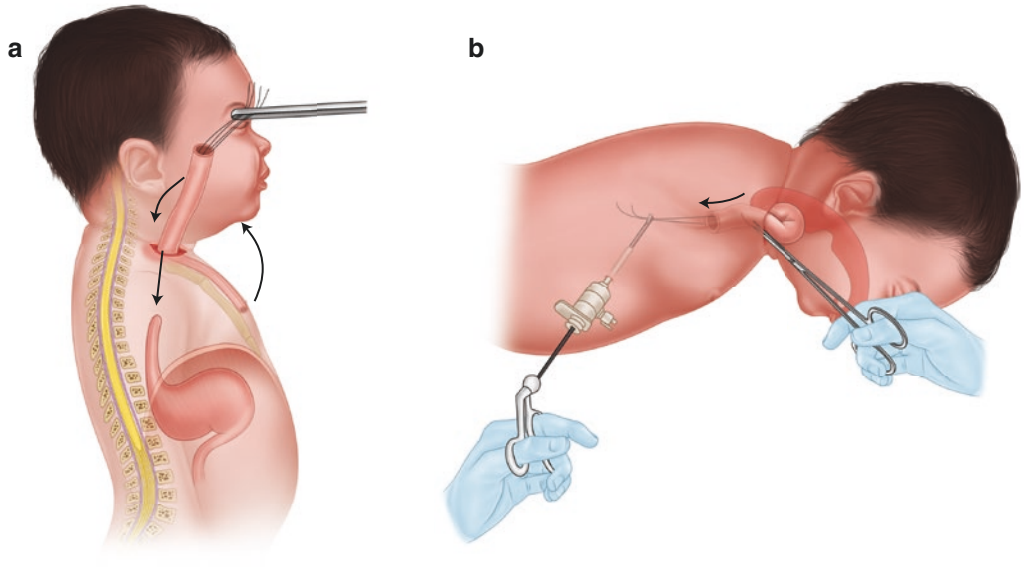

Fig. 23.12 When it is time to establish esophageal continuity, the proximal esophageal pouch is mobilized from the surrounding subcutaneous tissue (**a**). Following mobilization of the pouch, it is pulled through the prevertebral tunnel using the stay sutures (**b**)

must be sure that the esophagus is not twisted as it enters the thorax. Finally, the esophagoesophageal anastomosis is performed using the same technique described for DPA. Postoperative care is similar to DPA patients.

Esophageal Replacement (ER)

Esophageal replacement for EA is reserved for two groups of patients: (1) infants with a poor quality distal pouch requiring esophagostomy and

(2) infants with a damaged esophagus due to failed attempts at establishing esophageal continuity. While there is controversy as to the best conduit for ER, the colon was the first conduit used and remains the most commonly used replacement today. However, we prefer the gastric pull-up as it is technically straightforward and has excellent functional outcomes. Other techniques include gastric tube and jejunal interposition graft. The best reconstructive option for each patient depends on many factors including the length of usable esophagus, length of esophageal gap, and prior operations to the esophagus, stomach, and colon. In general, the shortest, straightest conduit will confer the best functional outcome. While a complete discussion of ER is beyond the scope of this discussion, thoracoscopic and laparoscopic techniques can be used to mobilize the conduit on its vascular pedicle and create the anastomosis. The surgeon must not only consider the optimal type of conduit, but also its preferred location. We prefer placing the conduit in the mediastinum because it offers the shortest, straightest route to the abdomen. However, if there is a thoracic vascular malformation on preoperative CT, the retrosternal position is used.

Conclusion

EA is an uncommon rare congenital defect that is particularly challenging to treat, not only because of the large esophageal gap that must be bridged but also because of the many anatomic factors that influence the strategy for reconstruction. The algorithm detailed in this chapter places patients into distinct treatment groups based on the anatomy and provides the groundwork for thoracoscopic esophageal reconstruction. Using this approach, the esophagus is preserved in 80 % of cases with excellent functional outcome. We advocate making every attempt at reconstructing the esophagus and keeping ER as a second option.

Part VI

The Growth Procedure for Long Gap EA

24 Growth Induction (the Foker Procedure) and a Flexible Approach for the Repair of Long-Gap Esophageal Atresia

John E. Foker

Introduction

Long-gap esophageal atresia (LG-EA) has posed repair difficulties for surgeons in rough proportion to the gap length. The possibility of repair will also be affected by the size and condition of the patient and the experience of the surgeon, effectively making the gap longer or shorter. As discussed under The Long-Gap Esophageal Atresia Problem (in this chapter), a good working definition of a long gap is whatever distance makes it difficult and risky for the surgeon to try a true primary repair. It is also clear that a gap length declared by some writers to be favorable for a primary repair will not necessarily be satisfactory in other operating rooms. Consequently, a long gap will not be defined here by a given length but will be left as a conclusion to be made by the surgeon. Certainly, the decision to attempt a primary repair in a patient with LG-EA should be carefully made with a good understanding of the operative techniques which will make it possible.

The purpose of this chapter is to present a flexible approach which will accommodate the broad spectrum of LG-EA and allow the desirable goal of a true primary repair to be reached in all patients. Our experience has included a wide range of gap lengths and certainly most or all would be considered long gaps by surgeons (Table 24.1). The gap length is principally determined by the size of the lower esophagus which, as will be seen in this chapter, can range from several centimeters long to a primordium only a few millimeters in length (Fig. 24.1). Currently, when the gap is considered too long for a primary repair, an interposition graft is often used to establish continuity [1–3]. Even the smallest lower segment, however, has a normal potential for development and requires only the growth signal to close the gap [4, 5]. We have shown this signal can be reliably enlisted to induce surprisingly rapid catch-up growth and produce an outwardly normal esophagus. The considerable variation in segment size that will be

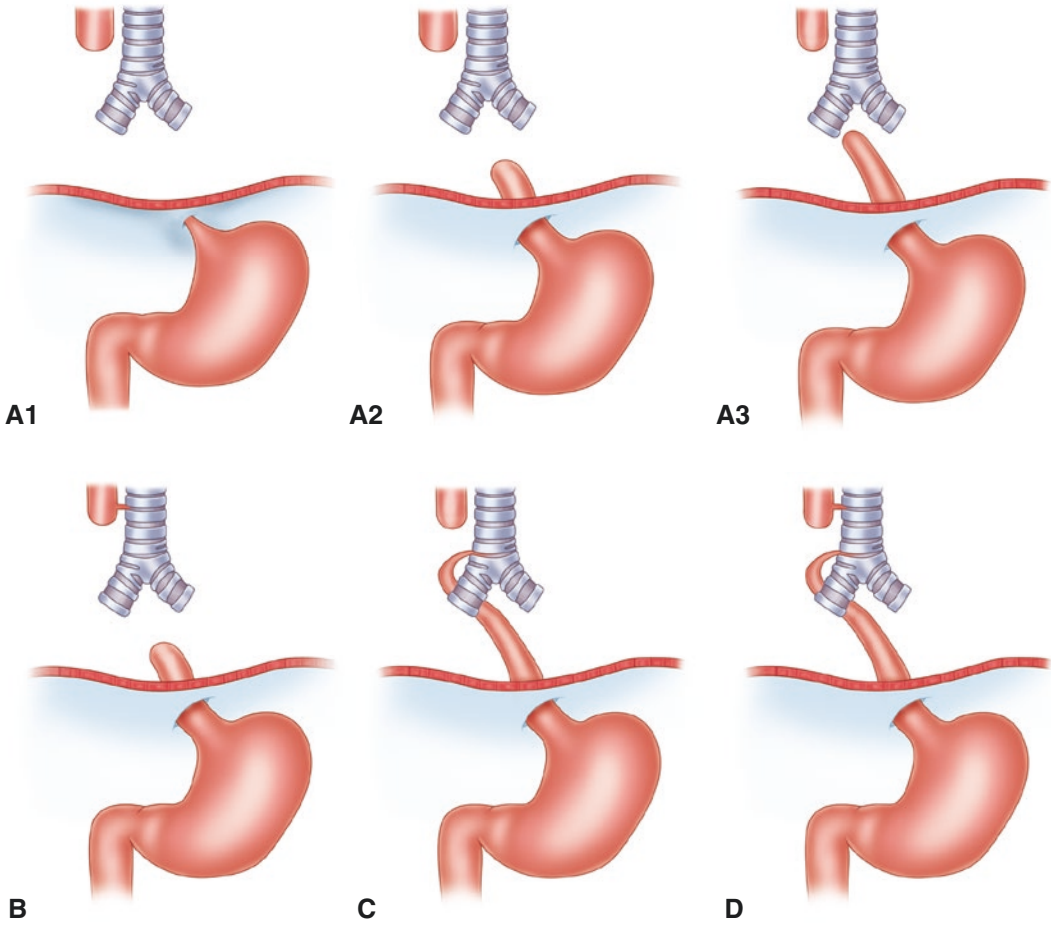

Fig. 24.1 Depicted are the major categories in the esophageal atresia (EA) spectrum. In reality, the spectrum is essentially continuous and intermediate configurations are common. The greatest variation exists in the lower segments. The "pure" EA (type **a**) examples may range from a lower segment not discernible preoperatively ($\mathbf{a}_1$) to one which nearly abuts the upper pouch ($\mathbf{a}_3$). In the group with only an upper pouch fistula (type **b**), a similar range of lower segment lengths presumably occur, but it is a rare type and the variation has not been well documented. There is also variation of where the lower segment enters the airway in types **c** and **d**. The tracheoesophageal fistula (TEF) may enter the membranous septum of the lower trachea or further down in the proximal main stem bronchus (most commonly right for patients with a left aortic arch and left for those with a right arch but other variations occur). These seemingly small differences in distance between the upper pouch and the end of the lower segment can shift an initial primary repair from straightforward to difficult

encountered, however, means the surgical approach must be flexible so that a primary repair can be accomplished across the full LG-EA spectrum [6].

To achieve the desired goal of 70 good years, the anatomy after the repair should be as close to normal as possible. A true primary repair is defined as an esophago-esophageal anastomosis without myotomies or displacement of the GE junction above the diaphragm [4]. In addition to a primary esophageal anastomosis, a good result will also depend on solving the common later problems of reflux and stricture; consequently, our treatment plan for LG-EA patients also includes effective post-repair resolution of these issues. With these problems controlled and despite the lower esophagus having only uncoordinated, sporadic contractions, emptying will be satisfactory with the aid of gravity, and essentially all of the LG-EA children will eat normally.

Our medium-term results support this active approach.

Previous Methods Used to Close a Long Gap

Traditionally, when an LG-EA has precluded a primary repair, numerous different approaches have been tried to achieve continuity, ranging from time to allow the segments to grow to placing an interposition graft. These techniques have had variable early and late results and most are described in other chapters in this book. Certainly, if the lower segment is of moderate size, a period of a few months may allow adequate growth for a primary repair to be done later [7, 8]. A period of relatively rapid induced growth, however, could greatly shorten the time until a primary repair can be done, reducing the intensive care unit stay and leading to earlier eating. Among the other surgical methods to close a long gap, two will be mentioned because of their common usage and significant consequences.

Myotomies, whether circular, multiple, or spiral, divide the muscular layer, allowing the underlying mucosa to stretch and close the gap. Unfortunately, the myotomies also bring their own complications. At the least, myotomies will interrupt coordinated peristaltic activity at that level and hinder emptying down to the anastomotic site. A more severe problem, however, develops when the unsupported esophageal mucosa stretches and forms a diverticulum (Fig. 24.2). Once underway, there is little to prevent an atonic diverticulum from continuing to expand, interfere with the passage of food, and, often, lead to frequent aspiration. With continued enlargement it may even compress the airway creating considerable difficulties in breathing [9, 10]. Consequently, myotomies are not used in our EA repairs.

Another method used by some to bring the esophageal ends together and allow an anastomosis is to open up the hiatus and pull the stomach partway up into the chest. This maneuver also brings very undesirable consequences. With the

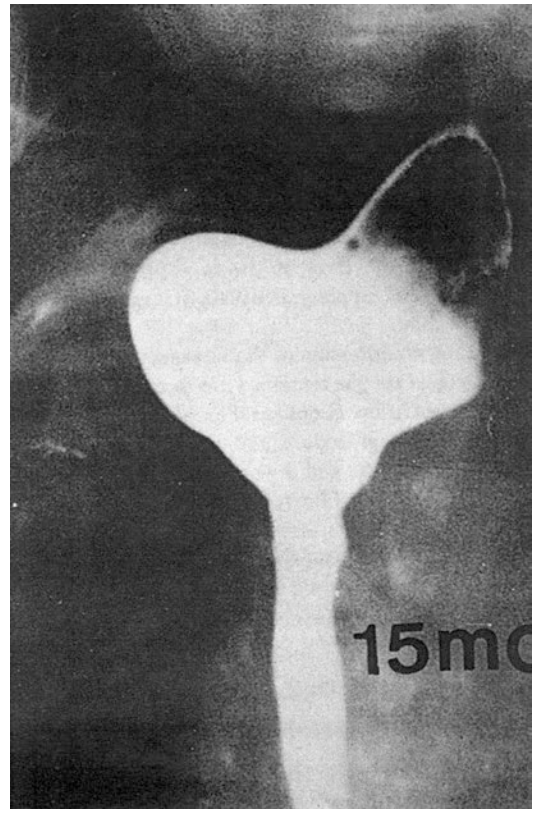

Fig. 24.2 An esophageal contrast study showing a large diverticulum which formed after a circular myotomy. Once a diverticulum begins to form, it tends to slowly enlarge becoming detrimental to swallowing, often resulting in repeated aspiration and may impinge directly on the airway

GE junction subjected to the negative pressure fluctuations within the chest, obligatory reflux up the esophagus will predictably lead to esophagitis and, eventually, Barrett's changes, a precancerous condition. Control of reflux will require establishing a pressure zone at the GE junction. Either the stomach must be returned to the abdomen, allowing a standard fundoplication or, by using a Collis gastroplasty, a type of fundoplication can be created below the diaphragm by wrapping the divided remnant of the greater curvature around the mid-stomach. The Collis gastroplasty, however, would seem to be a poor choice because of the resulting abnormal anatomy which includes leaving gastric cells in the chest and a type of fundoplication which may not function satisfactorily. Even though 20-year and

longer-term data are not yet available for a Collis gastroplasty done in young children, it seems unlikely this configuration will provide 70 good years.

Closing the Gap by Inducing Growth

The Incision and Dissection

The incision has been more completely described. The factors affecting the incision are the side of the aortic arch, the size of the infant, and the length of the gap. Knowing the location of the aortic arch is useful because the repair is better done on the opposite side [11]. Although the esophageal anastomosis can be done on the same side as the aortic arch, it is certainly easier if one does not have to work around the aorta. Furthermore, the presence of LG-EA suggests the possibility of aortic arch anomalies, which may add difficulties to the dissection and repair [12]. It should be remembered that the quality of the anastomosis will be very important to the child and so should be done under the most favorable conditions. Because of the potential consequences of the side of the aortic arch and arch anomalies including the presence of an aberrant subclavian artery, preoperative evaluation of the aorta by echocardiography or a scan will be helpful.

The smaller the lower segment initially, the more likely external traction will be necessary. For the longer gaps reached, there will be a greater advantage, therefore, to having a sturdier baby at least 3–3.5 kg in weight to lessen the possibility the tension sutures will pull out. Briefly, for a 3–5 kg infant, a transverse 3 cm skin incision, beginning just below and posterior to the tip of the scapula and carried back as far as the paraspinal ligaments, will provide an adequate opening (Fig. 24.3). The serratus anterior muscle is spared entirely which avoids later winging of the scapula. The esophagus, even with EA, is located posteriorly and an incision anterior to the tip of the scapula is "empty," and the commonly used large openings will add very little to exposure [13]. For surgeons used to a yawning opening, the incision described may seem limiting at first, but it will quickly become apparent that the exposure is very adequate. The assistant and others will not be able to observe, however, unless a small thorascope is inserted through another interspace. Most, if not all, of the unfortunate sequelae of the traditional, overly generous thoracotomy incision can be avoided with what might be considered a limited opening.

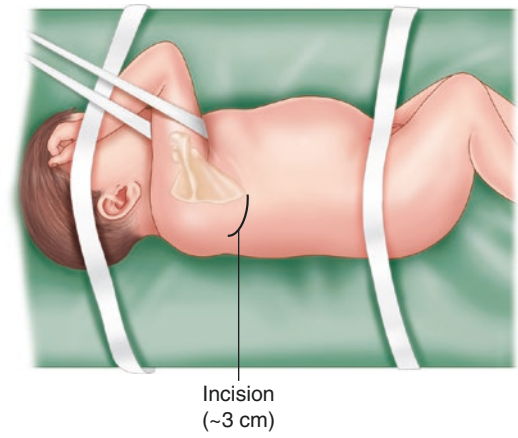

Fig. 24.3 With the patient in a straight lateral position, a 3 cm posterior-lateral incision will be ample for EA repair in newborns. For older children, a 4 cm or slightly longer incision should be adequate. To reduce the sequelae of the thoracotomy incision, the serratus anterior muscle should be spared in its entirety, and, posteriorly, the incision should not divide any perispinal ligaments. To gain access to a high upper pouch, it will be useful go through the third interspace instead of the commonly used fourth or fifth interspaces

Currently, the common type C EA lesions are often repaired thorascopically with equivalent early results to published open procedures [14–16]. One may question, however, whether results from either open or thorascopic procedures which include anastomotic leak rates of 10–20 % and a 5–10 % incidence of recurrent fistulas into the airway are entirely satisfactory. Attempts to improve these results will likely be more successful using open techniques at the present time, although the thorascopic approach will continue to improve as that technology advances.

The applicability of the thoracoscopic approach in LG-EA currently will be largely determined by the size of the lower segment; nevertheless, it has been used in a few cases and centers [17]. In general, the smaller the lower esophageal segment, the greater will be the initial potential problems with growth induction using the thoracoscopic method. The presence of only a primordium would seem to preclude placing traction sutures by this technique into the very small nubbins of esophageal tissue. The thoracoscopic approach has a reduced ability to use the fine sutures and needles which become necessary with very small lower segments. The visibility advantage of the thoracoscopic approach is not great, moreover, because most surgeons use significant magnification during open operations. The choice of how the procedure should be carried out will be better based on the anatomic variables, obstacles, and surgeon experience.

Which intercostal space(s) is opened will depend mainly on the location of the esophageal segments. If the upper and lower pouches are small, the ends may be widely separated and two intercostal openings will be better. The lower segment predictably will often be short if it does not reach the airway and form a fistula (types A and B) although considerable variation is seen (Fig. 24.1). For an upper pouch with a fistula (types B and D), the drainage of saliva into the trachea in utero reduces the growth stimulus of swallowing, and the segment may end relatively high in the neck, contributing to a longer gap. Small segments, whether upper, lower, or both, may be difficult to reach through the standard fifth intercostal opening, so the third and seventh interspaces are often opened instead. The described standard skin incision will allow both of these interspace openings to be made, and carrying them a little further anteriorly underneath the skin will effectively enlarge them and provide satisfactory access to widely separate segments.

A transpleural approach is recommended for any but the most straightforward EA lesions although some centers use it for all [18]. If some degree of growth induction is required, having the esophageal segments within the slippery pleural surface allows the movement of growth. In contrast, if the approach is retro-pleural, the pleural tissues will drape over the esophageal segments, form adhesions, and quickly halt growth. With a well-constructed anastomosis, which will be described in this chapter, there should be essentially no penalty for a transpleural approach [19].

A small lower segment may be difficult to find through a right thoracotomy incision because the esophageal hiatus is usually located on the left side (Fig. 24.4). To locate a small lower segment, a vertical opening is made posteriorly in the mediastinal pleura, the tissues near the vagus nerve are grasped, and with gentle upward traction the dissection proceeds toward the left hemidiaphragm. The undistinguished appearing tissue that is grasped near the vagus nerve contains tissues which envelop lower down, the lower esophageal segment and, sometimes, a small atretic cord from its tip, both of which allow the lower pouch to be pulled upward. With progressive dissection away from the surrounding tissues, the lower esophagus will usually be delivered up into sight, and a suture can be placed in the tip to aid the dissection (Fig. 24.5). Despite the vagueness of this description, this is a very effective technique; after all, the vagus nerves normally pass through the esophageal hiatus on each side of the lower esophagus and should serve as a landmark to begin the search for a very small lower segment.

Additional length in the lower esophagus is developed by taking down all investing tissues as well as limiting small vascular structures. Although the wisdom of dissecting free a small lower pouch has been questioned because of the segmental arterial supply to the normal lower esophagus, the wide experience has demonstrated its safety and confirmed the adequacy of the submucosal blood supply [20, 21]. Occasionally, arterial branches to the esophagus may course superiorly and these may not need to be divided.

The dissection will proceed toward the esophageal hiatus located on the left side of the mediastinum and, often, the left pleura will be visible. Even with a lower segment no more than 2 cm long, with continuing dissection and pulling

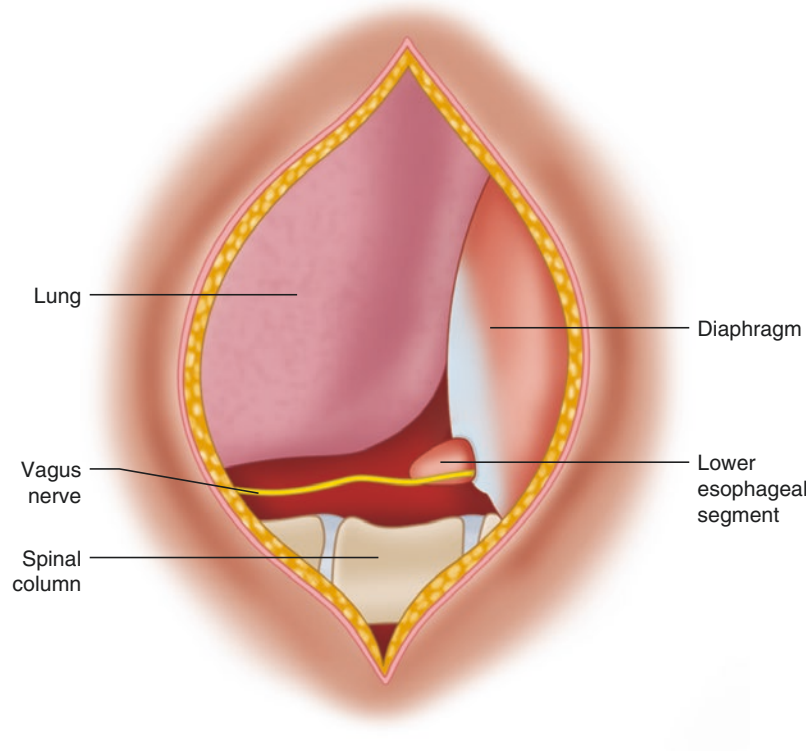

Fig. 24.4 The thoracotomy opening is portrayed overly large in this cartoon and there are no ribs present. If only a very short lower esophageal segment is present, then entrance through the sixth or seventh interspace will put the surgeon just above the diaphragm. The vagus nerve as viewed by the surgeon will be in front of the lower esophageal segment. The mediastinal pleura is opened vertically near the vagus nerve and the deeper tissues are grasped and pulled toward the surgeon. The dissection aims for the diaphragm posteriorly and to the *left* side

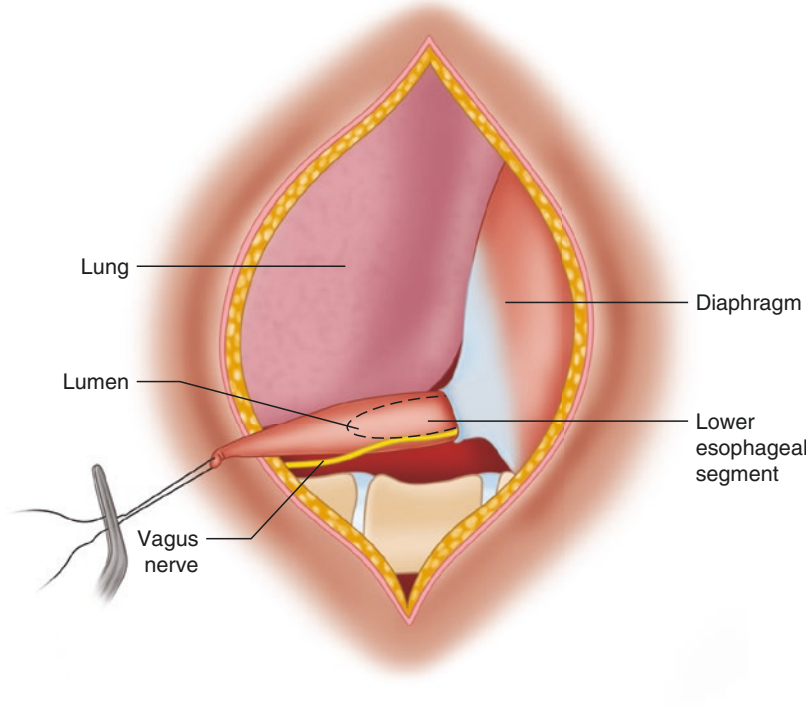

Fig. 24.5 A 5-0 Prolene suture has been doubly placed in the very tip of the lower segment to aid the dissection. This tissue is not strong enough for traction sutures and, more importantly, growth should only be induced at the level which contains a lumen. The vagus nerve is preserved. The dissection should go down to, but not into, the esophageal hiatus leaving the GE junction below the diaphragm

the tissue upward, it will be delivered over to the right side. Although it has been claimed that lower segments that do not appear to end above the diaphragm will be unsuitable for a true primary repair, the results with growth induction have negated this conclusion [22].

An important principle in the dissection of the pouches is to minimize grasping the esophageal ends. Once the segment is located, a 5-0 Prolene suture is doubly passed through the tip, tagged, and used to facilitate the dissection (Fig. 24.5). This technique reduces the need for repeatedly grasping the segment with tissue forceps and damaging the tissues. Cautery is only used on discrete vessels and a bit away from the esophagus.

If the lower esophagus is very small, however, and in effect, only a primordium on the surface of the stomach, an abdominal incision will be required to find it beneath the diaphragm. Inducing growth in a primordium 3–5 mm long is more technically difficult and will take longer, although the end result seems to be equally good. The specific techniques for growing a primordium will be discussed later in this chapter.

For the upper pouch with a suture in the dependent portion, the dissection is carried as high as can be reasonably achieved above the thoracic inlet (Fig. 24.6). The upper pouch may be fused to a variable degree with the membranous portion of the trachea and separation risks entering the airway. The tissue fusing the two structures lacks a defined plane which may make the dissection difficult. The placement of pairs of small vascular clips (Ligaclips®) will compress the fused tissue and allow it to be cut sharply with a #15 blade, reducing the risk of entering the trachea or causing troublesome bleeding (Fig. 24.6). Usually four to five pairs of clips placed successively higher will reach beyond the thoracic inlet and into the neck providing adequate mobility of the upper pouch. The vessels in the fused tissue are not large, and the period of being clamped will control the tendency to bleed even if the clip falls off sometime later.

Occasionally, the upper pouch may require additional freeing up through a cervical incision to achieve adequate mobilization. Mobility is important in realizing the effect of the traction sutures, and a very short upper pouch would be a sufficient reason for a cervical incision. Rarely, unusual or unexpected anatomy might also require cervical mobilization, as in the patient we encountered with a double atresia of the upper pouch. What appeared externally to be an upper pouch of normal length had a lumen which ended higher in the neck. An additional period of traction on the true upper pouch was needed to achieve a primary esophageal anastomosis.

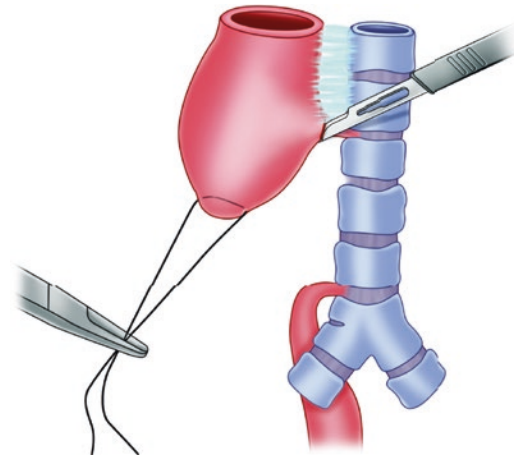

Fig. 24.6 The upper esophagus may be fused to a varying degree with the back (membranous portion) of the trachea. Separating the two structures may be difficult and risk entering the airway or producing bleeding. Clipping the fused tissue with Ligaclips® will help establish the plane between the membranous portion of the airway and the esophagus and allow the compressed tissue to be divided more safely with a #15 blade

For both the upper and lower segments, the dissection is best done by following closely along the esophageal wall. The wall has a characteristic appearance and staying in the plane on its surface is valuable to achieving a neat dissection and avoiding significant vascular structures. An aberrant subclavian artery, for example, would pass posteriorly through the upper chest and has been reported to be a source of bleeding problems during an EA repair. With the more common left aortic arch, an aberrant right subclavian artery would course posteriorly to the esophageal dissection. For a right aortic arch, a left thoracotomy incision might also reveal a left aberrant subclavian artery in a posterior location. Dissecting cleanly along

the wall of the esophageal segments, however, should avoid injuring an aberrant artery and the potential of significant blood loss.

Repair of a Lower Tracheoesophageal Fistula

In some cases of LG-EA, division of a tracheoesophageal fistula(s) may also be necessary. To take down the common configuration of a fistula from the lower esophagus to the trachea or mainstem bronchus, the fistula is first looped relatively near the trachea and dissected free including the neighboring area of the trachea. Once the fistula is well mobilized, it is sharply divided about 2 mm from the contour of the tracheal wall. The resulting cuff provides sufficient tissue for a secure closure without leaving too much behind which would allow a diverticulum to form or so little that closure would be under tension and could somewhat narrow the trachea. Simple interrupted, nonabsorbable 6-0 monofilament (e.g., Prolene) sutures, which have low reactivity and slide through the tissues easily, are placed carefully at the junction with the trachea (Fig. 24.7). These sutures should catch the edge of the membranous trachea surrounding the fistula which will provide greater holding power and a more secure closure.

For a large fistula, where there is concern about a significant air leak after division, sutures can be preplaced near each end before it is divided so the resulting air leak can be promptly controlled sufficiently to allow a careful closure. Because a recurrent TEF (recTEF) is due, at least in part, to microabscesses, using a monofilament suture of low reactivity should help avoid their occurrence.

A vertical closure of the airway defect is easier given the exposure through a posterior-lateral thoracotomy incision and will nicely follow the contour of the trachea. A transverse closure is not necessary and a larger fistula might require pulling the tracheal rings closer together, creating tension. When completed, the tracheal repairs are tested by holding the airway pressure at 40 cm H_2O with the area submerged in saline. Bubbles, of course, indicate a leak and the need for additional sutures. Carefully done, the closed TEF site should be barely discernible looking down the trachea with a bronchoscope.

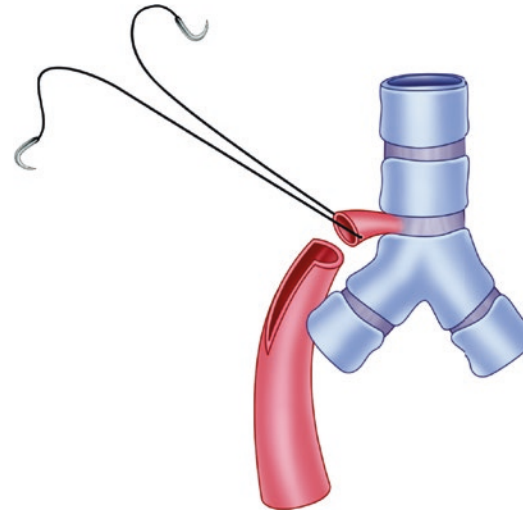

Fig. 24.7 Division of a lower esophageal-tracheal fistula should be done sharply about 2 mm from the junction of the two structures. The closure sutures are placed at the junction, incorporating a very small amount of the membranous septum for strength. A careful closure will neither narrow the trachea nor leave excess tissue which might allow a significant diverticulum to eventually form

Repair of an Upper Pouch Fistula

An upper pouch fistula is usually best approached through a low transverse cervical incision with the neck in extension. The upper pouch is first looped in the neck and retracted upward while the dissection proceeds inferiorly to reveal the fistula. Once divided, the principles of closure will be similar to a lower segment fistula. Closure of the esophageal opening is easily done vertically. The fistulas are relatively small and vertical closure will not compromise the lumen. More importantly, if traction sutures are also needed to induce growth of the upper pouch, the tension will put little distractive force on a vertical closure.

Presence of a Cervical Esophagostomy (Spit Fistula)

Often LG-EA patients have a cervical "spit" fistula created early in infancy to allow passage of saliva until continuity is established. If the decision is made later for a true primary esophageal repair, then growth induction of the upper pouch by one of two methods is desirable to allow the anastomosis to be done in the chest. The first method is to mobilize the upper pouch, securely close the esophagostomy site, and bring it down as far as possible alongside the spinal column. Blunt dissection will easily create a space for the upper esophagus alongside the vertebral bodies. Two pledgeted horizontal mattress sutures are placed in the upper esophagus proximal to the closure line and then into the fascia overlying the vertebral bodies down in the upper chest. By tying the sutures, the closed upper pouch is pulled down into the upper mediastinum, and this amount of tension should not compromise the closure. About 3–4 weeks are required for adequate healing before the upper pouch can be placed on external traction to induce further growth. Obviously, closure recreates the problems of esophageal atresia; however, it is surprisingly well tolerated in infants who easily accommodate to the required intermittent suctioning of saliva.

For patients 2 years of age or older, however, closure with the inability to swallow saliva may not be so well tolerated. In this case, the Kimura downward advancement technique for the spit fistula can be used at 2–3-week intervals [23]. This technique successively lowers the exit site on the anterior chest wall typically gaining about 2 cm on the skin surface and somewhat less in useful length. It is, therefore, a more laborious method which leaves several scars and is advantageous only when the patient will not tolerate the closure method.

In the Minnesota experience, both right ($n=11$) and left ($n=5$) spit fistulas were closed, allowed to heal, and, subsequently, put on external traction. After closure and healing of a left spit, the upper esophagus had to be brought under the trachea and down into the right pleural space so that the traction sutures could be placed and brought out the chest wall posteriorly. Although this was a larger undertaking, it was done successfully in all cases and a true primary esophageal repair was the end result. A recent attempt at closure of a left spit fistula in Boston in a Down patient who was an active air swallower, however, was unsuccessful because the force generated by the swallowed air produced repetitive air leaks into the mediastinum. This combination of congenital problems may be more difficult, making a spit fistula advancement technique the better choice.

The Flexible Approach: Evaluation and Choice of Growth Method

The best time to determine how to proceed with a long-gap EA lesion is in the operating room after both esophageal segments are dissected free and mobilized but before the ends are opened. The sutures in the end of the segments which aided dissection are crossed, and, with a moderate pull, an assessment of the effective gap length can be made.

The gap assessment will be important to choosing which technique to use for growth induction. The choices range from an anastomosis, to the one-time stimulus of internal traction, and to the external tension techniques which provide a repetitive signal and induce more growth. A general classification of the surgical approaches based on apparent gap length has been presented to aid in the decision between an anastomosis or a period of growth (Table 24.2). The specific approach chosen will depend on the surgeon's assessment and, therefore, numerical gap lengths are not given. In general, if there is doubt on which approach to use, the next lower technique in Table 24.2 will produce greater growth and make the eventual anastomosis easier and less risky. For example, external tension will be able to induce greater growth and close a longer gap than the one-time stimulus of internal traction.

Anastomosis

If the ends overlap during the assessment, an anastomosis should be possible. The main additional question will be where the lumens end, and a tube placed into the segments from above and below through the G-tube site will locate them. If the lumens are essentially touching, the ends can be opened, even though some retraction will be likely, and the resulting gap may be longer than anticipated. The anastomosis, nevertheless, should be able to be carried out successfully even if a period of traction in the operating room is needed. This useful technique will be described subsequently in this chapter under section "Growth Induction: The Anastomosis".

Internal Traction

For longer gaps where only minimal overlap of the ends is achieved despite moderate tension on the crossed dissecting sutures, a period of internal traction will make the anastomosis easier and safer. Traction sutures are placed into the esophageal segments in a similar fashion whether they are intended for internal or external traction. The internal traction sutures are anchored into the prevertebral fascia and when tied down will put tension on the segment.

Under more exceptional circumstances, up to three rows of traction sutures have been placed to maximize growth. Particular care must be taken with the middle rows so no significant wall damage occurs.

External Traction

The growth induced by the one-time stimulus of internal traction will be complete, after 5–7 days; nevertheless, it can be significant and make the difficult anastomosis much easier. The amount of growth-inducing tension created by the internal traction will depend on several variables mainly related to suture placement, and, if there is a question on its suitability, it will probably be better to use external traction.

For even longer gaps, when the ends remain apart despite firm pulling on the dissection sutures or when the gap is so long that an attempt to bring the segments together does not make sense, then significant growth by 2 or more weeks of external traction will be required (Table 24.2). The placement and configuration of the traction sutures will be discussed in detail in the next section.

Table 24.2 Flexible solutions for the long-gap problem

Moderate gap:	Traction in OR	(~10 min)
Longer gap:	Internal traction	(5–6 days)
Very long gap:	External traction	(7–21 days)
No apparent esophagus:		
	Grow primordium	(3+ weeks)

Fit the operation to the baby

For some cases with an upper or lower fistula, a period of growth may also be needed to achieve a successful anastomosis. Closure of the fistula site and placement of the two ends on either internal or external traction can be used to stimulate the necessary growth. Occasionally, even the common form (type C) may be judged to have a gap too long for a safe initial primary repair (Fig. 24.1). In that case, it would be better to securely close the fistula and place the two esophageal segments on internal traction for 5–7 days and avoid the problems of a failed anastomosis. This flexible approach should allow a successful true primary repair in virtually all type C lesions.

In the case of an upper fistula (type B), both the upper and lower segments may be short and require external traction to induce sufficient growth for an anastomosis. For the upper pouch, the fistula closure will be vertical and the traction sutures should be placed to avoid the site and not put direct stress on it. Typically, the closed fistula will be near the end of the upper pouch, and the traction sutures can be placed above and away from the closure site. The length of lower segment will be the most variable component and similar to the range found in type A lesions; consequently, in many cases external traction will be necessary to induce sufficient growth for a well-constructed anastomosis.

For all of these techniques, when adequate growth has been achieved, the esophageal ends will retract when released from traction and if finding and opening the lumen also proves difficult, the anastomosis may need to be created under some tension. Consequently, the creation

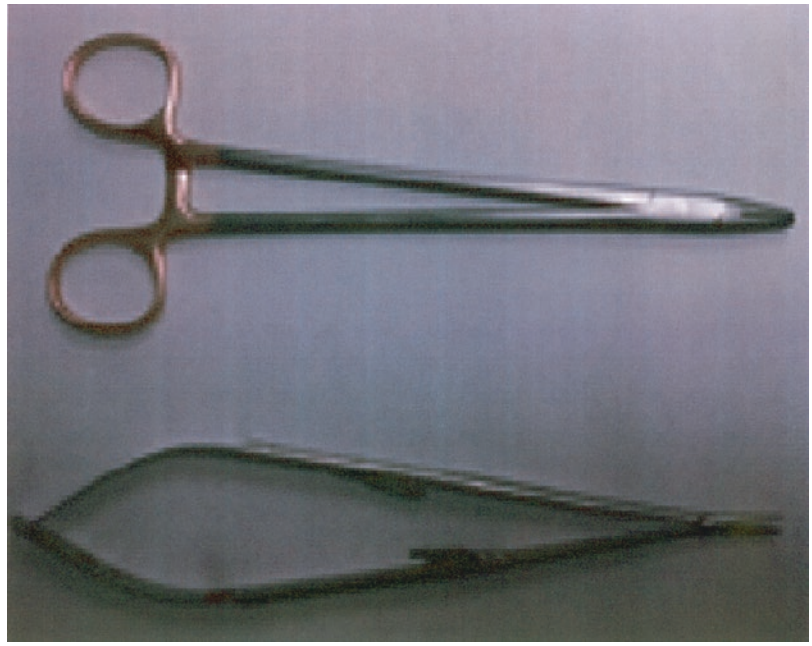

Fig. 24.8 The two basic types of needle holders are pictured. Use of the upper, standard needle holder relies primarily on wrist action although guided by the forefinger. The lower, Castro-Viejo-type needle holder depends mainly on finger motion and provides more feel in the placement of fine needles into delicate tissues

of a well-constructed and reliable anastomosis becomes an important part of the overall growth induction process. The technique of creating a successful repair even under moderate tension will be described in detail subsequently in this chapter (section "Growth Induction: The Anastomosis").

Growth Induction: The Traction Sutures

The traction sutures provide the growth-inducing tension, and their placement will be increasingly difficult, the smaller the esophageal segment. The lower segments may be very small and composed of tissue that is not sturdy, leading to a tendency for the sutures to pull out if too superficially placed. Placed too deeply, however, the sutures will enter the lumen producing a leak and predictable problems. The difficulty in judging the location of the lumen makes suture placement inherently imprecise; nevertheless, good technique and concentration can minimize the problems.

The needle holder and type of suture are of importance. A Castro-Viejo-type needle driver provides the best feel for accurate placement because it is a finger instrument, while the standard needle holder depends more on wrist motion (Fig. 24.8). By using the finger tips for touch and concentrating on the needle placement, a good amount of tissue can be scooped up while still avoiding the lumen. In the smaller segments, the stitches will be relatively longer but less deep. A feel for the amount of tissue incorporated will develop with experience, and the Castro-Viejo needle holder will likely be used for virtually all suturing.

To place a traction suture, the needle enters at a right angle to the surface at a point where the lumen is judged to begin. If the traction sutures are placed at the very end of the segment, much of the growth will be induced in the solid end and without a lumen. The depth is by feel and when the muscular layer seems to have been included, the needle should be turned to avoid the mucosa. A relatively long tissue bite is taken for strength (Fig. 24.9a). These are important sutures and the surgeon should concentrate on the placement.

For traction sutures, we have used a monofilament, nonabsorbable suture such as polypropylene (Prolene) because it is smooth and nonreactive. For the larger suture sizes (e.g., 4-0), a small needle is not readily available; consequently, for infants with LG-EA, a 5-0 suture is

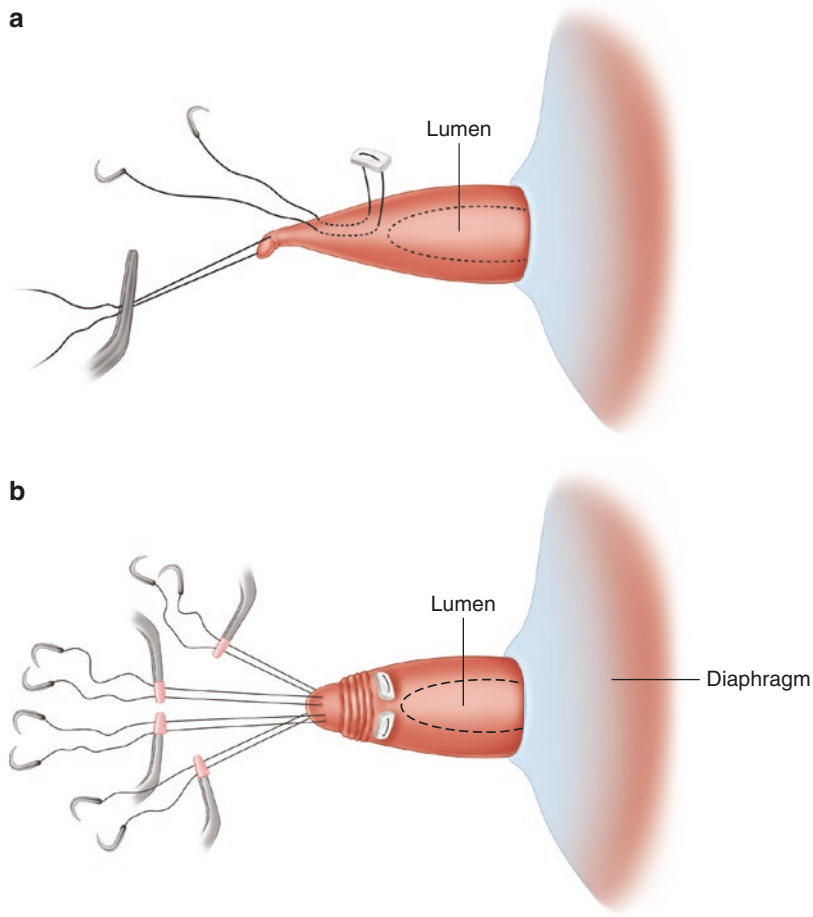

Fig. 24.9 (**a**) This figure portrays the placement of the pledgeted traction sutures. A pledgeted 5-0 Prolene in infants or, perhaps, a 4-0 Prolene in older babies seems to be the best choice for size. Prolene moves easily within the pleural space and through the chest wall tissues. The tissue bites are begun where the lumen is thought to end and should be generous to provide holding power but should not be too deep to avoid the lumen and a leak. The "touch" necessary to place theses sutures is better with Castro-Viejo needle holders. If one places the horizontal mattress stitch where the opening of the lower segment will presumably be made, then no usable length will be lost. (**b**) Four traction sutures, the usual number, are shown placed in the lower segment. In the very small lower segments, only two or three sutures can be placed. The configuration of the upper pouch traction sutures will look very similar

commonly used. The 5-0 monofilament suture, however, will stretch on traction and usually requires periodic retying to reduce its length and the number of pieces of tubing needed under each loop to provide tension. For the tiny (primordial) lower segments, a 6-0 or even a 7-0 suture may be used initially to provide internal traction and stimulate growth until the segment is large enough for 5-0 traction sutures.

The holding power is increased by using pledgeted, horizontal mattress sutures and, usually, four are placed (Fig. 24.9b). The pledgets can be cut from packaged material such as bovine pericardium or harvested from the patient's fascia or pericardium. Woven Teflon or Dacron pledgets, in contrast, encourage ingrowth of tissue and will be more difficult to remove at the time of the anastomosis. After the horizontal mattress sutures are

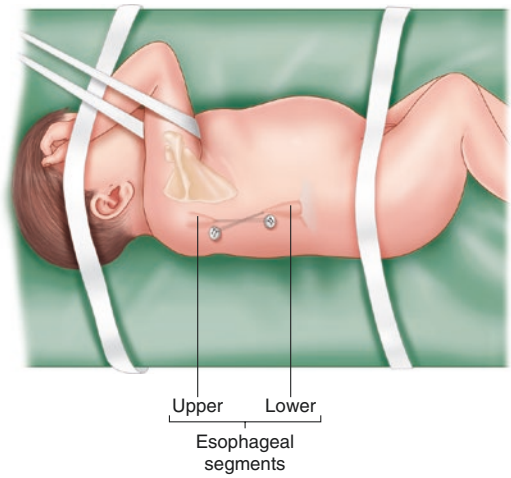

Fig. 24.10 The traction sutures are brought out posteriorly on the chest wall and threaded through a thick silastic button cut for the purpose. There will be significant force exerted by the traction sutures and a broad platform on the skin is useful to prevent the sutures from pulling through. The lower segment sutures are brought out above the incision and the upper pouch sutures below. This allows the segments to cross with growth which will facilitate the primary esophageal anastomosis. Small pieces of silastic tubing are placed underneath the tied sutures on a daily- or twice-daily basis to reestablish the tension lost by segment growth

placed, pulling on them will indicate if the placement and apparent holding power are satisfactory.

The upper pouch sutures are brought out to the skin surface posteriorly and below the incision, while the lower segment sutures exit above it (Fig. 24.10). Bringing out the suture pairs in a square pattern allows them to be placed in a relatively straight line from the esophageal segment to the skin. A piece of very thick silastic sheeting cut into a button shape with four holes cut out in a square configuration will allow the sutures to be brought through the skin in the same pattern as on the esophageal segment. The sutures are tied snugly and the tension increased daily by placing short pieces of silastic tubing under the loops. The lengths of silastic tubing (about 2–3 mm diameter) can be cut from a roll and are economical. It seems likely from basic cellular studies that intermittent increases in tension will produce greater growth than a continuous signal [24].

Alternative methods are certainly possible and in one report, crimpable beads on the traction sutures were used to produce tension with success [25]. Mechanical methods to maintain tension are being developed and one may emerge as an improvement [26]. Whatever method is used to increase the traction tension, one should avoid clamping the sutures which might fracture them and require replacement. A curved mosquito clamp placed under the loop and lifted will provide space for additional pieces of tubing to be inserted.

The button serves as a platform which keeps the sutures from pulling through and spreads the pressure on the skin surface although some skin necrosis often occurs beneath the button. The placement of a padded dressing material (e.g., Telfa) under the button may be helpful in reducing the pressure effects. After the button is removed, the site will heal, although it may leave a small, dimpled scar.

Metal clips placed superficially on the esophageal segments where the lumen is judged to begin allow the growth to be followed by X-ray. When the clips are at the same level or overlapping, the length should be sufficient for an anastomosis even though the segments will retract somewhat when released (Fig. 24.11a, b).

The traction sutures may pull out because of the weak tissue strength of the small esophageal segments (Table 24.3). If one or even two sutures pull free, it may not be significant; however, if more pull out, they may need to be replaced or the anastomosis carried out. Leaks caused by the sutures will be more detrimental although using the technique described, they did not occur during the Minnesota experience. If they occur, however, even with adequate drainage, difficulties may arise and the holes should be closed if more traction is needed.

Certainly, the described traction technique is imprecise and somewhat ornate. It seems very likely that better methods will be developed; nevertheless, the biological principle of tension-induced growth will remain and be utilized for the best results. In the Minnesota series of LG-EA infants without a previous attempt at repair, the initial gap length ranged from 3.1 to 10.6 cm; nevertheless, in all cases sufficient

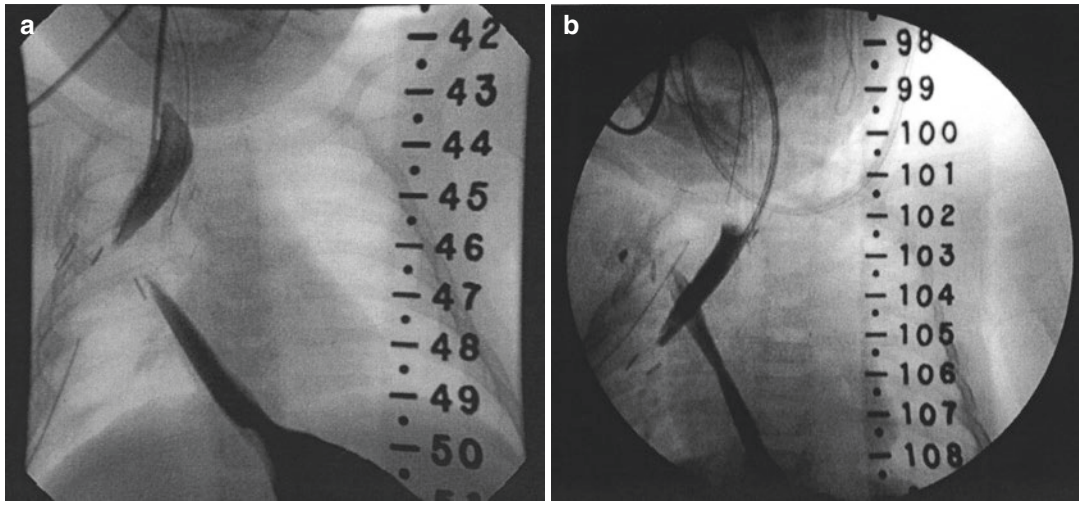

Fig. 24.11 (**a**) A contrast study reveals satisfactory growth and almost enough length for a reasonable primary repair. (**b**) A study shows the segments on traction now overlap and will have suitable length for an anastomosis

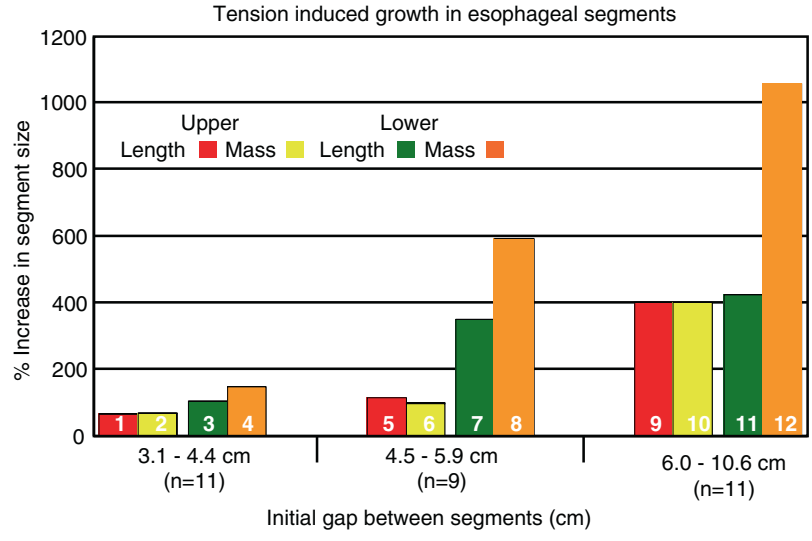
Table 24.4 Tension-induced growth in esophageal segments



growth was induced for a primary repair (Table 24.4). In two patients, age 2 and 4 with previous attempts at repair, the measured gaps upon arrival at Minnesota were 12.5 and 16.5 cm, and in these too, growth was successful. Growth was successfully induced in an 8-year-old boy with a long hypertrophic fibromuscular stricture indicating the response remains active well into childhood. Growth induction in our experience has always been effective, making a true primary repair possible across the entire EA spectrum.

Growth Induction: The Primordial Lower Esophagus

At the furthest and most difficult end of the esophageal atresia (EA) spectrum are those very uncommon cases in which the lower esophagus is so small that it does not reach the diaphragm. Previously, it was concluded that in these cases, a true primary esophageal repair with the GE junction remaining in the abdomen was not possible [22]. The ability to reliably grow even the smallest primordial nubbins, however, has changed this outlook (Fig. 24.12a–c). In the case illustrated, approximately a 50-fold growth response was necessary to close the gap (Tables 24.5 and 24.6).

These extreme cases have included lower segments whose luminal length was 4 mm or less, and in some, the lumen could not be found preoperatively either by contrast study or endoscopy (Figs. 24.13a, b). Nevertheless, at laparotomy, a lower segment 3–4 mm in length and 2 mm in width was found coming off the stomach at the usual esophageal location high on the lesser curvature. In essence, these nubbins were a primordium, but despite the small size, all the developmental information was present and within 3 weeks a lumen could be seen (Fig. 24.13c). Further growth resulted in an outwardly normal and full size lower esophagus suitable for a primary esophageal anastomosis (Fig. 24.13d). This and other remarkable cases raise the question of whether or not a lower esophagus is ever truly absent.

For the tiny primordium, a 50-fold or greater growth response may be required to turn it into an adequate lower esophageal segment (Table 24.4). The technical details become more important the smaller the segment and will be described in detail. Growing a 3–4 mm lower segment will require time, and it should also be expected that reconfiguration of the traction sutures will be needed on several occasions to maintain the growth-inducing tension.

The surgical steps to grow a primordium must be precisely done. To start growth, two 7-0 Prolene horizontal mattress sutures are carefully placed in the nubbin and fixed only internally to the neighboring fascia to provide tension. The amount of tension should not be too great; the sutures must both hold and stimulate growth. Although internal traction provides only a single episode of tension, it will convert the primordium into a more workable lower segment, perhaps tripled in length and width. Despite the small initial size, the response has been surprisingly vigorous.

As expected, the traction sutures needed to be reconfigured in 5–7 days to maintain the growth signal. The tissue sutures themselves, however, should not be replaced unless necessary in order to minimize trauma to the primordial nubbin and preserve its potential for development. The traction sutures can be tied as a loop over another, heavier, suture such as 4-0 Prolene which can then be anchored and, later, re-anchored into the fascia or the undersurface of the diaphragm to increase tension. Although growth is relatively rapid, it may be 3–5 weeks before the developing lower esophageal segment will be large enough to be brought into the right chest where the more continuous signal provided by external traction can be applied.

Once the length of lower esophagus is sufficient, it is completely mobilized in the abdomen and a pathway into the right chest is created. The normal position of the liver will interfere with this route; therefore, the ligaments of the left lobe are taken down and reattached anteriorly and to the right, moving the liver forward and allowing passage of the lower segment through the diaphragm. The segment will be brought through the right hemidiaphragm rather than a site near a normal esophageal hiatus on the left hemidiaphragm.

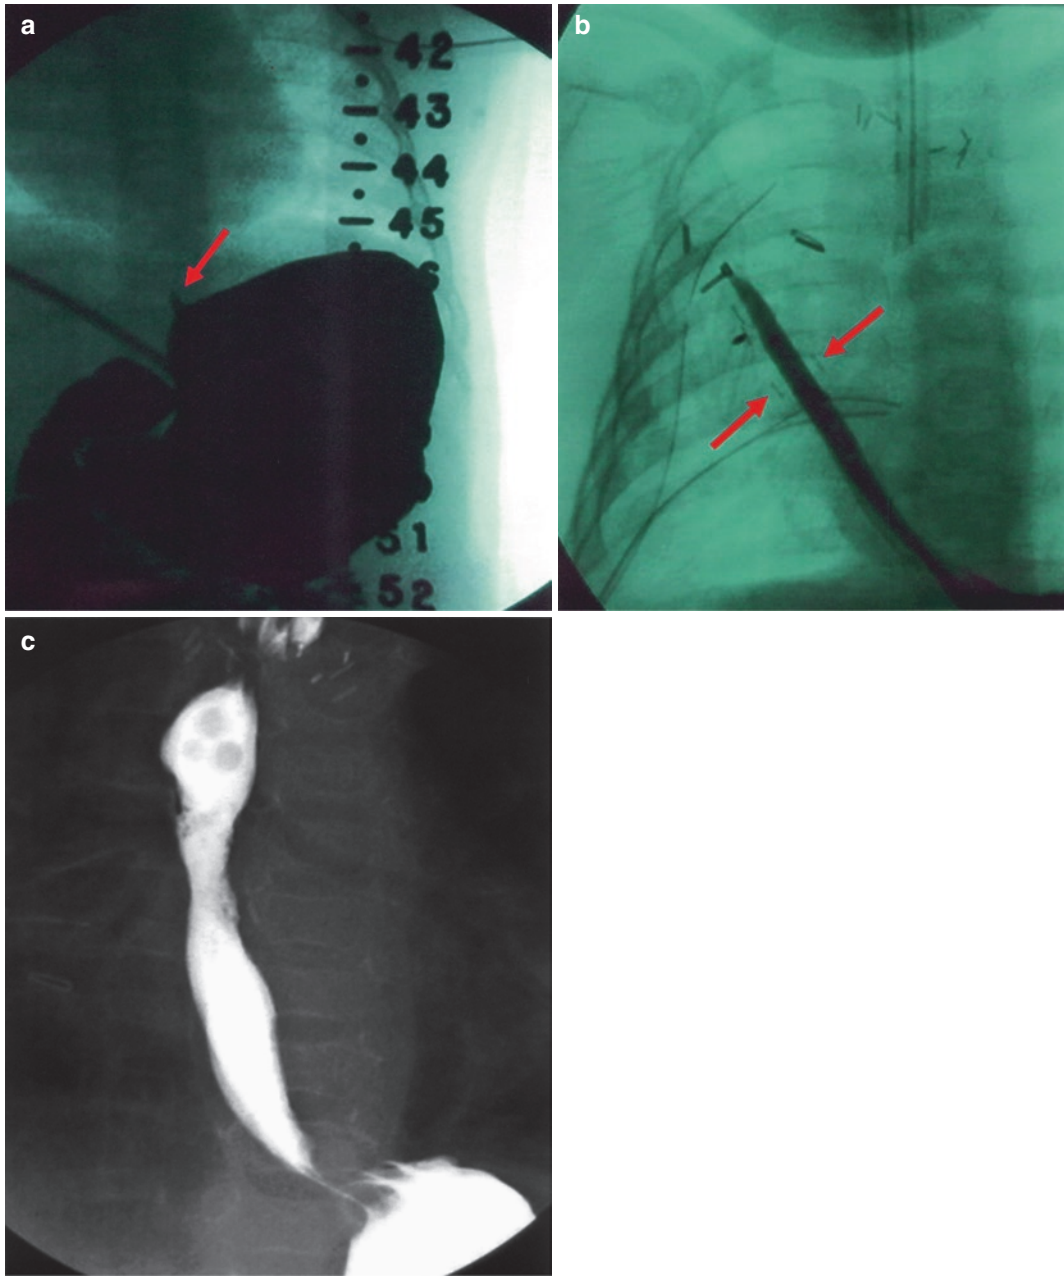


Fig. 24.12 (**a**) A contrast study showed a tiny lower esophageal segment. Two sutures were placed to provide the initial growth stimulus. Subsequently, the sutures were reconfigured and augmented by others. (**b**) In under 3 weeks' time, the lower segment made remarkable growth in both length and also in width as indicated by the *arrows*. (**c**) A contrast study following a primary anastomosis and later fundoplication shows an outwardly normal-appearing esophageal segment with the anastomosis in the usual place

Table 24.5 Growth response (for one patient)

Growth within 12 days:
Lower segment
Length: 3–42 mm (14-fold)
Width: 4–14 mm (3.5-fold)
Total mass (est.): 50-fold increase
Therefore, significant growth, not stretch

Table 24.6 Learning to eat after growth induction LG-EA repair

	LG-EA ($N=21$) months	Normals ($N=26$) months
Finger feeding	15 ± 2 (12)	11 ± 2 (5)
Solids with spoon	22 ± 2 (14)	20 ± 2 (8)
Drinking from cup	21 ± 2 (15)	19 ± 2 (8)
All milestones	26 ± 2 (9)	28 ± 2 (8)

To create the hiatus as well as reconfigure the traction sutures of the lower segment in the right chest, a simultaneous right thoracotomy and laparotomy will be useful. A convenient spot is selected in the right hemidiaphragm relatively near the pericardium. The lower esophagus will pass under the pericardium and anterior of the inferior vena cava leaving only the phrenic nerve as a structure at risk. This nerve, however, is easily identified through the right chest as it courses down the pericardium. The neo-hiatus should be large enough for the lower segment to pass through and accommodate some increase in width but not so large as to admit the upper portion of the stomach.

With the lower segment through the diaphragm, the traction sutures are brought out the chest wall more laterally than superiorly because the segment will be relatively short. More esophageal length will be necessary before it is able to turn superiorly to continue growth; therefore, at least one more reconfiguration of the traction sutures will be required. As before, if the tissue sutures are still well positioned in the esophagus, additional length can be gained by tying the traction sutures over yet another 4-0 Prolene suture. After further growth, the lower esophagus should have a relatively normal intrathoracic course, and a satisfactory anastomosis with the upper esophageal segment will eventually be possible.

As an aide to the growth process and making easier the repeat thoracotomies, the placement of pieces of very thin silastic sheeting around the segment to allow the movement of growth and others to maintain a space between the ribs on closure will be helpful.

When only a tiny lower segment is present, the question of what should be done is certainly relevant. With such a small starting point, should an attempt be made to induce growth? Because of what we believe are the superior long-term results with a repair using one's own esophagus, our answer would be yes. An important caveat, however, would be that attempting to accomplish the needed amount of induced growth should not be undertaken lightly nor without previous experience with this approach. This situation underscores the desirability of having a few centers of substantial competence for the very difficult cases [2].

Growth Induction: Tension and Growth

The ability of axial tension to induce esophageal growth has been well established in numerous human patients. It is also clear that true growth in both length and thickness of the esophageal segments is induced, and these increases are not a product of stretching (Table 24.4). All the necessary information for normal development is contained in the smallest lower segments, and follow-up assessment reveals a normal-appearing wall structure [27, 28].

The details of the amount and timing of tension increases, however, have not been systematically studied. It seems likely that the greatest response will occur with moderate tension, and further increases in force may become ineffective or even detrimental: but this question has not been studied. The amount of tension is clearly limited by the esophageal tissue strength and the holding power of the traction sutures. The lower segment varies most in size and strength, while the upper segment, even with a fistula, will be relatively thick walled from the action of saliva in utero. The variation in reflux in utero means the lower segment may remain only a diminutive

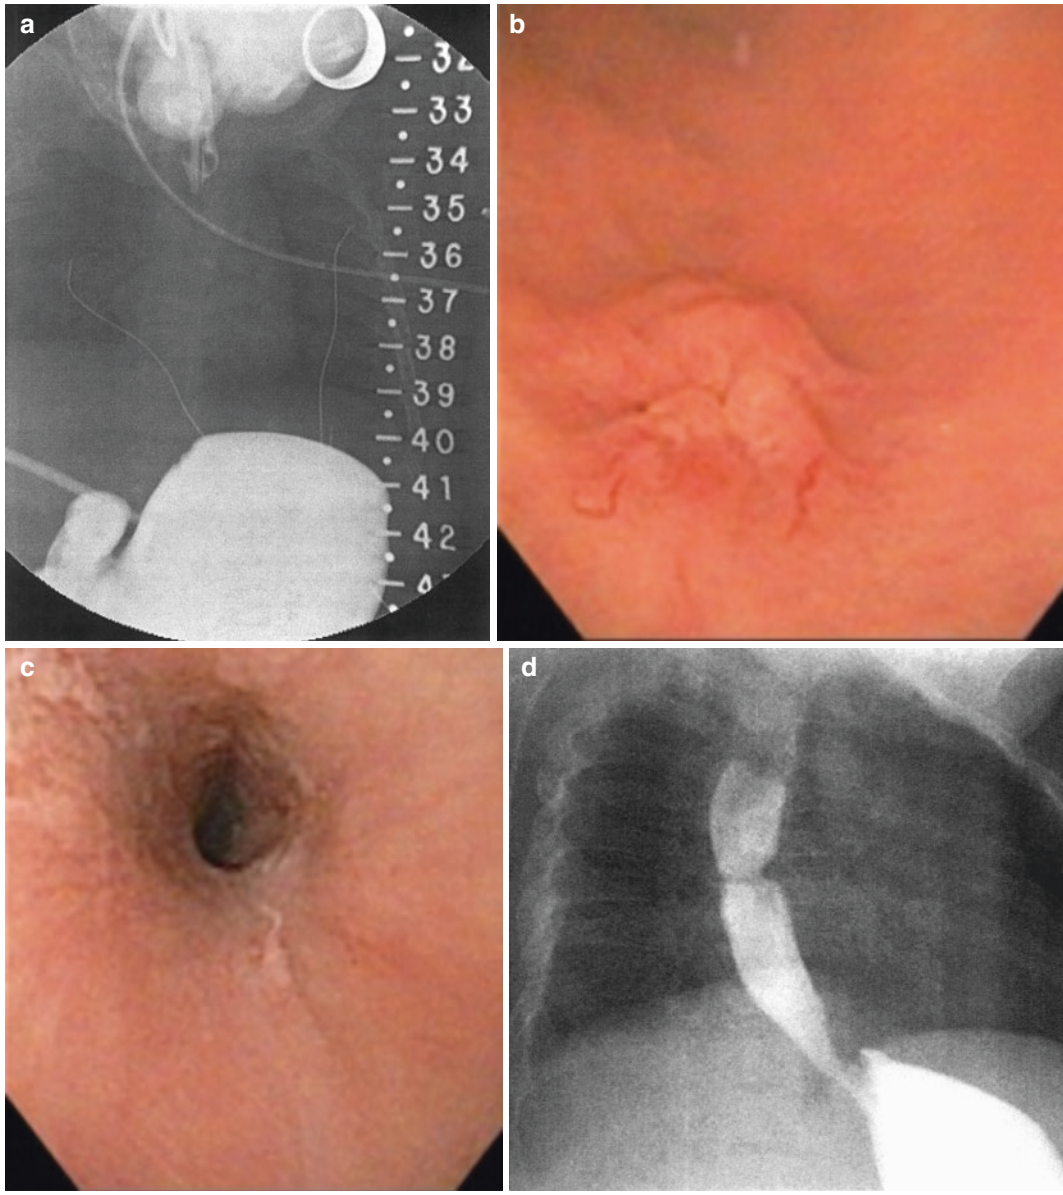

Fig. 24.13 (**a**) In another patient, a preoperative contrast study through the G-tube failed to provide any evidence for a lower esophagus. (**b**) Endoscopy provided more information on the possible lower esophageal segment. No lumen was seen and only a small amount of heaped up tissue, perhaps 4 mm in diameter, was found where the lumen should be. Through a transverse laparotomy incision, a nubbin of tissue, 3 mm long, was seen arising from the stomach high on the lesser curvature. A 7-0 horizontal mattress traction suture was placed in the nubbin and the suture tagged. By gently pulling up and down on the suture, the area of heaped up tissue was seen to move in an upward direction indicating it was part of the esophageal primordium. A second traction suture was placed and both were anchored in the diaphragmatic fascia to provide upward tension and initiate growth of the primordium. (**c**) After 2 weeks of internal traction, a short esophageal lumen could be seen endoscopically through the G-tube site. (**d**) After a little over 5 weeks, there was sufficient growth for a true primary repair. This contrast study was done after a subsequent fundoplication

nubbin (primordium) 3–4 mm in length or less and with little tissue strength or be relatively thick walled and reach nearly to the upper pouch. The structural variation of the segments will mean that the amount of tension applied will fall to the judgment of the surgeon.

The traction sutures must strike a balance between speeding growth and not exceeding tissue strength. The sutures occasionally pull out, which reinforces the need to avoid the lumen (Table 24.3). A traction suture(s) which pulls out with no leak from the lumen has minimal consequences. If more pull out, they will either have to be replaced or the esophageal anastomosis carried out. If growth is too slow, however, the esophageal segments can become encased in adhesions and progress stopped. The tension, therefore, should be increased at least daily to insure that growth will continue.

The optimal timing of the increases in tension also has not been worked out. At present we increase it daily or, even, twice daily by adding short pieces of silastic tubing under the traction sutures as described. This brings the stimulus to a maximum daily, but the response will largely dissipate the tension by the next day. Basic studies have indicated the biomechanical growth stimuli are most effective when intermittent rather than continuous [24, 29]. This principle may also apply to induced catch-up esophageal growth and an intermittent increase in tension may provide the best overall stimulus.

The current method has in its favor simplicity and practicality. Nevertheless, devices designed to increase tension at intervals may be beneficial and supplant this method. Improvements in the technique of growth induction will likely be made but the biological principles will remain the same.

Growth Induction: After Failed (Colon) Interposition Graft

Interposition grafts may fail or be unsatisfactory for one of three general reasons: inadequate blood supply, poor graft function, or developing an intrinsic disease. We have had two patients with colon interpositions which failed. One had a poor blood supply which quickly progressed to graft necrosis and was removed. The aperistaltic graft in the other patient progressively dilated causing significant dysphagia and aspiration. In both patients, a short lower esophageal segment was found on contrast study and judged to be satisfactory by endoscopy. Because the patients were 2 and 4 years old, respectively, the cervical esophagus was not closed but grown using the Kimura advancement technique [23]. In both, the lower segment was grown using external traction until a primary anastomosis was carried out. Both are now eating normally by mouth and the first patient is over 10 years old and 13 years old [30].

These two patients and along with an 8-year-old boy with a long congenital stricture treated by growth induction and resection indicate that the esophagus will respond to axial tension at least into childhood. This was predictable because even the smallest primordium has been programmed to develop into a normal esophagus and to shut this response down would likely require an elaborate and unnecessary genetic mechanism. Of interest of course is whether or not the growth response remains in adulthood?

Problems with Growth Induction

The techniques described used a flexible surgical approach to stimulate growth by axial tension and solve the long-gap problem. Importantly, the application of this biological principle has been effective across the full range of segment sizes encountered and well into childhood. Axial tension now has begun to be used worldwide, and a recent survey of attendees at a meeting of the British Association of Pediatric Surgeons revealed that growth induction was used by about 40 % of the pediatric surgeons to close a long gap [31]. The same study, however, reported that about 24 % of this group "were not entirely satisfied with the procedure."

The main difficulty with this method of growth induction is in accurately placing the

traction sutures and incorporating sufficient tissue to hold under tension yet avoiding the lumen and a leak. Effective suture placement becomes increasingly more difficult the smaller the esophageal segment and the more delicate the tissues. In our Minnesota experience, several sutures pulled out and some had to be redone. As expected, some sutures were moved higher on the chest wall (reconfigured) after growth had occurred to maintain the growth stimulus (Table 24.3). Both placing traction sutures and having them pull out, however, are new experiences for pediatric surgeons and will temper enthusiasm for the procedure until more experience is gained.

To maximize tension and the growth response usually also requires ventilator support in an intensive care unit and may require 2 or more weeks for completion. Finally, once growth is adequate, a second operation will be required. These difficulties, however, in our opinion, do not justify returning to gastric or colon interpositions for solutions to the long-gap problem.

There is no doubt that the technique of placing traction sutures and producing tension will be improved. Certainly, minimally invasive thoracoscopic techniques and technology will improve, although, at present, they seems more suitable for larger esophageal segments. Eventually, the techniques for growth induction will advance and be used more frequently with good results.

Among the technical points, we believe it is important to stay out of the lumen while inducing growth in order to avoid esophageal leaks. Consequently, we avoid using intraluminal devices which may produce pressure necrosis of the esophageal wall. The once heralded use of intraluminal magnets violates this principle and could lead to perforation [32]. This criticism can also be applied to the use of intraluminal hydrostatic pressure to enlarge the lower segment [33]. This technique produced necrosis of the entire lower esophageal segment with its use in one patient after the publication appeared. Certainly, intraluminal devices would not be satisfactory and not possible for the very small lower segments where the lumen may be tiny or even absent.

In summary, axial tension has been effective in inducing growth throughout the entire EA spectrum supporting it as the basic biomechanical stimulus which triggers the esophageal growth response [29]. Furthermore, application of this principle has demonstrated than an adequate developmental potential exists no matter how small the primordium.

Growth Induction: The Anastomosis

A true primary repair done across the EA spectrum, even including the common type C lesions, will require some anastomoses to be done under tension. Consequently, the construction of a reliable anastomosis will be important to both the early- and longer-term success of the LG-EA repair and to esophageal repairs in general.

The operative details of the anastomosis are based on the methods used by the author for the repair of the various forms of EA, usually LG-EA. Varying anastomotic techniques, however, are used by other surgeons with good results. The reader can evaluate the technical details and the reasoning behind them for our method in this chapter and decide which components they wish to incorporate into their repairs. Others have also used myotomies, created flaps, or partially pulled up the stomach to allow the anastomosis to be made. These methods have drawbacks, however, as has been discussed. The anastomosis described here will only be an end-to-end true primary repair [4, 19, 34, 35].

An anastomosis becomes more difficult to accomplish under one of three general conditions. The first, and the subject of this chapter, is when, for whatever reason, there is a significant gap between the two ends. The other two general problems are a discrepancy between the size (diameter) of the segments and, second, poor alignment of the edges that are to be joined together. The size discrepancy problem will be addressed in this section and alignment difficulties in Chap. 40: Redo Operations.

When the anastomosis is under tension because of a gap between the ends, an anasto-

motic leak or even disruption, as well as the later problems of stricture formation, GER, or recurrent tracheoesophageal fistula (recTEF) become more likely [36, 37]. These problems, moreover, may have chronic consequences and produce an unsatisfactory long-term outcome. For these reasons, both the anastomosis and the follow-up issues are important to achieving a good and durable result.

A true primary esophageal repair requires the esophageal segments to be long enough to accomplish an anastomosis, and the decision should be made before the ends are opened. Otherwise, if it is necessary to reclose them or bring the upper pouch out as a spit fistula, length will be lost, and it will be much less likely that a primary anastomosis will eventually be achieved. As discussed, by making the final assessment in the operating room, the best approach can be made for a successful outcome (Table 24.2).

With the decision that a primary repair is possible, the ends can be opened. To open the upper pouch, a round-tipped catheter is placed down it and kept on gentle pressure, allowing an opening to be made by cutting down on it with a #15 blade. This technique will avoid tissue damage caused by grasping the pouch. Finding the lower lumen, however, which is often narrow after a period of tension-induced growth, may be difficult, and length may be lost by multiple incisions into the lower esophagus (Fig. 24.11a, b). Threading a tube, wire, or even a thin endoscope up through the G-tube site into the lower segment will make finding the lumen much easier and make the opening cleaner.

The lower segment often tapers at the upper end, and cutting vertically downward along the outer curvature will effectively enlarge the anastomosis (Fig. 24.14a). The extent of the incision is limited by the effective increase in gap length it produces. The depth of the incision becomes the new gap length and must be considered. If the circumference discrepancy still exists after the vertical incision, the sutures should be evenly spaced to make up the difference, wider on the larger segment and closer on the narrow end.

Once the opening has been made, a stay stitch placed at the opposite corners from within the lumen outward will help stabilize the segment and facilitate subsequent suture placement. Again, to avoid tissue damage, a tissue forceps (pickup) is placed within the lumen and gently spread open without grasping the tissues, revealing the mucosa which is considerably lighter in color and readily identified.

The anastomotic sutures are placed in a square, full-thickness fashion, taking generous tissue bites and then tagged (Fig. 24.14a). To create an effective single-layer anastomosis, we prefer simple sutures carefully tied. A variety of two-layer anastomoses have been used beginning with the first repair by Cameron Height [38]. In the early days, anastomotic leaks were common with serious consequence and the two-layer repair attempted to prevent them. As technique improved, the more difficult strictures which were frequent in two-layer repairs became less acceptable, and surgeons switched to a single-layer anastomosis. As noted, however, leaks and recTEFs are still a problem; consequently, surgeons have tried a variety of suturing techniques. We believe simple sutures carefully tied off tension will provide the best results. Such techniques as horizontal mattress sutures may produce necrosis of trapped esophageal wall and do not seem to be satisfactory [39].

For an anastomosis under tension, the back row of sutures is placed to be tied on the inside with the corner sutures configured for tying on the outside. The gap and the amount of tension necessary to bring the ends together will determine how the sutures are tied. If there is not much tension, the back row, except the end sutures, are tied and cut close to the knot. The end sutures are not tied to allow mobility for the placement of the anterior row of sutures (Fig. 24.14b). The anterior sutures are tied after a small caliber catheter (8–12 French) is passed down from above through the anastomosis. The tube is removed within 12–24 h so it does not produce pressure injury of the esophagus.

Closure is done after a chest tube is placed and loosely anchored to the parietal pleura to prevent

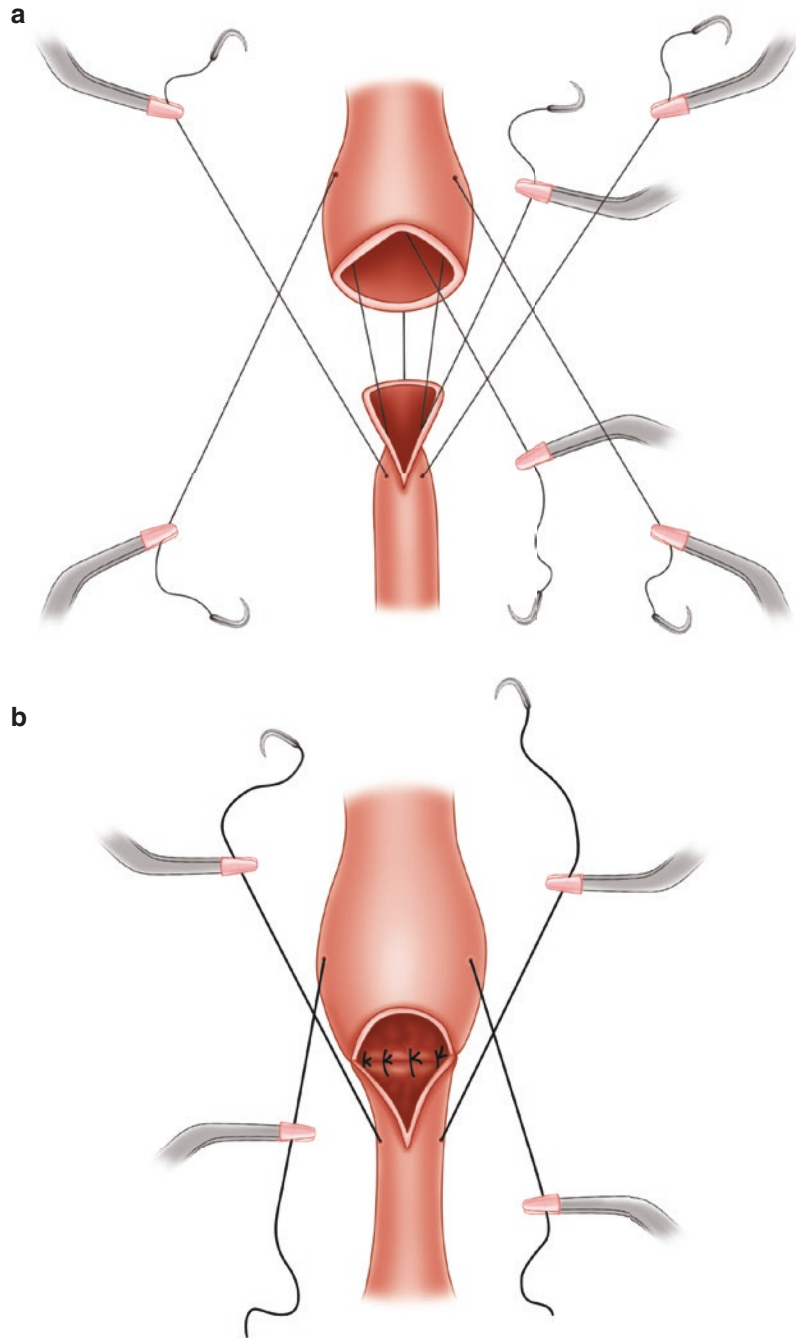

Fig. 24.14 (**a**) For an anastomosis when a gap remains between the opened upper and lower segments, the back row of sutures is placed and each end tagged with shod, small clamps and crossed. Typically, six to eight sutures are placed first. Notice that generous bites of esophagus are taken. Note the narrower lower segment has been cut back to effectively enlarge the anastomotic circumference. This incision, however, also effectively lengthens the gap and, therefore, must be limited in extent. The sutures should be evenly spaced according to circumference, wider on the larger and closer on the smaller opening. (**b**) The crossed sutures are used to gradually pull the ends together. When the ends are touching, one suture pair is freed up and carefully tied while tension remains on the crossed suture pairs. In this way, the individual sutures are tied off tension in an anastomosis that may end up under tension

direct contact with the esophageal anastomosis. The ribs are looped loosely by a pericostal suture and a normal space is left between the ribs which help prevent fusion. In addition, we often place sheets of very thin silastic sheeting between the ribs to hinder fusion.

For the more difficult anastomosis, when pulling the crossed dissecting sutures does not bring the ends together easily and/or the anastomotic sutures will be under tension, a period of traction in the operating room will be very helpful (Moderate Gap, Table 24.2). The back row of sutures are placed as before, tagged individually, and crossed. Slowly pulling on the tagged sutures will increase the tension and bring the edges together over a number of minutes. Once the edges are touching, tension is maintained on all sutures except for one pair at a time which is peeled off and tied without tension, and, therefore, the sutures are much less likely to tear through the esophageal tissues. As the tying proceeds, the tension holding the esophageal ends together is transferred from the untied to the tied sutures. This is an effective way to create a well-constructed and reliable anastomosis despite moderate tension, and in the overall Minnesota experience, no clinically evident leaks occurred [4, 6, 19, 34, 35].

When the tension required to complete the anastomosis is even greater, an additional advanced technique is to use small peanut sponges and even thumb sponges held by clamps to push the segments together while also pulling on the crossed sutures. Once together, the crossed sutures will be used to hold the ends together for several minutes, allowing the tension to somewhat dissipate. This period of traction and holding will also allow individual pairs to be tied off tension. An anastomosis in this setting will be under significant tension and both the generous tissue bites and the tying will have to be carefully done. It is emphasized that this maneuver is only for the most experienced surgeons and, again, argues for the very difficult cases being done at established centers.

We have used 5-0 or 6-0 nonabsorbable, monofilament (Prolene) sutures for the anastomosis, because they are essentially nonreactive. These sutures also help to maintain anastomotic integrity during the subsequent dilations which are done (gently) as soon as 2–3 weeks later. The sutures are only very slowly sloughed into the lumen, and for early endoscopic examinations, they will be quite visible even when using only 4–5 throws and cut close to the knot. After 6 weeks or more, the endoscopist can often pull some out or shorten the ends.

Making the Choice in Very Long-Gap EA: Growth Induction or Interposition Graft

As shown, growth can be reliably induced in the smallest esophageal segments and produce an outwardly normal esophagus. The function even with disordered contractions below the anastomotic site will be satisfactory and equivalent to the common EA-TEF repair. The time required for adequate growth will be roughly in inverse proportion to the starting gap length, and, at a minimum, a period of 6–7 days and two operations will be required. When starting with a primordium, growth may require 4 or more weeks and additional procedures may be necessary to reconfigure the traction sutures. Consequently, the question will be whether or not this approach is worth it in the long run. In our opinion, it clearly is, with the important realization that GER and post anastomotic strictures must be addressed. It must also be recognized that recent national studies have shown that even adults with short gap EA (type C) repaired in infancy frequently have problems with dysphagia and reflux, indicating that these are issues that often must be followed and treated for the long term across the entire EA spectrum (Entire section on: The Active Pursuit of Normalcy; Chaps. 43: Aronson; 44: Rintala).

If these issues are effectively treated, the children will do very well indeed and essentially all will eat normally and as well as their siblings. Most importantly for the LG-EA children, there is no reason to suspect late deterioration and failure of the esophagus grown by tension.

This predicted long-term outcome is in sharp contrast to either a colon interposition or a gastric pull-up, both of which fall heir to a variety of problems, increasingly difficult to solve with time. The gastric interposition is an alternative which is instructive because the surgical techniques have been well worked out [40]. Initially, a cervical, "spit" fistula and a G-tube are placed, and when the child reaches suitable size, it is usually a one-stage reconstruction. A comparison with the Foker procedure might seem favorable early with usually these two operations completed typically by 1–2 years of age for the gastric pull-up.

What it also brings, however, are severe consequences for the short and, especially, the long term. Initially, there will be feeding difficulties as dumping problems will exist to some degree. Many small meals, low weight gain, and, apparently, universal anemia become part of the new chronic disease constellation [40]. Frequent aspiration may be common and lung disease becomes a significant possibility. For the longer term, the obligatory reflux of a high gastroesophageal anastomosis will produce cervical esophagitis and eventually Barrett's esophagus and beyond [41]. The gastric tissue can be wrapped to hinder reflux, but the wrap will be at the thoracic inlet and difficult to fashion adequately. In addition, gastric atrophy and atrophic gastritis may also develop and these changes too are a precancerous condition. The short term is predictable and can be acceptable but difficulties will increase with time.

Colon interpositions are also beset with chronic problems and because this interposition will lack peristalsis, it frequently dilates and chronic aspiration becomes common. Although about half of these patients are satisfactory after 20 years, the rest are not and with the colon being heir to a variety of diseases, additional problems should be expected later [42].

Seventy good years appears very unlikely for either of these interpositions. This goal, however, is only beginning to weigh on the surgeon and the pediatric world in general. For the surgeon, peace of mind as well as reputation depends on fewer early complications and shorter lengths of stay (LOS) rather than events which may occur 10 or even 30 years later. A somewhat cynical but often accurate statement would be that for many pediatric caregivers, their patient's life ends at 16 years of age. Despite the fact that there is significant evidence that this is not true, one goal seems to be to hand off the teenage patients with them apparently "doing well."

Esophageal growth induction, however, can be reliably done at 3.5 kg, and if the lower segment is 2 cm or more long, then the growth time will vary from 1 to 3 weeks and is typically well tolerated. The anastomosis is frequently followed, however, by a fundoplication and a series of dilations. Nevertheless, once completed, these patients typically eat normally and progress well and fulfill the adage that "one's own esophagus is best" [43]. Currently, growth induction has been successfully used worldwide in small numbers of cases, and it seems likely that larger series of cases will appear [25, 26, 44–48]. For the longer term, moreover, the advantage seems to clearly be with growth induction. Long-term results are certainly needed, but the growth-induced esophagus should not deteriorate although it will need to be followed for later reflux and dysphagia. Among the interpositions only a jejunal graft seems to have satisfactory stability and, if necessary, would be the best interposition choice [49].

The decision between growth induction and an interposition graft for LG-EA will depend on a number of important considerations and eventually will depend on the longer-term results. Clinical comparisons are better made when there is one variable or at most, a few which can be adequately controlled in the study. The comparison under discussion, however, involves an uncountable number of variables, and, therefore, the answer will need to be based on at least a 10- or 20-year follow-up as an adequate approximation to the long-term goal of 70 good years.

Thoracoscopic Elongation of the Esophagus in Long-Gap Esophageal Atresia

25

David C. van der Zee

Introduction

Esophageal atresia has always been the hallmark of pediatric surgery. Long-gap esophageal atresia (LGEA) has been a challenge for many pediatric surgeons for many decades. Several alternative techniques have past the revenue, some to stay, and some to go. As early as in the late 1950s of the past century, Rehbein [1] already described the approximation of both ends with two metal balls in the esophagus attached to a thread in between the two ends that were slowly pushed to one another.

The fact that many different procedures have been developed over the years since indicates that the procedures do not have a guaranteed adequate success rates, and in many instances, it was wise to postpone treatment until the child was somewhat older. Meanwhile the child was either given a spit fistula or there should be continuous suction from the proximal esophagus to prevent aspiration, requiring intensive nursing care.

Two main principles are at hand when to decide which technique will be used. A popular technique that has been used over the years is the replacement of the esophagus with either the stomach, jejunum, or colon [2–4]. Others advocate that the original esophagus is always the best and pursue techniques that will result in elongation of the esophagus [5]. Whatever technique is used, there will always be two ends put together that were not tuned to each other, and motility disorders will occur in either technique.

In 1997, John Foker et al. [5] published an article in which they described a technique in which they approximated the two ends of the esophagus with traction sutures that were brought outside, and with traction, the two ends could be approximated and a delayed primary anastomosis could be made. They hypothesized that traction and growth were responsible for the elongation. Some other publications followed with similar good results.

With the advent of minimal invasive surgery, it was just a matter of time before the first publications came with results from thoracoscopic repair of esophageal atresia. In 2005 Holcomb et al. [6] published the results from a multicenter study where 103 children had undergone thoracoscopic repair of their esophageal atresia. In 2007, van der Zee and Bax [7] published a single center study on 51 neonates with thoracoscopic repair of type C esophageal atresia.

With increasing experience in the thoracoscopic repair of esophageal atresia, it was a logical step to attempt a thoracoscopic approach to the repair of LGEA.

In 2007, van der Zee et al. [8] published the technique of thoracoscopic elongation of the esophagus in LGEA.

In this chapter, the technique will be described and the results will be discussed of thoracoscopic repair of LGEA.

Technique

After the general work-up for VACTERL association, the principal first step in LGEA is to make a (laparoscopic) gastrostomy for feeding and to perform a contrast study to determine the length of the distal esophagus. Principally one could keep the child on parenteral nutrition during the process of the elongation procedure, but enteral feeding is preferred and has the benefit of gastroenteral stimulation.

With the aid of the Replogle tube in the proximal esophagus, the length of the proximal esophagus can be determined.

There is no strict age or weight limit.

For the procedure, the child is put in left semiprone position, with a support under the left arm pit to avoid compression of the vasculature. The right arm is extended over the head.

In some centers, the procedure is preceded by a bronchoscopy to determine or exclude a proximal fistula.

A 5 mm trocar is placed approximately 1 cm. below and anterior of the scapula point for the optic device. Two 3 mm trocars are placed in a triangle around the first trocar, as far apart as possible to avoid entangling.

CO2 insufflation is started with 5 mmHg pressure and a flow of 2 lt/m. It is waited for the anesthesiologist to settle the ventilation satisfactory. Usually this means that the frequency needs to be turned up.

By pushing gently with two 3 mm. graspers on the lung desufflation of the lung is accomplished. When and only when adequate view is obtained, the proximal and distal esophagus can be identified. When insufficient desufflation is obtained, a fourth 3 mm. trocar can be introduced with a flexible retractor to carefully press down the lung as far is necessary for adequate view.

It is started with the mobilization of the proximal esophagus up to the thoracic aperture (Fig. 25.1). It is important to determine that there is no proximal fistula; otherwise, this should be dealt with. In general, it is possible to close the proximal fistula thoracoscopically, but when the fistula is too high up in the neck, this should be done from the neck.

Then the distal esophagus can be mobilized under control of the vagal nerve, if necessary down into the hiatus (Fig. 25.2).

As the esophagus naturally lies in the posterior mediastinum, the traction sutures should be brought out as much posteriorly as possible to maintain its course, as well as the sutures not interfering too much with the lung after insufflations of the lung at the end of the procedure.

An Endoclose® device is used to introduce Vicryl® 4×0 sutures together with the needle (Fig. 25.3). For this purpose, a tiny skin incision is made at a level, either maximal cranial next to the scapula or caudal next to the spine. In total four sutures are laid at four corners of both the proximal and distal esophagus and pulled out again with the same Endoclose® (Figs. 25.4 and 25.5). A small silicone tube is used to bring the four sutures together and above this tubing traction is carried out with a mini-mosquito clamp. At the top of both the proximal and distal esophagus, a metal clip is attached to the sutures to allow for radiological determination of the progress of the elongation over the coming days.

After finishing the first procedure, the trocars are removed and the defects are closed with Vicryl® 5×0 sutures and Steri-strips® (Fig. 25.6).

Postoperatively, the child is extubated and only remained on light sedatives. Feeding is started the next day via the gastrostomy. Twice daily the sutures are checked for patency and traction is reinstalled on the sutures. Once daily a plain X-ray of the thorax is performed to determine the position of the clips.

When the clips have approximated sufficiently, a second procedure is executed. The patient is put in a similar position and the trocars are reinstalled. The amount of adhesions usually is limited and can be released without great difficulty. By releasing the tension from

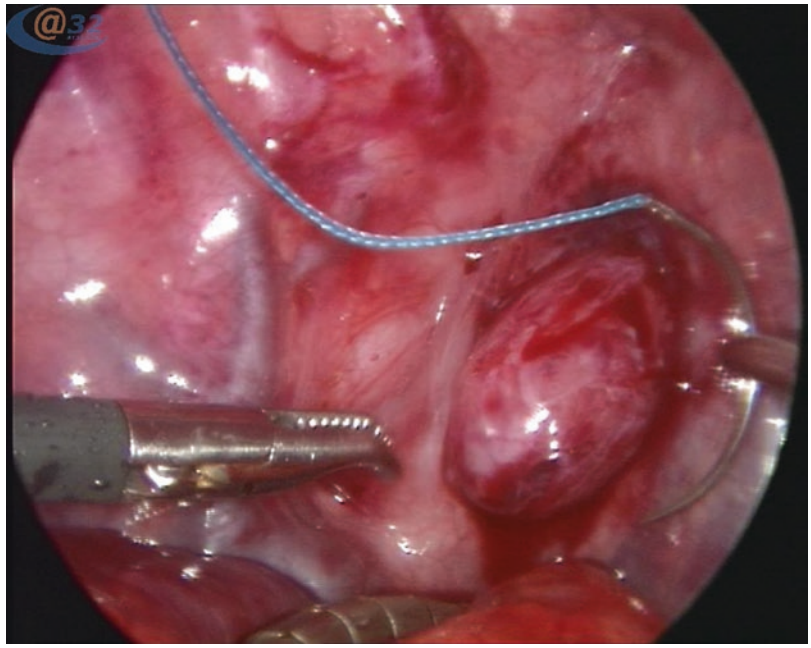

Fig. 25.1 Mobilization of proximal esophagus

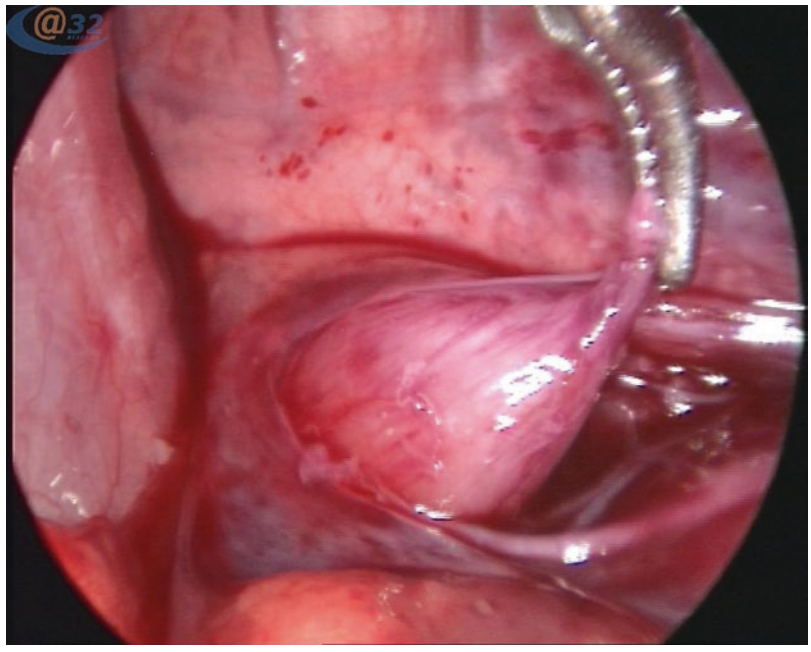

Fig. 25.2 Mobilization of distal esophagus

the outside sutures, it can be determined whether the esophageal ends can be approximated sufficiently at the level of the posterior mediastinum (Fig. 25.7).

The traction sutures are cut and taken down. Vicryl®5×0 sutures are used for the anastomosis. The esophageal ends are cut open with scissors, and the first one, two, or even three sutures are

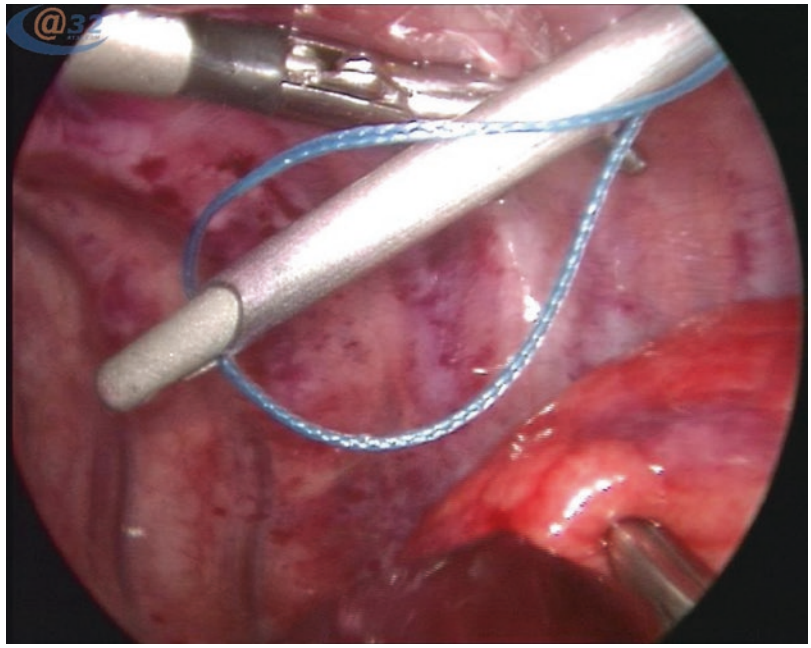

Fig. 25.3 The use of an Endoclose® to introduce a Vicryl® 4×0 suture and needle

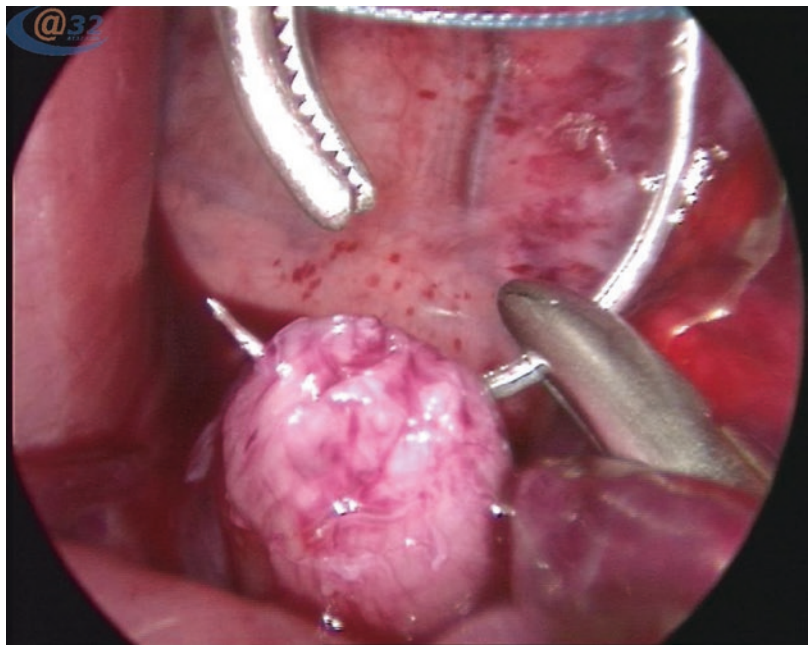

Fig. 25.4 Placing of first suture in distal esophagus

laid with a sliding knot to slowly approximate the proximal and distal esophagus. Thereafter, additional sutures are laid to complete first the posterior wall and introduce a 6F silicone nasogastric tube and then finish the anterior anastomosis (Fig. 25.8).

The trocars are removed and the defects are closed using Vicryl®4×0.

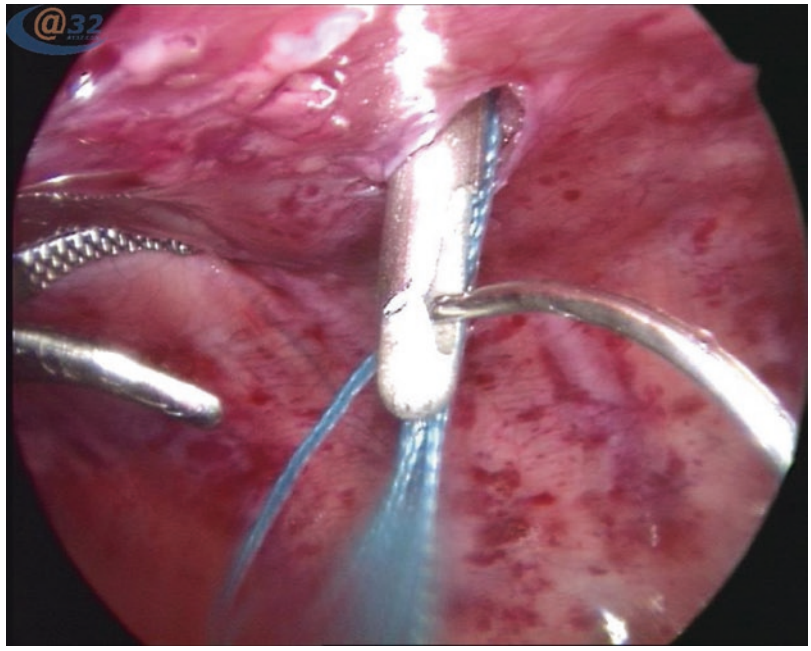

Fig. 25.5 Retrieval of suture and needle with the use of an Endoclose®

Fig. 25.6 Sutures are placed under traction over a Silicone tube

The child is extubated and kept on mild sedatives for the first 2–3 days. Antacids and prokinetics are started.

Gastric tube feeding is usually started after 2 days, although gastroesophageal reflux is frequently occurring, necessitating the gastrostomy feeding tube to be advanced into the duodenum.

After 5 days, an esophageal contrast study is performed to determine the patency of the esoph-

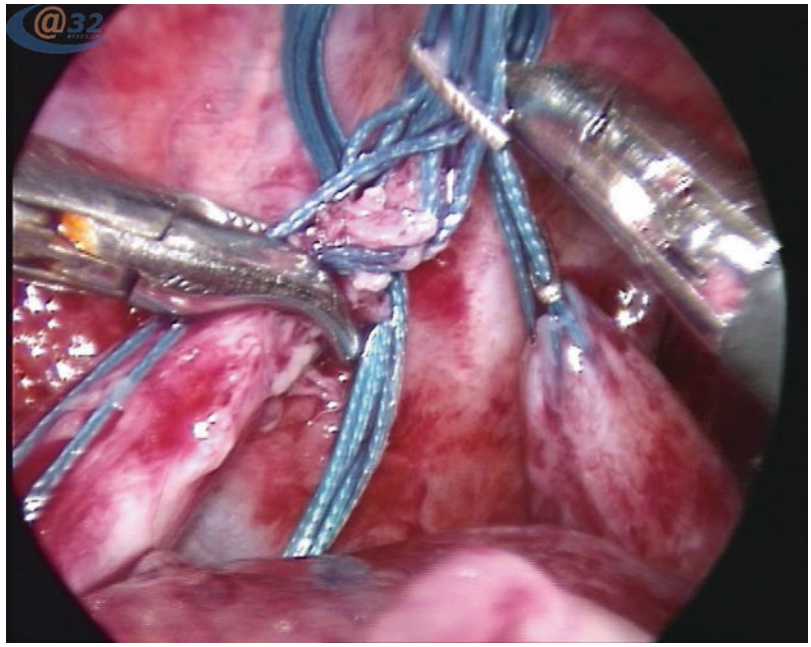

Fig. 25.7 Both ends of the esophagus have approached each other sufficiently to perform a delayed primary anastomosis

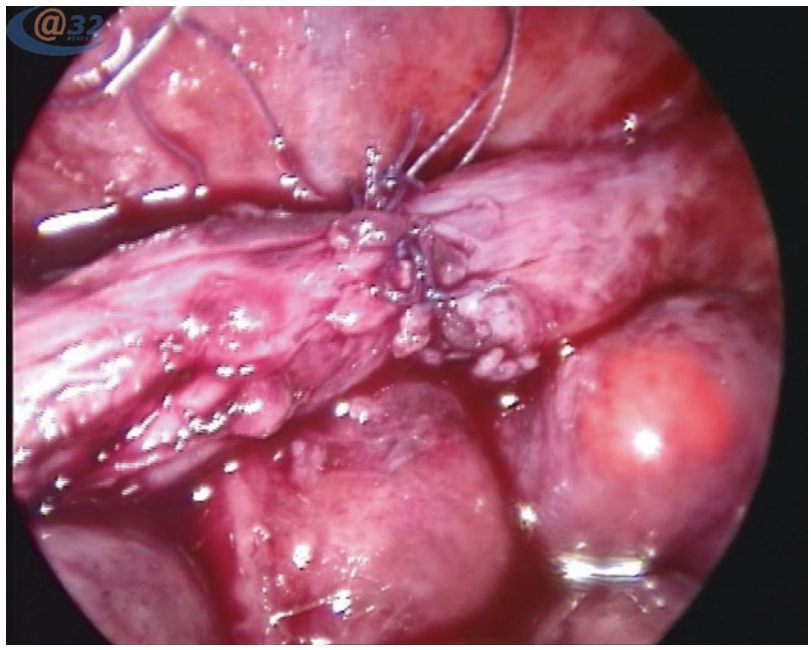

Fig. 25.8 Result after delayed primary anastomosis of proximal and distal esophagus

agus. When there is no leakage, oral feeding can be progressively started.

When the child is on full oral feeding, it can be discharged from the hospital.

The child is seen at the outpatient department every second week for the first 6 weeks. Thereafter, the follow-up is extended up to 1, 3, 6, and 12 months.

Complications

Preoperative

When a proximal fistula is present, the child can suffer from pulmonary complications. Many institutions advocate early trachea-bronchoscopy to exclude a proximal fistula.

The child can also present with complications from comorbidity, such as cardiovascular disease.

Intraoperative

Rupture of the traction sutures may occur. If this happens, the child needs to be taken back to the operating room to replace the traction sutures. However, when due to this complication one of the esophageal ends has ruptured, it is advised to abandon this technique and go back to one of the other alternative techniques, like gastric pull-up or jejunal interposition.

Postoperative

When an anastomosis is made under tension, the risk for anastomotic leakage is present. When leakage occurs, it usually suffices to place an intrathoracic drain, preferably through one of the trocar holes. Over a few days, the leakage stops spontaneously, and the drain can be withdrawn afterward.

In case a small residual diverticulum persists, this can usually be treated conservatively, as long as there are no sequelae from the diverticulum. Otherwise the diverticulum can be resected thoracoscopically at a later stage.

Usually esophageal stenosis occurs, in spite of the antireflux medication, necessitating esophageal dilatation, the first 2–3 weeks postoperatively. When recurrence of esophageal stenosis persists, a laparoscopic antireflux procedure can be planned between 4 and 6 weeks postoperatively.

Own Results

Between 2007 and 2009, there were four children with a long-gap esophageal atresia that were presented to our department.

The first child was born prematurely at 32 weeks of gestation with a birth weight of 1,500 g. She soon after birth showed signs of aspiration, due to a proximal fistula.

We initially deemed the child too small for a first case of thoracoscopic elongation; thus, we performed a thoracoscopic closure of the proximal fistula as a first step.

Four weeks later at 36 weeks of gestation and 2,000 g, she underwent the thoracoscopic elongation. She endured the procedure without any problem.

During postoperative follow-up over the next days, the clips approached each other progressively; until on the fourth day, the distal traction sutures came out, after a change of position in the crib. She was taken into theater and new traction sutures were placed.

After another 2 days, the esophageal ends had approximated sufficiently to perform a delayed primary anastomosis without complications.

At the contrast study on day 5, there was some minor extravasation of contrast at the site of the anastomosis. The feeding over the gastrostomy was continued for another 3 days after which oral feeding was started without complications.

Ten days after surgery, she was discharged from the hospital.

At follow-up after 2 weeks, she had developed an esophageal stenosis, which was dilated up to

F8. After 2 weeks at planned endoscopy, she showed a renewed stenosis that was dilated up to F10. After dilatation, the stenosis could be passed with the endoscope and a large hiatal hernia was seen.

She was therefore planned for a laparoscopic antireflux procedure 1 week later, at which occasion the esophagus was dilated again up to F10.

Thereafter, she required no more dilations and now is 3 years old and eating all that is offered without any restrictions. She has a normal development and length and weight are according to her age.

The second child was a term born boy with a weight of 3,500 g. There were no other anomalies. He underwent the first step of the procedure at the age of 3 days without any complication. After 3 days, the sutures form the distal esophagus came out and he was taken back into surgery. At renewed thoracoscopy, there were few adhesions, but the distal esophagus had been torn open. Closure of the rupture would increase the distance again and new sutures would have to be placed at the site of the rupture. Also because it was the distal esophagus, there was an increased risk of infection. It was therefore decided to close the rupture in the distal esophagus and abandon the thoracoscopic elongation procedure.

He was put on antibiotics for 5 days and underwent a jejunal interposition 2 weeks later.

The boy is now 2½ years old, has a normal development, and is eating everything with the family without restriction.

A third child came to us from abroad at the age of 5 months with a weight of only 3,800 g. She had a gastrostomy for feeding and a suction tube in the proximal esophagus.

After inventarization, she underwent the first step thoracoscopy without any complication. Because of her malnutrition, she was fed intravenously and kept on the ventilator postoperatively while mildly sedated.

After 5 days, the esophageal ends had approximated sufficiently for thoracoscopic delayed primary anastomosis. She underwent the procedure without complications, although the anastomosis had been made under considerable tension.

On the fifth postoperative day, she developed leakage with pleural effusion for which a thoracic tube was placed. On starting gastrostomy feeding, the milk came out of the drain. The feeding tube was therefore advanced into the duodenum and feeding was accepted.

The drain was productive for 5 days after which it could slowly be withdrawn and removed after 10 days. On contrast study, there remained a small sinus at the site of the anastomosis, which gave no clinical symptoms. After 15 days, the mother could give her daughter the first bottle feeding in 6 months (Fig. 25.9).

After 4 weeks, she underwent a laparoscopic antireflux procedure for recurrent stenosis. The small sinus remained unchanged.

After they returned to their home country, she has had some more dilations to maximize the diameter, in order not to increase the pressure on the diverticulum and with that have the risk of increasing the size.

She is now 1½ years after the procedure and eating well. Her length and weight have improved considerably after the operation.

The fourth child also came from abroad and had undergone multiple prior attempts on open Foker procedure elsewhere without success. As he came to us, he was 2 years old, weighing 12 kg.

He had a spit fistula after several attempts of Kimura elongation of the proximal esophagus.

After mobilizing the proximal end, the esophagus merely just reached up to the thoracic aperture.

When opening up the thorax, it became apparent that the whole esophagus had changed into solid scar tissue without any patency. It was decided to make a jejunal interposition, of which the proximal anastomosis could just be made inside the thoracic aperture.

The postoperative course was without complications and he could be discharged after 2×s. He is now over 1 year after the jejunal interposition and eating a normal diet with the rest of the family (Fig. 25.10).

Fig. 25.9 Third patient receiving first bottle feeding after delayed primary anastomosis at the age of 5 months

Fig. 25.10 Patients three and four 2 and 1½ years after operation, respectively, during encounter at airport abroad

Discussion

Long-gap esophageal atresia, i.e., without a distal fistula, has always been a challenge for pediatric surgeons. In a recent survey by Ron et al. [9] in the UK, the majority of pediatric surgeons would either choose for a gastric pull-up or perform the Foker technique for long-gap esophageal atresia.

With regard to the thoracoscopic approach of esophageal atresia with trachea-esophageal fistula, about half of the pediatric surgeon had experience in endoscopic surgery, but only a small percentage

had experience with thoracoscopic repair of esophageal atresia. On the other hand, about three-quarters of them is considering on starting on thoracoscopic repair of esophageal atresia.

The thoracoscopic repair of long-gap esophageal atresia, however, is of another dimension.

It requires expert skills in endoscopic dissection and suturing, often under considerable tension. In case complications occur, a broad armamentarium of alternative techniques should be available to deal with the problems and bring the procedure to a good end.

It is known from aviation that airplane crashed always are a resultant of multiple mistakes and/or misjudgments. The (thoracoscopic) Foker technique can give excellent results, if all goes well. However, if complications do occur, there should be a low threshold to change to alternative techniques. Therefore, the thoracoscopic Foker technique should be foreclosed to a limited number of centers of expertise.

26 Perioperative Management of the Esophageal Growth Procedure

Michael Sweeney

Introduction

Pediatric patients with long-gap esophageal atresia (LGEA) pose a series of problems from the perioperative management of the growth procedure through the surgical repair and later in learning to eat. What constitutes LGEA is not precisely defined but is at least a gap of 2–3 cm or greater. Ultimately, of course, it is in the eye of the beholder who must accomplish the anastomosis initially or first grow the esophageal ends. The growth approach to long-gap esophageal atresia has the goal of a primary esophageal repair and to ultimately achieve normal esophageal eating and drinking, avoiding a "chronic illness" syndrome [1, 2]. This process, however, can be long and sometimes difficult and is best achieved through a collaborative approach among dedicated surgeons, anesthesiologists, gastroenterologists, otolaryngologists, anesthesiologists, intensivists, nurses, respiratory therapists, radiologists, rehabilitation specialists, social services, and the family.

M. Sweeney, MD

e-mail: sween001@umn.edu

The incidence of esophageal atresia with/without tracheoesophageal fistula (TEF) has remained fairly constant since 1948 [3] at around 1:3,500 live births with type A accounting for 4.87–7.7 % and type B between 0.5 % and 2 % (although Klaas et al. recently published the incidence of type B as high as 5.69 %) [3]. Between 10 % and 40 % of these infants will be diagnosed prenatally with the remainder diagnosed shortly after birth [4–6]. Initial stabilization is aimed at decreasing the risk of aspiration and preventing gastric distension/perforation. Positioning prone or with the head of the bed (HOB) elevated 30° and keeping the upper pouch free of secretions is necessary to preventing aspiration and pulmonary injury that can occur in the face of chronic aspiration [7]. To avoid gastric distension in the face of a TEF, positive pressure ventilation should be controlled and ventilation by bagging should be avoided [8]. The serious nature of the other defects that may be associated with EA means that surgical palliation including TEF ligation, gastrostomy, pharyngocutaneous fistula creation, cardiovascular (CV) surgery, and occasionally tracheostomy may be necessary before more extensive work-ups are completed. Ideally enteral nutrition should be provided via a gastrostomy tube (G-tube) prior to staged long-gap repair; however, if that is not an option, parental nutrition should be given [9, 10].

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_26

Preoperative Preparation

The initial evaluation of infants presenting with EA must be thorough, as 50–70 % have associated anomalies [11–13]. In addition to detailed esophagrams to delineate the esophageal gap length and the presence or absence of a TEF, radiological studies must look at associated limb, rib, and/or vertebral anomalies. Gastroenterology studies should be performed or reviewed to identify associated anal defects, duodenal atresia, and malrotation or pancreatic anomalies. A renal work-up to detect kidney abnormalities and/or urethral/uretal anomalies should be completed. Detailed cardiac echo must be undertaken to evaluate for the presence of congenital heart defects and reveal the side of the aortic arch [13]. Approximately 10 % of these children will meet diagnostic criteria as either VATER, VACTERL, or CHARGE association and warrant a genetic consult [14].

If the child is referred in from another facility, records of all prior surgical procedures, anesthesia records, and inpatient experiences should be available for review for a meticulous preoperative evaluation. This should help avoid undesirable surprises and unnecessary problems in the areas of airway management, mechanical ventilation, hemodynamic stability, genitourinary anatomy, and pharmacological dosing. These data should then be reviewed with the team as well as the parents and a treatment plan developed tailored to the individual child. The patients should be screened for any acute or chronic condition or infection that is not optimally managed. Steps are then taken to correct identified problems and optimize the overall patient condition prior to the operating room.

Studies should include at a minimum, a baseline hemoglobin level should and packed red blood cells made available for transfusion because there is a small but definite chance for rapid intraoperative blood loss. If the child has been on total parental nutrition (TPN), a complete chemistry panel should be reviewed and the liver function determined. In the event of any bleeding concerns, a coagulation panel should be completed and any abnormalities corrected prior to surgery. Prior to anesthesia, a baseline 12-lead EKG can be helpful especially in children with congenital heart disease (CHD), and a recent chest radiograph (CXR) is desirable as well as an airway evaluation if there is concern for underlying tracheomalacia which is common in EA patients [2, 3, 15–17].

The Esophageal Growth Operation: Anesthesia Considerations

The first stage growth procedure is typically done around 2–3 months of age at a minimum of 3.5 kg, although can be undertaken at any age [2]. If the child has had prior medical or surgical procedures, the operative notes should be reviewed just prior to the first stage so unexpected findings are avoided. The first stage of the growth procedure is typically done through a right lateral thoracotomy with the patient in the left lateral decubitus position. If a cervical esophagostomy is present and will be relocated or oversewn and internalized, the neck and right arm should also be prepped in to allow manipulation of the esophagus at the neck and through the thoracotomy opening simultaneously. The G-tube should be removed prior to prepping to allow lower pouch esophagoscopy during the procedure if desired or to allow placement of a Red Robinson catheter up the lower pouch to facilitate repair.

All routine general anesthetic (GA) monitoring can usually be established prior to GA. The upper airway is frequently laden with saliva of varying amounts and viscosity and should be thoroughly cleansed and evacuated with suction prior to induction of GA. This suctioning will prevent excessive tracheobronchial aspiration prior to endotracheal (ET) intubation.

Induction may be inhaled sevoflurane or intravenous (IV) agent if reliable IV access is available, at the discretion of the anesthesiologist. Neuromuscular (NM) blockade is generally used to facilitate tube placement, with IV atropine and lidocaine to blunt unwanted autonomic and reflex reactions to ET intubation such as bradycardia and bronchospasm. Additional suctioning is usually needed during direct laryngoscopy. A cuffed ET tube is useful because of the reduced total respiratory dynamic compliance during the intra-

and postoperative periods. Because of the need for future prolonged positive pressure ventilation on the pediatric intensive care unit (PICU), the recently developed Microcuff® ET tube is preferred at our institution, for prevention of chronic subglottic complications as well as nosocomial pneumonia. The tip of the ET tube is positioned approximately 1 cm above the carina and confirmed by using auscultation of breath sounds. The position of the tip relative to carina and site of prior TEF repair (if present) is confirmed using a fiber-optic bronchoscope (FOB) via the ET tube. The ET tube is then secured at the right side of the mouth with a "saliva-proof" taping technique.

Intraoperative airway obstruction may occur in these patients and is usually due to occlusion of the central airways by secretions and/or blood clots from local or pulmonary hemorrhage related to prolonged retraction. The first indication that this problem is developing may be a rise in peak airway pressure during positive pressure ventilation. Vigorous tracheal normal saline lavage and suctioning with Ambu® bag ventilation can be a lifesaving maneuver in this situation. A FOB may also be needed to dislodge clots and insure that the ET tube tip has not migrated past the carina or into a tracheal diverticulum (prior TEF). Tracheomalacia with long-term secretion clearance difficulties and subsequent bronchospasm are also frequently encountered and may respond to intermittent bronchodilator administration. If the patient comes to the operating room with a tracheostomy tube in place, it is usually changed to an oral ET tube for the procedure and changed back to an identical clean tracheostomy tube prior to transport to the PICU.

Volume-controlled mechanical ventilation with a low-compliance breathing circuit is generally used intraoperatively. Inspiratory to expiratory time ratio is typically 1:2.5–1:3.5, to allow for avoidance of air trapping from bronchospasm and/or inspissated secretion ball-valve effect, especially in the "down lung." Positive end expiratory pressure (PEEP) is at 0–4 cm H_2O and FiO_2 adjusted to keep oximetric oxygen saturation ≥92 %. After the chest is closed, a PEEP level of 5–10 cm H_2O is used to restore functional residual capacity (FRC) in the PICU setting. Ventilation strategy at this point should transition to a style which reduces ventilator-associated lung injury (VALI).

Intraoperative Monitoring Capability

The anesthetic maintenance is principally a balanced inhalation technique with isoflurane, taking into account the patient's prior anesthetic experience, renal function, and chronic medication regimen. Those patients with extensive previous narcotic exposure are generally given 25–50 mcg per kg fentanyl during surgery. Fentanyl and midazolam infusions can be started prior to leaving the OR, helped with the administration of rectal acetaminophen and, occasionally, dexmedetomidine [20]. In addition, the thoracotomy incision is infiltrated with an appropriate dose of a long-acting local anesthetic such as bupivacaine or ropivacaine. Epidural analgesia is avoided at present since NM blockade is a regular feature of PICU care [21].

When CV shunts are present, extra care should be taken to avoid paradoxical air or particulate embolization [19]. Blood pressure instability is relatively common and may be due to a retraction-related mediastinal distortion, inadequate pulmonary gas exchange, possible sudden hemorrhage, or even septicemia. The desirability of monitoring right heart filling pressure, rapidly provide volume, and check blood gases make deep or central venous line placement necessary. At times, the upper body may not provide the best central venous line site, due to the presence of a cervical esophageal fistula with associated heavy bacterial skin colonization. In this situation, the common femoral vein can be used for low inferior vena cava access. Pre- and intraoperative ultrasound is especially useful for line placement because many patients will have had several lines previously placed. An arterial line is also recommended, particularly if the lower esophageal segment is very small, and considerable retraction of the liver and diaphragm will be necessary to get it on the correct path up into the right pleural space. The arterial line is usually removed after the first postoperative night.

Temperature monitoring is best accomplished at the nasopharyngeal (NP) site. A forced-air warming device and IV fluid warmer is always used for avoidance of extreme temperature swings. NP temperature is maintained in the 36–38° range. Subacute bacterial endocarditis (SBE) prophylaxis may be warranted and should be of an esophageal variety, irrespective of wound infection prophylaxis [18].

Care During Growth Period

The postoperative care of these patients is complex and sometimes quite protracted. The early phase of this care is directed at vital sign stabilization and recovery of pulmonary function. A chest radiograph is quickly obtained to verify correct tube placements and to rule out abnormal gas collections. Upper and lower pouch markers with Ligaclips are placed at the time of the first stage and must be identified with the surgeon on the post-op film as well as the "stop markers" placed on the posterior thoracic wall to signify the extent of the available space in which to advance the pouches. The upper right lung field will commonly reveal changes consistent with pulmonary contusion and accompanying atelectasis.

The PEEP level is then set to allow for alveolar recruitment, with tidal volume (6–8 cc/kg effective) and peak positive airway pressure adjusted ($\leq$35 cm H_2O) to minimize the chance of significant VALI. Aspects of preoperative respiratory care such as chest physiotherapy and bronchodilator therapy are then resumed and perhaps intensified as needed. Also, whenever possible, the patient should be nursed in the $\geq$30° semierect position. Prone positioning has been undertaken with great success in recruiting alveoli.

A daily CXR is used to follow FRC maintenance, proper tube position(s), contusion evolution, and atelectasis or pneumonia development as well as gap length. If the markers appear further apart on CXR or the sutures have pulled free, the surgeon needs to be notified and an esophagram should be performed to identify if an esophageal pouch has pulled free of its traction mechanism. If the pouch has pulled free, the child should be taken back to the operating room to replace traction sutures in a timely manner (24–48 h) to avoid losing the length that has been gained. In addition, recalcitrant lung field opacities on CXR should be investigated with FOB and bronchoalveolar lavage (BAL), for early and aggressive treatment of nosocomial pneumonia.

There should be no vigorous diaphragm movement, especially "hiccups," during the time the esophageal ends are on increasing traction or for 3 days following fixed or internal traction. In order to facilitate this, we routinely employ paralyzing agents such as vecuronium. NM blockade has been continued for as long as 1 month, especially when staged repair with traction sutures is the chosen surgical strategy. A continuous dosing strategy that avoids complete paralysis with daily NM blocker "holidays" is useful to ensure neurologic integrity and lessens the chances of long-term PICU neuromuscular syndrome [22, 23]. Although it is possible to only use paralytics to prevent violent diaphragm movement such as coughing, vigorous crying or hiccups, we have found that it is difficult for the nursing staff to allow for wiggling of fingers and toes and yet prevent potentially detrimental movement. Nevertheless, this should be the goal.

The addition of narcotics and antianxiolytics to this regimen is necessary for the child's comfort and dependence is inevitable. Frequent dexmedetomidine holidays may be helpful in reducing the total accumulative dose, and whenever possible, short-acting agents should be transitioned to methadone and Ativan for long-term control and weaning [24]. Withdrawal scales are routinely employed and are helpful in developing a weaning plan for each child. Following subsequent surgical procedures, additional pain management is provided in excess of baseline medications and used for the duration of acute pain.

Significant perioperative cardiac care is commonly required. Inotropic support may be necessary during acute inflammatory stages but is rarely needed for the long term or at a high dose. Occasionally, there may be evidence of myocardial irritation in the OR during aggressive

retraction, but this generally resolves with adjusting the force of retraction. Central lines placed in the OR are removed as soon as possible in the postoperative period, and ventilator support is managed with the use of VBGs and end-tidal CO_2 monitoring. Central venous lines are exchanged for long-term peripherally inserted central catheter (PICC) lines placed on the right side ideally to prevent thrombus formation in the innominate vein, thus predisposing the child to chylous effusion [2].

The Growth Period and Postoperative Care

Gastric feedings are avoided, while the lower pouch is on traction because of the possibility of esophageal perforation and leak and the common gastroparesis/delayed emptying and subsequent reflux present when the patient is on high-dose narcotics/benzodiazepams and paralytics. If a gastrojejunostomy (GJ) tube is in place, feeding may be provided either as trophic support or full enteral support if tolerated. If parental nutrition is required, particular care must be given to ensure that optimal nutritional support is provided. The actual measured energy expenditure of these infants while sedated and ventilated may be as low as 50 % of what would be expected if they were healthy and normally active [25, 26]. The glucose infusion rate (GIR) goal is typically 7–9 mg/kg/min while paralyzed and increased to 10–12 mg/kg/min when extubated with adjustments made when there is evidence of high CO_2 production from over feeding. Amino acid (AA) goals for infants are 2.5–3 g/kg/day and intralipid (IL) goals are 3 g/kg/day. Based on adult studies, glutamine-supplemented TPN may be beneficial starting at 0.1 mg/kg/day and advancing to 0.3 mg/kg/day in the absence of renal failure or metabolic disorders. Levocarnitine may be added to shuttle the fatty acids into the mitochondria. Low-dose heparin is routinely added to prevent thrombus formation in the inactive child.

Close attention must be provided to ensure a calcium phosphorous ratio of 1.3:1 to help prevent osteoporosis in the inactive infant on paralytics and heparin. Nutritional supplements with calcitriol or Fosamax may be necessary if there is early evidence of osteoporosis and clinicians should work closely with radiology, clinical nutrition, and pharmacy to identify early evidence of derangements including fractures. It is important to ensure all requirements to maintain bone structure are being met [27, 38]. Range of motion (ROM) exercises are beneficial to boney structure and should be done at least once a shift by the nursing staff.

As mentioned above, the child should be nursed with the head of the bed (HOB) elevated at least 30° to facilitate secretion clearance. When suctioning the oropharynx, it is essential that the child not be suctioned too deeply. The measurement from the tip of the nose to the ear to just above the clavicle should be recorded and suctioning limited to this distance to avoid perforation of the upper pouch. If necessary, a small sump or Replogle tube can be placed in the upper pouch proximal to the end and placed to low intermittent suction if there is concern for chronic aspiration and airway soiling [7, 28].

When not being fed, the gastric tube should be left open to air to allow for decompression. Gastric pH is strictly maintained between 5 and 7 with the aid of intravenous (IV) H_2 blockers and/or PPIs. While the lower pouch is on tension potentially distorting the lower gastroesophageal junction, it is presumed that there is free reflux, and any acid exposure of the lower pouch may produce erosion and ultimately perforation [29–31]. Continued vigilance at medically managing reflux (which has been well described in the literature) is maintained until surgical management can be achieved. Most commonly here, around 2–3 weeks postprimary repair, a fundoplication is done for significant reflux. Reflux treatment is continued for several months after Nissen fundoplication until esophagoscopy and biopsy reveal no esophagitis is present. While the patient is NPO, routine Maalox and Carafate use is avoided because of the concern for bezoars formation [32]. G-tube medication in general is avoided, as there is the potential that anything put in the stomach could end up in the pleural space, via lower esophageal pouch leak, especially if it is

given in large volumes or with great force. Any medications deemed necessary to be delivered in the stomach while the lower pouch is on tension must be given gingerly, and the G-tube should be open and elevated following administration rather than clamped.

Chest tubes are routinely placed in the OR following each thoracotomy and are typically held away from the esophageal pouch/anastomosis with a retention suture placed on the lateral thoracic wall to prevent esophageal damage as a result of direct contact with suction from the Pleur-evac or stripping of the chest tube. During the growth stage, the chest tubes can safely be removed on postoperative day 2–3 if no air leak is present and drainage is minimal. At the time of the primary repair, it is advisable to leave the final chest tube in place until the child is awake and swallowing secretions as evidenced by G-tube drainage. No saliva should be seen in the chest tube to ensure no significant esophageal leak is present prior to removing the chest tube.

Intensive physical therapy is initiated as soon as the child stabilizes after the operation. Full passive ROM exercises are provided on a daily basis paying particular attention to the right arm to prevent adhesions of the scapula and a frozen shoulder. As soon as the child is off paralytics, resistance therapies are provided to help prevent osteoporosis. Once the child is extubated, speech and occupational therapy (OT) is initiated and provided on a daily basis to begin oral stimulation and facilitate transition to oral feeds. Feeding therapy may be a long-term task because eating and the act of purposeful swallowing itself is foreign for these infants and must be learned. This lack of understanding of the need to eat may produce an oral aversion [2, 11, 15, 31, 33–37]. A dedicated speech therapy/OT team is critical to long-term success and will follow these patients throughout their hospital stay and as an outpatient to support normal eating habits. These therapists may detect early strictures and are central to helping the family learn healthy habits.

Infectious issues may also be significant in the perioperative period and range from blood stream infections (BSAs) to ventilator-associated pneumonias (VAP) and empyema. Routine prophylactic antibiotics are generally only provided for the first few postoperative days and then discontinued while strict preventative maneuvers are undertaken to avoid BSA and VAP. If an esophageal leak is present, appropriate antibiotics and antifungals are provided based on culture and sensitivities. In many cases, a small contained leak can be treated with placement of a chest tube near the site to allow drainage of the fluid and promote sealing of the hole. Once the leak has sealed, the chest tube is backed out slowly about a centimeter a time over the course of a week or 2 to allow proximal healing and adhesion formation.

The Effects of Near Paralysis

Long-term immobility and postsurgical inflammation/cytokine release produces fluid overload and edema. Keeping the serum albumin level in the high normal range can help maintain intravascular volume by the oncotic pressure despite the leakage that occurs. These patients, however, will typically also require long-term diuretic therapy, which, although necessary, has risks and must be monitored. Prolonged loop diuretic therapy can result in chronic hypercalciuria, which predisposes to nephrolithiasis, renal calcifications such as staghorn calculi and nephrocalcinosis, and bone mineral depletion [38]. As discussed earlier, one of the problems for these patients is osteoporosis and diuretic therapy adds to the risk. Electrolytes must be carefully replaced and frequent monitoring of serum levels is essential as is early recognition of renal stone formation with ultrasound. Neonates in whom furosemide has been combined with prolonged total parenteral nutrition may also develop gallstones [38]. Any child on long-term or high-dose diuretics such as furosemide is also at risk for hearing loss. The consequences of diuretic therapy are now better understood and hearing loss avoided; nevertheless, hearing screens may be warranted if concerns arise.

Comprehensive social support is frequently overlooked with these children and families. Often times, a family travels a great distance to

arrive at a program specializing in long-gap repair, and they have left behind financial security and their emotional support systems. Early intervention with social services may provide financial and emotional support as well as help families cope with this difficult time period. Meeting with the family for an extensive discussion of the various stages and the anticipated hospital course is beneficial.

It has also been valuable to identify the times frequently associated with the greatest potential for frustration. These include dealing with oversedation vs. withdrawal, with slow progress in feeding, and with leaks and strictures. Often the families find it helpful to have written information of the various stages and radiographic studies as well as target care issues.

Explanation must be provided that each child is different and the surgical approach and time frames are rough estimates and their child may progress to the next stage more rapidly or may take much longer. Routine updates as to patient progress and the next goal will benefit both the family and the care providers. Allowing time for questions and expression of concerns is essential.

Finally, the importance of a team approach cannot be overemphasized. Daily review of the studies and pertinent data with the key providers is crucial with frequent whole team discussions. As each child's anatomy and response to growth is unique, viewing the patient from all angles by all providers is the best way to develop a plan that fits each child best and has the greatest chance of complete success.

27 The Growth Potential (Form and Function): The International Esophageal Growth Experience

Khalid M. Khan

Introduction

Growth and development are the biological processes that lead to maturation of living organisms. Tissue growth is a regenerative response to injury although not in all organ systems and not as part of all types of injury or defect. Some organ systems have immense regenerative capacity such as the liver after resection, while ischemic injury of the heart and brain by disease are followed by replacement with significant scarring. In the alimentary tract, the small bowel is well known to have the ability to adapt to shortening by disease or resection especially in infants. It does this by increasing the surface area through luminal dilation and altering mucosal structure to improve absorption. The finding that the response is related to glucagon-like polypeptide (GLP)-1 has led to the development of a specific treatment for short bowel syndrome by enhancing this effect [1]. To an extent, the natural growth potential noted in other tissues has also been demonstrated for esophageal pouches in patients with long-gap esophageal atresia (LGEA) in the first few months after birth [2]. To restore the esophagus, i.e., form and function in patients with LGEA, enhancing this growth potential would be a way to bring the two esophageal pouches close enough to each other for primary repair to be accomplished.

The Esophageal Response to Traction

Traction as a method of esophageal growth has been primarily developed by Dr. J.E. Foker at the University of Minnesota with a unique procedure developed over two decades ago (see Chap. 45 for a detailed discussion of the procedure). The aim was to bridge EA gaps that were long (>2.5 cm, <3.5 cm) or ultra-long (>3.5 cm) at birth. In the case of ultra-long EA surgery to elongate the esophagus or an interpositional graft would otherwise be necessary [3]. Beyond the notion that the esophagus is the best conduit to the stomach, he sought to take advantage of the natural potential for growth in children and determined that tension would be a stimulus for growth of the esophageal pouches. This assumption was not without precedence as over three decades ago Puri et al. showed that primary delayed closure was a possible method to manage some cases of LGEA [2]. The presumed stimulus for the natural growth of the upper pouch was the swallowing reflex and for the lower pouch the stimulus was reflux of gastric

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_27

contents. It was noted that the maximal natural growth of the esophageal segments occurred during the first 8–12 weeks of life, and it led the investigators to purpose that the ideal time for delayed primary closure of EA was when the infant reached approximately 12 weeks of age [2]. The traction procedure as proposed by Foker was therefore as an extension of primary delayed closure; applying traction to the end of the pouch would simply enhance the natural tendency of the pouches to elongate. Other methodologies with a similar premise including daily bougienage of the proximal esophageal pouch during the waiting period and the use of high-volume bolus feeding through the gastrostomy in the hope that gastroesophageal reflux will occur and result in stretching of the distal esophageal segment have not been demonstrated to be effective [4]. The major drawback to the principle of delayed closure is the time period involved and the possibility of respiratory complications. Furthermore, ultra-long gaps with a very small lower esophageal pouch cannot be adequately developed to be able to bridge the gap simply by waiting.

The esophagus is a highly elastic viscus that normally retracts when transected and in the type A or pure EA where there is no lower pouch fistula to the trachea the pouch itself maybe very small and retracted in appearance. While there is likely some recoil in the lower pouch, the extremely small pouch clearly lacks mass (Fig. 27.1) and therefore real growth has to occur for it to be anastomosed. The integrity of the very small lower esophageal pouch for an attempt at primary repair of LGEA has always been questioned. At the University of Minnesota, it was previously shown that the anatomic structure and in particular the muscle layers are well preserved after traction has resulted in elongation of the lower and upper pouches including the overall luminal thickness [5, 6]. And despite the initial size of the pouch, the physical appearance and indeed the feel of the viscus are astonishingly normal even after significant lengthening following traction (Figs. 27.2 and 27.3). Of note, traction applied to the small bowel in an animal model was shown to result in growth of the small bowel as measured by tissue components including protein content and the bowel appeared morphologically normal [7]. The rate of growth of the small bowel in this study was similar to that achieved with esophageal trac-

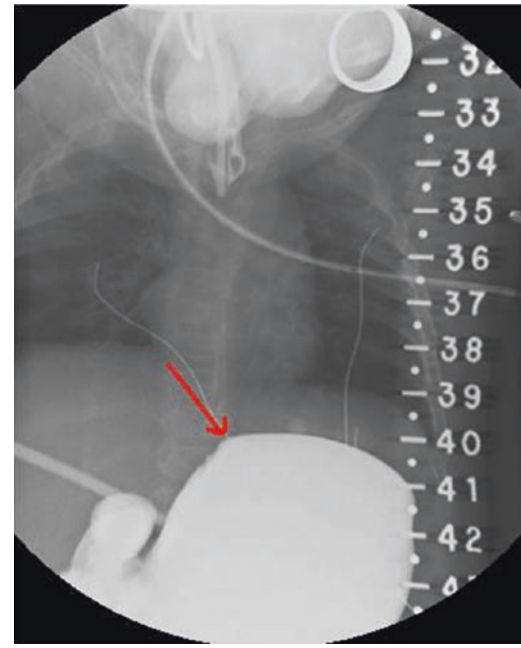

Fig. 27.1 Radiograph showing a miniscule lower esophageal pouch

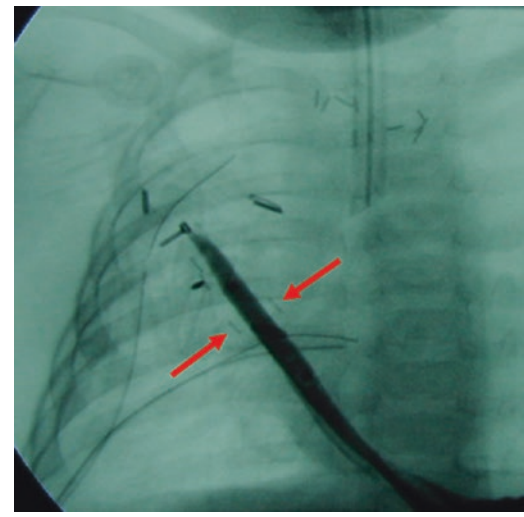

Fig. 27.2 An intraoperative field showing the esophageal form after traction

tion described in the Foker technique [5, 6]. An estimation of the rates of growth and lengthening of the esophagus and what is tolerable by the esophagus was a principle learned throughout the development of the technique by Foker [3, 8]. The estimate of growth of the esophageal segments in the series averaged between two and three times the original length, and this was accomplished within 2 weeks and up to 4 weeks (Fig. 27.4) [9, 10].

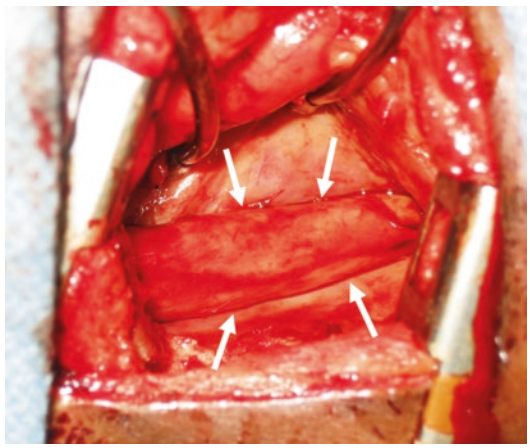

Fig. 27.3 An intraoperative field showing the esophageal form after traction

International Experience with the Growth Procedure

As with any new and novel technique, there have to be periods of assimilation and investigation by others as to the validity and feasibility of such an enterprise. There are some natural boundaries to this. While EA with tracheoesophageal fistula (TEF) presents frequently enough to pediatric surgeons for them to develop familiarity with the logistics of primary repair, LGEA is a relatively uncommon condition even for pediatric surgeons [11]. In its different forms, LGEA represents a challenge, and most pediatric surgeons will have their own algorithm for dealing with the complexities that include managing comorbidities that constitute the various syndromes associated with EA.

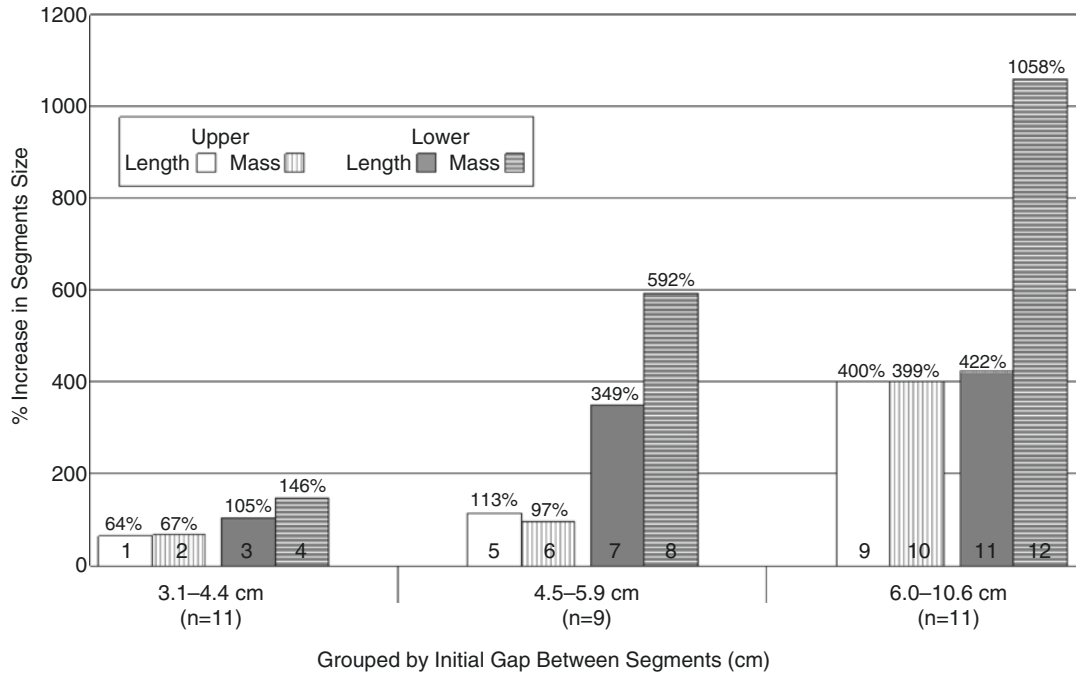

Fig. 27.4 Tension induced growth in upper and lower esophageal segments

The Algorithm for Long-Gap Esophageal Atresia Repair

Where radiological measurement of the esophageal gap has been supportive enough for delayed primary repair, the initial decision to wait is a reasonable consideration. Similarly the subsequent confirmation that the pouches can be approximated is also a decision that would be made without great deliberation though there is no certainty that primary anastomosis will be possible in the operative filed. It has been proposed by Foker that this is the ideal stage at which traction should be considered, i.e., when it is clear that a primary repair cannot be concluded [10]. The intuitive surgery for the truly long gap at this time is to acknowledge that the extremely short lower pouch is not useful and proceed to non-esophageal options. The gastric cavity is therefore either fashioned in to a conduit or bypassed by an intestinal component. In a survey of 88 pediatric surgeons from various countries, it was noted that the preferred method of bridging large gaps is with part or entire gastric cavity [11]. In the same survey, it was noted that approximately 40 % of surgeons would attempt the Foker procedure, and this was consistent in a follow-up survey [12]. These figures would suggest that in the case of the miniscule lower esophageal pouch, there is likely conviction in a significant proportion of surgeons that even the Foker procedure would be able to facilitate a primary repair.

Physiology of the Growth Procedure

Although it is not difficult to imagine normal physiological growth in early life, there is perhaps resistance to the concept as a treatment method and the notion that true growth can occur as part of the reparative process. In this debate, an appropriate response would be that regrowth involving limbs is a known phenomenon in some organisms, and as noted above, there is evidence to support the premise that functional growth can be stimulated even in the human alimentary tract. The success of tissue distraction most clearly for the skin and bone is testament to the concept that tension is a normal stimulus for growth in other organ systems. While it might be argued that to apply the principle of traction to growth of a complex structure such as a viscus may interfere with or cause derangement of function, the primary function of the esophagus is as a conduit to the stomach, and this is clearly achieved with primary repair of LGEA. Furthermore, in the case of EA, reestablishing esophageal continuity allows the stomach to be used for its proper purpose rather than being cannibalized to fashion a conduit. And normal esophagogastric function not only has implications for pathophysiological well-being but also for psychosocial development and later a normal relationship to food [13]. Further support for the concept of growth comes from the field of tissue regeneration, including the use of stem cells, an area that has developed in to a specialty in its own right [14]. Similarly to the use of traction this area of therapeutics is based on the premise that the natural process of growth can be reproduced for repair of tissue and organ systems (see chapter on tissue regeneration and stem cells).

A particular concern in regard to the principle of growth through traction has been the frailty of the lower esophageal segment in type A esophageal atresia when there is only a miniscule lower segment (Fig. 27.1). Overstretching of the esophageal muscle could potentially lead to fiber damage, and excessive mobilization of the very small lower segment may result in ischemic damage. There are however reports noting that the inferior segment of the esophagus can be mobilized without fear of provoking ischemic necrosis and that this results from the fact that the distal esophagus does not receive its blood supply from the thoracic aorta, as it has been thought, rather the supply is from the phrenic arteries or the proximal gastric collaterals [15].

Technical Aspects of the Foker Procedure and "Thoughtful Persistence"

In an international survey of pediatric surgeons, a proportion of those who attempted the Foker technique (24%) were not satisfied with it [11]. As noted above, successfully performing a surgical procedure such as the Foker technique with all of the nuances will involve a learning curve, and in the above survey, individual surgeons managed <2 cases/year. In describing the first use of the Foker technique for a case of an ultra-long-gap EA performed at their institution by Paya et al., the clinical course of the child was "surprisingly uneventful" [16]. Compared to other procedures, the authors reported that the complication rate was acceptable and primarily related to their lack of experience with the new method. It has to be noted therefore that with the relatively few cases of truly LGEA, the failure rate in performing the growth procedure may remain high in part related to the paucity of experience of individual surgeons.

The most specific intraoperative issue that has been discussed is the potential for traction sutures to detach and the possibility of mediastinitis, especially if esophageal perforation occurs [17]. Although the use of pledgeted sutures should minimize shearing forces at the tissue level, these sutures have been noted to cut through [18]. Al-Qahtani et al. in their discussion of pledgeted sutures cutting through suggested that the optimal size, quantity, material, and placement technique for the traction sutures has yet to be determined [19]. In a case series, Abraham et al. used purse string sutures and found that they did not slip as compared with their experience with single sutures [17]. The authors indicated that in their opinion sutures slippage was one of the reasons preventing the widespread acceptance of the growth procedure. This case is an illustration of how potential modulation of the technique by individuals within their own circumstance is possible if there is resolve to achieve primary repair. One can therefore postulate that a reason for lack of success is resorting to alternative methodologies rather than thoughtful persistence. Of course the reason to persist in trying to achieve a primary repair would be a conviction on the part of the surgeon that the patient would be better off with his/her own esophagus in place and that this end justifies persistence on the part of the physician and parents. Other reports have also commented on the effect of tension on the extracorporeal sutures and recognizing the suture rupture early on as an important potential technical problem [16]. The authors in this report determined that "such a rupture could be depicted better by placing the clips on the end of the esophageal pouch rather than across the sutures" and that if rupture occurs, applying new traction sutures would be better than forced anastomosis under tension.

The most significant potential early postoperative complication of a primary anastomosis under tension is an anastomotic leak. In a report by Burjonrappa et al. of two infants among 15 with LGEA who underwent the growth procedure, one anastomosis performed at 18 days of life was complicated by an anastomotic leak that healed spontaneously [20]. Unfortunately, the subsequent course was complicated by an esophageal diverticulum that was not salvageable and led to an esophagogastric dissociative procedure in the end. This case clearly serves to highlight the complex issues that may be faced in this patient group and that there will be cases that defy even the most obvious and routine treatments. It has to be borne in mind that these instances do not necessarily determine a change in approach to all cases but rather to acknowledge the particularly challenging ones.

As noted earlier, predetermined ideas about what may or may not be possible in any given clinical circumstance determines the approach taken, and the natural instinct for LGEA is that a primary repair will be impossible. It has been discussed that to accomplish a primary esophageal repair with a particularly long gap of 5 cm or greater, usually it would be necessary to pull up part of the stomach up through the esophageal hiatus and that this maneuver, however, may lead to severe continuing reflux, so that most surgeons would choose to replace the missing esophagus

with a gastric or colon interposition [21]. Gastroesophageal reflux following primary LGEA repair is the most significant problems faced by physicians caring for these patients both in the short and long term. It can be agreed upon that the short-term surgical solution is predicated on the concern that the gastroesophageal junction is naturally displaced upward with traction and that free reflux would further complicate any anastomotic leak, the possibility of stricture formation, and respiratory complications. The most suitable surgical procedure to deal with a displaced gastroesophageal junction is debated but having a dysmotile lower esophagus implies that a tight fundoplication may be counterproductive [22]. Indeed it can be argued that the most important consideration is having the gastroesophageal junction below the diaphragm. The limited data on the long-term outcome does indicate that a fundoplication will be necessary after primary repair of LGEA and that even after a fundoplication reflux may be an issue and requires follow-up [23].

Drawbacks to the growth procedure have been argued to be the need for repeated surgeries, including thoracotomies, the high incidence of postoperative gastroesophageal reflux requiring fundoplication, and a high risk of stricture formation dedicating the patients to a prolonged series of repeated esophageal dilations [24]. Despite all these possibilities, the outcome may justify the use of the growth procedure. For instance, in a case discussed by the editors (H Till and JE Foker) where an anastomotic stricture developed following traction and gastroesophageal reflux was evident, dilations were effective in relieving the stricture and a fundoplication successfully controlled the reflux [24]. Although the entire event required three operative procedures and the patient was hospitalized for 2 months, the outcome was deemed to be "very acceptable," given that an esophagus-only repair was achieved with the gastroesophageal junction below the diaphragm and the authors postulated that the "benefits of the repair should only increase with time." Similarly other authors have described how challenging EA repair was successfully brought to an acceptable conclusion eventually with the use of the growth technique [25]. By way of contrast in a series of gastric transposition, anastomotic leaks and strictures were not uncommon by report [26]. In the overall analysis, it has to be acknowledged that management of the LGEA using traction to enable primary repair is not a singular event but a process that extends from initial assessment until a functional esophagus has been completed and this entails assembling a suitable team of physicians and related staff who then would develop a specific expertise in treating LGEA. It goes without saying that problems may be faced at any stage of the process and there has to be a resolve to work through these. Regardless of whether there is a lengthening procedure or transposition to manage LGEA, it is now clear that these patients will require long-term follow-up.

Summary

The procedure of inducing growth of the esophageal pouches by traction to enable primary repair of LGEA is acknowledged to be a relevantly recent innovation [10]. Despite this, it was the second most commonly performed technique for LGEA among international surgeons surveyed (76%) [10]. There is also no doubt that surgeons have found challenges when applying the technique and have not always achieved success. It can be argued that the alternative, that is, to replace the esophagus though not an easy option, intellectually makes great sense from a practical standpoint at the time of the surgery. The challenging nature of the growth induction method cannot be denied; however, the ultimate aim if achieved is far more acceptable for patients than replacement of the esophagus. It remains to be seen as to the resolve of physicians in achieving this goal.

Part VII

Interposition Grafts to Establish Continuity

Gastric Transposition in Infants and Children

28

Robert A. Cowles and Arnold G. Coran

Introduction

The importance of an intact and functional esophagus cannot be overemphasized. Congenital and acquired diseases of the esophagus have significant adverse effects on growth and development. Conditions such as esophageal atresia with tracheoesophageal fistula can usually be adequately treated with direct surgical techniques, and these have been shown to result in excellent long-term outcomes. In other children, however, such as those with complex long-gap esophageal atresia and those with severe corrosive esophageal injury due to caustic ingestion, an excellent outcome cannot be guaranteed via the standard surgical approach. In these cases, replacement of the esophagus with a conduit may be the only viable alternative in order to restore anatomic and functional continuity between the mouth and the gastrointestinal tract. It is generally accepted that the ideal esophageal replacement conduit for children should (a) be long-lasting, (b) be associated with minimal reflux, (c) be technically feasible, (d) not affect cardiac or pulmonary function, and (e) allow oral consumption of nutrition. While the colon interposition and gastric transposition are the most commonly applied esophageal replacement procedures, other techniques have been described (Table 28.1) and can be considered under certain circumstances. This report will review the experience with gastric transposition procedures for esophageal replacement in infants and children.

History

The concept of using a gastric conduit for esophageal replacement was developed while treating adult patients with esophageal cancer. These procedures involved a combined abdominal and cervical approach with eventual cervical esophagogastric anastomosis. When compared to transthoracic esophagectomy, this approach resulted in no thoracic incision and left the anastomosis in the neck, where a leak, if it occurred, would be

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_28

more easily managed. The use of this procedure in children is limited mostly to treatment of benign processes and has gained increasing support.

Indications

Indications for esophageal replacement are varied (Table 28.2). In the pediatric population, the majority of cases involve esophageal atresia with long gap or patients who failed primary esophageal repair. When a primary anastomosis is impossible due to the distance between the two esophageal pouches, an esophageal replacement procedure should be considered. Whether a cervical esophagostomy is performed or not is a matter of surgeon preference. Children can be effectively managed with nasoesophageal suction temporarily while awaiting a definitive procedure. If the delay prior to definitive repair is predicted to be lengthy, however, a cervical esophagostomy may allow for sham feeding and care at home without fear of aspiration.

Caustic ingestion injuries to the esophagus remain an important indication for esophageal replacement. This indication is more commonly seen in developing countries, where caustic agents are an ongoing cause of injury due to poor packaging and care of these agents. While some caustic injuries are treated with dilation and supportive measures, severe injuries may not respond and replacement can be considered. Severe, unresponsive peptic strictures, tumors, and inflammatory conditions are uncommon indications for esophageal replacement [1].

Foreign body injury (e.g., battery)
Achalasia

Timing of Surgery

Esophageal replacement is an elective operation and should not normally be considered in an urgent or emergent setting. The timing of esophageal replacement depends primarily upon the underlying condition leading to replacement surgery. In cases of caustic ingestion with persistent stricture, surgery is often considered once standard therapy consisting of serial dilations has failed, usually after 6–12 months. The timing of surgery in infants with esophageal atresia, however, is more variable. Traditionally, a feeding gastrostomy is inserted once the diagnosis of long-gap esophageal atresia is made. Some advocate a cervical esophagostomy to allow sham feedings and safe discharge home without suction or before eventual transfer to a facility for definitive care. Alternatively, a sump suction tube can be left in the pouch for drainage of oral secretions until a definitive repair can be performed. Often the final decision to perform a definitive esophageal replacement is made once other options have failed or if the gap between the ends of the esophagus is deemed far too great to even attempt primary repair. This determination can be made after about 3 months of age. When considering gastric transposition in the setting of long-gap esophageal atresia, enough time must be allowed for adequate growth of the stomach as an adequate conduit will need to reach the region of the left neck.

Preoperative Preparation

Preoperative evaluation of children who are being prepared for gastric transposition should be

geared toward the underlying condition. In cases of esophageal atresia, a cardiac evaluation, pulmonary functional assessment, and a reliable measurement of gap length should be performed. In the setting of caustic ingestion, pulmonary function and the quality of the stomach should be assessed. An endoscopy, if possible, will delineate the stomach, and an assessment can be made of its usefulness as a potential conduit. We recommend a formal bowel preparation in the event that the stomach is not usable and an alternative conduit is contemplated. If possible, an evaluation of vocal cord movement is advisable preoperatively in all cases to document the status of the recurrent laryngeal nerves before surgical manipulation of the neck.

Technical Details of Gastric Transposition

The patient is placed supine on the operating table, generally with the left chest elevated and the left arm prepped and mobile in the field. This allows for exposure of the left neck. The IV lines should be placed in the lower extremities. In this manner, the neck, chest, abdomen, and left upper extremity are prepped and draped. The abdominal incision is made first. A gastrostomy is often present and should be taken down from the abdominal wall. The stomach should be freed from adhesions and, if present, a fundoplication should be unwrapped. The gastrocolic omentum with the short gastric vessels should be carefully divided as should the gastrohepatic omentum. The right gastric vascular arcade is preserved and the left gastric vessels are divided.

The distal esophageal remnant is then dissected from the mediastinum (Fig. 28.1a). In isolated esophageal atresia, this is often seen as a short diverticulum, which is easily dissected (Fig. 28.1a), but in cases of corrosive injury, the scarred esophagus is often difficult to dissect from the mediastinum. The gastroesophageal junction can be divided with a stapler or amputated and closed with sutures. The gastrostomy site can be removed similarly. These maneuvers free the stomach completely, preserving the blood supply via the right gastric artery and right gastroepiploic vessels (Fig. 28.1b).

By definition, the vagus nerves are divided bilaterally during the gastric transposition procedure, and most authors recommend either a pyloroplasty or a pyloromyotomy. Our group has used the pyloromyotomy with excellent success, and we feel that a formal Heineke-Mikulicz pyloroplasty is placed under tension when the conduit is pulled into the neck. It should be noted that the performance of a pyloromyotomy on an essentially normal pylorus requires significant care in order to avoid violating the mucosa. If necessary, a Kocher maneuver may be performed in order to allow the conduit to reach the neck.

The esophageal hiatus is opened from the abdominal approach. With retraction of the left arm, a left cervical incision is made and the cervical esophagus, or the esophagostomy, is isolated. Care should be taken in this area to avoid injury to the recurrent laryngeal nerves. In isolated esophageal atresia, when no esophagus lies in the posterior mediastinum, a path can be created for the gastric conduit using blunt dissection from the abdominal and cervical approaches (Fig. 28.1c). When the native esophagus has been present, it can be dissected bluntly and the resulting path can be used for the conduit. A large chest tube (28–32 French) can be passed from the cervical incision into the abdomen via the posterior mediastinal path. On the abdominal side, the tube is sutured to the fundus of the gastric conduit, which is the highest point on the stomach, with care taken to avoid twisting of the conduit as it is pulled through the posterior mediastinum. Once the conduit is comfortably pulled to the level of the left cervical incision, we recommend anchoring the conduit to the sternocleidomastoid muscle's medial boarder laterally and the strap muscles medially. A gastrotomy is performed and the upper esophageal pouch is opened. The most distal part of the upper esophagus and the apex of the gastric conduit are connected with a single layer anastomosis using interrupted sutures (Fig. 28.1d). A transanastomotic nasogastric or orogastric tube is left in place for decompression of the gastric conduit and to be used for a postoperative contrast study. The cervical incision is

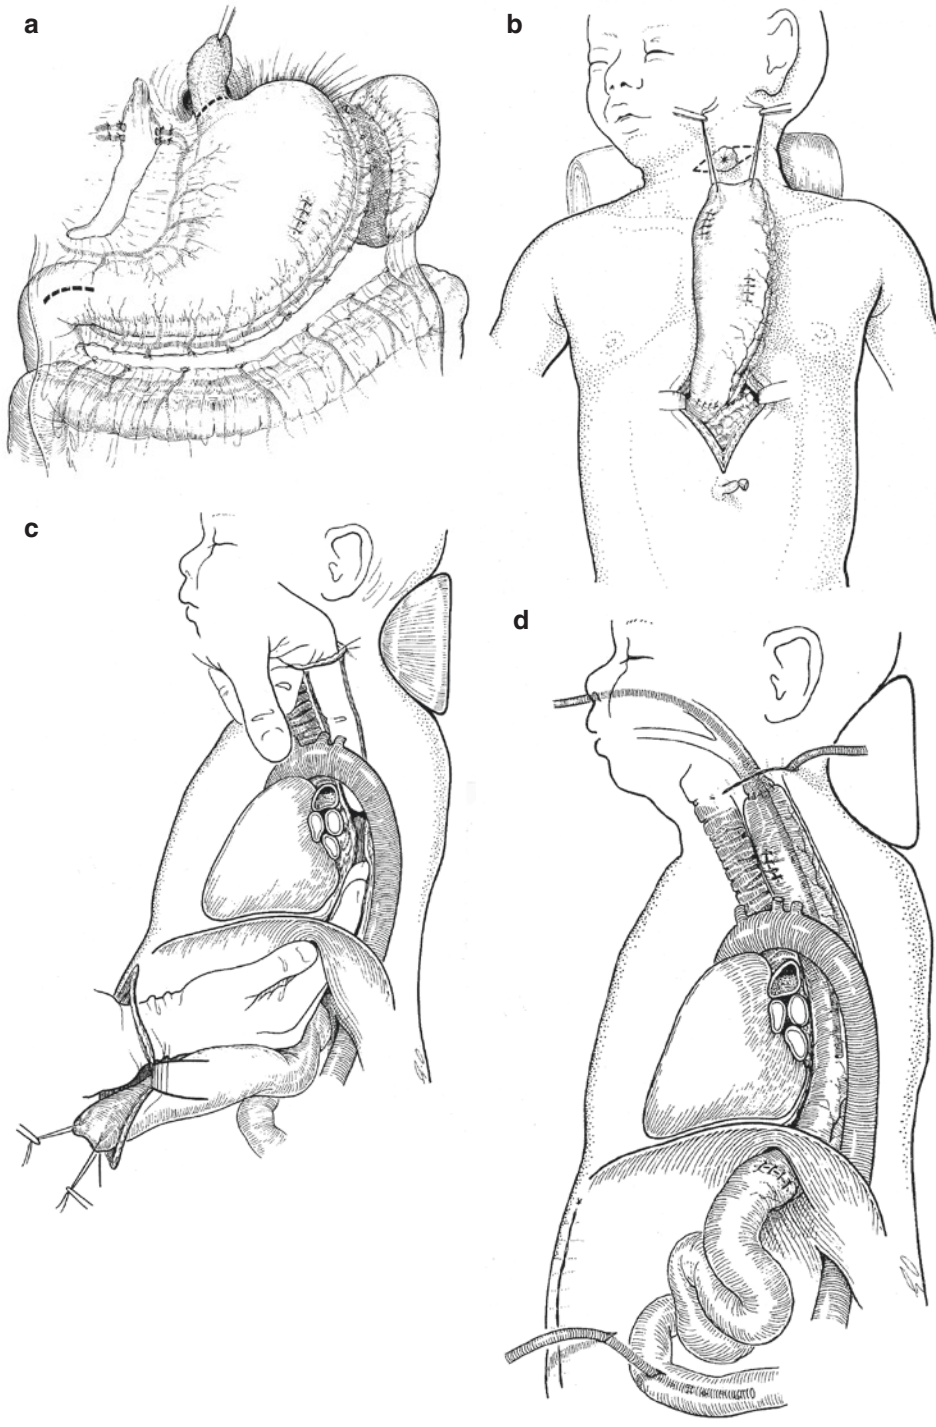

Fig. 28.1 (**a**–**d**) Technique of gastric transposition: (**a**) The stomach is dissected with care to preserve the right gastric and right gastroepiploic vessels. The distal esophagus is dissected from the mediastinum. In long-gap, isolated esophageal atresia, the distal esophagus is often a short diverticulum that comes off the stomach (shown). (**b**) The stomach is completely freed. The gastrostomy site and gastroesophageal junction are closed. Note the length that can be expected from the gastric conduit. (**c**) A posterior mediastinal tunnel can be created with blunt dissection. (**d**) The conduit is carefully passed via this tunnel and into the neck, where a cervical esophagogastrostomy is performed (Figures from Spitz [11] with permission)

closed over a Penrose drain. We obtain a contrast study of the conduit during the postoperative period to assess the anastomosis, evaluate for leak, and document gastric emptying (Fig. 28.2).

Postoperative feeding is achieved using a variety of methods. It should be stressed that the gastric conduit is aperistaltic and surgically denervated. For this reason, it must drain by gravity, making it imperative that these children feed orally in the upright position. Despite these maneuvers, however, many children have delayed oromotor function, and it is often difficult to fully nourish them orally immediately following gastric transposition. Nasogastric tube feedings can be employed but rely upon the security of a nasal tube. Alternatively, a feeding jejunostomy may be placed and used during the postoperative period. This latter approach must be considered in patients who have been fully reliant on their gastrostomy prior to esophageal replacement. Our preferred method is a "button-loop" jejunostomy rather than the standard Witzel tube jejunostomy. Briefly, the jejunum just distal to the ligament of Treitz is isolated, folded on itself, and anchored in a side-to-side configuration. The apex of the jejunum is opened, and an endoscopic stapler is used to create a side-to-side common opening between the two limbs. Two purse-string sutures are placed, and the tube is anchored once these sutures are tied and the tube is then brought through the skin (Fig. 28.3). The details of this technique have been previously published [2]. The technique allows for insertion of a replaceable button device that is secure, and the jejunostomy is not prone to obstruction. Another advantage is that when the jejunostomy is no longer needed, the button can be removed. Thus, this type of jejunostomy functions like a Roux-en-Y jejunostomy but is simple to perform and requires no operation to close.

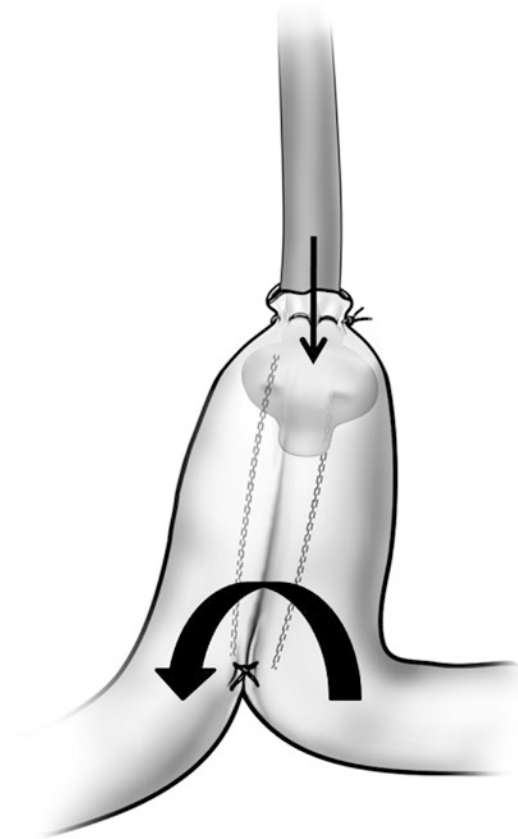

Fig. 28.3 Jejunostomy technique that creates a jejunal "loop" diverticulum. A replaceable balloon device can be used. Feedings are infused via the jejunostomy tube (*straight arrow*) and intestinal contents pass distally (*curved arrow*)

Outcomes

Few large studies exist that document outcomes of gastric transposition in infants and children. In 1948, Sweet published his description of gastric transposition which brought the stomach behind the hilum of the left lung and into the neck [3]. In 1984, Spitz reported his initial experience with four children with long-gap esophageal atresia where the gastric conduit was brought into the neck via the posterior mediastinum without thoracotomy in order to achieve a cervical esophagogastric anastomosis, an approach similar to what is often used in the treatment of esophageal cancer in adults [4]. Spitz published updates of his growing experience with gastric transposition in 1992, in 2004, and again in 2009 [5–7]. In the latest report, 192 cases were reviewed. Mortality rates were low (<5 %), but morbidity such as anastomotic leak (12 %), anastomotic stricture (19.6 %), swallowing dysfunction (30.6 %), and delayed gastric emptying (8.7 %) was not uncommon over the 25-year period [7]. Hirschl et al. reported a multi-institutional experience with gastric transposition in 2002 [8]. Of the 41 patients described, 26 had esophageal atresia. The mortality rate was zero and no conduits were lost. Interestingly, the reported rates for anastomotic leak (36 %) and stricture (49 %) were higher than those reported by Spitz. These differences are likely related to each group's definition of leak and stricture.

Davenport et al. reported long-term outcomes after gastric transposition in 17 patients who had undergone surgery more than 5 years previously [9]. In this study, gastric transposition was associated with diminished lung capacity, efficient gastric emptying, low iron stores, and overall excellent parental satisfaction. On average, children were also smaller than normal, but it is unclear whether this result is associated with the underlying condition or with the gastric transposition itself. In 2003, Ludman and Spitz reported on the quality of life of their gastric transposition patients [10]. Overall, nearly all patients reported high satisfaction and led a "normal" life after gastric transposition. There was a tendency toward social and emotional delays, and there appeared to be quality of life benefits for those who underwent primary gastric transposition versus those who had failed attempts at primary esophageal repair initially.

Since 1987, the senior author (AGC) has been involved in 169 cases of gastric transposition treated at several institutions, and, of these, 144 have adequate follow-up for analysis. In 111 (77 %), gastric transposition was performed for esophageal atresia, most commonly with long gap; 17 (12 %) for caustic stricture; 5 (3 %) for diffuse leiomyomatosis; and the remaining 11 (8 %) for failure of previous esophageal, tracheal, or upper gastrointestinal procedures. Currently, our approach is to perform the mediastinal esophageal dissection via a combined abdominal and cervical incision. No significant bleeding has been encountered as a complication. There are no postoperative deaths or loss of conduit in this series. One child developed cardiopulmonary arrest during a routine dilation procedure several months after a successful gastric transposition and suffered significant brain damage. This patient eventually died 1.5 years later from chronic renal failure. Another child with severe pulmonary insufficiency prior to the gastric transposition died 3 years after a successful gastric transposition from progressive respiratory failure. Another required takedown of a viable conduit due to persistent stricture at the esophagogastric anastomosis; this complication was felt to arise due to poor compliance with medication and follow-up. The relative rarity of major complications emphasizes the safety and efficacy of the operation.

Treatment Algorithm

Since most gastric transposition procedures are performed for long-gap or isolated esophageal atresia, the following algorithm has been adopted over the past 2 years by the senior author (AGC) when staging the care of these challenging patients:

1. The diagnosis of isolated (or long-gap) esophageal atresia should be confirmed, and the presence or absence of a proximal pouch fistula should be assessed via bronchoscopy or

during a careful contrast study of the upper pouch. A feeding gastrostomy is indicated early to facilitate feeding and to allow the stomach to grow and dilate.

2. At 6 weeks of age, the esophageal gap can be measured. The authors prefer a technique that uses a soft bougie in the upper pouch and a neonatal endoscope advanced via the mature gastrostomy site and into the lower pouch under direct vision (Fig. 28.4).
3. If the gap between the upper and lower pouches is three vertebral bodies or less, then a primary repair may be attempted. If the gap is greater than three vertebral bodies, then it is advisable to remeasure the gap after a second 6-week interval (a total of 12 weeks).
4. If the distal pouch resembles a small diverticulum or if primary repair appears impossible, a primary gastric transposition can be performed as described in this chapter at 12 weeks. If gap length suggests that primary end-to-end repair appears feasible, the child should be prepared for a right thoracotomy. The authors recommend patient positioning and an operative approach that would allow for conversion to a gastric transposition if primary repair turns out to be impossible. This requires that the abdomen, right chest, right upper extremity, and right neck be placed in the sterile operative field.
5. While wide dissection of the lower pouch is traditionally not recommended, taking down the diaphragmatic attachments to the esophagus, performing upper and lower pouch myotomies, and even ligating the left gastric vascular pedicle can facilitate a primary esophageal anastomosis. This approach has been used in five patients during this past year, with success in accomplishing a primary anastomosis in four. Only one of these five patients underwent a gastric transposition.

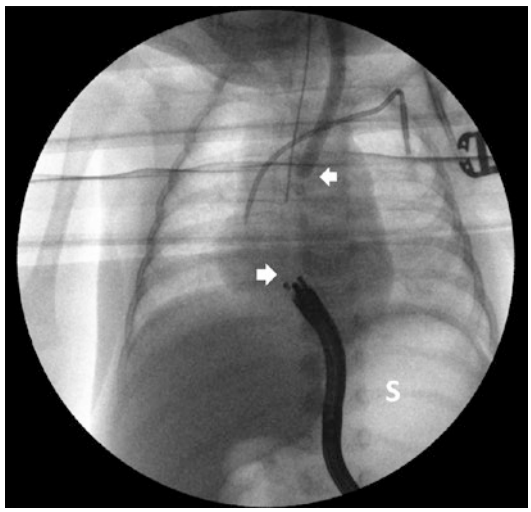

Fig. 28.4 Endoscopic technique to measure the gap between esophageal pouches in long-gap esophageal atresia. Placement of the endoscope into the stomach (*S*) via the gastrostomy ensures that the distal pouch is being clearly marked (*lower arrow*). A bougie dilator is placed from above to delineate the upper pouch (*upper arrow*). Fluoroscopic images are used to estimate the gap length

Conclusions

In children, esophageal substitution can be accomplished with a variety of intestinal conduits. Gastric transposition, while popularized for treatment of esophageal cancer in adults, is an effective esophageal replacement procedure. Gastric transposition obviates the need for a thoracotomy; places the conduit in the natural esophageal bed, preventing redundancy and lung compromise; requires only a single cervical anastomosis; and appears to be associated with excellent long-term outcome and patient satisfaction.

The Gastric Tube

29

Gabriel O. Ionescu, Simona Gavrilescu, and Gabriel Aprodu

Introduction

"The best esophagus is the native esophagus" [1–3] is an almost universally accepted belief and has spawned a number of techniques designed to salvage the injured oesophagus or to permit an anastomosis where there is inadequate length in an atretic organ.

In developed countries, oesophageal replacement has become a rare operation in childhood, yet in developing countries, it is still frequently necessary in patients with extensive oesophageal injury due to caustic ingestion and in some cases of long-gap oesophageal atresia (EALG) [4]. Colonic graft [5–9], whole stomach transposition [10–13], gastric tube oesophageal replacement [14–18] and jejunal interposition [19–22] have all been used successfully, and selection of the procedure depends upon surgeon preference and experience as well as the anatomy of the injury. Recently, all of these procedures have been performed laparoscopically with promising results [23–27]. Other techniques for oesophageal replacement or reconstruction have been reported in small numbers including colonic patch [3, 28], sigmoid transposition with microvascular anastomosis [29] and different types of small bowel interposition [19, 21]. A few cases with isolated pedicled gastric tube graft and intrathoracic transposition have been also published [30–32]. Current research holds the prospect of oesophageal replacement using grafts created in the laboratory by tissue engineering techniques [33]. The long-term outcomes in adults following oesophageal replacement in childhood have been widely reported [34–37].

This chapter is devoted to the technique of gastric tube replacement of the oesophagus (GTER) in children.

Short History of the Gastric Tube

The history of the gastric tube oesophageal replacement began at the turn of the nineteenth century when several surgeons in Europe and North America started experimental work on replacement of the oesophagus. The modern era began with Pr Amza Jiamu, Professor of Surgery at Bucharest, Romania. Between 1910 and 1936, he devised and successfully performed many gastric tube operations on animals [38]. He performed these experiments with his assistant Dr Dan Gavriliu but never performed these operations on humans (Fig. 29.1).

Thus, the use of a well-vascularised graft, such as the gastric tube, as an oesophageal replacement in humans is not a new concept but owes its current popularity to the pioneering work of Dr Dan

Gavriliu, a general surgeon from Bucharest, Romania. In 1951, Dr Gavriliu reported his first series of 21 reversed gastric tubes in adults [39]. Initially he positioned the tube presternally and latterly retrosternally, although he never used the transpleural or mediastinal routes. In his original description of the procedure, he recommended routine splenectomy in order to facilitate the tailoring of a gastric tube of sufficient length to reach the neck without tension and to improve blood flow within the tube by diverting splenic blood into the stomach. Finally, he wrapped the tube in omentum. There are no data to confirm the value of these complementary procedures. In 1957, he published a book on surgery of the oesophagus which broadened acceptance of the procedure throughout Romania, Europe and ultimately North America [40, 41].

In America, Dr Heimlich from Ohio, without knowing of the work and publications of Dr Gavriliu, described a similar technique and published his experience in 1959 [42]. The first reversed gastric tube oesophageal replacement (RGTER) in Canada was performed by Dr. James Fallis, and Dr. S Ein has extensively used the procedure in children and published long-term results [16, 17, 35, 43].

More recently, Burrington [44] and Pederson [4] have reported short series of gastric tube oesophageal replacement (GTER) in patients with long-gap oesophageal atresia performed in the neonatal or early infancy period.

Fig. 29.1 Dr Dan Gavriliu when being a visiting Professor in the USA

Over time, several modifications of the procedure have been developed including transhiatal oesophagectomy [45–48], which was later incorporated into a one-stage operation with colonic interposition by Rodgers [48].

In recent years, the most common procedure for paediatric oesophageal replacement has been a combination of transhiatal oesophagectomy and replacement of a substitute (colon, small bowel, gastric tube or whole stomach) through the posterior mediastinum in a one-stage operation. For the reversed gastric tube, the first report of such a one-stage procedure was published by Ionescu in 1985 [18].

Surgical Anatomy of the Gastric Tube

In this section, the vascular anatomy relevant to the creation of a gastric tube is discussed. For details on other aspects of gastric anatomy, please see the chapter devoted to anatomy.

Any oesophageal replacement must be well vascularised. Every large series of oesophageal replacement has a few cases of graft failure due to vascular causes (thrombosis, poor perfusion, compression or twisting of the pedicle) [49, 50]. Some surgeons recognizing these difficulties have combined replacements with additional microvascular anastomosis in the neck (with facial, internal mammary or even external carotid arteries) in order to provide additional blood flow [19, 21]. The stomach has a rich vascular network with multiple anastomosis and its acid secretion reduces the risks of infection. As the majority of surgeons use the reversed gastric tube as an oesophageal replacement, the discussion here is focused on the blood supply of the greater curvature of the stomach. The greater curvature of the stomach is bordered by the gastro-epiploic arcade (gastro-omental) representing an anastomosis between the left (taking origin from the splenic artery) and the right (taking origin from the left gastric artery) gastro-epiploic arteries. Multiple collateral vessels course within the wall of the greater curvature where they make large loops in a rich anastomosis.

In some cases, the arcade bordering the greater curvature is incomplete. A vascular gap of anything between 2 and 7 cm might raise concern in the mind of the surgeon about the quality of blood supply available for the perfusion of a gastric tube. This "long gap" was seen in 30 % of the cases in my personal experience of 109 reversed gastric tubes. Studies of the microvascular anatomy of the stomach confirm the excellence of the vascularity, and such short gaps in the arcade are not a contraindication to the use of the gastric tube. Several studies have shown that the fundus of the stomach is not as well perfused as the body or the antrum. It might therefore appear that a tube based on the right gastro-epiploic vessels would have some deficiency of vascularity at the fundal end, in contrast to the standard iso-peristaltic tube based on the left gastro-epiploic vessels [51]. However, in clinical practice, there is no difference in the quality of blood supply in either iso- or antiperistaltic tubes (Fig. 29.2).

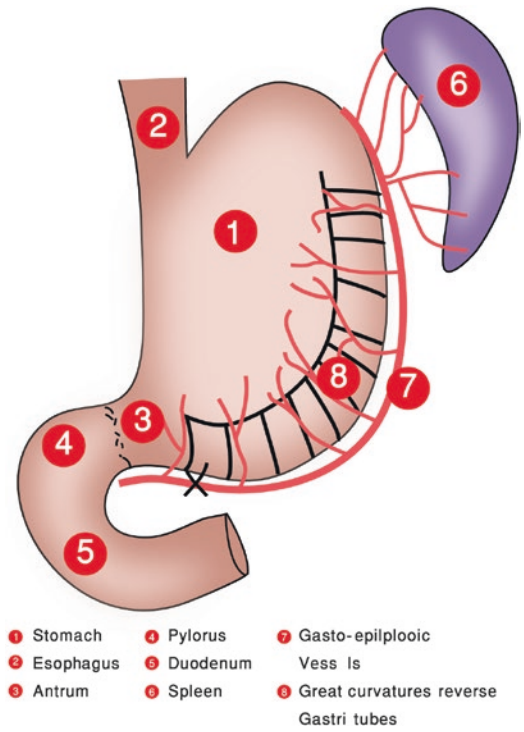

Fig. 29.2 Vascular anatomy of the gastric tube (Illustrated by M. Hassanieh)

Using Doppler flowmetry studies of both iso- and antiperistaltic tubes (with right or left gastro-epiploic blood supply), Shilling [51] concluded that the fundus was a well-perfused area of the stomach and suggested a gastric tube based on lesser curvature vessels (fundus rotation gastroplasty), which is technically challenging and may provide insufficient length. They further recommended the use of an intraoperative Doppler study to allow early detection of a poor vascular graft with risk of ischaemia [52]. In 2006, Nishikawa studied 13 gastric tubes used for oesophageal replacement measuring thermal images during the procedure [53], clearly demonstrating a lower surface temperature at the cranial end of the tube, suggesting reduced perfusion. It was concluded that intraoperative thermography, a non-invasive, reliable test, should be used to guide construction of a gastric tube [53]. Lazar [54] proposed the use of thoracic epidural anaesthesia to improve the microcirculation when a gastric tube is constructed.

In surgical practice, most gastric tubes are made as antiperistaltic tubes with no significant increase in the number of vascular complications compared to iso-peristaltic tubes. The authors have no personal experience with indirect methods of assessing perfusion. Some authors have recommended testing the vascularity of the tube by temporary occlusion of the proximal and distal circulation with vascular clamps as is frequently done when preparing a colonic oesophageal replacement. This procedure was performed early in our experience without yielding any useful information; we do not recommend its use.

Incorrect positioning of a previously placed gastrostomy on the greater curvature, particularly if the procedure has damaged the gastro-epiploic arcade, may constitute a contraindication to the creation of a gastric tube. In our experience, two patients presented with this dilemma. In one patient, a colonic replacement was performed with excellent results and the other had an atypical gastric tube created involving the posterior wall of the stomach. Complete necrosis of the graft occurred necessitating removal of the tube

and usage of a colonic interposition. It must be stressed that a preliminary gastrostomy should be placed on the anterior gastric wall as far away from the greater curve as possible.

In conclusion, the vascularity of the stomach offers a well-perfused organ for oesophageal replacement with few anatomical variants and a low risk of vascular failure within the graft, unlike the small bowel or colonic interpositions.

Indications for Gastric Tube Oesophageal Replacement

Medical Indications for Oesophageal Replacement

Long-gap oesophageal atresia [1, 4, 55–59] and extensive stricture following caustic ingestion [9, 17, 60–65] are the most common indications for oesophageal replacement in children. Foker's technique [66–70] of rapid oesophageal elongation, together with various techniques of delayed primary anastomosis [59] including Kimura's progressive elongation of the upper pouch, which remains popular in some parts of the world like Argentina, has almost eliminated the need for oesophageal replacement in EALG [71]. The complete failure of the anastomosis after primary, delayed primary or secondary surgery may still however necessitate oesophageal replacement as a salvage procedure.

The aggressive treatment of caustic injuries with steroids [72, 73], both systemic and local, early dilatation using balloons or endless loop bougienage [74–76] and the use of resorbable stents for resistant strictures [77, 78] have significantly reduced the number of patients requiring oesophageal replacement.

Occasionally, for patients with severe oesophageal stricture due to epidermolysis bullosa [52], achalasia, long oesophageal duplication [79] or infectious stricture [80], a replacement of the oesophagus may be indicated. Historically, gastric tube replacement has been used in a desperate attempt to control bleeding from oesophageal varices [81].

In children, oesophageal malignancies are rare indications for oesophageal replacement. In our experience, there are only two patients, one with an adenocarcinoma of the oesophagus and one with an aggressive infantile fibromatosis of the neck and mediastinum with involvement of the oesophagus.

Finally, gastric tubes have been used in selected cases for other purposes such as drainage for a ventricular shunt (ventriculo-gastric shunt) in biliary atresia (porto-gastrostomy) and as a palliative short iso-peristaltic tube as a continent, tubeless gastrostomy in patients with unresectable oesophageal cancer.

Choice of Type of Replacement

The choice of technique for oesophageal replacement very much depends upon each surgeon's preference and experience with the two most popular being colonic interposition [5–9, 49, 82] and RGTER [1, 14, 16, 17, 36, 37, 58, 60, 83, 84]. Since the early 1980s, total gastric transposition, popularized by Lewis Spitz, has been extensively used in England and North America [11–13, 23, 24]. A very small stomach as seen in early type 1 oesophageal atresia; gastric scarring from caustic ingestion, especially the ingestion of strong acids; an inappropriately placed gastrostomy that impinges on the greater curvature; or patients with previous gastric surgery, such as Nissen fundoplication with or without gastrostomy, all make gastric tube construction hazardous.

However, GTER is the preferred option when a colonic graft is unavailable as may be seen in VATER/VACTERL syndrome with a previous colostomy, oesophageal atresia associated with malrotation, congenital megacolon, congenital short colon, previous episodes of necrotizing entero-colitis, multiple intestinal atresia, etc.

Despite several small series with good results after jejunal interposition [19, 20], the vascular risk, the frequent need for an additional microvascular anastomosis in the neck, the quality of the graft and the need for two intrathoracic

anastomoses make small bowel interposition a less favoured option.

Harmel [52] performed oesophageal replacements on two siblings with epidermolysis bullosa and severe strictures: one a RGTER and one a colonic interposition. He reported that the gastric tube was performed more easily and more quickly than the colonic interposition but that the results were good in both cases.

Total gastric transposition, although a popular and safe procedure, should be used with caution pending assessment of the long-term quality of life provided and the severity of side effects such as delayed gastric emptying and bile reflux.

Other replacements such as small bowel, gastric tubes fashioned from the fundus or lesser curvature, Scharli's partial gastric transaction [85, 86] should all be reserved for use in the exceptional circumstances when both GTER and colonic interposition are contraindicated.

Planning a Gastric Tube Oesophageal Replacement

Optimal Time for Oesophageal Replacement

The best time for oesophageal replacement depends upon many factors: primary disease, comorbidity, the availability of post-operative intensive care and often an arbitrary policy of the surgeon (e.g. not earlier than 1 year of age or 6–8 kg). In children with oesophageal atresia, there is general agreement that repair or replacement should be performed as early as possible in order to establish oral feeding [1, 4, 44, 55, 57, 58]. All types of replacement (gastric tube, colonic interposition and gastric transposition) have been successfully performed in the neonatal period or early infancy. A large volume stomach is the most important requisite for a successful gastric tube as it enables the gastric reservoir to be preserved, along with normal motility and gastric secretion. In pure oesophageal atresia, the stomach is notoriously small; after several months of gastrostomy feeding, an increase in volume can be anticipated (Fig. 29.3) allowing the safe construction of a gastric tube. Most of the patients in our series underwent gastric tube oesophageal replacement around 1 year of age.

In patients with extensive oesophageal strictures resistant to dilatation, replacement is indicated when it is recognized that all methods have failed to relieve stricturing. In our experience, dilatation using an olive dilator passed over a string which is passed from nose to gastrostomy in an endless loop is effective at reducing the need for oesophageal replacement [74, 75, 79]. This method has the advantages that it can be done twice daily, without anaesthesia, at home by the mother, or the patient himself. It is a safe procedure with few complications (nasal, choanal, soft palate ulcerations, granuloma, etc.) and allows concomitant oral feeding. These advantages must be weighed against the need for a gastrostomy and the permanent presence of a string passing from the nose and the potential psychological stress of such a procedure (Fig. 29.4).

Replacement should not be attempted within 6 months after the initial injury. Some authors suggest earlier replacement based on the intuitive belief that progressive mediastinal fibrosis will develop over time making transhiatal oesophagectomy hazardous [9]. Following previous mediastinitis, iatrogenic perforation during dilatation, pleural effusion or empyema, a minimum interval of 1 year is advised, particularly if a posterior mediastinal replacement is planned. In some patients, it may be prudent to place the graft retrosternally. The damaged oesophagus should always be removed, preferably at the time of reconstruction, but alternatively as a second procedure [87].

Pre-operative Preparation for Gastric Tube Oesophageal Replacement

Oesophageal replacement is a major operation irrespective of the technique chosen. Post-operative morbidity and occasional mortality are recorded in most series. In some countries, a nationally accepted protocol for oesophageal replacement is in place and patients are referred to selected tertiary centres of excellence, and

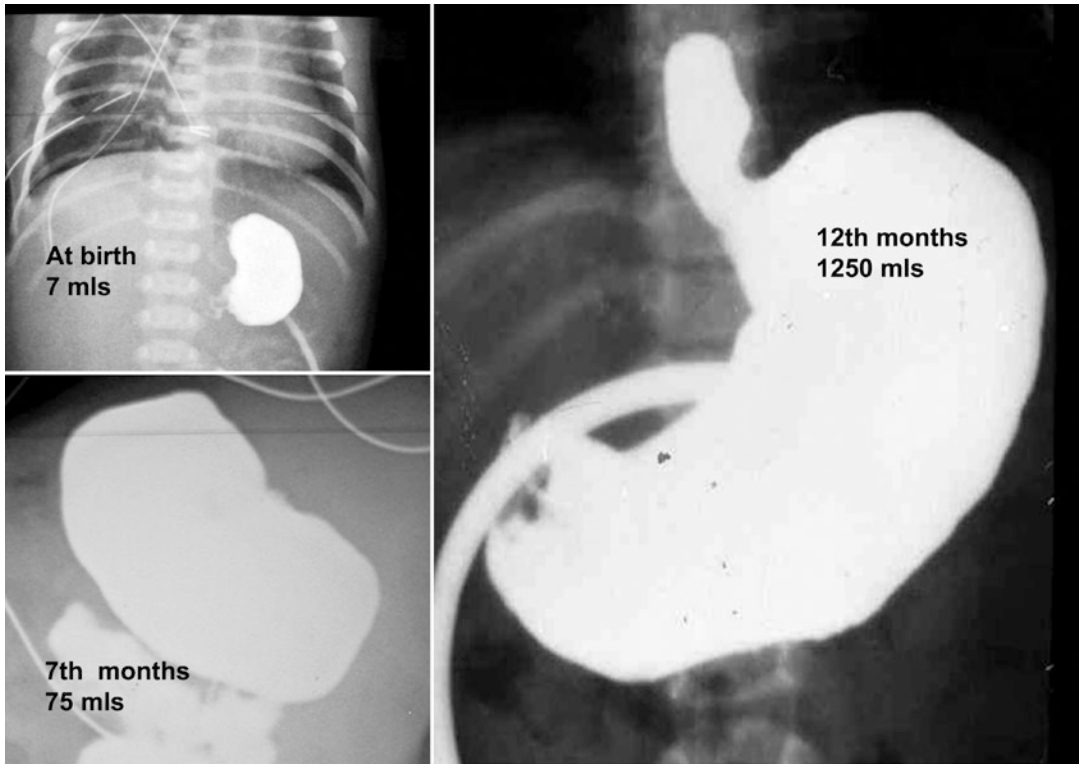

Fig. 29.3 Under feeding through the gastrostomy, the progressive increase in volume of the stomach is noticed (EALG)

these operations are performed by experienced surgeons and patients cared for by specialized ICU staff.

Pre-surgical care should be provided ideally by a multidisciplinary team including a paediatric gastroenterologist, nutritionist, pulmonologist, experienced endoscopist, stoma care staff, experienced surgeon and anaesthetist and should also include a psychologist for family and older child support. Prior to surgery, several conditions must be discussed.

Tracheostomy

The decision to perform a RGTER should be reviewed to ensure that it is the right operation for the right patient. The optimal timing of surgery has been discussed. Many children, however, particularly those with malformation syndromes or caustic injuries present with severe malnutrition. Improving the nutritional status of the patient is an essential part of pre-operative preparation; this can take months.

Some patients will have had a tracheostomy performed for various reasons. The presence of a tracheostomy is not an absolute contraindication to oesophageal replacement, but it does increase the risk of complications at the cervical anastomosis. So, if possible, surgery should be delayed until removal of the tracheostomy has been accomplished. Four patients in our series had tracheostomies in place at the time of surgery and replacement went without incidents.

Enterostomies

Most patients presenting for oesophageal replacement will have a feeding gastrostomy in place, usually of the Stamm variety. Sometimes the gastrostomy has been performed elsewhere and could be inappropriately sited or giving rise to complications such as leakage, inflammation or skin erosion caused by gastric acid. In a few cases, it may be wise to close an existing gastrostomy and reopen a new one as a preliminary step before oesophageal replacement. The surgeon

Fig. 29.4 Endless loop dilatation for severe stricture of the anastomosis and hypoplastic lower oesophageal segment after Foker's technique

who performs such a revision must make careful note of the gastric blood supply.

Some surgeons have advocated a feeding jejunostomy in order to leave a stomach undisturbed by previous surgery; however, a gastrostomy has the effect, not only of allowing intermittent feeding but also of enlarging the gastric reservoir. After several months of feeding via a jejunostomy, the stomach becomes very small and a gastric tube may no longer be possible. If a patient presents with a jejunostomy in place, this should be closed and a gastrostomy created, particularly if the stomach is small. An alternative would be to plan a colon interposition rather than attempt to create a gastric tube from an inadequately sized stomach. Feeding via a gastrostomy should be given as a bolus which should reach 250–750 mls depending upon the age of the patient.

In patients with cervical oesophagostomy and long-gap oesophageal atresia, a programme of sham feeds is essential and should be implemented immediately after birth. In patients being treated by continuous pharyngeal suction, sham feeds can be simulated by having the baby suck on an empty bottle.

Contrast Studies

Pre-operative contrast studies of the stomach and colon have been recommended. In our experience, these pre-operative studies are not necessary.

Bowel Preparation

The day before surgery, a full bowel preparation using Golytely® or Kleenprep® should be carefully performed. Should intraoperative findings mandate a change from gastric tube to colonic interposition, it is essential to have a fully

prepared bowel. The operating surgeon must be prepared to perform any type of oesophageal replacement. In our series, two patients were switched intraoperatively from a gastric tube to colonic interposition and one from a planned colonic interposition to a gastric tube.

Informed Consent

A comprehensive informed consent is crucial and should be taken by the surgeon who will perform the operation. Obviously, the planned operation will be described as well as the possible complications. Alternative techniques must also be explained. The use of a short video of the operation is recommended.

The Standard Technique of Reversed Gastric Tube Oesophageal Replacement

General Data

We describe here the technique for the most popular oesophageal replacement procedure, the reversed or antiperistaltic gastric tube. This description is based on our series of 109 operations performed by the same team of surgeons between 1975 and 2009 [18, 37, 88].

Broad-spectrum antibiotic prophylaxis is given 30 min before surgery and maintained for 3–5 days. Good venous access is assured by insertion of double-lumen central line.

The left side of the neck from the angle of the jaw and the whole chest and abdomen are meticulously prepared and draped using Opsite® (Fig. 29.5). In adults, the operation can be performed by two surgical teams working simultaneously: one intra-abdominal, preparing the gastric tube, and the other preparing the neck. In children, the operation is performed by a single surgical team.

Tailoring the Gastric Tube

Through a midline laparotomy incision, the stomach is approached and inspected. The gastrostomy tube is pulled out and the site of the gastrostomy is separated from the abdominal wall and the stoma is temporarily closed. Great care should be taken to avoid damage to the vessels along the greater curvature; the left triangular ligament of the liver is divided and the lower oesophagus is prepared as if for a fundoplication. The vagus nerves are identified and separated from the oesophagus. Often the posterior vagus is not clearly visible, but its identification is not essential. No upward dissection of the oesophagus or oesophageal stump is performed at this stage in order to prevent an accidental pneumothorax or, worse, bleeding from the mediastinum at the beginning of a long operation.

Fig. 29.5 Preparation of the operative field for RGTER in case of EALG

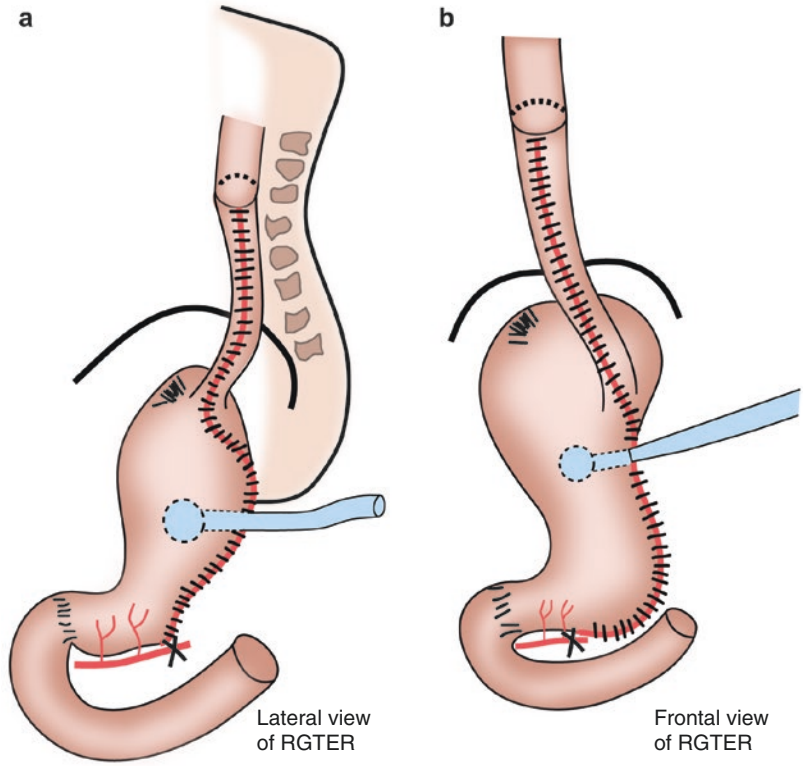

Fig. 29.6 (**a**, **b**) Configuration of the reversed gastric tube (Illustrated by M. Hassanieh)

On the greater curvature, the site from which the gastric tube will be divided is marked with a transfixion suture. The length of tube that is required is measured with a feeding tube from the middle third of the greater curvature to the mastoid process.

Usually the tube starts 2–5 cm to the left of the pylorus on the antrum. The gastro-epiploic vessels are identified but not yet divided. It is still possible to perform either an iso-peristaltic tube or an anti-peristaltic tube. The gastro colic omentum is progressively divided from right to left. The greater omentum remains attached to the colon and the gastro-epiploic arcade stays with the stomach. In his original description, Gavriliu recommended mobilization of the spleen and even splenectomy. These manoeuvres are no longer recommended.

The calibre of the gastric tube is very important and should be approximately the diameter of the native oesophagus. For modelling the tube, we suggest a chest drain tube size CH 10–14 for babies and size 18–22 for older children. The gastric tube is then separated from the greater curvature (Figs. 29.6 and 29.7). A decision must now be made whether to create an iso- or an anti-peristaltic tube and the appropriate gastro-epiploic artery is divided.

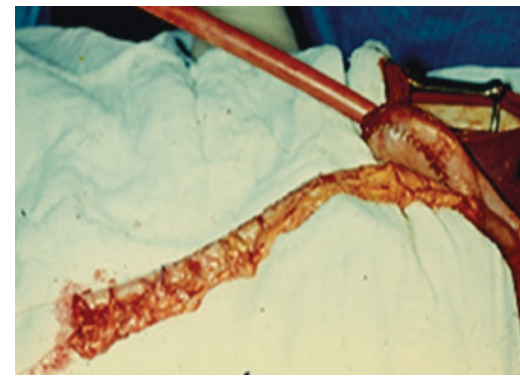

Fig. 29.7 An old-fashioned hand-sutured gastric tube

The gastric tube itself can either be created with hand suturing or using mechanical staples. A 2 cm incision is made on the antrum at the chosen

level and the chest tube inserted towards the oesophagus and held against the greater curvature. To prevent unnecessary blood loss, pairs of transfixion sutures are placed over the vessels during separation of the gastric tube, using a Vicryl® suture on a straight needle. These sutures will be removed as the gastric tube is developed (P. Orsoni [2]). The gastric tube is separated from the body of the stomach and progressively tubularized. The first 3–5 cm of the gastric tube should be wider than the rest of the tube giving a funnel shape which is preferable for cervical anastomosis. In our series, the first 97 gastric tubes were all hand-sutured. The first 3–5 cm of the tube is created with interrupted absorbable sutures in two layers (Vicryl®, PDS®, Monocryl®). The rest of the tube can be quickly made using a continuous suturing of similar material in two layers. The gastrostomy tube is re-positioned, usually through its original site. Often the gastrostomy can comfortably be accommodated in the long suture line that reconstitutes the greater curvature. In babies, we prefer the handmade gastric tube which only takes 10–15 min to complete. The gastric tube must be made watertight, and this is checked by filling it with saline under moderate pressure.

The most recent 13 gastric tubes (since 1993) have all been created using stapling devices (Ethicon® linear stapler either 55 or 75 mm). This is a fast and easy technique and even a very long gastric tube can be created in 10–15 min.

At the chosen level on the antrum, a 2 cm incision on both the anterior and posterior wall is made, the chest tube which acts as a template is inserted and the linear stapler is deployed as close to the chest tube as possible. The division is bloodless. In older children, the staple height should be 11–14 mm. Any leak due to faulty stapling could create life-threatening complications (one personal case complicated by mediastinitis). It is now usual to oversew the mechanical suture line with a continuous absorbable suture (e.g. PDS® 3/0–5/0) along both the tube itself and the reconstituted greater curve. In the most recent three cases, the use of endosurgery linear cutting devices, with three layers of staples, made the suture line very secure (Endopath®, ETS Flex 60® or Endo GIA Universal; 12 mm®) (Fig. 29.8).

The gastric tube should nonetheless still be checked with saline under moderate pressure to identify any leak. To supplement either the suturing or stapling of the tube, the wounds can be sealed with biological glue (Tisseal®) to further decrease the risk of leakage. Although not confirmed in a prospective study, we have regularly used Tisseal® to seal the gastric tube, and this technique has recently been reported as a supplement to sutures at cervical anastomosis [89].

Conventional (Iso-peristaltic) vs. Reversed (Antiperistaltic) Gastric Tube?

It has been confirmed by video-recorded contrast studies and 24 h manometry studies that there is no regular peristaltic activity in a gastric tube; the passage of food through the tube depends upon gravity. There is therefore no peristaltic reason to prefer one conduit over the other, although there are still some surgeons performing iso-peristaltic tubes in the belief that this improves propulsion. However, experience in both adults [90] and children [91] confirms the higher morbidity and mortality associated with iso-peristaltic tubes (Figs. 29.9 and 29.10), with some patients requiring a secondary gastrostomy or jejunostomy for feeding.

At the beginning of our experience with gastric tube oesophageal replacement, two patients had iso-peristaltic tubes fashioned. Both patients developed anastomotic fistulae which closed spontaneously in one child, but which required revision in the second. One of these children presented with severe dumping syndrome that persisted for many years, due to the rapid passage of food through the antrum and pylorus, bypassing the gastric reservoir. In both patients, contrast studies failed to show regular peristaltic waves, only some non-propulsive contractions.

We think that iso-peristaltic tubes should only be considered when anatomical conditions preclude the use of an antiperistaltic tube.

Compared to the reversed gastric tube:

- The iso-peristaltic tube is less well perfused at the craniad anastomotic site.
- The iso-peristaltic tube has to be made much longer.

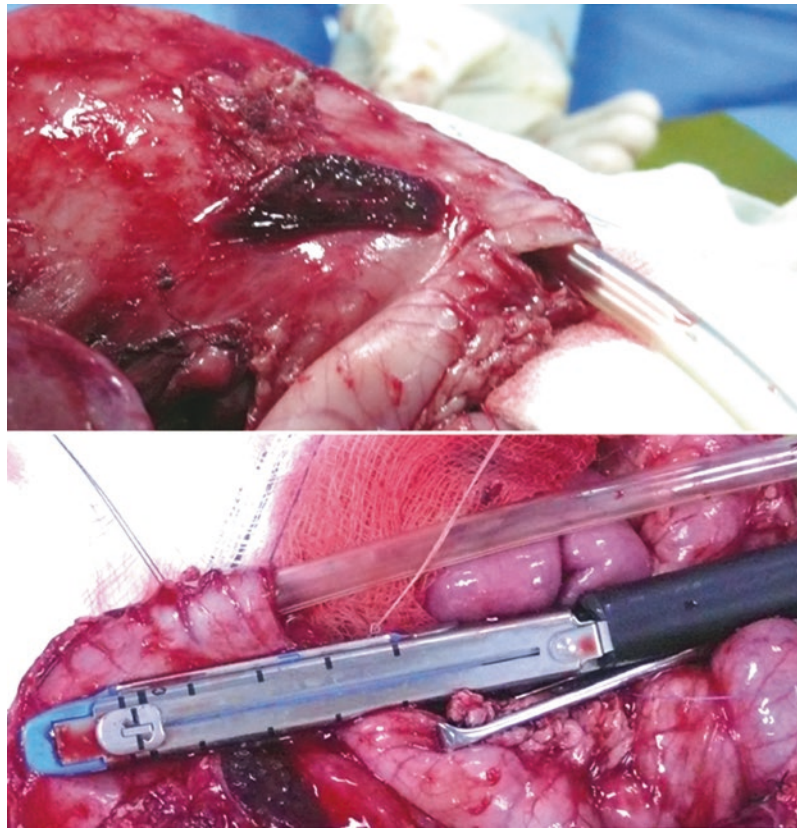

Fig. 29.8 A reversed gastric tube is separated from the great curvature with Endo GIA cutter

- When creating an iso-peristaltic tube, the stomach and duodenum must be expensively mobilized to allow the conduit to reach the neck.
- There is no evidence of propulsive peristaltic activity in any gastric tube.
- The iso-peristaltic tube could complicate dumping syndrome.

Pyloroplasty: Is It Really Necessary?

Pyloroplasty is a standard adjunct to total gastric transposition and added by many surgeons when the oesophageal substitute is brought through the posterior mediastinum. Pyloroplasty or pyloromyotomy is intended to prevent delay in gastric emptying due to the inevitable damage to the vagus nerves. The use of pyloroplasty has not been studied in a prospective fashion. In our series, no patients had a pyloroplasty nor a pyloromyotomy and no problems with gastric emptying have been observed. In our view, these procedures are unnecessary and occasionally lead to complications. Dumping syndrome as well as bile reflux into the stomach and oesophageal substitute have been recorded, and their treatment is often unsuccessful.

Route of the Gastric Tube to the Neck

There are only four possible routes for an oesophageal substitute to traverse the thorax: presternal, retrosternal, transpleural (placed within the cost vertebral angle) or posterior mediastinal, using the normal anatomical position of the oesophagus. Currently the transhiatal posterior mediastinal route is the preferred route in both adults and children (90 cases 83 % in our series), and other routes are reserved for difficult cases with abnormal anatomy [45–48].

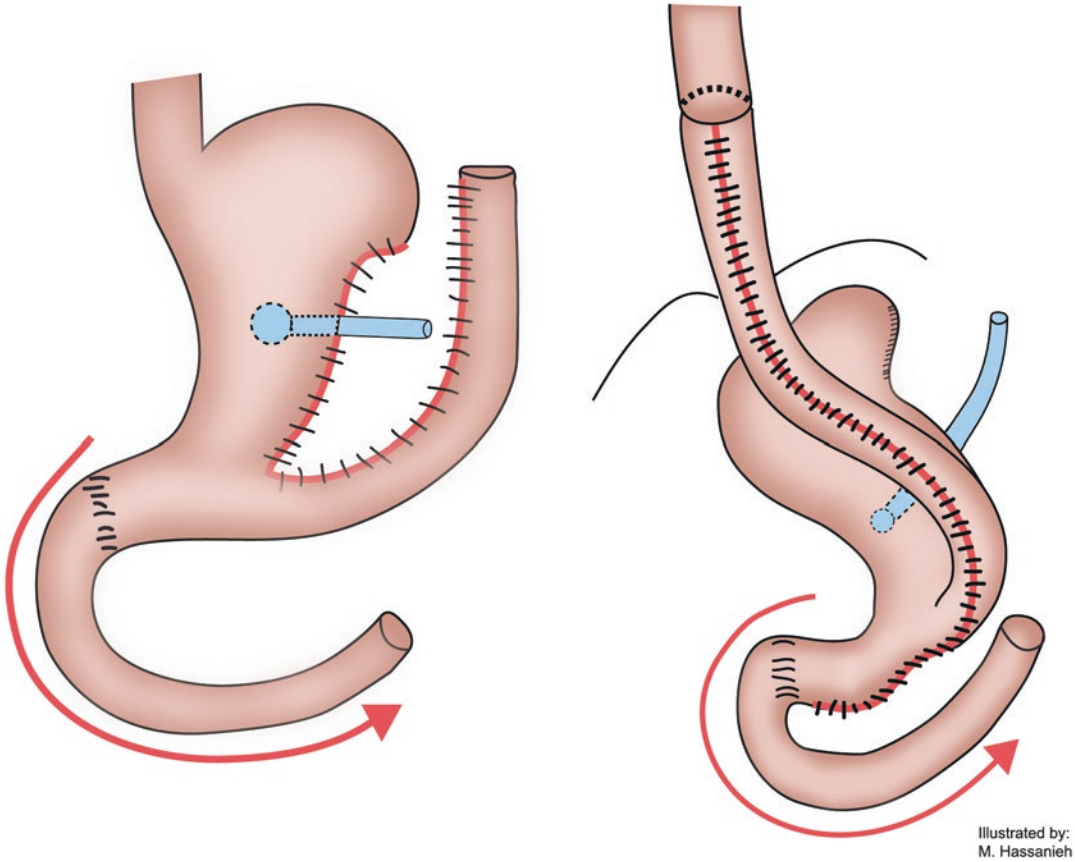

Fig. 29.9 The iso-peristaltic gastric tube (Illustrated by M. Hassanieh)

The digital dissection of the posterior mediastinal tunnel starts at the oesophageal hiatus and proceeds craniad. The dissection should stay strictly in the midline on the vertebral bodies. The cervical oesophagostomy is taken down and a retro-tracheal dissection is started within the posterior mediastinum. If the replacement is being performed for stricture, the dissection proceeds on the wall of the oesophagus.

The transhiatal and cervical dissector fingers meet in the posterior mediastinum and create a wide and comfortable space (Fig. 29.11). A lateral widening of the tunnel is recommended with care being taken not to injure the pleura and create a pneumothorax. The gastro-oesophageal junction is transected and closed with a linear stapler.

A large catheter is now passed from the neck to the oesophageal hiatus, and the gastric tube is attached to the catheter and gently pulled up under direct vision. The long suture line on the tube should be placed anteriorly to avoid twisting. About 2–0.5 cm of gastric tube should remain within the abdomen in order to minimize gastro-gastric tube reflux. Together with the gastric tube, a strong silk thread is passed through the posterior mediastinum, and this will be used to accurately position a long 6–16 mm J-vac® suction drain. This emerges through a short incision in the neck.

Indications for choosing the retrosternal route and the required technique are presented elsewhere.

Cervical Anastomosis

Before any anastomosis is attempted, the perfusion of the gastric tube should again be checked. In most cases, the robust nature of the blood supply is obvious with a pink gastric tube and bleeding

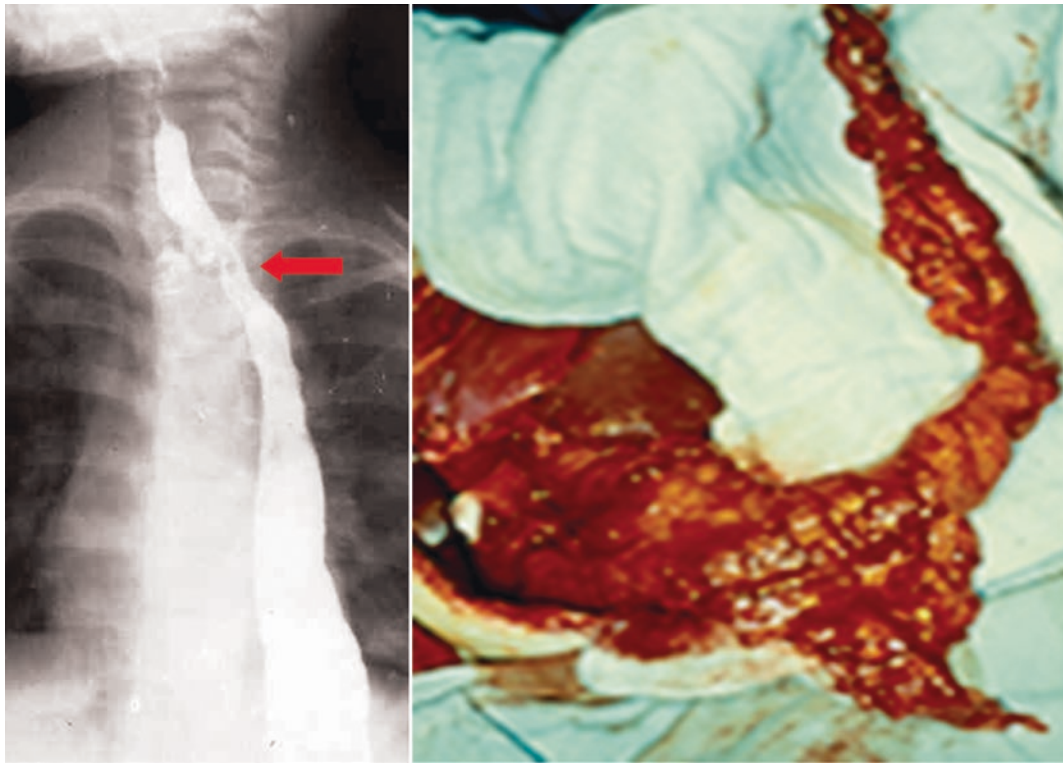

Fig. 29.10 Intraoperative view of an iso-peristaltic gastric tube

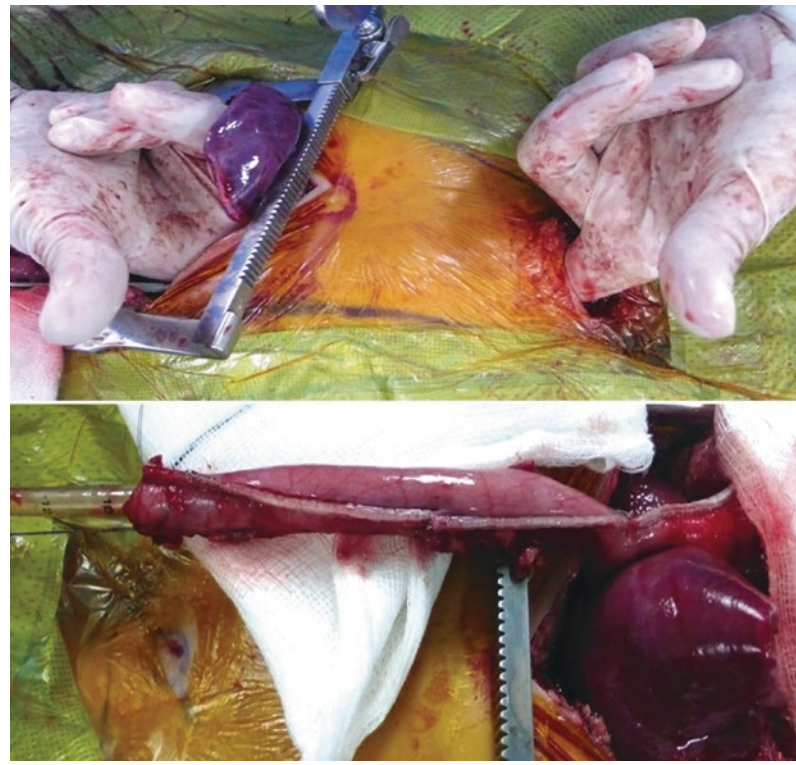

Fig. 29.11 Blunt transhiatal digital dissection of the posterior mediastinal route (*Top*). The gastric tube made with a stapling technique (*bottom*)

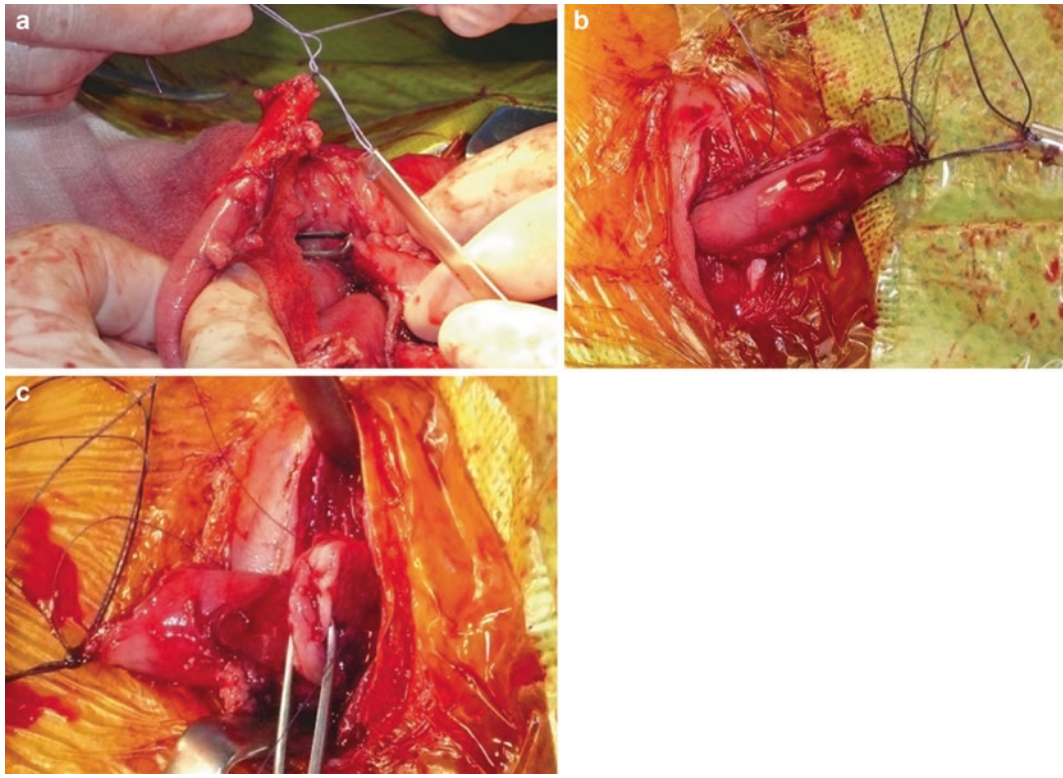

Fig. 29.12 Pull-up of the gastric tube to the neck via posterior mediastinal route and end-to-end gastric tube – oesophagus anastomosis

mucosa (Fig. 29.12). It is prudent to trim 1–2 cm of the tube to allow healthy non-traumatized tissue to be used for the anastomosis.

It is therefore important that the proximal end of the tube is closed with interrupted sutures as the use of a continuous suture would not allow this trimming. If the gastric tube is blue or has obvious ischaemia, the entire tube must be checked for a cause (kinking, compression, torsion, damage to the supplying vessels, etc.). If concern about the perfusion persists, the tube must be pulled back into the abdomen and carefully inspected. Often this restores perfusion and allows widening of the mediastinal tunnel. Rarely damage to the gastro-epiploic vessels leads to a definitely ischemic tube. Such a tube must be removed and another replacement option chosen, either at the same operation or at a later date. It is important to make the tube initially "too long" as an apparently ischemic tube becomes well perfused if trimmed by 1–4 cm.

The anastomosis is made end to end with interrupted 5/0 absorbable sutures, our preference being for PDS®. For the last 47 cases, the cervical anastomosis has been sealed with fibrin sealant (Tisseal® fibrin glue) with a rewarding decrease in cervical fistulae [89]. Recently, this same manoeuvre has been shown also to be advantageous in colo-oesophageal anastomosis [89].

Most cervical oesophagostomies are sited on the left at the anterior border of sternocleidomastoid muscle in its lower third. If the oesophagostomy has been made on the right, the gastric tube simply needs to be a little longer.

At the end of the operation, the gastrostomy is recreated either at the original or at a new site. In our first 10–20 cases, the peritoneal cavity was drained with a Penrose drain, but this is now considered totally unnecessary.

The procedure lasts from 1.5 to 3.5 h (mean 2 h 10 min). The use of mechanical stapling devices makes the procedure much shorter.

Gastric Tube Oesophageal Replacement for Long-Gap Oesophageal Atresia

The standard reversed gastric tube as described above is also used in patients with long-gap oesophageal atresia [1, 57, 58]. In recent years, oesophageal replacement has become an uncommon procedure for EALG and is most commonly needed as a secondary procedure after failure of a primary strategy such as delayed primary anastomosis [59], active elongation using Foker's technique [66–70] or Kimura's elongation of the upper pouch [71]. In our experience, 23 reversed gastric tubes were performed for EALG, but only two were done in the last 10 years: one with oesophagostomy and gastrostomy performed elsewhere and the second after failure of Foker's technique.

The operation is well tolerated in infancy and can be performed as soon as a reasonable gastric reservoir is demonstrated. When oesophageal replacement is indicated in VATER or VACTERL syndromes, a gastric tube is preferred over colonic replacement, particularly in the presence of an anorectal malformation. In complex malformations (e.g. CHARGE syndrome), many children have respiratory diseases requiring a tracheostomy, which increases the risk of a gastric tube oesophageal replacement. Consequently a long delay, often years, is recommended. In many centres, a total gastric pull-up is suggested for such patients, but our experience confirms that a reversed gastric tube oesophageal replacement is satisfactory even in these complicated situations.

The Short Gastric Tube in Long-Gap Oesophageal Atresia

In our limited experience of Foker's oesophageal lengthening procedure, there has been consistent success in the upper pouch, but it has been less effective in the lower oesophagus. In this situation, a short gastric tube with an intrathoracic anastomosis is an attractive option. This may also be an appropriate procedure after Kimura's technique has reached its maximum lengthening (Fig. 29.13).

Gastric Tube Oesophageal Replacement for Severe Oesophageal Stricture and Allied Diseases

In patients requiring oesophageal replacement for caustic injuries or acquired diseases, removal of the diseased oesophagus is mandatory. Several reports of malignancy within a retained oesophagus have been published [87]. In Gavriliu's series, three patients died due to carcinoma in the retained oesophagus. Peptic ulceration, bleeding and cystic transformation of the diseased oesophagus (oesophageal mucocele) have also been reported [92]. Oesophagectomy can be performed after successful oesophageal replacement as a separate operation through a right or left thoracotomy, or transhiatally by blunt dissection or stripping, as part of the replacement operation. This one-stage procedure has become the "gold standard" for most surgeons.

Pre-operative preparations are the same as for any gastric tube oesophageal replacement with a full bowel preparation being performed through the gastrostomy.

The operation begins with a left cervical approach to the oesophagus, identifying and protecting the left recurrent laryngeal nerve and the vagal trunk. The oesophagus is separated from the trachea. A large bore tube is passed into the oesophagus to define the level of the stricture, thus avoiding the risk of performing an anastomosis below a stricture. Three patients in our experience with total gastric transpositions performed elsewhere had the anastomosis performed below an unrecognized moderate stenosis. A soft catheter is passed around the oesophagus in the neck to facilitate manipulation during dissection.

The gastric tube is now fashioned as previously described. Transhiatal oesophagectomy is performed by combined digital dissection upwards from the abdomen and downwards from the neck. Keeping the finger very close to the oesophagus, gentle but firm digital dissection

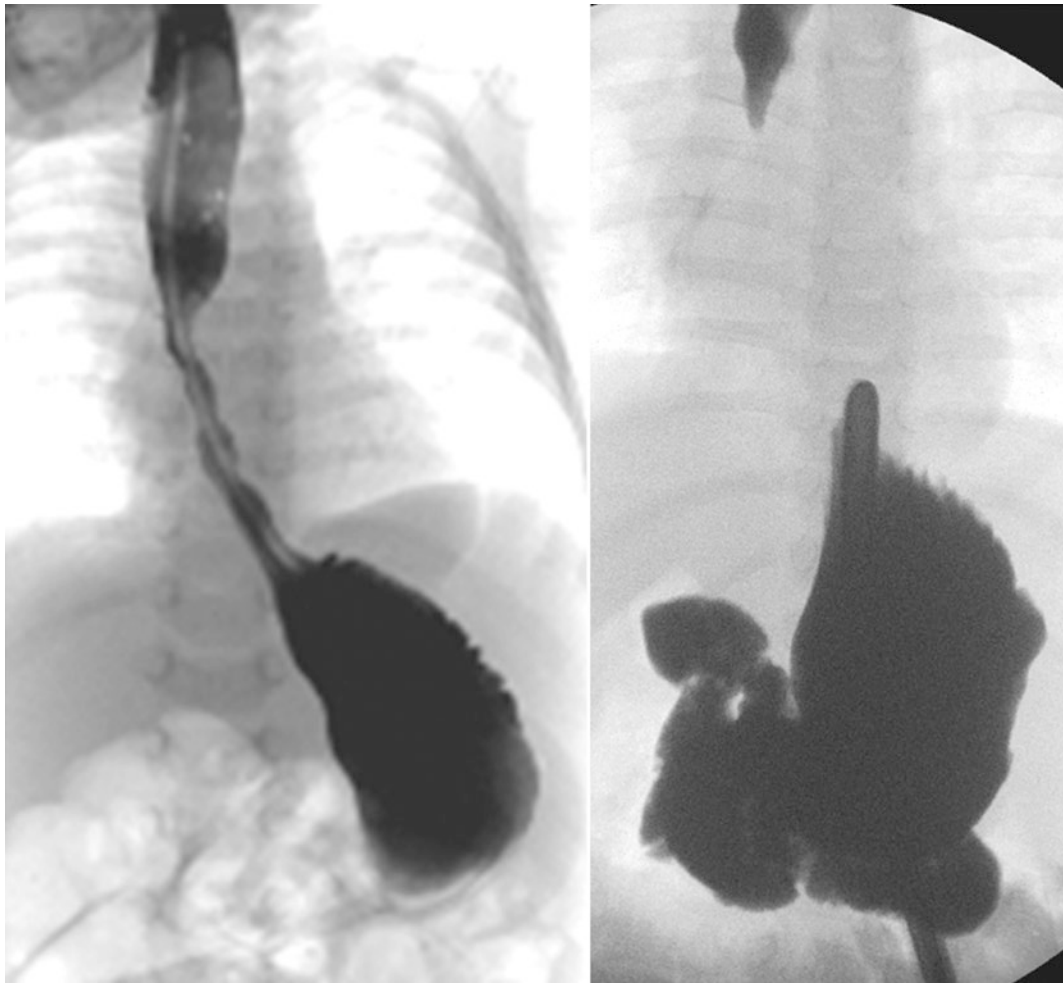

Fig. 29.13 Contrast study in a case of EALG and failure of elongation of the lower oesophageal stump. A short gastric tube with intrathoracic anastomosis is a good option

proceeds uneventfully in most cases with surprisingly little bleeding. The most common complication is a pneumothorax, which may require drainage. Injuries to the aorta, trachea, main bronchus, thoracic duct or pericardium have all been reported, probably reflecting adhesion to the primary pathology. In patients with a documented history of severe mediastinitis due to perforation (pleural effusion, empyema, mediastinal drainage for pus collections, etc.), blunt transhiatal oesophagectomy should be avoided (Fig. 29.14). Pre-operative imaging, no matter how sophisticate, cannot exclude the possibility of catastrophic complications. Two options should be considered:

1. One-stage operation with oesophagectomy performed by open thoracotomy following oesophageal replacement via the mediastinal route.
2. Retrosternal positioning of the gastric tube followed several months later by oesophagectomy. This second strategy is preferred by the authors, but several observations were made:

   (a) The gastric tube should be made longer.
   (b) In the retrosternal position, any tube makes two 90° angulations (at the manubrium sterni and at the site of passage through the diaphragm. Due to these angulations continuous suction of saliva

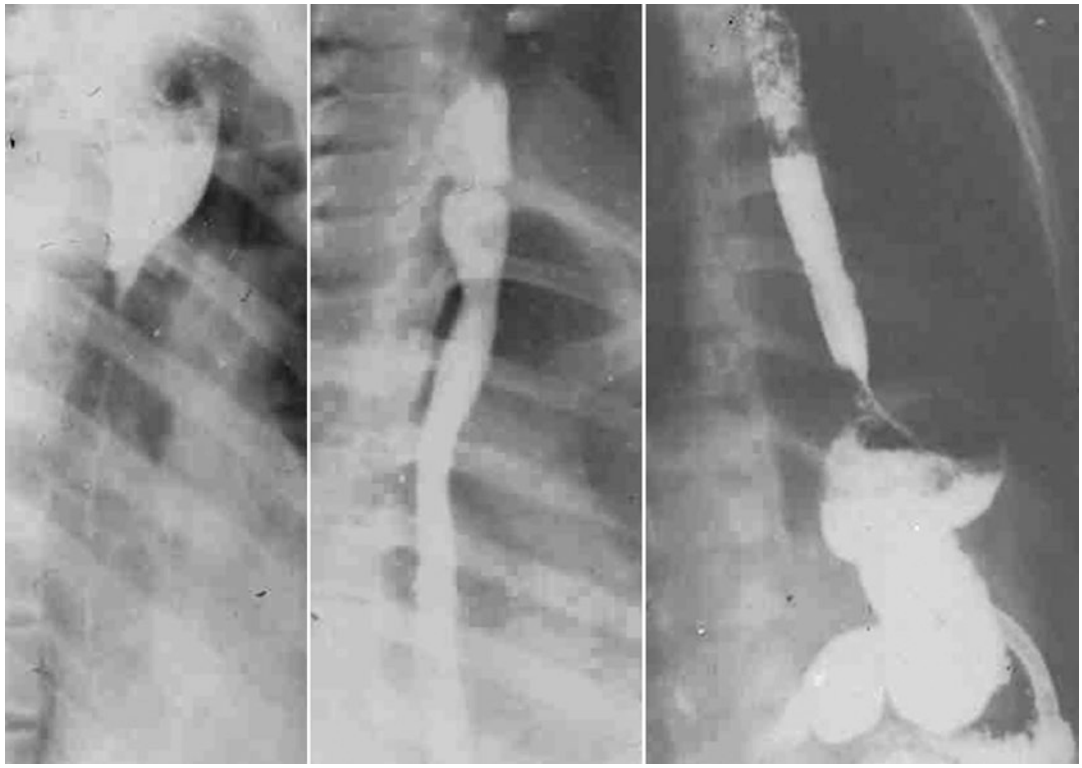

Fig. 29.14 Excellent medium-term result after RGTER for severe stricture sited within posterior mediastinal route

is required in the early post-operative period.

(c) The rate of anastomotic fistula is significantly higher.

(d) In the long term, the gastric tube is prone to progressive dilatation.

(e) Transmission of a bolus through the conduit is slower than when the conduit is in the posterior mediastinum. Often stasis of food within the conduit is noticed.

(f) Follow-up endoscopy of the tube can be difficult or even impossible.

For these reasons, the retrosternal route (Fig. 29.15) should only be used when the mediastinal option is unavailable.

In the case of major bleeding during transhiatal oesophagectomy, the surgeon should not hesitate to open the chest to gain control.

After mobilization, the oesophagus should be freely moveable up and down within the posterior mediastinum. In several teenagers, the digital dissection was not possible, and in these, as in adults, stripping the oesophagus becomes necessary. In three patients, we have removed easily the oesophagus using an ordinary vein stripper without complication.

The completed gastric tube is brought up to the neck through the bed of the oesophagus and end-to-end anastomosis performed.

The Ultra-Long Gastric Tube Including the Duodenum to Allow Concomitant Pharyngeal Reconstruction

In patients with caustic injury resulting in extensive oesophageal strictures, the pharynx may also be involved or completely destroyed [93]. On video fluoroscopy, contrast material is seen to immediately regurgitate through the nose when swallowing is attempted. All of these patients (three in our series) had concomitant laryngeal

Fig. 29.15 RGTER performed for caustic stricture complicated with mediastinitis. GT positioned retrosternally. Very good result

injury requiring a permanent tracheostomy. The most common approach to this apparent impasse is pharyngeal reconstruction using skin flaps, colon or short bowel segment augmented by a microvascular anastomosis, followed by an oesophageal replacement. The final result is usually disappointing with many repeated operations. Only a few such patients achieve reasonable oral feeding.

Reconstruction of the pharynx and oesophagus can be achieved in a single operation, a one-stage pharyngo-oesophageal reconstruction using the stomach and first part of the duodenum, with transhiatal oesophagectomy [40, 41].

Several modifications of the basic gastric tube operation are required. The operation starts in the neck with a long vertical incision identifying the pharyngeal remnant. An intra-oral finger pushing down in the pharynx facilitates identification and preparation of the later site for the anastomosis. If possible, the anastomosis will be sited on the posterior or lateral pharyngeal wall, and it should be made as wide as possible (Fig. 29.16).

The first part of the duodenum is prepared as for a gastric resection, and it is divided as far distally as possible, meticulously preserving the vascular supply. A Ch18–22 chest tube is placed within the duodenum and passed back into the stomach along the greater curvature. On the antrum, 2–3 cm from the pylorus, a 75 mm linear stapler is placed and the first gastric tube division is performed. Often a very long tube is required to reach the pharynx and the tube usually incorporates the fundus. The longest tube created in our series measured 54 cm (21.5 in.). Gastrointestinal continuity is restored by duodeno-gastric anastomosis. After transhiatal oesophagectomy, the long tube is brought to the neck via the posterior mediastinal route. Pharyngo-duodenal anastomosis is difficult. A multidisciplinary team involving experienced ENT or facio-maxillary surgeons is of great

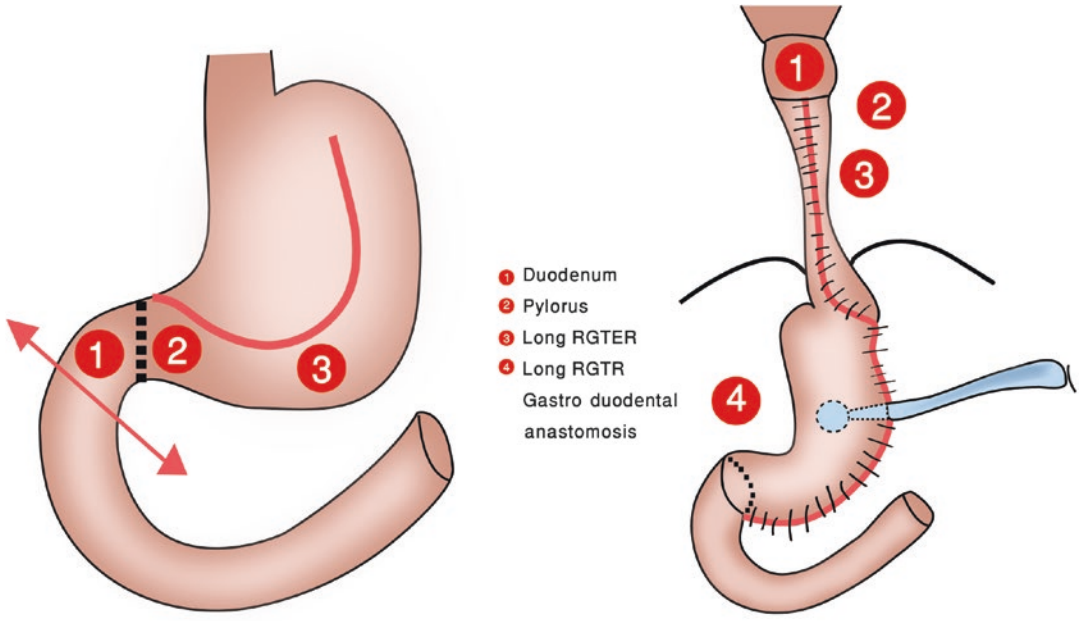

Fig. 29.16 Configuration of the duodeno-gastric tube for pharyngo-oesophageal replacement (Illustrated by M. Hassanieh)

benefit. As the patient is intubated via tracheostomy, the surgeon has free access to the mouth which can facilitate anastomosis.

Oral rehabilitation takes time and should involve a speech therapist.

In all three of our patients, the post-operative video fluoroscopy showed that the pylorus, which was in the position of a pharyngo-oesophageal sphincter, maintained its original function and opened intermittently. Perhaps in these patients an extra-mucosal pyloromyotomy might have been of value. In each of our patients, oral feeding for liquids and solids was established, but this took up to 2.5 months of intensive rehabilitation. Two patients had excellent long-term results, whilst one died in obscure conditions 2.5 years after surgery due to complications of his tracheostomy.

Laparoscopic Surgery for Oesophageal Replacement

With the recent tremendous popularity of laparoscopy in all fields of surgery, its application to oesophageal replacement is hardly surprising. Since 2007, there are four reports of laparoscopic-assisted oesophageal replacement in children with oesophageal atresia and caustic injuries. In seven patients (four EALG and three caustic strictures), the whole gastric conduit transversed the posterior mediastinum [23, 24]. Pyloroplasty was done laparoscopically, but open neck anastomosis was performed. In two patients with caustic strictures, the oesophagectomy was performed thoracoscopically in one and by open thoracotomy in the other. In two patients with oesophageal atresia, the entire procedure was performed transabdominally [26] with creation of the posterior mediastinal tunnel being performed laparoscopically in one and by thoracoscopic guidance in the second.

Esteves from Brazil [25] published his experience in five patients in whom oesophagectomy and colonic interposition was performed entirely laparoscopically. These interesting experiences should be viewed as successful case reports. There is no significant advantage in terms of early or late complications or on the early or late post-operative course of patients following the laparoscopic approach.

Although there has not yet been a report of a true reversed gastric tube oesophageal replacement being performed entirely laparoscopically, experience with the very similar bariatric sleeve procedure used to manage obesity in children suggests that it will be soon forthcoming. However, all laparoscopic techniques, though seductive and modern, should demonstrate real advantages over the open procedure before being universally adopted.

Post-operative Course and Complications of Reversed Gastric Tube Replacement

Initial Post-operative Care

The great advantage of the gastric tube is its excellent blood supply and the low risk of sepsis. In our experience of 109 patients over a 34-year period (1975–2009), 50 % of the patients had an uneventful post-operative course. Patients were admitted to the ICU for 1–3 days, but ventilatory support was for a short period only (12–24 h). Half of the patients were extubated at the end of the operation in the operating room. There was no need for post-operative parenteral nutritional support.

Generally speaking, broad-spectrum antibiotics are given for 2–4 days intravenously; however, there are no prospective studies that confirm the need or efficacy of this policy. Pharyngeal suction is frequently necessary during the early post-operative period but may be avoidable in patients with a gastric tube in the posterior mediastinum. In patients in whom the gastric tube is placed retrosternally, pharyngeal suction must be continued for 2–5 days and should be continuous.

The "J" vacuum drain is removed when nothing has drained for 24 h. This is usually after 2–5 days. Enteral feeding via gastrostomy is introduced as soon as bowel function has restored.

In patients, who have an uneventful post-operative course, the integrity of the gastric tube can be simply checked at the bedside by giving the patient a coloured cool drink to swallow. This should flow quickly and easily out through the gastrostomy tube. Some surgeons prefer to request a contrast swallow under fluoroscopy.

Oral liquids, then a soft diet are introduced progressively until normal feeding for age is reached, usually around day 14–21 postoperatively. The gastrostomy is kept for 2–3 months in case a late stricture of the upper anastomosis requires intervention.

In children with serious co-morbid conditions, oral feeding can be delayed for weeks or months despite intensive speech therapy.

After gastric tube oesophageal replacement, the risk of progressive narrowing of the cervical anastomosis mandates regular follow-up. Routine post-operative dilatations are not recommended. Follow-up by clinical examination, video-recorded contrast swallow and endoscopy should be carried out monthly for the first 6 months to identify early stricture formation that may require dilatation. In our experience, 40 % of the patients had between one and six post-operative dilatations of the cervical anastomosis. Dilatations should preferably be performed with balloon dilators or over a guide wire. Long-term follow-up is essential for all patients having oesophageal replacement and this is the main topic of the second chapter on oesophageal replacement.

Early Post-operative Complications

Cervical Anastomotic Stricture

Fistulation at the oesophago-gastric anastomosis is the most common complication of gastric tube oesophageal replacement (Fig. 29.17). The frequency in large series (both gastric tube and colonic interposition) ranges from as high as 66 % [43] to 13 % in our experience with a mean of 50 %.

Anastomotic leaks vary in severity from minor leaks that close spontaneously within 10–14 days without stenosis to complete anastomotic disruption due to ischaemia at the cervical end of the gastric tube. Fistulae are more common after retrosternally sited tubes than posterior mediastinal tubes. In our experience, fistulae arose in 7 of 19 retrosternal tubes (37 %) and in 8 of 90 (7 %) posterior mediastinal tubes. There

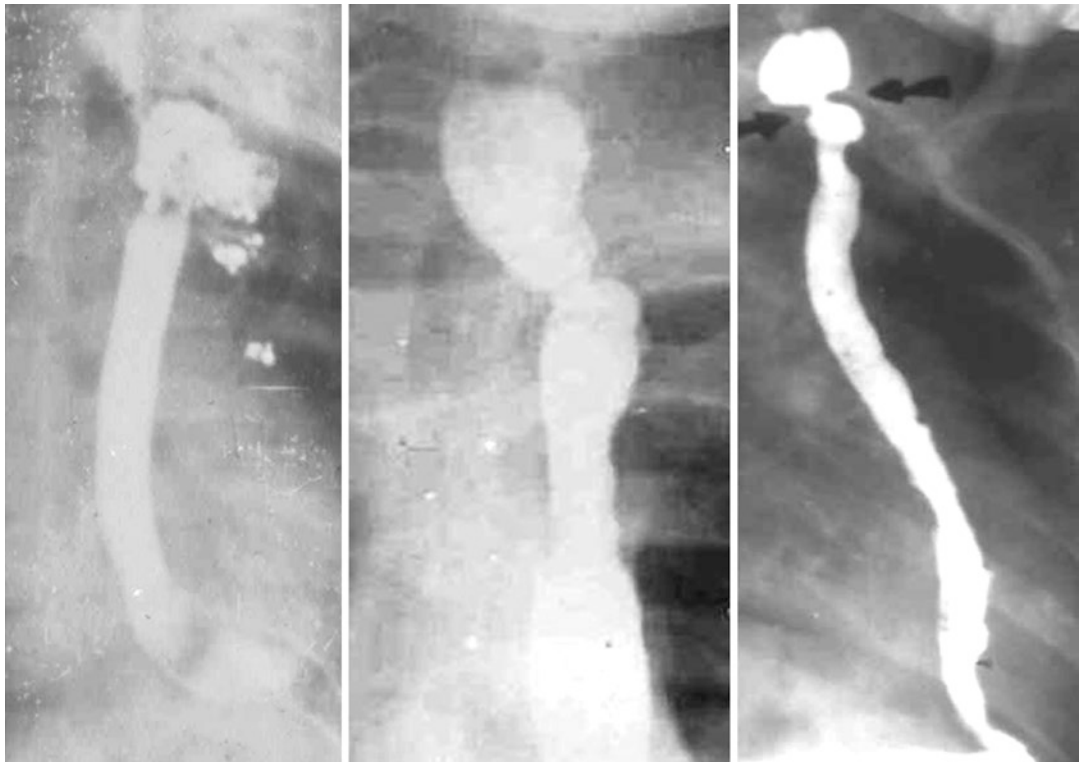

Fig. 29.17 X-ray of common complications of cervical anastomosis: fistula, mild or severe stenosis

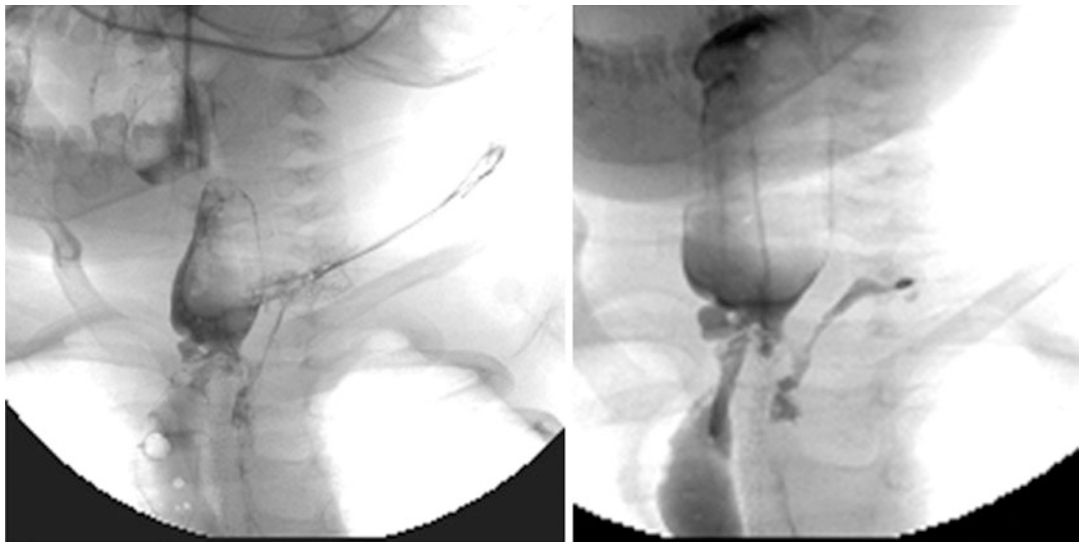

Fig. 29.18 Fistula of cervical anastomosis on post-operative day 6 with spontaneous closure in 14 days

is no clear explanation for the difference, but perhaps the shorter tube and fewer angulations of the mediastinal route represent contributing factors. Following a fistula, a stenosis must be expected, and these patients should be followed closely with regular contrast studies and have early dilatation if necessary (Figs. 29.18, 29.19, and 29.20).

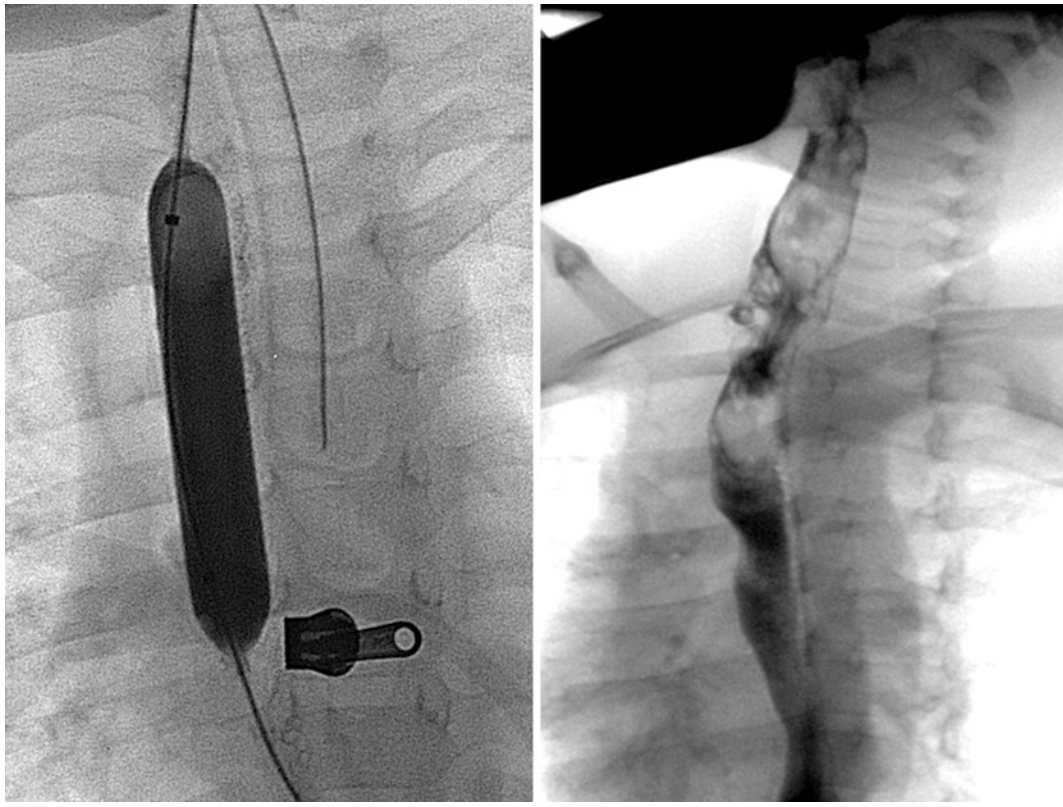

Fig. 29.19 Same case as Fig. 29.18. with balloon dilatation of the stricture day 28 postoperatively

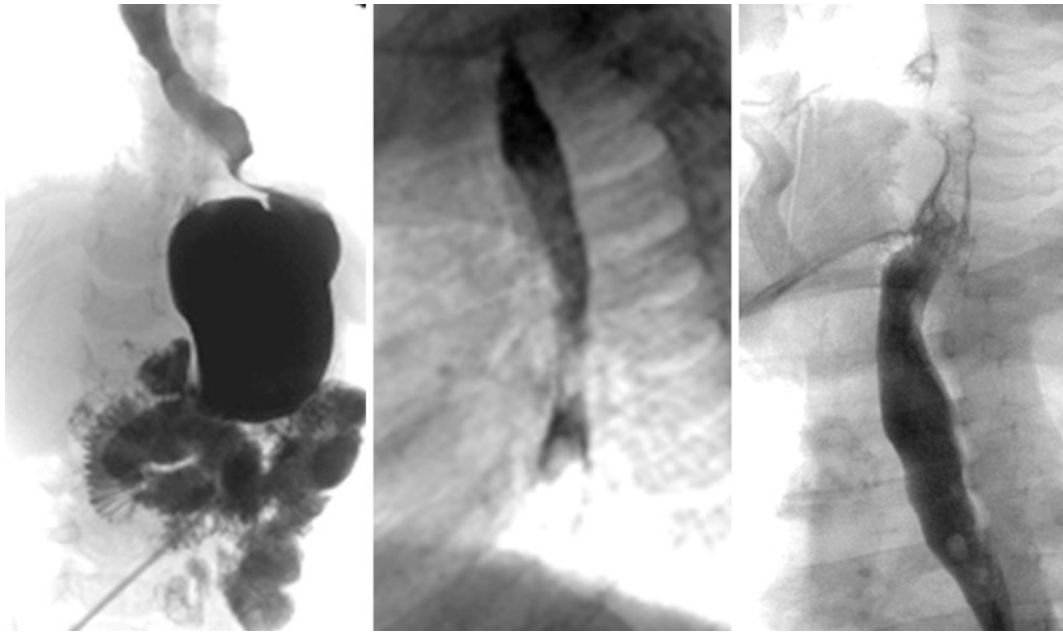

Fig. 29.20 Same case: very good result 6 months later; normal oral feeding, good volume of the gastric reservoir

A well-perfused gastric tube created with surgical precision and the placement of the tube in the posterior mediastinal position have allowed us to reduce our incidence of these complications from 37 to 6 % with a mean of 13 % in our 109 patients.

Post-operative Mediastinitis

This is a serious challenge in the early post-operative period and the viability of the graft should be confirmed without delay. Whilst imaging may be helpful, surgical re-exploration is the safest way to confirm gastric tube viability.

Mediastinitis is heralded by the sudden onset of clinical sepsis, often presenting with septic shock, and the chest X-ray may demonstrate a pneumo-mediastinum with or without a pleural effusion. Despite early drainage, aggressive antibiotic therapy and full supportive measures mortality are frequent. The most frequent underlying cause is a leak from the long suture line, and when this is performed with a stapler without oversewing, the risk is high. Newer stapling devices closing the tube with three layers of staples may further minimize this complication. No intraperitoneal sepsis occurred in our patients.

Necrosis of the Gastric Tube

This is a rare but potentially life-threatening complication. The cause is always vascular and most frequently results from the stubborn decision of the surgeon to persist with a tube that is blue and with poor bleeding when it is brought to the neck. The only treatment is emergency removal of the necrotic graft. All attempts to salvage a compromised gastric tube will end in failure.

When the gastric tube is in the mediastinal position, severe mediastinitis accompanies graft necrosis and may result, as in one of our patients, in death.

Removal of an ischemic tube will need to be followed by a new substitute (colon or jejunum) placed retrosternally after a delay of several months. The problems of failed oesophageal replacement have been the subject of several papers [30, 49].

Conclusion

Our experience after 34 years of oesophageal replacement (1975–2009) includes 109 gastric tubes (the first 19 retrosternal and the remainder sited in the posterior mediastinum), in addition to 37 colonic interpositions using the transverse colon in 35 and the left colon in two. Colonic interpositions were placed retrosternally in 29 patients and transmediastinal in 8.

The advantages of a reversed gastric tube oesophageal replacement as a one-stage procedure without thoracotomy and with placement of the tube in the posterior mediastinum can be summarized as such:

1. The gastric tube has an excellent blood supply.
2. Due to acid secretion, there is a low risk of sepsis.
3. The operative procedure is straightforward when performed by an experienced surgeon and made safer and quicker by the use of stapling devices.
4. The gastric reservoir as well as gastric and pyloric function is fully preserved.
5. Performed by an experienced team, the operation has a low morbidity and mortality.

However critics would present the following arguments:

6. After gastric tube creation, the stomach is of small capacity.
7. Gastric tube creation could induce megaloblastic anemia resistant to treatment.
8. There have been reports of Barrett's oesophagus occurring within the cervical oesophagus with a potential for malignant transformation.
9. Some patients could develop post-vagotomy syndromes such as dumping.

These hypothetical disadvantages were not encountered in our experience. Dumping is particularly common after iso-peristaltic gastric tubes, and these are not recommended for this reason. The major problems with reversed gastric tube oesophageal replacement relate to the cervical anastomosis, but with meticulous technique, strict follow-up and early dilatation when necessary these problems can be controlled.

Oesophageal replacement in childhood remains a major operation, which requires expertise, experience, modern technology and a multidisciplinary team working at a specialized centre. Although the total gastric transposition appears a safe procedure and is popular in many countries, it cannot be recommended universally as it inevitably causes complete or partial loss of the gastric reservoir and normal gastric function [94]. From the author's perspective, gastric tube oesophageal replacement and colonic interposition remain the two recommended procedures for children as both preserve gastric reservoir and functions that are essential to normal growth and development [95].

Colon (Including Ileum) Interposition

30

Mohammed Abdel-Lalif Ayad,
Khaled Mohamed El-Asmer,
and Alaa Fayez Hamza

Introduction

It is a fact that the native esophagus is the best; there is no better substitute for the native esophagus; no ideal graft. In pediatric surgery efforts are not saved to preserve the native esophagus, but reconstruction is considered in cases of failure. Cases that have irreversibly lost their ability to normal oral feeding due to certain esophageal disorders either congenital or acquired are indicated for esophageal replacement. Arguments are still present about the organ used (whole stomach, gastric tube, small bowel, or colon), the route passed from the abdomen to the neck (subcutaneous, retrosternal, transthoracic, or posterior mediastinal), the surgical technique, and the urge to remove the native diseased esophagus. The colon is the most commonly used organ, and experienced centers consider the colon as a good substitute in caustic strictures.

Arul and Parikh [1] defined the requirements for the ideal esophageal substitute. Ideally, esophageal conduit allows normal feeding and functions normally throughout the whole life of the individual. Preferably, the chosen graft permits replacement of the entire esophagus whenever indicated. At the same time, it does not cause respiratory compromise, does not become tortuous or redundant, nor has increased risk of malignancy. Gastroesophageal reflux in the conduit should be minimal. The procedure should be technically adaptable for small children, and replacement results should be reproducible by different surgeons.

Over the last 40 years, more than 1,000 cases of esophageal replacements were done in the Pediatric Surgery Department, Ain Shams University. The technique has been evolved from gastric pull-up to colon replacement, initially subcutaneously and then retrosternally. We used the left colon in all cases since 1972. In the last 22 years, we started transhiatal esophagectomy with posterior mediastinal colon interposition.

History of Esophageal Replacement

The importance of the esophagus is invaluable to everyday life and health. Swallowing food is a process that is fundamental to life. Dysphagia interferes with the basic body needs of nutrition and hence requires to be remedied at the earliest [2]. The sentence "He who cannot take part in the friendly meal is half cut off from the society of man," which is quoted by Myers [3] from Thomson [4] who, in 1878, wrote an article entitled "Notes on gastrostomy in stricture of the esophagus with report of a successful case by Professor F. Trendelenburg of Rostock," was used by Myers as the theme of his article which

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_30

was based on the 25th Herbert Michael Moran [5] Lecture in Medical History.

The greater part of the history of esophageal replacement relates to the management of carcinoma of the esophagus. The first attempt for esophageal reconstruction was done by Bircher [6] in 1894, when he used a skin tube. Since then, many methods for esophageal replacement have been developed.

Esophageal replacement in children was not employed until the second half of the twentieth century when it was introduced for the treatment of various types of esophageal atresia, particularly those with long gap between the two ends [7]. Before that, patients in whom esophageal continuity could not be restored were treated with cervical esophagostomy (spit fistula) and gastrostomy. Later on, connection was accomplished by a rubber tube passing from the cervical esophagostomy to the gastrostomy stoma [8]. The next step was the formation of a skin tube down the anterior chest wall, which was unsatisfactory for a variety of reasons including esthetics and development of malignancy [9].

Historically and till now, colon replacement continues to be the most preferred widely used procedure for esophageal replacement in children. In 1921, Lundblad [10] reported the first successful colonic bypass in a child 3 years old suffering from caustic esophageal stricture. The patient lived and swallowed normally until his death in a car accident when he was 37 years old. In 1948, Sandblom [11] was the first to use the colon for replacement in esophageal atresia.

In 1951, Rudler and Monod-Broca [12] described the retrosternal ileocolonic graft. In the 1950s, colon replacement became more popular with the availability of antibiotics and better anesthetics. Dale and Sherman [13], in 1955, described two infants with esophageal atresia who had reconstruction of the esophagus at 2 years of age using a right colonic retrogastric anterior mediastinal interposition. Four years later, Battersby and Moore [14] reported five cases of right colon replacement for congenital atresia of the esophagus. They recommended delaying the procedure until the infant was at least 9 months of age. Sherman and Waterston [15] achieved major advances in colonic replacement in 1957. Waterston and coworkers [15, 16] and Belsey [17] used isoperistaltic transverse colon based on the left colic artery via the left transpleural route.

In 1967, Othersen and Clatworthy [18] stated that the colon was the best organ for esophageal replacement in children and recommended delaying the operation until the age of 18–24 months old so that gravity in the erect position would assist in food passage through the transposed colon. In 1981, Rodgers [19] was the first to publish transhiatal esophagectomy in children, and he replaced the esophagus with right colon retrosternally. Freeman and Cass [20], in 1982, preferred placing the colon in the route of the native esophagus in the posterior mediastinum and reported an impressively low rate of complications.

Evaluation and Indications

There are two main indications for esophageal replacement: long-gap esophageal atresia and undilatable caustic esophageal strictures or that is resistant to frequent dilatation sessions. Recently, the needs for esophageal replacement in pediatric surgical practice have been decreased. This decrease owes to the improvements that have occurred in the management of esophageal atresia leading to only minority of cases where esophageal continuity cannot be restored and the recent advances in nonsurgical management of caustic esophageal strictures, e.g., topical mitomycin C application that has improved the results of endoscopic dilatation. Failed esophageal surgery (e.g., congenital stricture) represents another indication for esophageal replacement. Other rare indications include tumors, epidermolysis bullosa, and extensive intractable reflux strictures.

Children younger than 5 years old represent the most vulnerable group for accidental caustic ingestion with incidence peaks at around the age of 2 years when children develop skills of localization but are poor discriminators between the harmless and harmful substances [21].

Corrosive injury usually causes dense cicatrization of the esophageal wall that results in rigid strictures that are difficult to dilate [22]. The degree and the extent of a corrosive lesion depend on the characteristics of the caustic agents (concentration and pH), the amount ingested, and duration of contact of the corrosive agent with the esophageal wall [23, 24]. Most caustic esophageal burns are caused by alkalis. Alkalis ingestion causes liquefactive necrosis with deeper penetration, while acidic substances tend to cause a coagulative necrosis of the mucosa, and the resultant eschar formation tends to limit penetration and the subsequent injury to esophagus [21].

The management of some patients with caustic esophageal stricture is challenging and time consuming. This mostly related to the extent and the depth of fibrotic reaction. Stricture recurrence after initial dilatation is frequent, especially in patients who have severe, long, and tight strictures at presentation that eventually necessitate substitution [25]. A period of 8–12 months of regular dilatation is enough to determine the need for surgery in most cases. Other indications for replacement in caustic patients include multiple extensive strictures, marked irregularity or pocketing of the esophagus, and the presence of tracheoesophageal fistula [26].

Replacement in cases of esophageal atresia is indicated in patients with wide gap esophageal atresia (more than three to four vertebrae) with or without fistula, birth weight less than 1,500 g, prematurity and respiratory distress hindering thoracotomy, major cardiac anomalies, and late presenting cases (after 5–7 days) suffering from sepsis and major chest problems (e.g., pneumonia), patients with major leakage after repair, those with disruption of the anastomosis and recurrence of fistula, or those with severe anastomotic stricture unresponsive to endoscopic dilatation.

Although the choice of a proper conduit for esophageal replacement is controversial and reflects the surgeon's preferences and experience, esophageal replacement with or without esophagectomy is a major surgical demand. Each known procedure has its own advantages and disadvantages [27]. Essentially, the substitution needs to function as an efficient conduit to satisfy the nutritional needs and should continue to grow with the child. Our center shares the view of many investigators [28–32], that an isoperistaltic left colon segment based on the left colic vessels is the preferred graft for esophageal substitution. We used to pass the graft from the abdomen to the neck within a retrosternal tunnel or through the posterior mediastinum.

Patients with caustic injury who are able to swallow and those with acceptable weight gain are prepared for surgery without a feeding gastrostomy. Otherwise, a Stamm gastrostomy is an essential preparatory step to improve weight gain which is an important factor contributing to postoperative healing and decrease incidence of leakage and dehiscence.

Patients with esophagostomy (spit fistula) in cases of long gap or failed esophageal atresia repair are encouraged to swallow (sham feeding); otherwise, feeding difficulties are encountered after colon replacement. Reconstruction in those patients is usually planned at age of 6–9 months after gaining acceptable weight.

Operative Technique

Preoperative Management

The site of the stricture is very important to have an idea about the location of the proximal anastomosis and the presence of healthy mucosa proximal to the site of the stricture should be confirmed. If the barium swallow is not conclusive, then on table, upper endoscopy can locate exactly the site of proximal stricture and the healthy mucosa proximal to it, where the coloesophageal anastomosis will be constructed.

Patients are admitted 2 days before surgery for routine laboratory and radiologic evaluation (only chest x-ray usually). Patients who can swallow are given clear fluids 48 h preoperatively and to be NPO over the night of surgery, when full maintenance intravenous fluids are started. Colonic washouts (enemas) with 20 ml/kg body weight are done every 8 h 48 h before surgery, to be increased every 6 h the day before surgery.

Those with a gastrostomy tube have Ringer's solution infusion through the tube with 10 ml/kg body weight over 15–20 min. This is repeated for another three times every 2 h in the night before surgery. All patients are given intestinal oral antiseptics 3 days before surgery (metronidazole and colimycin). The day of surgery, intravenous cephalosporin and metronidazole are given 2 h before operation.

Operative Technique "Isoperitaltic Left Colonic Graft"

Position and Sterilization The patient is put in the supine position with a pillow below his shoulders, and the head is tilted to the right side (Fig. 30.1). Preparation by povidone-iodine (in cases with no allergy to iodine) should include the whole body and the neck; drapes should expose the operative field, and both chest fields in case of emergency thoracotomy are needed. The anesthetist should put a rigid tube through the nose in the esophagus till it stops which is the location of proximal stricture. This helps during dissection of the esophagus especially in severely injured patients. Surgeons could be divided into two teams to decrease operative time (neck team and abdomen team).

The Neck After positioning the tube in the esophagus, left transverse supraclavicular incision is made (Fig. 30.2), which can be extended upward in a hockey stick manner over the anterior border of the sternomastoid. Division of the strap muscles makes dissection easier. Isolation of the esophagus is done after identification of the recurrent laryngeal nerve. Dissection of the esophagus (Fig. 30.3) should be done carefully to avoid injury of the blood supply. Distal dissection around the esophagus is usually done bluntly

Fig. 30.1 Position of the patient

Fig. 30.2 Abdominal and neck incisions

Fig. 30.3 Neck dissection of the upper esophagus

through the posterior mediastinum. Proximal dissection should extend up until normal pliable esophagus with healthy looking is reached. In cases of pharyngeal strictures, higher dissection is needed and the incision should be extended to the angle of the mandible. Cutting through the pharyngeal muscles is done, and stay sutures are taken on the wall of the pharynx before incising it with the help of an intraoral instrument or a finger of the assistant. Anastomosis is usually done at the level of the pyriform sinus. When the neck is ready, then both teams are joined together to pull the colon through:

- Note: incoordination and swallowing problems are present in all patients suffering pharyngeal strictures; however, most of them show variable degrees of gradual improvement. The sensory and motor functions of the pharyngeal tube are affected due to the direct corrosive damage of the pharyngeal wall mucosa and muscles. Incoordination and swallowing problems vary according to the severity of injury and the age of the child. Younger children may suffer more as their pharyngeal tube is narrow with low total surface area. The corrosive pharyngeal injuries may also affect severely the larynx up to suffocation, necessitating tracheostomy. In addition, loss of sensation in the hypopharynx and supraglottic larynx plays a major role in the development of aspiration observed in those patients.

Dissection of the Colon The abdomen is entered through a midline incision (Fig. 30.2), and usually some adhesions are encountered in cases of previous gastrostomy, but this is much avoided with the use of laparoscopic gastrostomy. Mobilization of the colon is done, with careful dissection and avoiding any hematoma or injury to the vessels. The graft is chosen on the territory supplied by the ascending left colic artery (Fig. 30.4), and the graft length is measured from the site of the healthy part of the esophagus to the site of anastomosis on the stomach. We usually ligate the middle colic artery to have a good length, but if there are any vascular anomalies, the right or even the middle colic artery is utilized. After choosing the colonic graft, bulldogs clamp the blood supply, and the colon is left inside the abdomen to verify adequate circulation (Fig. 30.5). The colon is reevaluated and resected at the proximal end (right side) of the colon only after verification of its vascularity and length. The graft is washed with diluted povidone-iodine solution with an intestinal clamp on the distal part to wash only the desired segment, and then it is passed behind the stomach through the gastrohepatic ligament in an isoperistaltic manner. To facilitate passage through the chest, a silk suture is applied to the proximal end of the colon and pulled through the cervical

incision until the colon is in place, either in the tunnel retrosternally or in the posterior mediastinum. To avoid redundancy, the proximal anastomosis is done first before resecting the distal part of the colon.

Retrosternal Colon Bypass Dividing the endothoracic fascia very close to the sternum makes a wide retrosternal tunnel (Fig. 30.6); blunt dissection is done carefully to avoid pleural injury. Suprasternal dissection is important, and the tunnel should be widened with the fingers from above and below to avoid colonic obstruction especially at the suprasternal notch. A long clamp is passed from the lower edge to the suprasternal notch and a catheter is grasped by the clamp, then it is pulled through the tunnel, the silk stitch of the proximal part of the colon is sutured to the catheter, and the colon is pulled through the tunnel with no rotation. In order to avoid redundancy, we measure accurately the colon and resect exactly the length needed before anastomosing the distal end in a simple two-layer anastomosis. Cologastric anastomosis is done to the anterior wall of the stomach with U-shaped stitches (similar to Belsey Mark procedure). As the colonic graft lies close to the inferior border of the liver, it could be kinked by it especially in the standing position; therefore, the inferior border of the liver is fixed to the diaphragm and/or to the anterior abdominal wall.

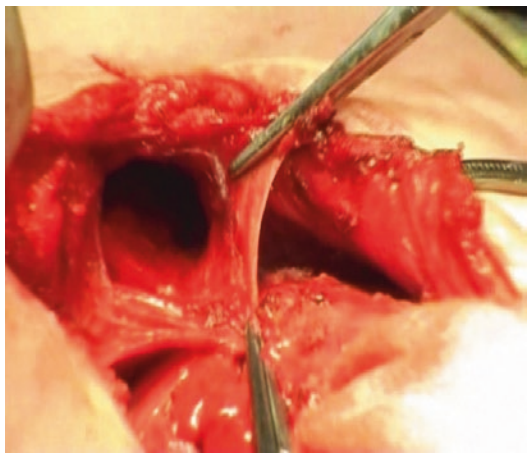

Fig. 30.6 Wide retrosternal tunnel

Transhiatal Esophagectomy In posterior mediastinal colonic replacement, the esophagectomy is done by cutting the left triangular ligament of the liver followed by dissection of the esophagus after encircling it with a tape. After freeing the esophagus from all its attachments, the esophageal hiatus is explored by dissection with the help of retractors inside the hiatus. With direct vision, all esophageal vessels are secured by diathermy (Fig. 30.7a, b), so there should not be fear of blood loss or damaging vital structures around the thoracic esophagus. Direct vision is ensured by retractors inside the hiatus and applying alternate traction on the esophagus. Running dissection strictly close to the esophageal wall is another safety factor during removal of a severely injured esophagus with dense periesophagitis.

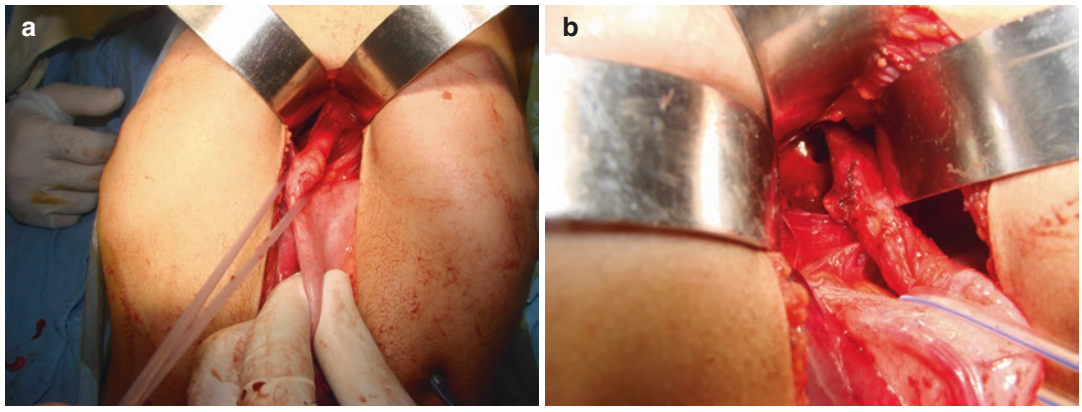

Fig. 30.7 (**a**, **b**) Transhiatal esophagectomy

With blunt and sharp dissection, the esophagus is freed as high as possible, often higher than the pulmonary ligaments. Care is taken to avoid entering the pleura, or an intercostal tube drain has to be inserted. Blunt finger dissection of the esophagus is carried on from above and below until the dissection is complete (fingers of both hands touch each other) (Fig. 30.8). The esophagectomy then is done by cutting the esophagus at the cardia; the esophagus then is pulled from neck incision after suturing a long silk stitch to the esophageal end. The silk is sutured to the proximal end of the colon and pulled through the posterior mediastinum and out of the cervical incision:

- Note: transhiatal route is direct and is the shortest route an esophageal substitute can traverse between the neck and abdomen. It permits removal of the scarred esophagus (Fig. 30.9), which has a definite increased risk of malignant changes, cyst formation, and empyema if left in place.

A single layer end-to-end esophagocolic anastomosis is done by the cervical team; in some cases, end to side is done if there is discrepancy between colonic and esophageal ends. In fixation of the colon to the neck muscles, the incision is closed after a drain is placed.

The colon is now accurately measured, and distal resection is done exactly with no extra length. Great care should be taken at this step not to affect the continuity of the distal marginal arcade. Gastrocolic anastomosis is performed at the cardia with an antireflux wrap of the stomach 270° (Fig. 30.10a, b) to avoid compression of the blood supply. Pyloroplasty is done in most of the cases, and the colon is fixed to the edge of the hiatus:

- Note: vagotomy done in association with esophagectomy helps reduction of symptomatic gastrocolic reflux and peptic ulceration of the colonic graft as it reduces gastric acidity and eliminates reflux symptoms. The accompanying pyloroplasty aggravates this effect as it promotes gastric emptying.

Stamm gastrostomy is fashioned for patients who underwent replacement without a preinserted gastrostomy tube. The colonic continuity is restored, mediastinal drain is inserted, and the abdomen is closed. On table fluoroscopy is done for exclusion of iatrogenic pneumothorax. If pleural injury is found, a chest tube is inserted immediately.

Postoperative Management

Patients usually stay in the intensive care unit for 2–4 days because occasionally, postoperative ventilation is needed. The tube drains are removed after 48 h, and patients are kept on nothing per mouth status (fed by the gastrostomy on the fourth day) for 7–10 days; oral feeding is then

Fig. 30.8 Blunt finger dissection of the esophagus

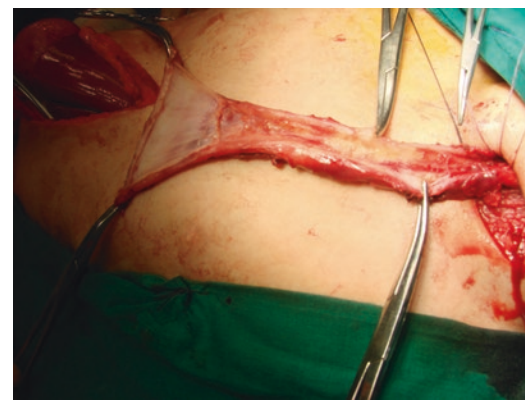

Fig. 30.9 Scarred esophagus due to caustic ingestion

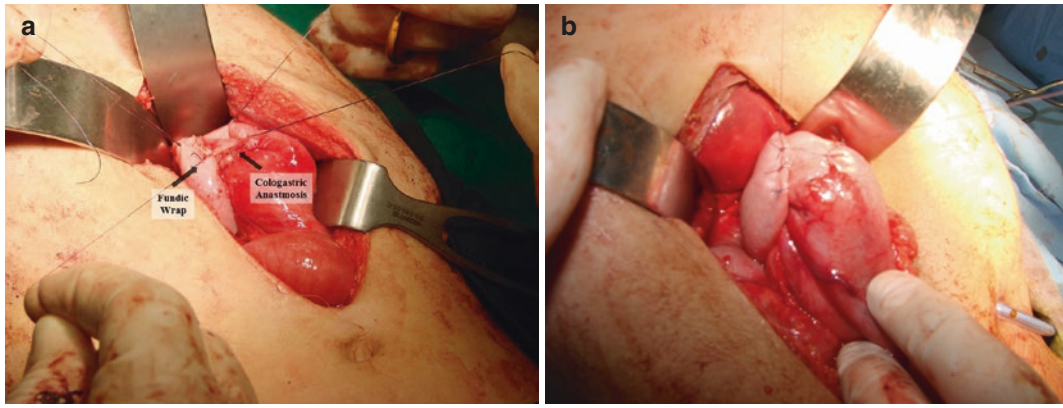

Fig. 30.10 (**a**, **b**) Antireflux 270° wrap around the cologastric anastomosis

started. A contrast study is not routinely necessary. Gastrostomy tube is usually removed after 3 months of being not used. If there is leakage from the cervical anastomosis, it usually stops spontaneously; oral feeding can be started after leakage ceases.

Most of the cases will be discharged after 10–12 days after resuming oral feeding with supplemented gastrostomy feeding till complete oral diet:

- Note: although utilizing the colon as a graft for esophageal replacement is a relative easy technique to perform, three anastomoses should be performed, namely, esophago- or pharyngocolic, gastrocolic, and colocolic.

Surgical Tips

How to avoid ischemia of the graft:

- Double blood supply; the left colic and marginal paracolic arcades vessels [33].
- Ligation of the middle colic artery during the gastrostomy procedure helps to improve the vascularity in the marginal arcades [34], provided that there are no vascular anomalies of the left colon.
- Ensure adequate venous drainage.
- Avoid tethering of the graft pedicle by the descending branch of the left colic artery and the descending colon by resecting about 5–10 cm of the colon just distal to the graft without affecting the marginal arcade by division of the small end vessels [33, 35].
- Ensure adequate width of the passage traversed by the graft to and from the thoracic cavity, especially in the retrosternal route, to avoid the potential for graft compression that may lead to ischemia.
- Avoid torsion of the graft during its passage to the neck.
- Mind tension-free, straight graft.
- 270° antireflux wrap is better for blood supply than 360° wrap.

How to avoid redundancy of the graft:

- Accurate measurement of the graft length
- Resection of the distal part (left side) of the colon after esophagocolic anastomosis and fixation of the colon to the neck muscles

How to prevent esophagocolic anastomosis leakage and strictures (should be 0% in the atresia patients):

- Very careful dissection of the esophagus.
- Tension-free anastomosis.
- In cases of scarred esophagus, esophagocolic anastomosis should be performed in an area lined by healthy esophageal mucosa.

How to avoid gastrocolic reflux:

- 270° wrap.
- Isoperistaltic colon graft.

- It is of value to mention that Jones et al. [36] and coworkers performed a study on nine adult patients underwent left colon interposition for benign esophageal strictures. The cologastric anastomosis was held in the posterior wall of the stomach at the junction of its proximal and middle third. When they experimentally stimulated the colonic graft with acid, the graft responded by reproducible colonic contraction which is comparable to the type II colonic contraction described for the colon in normal position. Also, they measured the resting supradiaphragmatic colonic pH. They proposed that interpositioned colon acts as a protective barrier between the stomach and the proximal esophagus, and any acid reflux is either buffered immediately by alkaline colonic secretions or induces colonic peristalsis with eventual return of the acid into the stomach. This proposal augments the role of isoperistaltic colon graft in preventing symptomatic gastrocolic reflux.

Advantages and Disadvantages of the Transhiatal Route

- More anatomical, straight, shortest distance to the neck, easy to do antireflux, and allows direct anastomosis to the cardia which is more anatomical and physiological.
- Permits resection of the unused nonfunctioning esophagus, which is important to eliminate the risk of Barrett's esophagus especially in cases of reflux esophagitis. Also, removal of the closed lower end scarred esophagus prevents possible complications like cyst formation, empyema, or even malignant transformation.
- The presence of the colon graft in the posterior mediastinum reduces the incidence of its progressive dilatation and hence protects both lungs from compression [31].
- Allows straight nonredundant graft with better functional results.
- On the other hand, the transhiatal route is more difficult, and its operative time is longer than retrosternal route. Also, its morbidity rate is higher especially pneumothorax.

Right Colon

In our series, we used the right colon in one occasion. It was a redo surgery after stenosis of the first left colon graft due to chronic ischemia.

Appignani et al. [30] and his colleagues used the right transverse colon, based on the middle colic artery, eight times in their series. Their indications to use the right transverse colon were redo surgery or unreliable left colic vasculature. The graft was placed in the isoperistaltic direction in all cases:

- Note: the left colon is less bulky and thinner than the right colon. Also, it has a more constant blood supply, which is rarely prone to anatomical variations. In their series, Bothereau [37] and coworkers could not perform right coloplasty after total esophagogastrectomy in 10 patients out of 81 patients (12%) due to insufficient blood supply, poor or missing right marginal artery, or venous stasis.

Results

Over the last 40 years, 965 colon interpositions for 963 patients (two redo cases) had been performed at the Pediatric Surgery Department, Ain Shams University. The indications for surgery were caustic esophageal injury in 849 patients and esophageal atresia in 116 patients. Transhiatal esophagectomy with colon interposition (Fig. 30.11) was performed in 395 patients, and retrosternal colon bypass (Fig. 30.12) was performed in 570 patients. The fact that various surgical procedures are accepted as esophageal replacements means that none of them is the ideal; all have their complications that may be in common or specific for each procedure type.

Intraoperative Complications

Pneumothorax either unilateral or bilateral occurred in 15% of patients, with higher incidence in the transhiatal approach (22%) as compared to the retrosternal route (10%). Intraoperative fluoroscopy (if available) or immediate postoperative

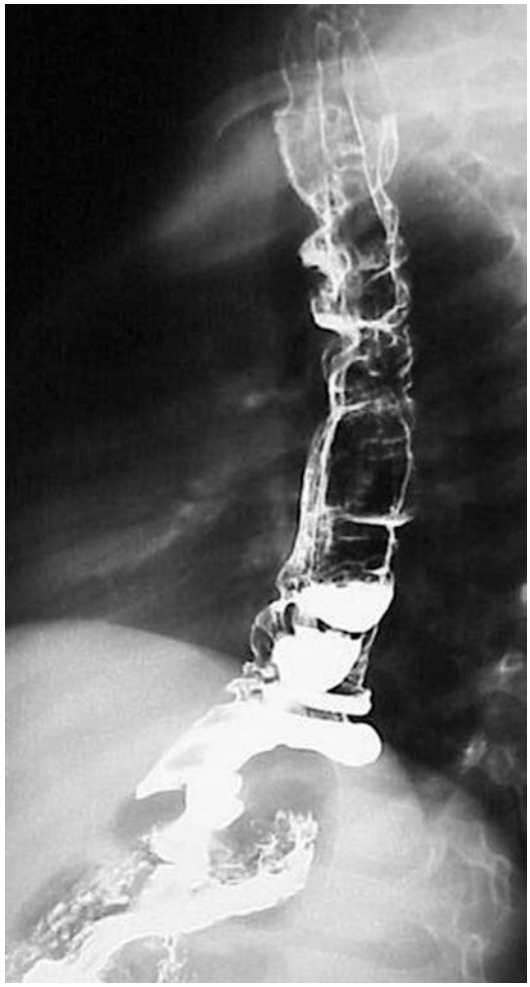

Fig. 30.11 Barium swallow and meal for a child 5 years post-transhiatal colon interposition

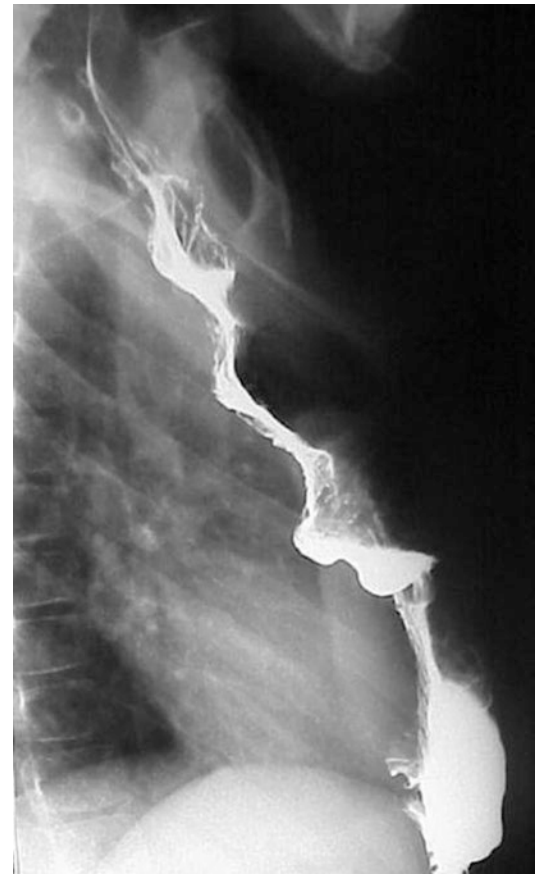

Fig. 30.12 Barium swallow and meal for a child 10 years post-retrosternal colon bypass

chest x-ray should be done in all cases. If there is a pleural tear, an intercostal tube is inserted under water seal till complete lung inflation followed by clamping the tube before its secure removal. Intraoperative tracheal injury occurred in three patients that had previous dilatation injury in our early experience. Major intrathoracic bleeding developed in another patient. All four patients underwent thoracotomy with successful control of the injury.

Postoperative Complications

The most common complication encountered postoperatively is leakage from the cervical anastomosis that occurred in 10 % of patients which is manifested as salivary fistula; all of them resolved nonoperatively within 1–3 weeks. Thereafter almost half of them developed stricture of the cervical anastomosis with varying degrees of dysphagia. These strictures were managed initially by endoscopic dilatation at 3-week intervals, and ten patients required surgical revision of the anastomosis after failure to respond to three sessions of dilatation. Leakage and stenosis of the esophagocolic anastomosis can be avoided by careful dissection of the esophagus avoiding injury to its blood supply and performing a wide anastomosis. The incidence of leakage should be extremely low when the proximal esophagus is healthy, i.e., anastomosis done in an area occupied by healthy esophageal mucosa.

Ischemic necrosis of the colonic graft has an incidence in literature between 3 and 20 % [38].

In our series, no instance of graft necrosis occurred; however, three patients had late graft stenosis (chronic ischemia), two in the distal colonic graft and one in the proximal segment. All three had redo surgery using the right colon in one case, left colon in another one, and gastric pull-up in the third.

The incidence of anastomotic leakage, stricture, and graft necrosis is greatly influenced by the blood supply of the graft. Therefore, using a double blood supply and avoiding any compression or twisting of the graft pedicle must be emphasized, and it should be noted that even minimal twisting that does not impede the arterial supply should be closely evaluated because venous thrombosis is thought to be the usual precipitating factor for graft necrosis, so that great care must be taken to avoid venous drainage impairment as well as the preservation of adequate arterial supply.

We had five patients manifest the effects of recurrent laryngeal nerve injury in the early postoperative period. One of those required tracheostomy. Postoperative bowel obstruction caused by postoperative intussusception, early adhesive intestinal obstruction, or internal herniation of the bowel occurred in 2 % in our series which were managed surgically in most of cases. There were six mortalities (0.6 %) in the early postoperative period owing to respiratory problems and sepsis.

Long-Term Complications

On long-term follow-up, graft redundancy and gastrocolic reflux are the most recognized complications. Redundancy of the interposed colonic graft is one of the late complications that leads to stasis and retention of food and liquid in the graft, causing obstructive symptoms such as dysphagia and regurgitation and increasing the risk of nocturnal aspiration; also redundancy in the chest may decrease the vital lung capacity causing restrictive pulmonary symptoms. In our series, 32 had redundancy, 25 in retrosternal group and 7 in transhiatal group; 6 of them required surgical revision with excision and reanastomosis of the redundant segment of the graft; meticulous dissection is necessary to avoid injury to the mesenteric and marginal vessels supplying the colonic graft.

In long-term follow-up by barium meal, scintigraphy, or pH study, gastrocolic reflux was detected in 22 patients: 18 in retrosternal group and 4 in transhiatal group, 18 of which were asymptomatic. All of those 22 patients were subjected to antireflux measures in the form of antacids and diet modification; only 2 patients needed antireflux procedure.

Chronic exposure of the colonic mucosa to gastric acid may induce ulceration, bleeding, and perforation. Perforation of the colon frequently can lead to empyema; in our series we have only one case of peptic ulceration in the colonic retrosternal graft that was diagnosed endoscopically and managed medically. Colonic mucosa is resistant to peptic ulceration which may be due to its mucus secretion. There are reported cases of malignancy arising in colonic interpositions after esophageal replacements for benign conditions [39–41].

Nishihara et al. indicated that the reconstructed colon had no contractions even after dry swallows [42], while other investigators reported that peristaltic contraction like that of the normally positioned colon was observed after dry or wet swallowing especially acidic swallows [43–45]. However, sufficient stimulus to start colon movement is required; graft distension after successive swallows [43]. Thus, they concluded that most of the time the colon did not show contractions. Generally in colon grafts, these peristaltic waves contribute little to the speed and efficiency of deglutition. Transit and stagnation in the graft are gravity dependent, and the occasional contractions can aid emptying [42, 43]. Manometry cannot always reflect the function of the graft; therefore, controversy still remains regarding the role of the movement in the colon graft. Dòmini [46] and his colleagues reported a case of a female patient, born with long-gap esophageal atresia. She underwent retrosternal substitution using a right transverse antiperistaltic colic segment, when she was 5 months old, but the reversely directed substitute never worked, and the baby was seriously dysphagic and failed to thrive. When she was 11 months old, she was

reoperated. The antiperistaltic colon segment was removed and replaced between the left and right colon; reconstruction was carried out with a retrosternal isoperistaltic ileocecal segment. The baby did well after that, and her problem was resolved.

Colonic grafts used for esophageal replacement seems to act as a barrier between the refluxed gastric acid and the remaining part on the native esophagus, hence protecting the remaining esophagus from developing Barrett's esophagus. The protective value of the colonic graft can be explained by the mucus secreted by the colonic mucosa, which exerts a buffering action against gastric acid. To our knowledge, there are no reported cases of Barrett's esophagus proximal to the esophagocolic anastomosis in cases that underwent esophageal replacement by colon.

Ileal and Ileocolic Grafts as Esophageal Substitutes

In 1991, Mao-Tang Han [47] reported a series of 12 cases that underwent ileocolic replacement of the esophagus through the retrosternal route in an isoperistaltic position. The indication was esophageal stricture secondary to ingestion of caustic fluid in 11 children, while the remaining child was suffering from congenital esophageal stricture. In all patients, the graft "terminal ilium and right colon" was based on the middle colic artery and the marginal arcades. The cologastric anastomosis was made on the anterior wall of the antrum. There was a single mortality on the seventh postoperative day in this series. Small leak occurred from the cervical anastomosis in three children, but it healed spontaneously within 2 weeks without stricture formation. Another child developed slight stricture that responded to dilatation therapy. Redundancy of the graft was found in two patients, however without clinical symptoms. Ten years after replacement, one child suffered massive gastrointestinal bleeding that resolved with antacid therapy without recurrence.

In their published series, Appignani et al. [30] and coworkers used a segment of ileocecum supplied by the ileocolic vessels ten times. They did not use the left transverse colon either due to unreliable left colic vasculature or it was a redo operation.

Bax and Van Renterghem [48] used a terminal ileal graft, 5 cm in length, just proximal to the ileocecal valve to bridge a long gap between upper and lower esophagus in a 10-month-old female infant born with long-gap esophageal atresia with distal fistula. This graft was based on the right branch of the middle colic artery and the vascular arcade of the terminal ilium and ascending colon. The right colon, appendix, and ileocecal valve were sacrificed close to the bowel wall to preserve the blood supply to the terminal ilium and to allow longer mesenteric pedicle to the graft. The graft was passed through the hiatus and transplanted in an isoperistaltic manner. There was a leak from the proximal anastomosis that healed spontaneously, while the distal anastomosis needed to be dilated on a few occasions. Also, contrast showed redundancy of the graft but with good passage. They found that preparing the ileal graft was not difficult, but removing the ileocecal region from the pedicle without interfering with the blood supply was somewhat more difficult. According to experience with children suffering short bowel, they stated that it seems unlikely that removing the right colon and part of the terminal ilium will have a major long-term impact on nutritional status.

- Note: Sonneland et al. [49] and colleagues found that the right colic artery is absent in 12.6 % of 600 examined specimens. In addition, Michels et al. [50] and coworkers stated that the terminal ilium is generally a poorly vascularized area. On the other hand, compromising the terminal ileum and ileocecal valve may affect the nutritional status of the growing child as they lead to impaired vitamin B_{12} absorption [51] and chronic diarrhea [52], respectively.

Conclusion

The cornerstone of a successful esophageal replacement is to fashion a graft with adequate length, is tension-free, and has sufficient blood supply. The colon offers a good substitute to

the esophagus, either in the first surgery or a redo. Although colonic grafts act as a passive conduit, they have acceptable long-term outcome. The colon is the most commonly used organ for esophageal replacement in children worldwide with satisfactory results.

There are different kinds of colonic grafts that can be used to replace the diseased esophagus according to the colonic segment used, the vascular pedicle, the route passed by the graft from the abdomen to the neck, and the peristaltic orientation of the graft. The isoperistaltic left colon graft based on the left colic artery, which passed through the posterior mediastinum, has preferred functional results with straight colon, less redundancy, low reflux rate, and no metabolic disturbances. We believe that using the left colonic graft for replacement of the esophagus through the posterior mediastinum when indicated is the ideal treatment for children with a nonfunctioning esophagus as it can compensate those patients with a near-normal esophagus, i.e., near-ideal graft.

Esophageal Replacement with Jejunum in Children

31

Klaas(N) M.A. Bax

Introduction

Reconstruction of the esophagus in children, when a larger part of the esophagus is absent or has been destructed, is still a challenge [1–3]. The most important indications for such a reconstruction in children are esophageal atresia (EA, either as a primary reconstruction in pure EA or after failed anastomotic attempts in AE/TEF) or destruction of the esophagus by accidental or suicidal ingestion of a caustic substance. Occasionally a peptic stricture may require esophageal replacement as well. Patients with such indications differ significantly in terms of characteristics: Patients with EA are mostly newborns or infants. When the newborn cannot swallow properly for a prolonged period of time, feeding difficulties persist even after esophageal reconstruction [4]. Early restoration of the esophagus seems therefore important. In contrast patients with extensive esophageal strictures due to caustic injuries or reflux esophagitis are usually much older and have swallowed properly before.

Jejunum as esophageal replacement has the advantage that its size matches the esophagus relatively well. Moreover jejunum either as a pedicle graft or as a free revascularized graft retains its peristaltic activity [2, 3, 5–8]. I got interested in jejunal pedicle graft reconstruction of the esophagus after visiting Mario Kasai in Sendai in 1981. Kasai had been using jejunal pedicle grafts for esophageal carcinoma and for caustic stricture [9], a technique he learned from his predecessor [10]. I used the technique for the first time in 1988 as a primary procedure in a child with pure esophageal atresia [1]. Altogether I have been involved in 28 jejunal reconstructions of the esophagus in children. This chapter is based on this personal experience.

Surgical Technique and Operative Steps [1–3]

The Preoperative Period

Most children requiring esophageal replacement will have received a gastrostomy earlier on. Preferably it should be created in the left hypochondrium via an upper midline incision, because this scar can be incorporated in the laparotomy incision for the definitive operation.

In children with a pure EA, a proximal fistula should be actively looked for. The incidence of a proximal fistula in the absence of a distal fistula is relatively high [11]. If such a proximal fistula is diagnosed, then the definitive procedure should not be delayed. A cervical esophagostomy should be avoided for two main reasons: firstly, the dissection interferes with the nerve supply of the

DOI 10.1007/978-3-642-11202-7_31

proximal pouch, which is likely to cause additional problems [12], and, secondly, it results in a longer gap to be bridged. If an esophagostomy cannot be avoided, this should be done on the right side, avoiding the region of the aortic arch, as the interposition will also be done on the right as well. If the aortic arch descends on the right, then the procedures should be performed on the left, but this did not happen in the present series.

Before embarking on a jejunal interposition procedure, it is wise to exclude an intestinal malrotation, which has a higher incidence in children with EA [13, 14]. In the event of a malrotation, the vascular supply of the jejunum may preclude its use as happened in one of the patients not included in this series. In this patient with pure esophageal atresia, a gastric pull-up was performed. In a patient with EA and a distal fistula but very short upper esophagus and two failed attempts of a primary anastomosis, a pedicle ileal graft was used for bridging the gap [15]. This patient is also not included in this series.

The day before surgery, the large bowel is washed out in order to have all surgical options for interpositions available. Cleanliness of the colon is checked on the operating table when the child has been anesthetized.

Taking Down of the Cervical Esophagostomy

If a cervical esophagostomy has been performed, this should be taken down first. The detachment of a right-sided esophagostomy can be done in the same lateral decubitus position of the patient, which is used for the right-sided thoracotomy. In case of a left-sided esophagostomy (but normally descending aorta), the patient needs to be repositioned for the right-sided thoracotomy. Care should be taken to avoid further loss of esophageal material. After detachment of the esophagostomy, the region behind the trachea is bluntly dissected down into the right superior mediastinum. The tip of the esophagostomy is "parked" there. The track between the cervical incision and right upper thorax can be dilated with Hegar dilators.

Thoracoscopic Approach

To be sure that an interposition is needed, nowadays, the right chest is always investigated by a thoracoscopy first. There is no need for a single lung ventilation. The child is placed in a true left lateral decubitus position at the left edge of the operating table. The table is tilted 15° to the left and 15° head up position. The right arm is positioned over the head of the patient so that the axilla is accessible. The surgeon stands on the left side with the cameraperson below him and the scrub nurse at the lower end of the table. The principal screen is in front of the surgeon on the upper right side of the table. First 6 mm cannula is introduced slightly distal and more anteriorly than the inferior tip of the scapula. A 5 mm 30° telescope is used. After being sure that the telescope is in the pleural cavity, CO_2 is insufflated at a pressure of 5–8 mmHg and a flow of 0.1–0.5 L/min.

In cases with EA/TEF, the dilated upper pouch with thickened wall is easily seen. Usually the upper pouch reaches up to the azygos vein. The body of the esophagus may be absent, but a small esophageal remnant is usually present at least above the diaphragm. In between both ends of the esophagus, the vagal nerves are clearly visible. Identification of the lower esophagus is much simpler thoracoscopically than open. Both ends of the esophagus can be mobilized. For doing so, two more cannulas, but now 3.5 mm in diameter for 3 mm instruments, are inserted, one more proximally and one more distally in the midaxillary line. If the patient has a proximal fistula, this fistula can be dealt with thoracoscopically. Just the ends of the upper and lower esophagus are mobilized as extensive mobilization interferes with circulation and innervation. If it has been decided to remove the distal esophagus, much of this dissection can be done thoracoscopically.

When the esophagus is strictured either due to reflux or caustic injuries, the involved segment can be dissected and removed thoracoscopically. Since the patient will need a thoracotomy later on anyway, not much time should be lost though in doing this thoracoscopically.

Thoracotomy

Since a jejunal interposition requires fashioning of one anastomosis high in the chest and a second one low in the chest, a wide exposure is mandatory. A classic posterolateral thoracotomy is performed sparing the serratus anterior muscle. The chest is entered through the bed of the sixth or seventh rib after complete subperiosteal removal of the rib from its head all the way to the chondro-osseous transition. It is important to incise the anterior as well as the posterior periosteum right in the middle along its longitudinal axis. When these incisions are separately closed with fine sutures at the end of the procedure, the rib will regenerate nicely. The azygos vein is transected. For the identification of the proximal pouch, the anesthesiologist is asked to push on the Replogle tube which sits in the proximal pouch. The distal pouch is situated very posteriorly and can be traced by looking at the vagal nerves. The overlying mediastinal pleura is opened. There is no need to mobilize the pouches extensively as the gap will be bridged with jejunum. If the proximal pouch is to be mobilized, it should be done laterally and posteriorly. There is no need to separate it from the trachea. The coexistence of a proximal fistula should have been excluded preoperatively. The vagal nerves should be saved but this may be impossible when these nerves are imbedded in a diseased esophageal wall. The distal esophagus may be mobilized extensively when removal is planned. After the initial thoracotomy, the chest is closed by skin suturing only. This is done with a running 3×0 nylon suture.

Abdominal Steps

Dissection of the Hiatal Region

The patient is put in a supine position. The gastrostomy catheter is removed and a midline incision made from the xiphoid process down to and around the left side of the umbilicus. It is amazing how much exposure is gained by going around the umbilicus. The gastrostomy is detached from the abdominal wall and provisionally closed.

A retractor is placed underneath the left lobe of the liver. The fundus is detached from the diaphragm, and the upper short gastric vessels are dissected, which gives access to the lesser sac and posterior hiatus. The left crus is freed, the posterior hiatus opened, and a large window made into the right chest. The passage from the abdomen into the right chest should allow easy passage of the transplant into the right chest. Dilatation of the passage with Hegar dilators is an option.

The Cardioesophageal Region

When the lowermost part of the esophagus has been destroyed, e.g., by reflux or caustic injury, it should be resected. As mentioned earlier, much of this dissection can be done thoracoscopically. In esophageal atresia without fistula, the most distal part of the esophagus is intact although it may contain tracheobronchial remnants with or without cartilage [16]. Moreover achalasia-like symptoms have been described in association with esophageal atresia [17]. But irrespective of the primary pathology, signs of functional obstruction occurred in all patients in which the distal esophagus was saved. It seems therefore better to resect the distal esophagus and to anastomose the jejunal transplant directly to the cardia. This does not seem to cause problems of jejunitis due to acid reflux, not even at long-term follow-up [5, 18]. In the present series, the distal esophagus was resected in one patient with esophageal atresia and in the two patients with peptic strictures. If resection of the distal esophagus is planned, the distal esophagus should be mobilized and brought into the abdomen at this stage of the operation.

Preparation of the Pedicle Graft

The creation of the pedicle graft is the most critical part of the operation. The first two or three mesenteric vessels are divided between ligatures close to the main mesenteric route (Fig. 31.1a, b). The mesenteric lymph nodes should be removed so that the vessels can be well inspected over their entire length. Tiny vessels can be coagulated with a monopolar diathermy tip. The proximal jejunum is transected close to the ligament of Treitz but leaving enough proximal jejunum for easy restoration of continuity later on. The blood supply to duodenum is not a problem, even not when the first mesenterial branch is taken. Transection of

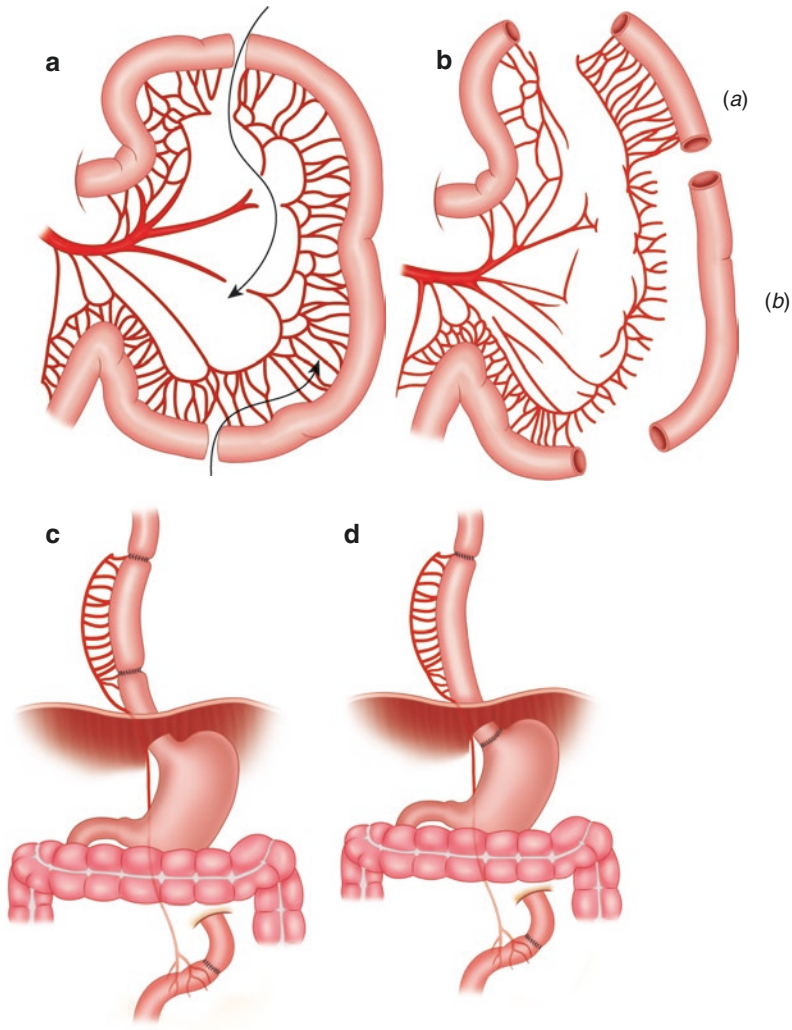

Fig. 31.1 (**a**–**c**) Schematic presentation of orthotopic jejunal pedicle graft reconstruction of the esophagus (Reprinted with permission, *Pediatr Surg Int* 1994 [1]). (**a**) The jejunum is transected close to Treitz ligament. The first two mesenteric arteries and venous branches are centrally divided between ligatures, leaving the peripheral arcades intact. The jejunum is transected again at the level of the third mesenteric artery and venous branch. The distal part of the upper jejunum is skeletonized close to the bowel wall. (**b**) The distal part of the jejunum (*b*) has been removed, leaving the uppermost part (*a*) for transfer into the chest. (**c**) The uppermost part of the jejunum has been transferred through the left mesocolon, behind the stomach, and through the posterior part of the hiatus into the right chest, were a double anastomosis has been made. Jejunal continuity in the abdomen has been restored behind the pedicle. (**d**) The distal esophagus has been resected. The uppermost part of the jejunum has been transferred through the left mesocolon, behind the stomach, and through the posterior part of the hiatus into the right chest. The graft has been anastomosed with the upper esophagus in the chest and with the cardia in the abdomen. Jejunal continuity in the abdomen has been restored behind the pedicle

the first two mesenterial branches has usually sufficed to reach the proximal esophageal pouch. In one patient with very short upper esophagus and high cervical esophagostomy on the left, the third branch had to be taken as well. The mesentery of the jejunal loop is now inspected. It is sometimes possible to save central arcades thereby leaving the peripheral arcades intact. More length is gained by skeletonizing the first centimeter of the proximal part of the future graft. This is done between fine absorbable ligatures, which will remind the surgeon at all times that this is the proximal part of the graft. By laying the distal jejunum over the chest, an idea is obtained as to

whether the graft will reach the upper esophagus. The graft should reach the neck. The circulation of the jejunum is watched all the times. No gauzes should cover the jejunum as this traumatizes the graft and hampers observation, but regular moisturizing is important. The jejunum is severed again opposite the level of the third mesenteric branch. Only jejunum is taken, not the arcade. The isolated jejunum is far too long. Only the most proximal part will be used. In infants with true long gap esophageal atresia not more than may be 5 cm is needed. This means that the rest has to be removed. This is done starting at the distal end of the graft. The best way of doing this is to use a monopolar diathermy needle right onto the serosa of the bowel. This should be done with care and short bursts of diathermy to avoid more central coagulation. Alternatively fine bipolar diathermy can be used. The mesentery has two leaves which should be diathermized separately. Some burning of the serosa is unimportant as this part of the graft will be removed. The upper part of the jejunum serving for the interposition should not be too long. Further skeletonizing of the graft later on in the chest is difficult as overview is lacking. The last 2 cm of skeletonized distal jejunum will remain well vascularized. If the graft is too long, these last 2 cm can easily be removed later on. Before starting to remove the distal part of the graft, the graft often looks a bit dusky, but during the process of removal of the distal part of the graft, the circulation to the remaining graft improves considerably.

Bowel continuity is restored behind the pedicle of the graft. The left part of the gastrocolic ligament is opened and a hole is made in the left mesocolon, close to its posterior insertion. The graft is passed through it taking care that the pedicle does not twist. Next the graft is passed underneath the remaining short gastric vessels to reach the area between the fundus and the spleen. The graft is then passed through the posterior hiatus into the right chest, which should go easily. Care should be taken to pass the proximal part first. The position of the pedicle is checked over and over again. If the lower esophagus is resected, the distal part of the graft should remain in the abdomen. The abdominal skin incision is closed quickly with a 3×0 running nylon suture.

Continuation in the Chest

The time between putting the graft into the chest and reopening of the chest should be short as the graft may have become kinked during its transport. The patient is repositioned in a left lateral decubitus position and the chest reopened. The graft is identified and positioned. When the surgeon intends to use the distal esophagus in esophageal atresia without distal fistula, the distal esophagus should be opened longitudinally in its posterolateral area before any trimming of the graft. One should make sure that the distal part is widely patent. In one of our patients, the distal segment was stenotic over about 2 cm, which was only realized after the graft had been trimmed resulting in an anastomosis under tension and postoperative leak. There is no need to transect vagal branches unless they are part of the destructive process. Next the upper pouch is opened. This is done with the diathermy needle over the pushed up Replogle tube. By doing so, this esophagostomy will be right in the middle of the distal wall of the pouch. This esophagostomy is then extended with scissors upward posterolaterally on the right.

An anastomosis is made between the upper esophagus and the proximal end of the graft using interrupted 5×0 absorbable sutures. The distal end of the graft is then trimmed and an end to side anastomosis between the graft and the distal esophagus is then made (Fig. 31.1c). Alternatively the distal anastomosis is made in the abdomen after resection of the distal esophagus. Before finishing the anastomosis in the chest, a nasogastric tube is passed through the graft. A chest drain is inserted and the thoracotomy closed in layers. Much attention is paid to close the posterior and anterior rib bed separately with 5×0 absorbable sutures.

Final Continuation in the Abdomen

The patient is repositioned supine and the abdomen reopened. If the distal anastomosis has still to be made, the distal esophagus is resected, the graft trimmed when needed and anastomosed to the cardia with interrupted 5×0 absorbable sutures (Fig. 31.1d). No antireflux procedure is

added. The gastrostomy is refashioned and the abdomen is closed.

Postoperative Care

The patient is weaned from the ventilator when appropriate. It is important to keep the patient well hydrated as fluid will sequestrate into the chest and abdomen. Gastrostomy feedings are started when there are no gastric retentions anymore. The chest drain is removed after 5–6 days after a contrast study has ruled out any leaks. Oral feeding is then started. It is important to control the patient regularly on an outpatient basis to check for stenoses. In case of a distal stenosis, the graft will dilate, which is to be avoided at all times.

Results

In a period of slightly over 20 years (1988–2009), 28 orthotopic jejunal pedicle graft interpositions have been carried out. Adding the two patients that had another form of interposition all together, only 30 patients were treated with an esophageal substitute indicating the rarity of such procedure. Besides these 30 "in-house" patients, 11 were operated outside the author's home institution. To gain and to keep enough experience in this field of pediatric surgery, these patients should be centralized.

Indications		Age at interposition
Esophageal atresia	21	
Primary interposition	17	76 days median (range, 16–309)
No fistula	11	
Proximal fistula	6*^{R}	
Secondary interposition	4	50, 120, 1080, 1100 days
No fistula	2	
Distal fistula	2*^{L}	
Caustic stricture	4	1, 3, 5, 16 years
Peptic stricture	2	10, 14 years
Battery necrosis	1*^{R}	2 1/2 years
Total	28	

^{R}Right, ^{L}left
*Stands for the one cervical esophagstomy

Early Results

The results of the first 24 jejunal interpositions, 19 for esophageal atresia, 3 for caustic stricture, and 2 for peptic stricture, have been described in detail elsewhere [3]. The median follow-up at the time of that publication was 5.5 years in the esophageal atresia group, 4.4 years in the caustic stricture group, and 7.4 years in the peptic stricture group. Since that publication four additional jejunal interpositions were carried out.

None of the 28 grafts were lost, but postoperative respiratory distress syndrome occurred in three patients of the esophageal atresia group that had a primary interposition.

There were five early postoperative leaks in the esophageal atresia group, four in the chest and one in the abdomen. One leak in the chest and the only leak in the abdomen were treated surgically. In one patient a proximal fistula had been missed primarily and required ligation through the neck in a second operative session. One patient developed early distal graft anastomotic occlusion requiring surgical correction. Dilatation in this patient could not be performed as the nasogastric tube had been removed prematurely and no lumen could be seen at esophagoscopy. There were no leaks in the remaining patients except for one of the patients with an extensive peptic stricture. That patient had multiple previous operations. The leak settled by chest drainage. In one of the patients with caustic stricture, there was a postoperative intra-abdominal bleeding requiring re-exploration, but no major source was found. The same patient had a pyloroplasty later on because of ongoing gastric outlet obstruction.

Long-Term Results

One patient has died so far. He had trisomy 21 and esophageal atresia without fistula. He developed severe respiratory distress postoperatively. He was never able to eat and was always fed by gastrostomy. He was cared for in an institution and died suddenly. The exact cause of death is unknown.

Anastomotic dilatation was required in 12 patients, 10 of them belonging to the atresia

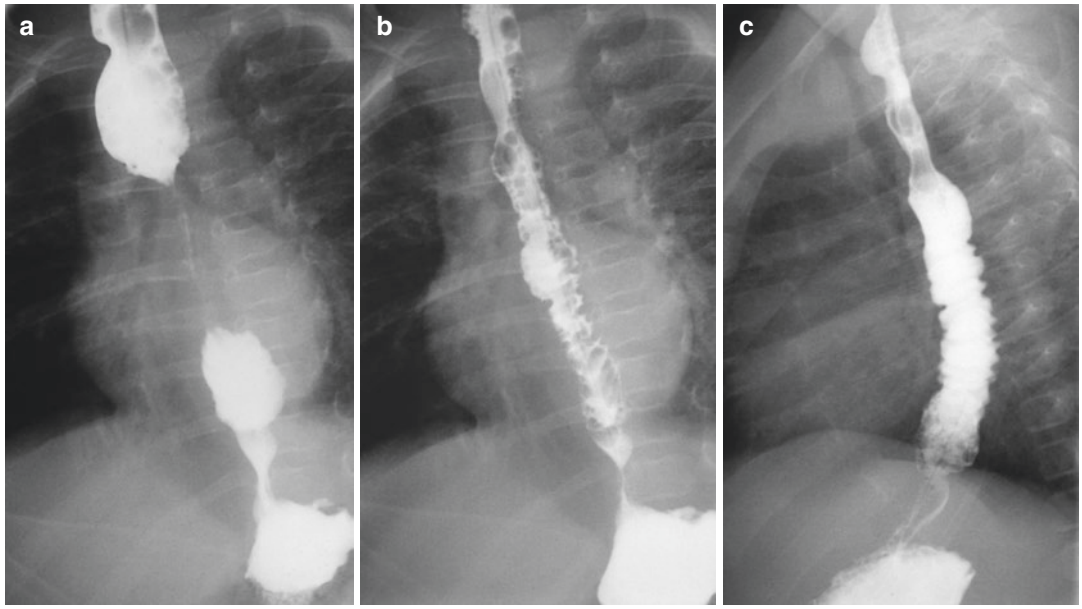

Fig. 31.2 Barium meal 3 months after jejunal grafting (Reprinted with permission *J Pediatr Surg* 2007 [3]). (**a**, **b**) Anteroposterior view showing vigorous contractions and emptying of the jejunal graft. (**c**) Lateral view

group. Six patients were dilated five times or more. In one patient the graft was perforated during dilatation requiring thoracotomy for closure.

With time there was no tendency for the graft to elongate, but there was always some obstruction at the distal anastomosis, which appeared functional in most of the patients. This led to widening of the graft in one of the patients. A widening plasty of the distal anastomosis was unsuccessful. Finally the distal esophagus was resected and the very much dilated conduit was anastomosed to the stomach. Significant reflux and pulmonary problems resulted.

Reflux in the other patients was not a problem even not in the patients with resected distal esophagus. On barium swallow there was always vigorous peristalsis of the graft (Figs. 31.2 and 31.3). Most patients are eating everything and bolus obstruction is rare. Most patients grow well.

Discussion

Especially in long gap esophageal atresia, pediatric surgeons have embraced the adagio "the child's own esophagus, no matter what has to be safely done to bring it together, is infinitely better than any replacement that can be constructed" [19–22]. That the healthy own esophagus is best is beyond doubt, but this does not necessarily apply to the diseased esophagus. In esophageal atresia without distal fistula, the esophagus is largely absent. It is not a matter only of getting the ends together, it is a matter of function. In order to unite the two ends of the esophagus, the remnants have to be mobilized extensively, which impairs esophageal function further. The risk of stricture and severe gastroesophageal reflux after primary repair is as high as 30 % [21]. Moreover reflux in these patients is very difficult to treat. Looking from the medical point of view, the long-term results after esophageal atresia repair are not very good, which contrasts with quality of life assessments [12–15, 23–26]. This conflict is undoubtedly caused by the fact that the patient doesn't know better.

The question of course arises whether an esophageal replacement in these patients would be better. Maish and DeMeester wrote that any replacement suffers from a lack of effective peristalsis and the absence of a physiologic barrier to reflux [27]. This statement does not hold fully true regarding the jejunum. A jejunal graft does not display a normal motility, but retains peristaltic activ-

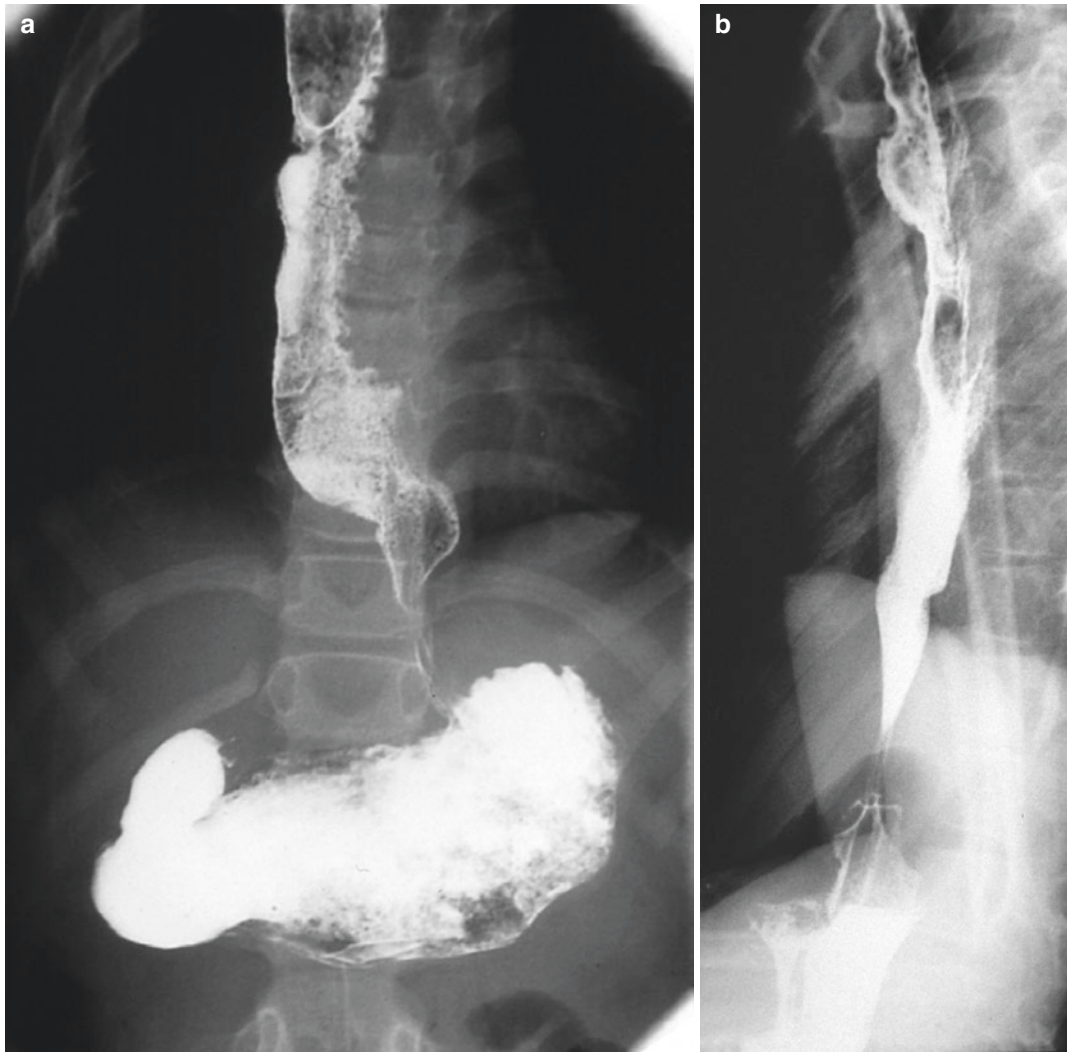

Fig. 31.3 Barium meal in another patient, 7 years after grafting [3] 3 months after jejunal grafting (Reprinted with permission *J Pediatr Surg* 2007 [3]). (**a**) Anteroposterior view. (**b**) Lateral view

ity [1–3, 5–8, 28, 29]. Contractions are rather segmental than peristaltic, which accounts for a delayed transit time [29]. Interestingly, none of the adult patients described by Wright et al. admitted to dysphagia for liquids or solids on direct questioning [29]. In adults free jejunal grafts showed phase III migrating motor complexes, which were not interrupted by swallowing water [8]. But again, swallowing in the vast majority of adult patients with a free graft in the neck is good [6, 7]. Swallowing function was also good in the 10-year-old child who had a free jejunal graft [30].

In contrast as what would be expected, jejunum when used as a distal esophageal substitute seems to act as barrier against reflux [5, 18, 29]. Recently, replacement of the distal esophagus with jejunum in adults as a treatment of early adenocarcinoma is gaining more attention [31]. Reflux in these patients does not seem to be a problem.

In pediatric surgery jejunum as an esophageal substitute has never gained real acceptance. A few relatively large series of pedicle grafts however have been reported. Ring et al. published in 1982 a series of 32 children with 18–33-year follow-up in

16 of them [32]. They used a staged approach. In the first procedure, the graft was placed antesternally but was moved subsequently into a retrosternal position through a sternotomy. All grafts reached the neck and none of the grafts was lost. All patients could eat a regular diet. A second large series was published by Saeki et al. in 1988 [33]. The technique used was very much the same as the technique presented in this chapter, except for doing two right-sided thoracotomies, one through the third and one through the seventh intercostal space and except for the relative late timing of the reconstruction. Only one graft was lost. Cusick et al. [34] used jejunum in six esophageal atresia patients, but two of the six patients died. The graft was put in a retrosternal position, and five of the grafts received a dual blood supply by anastomosing the terminal arcade vessels to vessels in the neck. In the last patient, a free graft was used with success. In most studies in children regarding jejunal pedicle graft interposition, the distal part of the graft was anastomosed directly to the stomach [32, 34]. One of the reasons for not using the distal esophageal remnant has been the observation that the distal esophageal remnant may contain abnormal embryonic tissues such as cartilage [35, 36]. I originally thought that the distal esophagus should be retained whenever possible in order to prevent reflux. In all patients in whom the distal esophagus remained in place, however, some hold up of contrast was seen in the distal part of the jejunal interposition and the retained esophagus did not open up nicely. A number of patients were dilated for that reason. In one patient the functional obstruction resulted in marked dilatation of the graft. Eventually we had to resect the distal esophagus, but this created a common channel of dilated jejunum and stomach with reflux and respiratory symptoms. In the patients with peptic stricture of the esophagus and in one patient with esophageal atresia, the distal esophagus was resected and a direct anastomosis with the upper stomach was performed. In these patients there was no distal functional obstruction. Moreover reflux has not been a problem, which is in line with observations in adults [5, 18, 29].

Gaining enough jejunal length has not been a problem. In all but one patient of this series, however, we replaced the middle part of the esophagus in the esophageal atresia and caustic burn patients and the distal esophagus in the patients with peptic stricture. If the more proximal esophagus has to be replaced, getting enough jejunal length may be a problem. In one patient the jejunum was brought up into the neck, which resulted in a tortuous graft. When a high replacement of the esophagus is required, an ileal pedicle graft may be better [15].

Age at which replacement of the esophagus is required is not a contraindication for jejunal interposition. If a patient with esophageal atresia without distal fistula tolerates suctioning of the upper pouch well, the interposition can be postponed until the end of the neonatal period. If, however, problems of recurrent aspiration occur, the time of the interposition can be advanced. Under such circumstances one should reconsider the presence of a proximal fistula. If such a fistula is present, it can be dealt with at the time of the interposition, either through the neck or thoracoscopically. It is important not to defer the reconstruction for too long. Swallowing seems not a problem in esophageal atresia without fistula when the reconstruction is carried out before 6 months of age.

One should try to avoid the creation of a cervical esophagostomy but if this is not possible, it should be created on the right side as the interposition will be done through the right chest. By choosing for the right chest, the aortic arch is not in the way as long as it is descending normally. If the esophagostomy is on the left, it can be mobilized and tunneled behind the trachea into the right chest. But this maneuver is more difficult than if the esophagostomy was on the right. Moreover it requires repositioning of the patient for the thoracoscopy/thoracotomy.

As said before, intestinal malrotation should be excluded before embarking on jejunal pedicle graft reconstruction of the esophagus.

Esophageal replacement with jejunum in children is a demanding operation with considerable morbidity, but in this series there was only one late mortality and none of the grafts were lost. Moreover long-term function in most patients was good. Jejunal pedicle grafting should be part of the armamentarium of pediatric surgeons dealing with complex esophageal reconstruction.

32 Oesophagus Tissue Engineering: Future Options in Oesophageal Replacement Through Regenerative Medicine

Amulya K. Saxena

Introduction

Despite the notable success of oesophageal replacement procedures, such as gastric, small intestine and colon transposition and gastric tube formation, these techniques are associated with a high incidences of complications including leakage, stricture, elongation and malnutrition due to shortening of the gastrointestinal tract and are the main reasons driving research in oesophagus tissue engineering [1–3]. Recent studies exploring the use of biomaterials for oesophageal replacement have also been hindered by severe limitations including slow ingrowth of cells onto the biomaterial grafts from surrounding tissue and little to no muscle regeneration [4]. Consequently, there is an urgent requirement for viable alternatives which bypass such complications, and the emerging technology of tissue engineering may provide much needed solutions.

Tissue Engineering and Regenerative Medicine

Tissue engineering began as a branch of biomaterial science, in which scientists involved in polymer chemistry investigated the interaction of cells with newly developed biodegradable materials. The enormous potential of this unique area of research soon became aware and was reflected by a European public expenditure of €10 billion in the period between 1994 and 1998 [5]. The rapid emergence of regenerative science in medicine led to the establishment of *tissue engineering* as a field in its own right within the area of biotechnology.

Tissue engineering is a multidisciplinary science applying the principles of engineering to the fields of clinical medicine and cell biology. The complexity of this field of research requires contributions of experts from various specialties and the accumulation of knowledge from interrelated disciplines, for progress to be achieved. The multidisciplinary approach of tissue engineering begins with the identification of pathologies that require tissue engineering solutions based on clinical experience and epidemiological data. Basic science is then referred to in order to better understand the structure and physiology of tissue and organs so that the blueprints of the organs to be engineered may be drawn. The options of various sources of cells for tissue engineering are

DOI 10.1007/978-3-642-11202-7_32

explored, and scaffold materials which act as carriers for cell attachment and organisation are designed and fabricated from natural or synthetic materials in line with requirements of the target organ. Growth factors and such biomolecules may be attached to the scaffold surfaces to promote biosignalling and influence attachment, proliferation, differentiation and organisation of cells [6]. As the unique demands of in vitro culture are realised, techniques for the proliferation of large quantities of cells and the design of scaffold architecture to allow for the seeding of cells within the core of scaffolds must be investigated [7]. In order to keep cells viable for prolonged periods of in vitro cell culture, devices have been designed such as the flow bioreactor which may enhance cell seeding and improves mass transfer of nutrients and gases. Similarly, alternative in vivo strategies have been developed by surgeons in which the body is utilised as an in situ bioreactor. Throughout the phases of tissue engineering research, contributions from diagnostics, imaging and other biomedical fields are continuously applied to assess the success of tissue-engineered constructs and provide feedback to the cell biologist and polymer scientists.

The Concept of Tissue Engineering

The concept of tissue engineering has its origins in experiments of the 1930s in which organs were cultured ex vivo with the aim of repairing or replacing damaged or diseased organs [8]. It was only in the late 1980s that scientists, engineers and clinicians began to study the possibility of de novo tissue generation as a solution to the acute shortage of organs for transplant. The basic concept of tissue engineering is similar, irrespective of the tissue or organ to be engineered. Cells are sourced, isolated and proliferated. Scaffolds are fabricated and seeded with cells to create a construct which is cultured within an in vitro or in vivo bioreactor. The specific issues related to this technology including cell sourcing, scaffold selection and systems of cell culture will be addressed in the following subsections.

Cell Source

The engineering of neotissues requires a suitable source of cells. The criteria of an appropriate cell source for tissue engineering are as follows. The cells should be easily obtained, be capable of substantial expansion in number in vitro, survive implantation, avoid immune rejection, display normal function and must not show malignancy. Cells may be procured from the patient's own cells (autologous), which are immune compatible, or from human donors (allogenic), which offer off-the-shelf availability yet have issues with immunocompatibility and theoretical risk of infection. After the appropriate cell source has been selected, functional characteristics of the cell may be manipulated via stimuli from the microenvironment or genetic manipulation. Genetic manipulation could be used to programme the cell for specific tissue engineering purposes including the inhibition of immune responses, alteration of matrix synthesis, improvement of cell proliferation and the enhancement in secretion of specific biologically active molecules. For tissue engineering of the oesophagus, a wide variety of cell types are required. Principally, the two major cell types are epithelial and muscular cells. In addition the tissue-engineered oesophagus required endothelial cells for vascularisation and neurogenic cells for innervations as well as connective tissue for maintenance of structural integrity. Cell sources generally can be categorised as mature or progenitor cells, the latter of which is best represented by the adult stem cell. The pros and cons of both groups are detailed below.

(a) *Mature cells*
Mature cells are fully differentiated cells of a specific cell type. Such cell types can be obtained through a biopsy and expanded in number in vitro to produce the desired cell number for tissue engineering. Mature cells are traditionally isolated from tissue via the "explant" culture technique whereby a small biopsy of tissue is glued to the base of a tissue culture plate [9] (Fig. 32.1). Over a period of culture, cells grow out from the

biopsy and invade the tissue culture plastic. These cells have the benefit of not requiring any in vitro manipulation to produce the desired phenotype. The major drawback is the relatively poor proliferative capacity of mature cells. Whilst the explants technique produces sufficient success in particular cell types, other cell types show a slow rate of outgrowth and are prone to becoming overrun by fibroblast contamination. In response to these limitations, alternative techniques for optimising cell isolation and improving cell proliferation have been researched and will be discussed in section "Tissue Engineering of the Oesophagus" [10].

(b) *Adult stem cells*

Precursor or progenitor cells have the principle benefit of a high proliferative capability. In recent times there has been a great interest in the application of stem cells for tissue engineering, with the focus of attention on embryonic (ES) and adult stem (AS) cells. ES cells are sourced from discarded human embryos. These cells show a high degree of plasticity; however, generation of pure populations of desired cells is problematic [11–15]. ES cells also have been associated with the risk of teratoma formation as well as ethical controversy over the use of embryonic tissue [16].

In comparison with ES cells and the associated controversies, adult stem cells present a more direct route to clinical translation. Whilst the capability of differentiation may be lesser than ES cells, AS cells also display potential for differentiation along a variety of lineages. Mesenchymal stem cells (MSCs) are a class of AS which have shown enormous potential in tissue engineering and regenerative medicine. MSCs give rise to cells of the mesenchymal lineage (bone, cartilage, tendon, muscle and fat) and have been much researched for applications in both musculoskeletal and vascular tissue engineering [17–19]. There is also evidence that MSCs have a capacity for differentiation into cell types outside of the mesenchymal lineage. Others demonstrated that MSCs cultured on an air-liquid interface displayed phenotypes similar to those of airway epithelial cells.

Initially, MSCs were identified in the bone marrow, in which they exist in relatively high concentrations [20, 21]. Since then, MSCs have been further identified in a wide range of tissues including adipose tissue which can be easily obtained through liposuction procedures [22].

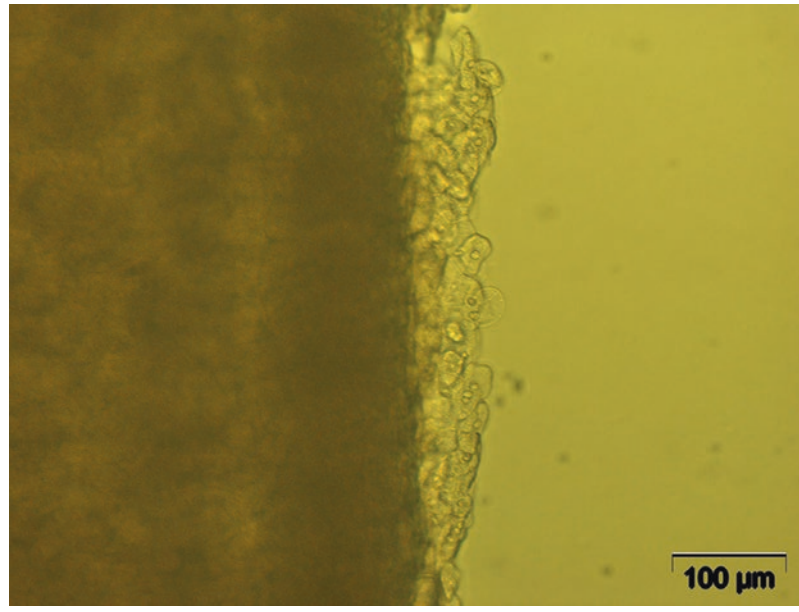

Fig. 32.1 Rodent oesophageal epithelial cell isolation using the explant technique showing the light microscope image early phase of cell detachment from the explants in vitro

MSCs can also be sourced from amniotic fluid or chorionic villi and can give rise to cell types representing all three embryonic germ layers [23, 24]. Amniotic fluid stem cells in particular can be proliferated over 200 times without senescence or telomere shortening. As with ES cells, safety concerns have also been raised with AS cells. By removing MSCs from their native environment and encouraging high levels of proliferation, there is an increased risk of tumorigenesis as observed by the development of sarcomas after implantation into mice of MSCs seeded onto bioscaffolds [25].

Scaffolds and Polymers

Scaffolds are supportive biomaterials which provide cells with an artificial extracellular matrix (ECM) allowing for the in vitro promotion of organisation towards tissue formation [26]. Ideally, a scaffold for tissue engineering should (a) promote cell-scaffold interaction, cell adhesion and deposition of ECM; (b) support cell proliferation, differentiation and viability through permitting the transport of gases, nutrients and metabolites; (c) display controlled degradation with non-toxic breakdown products; and (d) minimise the elicitation of inflammatory responses in vivo.

Biodegradable scaffolds can be produced from synthetic polymers such as poly(l-lactic acid) (PLLA), poly(glycolic acid) (PLGA), poly(ε-caprolactone) and polydioxanone (PDS) or biological biomaterials such as collagen, fibrin, alginates or chistosan [27]. Scaffolds can be designed and fabricated to produce a variety of architectures with regard to both the dimensions of the struts and fibres and the structure of the porous space within the scaffold. The structure and composition of a scaffold influence a range of factors including biomechanical function, biodegradation, cellular function and orientation of tissue. Scaffold architecture can be controlled by a variety of fabrication techniques including fibre bonding, electrospinning, extrusion, foaming, rapid prototyping and peptide self-assembly.

Scaffold matrices can also be derived from the decellularisation of tissues. Decellularisation enables the removal of cells whilst retaining the structure and function of the ECM. The ECM provides a multitude of functions from signalling to structural support. The presence of growth factors sequestered within decellularised tissue provides a bioactive element to these scaffold materials. Decellularised tissues such as small intestinal submucosa, porcine dermis and bovine pericardium have been used widely in reconstructive surgery and more recently in tissue engineering. Our group has also successfully decellularised the oesophagus and investigated it as a scaffold for possible tissue engineering applications [28].

In addition to solid-state scaffolds, there is an increasing application in tissue engineering of hydrogels fabricated from both synthetic and natural-derived materials [29–31]. Common, naturally derived materials for hydrogel fabrication include collagen, fibrin, hyaluronic acid, chitosan, alginates or silk fibrils, whereas synthetic hydrogels are commonly fabricated from polymers such as poly(ethylene glycol) (PEG), poly(vinyl alcohol) and poly(2-hydroxyethyl methacrylate).

Hybrid Constructs and Coculture

The engineering of complex organs requires the combination of multiple tissue types into a single construct. Such constructs may be realised through the hybrid construct or coculture approach (Fig. 32.2). Critically, in vitro, the optimal physiological culture conditions vary between cell types, with different cell types requiring specific media compositions and environmental cues. In the hybrid construct approach, homogenous cell types seeded onto scaffold sheets are first cultured in separation under cell type-specific culture conditions, followed by assembly of multilayered constructs of different cell types, prior to implantation in vivo [32].

In contrast, coculture involves first combining two or more cell components together onto

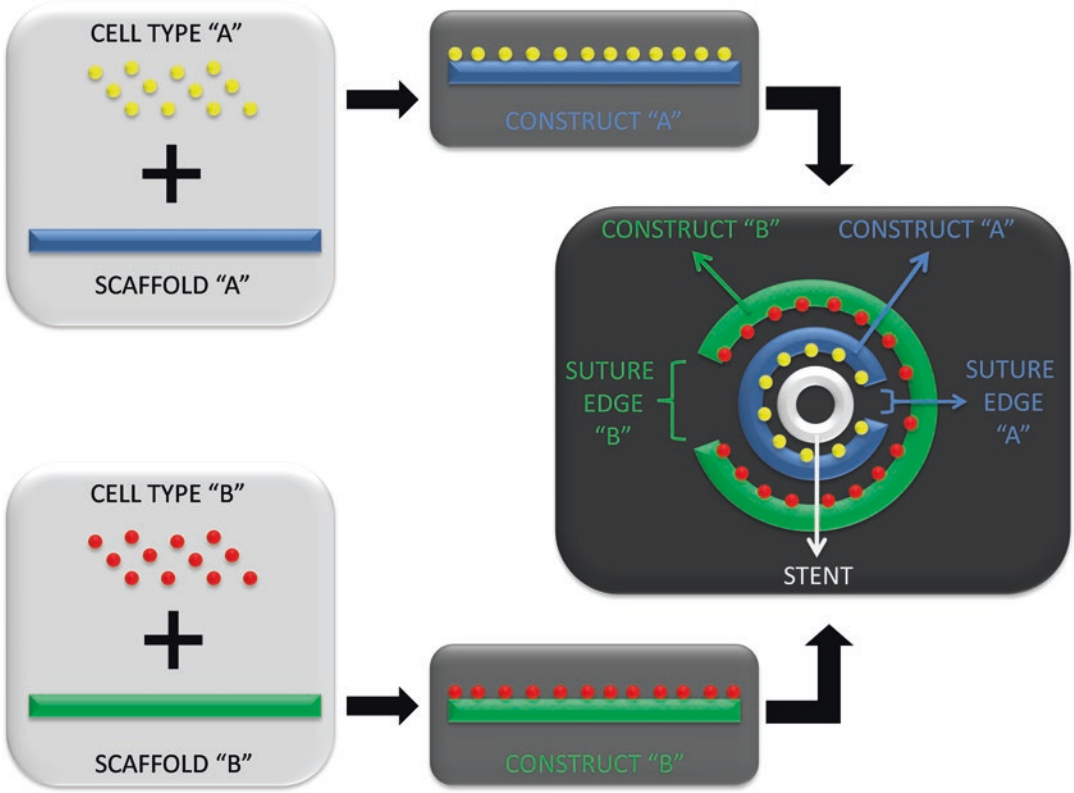

Fig. 32.2 Schematic representation of the concept of hybrid constructs formation for complex tubular organ tissue engineering

a single scaffold, followed by culturing in an environment whereby the requirements of the different cell types are provided for. Such a coculture approach often requires (1) the design of dual-layered scaffolds for the separation and organisation of the different cell types and (2) a device for isolating the different media types. An example of coculture can be seen in the tissue engineering of oral mucosa whereby one side of a scaffold was seeded with fibroblasts, whilst the alternate side was seeded with keratinocytes [33]. The construct was then cultured at an air-liquid interface in which the scaffold side seeded with fibroblasts was submerged in culture media, whilst the keratinocyte seeded surface was exposed to the air. The air-liquid interface encouraged organisation of a stratified epithelium whilst maintaining the viability of the underlying fibroblastic feeder layer.

Bioreactors

A bioreactor is a device for culturing of tissue-engineered tissues, providing a controlled environment with physical stimuli similar to those of the human body [34]. During traditional static cell culture conditions, cell-seeded scaffolds are maintained in a stagnant culture media in which media is changed at intervals of 24–48 h. The limitation of such systems is a continuous depletion of nutrients and gases accompanied by an accumulation of waste products. In comparison, the bioreactor offers dynamic cell culture conditions, whereby a pump system provides a constant and regulated flow of fresh culture media to the cells within the scaffold. Bioreactors, therefore, hold numerous advantages over traditional static culture techniques. The two major advantages are improvement in the efficiency of mass transport

of gases nutrients and regulatory factors and the provision of mechanical stimulation.

Bioreactor design has enabled the transmission of a variety of different mechanical stimuli to the cell/scaffold constructs including pulsatile flow, stretching, torsion and compression [35–37]. Such mechanical stimulation may improve proliferation, induce differentiation and promote the organisation of tissues [38, 39].

Perfusion bioreactors are also capable of seeding cells onto a scaffold, whereby they have control over the initial cell distribution within 3D scaffolds. A variety of commercial bioreactors are available to the tissue engineer. Based on the improved understanding of physiological conditions required for directing cell differentiation and tissue assembly, much progress has been made in the design of advanced bioreactors.

Tissue Engineering of the Oesophagus

There are many challenges in the engineering of the oesophagus. This begins with the anatomical complexity of this tubular organ. The oesophagus transverses three anatomical planes and varies according to localisation in both function and histological appearance [32]. Early studies investigating the possibility of cell-free biomaterials to replace segments of the oesophagus varied in success depending on the location of the oesophageal defect. For example, a double-layered tube of collagen sponge matrices on a silicon stent was utilised to replace a 5-cm cervical oesophagus defect in a canine model [40]. After removal of the stent at 4 weeks, oesophageal tissue was detected in the implanted scaffolds, and the animals were able to tolerate feeding. The same scaffolds applied to the repair of a 5-cm thoracic defect showed full regeneration of the mucosa within 3 months and of the glands within 12 months; however, formation of the muscularis mucosae was weak, with only islets of smooth muscle present after 12 months, whilst the skeletal muscle failed to extend towards the middle of the regenerating oesophagus after 24 months [41]. The poor regeneration of muscle layers was attributed to the lack of blood supply from surrounding tissues within the thoracic segment, although attempts to increase vascular ingrowth into the collagen scaffolds, via an omental wrap or basic fibroblast growth factor, also failed to improve the outcome [41, 42]. In addition to collagen scaffolds, decellularised scaffolds, including porcine small intestine submucosa and urinary bladder submucosa, have also been employed as oesophageal replacements in large animal models. These scaffolds showed migration of host tissue and coverage by skeletal muscle, yet suffered from strictures resulting in severe morbidity [43–45].

Other than highlighting the anatomical complexity of the oesophagus and its influence on regeneration, these studies also demonstrate how biomaterials implanted alone, without prior combination with a cellular component, result in delay and, in some cases failure, of tissue regeneration. To advance the rate of regeneration and to improve the overall outcome of such studies, recent research has adopted the tissue engineering approach for the repair of oesophageal defects. In principle, a tissue-engineered construct should mimic the structure and biomechanical properties of native oesophageal tissue, possess a luminal surface covered by a continuous epithelial layer and an orientated muscle component capable of contraction and must be readily innervated and vascularised, resulting in a functional and viable organ.

Tissue engineering of complex organs necessitates either a hybrid approach, which involved the generation of individual tissue grafts before assembly as a complete organ or a coculture approach whereby the different tissue components are cultured together. Initial experiments with the hybrid approach have led to the generation of oesophageal epithelium as well as the smooth muscle components in vitro [32]. Such studies form the basis for future in vivo implantation studies. Rat oesophageal epithelial cells (REECs) were isolated by a modified explant technique. Oesophageal epithelium was first mechanically separated from the connective tissue of the underlying mucosa and cut into 2–3 mm pieces. The oesophageal pieces were

attached to the surface of tissue culture dishes using a basement membrane matrix. Explants were then submerged in a specific media for the culture of epithelial cells. Explants were incubated at 37 °C and 5 % CO_2 for 48 h after which cells became dissociated from the epithelium and could be mechanically separated by a 10-mL pipette. After passing the cell solution through a 50-μm filter, cells were collected, resuspended onto tissue culture dishes and maintained in culture until confluence was reached (Fig. 32.3).

In the meantime, rat smooth muscle cells (RSMC) were isolated from the aorta. The tunica media was cut into pieces and glued to the base of tissue culture dishes using basement membrane matrix, before submerging in Dulbecco's modified essential medium (DMEM) and foetal calf serum. Explants were cultured at 37 °C with 10 % CO_2. After 7 days, RSMCs had begun to grow out from the explants. The explant tissue was removed, and adhered RSMCs were allowed to grow to confluence (Fig. 32.4).

The above-described explant technique for tissue isolation was found to be adequate for RSMC isolation; however, REECs cultured from mucosa explants were prone to becoming overrun by fibroblast contamination. The key obstacles to the engineering of an epithelial layer were, therefore, the efficient isolation of REECs from the original biopsy tissue and improvement of in vitro proliferation of REECs. In response, alternative techniques have been developed for the isolation of RECCs.

It was demonstrated that through enzymatic separation of the epithelial sheet from the underlying mucosa, fibroblast contamination could be minimised. Furthermore, mechanical disruption of the epithelial sheet resulted in the isolation of high cell densities [32]. The relatively poor proliferative capacity of EECs was addressed through the selection of specific subpopulations of EECs which display significantly higher rates of proliferation. In the large animal model (ovine), characterisation of various phenotypical subpopulations of ovine oesophageal epithelial cells (OEECs) demonstrated that 50 % of OEECs isolated from ovine oesophagi were proliferative [46]. Further investigation demonstrated the existence of a subpopulation of OEECs expressing markers for pan-cytokeratin 26 (PCK-26), which contained a percentage of proliferating cells significantly higher than that of the total population (Fig. 32.5). By isolating PCK-26+ cells through fluorescence-activated cell sorting and seeding onto collagen scaffolds, it was demonstrated that such high proliferating

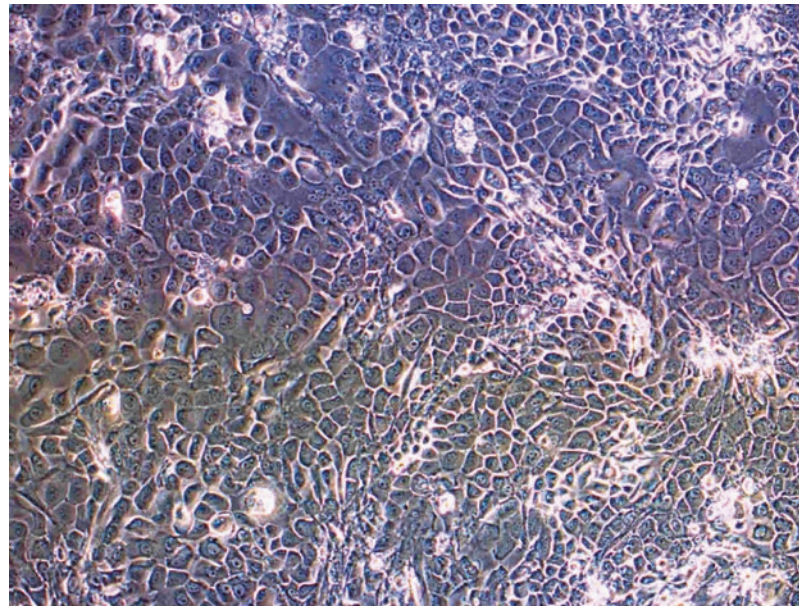

Fig. 32.3 Rodent oesophageal epithelial cells isolated using the explant technique reach confluence and differentiate to form sheets of epithelium on coated tissue culture dishes

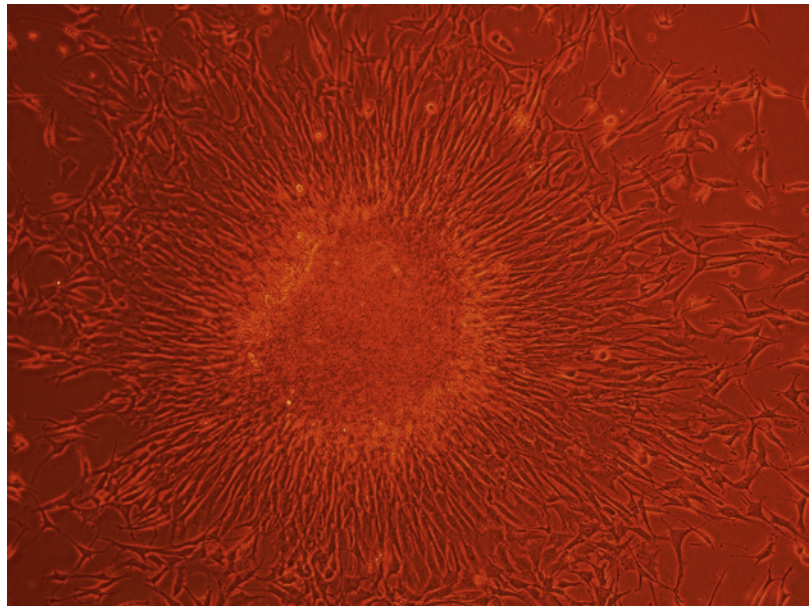

Fig. 32.4 Isolation and proliferation of smooth muscle cells from explants. Image shows the outgrowth of cell after removal of the explant and the first passage

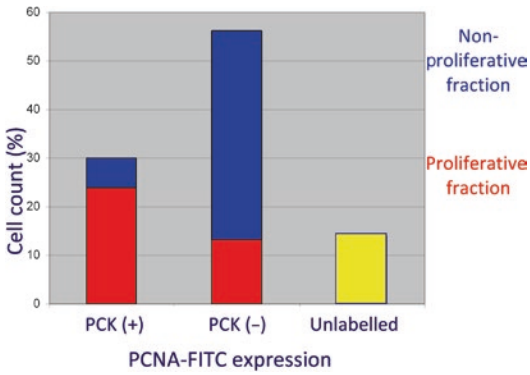

Fig. 32.5 Ovine oesophageal epithelial cells (OEEC) characterised by pan-cytokeratin markers (PCK-26) demonstrate that approximately 30 % of the OEECs are PCK-26+ and this subset has high proliferative capability that is necessary for generation of oesophageal epithelium

subpopulations produced a more uniform distribution of cells with a high attachment rate in comparison to unsorted cells.

Once isolated and cultured to suitable cell numbers, epithelial and muscle cells may be seeded on to scaffold materials. A scaffold, for tissue engineering of the epithelium, should encourage cell attachment and proliferation, and critically it should permit the organisation of a stratified epithelial layer. REECs were seeded onto both synthetic (PLLA, PLGA and PCL/PLLA) and natural scaffolds (AlloDerm®) to observe cell interaction [47]. After 18 days of in vitro culture, REECs seeded onto AlloDerm® showed a proliferative basal layer, epithelial stratification and a keratinised layer. In contrast, REECs seeded onto the synthetic scaffolds, with their highly porous structure, were unable to form a continuous epithelial layer.

The requirement of a smooth, 2D surface for epithelial layer formation has been further demonstrated in the comparison of EEC seeded onto 2D and 3D collagen scaffolds [10]. REECs seeded onto 3D collagen scaffolds failed to show organisation into an epithelium, whilst REECs seeded onto 2D collagen scaffolds formed a single-layer epithelial sheet after 3 weeks of in vitro culture.

In the generation of smooth muscle tissue intended for tubular tissues, it is important that the scaffold aids orientation of the muscle tissue to maintain proper structure and to generate coordinated muscle contractions in the tissue-engineered oesophagus. RSMCs isolated from the aorta were seeded onto collagen scaffolds containing either non-organised or unidirectional polymer fibres [32]. Constructs were assessed at regular periods by immunohistochemical techniques up until

8 weeks post cell seeding. RSMCs were shown to retain their phenotype during prolonged periods of in vitro culture, with markers for α-smooth muscle actin still detectable after 8 weeks. Furthermore, RSMCs seeded onto non-organised collagen generated non-organised smooth muscle tissue, whilst smooth muscle cells seeded on to unidirectional collagen polymers generated orientated smooth muscle strands. Such orientation of myoarchitecture can be used to mimic the circular and longitudinal configurations of the native oesophagus.

These studies demonstrate the importance of the scaffold in tissue engineering. By providing feedback to the biomaterial scientists, novel materials are being developed, designed to overcome particular obstacles. For example, to promote cell attachment and proliferation of OEECs, an electrospun scaffold was fabricated with a nano-topography [48]. The creation of nanopores within the fibres increased protein adsorption by 80 % and increased surface area by 62 %, resulting in the adherence of significantly greater numbers of viable cells. Likewise, adhesion of EECs was also improved by grafting of fibronectin, an adhesive protein, on to PLLC scaffolds via aminolysis [49]. Such scaffolds also showed accelerated epithelium regeneration, enhanced mitochondrial activity of the EECs and increased collagen synthesis.

The next step in the evaluation of tissue-engineered oesophagus is implantation in the small animal model to assess survival of the construct, tissue regeneration and neovascularisation. Human EECs were cultured on the surface of a collagen gel, embedded with a PLGA mesh [50, 51]. The mesh was then sutured into a tubular structure with the hEECs on the luminal surface. Tubes were implanted in the latissimus dorsi muscle flaps of athymic rats. Rats were sacrificed at intervals from 4 to 28 days and studied histologically. After 8 days, fibroblasts infiltrated from the muscle, and within the collagen layer, neovascularisation could be observed. The epithelial layer continued to grow in thickness until resembling human oesophageal epithelium. Finally, staining for laminin confirmed the presence of a basement membrane.

An alternative strategy to the isolation and culture of the individual cell types is the use of organoid units. Organoid units are multicellular units containing a mesenchymal core surrounded by epithelium obtained through enzymatic digestion and mechanical agitation. In the rat model, polymers seeded with organoid units were cultured in an omental fold, followed by interposition of the polymer/organoid unit construct into an oesophageal defect [52]. The implant sight showed oesophageal tissue similar to that of native oesophagus, with a keratinised stratified squamous epithelial layer. A muscularis layer was present and stained positive for α-actin smooth muscle; however, the development was less than that of native oesophagus, with separate slips of muscle rather than a continuous layer.

As mentioned previously, the evaluation of constructs is traditionally conducted by histology after removal from the implant site. In order to evaluate the constructs in vivo, new techniques need to be employed. One such technique is that of in vivo microcomputed tomography (micro-CT). Tissue-engineered oesophagus constructs were imaged using micro-CT following implantation in rat, allowing for localisation of the position of the construct and construct dimensions [53]. In addition the surrounding tissue could be evaluated for inflammation, cyst formation and fluid formation. As in vivo micro-CT is a non-invasive method, the evaluation can be repeated at various time points to record the progress of tissue regeneration and allow comparison between different scaffold types or treatments (Fig. 32.6).

Whilst the small animal model is of importance in the initial evaluation of tissue-engineered constructs, it is limited by a lack of relevance to the human situation and the complicated nature of anastomosis procedures in such small animals. The most recent research has begun to transfer lessons learnt in vitro and in vivo, to large animal models, in particular the ovine, canine and porcine models which are of greater clinical relevance.

The large animal model can be used to reproduce partial defects, e.g. ulcers, or full thickness, patch and long-gap defects, e.g. oesophageal

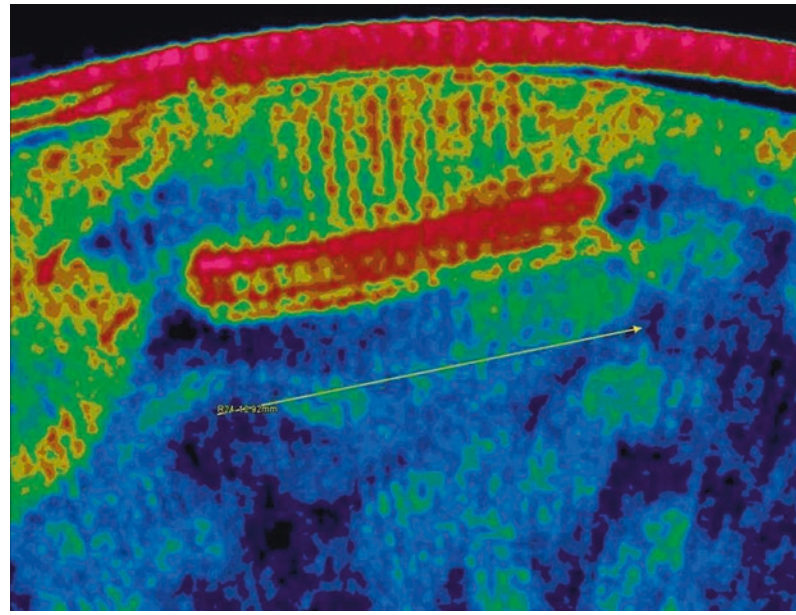

Fig. 32.6 Respiratory gated microcomputed tomography enables long-term evaluation of cell-scaffold constructs implanted in the omentum of small animals without sacrificing them. Image demonstrates a tubular stented construct in the rat abdomen 4 months after implantation

atresia. In the canine oesophageal ulcer model, tissue-engineered cell sheets were transplanted on to the underlying muscle layer at the ulcer site [54]. In cell sheet tissue engineering, cells are cultured in vitro on temperature-responsive tissue culture dishes. After forming a cell sheet, the temperature is reduced and the intact cell sheet may be removed. In the aforementioned study, cell sheets were created from canine oral mucosal epithelial cells. The transplanted sheets adhered to the underlying muscle layer resulting in complete healing and no observable stenosis. This was in comparison to the untreated oesophagi which showed fibrin mesh, inflammation and only intermediate stages of wound healing.

Whilst in this model, cell sheet tissue engineering without the use of a scaffold material has significant promise, in cases of full-thickness defects, a scaffold material is almost certainly required to provide structural support and guide tissue regeneration. In tissue engineering of the oesophagus, decellularised tissues have been the predominant scaffold material used in large animal model studies.

Small intestine submucosa (SIS) seeded with oral mucosal cells was used in the repair of patch defects in the canine model [55]. Patch defects, 5 cm in length and 50 % of the circumference, were created in the cervical oesophagus. Oral mucosal cells were isolated by separation of the epithelial layer through treatment with dispase, followed by dissociation of the cells from the epithelium with trypsin/EDTA. Cells were expanded in number through a series of passages followed by seeding onto single-layer SIS scaffolds. After 1 week of in vitro culture, the cell-seeded SIS and cell-free SIS were sutured across the defect and left for 4 and 8 weeks. The oral mucosa epithelial cells showed well spread morphology and covered the entire SIS scaffold after 1 week in vitro culture. After implantation, no serious complications were seen in either group. Dogs treated with SIS with oral mucosa epithelial cells showed a smoother lumen surface and a quicker regaining of weight in comparison with those treated with cell-free SIS. After 4 weeks, histological examination showed that the group treated with SIS with oral mucosa epithelial cells had a well-developed epithelial lining with only slight inflammation, whilst the cell-free SIS showed partial epithelial coverage and a large number of inflammatory cells. After 8 weeks, numerous long bundles of skeletal muscle had extended to the graft from surrounding muscle in the SIS with oral mucosa epithelial cells; however, in the cell-free SIS, many new blood vessels had formed,

yet few skeletal muscle bundles had extended onto the graft. No nerve fibre regeneration was observed; however, this was likely due to the relatively short duration of the experiment.

Human amniotic membrane has also been used as a scaffold for oesophageal tissue engineering, in this case, for repair of a 3-cm gap defect also in the canine model. Amniotic membrane was decellularised by treatment with EDTA and gentle scraping, was seeded with a mixed suspension of canine oral keratinocytes and fibroblasts and was cultured in vitro for 1 week [56]. After culture, amniotic membranes seeded with cells were sheeted on a polyglycolic acid (PGA) felt containing minced smooth muscle tissue, resected from the anterior wall of the stomach. The scaffolds were rolled around a polypropylene tube and wrapped within the canine omentum. After 3 weeks of abdominal implantation, the scaffolds were moved up, through the hemidiaphragm, into the thoracic space as a pedicle graft. The oesophageal defect was created and replaced with the tissue-engineered construct. The results show that after 1 week of in vitro cell culture, keratinocytes organised into a stratified layer upon the amniotic membrane whilst fibroblasts penetrated within. After the 3 weeks of abdominal implantation, the majority of constructs showed a well-differentiated luminal surface with smooth muscle-like tissue. In a small number of cases, degradation of keratinocytes and desquamation were observed. Finally, 1 week post-oesophageal replacement, strictures developed in the dogs treated with cell-free amniotic membrane control. In contrast, animals treated with the amniotic membrane seeded with cells showed no problems with passage and feeding, except for two cases of strictures which correlated with the cases of epithelial desquamation. The oesophagus in the tissue-engineered group was capable of transferring food to the stomach via peristalsis; however, there was an absence of peristaltic activity in the tissue-engineered oesophagus segment itself.

The porous areas of decellularised tissues result from the extraction of cells; however, such pore sizes are often inadequate for the ingrowth of microvessels after implantation [57]. Treatment with acetic acid and collagenase can be used to enlarge pore sizes and improve vascular ingrowth, although such treatments can also be detrimental to the stability of the tissue.

Other than decellularised tissue, few scaffold types have been applied to oesophageal tissue engineering in the large animal model. Recently, collagen sponges have been reported in the creation of a rudimentary oesophageal conduit in the adult sheep model [58]. The aim of this experiment was to create a hollow tubular construct similar in structure to that of the native oesophagus. Highly porous collagen sponges cross-linked with glutaraldehyde and preseeded with fibroblasts were seeded with cultured ovine oesophageal epithelial cells (OEEC), followed by a period of 48 h in culture to allow for cell attachment to the scaffolds. The constructs were then draped over sterile stents and closed by gently tying three Vicryl sutures looped around the construct (Fig. 32.7). The size of stent (an endotracheal tube) was matched to that of the native oesophagus to ensure the formation of a conduit with appropriate dimensions. The constructs were implanted into the omentum of adult sheep to promote vascularisation. Without a sufficient blood supply, implanted constructs will quickly become necrotic. Strategies for promoting neovascularisation of tissue-engineered constructs include fabrication of scaffolds combined with angiogenic factors, coculture with endothelial cells and implantation into an in situ bioreactor. The omentum is a highly vascular, fatty tissue, which has been used to provide vascular ingrowth in ischemic tissue and avascular grafts [59, 60]. As such, the omentum is well suited as an in situ bioreactor for tissue engineering of the oesophagus.

After a period of 8 and 12 weeks post-implantation, the constructs were removed for histological examination. The stented construct was well integrated within the omentum. After 8 weeks post-implantation, vasculature branches were observed developing around the construct. Cellular and vascular ingrowth was observed within the porous structure of the collagen scaffold, and no inflammation was noted (Fig. 32.8a). Also, OEECs were detected in patches along the

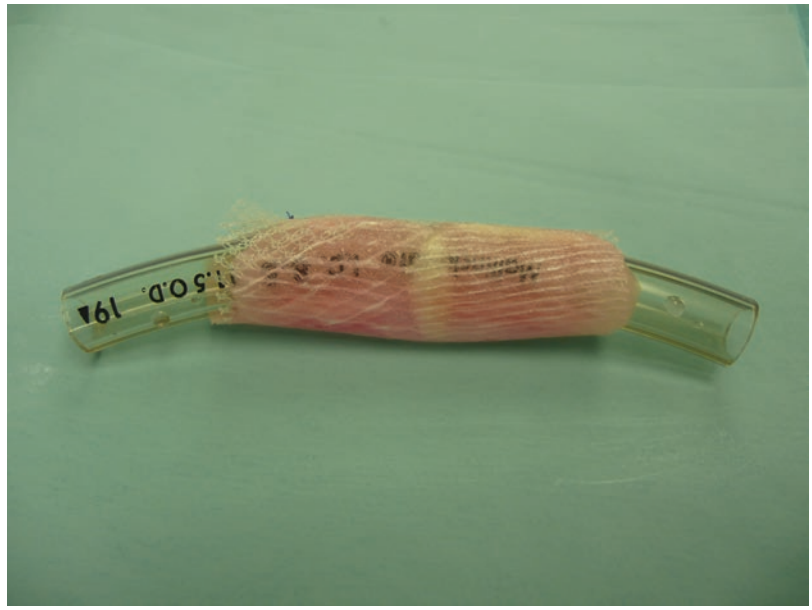

Fig. 32.7 Scaffold seeded with cells and sutured around a stent to create a tubular construct for in vivo or in situ implantation

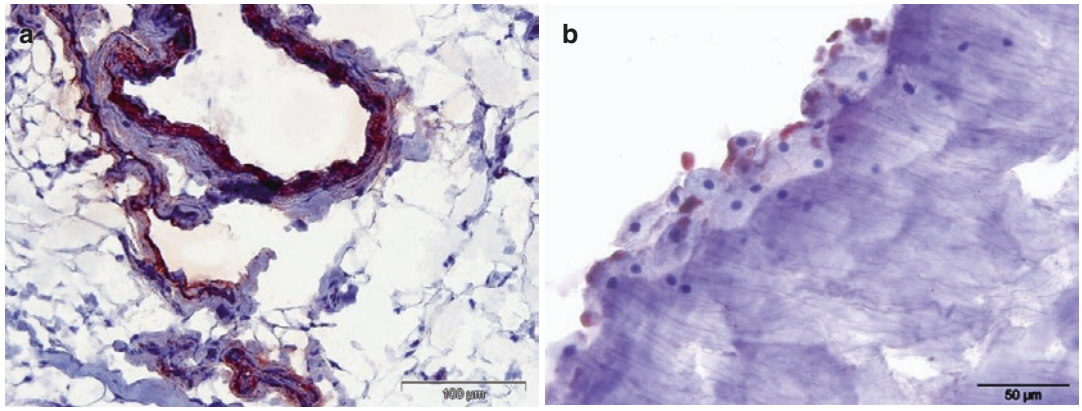

Fig. 32.8 (**a**) Vascular ingrowth into the implanted stented construct was evident at the time of explantation. Image demonstrates the immunohistochemical identification of vessel through smooth muscle actin and von Willebrand factor markers. (**b**) The luminal surface of the constructs demonstrated patches of ovine oesophageal epithelium. Image shows the inner layer of construct with ovine epithelium marked with pan-cytokeratin-26 markers

construct (Fig. 32.8b). By 12 weeks post-implantation, the implant demonstrated a hollow tubular tissue with a smooth inner lining similar in morphology to that of the native oesophagus (Fig. 32.9).

In the above-mentioned study, the scaffold was sutured to create a tubular structure. Tubular scaffolds can also be fabricated [61]. Whilst prefabricated tubular scaffolds benefit from the avoidance of suturing, and the convenience with which that entails, cell seeding of prefabricated scaffold tubes is technically difficult, accounting for low seeding densities and limited scaffold coverage. In the suturing of scaffolds for oesophageal tissue engineering, the selection of appropriate suture type and technique is of importance. The efficacy of different suture materials and techniques were investigated for porous 3D collagen scaffolds [62]. Collagen scaffolds, in both dry and wet states, were sutured using braided and monofilament sutures by continuous loop, interrupted loop, interrupted edge and continuous running edge sutures. It was observed that the suturing of dry scaffolds leads to tears during

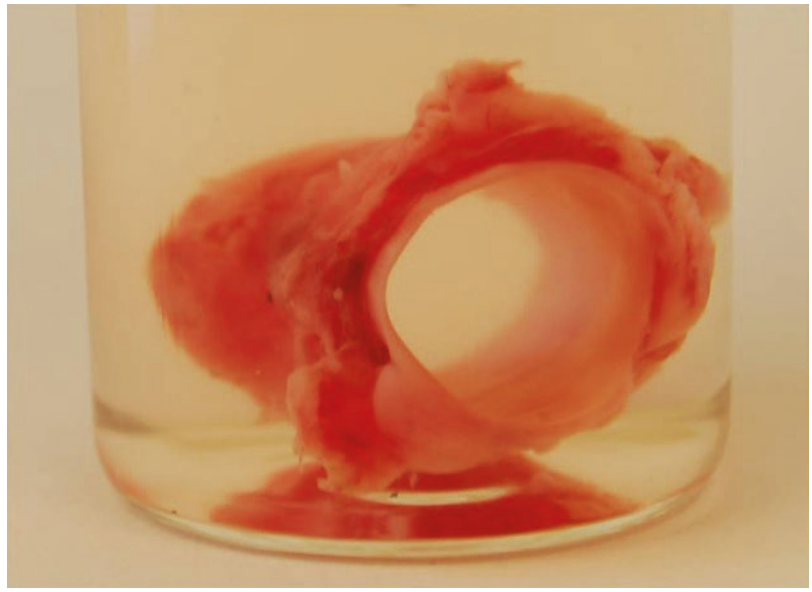

Fig. 32.9 Tubular construct after removal from the ovine omentum demonstrating the morphology of the rudimentary tissue-engineered oesophagus

knot tying and fractures when draped around a stent. Braided sutures caused friction during suturing resulting in tearing in both the wet and dry states, whilst continuous and interrupted loop suturing were limited by poor approximation of edges strangulation of the scaffold in the area of loop positioning, crushing of microarchitecture and distortion of scaffold morphology. Suturing of pre-wetted scaffolds with monofilament sutures using both the interrupted and continuous running edge suture was the most suitable technique, resulting in undistorted scaffold morphology with excellent edge adaptation. Between these two techniques, the continuous edge running suture was favoured due to the minimal use of suture material, which may avoid adverse tissue reactions [63].

Whilst many advances have already been made in tissue engineering of the oesophagus, further research is necessary, and a number of key obstacles need to be overcome. There is a requirement for development of a new generation of hybrid scaffolds and the application of stem cells. The continued increase of in vitro studies should be matched by an increase in the number of large animal model studies to allow for greater feedback for the polymer scientists and cell biologists. Finally, current tissue-engineered constructs remain as passive conduits, and therefore, future work must focus on the development of a functional construct, with a neurogenic component, that may become integrated into the peristaltic activity of the oesophagus.

Conclusion

To summarise, tissue engineering offers great potential for oesophageal replacement. Future research will focus on the improved design of scaffold materials for guided tissue growth and organisation, the development of protocols for the isolation, proliferation of oesophageal and stem cells and the optimisation of devices for prolonged in vitro culture [64]. Present research has enable generation of rudimentary forms of oesophageal conduits; however, enormous work and resources are still necessary to replicate and generate a functioning oesophagus.

Part VIII

After EA-Repair: Complications and Post-repair Issues

Overview: The Post-repair Issues and the Active Pursuit of Normalcy

33

John E. Foker

Introduction

The goal of this book is to help patients with esophageal and gastric disorders realize 70 or more good years, an admittedly stringent requirement. When starting life with a congenital defect as severe as esophageal atresia (EA), this goal is even more difficult to attain. The majority of patients with EA and a distal tracheoesophageal fistula (EA/TEF) have a shorter gap allowing an outwardly successful primary repair. Consequently, they are generally thought to be "getting along well." The longer-term follow-up reports, however, from Finland, the Netherlands, and Canada as well as smaller studies have revealed that many of these patients have related, residual problems [1–16]. In these series, the adult patients who had EA/TEF repaired as infants were often found to have dysphagia and/or the consequences of gastroesophageal reflux (GER), potentially significant obstacles to the goal of 70 good years (see also Chaps. 50: "Long-Term Follow-Up of EA/TEF Patients" and 52: "Follow-Up of EA Repair: The Helsinki Experience").

Most EA/TEF patients, nevertheless, believe they are doing well in terms of quality of life (QOL) unless these difficulties clearly impact on their well-being [3, 7, 9]. The generally positive responses to QOL questions by EA/TEF patients are similar to the relative optimism found in similar surveys of patients with other serious, chronic diseases. Despite this favorable opinion of their lives, many EA/TEF patients have significant problems both early and over the longer term which, in many cases, could be assessed and treated, improving the actual QOL.

The outlook is even less favorable, however, for infants who either began with a long gap (LG) between the esophageal segments or had a failed EA/TEF repair which converted a short-gap EA to a long-gap problem. Patients, with either primary or secondary long gaps, comprise the difficult end of the EA spectrum and pose great difficulties for the pediatric surgeon.

Currently, a patient with a moderately long gap which is felt to preclude a true primary repair may have some combination of esophageal myotomy and/or partial gastric pull-up to make an anastomosis possible. If the esophageal defect is even too long for that approach, continuity will be established when the child is older and larger, usually by either a gastric pull-up or a colon interposition graft. These solutions allow the LG child to eat, but, interpositions are not functionally reliable and the problems with them typically

increase in number and severity with time, making it unlikely that the long-term goal (70+ good years) will be reached.

We have presented, in contrast, the surgical approach which will induce catch-up esophageal growth so that both primary and secondary LG-EA patients can have a true primary repair with no myotomies and the GE junction below the diaphragm [17–20]. The resulting, newly grown esophagus appears normal structurally and has allowed a primary esophageal anastomosis to be reliably achieved. Overall function which includes lower segment dysmotility is, nevertheless, satisfactory and has resulted in normal eating [20–22] (Table 33.1) (see Chaps. 25 "Growth Induction"; 40 "The Reoperation").

Follow-up studies of the LG-EA patients have indicated that they may also have related problems such as GER and dysphagia which can produce difficulties. Consequently, we have actively pursued normalcy in the early postoperative period by assessing and treating any remaining repair-related issues. By this active approach, the potentially long-term problems can be identified and largely prevented from producing chronic disease.

Our working hypothesis has been that if the problems following a primary LG-EA repair are effectively treated early, they will be less likely to persist or even reappear later. This approach may also have value for a patient with the much more common EA/TEF repair who has one or more related problems. With an active follow-up and effective treatment of any difficulties that appear weeks or even months after repair, we believe the patient's QOL from an esophageal standpoint should remain favorable far into adulthood.

Table 33.1 Growth induction follow-up

External traction (initial gaps 5.8 ± 1.9 cm)	
Questionnaire answers (28/36 returned)	
Results >3 years after primary repair	
Eat normally for age	27/28
Occasional g-tube supplementation	3/28
PPI medication	5/28
Possible reflux	4/28
Pulmonary symptoms	0/28

Problems After a LG-EA Primary Repair

The considerable advantages in eating for LG-EA patients following a primary esophageal repair are clear. The growth method, however, may have postoperative problems that deserve attention. Roughly in order of frequency are gastroesophageal reflux (GER), strictures, and aspiration (pulmonary problems), as well as nutrition, airway, and skeletal issues which may complicate the outcome of the growth approach for LG-EA [17–20]. Reflux and strictures are the most common and, if untreated, are likely to produce problems even into adulthood. Consequently, we carry out early evaluation and any necessary treatment to prevent the patients from slipping into a state of chronic illness.

Aspiration may result from any combination of GER, strictures, an aperistaltic colon or gastric interposition graft, or the presence of a residual or untreated pouch in the tracheal membranous septum. The consequences of aspiration may be serious either acutely (pneumonias) or chronically by producing significant lung injury. Chronic lung damage can be insidious as well as a serious consequence. Whenever suspected, the presence of aspiration should be assessed, and the cause, if found, should be effectively treated.

There are other possible problems that are also secondary in nature. Continuing gastrostomy tube feeds may be necessary to avoid malnutrition until eating by mouth becomes established. Airway problems may be significant, and even moderate tracheomalacia can lead to air hunger and apneic spells. Skeletal problems can be acquired, usually from sequelae of the thoracotomy incisions or may be congenital in origin such as the vertebral and rib anomalies.

The great majority (>90 %) of LG-EA patients that came to Minnesota already had one or more failed attempts at repair, further complicating what was required to eventually achieve normalcy. These patients came from many other centers which also revealed that wide variation exists in the diagnostic criteria for these issues and in the treatment plans for them. GER and strictures occur in a spectrum of severity, and the clinical

variety was matched by the differences in judging their significance as well as in the therapies formulated. The same diagnosis and treatment variations were found regarding aspiration, pulmonary issues, and the consequences of tracheomalacia which may occur after LG-EA repair. Add to these the differing experience and capability of the practitioners, and it is understandable why therapies vary widely and meaningful comparisons of results are difficult.

The purpose of this chapter, therefore, is to present our approach for the LG-EA patient after a period of growth and a primary anastomosis. Our approach, which was developed at the University of Minnesota, evolved to meet the circumstances and problems encountered and was not derived from evidence-based medicine. The variety and complexity of these patients would certainly defeat any attempt at controlled studies. The final judgments about our approach, however, will only come with the passage of considerably more time as the longer-term results become apparent. Nevertheless, the results to date of the early identification and active treatment of related issues have been very encouraging with the great majority of our LG-EA patients eating normally and free from most residual symptoms [19, 20] (Table 33.1).

Gastroesophageal Reflux

Following LG-EA repair, GER is the most important complication because of its common occurrence, frequent severity, and difficulty in achieving effective control despite the many treatment options. The concerted efforts among acknowledged experts to set up guidelines for GER evaluation and treatment, notwithstanding, a relatively uniform approach has not emerged and local methods and individual experience often dominate [23]. As a result, there has been a surprising lack of consistency across centers in deciding how much GER is too much and how it should be treated.

Even during the esophageal growth period, reflux into the lower esophageal segment could be injurious and produce ulcerations. Reflux was minimized, therefore, by keeping the patients on hyperalimentation for nutrition and by elevating the head of the bed to at least 30°. Proton pump inhibitors (PPIs) were given to reduce the acid content (the gastric pH was kept greater than 5), although bile reflux could not be prevented. Following the primary anastomosis, this regimen was usually maintained until the decision regarding a fundoplication was made. After the fundoplication, oral feeding, more accurately, the efforts to encourage learning to eat, was promptly begun and usually the antacid therapy (PPI) continued for another 1–2 months. Once back in the home area, PPI therapy might be continued without clear rationale.

There are structural and functional reasons why GER is almost always significant after a primary repair of LG-EA. The lower esophageal sphincter (LES) often appears to be virtually absent as an anatomic and functioning unit prior to growth induction. Initial contrast studies frequently show the distal esophagus to be broad based without any narrowing above the stomach, suggesting a physiologic GE junction is not present (Fig. 33.1). And, at the most extreme end of the EA spectrum, the lower segment may be nothing more than a primordial nubbin with an uncertain potential for

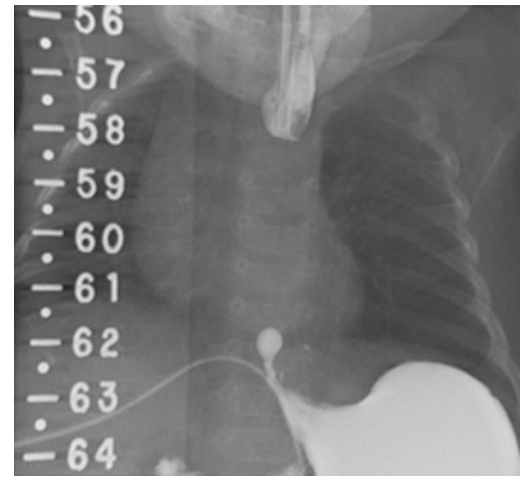

Fig. 33.1 Contrast study of long-gap esophageal atresia prior to growth induction and repair. The lower esophageal segment is notable for a very broad base at the junction with the stomach, suggesting very little or no functioning tissue which would hinder reflux

developing a structural GE junction (see Chap. 25: "A Flexible Approach", Figs. 14a and 15a, b). Axial tension will reliably induce growth and produce a structurally outwardly normal lower esophagus; however, nothing is known about its effects on the development of a functional GE junction [21, 22].

The development of a barrier to GER takes 5–7 weeks after birth even in the normal child. The well-described motor dysfunction of the lower esophagus after straightforward EA/TEF repairs allows increased reflux, and, in one study, the incidence of GER continued to increase for at least 3 years following repair [6, 9, 10, 24–27]. It is unknown whether or not a functional GE junction would develop even over a much longer time period in LG-EA patients following growth induction [23]. Based on the degree and frequency of GER after a primary LG repair, it is likely the specialized area of the gastroesophageal sphincter would, at best, be very slow to develop.

For virtually all repaired EA patients, whether long or short gap initially, the peristaltic wave which begins in the cervical esophagus does not pass through the anastomotic site. Normally, peristalsis is largely propagated within the syncytium-like muscular layer and is easily stopped by nonconducting fibroblasts and myofibroblasts at the anastomotic site. Furthermore, what segmental vagal innervation is present in the lower esophagus is not sufficient to reliably restore effective peristalsis below the anastomotic line. Esophageal function below the anastomosis, or below the highest myotomy, will typically consist of only sporadic contractions on manometry studies. In addition, because of the dysfunction, there will be little barrier to reflux, and the ability to clear the lower esophagus will also be impaired [25–28].

There are three main consequences of GER, of which progressive inflammation leading eventually to Barrett's changes is best known [1, 28–34]. Unchecked, the metaplastic changes described by Barrett are precancerous, and reflux, as a type of environmental carcinogen, can begin to result in cancer forming about 15–20 years later. Because of the importance of this detrimental progression, it has been well described in other chapters (Chaps. 72: "Pathophysiology" and 73: "The Esophageal Mucosa").

The other two consequences are also of importance to EA patients and infants in general. Significant GER may reach well above the level of the carina making aspiration likely. Pulmonary symptoms and even infections may be the most important consequence requiring fundoplication in infants with or without EA [35–41]. Pulmonary symptoms from aspiration in EA patients may also result from strictures, tracheomalacia, or a recurrent diverticulum or fistula. The presence of pulmonary problems requires a careful evaluation to establish and effectively treat the cause.

Finally, GER also produces an unpleasant sensation which the infant cannot verbalize but often responds to by refusing to eat. GER may, therefore, be an important component of oral aversion. Although the discomfort of GER is usually reduced by antacid therapy, bile may also produce a less symptomatic inflammation and the sensation of reflux often remains [28, 31, 33]. Learning to eat may also be complicated by the presence of a stricture with dysphagia. These adverse functional consequences of repaired EA, as well as the fact that the instinct to eat has faded, are more than enough reasons why learning to eat can be slow and difficult.

The connection must be made between being hungry and eating. The presence of one or more of these negative functional components, together with a vanished instinct to eat, may make efforts to teach taking and swallowing of food arduous. Why one should put food in one's mouth is not obvious and if it does not pass easily into the stomach and/or brings the unpleasantness of reflux, it may be resisted. Oral aversion would seem to result from some combination of these factors, rather than being a specific mechanism.

Establishing the connection is greatly helped by stopping gastrostomy feedings for 2 or more hours before offering liquids by mouth. Nighttime infusions by g-tube should be stopped at least 4 h before the morning attempts at oral feeding. They need to be hungry for the connection to be made. Patience will be required for the many attempts

needed, but once the connection is made, our experience has been that the learning usually proceeds very quickly and the children will soon dislike g-tube feeds (see Chap. 45: "Learning to Eat After EA Repair").

All of these issues, if linked to GER, we believe, make a strong case for an anti-reflux procedure (usually a fundoplication). The GER will be controlled and the consequences eliminated. In addition, if necessary, feeding through the gastrostomy tube will be more easily available to prevent malnutrition.

Fundoplication After LG-EA Repair

The LG-EA patient after primary repair usually presents a difficult problem, both in the severity of the GER and in achieving effective and durable surgical anti-reflux treatment. A primary repair of a true long-gap lesion, even after a period of induced growth, may still require an anastomosis under some tension. As a result, the GE junction will usually be pulled up tightly against the diaphragm at the hiatus, hindering creation of the fundoplication.

GER in LG-EA patients, as opposed to otherwise normal infants and after most EA/TEF repairs, will be unlikely to resolve on its own; consequently, we have favored early evaluation and treatment [6, 18, 19]. LG-EA patients were studied about 3 weeks after the primary repair by an esophagram done in a semi-upright position to assess both the anastomotic site and the amount of GER. If free reflux to the carina and above was present on the contrast study, we usually recommended a fundoplication. Although early fundoplication precluded determining whether or not the GER would resolve on its own, a functional LES seemed unlikely to eventually develop [16, 19]. The incidence of significant GER has been observed to double from 6 months to 1 year following EA/TEF repair and was greater than 50 % after 5 years [6]. Not only would a wrap reduce the inflammation and stricturing effects, it would also remove the reluctance to learn to eat.

We realized the standard approach would be to wait much longer before recommending a fundoplication; however, a wrap solved these post-repair issues and put the patient and family on the path to normalcy. Our approach also avoided long-term medical GER treatment which incurs significant cost, requires continuing clinic visits, may have side effects such as bone and muscle weakness, and, very importantly, conveys to the child and family a state of chronic illness [42–46]. Furthermore, the adverse consequences of GER are often difficult to determine by symptoms, potentially giving a false sense of security [47]. The seriousness of Barrett's changes over 15–20 years should not be doubted, however, as even cancer of the cervical esophagus has occurred in gastric pull-up patients.

A fundoplication in EA patients, however, might produce its problems. The wrap tends to create a partial obstruction, which may, potentially, further decrease effective esophageal function and the ability to eat. As with adult patients, a partial wrap has been advocated to avoid producing a degree of obstruction [48]. We, and others, have found that a more common problem with fundoplications is that the wrap may loosen with time and has been reported to become ineffective in about 33 % of EA patients [49–52]. Although paraesophageal herniation has been cited as the most common reason for the failure of fundoplications, we have found loosening of the wrap itself is, by far, the most frequent reason for recurrent reflux [52]. The reported difficulties with fundoplications both in EA patients and otherwise normal children have tempered recommending them in many centers [50–53]. Similar difficulties have also been reported with the redo-fundoplication [54, 55]. Our experience, nevertheless, has found them very beneficial to the repaired LG-EA patients even though some fundoplications were too tight initially or, more commonly, loosened later and required redoing in about 20 % of cases. These problems can be solved, allowing the substantial benefits of a barrier to reflux to emerge.

The technique of loosening a fundoplication by endoscopy will be described. For wraps that became too loose, reoperation restored the anti-

Table 33.2 Learning to eat after growth induction LG-EA repair

reflux function, although in a few cases, a third wrapping was required. Despite the potential contribution to esophageal dysfunction by the fundoplication, the sporadic contractions together with the effect of gravity will result in satisfactory emptying, and for these children, eating will be normal (Table 33.1) [19–22]. Furthermore and remarkably, these children have learned to eat after fundoplication at the same rate as normal children do after birth despite the severity of their initial EA defect [20] (Table 33.2).

The principles and results of fundoplication for GER have been well presented in several chapters (see Chap. 43: "Surgical Considerations of GE Reflux Pre and Post EA Repair") and also chapters on non-EA patients (Chaps. 92: "Gastroesophageal Reflux: From a Surgeons Perspective"; 93: "The Spectrum of Surgical Anti-reflux Procedures" and 94: "Minimally Invasive Fundoplication").

The Technique of Fundoplication in LG-EA Patients

To accomplish a satisfactory fundoplication after growth induction for LG-EA, the following operative approach has been used. Through a short left subcostal incision, the left lobe of the liver is mobilized after dividing its ligaments and retracted to the right which reveals the stomach and diaphragm. After a growth procedure and later anastomosis, the GE junction and gastric fundus will usually be tight against the diaphragm, seeming to make it difficult to expose a 2–3 cm length of esophagus. The GE junction may be unapparent but can be reliably located at the very upper margin of the lesser curvature. The vagal branch to the liver and gall bladder arises at a right angle from the vagus nerve and together with a small vein crosses and identifies the GE junction and then passes over the quadrate lobe on the way to the liver hilum. This vagal branch is easily recognized and spared by keeping the dissection above it. If the wrap is done above the nerve, it will be around the esophagus and not the stomach.

To aid in bringing down the GE junction and exposing a length of esophagus for the wrap, a 4-0 or 3-0 Prolene suture is placed around the presumed GE junction by taking very superficial tissue bites just above the nerve (Fig. 33.2). The suture is tagged and placed on traction which will aid in bringing below the diaphragm a 2–3 cm length of esophagus (Fig. 33.3). The crura of the hiatus are identified and 4-0 Tevdek sutures used to narrow the opening by taking generous bites of muscle with careful tying of the sutures to avoid tissue necrosis. Pledgeted sutures are used if tissue quality seems poor. The wrap can then be constructed around the esophagus.

Sizing the Fundoplication

We prefer a relatively tight fundoplication because recurrent reflux from wrap loosening was by far the most frequent important problem that developed. To size the hiatal closure and the subsequent wrap, a nasogastric tube was passed down into the stomach; a 14 Fr nasogastric tube would be used for patients up to a year of age and a 16 Fr tube for 1 to 2 year olds.

An important reason for wrap loosening was retching caused by overfeeding through the g-tube. To minimize stress on the fundoplication, when retching first begins, the feeds were stopped and the g-tube quickly vented to decompress the stomach and remove the stimulus to vomiting. Parents were instructed to carry out these maneuvers as quickly as possible with the onset of retching to stop the forceful abdominal contractions which loosen the fundoplication.

If the fundoplication seemed too tight after attempts at feeding or even inability to swallow saliva, it was loosened, but only rarely actively

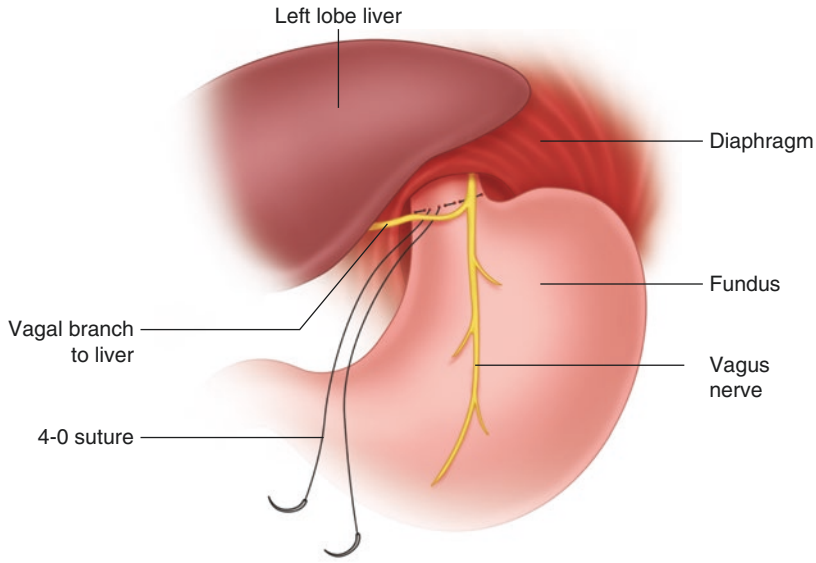

Fig. 33.2 Diagram of a stomach pulled tightly up against the diaphragm after an esophageal growth procedure and primary repair. This consequence makes a fundoplication more difficult to create. The esophagus must be dissected free and mobilized for the fundoplication. An important landmark is the vagal branch to the liver and gall bladder which crosses at the level of the GE junction. If the dissection is kept above this branch, the wrap will be around the esophagus. The first step is to take superficial tissue bites with a 4-0 Prolene suture around the esophagus above the vagal branch as shown

dilated. Under general anesthesia with an ET tube in place, an extra stiff wire was passed either up from below through the gastrostomy site or down from above through the oral pharynx to guide a smaller 6–8 mm (4 cm long) balloon. With the balloon fully inflated (4 ATM), it was pulled or pushed to cross the fundoplication. If it would not cross without significant force, the balloon was gradually deflated until it would pass. The process was repeated with the diameter of the balloon increased by 2 mm increments up to at least 10 mm. To finish the loosening, the balloon was pushed or pulled across the fundoplication one last time.

Most of the time, with the first attempt, a 10 mm balloon was able to be pulled or pushed through the fundoplication, even in very young children. A smaller balloon was only used when the distal esophagus was smaller than 10 mm in diameter. The amount of force used to push or pull a balloon through the fundoplication was subjective, although more force was needed pushing from below. It might take 10–20 s pulling/pushing on the balloon before it would slide through, particularly with a recently constructed fundoplication. Very occasionally, the balloon was inflated within the fundoplication to dilate it, but only when the amount of force required to pull it through seemed too great.

These simple techniques have proven surprisingly effective in slightly loosening, but not disrupting, a too-tight fundoplication. This method was devised and routinely carried out successfully by Charles Dietz MD, Chairman, Department of Radiology, University of Minnesota Medical School.

Anastomotic Strictures

There are several reasons why a stricture develops at the anastomotic site. The circular nature of the anastomosis sets up the geometry of a stricture, and healing will necessarily be accomplished by myofibroblasts. For the LG-EA patient, tension on the anastomotic site is often present, and the distractive forces would logically make a thicker ring of healing with greater potential for contraction.

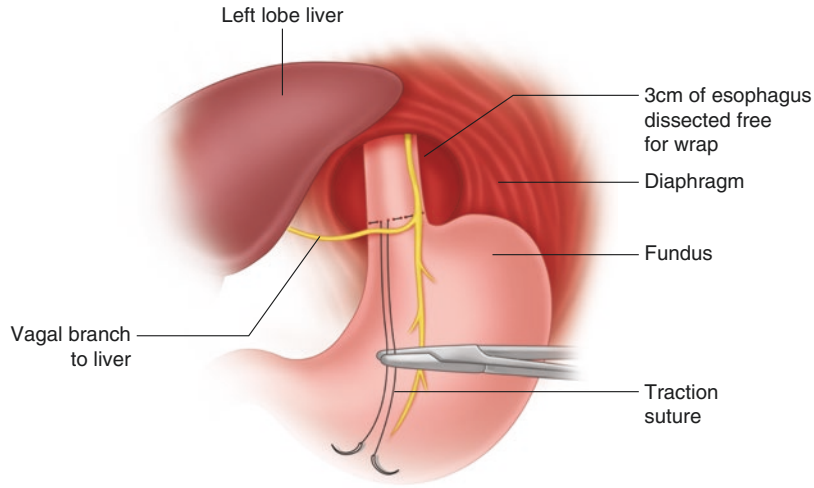

Fig. 33.3 The circumferential suture is tagged, and with downward traction, the lower esophagus is dissected free as shown. When a 3 cm length is freed up, the hiatal opening is reduced by suturing the crura and a standard wrap carried out. The smaller hiatus keeps the wrap and GE junction within the abdomen. The traction suture is removed

Tension on the anastomotic site may also produce an effect resembling a finger pull toy in which pulling on each end narrows the center, reducing the diameter of the anastomosis.

The much greater tendency of LG-EA patients to develop GER will also lead to increased inflammation and fibroblast differentiation at the site. The healing anastomosis normally contains a lot of cellular activity which will be increased by the cytokine products of inflammation. Cytokines trigger fibroblast differentiation into contractile myofibroblasts which also lay down a contractile collagen; both contribute to building a stricture. With the anastomosis under tension, and somewhat distracted, a longer time will be also needed until the area is covered with mucosa and the inflammation reduced.

All of the preceding factors tend to produce a stricture which narrows the lumen (see Chap. 37, "The Biology of Stricture Formation").

The Treatment of Strictures

The goal of therapy is to both reverse the obstructive narrowing and allow the structuring process to relent which it will naturally do as the stimuli recede. A durable, generous sized anastomotic site should be the result. Dilations were usually begun after the GER was controlled by a fundoplication because effective treatment of a stricture is difficult if significant reflux is present. Although one must respect the recently constructed anastomosis, we began to gradually enlarge it by very gentle balloon dilations as soon as 3 weeks after primary repair. Early, before dense scarring develops, the anastomotic area can be more stretched than split.

The mucosal layer, however, may not be intact at the site, and the dilations should avoid disrupting the ingrowing mucosa as much as possible. Traditional push-through dilators of the Maloney or Savary type produce a shearing action, denuding the area more than a carefully done balloon dilation. By adjusting the balloon pressure during inflation, the vigor of the dilation can also be modified, making the mucosal injury less. These considerations favor more frequent (weekly or biweekly) but less vigorous dilations which will allow a normal contour to be achieved without excessive splitting and scarring of the esophageal wall and with minimal disruption of the mucosal layer.

If one waits to dilate until the patient becomes symptomatic and the lumen quite narrow, then one is, in effect, starting over each time and the dilation must necessarily be more traumatic.

An incremental and less damaging enlargement of the anastomotic site will allow the stricturing tendency to relent while slowly increasing the lumen diameter. To begin the dilations, a 10 mm balloon was passed through the anastomosis or it

would be dilated first. The balloon diameters were gradually increased until they were 2–3 mm larger than the esophagus above and below the strictures. The over-dilation will allow the esophagus to accommodate passing solids normally. By continuing the dilations until the esophageal lumen was normal in contour and remained stable, the patients were commonly free from even mild stricture symptoms [19, 20]. Stability of the anastomotic site opening can be demonstrated by a contrast esophagram done 2–3 weeks after the last dilation.

For the more difficult strictures, other methods are evolving. The short-term placements of stents, the use of the dynamic stent, and even incisions with a cutting cautery knife are showing promise. In addition, injections with steroids or mitomycin C may be used, although their effect seems limited. These methods are continuing to evolve and their value will be expected to increase with time (see also Chaps. 38: "Pathobiology and Treatment of Strictures" and 39: "The Dynamic Stent").

Not all strictures, however, will respond completely to these measures alone or in combination. During this time, the patient will be out of the hospital and returning for the dilations; nevertheless, these procedures and the stricture itself may interfere with the child's overall progress and certainly will convey an image of chronic illness. Dilations should not be continued indefinitely without signs of improvement. The judgment of how much swallowing difficulty should be tolerated will not be uniform among practitioners nor will the treatment recommendations. The decision that a stricture is truly recalcitrant and treatment will not be effective no matter how long it is continued will vary from center to center.

The stricture should either relent after a number of dilations or it may make sense to recommend resection. This decision will depend on the length and severity of the stricture, the experience and capability of the surgeon to carry it out, and, of course, the willingness of the family to have another operation performed.

Anastomotic strictures are typically relatively short in length (1.0–1.5 cm), and the esophagus above and below will have grown sufficiently so the reanastomosis can be generous in size and the resulting tension mild or, at most, moderate. It is important to realize, however, that the esophageal ends will retract and what was visualized to be a 3 cm gap will be 6 cm in length. This predictable gap increase has led to the frequent use of additional, undesirable methods such as partial gastric pull-ups and circular myotomies to make the anastomosis less daunting.

For the long stricture, growth induction of the normal esophagus above and below by a staged growth procedure has been very effective even for lesions seemingly beyond the possibility of complete resection and primary repair. Resection of a stricture, whether short or long, requires sufficient surgical expertise to achieve a satisfactory result (see Chaps. 41: "The Redo Operation" and 42: "Growth Induction for Long Strictures").

Once the stricture resection and reanastomosis is accomplished, a series of postoperative dilations will be needed beginning 2–3 weeks later. The circular anastomosis after the resection will also have a tendency to contract; however, only two to three dilations are typically needed after complete resection for a stable result.

Aspiration

Aspiration is an important symptom with more than one potential cause in LG-EA patients. Anything which interferes with esophageal emptying will cause backup and aspiration leading to acute problems including pneumonia and, importantly, to chronic lung damage. There are several possible causes including significant GER, a stricture, or a residual tracheal diverticulum, and more than one may be operative. GER is a well-known cause of aspiration and pulmonary problems even in normal infants [35]. Aperistaltic, dilated colon, and gastric interposition grafts are among the causes most likely to produce significant lung injury with severe long-term consequences. Because of its seriousness and the various possible causes, the presence of aspiration should lead to a systematic evaluation to arrive at an appropriate treatment plan. Again, it is a serious symptom, capable of significant injury and problems and when present requires attention.

Airway and Skeletal Problems

Several airway and skeletal problems are associated with LG-EA lesions and repairs. Tracheomalacia, presumably caused in part by the dilated upper pouch of EA, is well known. The presence of a diverticulum in the posterior tracheal membrane, whether an isolated anomaly or left after an EA/TEF repair, may also produce significant infectious pulmonary consequences.

Because of the specialized nature of these problems, they have been covered in specific chapters (see Chaps. 12: "Skeletal Anomalies"; 40 "The Redo Operation"; 46: "Apparent Life Threatening Events" and Cossi; 49 "Tracheomalacia and the Effective Aortopexy").

Summary

Our continuing follow-up studies support this active overall treatment plan. All patients who have returned for our ongoing evaluation ($n = 15$) had a normal esophageal contour, and the anastomotic line was not discernible (Table 33.3). Importantly, these children generally eat whatever they wish and do not need to cut the food into tiny pieces. By questionnaire, 27/28 parents said their child eats normally and has no signs or symptoms of swallowing difficulty (Table 33.1).

These results do not prove this treatment plan should be followed; however, it certainly provides evidence for its value. All of the LG-EA patients had very long gaps initially, and a period of external traction and growth was necessary to allow a true primary repair. Despite the time required to achieve adequate esophageal growth and later to resolve the various issues, the patients were on a path to normalcy in terms of their esophageal defect. The children will not remember the procedures and treatments, although the parents will. Without growth induction and the development of an outwardly normal esophagus, they would have faced a very uncertain future.

We have acknowledged this approach was developed without controlled studies; however, it has been based on the observation and treatment of many patients. The result has been that the great majority of Minnesota LG-EA patients are of acid-inhibiting medications, are able to eat at a normal pace, and are free from long-term stricture-related symptoms (Table 33.1) (Chap. 52: "The Minnesota Experience with LG-EA"). Very importantly, they do not carry the emotional and developmental burden of chronic illness with frequent clinic visits, juggling of medications, and somber discussions about their current health.

Table 33.3 Growth induction EA repairs clinical evaluation ($N = 15$)

Traction method: external 12, internal 1, both 2	
Esophagram	
Normal contour	15/15
Endoscopy	
Gastric mucosa >2 cm above LES	2/15
No visible esophagitis	15/15
Appearance normal	15/15
Biopsy: mild esophagitis	2/15

Even though the defects of esophageal atresia (EA), and especially LG-EA, often pose difficult problems, solutions can be chosen which create a close approximation of normalcy. Virtually, all children from our series who are 10, 15, and more years from esophageal repair are outwardly normal from an eating standpoint. Furthermore, because the anatomic and physiological principles underlying this approach achieve, as closely as possible, the normal state, there seems to be no reason to expect later deterioration. This outlook, in contrast to more palliative solutions for LG-EA such as a gastric pull-up or colon interposition, often brings greatly increasing problems with time.

This long range view, however, may pose difficulties for the surgeon whose time line is often much shorter and aims for the patient to have a relatively quick discharge without unacceptable early postoperative complications. Unfortunately, for LG-EA patients treated by growth induction, a short length of stay will be uncommon; however, it will be the approach that places the child on a path to 70 good years. To maximize the chance of the patient reaching this goal, the guiding principle should be to make the end result of treatment as close to normal as possible.

34 Evaluation After EA Repair: Endoscopy, Ultrasound, and Function

Khalid M. Khan

Introduction

This chapter focuses on the use of upper endoscopy or esophagogastroduodenoscopy (EGD) in patients with esophageal atresia (EA), with or without a tracheoesophageal fistula (TEF). The typical indication for endoscopy is to investigate upper gastrointestinal (GI) and respiratory symptoms in patients who have undergone EA repair. Diagnostic findings may include gastroesophageal reflux (GER), esophagitis, Barrett's metaplasia, and anastomotic narrowing. Endoscopy is useful for assessment of fistulas and diverticula, estimation of lower esophageal sphincter (LES) dysfunction and/or adequacy or "tightness" of a fundoplication, or disordered motility that is seen in patients with a history of EA repair. Therapeutic endoscopy may involve dealing with food impaction, potentially addressing fistulas or leaks and management of anastomotic stenosis (covered elsewhere in this book).

We have found endoscopy to be of particular value in infants with long-gap EA (whose esophageal gaps exceed 2.5 cm) in the pre- and perioperative period. EA, with or without a TEF, is an uncommon pediatric surgical problem [1]. Most esophageal defects are small; primary repair is usually possible soon after birth. But long-gap EA is more challenging, with no single agreed-on technique for repair [2]. The methods commonly used involve either esophageal lengthening or esophageal substitution with an intestinal segment or gastric transposition [2].

Over the last two decades, we have developed a technique at our institution to salvage the esophagus in children with long-gap EA [1, 2]. Most of them have additional morphologic issues, which often need to be addressed simultaneously with their esophageal problems. Not surprisingly, a large proportion of them have type A, or pure EA, in which the lower esophageal pouch may be diminished and difficult to use for primary repair.

The technique involves traction to grow the esophagus so that a primary repair can be performed. Our overarching belief is that the patient's own esophagus should be preserved.

In this chapter, we have focused on upper endoscopy technique and important considerations in small children and how we have further adapted standard techniques in infants with long-gap EA. We use endoscopy from the initial assessment of these patients, then throughout the repair process as well as during follow-up. We also discuss the potential luminal pathologies in this patient group and how endoscopy can be useful.

Endoscopic Procedures

Preparation

In describing the procedure, we have focused on the nuances of endoscopy in infants and small children and how it pertains to the EA population. Routine EGD in older children and adults does not differ significantly from the normal population apart from taking into consideration childhood problems that persist (as noted here). Preparing patients for any procedure requires obtaining a history and performing a physical examination and taking care to review comorbid conditions along with upper airway and respiratory status. Infants with EA may have additional issues related to the VATER (*v*ertebral defects, imperforate *a*nus, *t*racheo*e*sophageal fistula, and *r*adial and *r*enal dysplasia) complex. Asking for informed consent from the patient (or parent or guardian) is mandatory [3].

Emotional and psychological preparation of pediatric EA patients (and parents or guardians), including counseling, may help them tolerate the procedure [4, 5]. No data specifically support such preparation in EA patients; however, one study that randomly assigned some pediatric patients to psychological preparation found that they had significantly less anxiety before, and greater compliance during, endoscopy; they also required less sedation [6]. For young children, the presence of a parent until sedation begins is helpful in allaying anxiety; similarly, locally applying anesthetic skin cream before placing an intravenous (IV) line and premedicating children with oral benzodiazepines can significantly allay anxiety [7].

Before undergoing endoscopy or anesthesia, an oral fast is standard. Guidelines in the United States regarding children have been developed by the American Academy of Pediatrics (AAP) and regarding adults, by the American Society of Gastrointestinal Endoscopy (ASGE) [8]. Gastric emptying times do not necessarily correlate with fluid volume in the stomach [9]. Despite fasting, the interval before endoscopy should be a minimum of 2 h for clear liquids, in order to reduce the risk of pulmonary aspiration [10]. In patients with suspected ileus or gastric delay, precautions are needed during induction of anesthesia. Gastric emptying can be delayed in children with EA. In our population of EATEF, we have noted gastric delay in 10–15 % of infants.

Bacteremia is unusual in healthy patients undergoing diagnostic endoscopy, and children may be less susceptible [11]. In a survey of 16 North American pediatric endoscopy centers, most endoscopists restricted use of prophylactic antibiotics to patients undergoing percutaneous placement of gastrostomy tubes and to patients with moderate-to-severe structural heart disease, which is associated with a risk of bacterial endocarditis [12]. Those restrictions are in keeping with guidelines established by the American Heart Association (AHA) and by the ASGE. Bacteremia does occur with esophageal therapeutic procedures, yet it appears to be transient [13]. Antibiotics may need to be considered in EA patients undergoing therapeutic procedures, but their use must be individualized; complex cardiac defects are also an association with the VATER syndrome and a thorough evaluation of the cardiac defect is prudent prior to endoscopy.

Sedation or Anesthesia

In adults, routine upper endoscopy is rarely performed under anesthesia; instead, sedation (with careful monitoring) is standard. In children, guidelines detailing sedation and monitoring during endoscopy have been published, including by the AAP; such guidelines likely determine clinical practice, at least in the United States [5, 14, 15]. *Conscious* sedation is defined as a state in which patients retain the ability to respond to verbal commands, i.e., the respiration and protective reflexes remain intact. *Deep* sedation is a depressed conscious state from which it is difficult to rouse patients. In the typical clinical situation, a continuum likely exists between conscious and deep sedation [16]. The exact level of sedation reached is determined by patient characteristics and drug dosage.

Younger children may require deeper sedation to reduce agitation, although, except in infants, the metabolism of sedatives is not dissimilar in children and adults [3, 10]. Nonetheless, deep sedation may be more of a problem in children than in adults [5]. In children—given their smaller size, increased compliance, and the prominence of the tongue within the oral cavity—airway resistance is greater. With manipulation of the upper airway, infants are prone to apnea. Older children may have tonsillar or adenoidal hypertrophy. Furthermore children with EA also have poor esophageal clearance.

In children and adults, conscious sedation involves a combination of a benzodiazepine and an opioid [5, 17]. Administration is titrated, allowing time between doses to assess the response. The current practice in the United States, most often, is to use a combination of midazolam (in boluses of 0.1–0.2 mg/kg body weight) and fentanyl (1–3 μg/kg body weight) [5, 18]. Both of those drugs have a short duration of action. The dose-dependent respiratory depressive effect of a benzodiazepine is exacerbated by simultaneous administration of an opioid [19].

For pediatric endoscopy, propofol (a sedative hypnotic) is being used with greater frequency [5]. It has a very short half-life and therefore the potential for rapid onset of, and rapid recovery from, sedation [20]. With propofol, the level of sedation can be controlled for a prolonged period. But because of its narrow therapeutic range, it has a propensity to cause deep sedation; at most centers, administration and monitoring must involve an intensivist or anesthesiologist [5, 21, 22]. In smaller children, recovery after sedation with propofol may be prolonged. Ketamine is also used as a single agent and is preferred at some centers. However, significant contraindications to its use [5] and an associated risk of laryngospasm make it less suitable for upper endoscopy, especially in younger children [23, 24].

Subjecting small children to general anesthesia for endoscopy is based on the perception that they will not tolerate sedation. It is agreed that complex prolonged procedures should be performed under general anesthesia, especially if they increase the risk of pulmonary aspiration [10, 25–28]. One prospective study of 226 endoscopic procedures, comparing conscious sedation with general anesthesia, found that the comparative completion rate with conscious sedation was 95 % [19]. Another prospective study of conscious sedation for upper endoscopy in children, including a significant number of high-risk patients, found that all 34 procedures were completed [29]. Similarly, a retrospective study of over 600 outpatient procedures found that the completion rate with conscious sedation was more than 99 % [30]. Regarding safety, one prospective study of 36 children under 6 years of age found that a significantly greater number of oxygen desaturation episodes occurred in sedated children than in those who underwent general anesthesia; in addition, operator satisfaction was better with general anesthesia [31]. A prospective study of capnography during sedated endoscopic procedures documented poor ventilation during 3 % of the procedures, alveolar hypoventilation during 56 %, and apnea during 24 % [25]. It is understandable that exclusive use of general anesthesia for all endoscopies may be increasing, especially in younger children [21]. The argument against general anesthesia includes the possibility of mechanical injury during endoscopy, because of excessive force in a patient who is unable to respond. Mucosal damage can be significant, but reports of upper and lower endoscopic perforation are rare [18, 32].

There is no data comparing sedation and anesthesia specifically in EA patients. General anesthesia is not necessary for endoscopy in adults with a remote history of EA. At our institution, in small children with EA, we have always used general endotracheal anesthesia for any endoscopic procedure.

Long-gap EA patients at our institution have mostly been referred from outside centers and have had the most challenging histories. Typically, those EA patients were not able to undergo a primary repair or underwent one or more failed attempts at repair elsewhere. Such attempts may have led to an esophageal fistula to the hemithorax, compromising lung function and leading to chronic empyema. Also common in

referred long-gap EA patients has been a history of recurrent pneumonia (associated with prolonged drainage of the upper esophageal pouch) or the presence of an esophagostomy, not uncommonly tracheal stenosis (from repeated or prolonged intubations), tracheomalacia, bronchomalacia, or the presence of a tracheostomy. Clearly in this patient group, it is imperative to control the airway during any sedated procedure, and anesthesia is the preferred method for endoscopic procedures.

Equipment and Technique

Developments in endoscopic equipment and techniques have been well described in most relevant textbooks and, especially in children, have been updated periodically [10, 33, 34]. In adults, larger-caliber upper endoscopes have better optics and more channels for instruments; in children and in nonsedated adults, smaller-diameter scopes more easily facilitate procedures. Standard adult gastroscopes (>8.7 mm in diameter) are also used in older children (weighing 10 kg or more); smaller instruments (5–8 mm in diameter) are available for gastroscopy in infants. Scopes of 5–6 mm in diameter can be used in infants as small as 2.5 kg. I have accessed gastrostomy sites using adult bronchoscopes; however, visibility, maneuverability, and instrumentation are limited.

The principles of upper endoscopy with or without therapeutic intervention are the same in children and in adults. Because of the limited data in children, guidelines for them are mostly extrapolated from adult data [10]. The smallest instruments (5–8 mm in diameter) have smaller channels (2.0 mm) than standard gastroscopes (2.8 mm in diameter). Specifically, catheters of 7 French (7F) and greater cannot be inserted, limiting the use of electrocautery.

No studies in small children have been published that would help define the choice of injectable agents and doses, heater probes, monopolar and bipolar cautery, or specific devices and settings. However, case reports have described most techniques used in adults [3, 10], and detailed reviews of methods used in children have been published [34]. Operator decisions depend on training, experience, and preference, with safety kept in mind at all times [10]. For upper endoscopy at our institution, we typically use a scope with a channel of 2.8 mm in diameter in patients who weigh at least 10 kg [35]. We have previously showed that argon plasma coagulation can be performed through smaller endoscopes using a small probe (1.5 mm in diameter) [35, 36]. Intubation of the esophagus is not of special concern as compared to other infants though if stenosis is suspected such as at the anastomotic site, a small-caliber endoscope is ideal for the initial examination.

Monitoring

During sedated adult and pediatric procedures, including endoscopy, the use of pulse oximetry and hemodynamic monitoring is routine. In the case of infants regardless of whether they have EA, we have found it essential to use anesthesia either in the operating room or in the pediatric intensive care unit with propofol, in order to optimize monitoring and support [10, 35–38].

During sedated procedures, a nurse trained in pediatric life support should monitor vital signs throughout the procedure [5]. Oxygen administration has been advocated: data suggest that a significant proportion of children develop oxygen desaturation and/or arrhythmias during conscious sedation for endoscopy [25, 31]. In deeply sedated patients, hypoventilation may be a significant issue that is potentially masked by oxygen administration [25]. In children, their greater surface-to-volume ratio and thinner skin predispose them to hypothermia and to fluid depletion. Endoscopic procedures are usually brief, but those involving therapy may be prolonged, so children should be well draped. Additionally, room temperatures will need to be controlled to avoid hypothermia. Similarly, fluid balance should be managed scrupulously. Monitoring should continue throughout the recovery period, until the patient shows spontaneous activity and maintains cardiovascular reflexes.

The principles of monitoring are not different in EA patients, whether infants or older. For intubated procedures, especially in very young patients, careful monitoring should include vigilance for potential dislodgement of the endotracheal tube. Infants, whose trachea may be only 2–3 cm long, are intubated with uncuffed endotracheal tubes, making dislodgement of the tube very possible during withdrawal of the endoscope.

Complications

Complications are uncommon during routine endoscopy in adults and children [38, 39]. Methemoglobinemia from the use of topical benzocaine is periodically reported [40]. In sedated patients, transient hypoxemia and arrhythmia can occur. Persistent hypoxemia and hypoventilation should prompt removal of the endoscope and physical assessment. In patients who have respiratory difficulty during or after the procedure, pulmonic aspiration should be considered.

Complications that begin beyond the immediate post-procedure period are less significant. In a survey of 393 pediatric patients 30 days after upper endoscopy, 42 % noted one or more symptom, the most common being a sore throat; 6 % sought medical advice for their symptoms, but none had a serious complication [41]. In a similar study of surveys taken after upper and lower endoscopy, symptoms were reported in 15 % of children [42].

As mentioned, bacteremia is unusual after routine endoscopy. In otherwise healthy children who have undergone endoscopy limited to the esophagus, traumatic perforation and bleeding as a result of mildly abnormal coagulation studies are rare [43].

There is little data specifically addressing complications of endoscopy in EA patients, and it is reasonable to assume that complications reported in non-EA patients can occur equally frequently in EA patients. As noted above, the potential for accidental extubation is significant in small children, especially during therapeutic procedures or with prolonged manipulation of the endoscope. In our patient population, we place devices such as high-resolution endoscopic ultrasound (EUS) probes and dilating balloons alongside the endoscope in small children. Doing so adds to the degree of complexity and to the possibility of complications.

Patients with Esophageal Atresia (EA)

The most common symptoms in EA patients are a combination of dysphagia, food impaction, heartburn, regurgitation, and respiratory symptoms. The pathophysiology of upper GI problems in EA patients is related to esophageal dysmotility, an inability to clear the lower esophagus, a reduced lower esophageal sphincter (LES) tone, and the absence of a normal reflex opening of the LES, the potential for a hiatal hernia, and narrowing of the anastomosis.

Long-Gap EA

At the University of Minnesota program for long-gap EA repair, the initial workup of patients includes endoscopy as well as contrast imaging. Again, our patients are typically outside referrals for primary repair with traction, so they often have an upper pouch that is constantly drained by an oral tube under some degree of suction. It is important at this stage to know the integrity of the most distal portion of the pouch before traction and to examine the effect of constant suction on mucosal integrity. Of critical importance is the presence of an upper pouch fistula; at our institution, we have located upper pouch fistulas that had not been identified in previous investigations.

Similarly, any lower pouch fistula must be identified and some impression of lower pouch integrity obtained before traction.

Details of the surgical technique for long-gap EA repair at our institution have been published elsewhere [2]. In brief, to estimate the esophageal gap, we use radiologic studies before surgery and confirm the results intraoperatively. During the initial operation (a posterior right thoracotomy

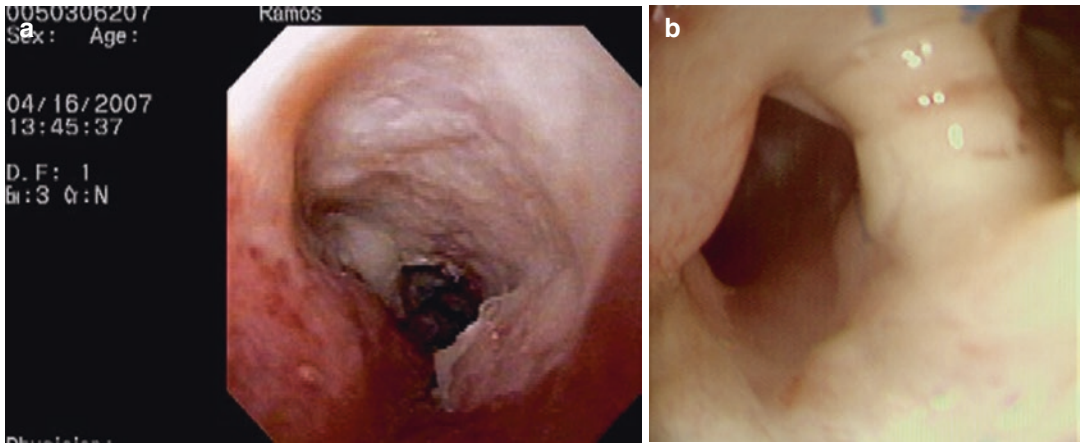

Fig. 34.1 (**a**) Extensive granulation at the site of an anastomosis signifying an underlying mural defect. (**b**) A large fistula at the site of an esophageal atresia repair

between the fourth and seventh ribs), the two ends of the esophagus are dissected and the possibility of a primary anastomosis assessed. If such an anastomosis is not possible even under tension, pledgeted traction sutures (5.0 Prolene horizontal mattress sutures) are placed in the esophageal ends and then traction applied. For external traction, the sutures are brought out of the back, above, and below the incision and tied over Silastic buttons. Between one and three times per day, the sutures are shortened to maintain tension until the two ends of the esophagus are 1 cm apart (per radiologic assessment of clips applied near the ends of the esophageal pouches).

The role of endoscopy during placement of traction, and then intermittently during maintenance of traction, includes examination for leaks. At our institution, we have also found it important to compare lumen depth (as gauged by endoscopy) with the position of the radiopaque markers that distinguish the position of the traction sutures; doing so helps determine whether the sutures have slipped and therefore need to be replaced. The clearest indication of slippage is a large gap between the end of the scope marking the most distal position of the lumen and the sutures. Further evidence of slippage is advancement of sutures while lumen depth remains the same.

During placement of traction sutures, simultaneous endoscopy can facilitate examination of the distal portion of the pouch for integrity. It can also help identify the distal end, a task that may be difficult in patients who have undergone multiple operative procedures with resulting scarring. We have used direct vision for placement of rubber tubing, in order to intraoperatively align the two pouches in patients whose distal pouch lumen is small and narrowed.

Anastomosis

In typical EATEF patients, the ends of the upper and lower pouch are not difficult to bring together, so a primary repair is performed soon after birth. In such patients, endoscopy is not necessary either before or after the surgery. An assessment of the anastomosis may be necessary only to determine the cause of upper GI symptoms. Our long-gap EA repairs are only possible with significant tension during the anastomosis. This likely increases the possibility of a leak at the anastomosis and of eventual stricture formation. To explore for leaks, we have therefore used a combination of endoscopy and water-soluble contrast. Radiologically, a leak may be missed if there is a great deal of granulation tissue at the anastomosis (Fig. 34.1).

The anastomosis is examined endoscopically most often to determine the presence of narrowing that needs to be dilated and for the presence

of inflammation, which suggests acid reflux as part of the pathophysiology for stricture formation. Diverticula though rare do occur after EA repair and may be a cause of symptoms. In our patients, endoscopy and EUS (see below) have been used together to examine diverticula muscular integrity and estimate the length of the stricture in patients with recurrent stricturing; diverticula devoid of muscle tissue may benefit from excision, and a long stricture may benefit from surgical revision, rather than persisting with dilation.

Lower Esophageal Sphincter (LES)

To ascertain dysfunction of the LES, endoscopic assessment is an important adjuvant to manometry and radiologic studies. The most critical findings are the location of the Z-line and differentiation between a true Z-line and gastric or intestinal metaplasia (see next section). A patulous LES is an obvious sign of dysfunction; combined with a finding of Z-line migration caudally, it can be good evidence of a hiatal hernia and therefore the need to relocate the LES in the abdomen. In some patients, the LES may be tight following fundoplication; resistance to passage of the endoscope can indicate that the LES needs dilation. The lower esophagus otherwise lacks propulsive motility and the normal relaxation reflex of the LES. The degree of dysfunction of the LES after a fundoplication can also be gauged by examination of the fold that appears in the fundus of the stomach. Loosening of the fundoplication is characterized reduction of these folds.

Dysphagia and Endoscopic Findings

Patients with a history of EA repair most commonly suffer from dysphagia and food sticking in the chest. The diagnostic possibilities include a narrowed or stenotic anastomotic area, a tight LES, and extrinsic compression from a narrowed diaphragmatic hiatus. Even in the absence of an obstruction, the lower esophagus is devoid of propagating contractions, and the LES does not open in the normal manner to allow progression of a swallowed food bolus. Therefore, depending on the characteristics of the bolus, dysphagia may occur in most EA patients, even those with no complaints [44].

Reflux of gastric contents can also cause the same symptoms, only rarely are defects, such as shelves and diverticula, from the repair process to blame. Data specifically on EA patients are lacking, but in older children and adults, meat is the most common source of impaction [45, 46]. In otherwise healthy people without a history of EA, investigations of dysphagia are imperative; in EA patients, the value of such investigations needs to be balanced with what is already known about the patient since likely a degree of dysphagia is related to esophageal dysmotility. If food impaction does not resolve on its own and if noninvasive maneuvers have failed to relieve symptoms or there is suspicion of a foreign body, then endoscopy is indicated. All esophageal foreign bodies should be removed promptly, in order to prevent esophageal ulceration, perforation, and possible aortoesophageal fistula. One survey found a success rate of almost 99 % for removal of foreign bodies from the upper GI tract in children, with no significant complications [47]. Techniques for dealing with food impaction and for removal of foreign bodies involve a combination of snares, forceps, and overtubes. The exact method will depend on the nature of the foreign body, its location, and the preference of the endoscopist. Food can be advanced into the stomach using the scope itself, without the need to attempt removal. Endoscopic examination at the time can help assess additional reasons for dysphagia (Fig. 34.2).

In difficult cases, we have used a dilating balloon inflated to low pressures with contrast, examining the passage of the balloon through the anastomosis and LES for any subtle evidence of obstruction. We would also advocate obtaining a biopsy sample from the lower esophagus and anastomosis, in order to further elucidate the cause of the impaction. Eosinophilic esophagitis should also be considered in patients with new-onset dysphagia; it is increasingly reported in the general population of adults and children and

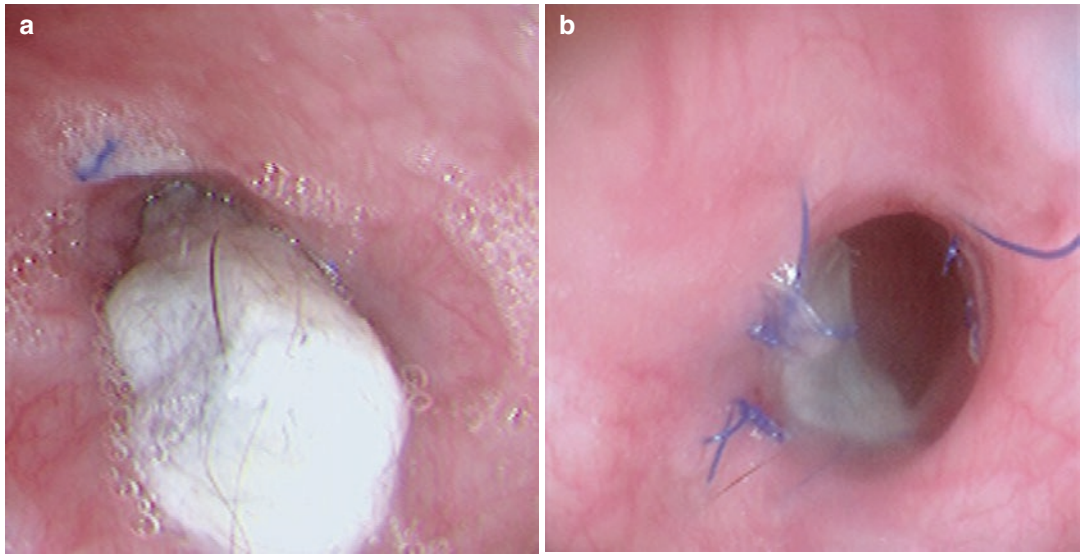

Fig. 34.2 (**a**) Findings in an infant who stopped feeding. (**b**) After removal of the cotton ball seen in **a**, the anastomosis was also dilated

typically presents as dysphagia. In our series of more than 70 patients with long-gap EA, 1 had eosinophilic esophagitis on long-term follow-up.

Esophagitis and Barrett's Metaplasia

As noted above, the lower esophagus after EA repair is dysmotile, and the LES does not normally relax to allow swallowing. Esophageal inflammation can therefore result from food bolus contact for prolonged periods, possibly complicated by pH changes. Such changes not only will cause erosions but may also give false-positive information on acid reflux. Still, the main concern outside of anastomotic problems is that of GER [44, 45, 48–53]. Most published data on endoscopy in EA patients is retrospective, and most available data is based only a proportion of patients surveyed and those consenting to procedures [49].

Data from long-term studies that have reported endoscopic findings make it clear that the prevalence of serious sequela (such as Barrett's esophagus) may be significant and that routine surveillance endoscopy should be the norm [44, 45, 48–53]. A long-term follow-up study of 23 patients who agreed to undergo EGD found that macroscopic Barrett's esophagus was diagnosed (and confirmed by histologic analysis) in one patient. A second patient developed squamous cell esophageal carcinoma [54]. A study of 62 patients who were at least 20 years old (identified from a database and invited to undergo a clinical endoscopy) found reflux esophagitis in 36, Barrett's esophagus in 7, and strictures in 26 [49]. And one patient had esophageal squamous cell carcinoma. Men who were at least 35 years old and patients with severe reflux symptoms were at high risk of having severe esophagitis or Barrett's metaplasia. One study of 49 patients 10 years after EA repair for EGD found severe esophagitis in 2 and macroscopic Barrett's esophagus in 2 [55]. Histologic analysis found esophagitis in 30 patients, gastric metaplasia in 3, and no intestinal metaplasia. Investigators surveying EA patients of whom a proportion consented and then underwent endoscopy have shown similar findings [44, 45, 48, 49]. Tovar et al. found, through histologic analysis, esophageal inflammation in 51 % and Barrett's esophagus in 6 % of their series of patients [50].

The difficulty with interpreting these long-term studies is often the degree of inflammation

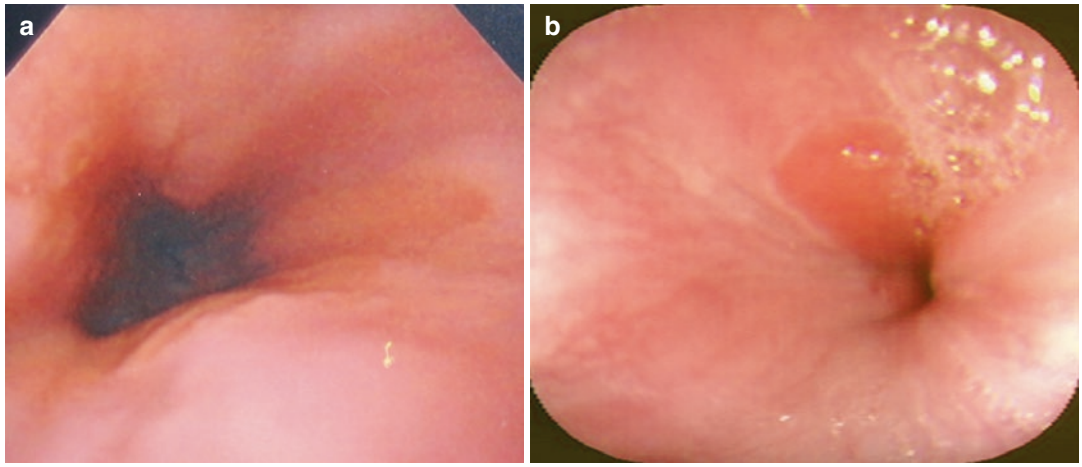

Fig. 34.3 (**a**) The appearance of the lower esophagus in a patient with a history of esophageal atresia repair suggestive of Barrett's metaplasia. Mucosal histology was consistent with gastric cardia-type mucosa. (**b**) A lip of abnormal mucosa in the lower esophagus that was confirmed to be gastric metaplasia

per histologic analysis and the rarity of histologically confirmed Barrett's esophagus. Most patients in such studies may have cardiac-like gastric metaplasia or movement of the Z-line upward as part of a hiatal hernia. In our group of long-gap EA patients, some abnormal mucosa to suggest was seen in 3 of over 70 children on follow-up endoscopy (Fig. 34.3). Histology showed mucosa characteristic of gastric cardia. Yet findings of inflammation of the lower esophagus are highly significant, mandating long-term follow-up. The precise schedule is unlikely to be decided by available data, so is at the discretion of the gastroenterologist familiar with EA patients. And while histologic Barrett's esophagus in children with EA is rare in such patients, we highly recommend regular endoscopy and appropriate treatment of any inflammation.

Endoscopic Ultrasound (EUS)

EUS is extensively used in the investigation of adult-onset GI pathology. It is a particularly useful diagnostic tool for hepatobiliary and pancreatic disorders. In the esophagogastric area, the typical indication for EUS in adults is to examine structures beyond the esophageal wall of the intestinal lumen. High-resolution EUS has limited depth but provides great detail (as compared with standard EUS). It is therefore ideal for studying the GI mural structure but has limited effectiveness for imaging structures beyond the esophageal wall. Perhaps as a result, it is not routinely used for any specific indication in adults but has been used to investigate esophagitis as well as esophageal and esophagogastric muscle contraction and motility [56–59].

Few reports have documented the use of high-resolution EUS for esophageal disorders in children [60–62]. Fox et al. [62] examined the esophagus in children with eosinophilic esophagitis and found an expansion of the mucosa and submucosa (as compared with controls).

Our practice of employing high-resolution EUS in EA patients dates back several years [63–65]. All EUS procedures are performed during EGD and under anesthesia, using a 20-MHz catheter ultrasound probe (2.4 mm in diameter) (UM-3R, Olympus America, Inc., Melville, NY) and an ultrasound processor (EU-30, Olympus). We have used standard endoscopes with a channel for infusion of water separate from the standard accessory channel (for the EUS probe), except in infants (<10 kg), in whom the EUS probe is passed alongside a smaller endoscope. Sterilized water (5–20 cc) is infused into the esophageal lumen for acoustic coupling (total of

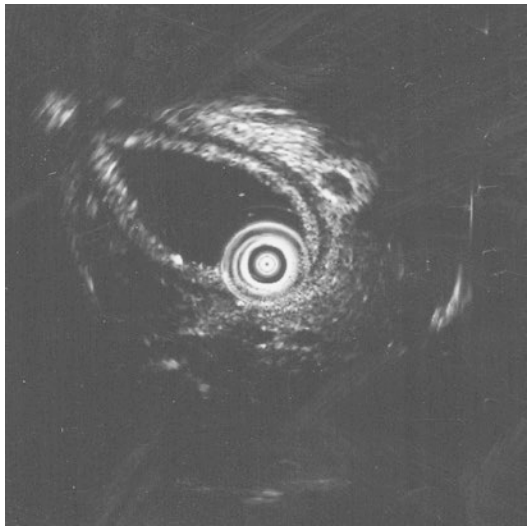

Fig. 34.4 The mural structure of the esophagus; the muscularis propria is most easily seen as a hypoechoic area

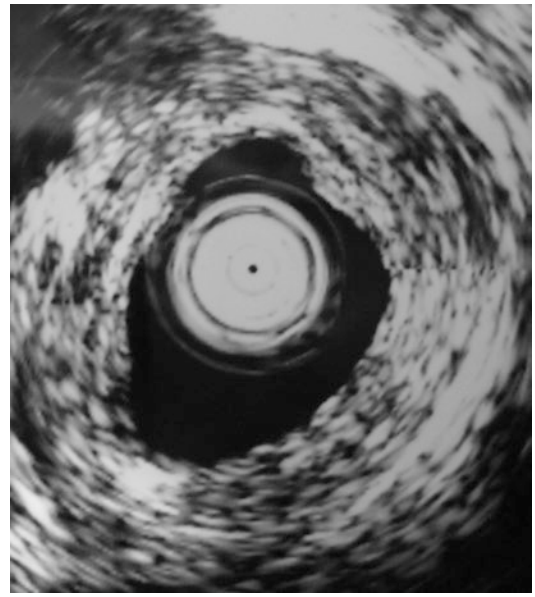

Fig. 34.5 The typical appearance of a fibrotic anastomosis on endoscopic ultrasound

100–120 cc). We used the method to assess the effect of traction on the mural structure of the esophagus. The main aim was to examine whether there is a simple stretch of the esophagus or actual growth of tissue when the esophagus elongates under traction. Ultrasound images were examined to establish anatomic layers as previously described [66]. The innermost hyperechoic layer corresponded to the echo interface and the adjacent hypoechoic layer to the mucosa; the third hyperechoic layer, to the submucosa; the fourth hypoechoic layer, to the circular smooth muscle layer; the fifth hyperechoic layer, to the interface between muscle layers; the sixth hypoechoic layer, to the longitudinal smooth muscle layer (muscularis propria) (Fig. 34.4); and the seventh, outermost, hyperechoic layer, to the adventitia.

In our study, we found that the depth of the mucosa and submucosa in patients with EA was 0.99–1.10 mm—similar to the depth previously reported in healthy control patients [64]. We interpreted this as good evidence supporting our hypothesis that mural growth under tension allows primary repair to be performed. Furthermore there was no significant change before and after repair of both the upper and lower segments [65]. In other case reports, high-resolution EUS has been used to determine the nature of esophageal stenosis before resection, differentiating cartilaginous from fibrotic strictures (Fig. 34.5) [60, 61]. Of potential relevance to EA patients, Kamijo et al. [67] showed that prognostic information could be obtained on stricture formation in the days after ingestion of corrosives. Similar to the experience of others [62], we were unable to always discriminate the intermuscular layer, mucosa, and submucosa as separate layers with the 20-MHz probe (Fig. 34.4). With high-frequency probes, others have occasionally found a nine-layer structure of the esophageal wall in which the mucosa, muscularis mucosa, and submucosa appear as separate layers [68].

We found that the high-frequency catheter EUS probe was easy to apply for examination of the esophagus in children with EA, although the need to infuse water for acoustic coupling was a limitation. That need was reported to be a particular problem when attempting to examine the upper esophagus in sedated children [62]. We would add that infusing water in the upper esophagus is also a risk for aspiration and that the airway should be protected especially in EA patients where there is

esophageal dysmotility. Other investigators have found infusion of ultrasonographic jelly to be effective for acoustic coupling [67].

Despite these shortfalls, we propose a number of further uses for high-resolution EUS in children with EA: when it is difficult to decide, perioperatively, on traction in very small distal segments; when stricture length needs to be assessed for the purpose of accurate resection; when the potential for formation of diverticula needs to be predicted after myotomy [69]; and potentially when esophageal motility needs to be examined in the proximal segment after traction, in order to predict esophageal function [59].

Summary

In the EA population, we have found upper endoscopy to be highly useful as part of the early management of difficult cases, and it is clear that long-term endoscopic surveillance of patients should be a routine part of their follow-up. We have added high-resolution EUS for critical assessment of the mural structure of the esophagus when using traction as part of the management of long-gap EA patients, and this modality may have other potential uses in this patient population.

Sigmund H. Ein

Complications Following Esophageal Atresia Repair

Philosophy and Reality of Esophageal Atresia Repair

The old teaching that the original esophagus, albeit not properly formed, is infinitely better (after its repair) than any substitute still exists. In 1965, Howard and Myers stated: "It is our firm conviction that the best esophagus possible is one which is constructed entirely from the elements originally developed for its formation" [46]. However, trying to repair the baby's original esophagus must not compromise the baby's life. Therein is the art, as well as the science, of pediatric surgery, and experience plays a huge part in both of these areas.

If pediatric surgeons do enough esophageal atresia (EA) surgery, they will have their share of complications! Nonetheless, they must minimize their occurrence and deal with them accordingly.

Anastomotic Leak

This is by far the most worrisome complication of an EA repair and classically occurs on the third or fourth postoperative day; many are relatively asymptomatic and therefore go clinically unnoticed. The clinical manifestations depend upon the size of the leak, but, surprisingly, there does not seem to be any correlation between the tight, difficult anastomosis and the incidence of anastomotic leak. The reported incidence of leak varies from 4 to 40 % with a higher leak rate in the far less commonly done end-to-side Duhamel anastomosis [17, 28, 39, 63, 82]; the two-layer anastomosis is reported to have a lower leak rate (and a higher stricture rate) but is not done as often as the single-layer anastomosis [17].

If the anastomosis virtually falls apart, the signs and symptoms of respiratory distress suddenly appear in an acute fashion, earlier than usual, on the second or third day. At the other end of the spectrum, the only evidence of a tiny asymptomatic leak may be the radiological finding of a bit of extravasated water-soluble contrast at the sight of the anastomosis, usually when the first routine contrast swallow is done at the end of a week. The baby can continue to feed via an intraoperatively placed nasogastric feeding tube [3] (or gastrostomy tube), and the contrast study should be repeated at weekly intervals until the leak disappears, usually in a week or so [33]. This leak would probably disappear even if the baby was allowed to feed per os on the day it was discovered; however, it is best not to allow the

DOI 10.1007/978-3-642-11202-7_35

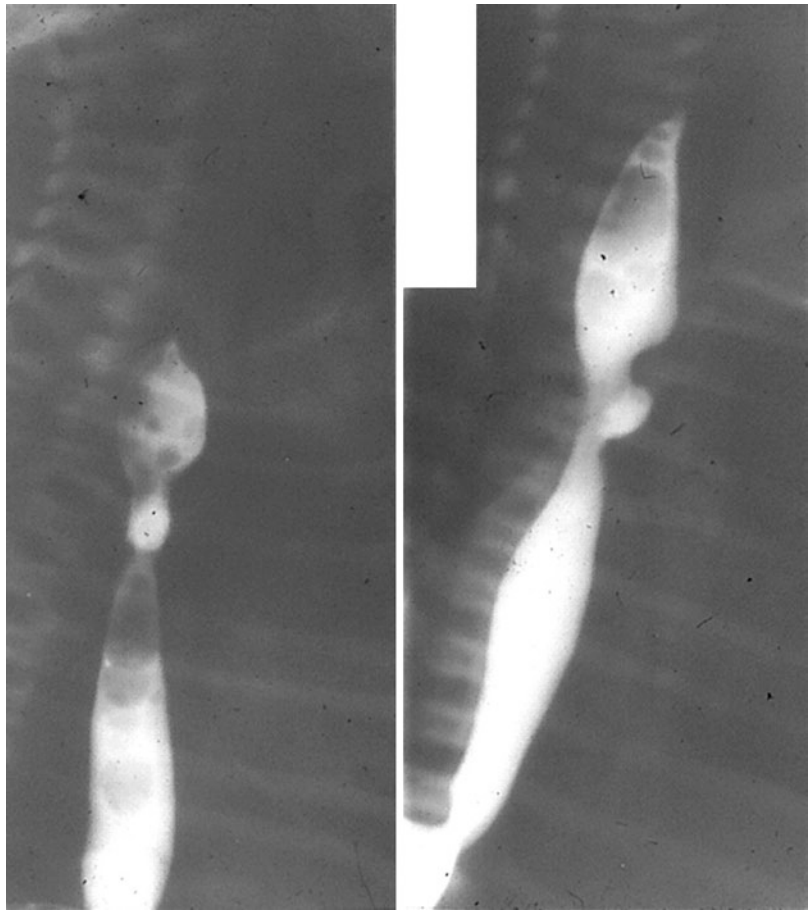

Fig. 35.1 Anastomotic diverticulum after EA repair

baby to feed by mouth to avoid an anastomotic diverticulum (Fig. 35.1) from developing, let alone a recurrent tracheoesophageal fistula (TEF). There have been as many esophageal anastomoses leak without a transanastomotic feeding tube as with one [33].

The typical anastomotic leak presents with some acute respiratory distress; the baby becomes cyanosed, tachypneic, gray, and septic. A chest x-ray usually shows the almost typical right pneumothorax (Fig. 35.2) or pyopneumothorax which is sometimes captured by the indwelling chest tube (Fig. 35.3). If the original chest tube, placed at the operation, does not work because it is plugged (more often than not), then a second one will have to be placed (nowadays, often by interventional radiology (IR) to be certain it adequately captures and drains the leak). It is for this reason that a chest tube is often not left at the time of repair [8]; there is nothing that upsets parents more than a second and a third chest tube.

The respiratory distress necessitates the following emergency measures: the upright positioning, the halting of feedings (oral and/or tube), and the administration of oxygen and antibiotics. If the respiratory distress is severe and/or the baby tires, he/she should be intubated and put on a ventilator for a few days until the emergency is over and his/her condition is improved. One or both chest tubes will almost certainly drain some saliva, and only when this stops does it usually mean that the leak has closed. It is at this time that a water-soluble contrast esophagus examination is carried out to assess the anastomotic leak (Fig. 35.4). Usually, the later the leak occurs, the smaller it is and the less severe the

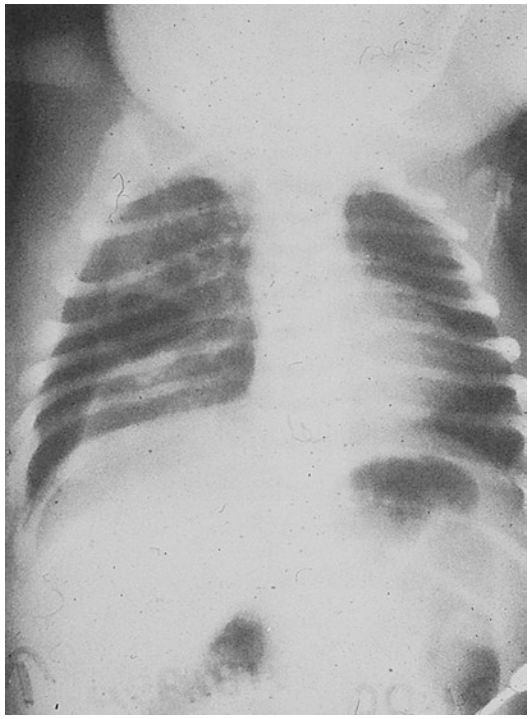

Fig. 35.2 Chest x-ray showing typical right pneumothorax because of leaking EA anastomosis

Fig. 35.3 Chest x-ray showing common pyopneumothorax, which is sometimes captured by the postoperative chest tube

clinical picture. When it has healed, the baby can feed by mouth. There is never any reason to get a contrast swallow as soon as the leak occurs, because the baby is often too sick for the study and besides, it should not influence the above treatment in any way. Moreover, there is never any indication for reoperation on a leaking anastomosis, because repair in the presence of inflammatory tissue is rarely successful and leads to total disruption of the two pieces of esophagus, which of course commits the baby to an immediate esophagostomy in the neck and later an esophageal replacement. It is amazing, but true, that these leaks all heal in time, albeit usually with some degree of stricture.

The chest tube(s) usually is not removed until the leak has closed; this may take several weeks and occasionally the chest tube slips out on its own. If this happens, it invariably means that it does not need to be there any longer because the pleural cavity has sealed itself around the tube. Sometimes after the tube is removed, all that remains is an esophagocutaneous fistula, which is occasionally perpetuated by the tube; that too will close in days, during which time oral feeds can restart. One of the supposed advantages of the retropleural (extrapleural) approach for the repair of EA is that this procedure minimizes the effects of such a leak by not soiling the pleural cavity and lungs; however, the babies are just as sick [38]. It is surprising how well the right chest improves as healing occurs over the next number of weeks.

Stricture and Gastroesophageal Reflux

The majority of babies who have undergone repair of EA do quite well and go home feeding normally within a few weeks after surgery. It is extremely rare to view a postoperative contrast swallow and not see the anastomosis; it is always somewhat narrowed (Fig. 35.5). If the neonate feeds well during the first few weeks and months,

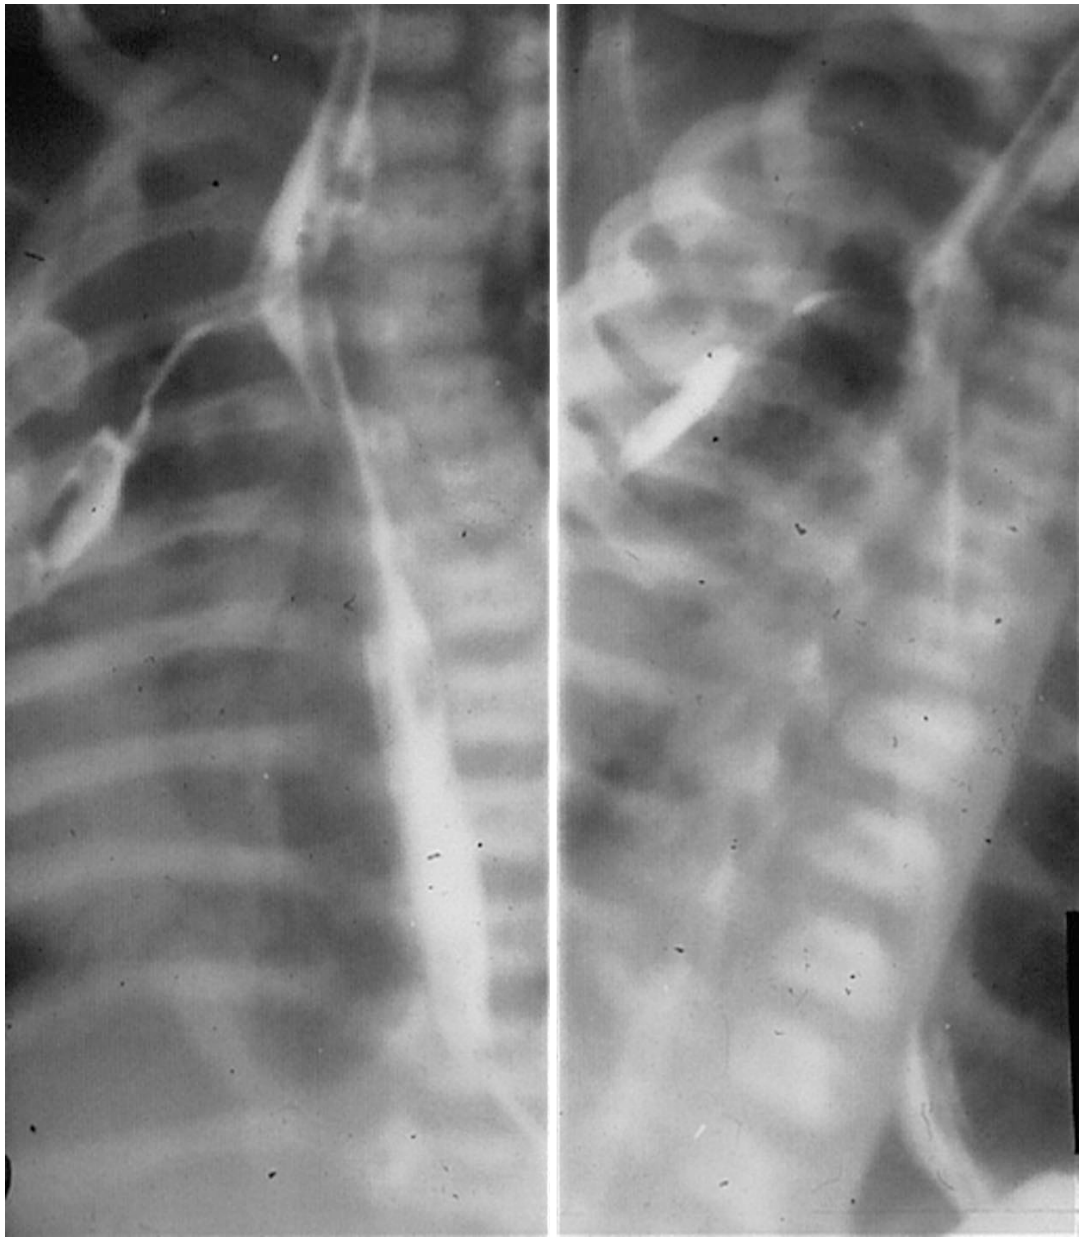

Fig. 35.4 Water-soluble contrast (safer than barium, which may remain outside of the lumen forever) esophagram examination to assess anastomotic leak

and even if the x-ray shows a fairly tight anastomosis, it is reasonable to just follow him/her; the patient should be treated and not the x-ray. The rationale of routine postoperative esophagoscopy after every esophageal repair does not seem warranted and is not done by many pediatric surgeons; moreover, most narrowings will improve on their own in time (Fig. 35.6). An important point to remember, when evaluating a postoperative contrast esophagram, is not to check how narrow the anastomosis looks, but to see how wide it can open. Some series report strictures requiring dilatation in as many as 80 % of EA patients [39]; this seems high.

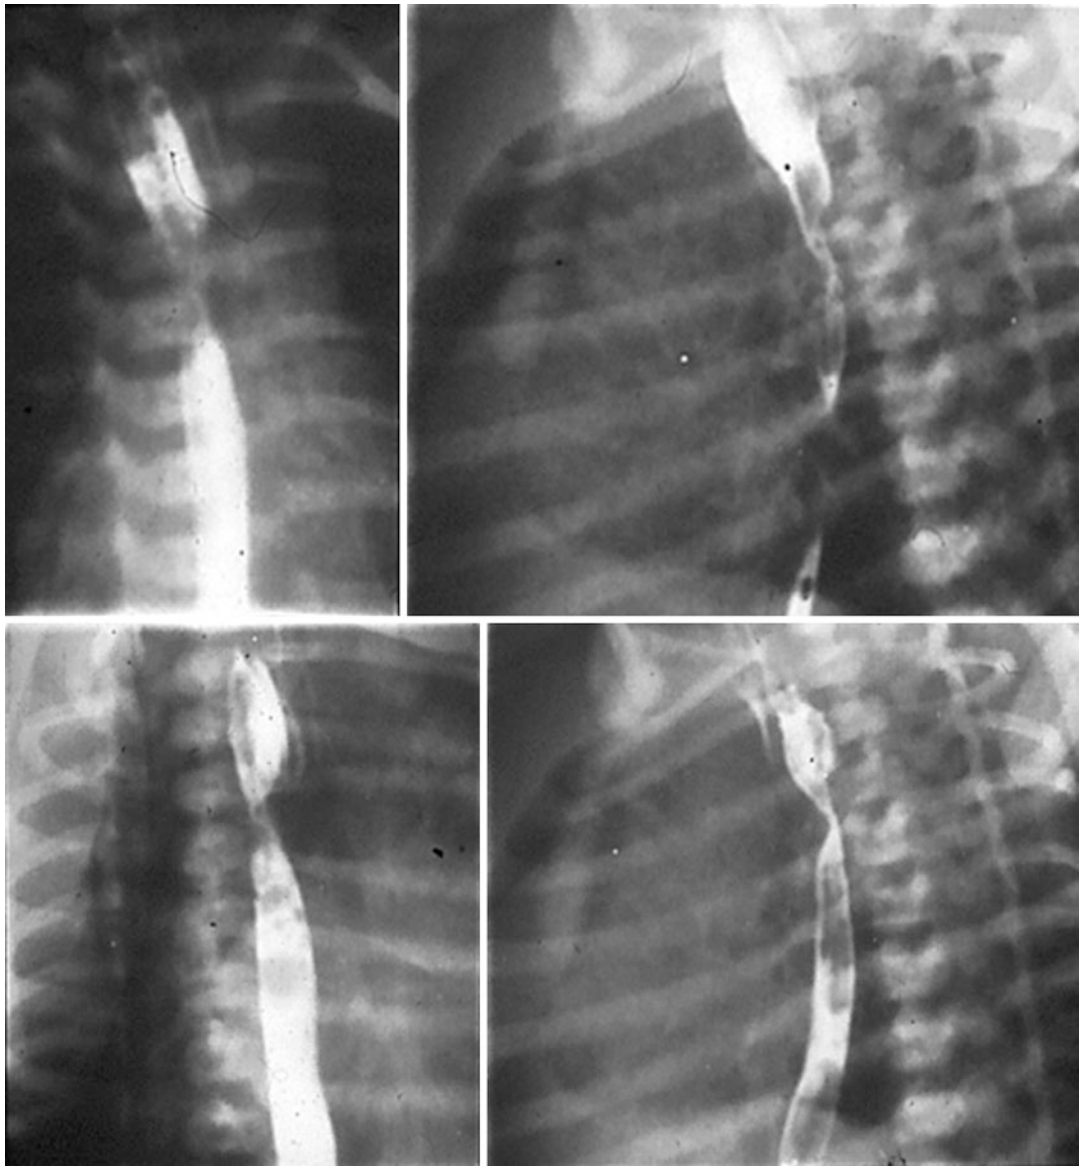

Fig. 35.5 Postoperative (PO) contrast esophagram (usually done on PO # 7) to assess EA anastomosis. It is extremely rare to not see the anastomosis, which is always somewhat narrowed

Stricturing at the site of anastomosis may progress quite far, before the infant on a fluid diet presents with coughing spells, aspiration, regurgitation, and failure to gain weight (Fig. 35.7). That is the time for a water-soluble contrast swallow (esophagram) to confirm the stricture. Most, if not all, strictures respond to dilatation, which can almost always be carried out prograde and without the use of a gastrostomy and stringing. There are several ways to go about these dilations: bougies blindly in the clinic; direct vision esophagoscopy in the operating room under general anesthesia; balloon dilators in the interventional suite; and Tucker bougies prograde or retrograde using a Marlex string as a guide wire coming out the gastrostomy.

Dilatations can be done on a routine planned basis (even if asymptomatic) or on demand (if

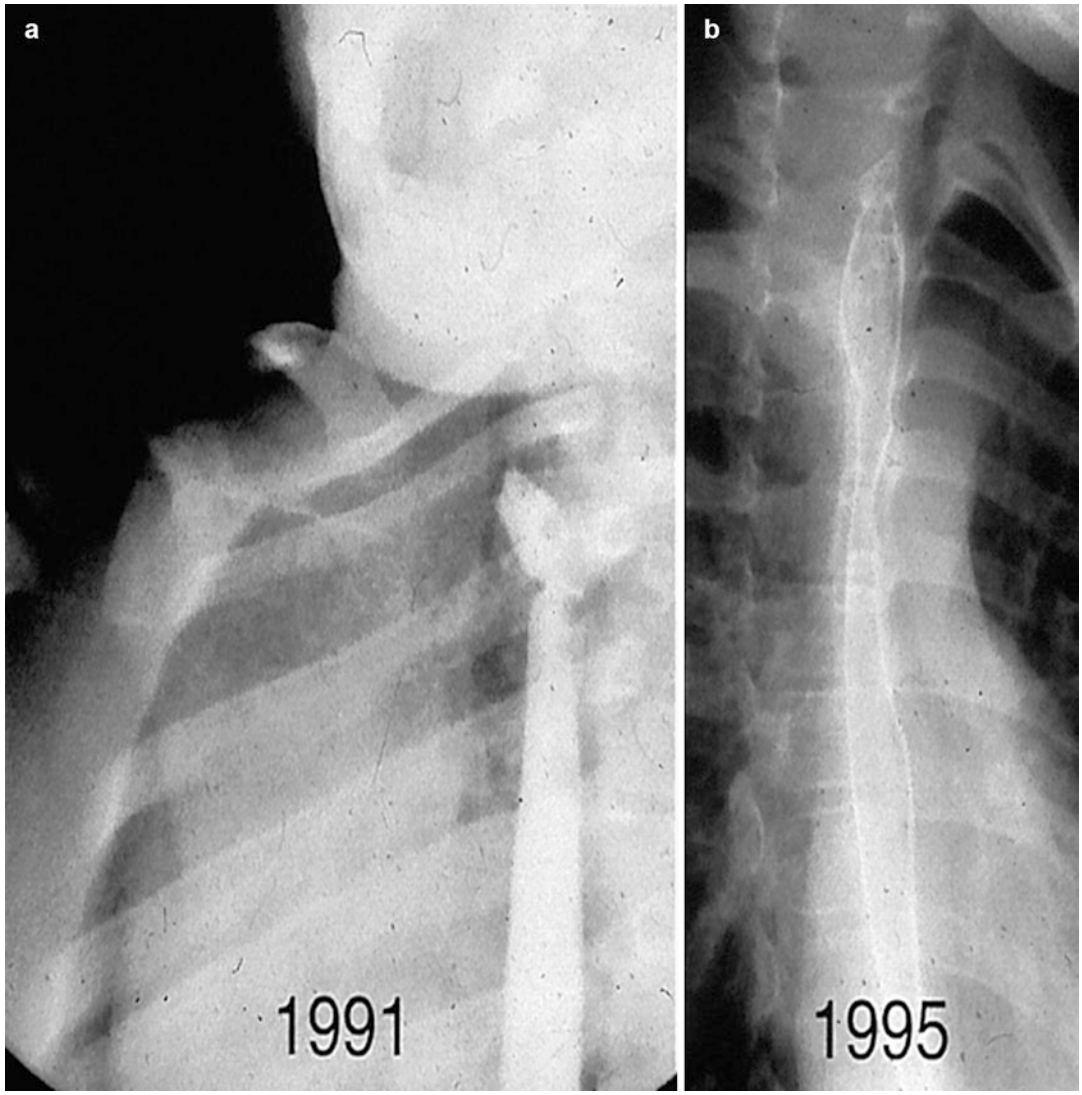

Fig. 35.6 Contrast esophagram of same repaired EA patient at age 1 year (**a**) showing asymptomatic anastomotic narrowing and (**b**) 4 years later a marked improvement without dilatation

symptomatic). Initially, dilatation of the short, tight strictures may have to be carried out weekly, but after a few such procedures, an obvious decrease in symptoms and increase in lumen size should be apparent. The interval between dilatations may then be extended on an individual basis. Many strictures respond to one to three dilations [39]. Should the stricture fail to respond to dilatation, or the response is transient, one must rule out gastroesophageal reflux (GER) (Fig. 35.8). It has been stated that about 80 % of EA babies reflux, but only 20 % of them are symptomatic, in that they require treatment [60]. Therefore, in such symptomatic situations, if the latter problem is not corrected medically or surgically, little permanent response to dilatation can be expected [62]. The drawback to an antireflux procedure is that because of the poor distal esophageal peristalsis in all babies with EA, they cannot be snugged up too tightly; otherwise, they will be obstructed and worse off than before. Therefore, of necessity, the recurrence rate of antireflux procedures in these

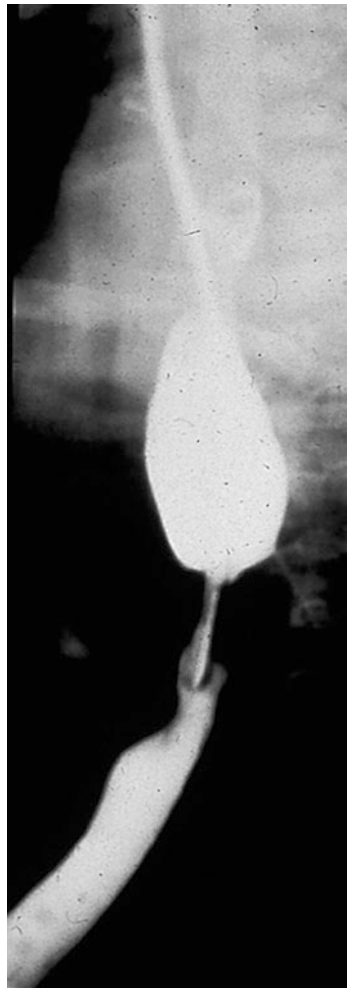

Fig. 35.7 Marked EA postoperative anastomotic stricture which has progressed quite far without symptoms because the infant is only on a fluid diet

Fig. 35.8 Marked GER (*arrow*) perpetuates a postoperative EA anastomotic stricture which has failed to respond to dilatations

infants is high (about 30%). Fortunately, aggressive medical treatment seems to be adequate in most cases. The same applies to the occasional distal esophageal narrowing (either congenital or acquired – GER).

It is unusual that dilatation is required beyond a year or 2 of age, and it is rare to have to resect a strictured anastomosis. Even when the anastomosis is virtually obstructed so that only a thin catheter can be passed through the stricture, dilatations, with or without an accompanying antireflux procedure, will solve the problem [62]. Antireflux surgery in such situations has markedly decreased over the last number of years, and this may well be due to the newer medications and the more aggressive use of them. The recent successful use of painting the stricture with mitomycin C has also reduced the number of dilatations [42, 67].

In long-term studies of EA and TEF patients, over half had difficulties in swallowing and symptoms of GER, but these symptoms occurred only occasionally and were regarded by most as inconsequential [14]. Pneumonia in these patients is associated with mild long-term lung damage [54].

Tracheomalacia

All babies with EA have some degree (75%) of tracheomalacia (TM), but, like GER, not every TM is symptomatic and needs treatment [39]. Recently, there has been more attention given to the trachea in regard to its relationship to postoperative EA problems. There is now well-documented evidence

(from Sheffield) that in the tracheal area of the TEF there is an area of squamous metaphasia, absence of cilia, and inadequately formed and missing cartilage, which account for the TM and brassy duck-like cough in these infants [84]. This cough is exacerbated by upper respiratory tract infections, which are more numerous because of a local absence of respiratory ciliated columnar epithelium needed to clear the airway of mucus and secretions. The more easily collapsible trachea adds to this problem to a greater or lesser degree. The level of tracheal collapse is usually in the region of the TEF in the distal trachea, at the level of the aortic arch [18, 32, 33, 36, 39, 58, 71]. All of these symptoms (in 10–25 % of postoperative EA and TEF patients) usually occur within the first 2 years of life until the trachea firms up, following which, this is usually no longer a significant problem. If the symptoms are mild to moderate, they do not require surgical treatment, because they tend to improve with time [39].

A small number of these symptomatic 10–25 % of infants some weeks or months after repair have definite sudden respiratory symptoms (or sometimes "dying spells") that are always brought on by feedings and will require repair [18, 32, 33, 36, 39, 58, 71]. The occasional "crib death" has occurred in this group of EA babies with an incidence somewhat greater than chance [60]. During feeds, the distended upper esophageal pouch flattens and obstructs the trachea posteriorly between it and the innominate artery and aortic arch anteriorly (Fig. 35.9a, b). Whether this is actually "reflex apnea" [32] or due to reflux of gastric contents (GER) in small amounts up to the oropharynx and over into the trachea is a good question [60]. The latter theory has also been popular as a cause of the sudden infant death syndrome, and any so-called near miss or dying spell prompts some pediatric surgeons to carry out an antireflux procedure. A full workup, however, should be undertaken to rule out other causes of these spells: neurological and cardiac (vascular ring) as well as airway and esophageal. The telltale x-ray sign of TM is a very narrow upper trachea just below the clavicles seen on a lateral chest x-ray view (Fig. 35.10); however, others argue that this narrowing of the trachea is a common x-ray finding after repair of EA in many infants without any respiratory symptoms.

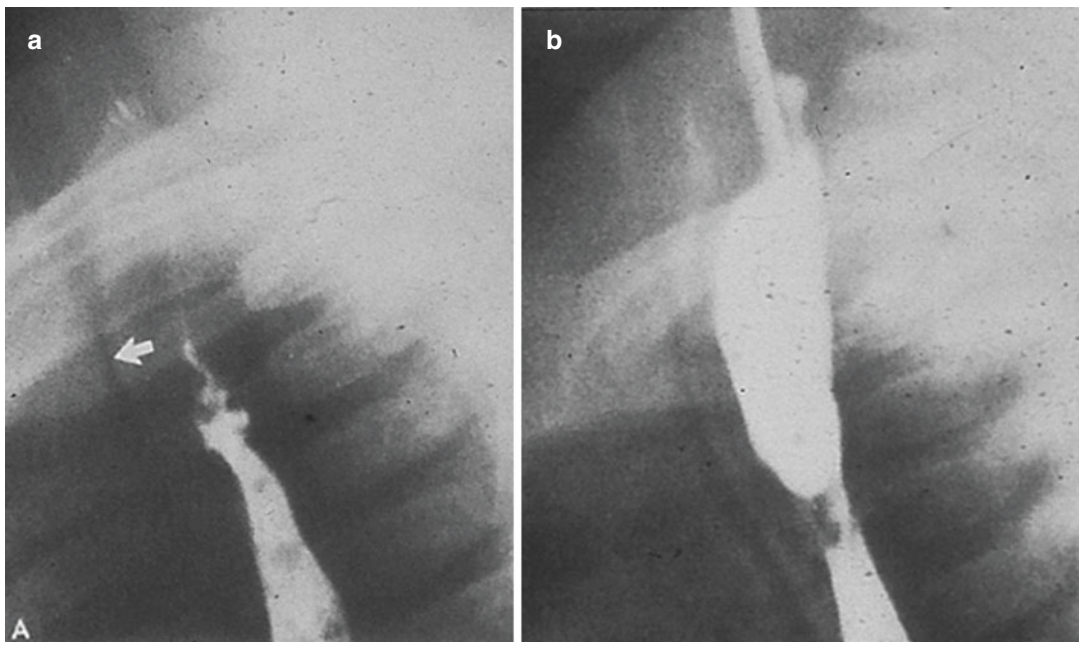

Fig. 35.9 Postoperative EA anastomosis and upper esophagus during contrast esophagram (**a**) which becomes distended during feeds, (**b**) flattening and obstructing the trachea (arrow in figure **a**) between the innominate artery and aortic arch anteriorly and the distended upper esophageal pouch posteriorly

At bronchoscopy the trachea is seen to be narrowed anteroposteriorly to a slit-like aperture, which may be completely obliterated during coughing or straining [18, 32, 33, 36, 39, 58, 71]. The anterior compression is located about 2 cm above the carina and is pulsatile from the aortic arch and innominate artery (Fig. 35.11) [18, 32, 33, 36, 58, 71]. Prior to the 1990s, the treatment for these "dying spells" was to suspend the aortic arch and innominate artery to the back of the sternum (Fig. 35.12a–c), thus pulling the artery forward, and by its posterior attachments to the front of the trachea, the airway was significantly opened up (Fig. 35.12d, e) [18, 32, 33, 36, 58, 71]. The type of operation for a very symptomatic TM that is required in these 5–10 % of EA and TEF repairs is controversial [18, 33, 36, 39, 58, 71] between aortopexy (and innominate artery suspension) from either the right [58] or left [33, 36, 71] chest (transthoracic or extra (retro) pleural), via an upper (limited) sternal split [18] or more recently by endoscopic placement of an intratracheal stent (Fig. 35.13) [33, 34]. Some believe the stent can be used either primarily or if the aortic suspension fails. Since the stents do become somewhat imbedded in the trachea wall and may cause some problems due to granulations, it is still undecided whether they should (or can) be removed at a later (asymptomatic) date in the infant or child's life.

All of this makes one wonder how all these patients with TM were treated over the years prior to the 1980s before the present increase in direct surgical attacks on the trachea and nearby anterior mediastinal arteries. Most of these babies in the past either had long-standing tracheostomies to stent the trachea and/or were fed by either nasogastric tube or gastrostomy (both of which bypass the actual swallowing mechanism said to stimulate the apneic problems), in the hope that in time the tracheal rings would achieve maturity and increase their cartilaginous support [39]. It is interesting that this TM is usually seen in infants and rarely in older children.

There is some evidence that in infants with post-EA major respiratory problems with proven TM and GER, regardless of which is surgically

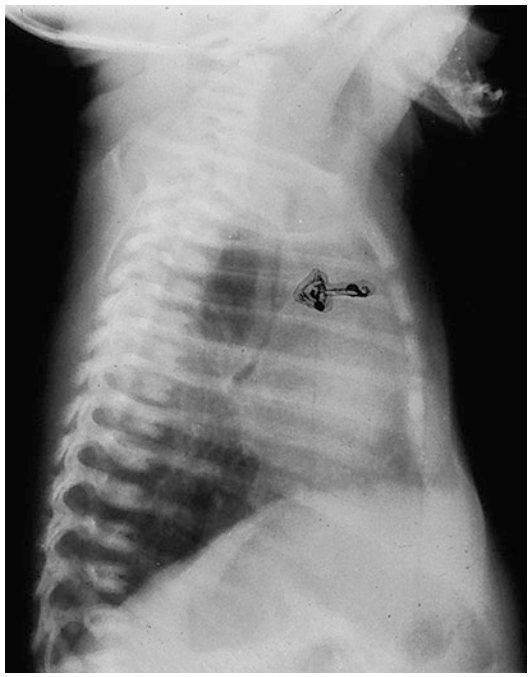

Fig. 35.10 The telltale x-ray sign of TM is a very narrow upper trachea just below the clavicle, seen on a lateral chest x-ray (*arrow*)

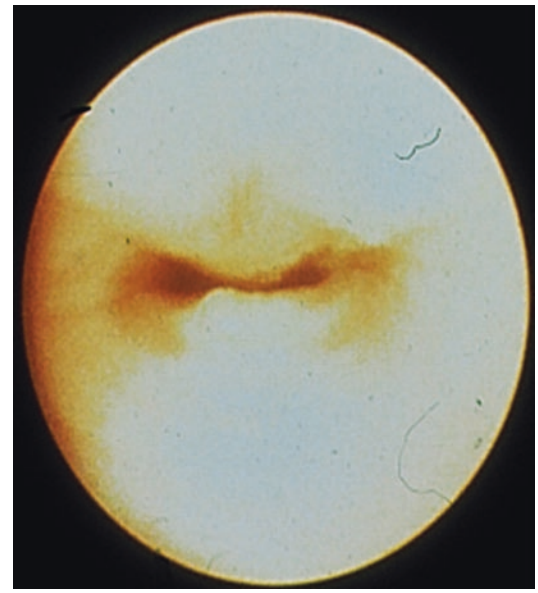

Fig. 35.11 Bronchoscopic view of narrowed trachea anteroposteriorly, which is completely obliterated during cough or straining. The anterior compression is located about 2 cm above the carina and is pulsatile from the innominate artery and aortic arch

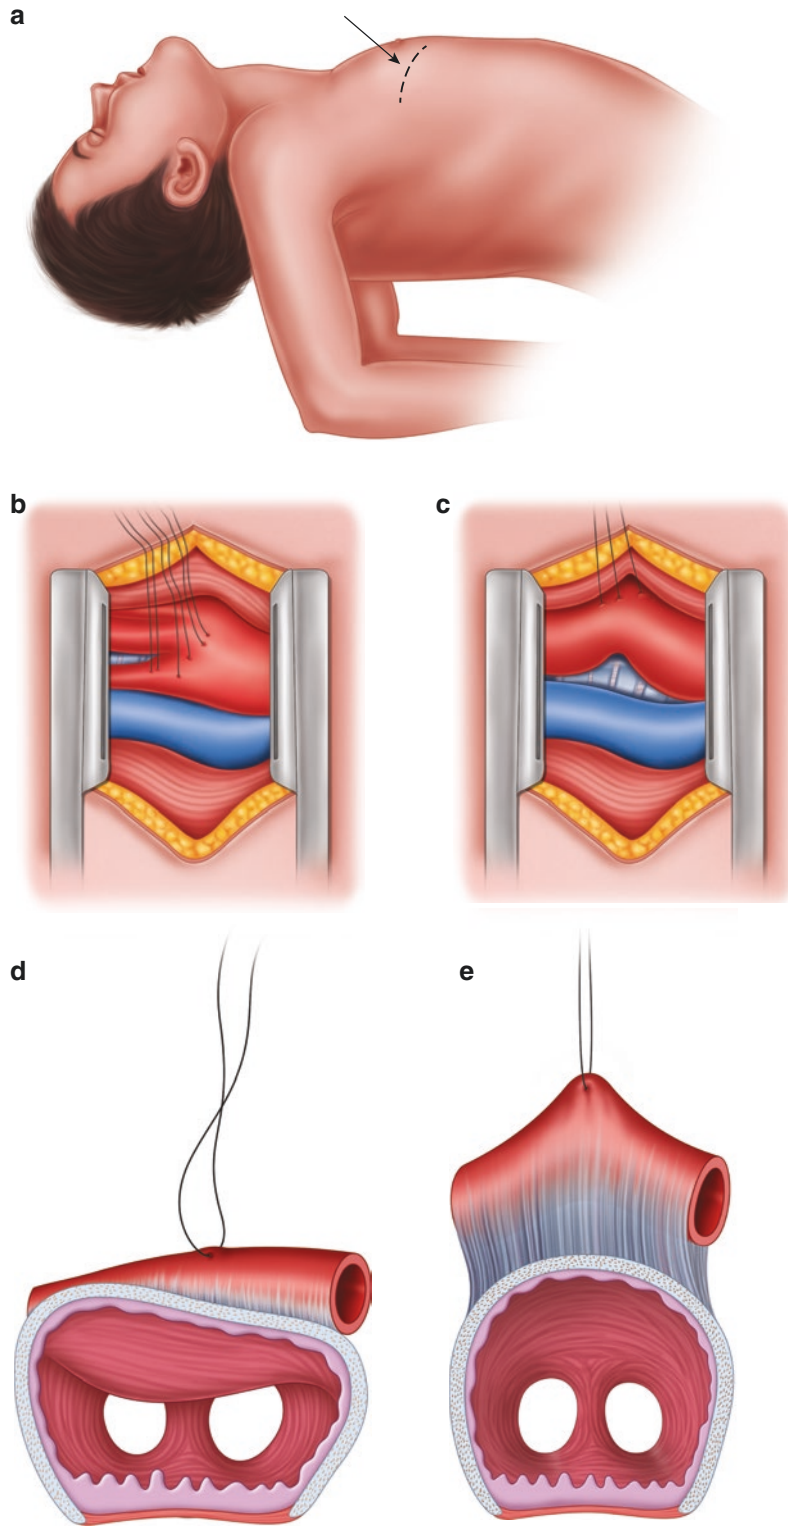

Fig. 35.12 Drawing from Mustard's paper [58] which shows a right extrapleural thoracotomy approach to suspend the innominate artery and aortic arch to the back of the sternum (**a**–**c**) thus pulling these two arteries forward and by their posterior attachment to the front of the trachea, the airway is significantly opened up (**d**, **e**) (With permission from Dr. George Trusler [58])

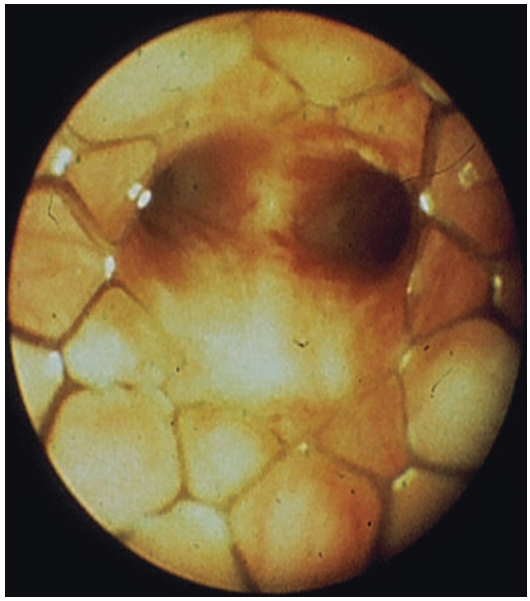

Fig. 35.13 Endotracheal stent can now accomplish the same improved respiratory results. Removal of these stents may be problematic

repaired (according to the preference of the surgeon), one third will have a recurrence of the same severe respiratory symptoms, requiring the other defect also to be surgically repaired. It is presumed that for the infants (mostly) and/or children who were clinically improved with a procedure for correction of TM, the continuing severe GER will be better handled by a noncollapsing trachea. It is similarly presumed that infants who are clinically improved with an antireflux procedure are better able to breathe through their narrow trachea as long as it is kept clear of stomach contents or not compressed by a full esophagus. Therefore, it is difficult to conclude which operation these patients should have first to eliminate their symptoms [60]. In a long-term study of EA and TEF patients, one third had a wheeze and one quarter had at least one episode of bronchitis a year, but these interfered little with their daily activities [14].

Recurrent and/or Missed Tracheoesophageal Fistula

Both of these TEF types present the same way and usually within weeks or months of the original EA repair. They present with coughing, choking, sputtering, and/or turning blue during a feed.

Fig. 35.14 Recurrent TEF (10%) will show up at the anastomotic area (*arrow*). This can be identified by a direct or prone contrast esophagram and/or endoscopy of the trachea

This symptom complex requires immediate attention with a chest x-ray (to rule out pneumonia) and a water-soluble contrast esophagram looking for a TEF, stricture, etc. Although debated by pediatric radiologists, this can be done by a direct esophagram [76] or by a prone esophageal tube pullback esophagram [53] to avoid the mistaken diagnosis, which can occur when contrast enters the trachea from above, rather than through the TEF. Of course, the recurrent TEF will show up at the anastomotic area and occurs in about 10% of repairs (Fig. 35.14) [29]. It can also be diagnosed by tracheal endoscopy. Strangely enough, it seems to occur in the

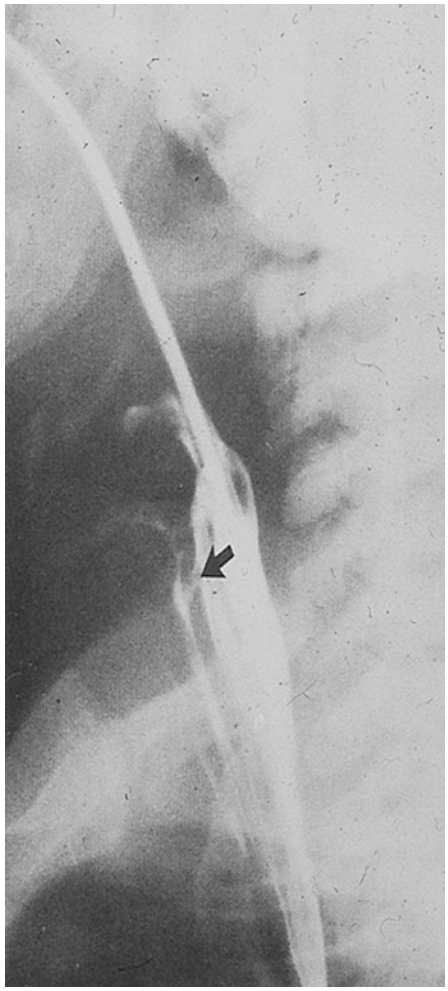

Fig. 35.15 The missed H-TEF (*arrow*) is much higher up at the level of the clavicles. Note that the H-TEF (sometimes referred to as N-TEF) runs upward from the esophagus to the trachea

easy, tension-free anastomosis; the explanation for this is because the anastomosis was not tight, the two suture lines (TEF closure and esophageal anastomosis) are touching, increasing the risk for a stitch abscess or small leak between the two to turn into a recurrent TEF [29].

The missed H-TEF, sometimes referred to as N-TEF (or upper pouch TEF), is much higher up, at the level of the clavicles (Fig. 35.15). It should never be missed if, at the time of the original EA repair, the upper pouch is mobilized up into the neck, staying on the esophagus. If that is done and it is not recognized, the bottom of the H-TEF will inadvertently be cut, making the surgeon incorrectly think that the trachea has been entered; the latter can never happen if one dissects on the esophagus. Be that as it may, these TEFs can be repaired either surgically or glued with or without the help of an ear, nose, and throat (ENT) surgeon and/or IR [11, 13, 83, 86, 87]. The surgical approach to repair the H-TEF is best done through the right neck [11]. Prior to that, some may have an endoscopist pass a soft ureteral catheter through the H-TEF from the tracheal side to more easily identify the fistula (since the fistula runs upward from the esophagus to the trachea; if it ran the opposite way, every time the baby drinks, it would "drown"). After the closure of the two holes (in the trachea and the esophagus), the more mobile esophagus is rotated 90° and stitched in that position so the two suture lines are not "kissing," thus avoiding a recurrent fistula. Occasionally, this high H-TEF is repaired through the right chest, which can be quite technically challenging.

The surgical repair of a recurrent TEF is approached through the original right fourth interspace thoracotomy incision used for the original EA and distal TEF repair, but it is a much more difficult operation than repairing the H-TEF especially since it is the second time around [11, 13, 83, 86, 87]. In both of these types of TEFs, an initial attempt (or 2) at endoscopic closure with glue is well worthwhile.

Of course, the option always exists to endoscope the newborn with an EA prior to the definitive repair to look for another (H-type) TEF [9]; this, however, still does not absolutely guarantee that it will be discovered.

Dysmotility

Early

In the first 3 months or so, there are no problems in swallowing for these neonates because the anastomosis only has to handle fluids. When baby foods are added, some dysphagia may become evident, and this warrants immediate investigation. One should warn parents to slowly increase the quantity and especially the quality of foods given, because, until the anastomosis has matured

and reached its maximal width and until the infant or toddler realizes that he/she will always have to chew their food well, eat slowly, and drink frequently to wash the food down, the parents will have to be the "swallowing conscience" of the child. The parents should be cautioned to call for help whenever the infant coughs, chokes, sputters, or turns blue during or even after feeding.

The early problems that occur from strictures, GER, TM, and recurrent and/or missed TEF have already been discussed, and if all investigations for the above are negative, one must rule out aspiration "over the top" because of muscular incoordination (pharyngoesophageal dyskinesia), which disappears in time, or fatigue aspiration. The term "fatigue aspiration" was coined by the Radiology Department at the Hospital for Sick Children, Toronto, and means aspiration toward the end of a feeding as a result of muscular fatigue. Its treatment is obvious, and it too disappears in time [21].

Late

After the repair has healed, a constant radiological pattern is seen in children who have had the common type of EA with a distal TEF; this was described by Möes (in a paper with Desjardins and Stephens) [23] and expanded upon by Cumming [20]. They noted that when swallowing is initiated, the arrival of the bolus at the lower esophageal sphincter is delayed by a noncontracting segment extending from about 2 cm above to 2 cm below the anastomosis and by a distal (lower) esophageal segment that does not contract until distended. The result is that relaxation of the lower esophageal sphincter, which is supposed to allow the passage of the downward moving food bolus, may have come and gone before the bolus arrives. Relaxation in the absence of a bolus heading down can result in upward reflux of gastric contents, and this may explain why these children often have GER, despite apparently normal lower esophageal sphincter pressures.

This abnormal swallowing pattern must be realized by the parents (and eventually the patient) in simple terms, so that they can deal with the distal dysmotility. Repeatedly warning them to "chew your food well, eat slowly, and drink frequently to wash it down" will stand them in good stead, to both understand and deal with the problem in a reasonable fashion.

Periodically during their teens, for some strange reason, they will have what must be an acute functional obstruction, in which they can swallow only fluids but not solids. Both contrast esophagram and esophagoscopy have shown no foreign body stuck and indeed a wide open anastomosis. These teenagers have come to realize on their own that this is only a temporary functional obstruction at the anastomosis, and after a day or so of fluids, the obstructed feeling will pass, and they will be back to eating normally again. At the best of times, when questioned about it, the older children and teenagers admit they feel the food temporarily hold up at the mid-sternal level (i.e., the anastomosis) in an asymptomatic way, and nothing more than a swallow or two of liquid will wash it down.

Anastomotic Foreign Body Obstruction

Once the anastomosis has reached its acceptable size (by a year or 2), the next problem that commonly occurs is an anastomotic foreign body (FB) obstruction. This happens in 10–15 % of EA repair patients [88]. The infant is now an exploring toddler, often out of the sight of his mother or babysitter, and experimenting with everything, which usually goes into the mouth. The foods that are notorious for causing an acute obstruction (which the parents quickly learn to recognize, because the child suddenly can only tolerate fluids) are lumps of hamburger, hot dog, carrots, potatoes, and bread. The parents must be warned about these notorious foods and told to advance lumpy foods slowly, to see if and when the toddler can tolerate them. If the lumpiness causes dysphagia, they should back off for a few weeks or months, before trying them again. Fortunately, the exploring toddler will quickly learn what he/she can get away with. When there is a history of an acute esophageal obstruction, one must always get a contrast esophagram, first to confirm the suspicion of a FB, and then it can be removed by esophagoscopy under general anesthesia. Fortunately, there are only a handful of "repeat

offenders." It is rare to see this problem occur once the child is in school and even rarer in teenage patients.

Other Complications to Remember

After the repair of the common EA and distal TEF, there is always a small pouch (diverticulum) in the lower part of the trachea usually on the right posterior aspect. This can only cause a problem to the unaware (uninformed) anesthesiologist who is attempting to intubate the infant or child after his/her EA and TEF repair. This pouch, if intubated, will prevent the patient from being ventilated with occasional dire results, if the problem is not recognized. This situation is easily resolved by pulling the endotracheal tube back a few centimeters and then rotating the bevel of the tube to the left so that it can pass into the distal trachea. This pitfall is as potentially disastrous as if the distal TEF is inadvertently intubated prior to repair, which, of course, leads to lack of pulmonary ventilation and instead ventilation and possible perforation of the upper gastrointestinal tract [4]. The solution to the problem aside from its prevention and avoidance is the same as mentioned above.

Postoperative vomiting in the baby or infant who has recently had the repair of EA or EA and TEF is not unusual, and if it occurs, the surgeon often thinks of a cause related to the original surgery. Since pyloric stenosis is more common (1:300) than EA ± TEF (1:5,000), its rare association with the more unusual latter problem is often forgotten [59]. Therefore, once the more common causes for vomiting in the newborn or infant with a recently repaired EA ± TEF (e.g., anastomotic obstruction, GER) are ruled out, pyloric stenosis should not be forgotten.

In a similar situation, the association of EA or EA with TEF and duodenal atresia or duodenal stenosis is well recognized although uncommon; the latter have been reported in 6 % of EA and EA with TEF babies [31]. Quite often, the diagnosis of the congenital duodenal obstruction is not appreciated until esophageal continuity is established and then the vomiting begins. Remembering the possibility is the key to making the diagnosis.

Chest wall deformities develop in one third of babies after a thoracotomy (almost always on the right side) for EA [15]; this is seldom reported. Indeed, it is the thoracotomy rather than the EA repair that is the culprit for the deformity, although an underlying congenital vertebral anomaly increases the risk [15]. The commonest (50 %) deformity is anterior chest wall asymmetry (Fig. 35.16), and it is more common in patients older than 25 years of age. Breast surgery to minimize the inequality may be required in some female patients with extreme asymmetry. The second commonest (10–20 %) is scoliosis, with both asymmetry and scoliosis occurring in about 10–15 % [15]. While scoliosis occurs twice as often in patients with a congenital vertebral anomaly, its incidence in the population is

Fig. 35.16 Scoliosis and right chest wall deformity after an EA repair

<2 % [24]. An old classification of thoracoplasty scoliosis (following resection of rib or ribs) or pleural scoliosis (secondary to extensive scarring from chronic infection) confirms the latter to be the cause in the EA situation [24]. The pleural curves have their convexity opposite the right side of involvement. The severe curve only develops in children usually 5 years of more after thoracotomy, with a 10° curve required for the diagnosis of scoliosis [24]. Bracing is suggested for curves that measure more than 20°; if progression occurs in the brace, it should be treated surgically. Its follow-up should be coincident with the long-term EA repair follow-up.

Presently, the thoracoscopic repair of EA and TEF babies can be safely performed by experienced endoscopic surgeons; however, "based on the associated musculo-skeletal problems following thoracotomy, there will likely be long-term benefits for babies with this anomaly undergoing thoracoscopic repair" [43].

Complications Following Esophageal Replacements

Introduction and Philosophy

Although the age-old teaching has always been that the baby's own esophagus is better (repaired) than any other type of swallowing tube that can be made ("The esophagus is certainly better than any substitute for it") [52] and still seems to be "The Golden Rule," one must never lose sight of the fact that the baby with an incompletely formed and/or defective esophagus must never suffer in the long run during our attempt to repair the original esophagus.

Having said that, it is becoming increasingly rare to not be able to save and repair the imperfect esophagus to the end point that it eventually requires replacement. This is mainly due, in part, to many (and continuing) methods (both surgical and nonsurgical) to retain the original esophagus in babies born with the so-called long (wide) gap (usually pure) EA. In addition, an increasing awareness of the damage that results from continuing gastroesophageal reflux (GER) has prevented this problem from irreparably damaging the esophagus, and, as a result, aggressive medical antireflux medications have prevented its permanent damage, and, when they have failed, antireflux surgery has quite nicely reversed the problem successfully [60, 62, 74]. Finally, because of a greater awareness of the preventable causes, which previously contributed to lye and caustic esophageal injuries, these disastrous and long-standing events are now being seen much less frequently [74]. These injuries involving the upper aerodigestive system with scarring of the pharynx, as well as the upper (cervical) esophagus, contribute to the very common postoperative swallowing problems (i.e., aspiration), which are increased when any esophageal replacement is sewn to the pharynx as opposed to the cervical esophagus [26]. Choi et al. [16] stated that "loss of sensation in the hypopharynx and supraglottic larynx plays a major role in the development of aspiration."

In spite of all of the above good news about the successful saving of the pediatric esophagus, there continues to be occasions where the esophagus requires substitution and therein has a major procedure (regardless of the particular substitute) and its inherent complications, which tend to be equally large and at times life threatening. Although most patients have postoperative complications [44], early complications are technical, and most survive [6]. The low mortality (3 %) is notable in relation to the complexity of the cases [44].

Throughout the literature, many words have been used by many authors to describe the same thing; that is another piece of bowel being used in place of the congenitally abnormal (missing) and/or irreversibly damaged pediatric esophagus. Therefore in this chapter, the following terms will be used in an interchangeable fashion to denote the above occurrence: bypass, conduit, graft, interposition, plasty, pull-up, reconstruction, replacement, restoring continuity, substitute, transplant, and transposition.

The new esophageal replacement can be made to replace all of or part of the esophagus, and some can be constructed either in an antiperistaltic or

isoperistaltic fashion. Although some can be placed retrosternally, they have also been positioned in the mediastinum, in either of the pleural cavities and even subcutaneously. If the entire esophagus is not damaged, usually the lower one half needs replacement, and the neoesophagus (constructed through an upper abdominal incision) can be passed through the old esophageal hiatus up into the mediastinum and then anastomosed to the upper one half of the esophagus via a right thoracotomy incision (Ivor Lewis abdominal and right thoracic approach) [12]. These total esophageal replacements can be completed in one stage with an immediate anastomosis between the cervical esophagus and the new esophageal replacement or staged with one or two stomas in the neck. Therefore, depending upon how the new esophagus is made [69] and where it is placed will dictate if, how, when and where the complications present themselves. An example of this is if the replacement is brought up through the left chest, it will have to pass through a small hole in the left hemidiaphragm, which may damage the left phrenic nerve paralyzing the left hemi-diaphragm. If the hole is closed too tightly around the replacement, its blood supply will be compromised. If the hole is left open too widely, then bowel can become incarcerated from the abdomen into the left pleural cavity.

Most of the serious complications occur within 3 years after surgery [55]. Interestingly enough, Raffensperger et al. [65] reported in a large long-term follow-up series that: "The patients with EA with or without an associated TEF consistently have not grown as well as those who required replacement for an acquired condition or injury." However, most of the pediatric patients who receive esophageal replacements tend to fall at or below the 10th percentile for height and weight in long-term follow-up [6].

Generally speaking, the complications of esophageal replacements are related to the actual graft, the most serious of which is that the viability (blood supply) may be compromised to a greater or lesser degree. The next commonest complication is usually found at the esophago-replacement anastomosis (usually in the neck); this is either an anastomotic leak and/or a stricture, often, but not always, related to each other. Strictures are more common in patients who had caustic burns, the latter which often involved the hypopharynx and cervical esophagus above the neck anastomosis [26, 65]. Since these pieces of bowel, wherever they are routed, are aperistaltic (whether anti or isoperistaltic), there are both acute and chronic respiratory problems, as well as the complications that accompany gastro-esophageal reflux (GER). These new esophageal conduits almost always cause feeding problems, in transit of liquids and feeds, which will require tube feeds of some sort for short or long-term lengths of time [6, 27]. Food aversion is also a common postoperative problem [27, 30, 44, 74]. Chronic mucosal inflammation also occurs in the proximal (normal) esophagus, especially where there is GER and/or the stomach is sewn to the proximal (cervical) esophagus. This similar problem also can arise in the distal esophageal remnant (if left in place) following any type of esophageal replacement [72]. GER must be controlled by H_2 blockers and diet to treat a possible end-stage Barrett's syndrome. Barrett's syndrome, usually a later problem (although it has recurred within 7 years of the definitive procedure) is also a possible precursor to later esophageal malignancy, has been sporadically reported in all types of esophageal replacements. Although most series have seen few, if any, cases of Barrett's syndrome [27], some authors have reported significant Barrett's involvement, but there is still indecision in the literature about specific (long-term) follow-up [19, 55, 61].

As with any replacement which occupies the retrosternal space, many surgeons leave in place the original esophagus, especially if damaged by caustic ingestion, with rarely any problems [25–27, 65]. If, however, there are respiratory problems which are hard to explain, one must be aware of the rare occurrence of a piece of retained original esophagus which can act as a blind loop compressing and obstructing the trachea and mediastinal vessels [41]. There is also the rare incidence of carcinoma in the remaining unused esophagus [7].

The one common complication that affects all replacements is the 7 % postoperative adhe-

sive obstruction that occurs after any pediatric laparotomy. Eighty percent of these obstructions happen within the first 2 years after the laparotomy and have the same chance of future recurrences [47, 51].

Each type of esophageal replacement has its own advantages and disadvantages [85]; the fact that there are several types of bowel replacements means that in spite of what is written in the literature in a supportive way for each, there is not really one that is more outstanding than the others. The complications from each type of esophageal replacement will be presented in an order of importance (i.e., quantity and quality). This section focuses on the disadvantages, as they are usually the precursors of the postoperative complications.

Gastric Transposition (Pull-Up)

Gastric transposition (pull-up) has probably replaced the colon as the most commonly used esophageal replacement over the last 20 years [74], but it has the same type and number of complications as all the others. However, it has been reported that these postoperative complications of gastric transposition occur less commonly in children than in adults [57].

The disadvantages of this procedure are directly related to its complications, which are [74]:

1. Stomach in thorax
2. GER
3. Poor gastric emptying
4. Interferes with pulmonary function
5. Delayed growth

As with the other esophageal substitutes, there are certain postoperative complications which are directly related to the route taken for the gastric pull-up, most often in the esophageal bed in the posterior mediastinum. This necessitates removal (either bluntly or by thoracotomy) of the abnormal and/or damaged esophagus [74]. Therefore, the risk of damage to other major organs and/or vessels in that area is significant and not without some risk, especially if blunt dissection is used. Although considered technically easier than a colonic conduit, in gastric pull-ups, postoperative complications are common [44], frequent, and often severe, and many require subsequent surgical procedures. Perioperative (early) complications occur in 52 %; most are respiratory, although significant cardiac arrhythmias requiring medical intervention also develop. Late complications are seen in 64 %, with many of them happening more than 12 months after the patients' definitive repair. These were more commonly gastrointestinal anastomotic stricture (40 %), severe GER requiring an antireflux procedure (15 %), adhesive small bowel obstruction requiring operation (10 %), peritonitis after misplacement of the jejunal feeding tube, anastomotic perforation during removal of impacted food bolus, and traumatic TEF after dilatation of anastomotic stricture [44, 74].

In the immediate postoperative course, because of the retro-tracheal blunt dissection, swelling in that area may cause respiratory compromise, and if not electively done at the end of the operative procedure, tracheal intubation and ventilation may be required for a few days postoperatively. The risk of one or two pneumothoraces is also common.

Esophagogastric anastomotic leaks (12–36 %) as well as strictures (12–49 %) are common in a similar fashion as with other esophageal replacements [74]; however, some authors have reported that gastric transposition patients have significantly less leaks and strictures than gastric tube patients [79]. Nonetheless, their treatment is also similar. Macksood et al. [57] reported that benign stricture, which may occur both early and late, is the commonest problem. Gastric pull-ups (as well as the three other substitutes in this section) have more anastomotic problems with the pediatric patients that had caustic damage to their original esophagus, mainly because the remaining cervical esophagus still has some residual caustic damage, which can start as high as the oropharynx [26, 74].

As with the other esophageal replacements, the gastric transposition patients also experience swallowing problems (30 %) and initially do better with small, frequent feeds [74]. Swallowing improves as the pediatric patient becomes more upright and learns how to feed appropriately with their new swallowing tube. Bilious vomiting, because the

stomach joins the esophagus in the neck and because most of these stomachs have pyloroplasties, is common in the immediate postoperative period, especially if not in an upright position. Because the intrathoracic stomach with its pyloroplasty acts more like a conduit than a gastric reservoir, a dumping syndrome is not unusual (80%), but these symptoms usually resolve within a month or so [74]. These pediatric patients also tend to grow slowly for a few years, but time alone tends to cure this problem; this seems to be one of the hallmarks of all esophageal replacements [74].

Colon

Over the last 20 years, the colon has probably been replaced, as the most popular way of replacing (completely or partly) the inadequately developed and/or damaged pediatric esophagus.

Its disadvantages, which often lead to postoperative complications, are listed as follows [74]:

1. Precarious blood supply
2. Graft necrosis
3. High incidence of leaks and strictures
4. Multiple anastomoses
5. Redundancy over the long term
6. Slow transit
7. Unable to be used if congenital colon problems, which require surgery

Some authors feel colonic conduits overall have a higher complication rate than gastric transposition, but this opinion [44] is not unanimous [78]. Most of the major postoperative complications occur within the first few weeks and are corrected, of necessity, during the first few months after the replacement operation [75].

Generally speaking, there is a higher morbidity rate among patients with the intrathoracic route as opposed to the retrosternal route [75] although some report better functional results with the former [64].

Although there is a small risk of vascular compromise of the colon replacement (especially the right colon), it still remains as the most serious complication of this procedure [56] and more so than in the other type of replacements [2]. If this occurs and there is a neck colonic stoma, it will be obvious; otherwise, it must be suspected if the infant or child is febrile, septic, and/or unwell within the first few days of the operation. Esophagoscopy will confirm graft compromise, and if so, it should be removed and the patient must receive an esophagostomy [56].

The most common complications are anastomotic leakage (6–87%) (especially the neck (esophagocolonic) anastomosis) and stricture formation (0–44%) [74]. The leaks are usually a result of a poor blood supply to the proximal end of the colon, often occur within the first week and resolve within a few weeks; some leaks end up with a stricture, while other strictures occur de novo. These strictures are often cured with multiple dilatations, although some will eventually come to a resection.

As with all esophageal replacements, there is GER, which often causes significant problems of pain, vomiting, ulceration, and stricture. These can be treated medically in the usual fashion, with surgery reserved for the resistant complications. Antireflux procedures will cause an obstruction to an already aperistaltic conduit, so these are seldom done [37, 80]. However, some authors claim their antireflux submucosal cologastric anastomotic gastric tunnel eliminated GER in most of their patients [37]; in spite of this, very few surgeons report success with similar antireflux procedures.

Another common postoperative complication with this type of replacement is redundancy and tortuosity, which increases in time and severity (Fig. 35.17); this not only leads to stasis and delayed emptying but eventually to aspiration, chronic chest problems, and failure to thrive. The position and placement of the colonic replacement are somewhat unrelated to this problem. However, Stone et al. [75] reported that reverse colon segments were more dilated and emptied more slowly, compared to patients with retrosternal colon segments. Nonetheless, if this dilatation and distention problem becomes severe enough, it eventually leads to a localized resection to reduce its length and straighten out the colon tube. Care must be taken in doing this resection as the blood supply is more tenuous than in a gastric tube (GT). If possible, this is

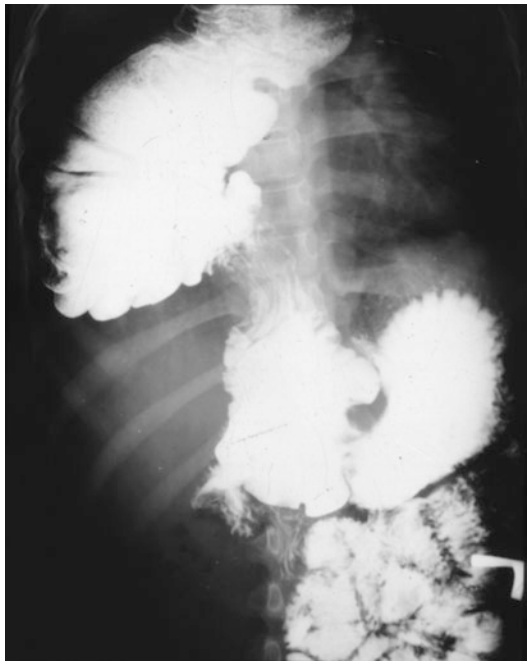

Fig. 35.17 Redundant and tortuous colon replacement; note normal size stomach

most easily done through an upper abdominal incision pulling down and resecting the lower end of the colonic graft and then reanastomosing it to the stomach. This almost always improves the passing of liquids and solids into the stomach. This could possibly be avoided if, at the time of construction of the colon replacement, using a large (? chest) tube as a guide, the antimesenteric half of the graft can be resected so that the piece of colon is narrowed and resembles a GT. Whether this colon will remain as such over the long term is yet to be reported [40]. The chronic lung aspiration (leading to pulmonary restrictive disease in up to 25 %) and nutritional problems due to the colon tube stasis tend to be present during infancy and up to 5–6 years of age, but as these infants and children begin to spend most of their time in an upright position and learn to swallow and eat in accordance with their aperistaltic tube, these problems tend to slowly disappear in most infants and children. Some authors feel that a gastric drainage procedure is an important adjunct in minimizing this long-term morbidity [74].

Although rare, an aortocolonic interposition fistula has been reported (presenting with hematemesis) after 20 years [22].

Gastric Tube

The disadvantages of the gastric tube (GT), which lead to many of the common postoperative complications, are as follows [74]:

1. Very long suture line
2. High incidence of leaks and strictures
3. GER leading to Barrett's syndrome

In spite of the above, some authors believe the GT procedure is easier to perform and has less mortality and fewer complications [27, 30, 35, 70].

Without a doubt, the biggest and most serious complication (albeit rarer than with the other replacements) during or after the construction of a GT is necrosis of part or all of the tube; however, the superior vascularity of the stomach gives rise to less risk than with the colon [35]. The few times that devascularization of the GT has happened were usually intraoperatively, when the gastroepiploic arterial arcade along the greater curvature of the stomach was inadvertently compromised by dividing the omentum too close to the greater curvature of the stomach. The other way that this excellent blood supply for the GT can be compromised is in its compression and/or obstruction in passing the GT up to the neck: either retrosternally (usually) through the mediastinum or through either hemi-diaphragm on its way into the pleural cavity up to or through the supraclavicular space (Sibson's fascia) into the neck. Goon et al. [35] has reported a higher risk of serious chest complications in bringing the GT through the chest with a primary anastomosis in the neck. If there is a primary anastomosis to the proximal esophagus, it will be much harder to recognize a GT which has become partly (usually) at the top (distal end) or completely necrotic. Otherwise, if the GT is staged, then the top will have been brought out as a neck stoma. If the top of an isoperistaltic GT consists of a small portion of distal esophagus (in a wide gap EA), this small piece of distal esophagus, while better to anastomose than a newly formed

Fig. 35.18 Postoperative leak at esophago-GT neck anastomosis

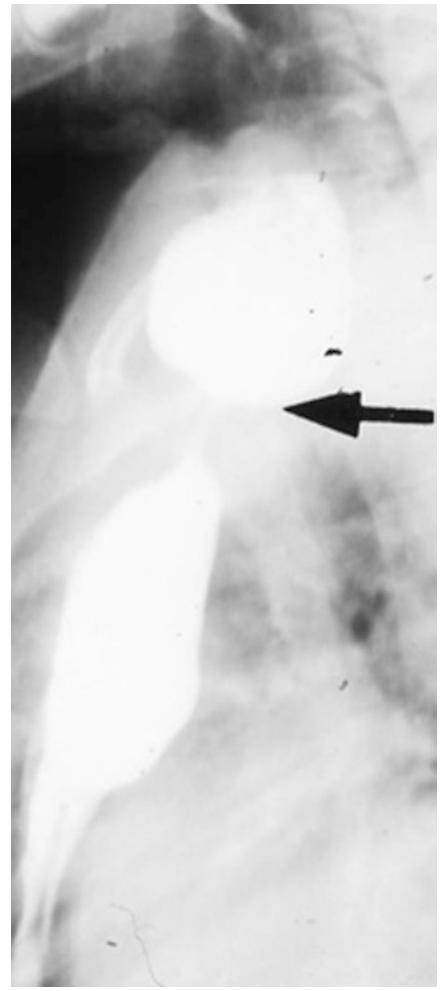

Fig. 35.19 Postoperative stricture at esophago-GT neck anastomosis (*arrow*)

GT, may have a borderline blood supply and as such cause a stricture. If the GT is completed in one stage and part, or all, of it is devascularized, the patient will be febrile and fairly soon septic, prompting one to think about this possible complication.

Generally speaking, the postoperative problems are directly related to the esophago-GT neck anastomosis and its subsequent leak (Fig. 35.18) and/or stricture (Fig. 35.19) [25, 27]. Not all the leaks (33–81 %) result in strictures, and not all the strictures (33–72 %) are preceded by leaks [70, 74]. There does not seem to be a pattern to this problem area at all. It has been reported that a two-layer interrupted anastomosis (along with constant proximal nasopharyngeal sump suction for 1 week) may provide a more problem-free postoperative course [30]. In spite of the above, as well as draining the anastomotic area, it is still impossible to predict an early, late, or no leak, the time of eventual closure of the leak, or the development and severity of any subsequent stricture and the results of its dilatation [27, 30]. If the stricture is so tight that it cannot be dilated at any time and/or it has not been successfully and permanently dilated after 1 year of dilatations, it is time to consider resecting the strictured neck anastomosis [27, 30]. Some resections are now done sooner than later, but the results of this decision remain to be seen. The use

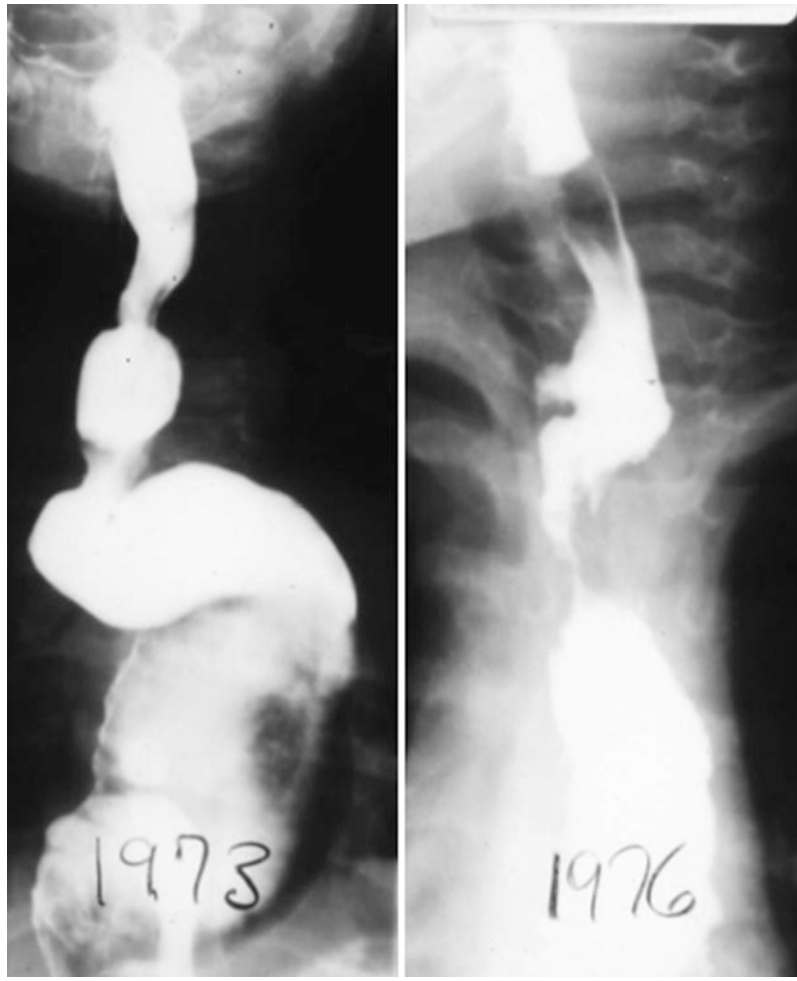

Fig. 35.20 Strictures, dilatation, and tortuosity of lower GT that was cut freehand

of topical mitomycin "C" placed endoscopically may improve the outcome of these strictures [42, 67]. Ten percent of GT neck anastomotic strictures require resection [27, 30].

Strictures of the GT below the neck anastomosis are usually due to the GT being cut or fashioned asymmetrically and probably freehand (Fig. 35.20) [30]. If it causes symptoms and does not respond to dilatations, it will also require a localized resection, but the operative approach will be more difficult.

Redundancy is rarely observed in any GT and is attributed to the thickness of the gastric wall [70]. Another similar complication that can and does rarely arise from a GT cut freehand is a localized dilated area (Fig. 35.20) [30]. This seldom reaches the extent of the dilated, tortuous colon replacement and unless extreme in its tortuosity, rarely, if ever, requires surgical treatment.

A lower stricture may also be due to GER, which can also play havoc with a staged GT construction with its stoma in the neck. In the latter situation, the GER can cause quite severe skin excoriation around the GT neck stoma, which is exacerbated by gastrostomy tube feedings. This annoying problem can be virtually eliminated (or at least minimized) by leaving the gastrostomy to straight drainage and feeding the infant by a gastrojejunostomy or jejunostomy tube [27, 30].

Although all GTs suffer from GER, only a small number have noticeable chronic nighttime coughing and aspiration. This can be, for the

most part, eliminated by keeping the stomach empty for a few hours before bedtime and elevating the head of the bed. Nonetheless, several children do develop chronic respiratory problems and/or failure to thrive (for no apparent clinical reason) until about 5 or 6 years of age, when they suddenly seem to improve [30]. This GER can create a major problem, because the GT, regardless of its construction (ante or isoperistaltic), is really an aperistaltic swallowing tube which empties by gravity; therefore, any type of antireflux procedure would probably obstruct the GT as it enters into the stomach. There have been some reports of prevention of GER without obstruction of the aperistaltic GT by a partial anterior wrap antireflux procedure (Thal, Dor-Nissen) [50, 60] and/or 2–5 cm of intra-abdominal distal GT (due to the increased intra-abdominal pressure) [73]. Aside from the usual medical treatment for GER, if that fails, the best surgical treatment that can decrease the GER is to leave the gastrostomy in place (and frequently open to bedside bag at night), do a pyloroplasty to increase gastric emptying, and/or bypass the stomach for feeding. Fortunately, as the child grows up and spends most of his/her time in an upright position and/or eats more solid food, the GER tends to became much less of a problem [30]. In spite of this, all children with any kind of esophageal reconstructive surgery, especially replacements, must learn to eat slowly, chew their food well, and drink frequently to wash the food down. The incidence of a foreign body (FB) becoming stuck in a GT (or other replacement) is rare and if suspected requires the usual investigation and treatment done for any esophageal FB. The removal from a tortuous GT and/or one in which there is a natural kink or diversion in the cervical region (where the natural posterior esophagus angles anteriorly to join the common retrosternal replacement) may be more difficult.

Chest problems, both acute pneumonia and chronic aspiration from above (more than from below), are not uncommon; especially in the immediate postoperative course [30]. This begins after the esophago-GT neck anastomosis is completed either primarily or secondarily. These infants cannot or will not swallow their saliva immediately after the GT is connected, even when the anastomosis is patent. For this reason, they need constant oral suctioning and/or nasopharyngeal sump suction proximal to the anastomosis for about 1 week [30]. Some infants have chronic swallowing and/or feeding problems, especially if the GT was staged and they did not receive any oral sham feeds; nothing short of time will overcome this type of functional dysphagia. Until such time, gastrostomy or (better) jejunostomy feeds is the only solution [27, 30].

Ulcers (bleeding or perforation) have occasionally been reported both in the GT and the stomach remnant due to stress and/or GER [5]. Occasionally these ulcers do not respond to conservative treatment and require operative repair. While redundancy and partial obstruction with impaired drainage of the GT appear to be etiologic factors, distention of the antral part of the GT may also lead to hyperacidity and play a role in ulcerogenesis [5]. Similarly, a fistula between the GT and the pericardium and/or heart has been rarely reported; it presents with several symptoms and/or signs (chest pain, pericardial tamponade, and upper gastrointestinal bleeding) usually years after the GT was constructed. These complications often present after a significant local infection (empyema, mediastinitis) [27]. If there is a GT fistula with a part of the lung, or the trachea, the presenting symptoms and signs are pulmonary with both air and blood [1, 77, 81].

It is not unusual for the original abnormal esophagus (often from a long stricture due to GER or caustic liquid) to be purposely left behind for technical reasons, with the proximal end closed and the secretions left to drain distally into the gastric remnant. To remove the diseased esophagus can more often than not be very difficult and bloody and remains debatable [6, 27, 30, 65]. The risk of leaving this esophagus in situ in the long term can be the rare closed loop mucocele [41, 49] on either side of a stricture (which requires a segmental resection) and/or the rare esophageal carcinoma in adult life [45].

Although no longer routinely done (for technical reasons), splenectomy is occasionally required, and if so, the patient requires long-term

pneumococcal, *Haemophilus influenzae*, and meningococcal prophylaxis as well as antibiotic coverage to offset the rare but serious post-splenectomy overwhelming sepsis [48].

Jejunum

Jejunum cannot only be used as a true interposition replacing the lower end of the missing and/or damaged esophagus, but it has also been used to replace the entire esophagus. However, it is the most difficult and therefore the least popular procedure done for a missing, malformed, and/or damaged pediatric esophagus [10, 66, 68].

The disadvantages to this use of jejunum (either by pedicle or free graft) are related to its postoperative complications [74]:

1. Precarious blood supply.
2. Microvascular anastomosis (for free graft) and prolonged operating time.
3. High failure rate.
4. Length can be a problem for the complete esophageal replacement.
5. Three anastomoses.

The major complication associated with it, as expected, is its vascular supply and survival of the piece of jejunum. The blood supply, as precarious as it is, either stays intact as a pedicle graft or it is divided as a free graft with an intrathoracic microscopic vascular anastomosis. Either way, "…in children (it) is a demanding operation with considerably early morbidity…" [10].

As with the other three constructed esophageal substitutes, the jejunal one has similar complications to a greater or lesser degree [10, 66, 68]. Once again, depending upon its route of passage, it will also bring into play other specific complications relating to that anatomy (as discussed previously). Leaks (17–25 %) and strictures (6–33 %) also continue to plague this type of replacement and/or interposition [10, 66, 68, 74]. As expected, some strictures, if unremitting to repeated dilatations, will require a localized anastomotic resection [68].

GER also tends to be a problem here with the same type of treatment required; surgical cure is not a guarantee because of the dysfunction of the jejunal graft [68]. However, some authors have reported peristaltic activity with the jejunal graft, which tends to somewhat reduce GER [68]. Chronic respiratory and nutritional problems (all restricting growth) as well as dilatation of the jejunal substitute tend to occur to the same extent as with the colon. Nonetheless, the usual special precautions for drinking and eating must be taught and reinforced to the pediatric recipients of these jejunal grafts.

The Biology of Stricture Formation After Esophageal Atresia Repair

36

John E. Foker

Introduction

An anastomotic stricture after an apparent satisfactory repair of esophageal atresia (EA) can be a vexing problem for all concerned. Post-repair strictures are common and vary widely in severity; nevertheless, they are important enough that their formation and treatment have been studied by pediatric surgeons and GI specialists. The basic science of wound healing and contraction has also been a fertile research area, very applicable to the clinical situation. Whether from clinical sources or studies of cellular events, the information can provide helpful guidance for the treatment of strictures.

Definition

The definition of a stricture remains imprecise because of the subjectivity of the clinical findings and how they are judged. Even objective signs such as the degree of narrowing on an esophagram have failed to provide agreement on what should be considered a significant stricture. In addition, there is considerable variation in the degree of symptoms that must be present before treatment is recommended as well as what should comprise therapy. Consequently, there is no clear definition of an anastomotic stricture whether described by objective or subjective criteria. Variation in the definitions, the indications for therapy, and even the methods of treatment have not been agreed upon from center to center or even among care providers.

Despite the lack of a uniform definition, it is apparent that stricture formation is a very active biological process triggered by biomechanical factors and the consequences of inflammation on wound healing. Furthermore, there must be essentially equivalent, if opposite, biological changes which occur as the process relents and the stricture fades. Finally, experience also reveals that there is considerable individual variation in the vigor of these reactions. An understanding of the biology underlying the structuring process and its treatment will be helpful to improving therapy.

Treatments

The variations in judging severity carry over into the several aspects of treatment including method, timing, and frequency. At one extreme, some physicians have waited until food sticks before

doing the next dilation, while our approach, at the other end, has been to dilate earlier and often until evidence for a stricture is eliminated. A good case can be made, we believe, for the apparent absence of symptoms or a stricture or x-ray evaluation as the only satisfactory clinical result. This would begin with the virtual absence of stricture symptoms, although because of the poor function of the lower esophagus in repaired EA and the common presence of a fundoplication in long-gap EA, some degree of dysphagia is often present and complicates the clinical picture [3]. Evaluation will require a normal esophageal contour by contrast study. Consequently, although a stricture is only one component of the dysphagia which is common in adult patients after EA repair, it is one that can be successfully treated.

Strictures are a discrete component of dysphagia; nevertheless, a great deal of variation exists, both in how the strictures are judged and the methods of treatment that are used. Nothing has been settled in the method, technique, frequency, and vigor of dilations, and certainly, issues regarding adding such agents as steroids and mitomycin C or even patching remain open [6]. We believe effective treatment of strictures can usually be achieved.

Stricture formation is a dynamic process, and this chapter will concentrate on the underlying biology to provide information helpful clinically. Treatment is often necessary and we have used a vigorous program of balloon dilations which eventually reach a diameter slightly larger than the esophagus above and below the anastomosis. The over-dilating allows the esophagus to pass solids as normally occurs. This plan of treatment begins with gentle dilations as early as 3 weeks after the anastomosis is created. The dilations are repeated relatively frequently (weekly to biweekly) and with the balloon diameter steadily increased, usually in 2 mm increments to make steady progress. With this approach, the time for restricturing is reduced and, consequently, so is the amount of stricture formed. The trauma of later dilations is also less.

The adjuncts to treatment including steroids and mitomycin C are commonly used, but no agreed upon protocol exists. Nor are improvements reliable achieved. Frequent dilations can now be easily done using an indwelling balloon catheter which can be re-inflated repeatedly. We have also found removable stents placed for 1–2 weeks seem to impede restricturing and encourage it to relent. Although promising, the role of stents and direct injections remain to be determined. This overall regimen has usually been successful; nevertheless, some strictures may remain recalcitrant and resection becomes a better option. The eventual result needs to be a normal esophageal contour by contrast study and the achievement, within a reasonable length of time, the goal of eating normally.

Cellular and Subcellular Factors

With the esophageal ends pulled together, healing by fibroblasts of a roughly circular anastomosis begins and will be followed by some degree of contracture and narrowing. Cellular studies have shown that the anastomotic narrowing results from a series of events beginning with the ingrowth of fibroblasts. Without anastomotic tension, a relatively thin layer of fibroblasts can accomplish the healing. The contraction tendency often normally relents, allowing the anastomotic line to slowly dilate with the drinking of heavy liquids and later with eating solids. In the more routine short-gap EA case, the esophagus may have a normal contour and grow with the child. This is not always the case, however, but the basic and clinical studies on healing have provided useful information on stricturing and what may allow it to relent.

Experimental evidence indicates that the contraction and scar formation which produce the difficult strictures results from activation and further differentiation of the fibroblasts. If the fibroblasts do not further differentiate, stricturing will be much less of a problem and the anastomotic area will remain relatively quiescent. The activation is stimulated by many factors and limiting them should be helpful in lessening this clinical problem.

With increasing tension, more fibroblasts are required, and the factors are set in play which increase the stricturing tendency. Studies have identified some of the triggers for the sequence of

cellular and subcellular events which lead to scar contraction. The sequence begins early in healing with the fibroblasts producing cytoplasmic stress fibers (actins) which turns them into proto-myofibroblasts. With continued stimulation, most importantly from inflammation, the differentiation continues on to the contractile myofibroblasts which also secrete an actively contractile collagen and further increases stricturing. This differentiation sequence results from cytokines commonly released by inflammation, including VEGF and other transforming factors. [1, 2, 9–12, 16, 18, 20–22, 26, 27, 29, 31, 41, 44–46]

This cellular sequence and subcellular events which accompany them are set in motion by biomechanical factors which may be present at the anastomosis site as well as in the repaired esophagus. The first stricture inciting biomechanical factor is anastomotic tension which is well known to surgeons. Although no quantitative studies have been done, it seems likely that there is a correlation between tension and stricturing tendency. Unfortunately, some degree of anastomotic tension is often present in the longer gap repairs. Until there is evidence that an initial period of growth will be sufficiently valuable to incorporate it into the treatment plan for gaps of medium length, tension will continue to be a factor in stricture formation. In order to reduce the differentiation of fibroblasts into myofibroblasts, inflammation and the cytokines it gives off should be minimized. This is most effectively accomplished by establishment of an intact mucosal layer which will minimize inflammation within the esophageal wall caused by tension, pressure necrosis, and reactive sutures. Inflammation and the active stricturing tendency will likely be significant as long as the anastomotic line is not covered by mucosa.

Two common factors after difficult long-gap EA repairs are GER which will increase inflammation at the anastomotic site and stricturing, which when dilated will tend to denude the area and increase local inflammation. Inflammation clearly enhances stricture formation and will be increased by acid reflux up to the anastomotic site. GER is very common after anastomoses under tension and particularly in the long-gap EA group. We have found that the very LG-EA patients for whom a period of growth induction is necessary virtually always have significant GER. Among the several reasons for eliminating GER in the LG-EA group is to reduce stricture formation. The inflammation at the anastomotic site produced by reflux will likely contribute to the stricturing tendency. Without control of the GER, this stimulus to stricturing will continue and even the use of inhibitors of acid production, e.g., proton pump inhibitors, may not effectively control esophageal inflammation. As the DeMeester group has shown, it is bile reflux which is the chief culprit in producing inflammation and both esophagitis and an increased stricturing tendency [4, 7, 13–15, 17–30, 32–40, 42, 43, 47].

The stricturing tendency eventually relents but this process has been less studied, nevertheless, some methods of treating strictures would seem logical as a way to encouraging less stricturing. Our method is to begin early (about 2–3 weeks after the anastomosis), with a gentle balloon dilation to a diameter less than the esophageal lumen. Depending on how much dilation is needed, this is repeated every 1–2 weeks with the balloon increased in diameter by 2 mm each time. Ultimately, we recommend an over-dilation of 2–3 mm to be sure the lumen will easily pass solid foods as the child becomes older.

For the LG-EA group, at least three to four dilations are commonly needed early in the postoperative period and more may be required. To accomplish these dilations, we routinely use balloon dilators under fluoroscopic control. This seems to reduce the trauma of dilation, and, perhaps more importantly, because there is no shearing involved, the mucosa has a better chance to grow over and cover the anastomotic line. With a complete mucosal covering, the inflammation at the healing line of the anastomosis will be significantly reduced.

Clinical Studies of Esophageal Strictures

Clinically, there are both anatomic considerations and surgical principles which have long been known and utilized by pediatric surgeons to limit stricturing [5, 43]. The configuration of the

esophageal anastomosis is usually roughly circular and will heal principally by the action of fibroblasts. Normal healing involves scar formation followed by contraction which for a circular anastomosis means narrowing of the lumen. There are important clinical factors which will increase or decrease this tendency including the size and construction of the anastomosis, the presence or absence of anastomotic tension, and gastroesophageal reflux (GER). These factors have been well described, and the full treatment of EA includes elimination, or at least, minimizing them when significant. The biology of healing, moreover, is quite complex, but this information provides mechanisms behind the promoters of stricturing and in turn guides the reduction of their activity.

When the anastomosis is generous and heals with the aid of fibroblasts that do not become greatly activated, stricturing will be relatively limited. Presumably, this is why for a significant proportion of EA/TEF repairs, in which the two ends are close together pre-repair and GER is limited, stricturing is not vigorous, and, over time, dilation by food and drink will result in an outwardly normal caliber esophagus. These conditions are not always completely met, however, making some degree of stricturing common.

Most of the clinical mechanisms for stricture formation have been well proven or, at least, extensively debated. The more recent work on the cellular mechanisms, however, provided both the basis for stricturing tendency and clues to limit its occurrence.

This very active treatment of strictures seems to have the desired end result. The children in our growth induction treatment of LG-EA did not require dilations beyond the first year or so after the primary repair if the preceding program was followed.

In contrast, we have had a modest experience with patients referred for treatment of a recalcitrant stricture. These patients suggest that the plan of waiting until the patient becomes symptomatic because the stricture is tight, fails because the dilation must be vigorous. This means that, in essence, one is always starting over.

The dilation must be necessarily more dramatic and presumably involves substantial splitting of the esophageal wall in the area of the anastomosis and, presumably, damage to the mucosal covering. As a consequence instead of making progress toward the stricture relenting, it is actively reinvigorated at 2–6 month intervals. By putting together these plans based on the information and clues previously presented, we have developed a plan to actively treat any stricturing tendency and maximize the chance of a very satisfactory and durable outcome.

Our plan, then, follows in this chapter. A typical plan and the various techniques employed include the following:

When the anastomotic size is small, it can result from a narrow esophageal segment, almost always the lower segment, which after anastomosis the tension will be significant and postoperative GER present. Nevertheless, there are details regarding the construction of the anastomosis that will play a role in reducing stricturing. First, if the esophageal ends are small, and typically it is the lower esophagus, and on the back of the upper pouch, the anastomosis will necessarily be narrow. Cutting back (a vertical incision) on the lower esophagus will increase the diameter of the anastomosis and reduce the possibility of a significant stricture even though they will increase the tension.

The lower esophageal segment is also often small in the case of pure EA where there is no lower TEF, and often in these lesions (types A and B), there is usually a long gap between the segments. The long-gap EA (LG-EA) problem can be one of the most difficult repair issues for the pediatric surgeon, and a section of this book presents the issues involved (see Chap. 18). In these cases, the gap poses more of a problem than the potential size of the anastomosis. Narrowing may also be increased by anastomotic tension.

Tension is common in LG-EA repairs. Although tension does cause some narrowing, the advantages of having the esophagus joined outweigh it.

The method of suturing also plays a role. The older technique of two layer repairs not only

was cumbersome but clearly had a higher rate of stricture formation. Currently, anastomoses are almost always done in a single layer fashion; nevertheless, this does not eliminate the occurrence of strictures. The placement of the sutures also will likely have a role. Suturing is a compromise between generous bites of tissue to reduce anastomotic leaks and smaller bites to reduce the amount of tissue caught up in the suturing process which may encroach on the lumen. Large tissue bites, however, will not reliably eliminate leaks and dehiscence and the tying of the sutures becomes the next important factor. If the sutures are tied to just bring the tissues together and not bunch them up, the chance of pressure necrosis resulting in leakage should be reduced, and in turn, the stricturing tendency should be lessened. These techniques are important in performing the anastomosis, but they will not eliminate the possibility of stricturing. Nevertheless, a carefully done anastomosis provides several advantages.

The choice of suture material will also affect the structuring tendency. Reactive sutures, especially silk, are associated with the development of micro abscesses, anastomotic leaks and, therefore, increased stricturing [42]. Absorbable sutures are much better in this regard; however, breakdown by hydrolysis does result in some local reaction. A braided suture, although increasing strength, does promote microabscess formation. Strength does not seem to be an important consideration; the loop of suture will be quite small, and therefore, strong and breakage has not been observed. Our preference has been for fine (5-0 to 7-0) prolene sutures on a small noncutting needle. While prolene is the least reactive of readily available suture material, it does have the drawback of not being absorbed. The sutures themselves will eventually slough into the lumen of the esophagus; however, this may take weeks to months to complete. Because for the LG-EA patients, we do frequent endoscopies to assess the anastomotic site, and also for evidence of GER, many of the prolene sutures are easily removed at that time, for us, the best choice has seemed to be a non-reactive and, therefore, non-absorbable monofilament suture; however, an absorbable monofilament suture may serve equally well.

The stricturing effects of anastomotic tension and the presence of GER make general sense, and now they can be explained in biological terms as to why they increase stricture formation. At the surgical level, however, anastomotic tension frequently provides difficulty in EA repair. It has been a cardinal principle of surgery that an anastomosis should not be done under tension; however, tension is unavoidable in many cases of EA repair. In the earlier days of EA repair, significant tension did produce disastrous results [22]. We learned that a well-constructed anastomosis would withstand substantial tension and it had become increasingly apparent that some degree of tension was often difficult to avoid [8]. Some gaps are just too wide for a primary repair, however, and the ability to reliably induce growth when a long gap exists make a primary repair possible across the EA spectrum. The repair method is quite flexible and using the principle of growth induction will make a primary repair possible. Of interest and value is that growth induction not only lengthens but also greatly widens the small segments. If the tension will be too great for a safe anastomosis, then a week of internal traction of the ends will convert the repair into a more favorable anastomosis. Nevertheless, tension remains a problem in EA repair both for early anastomotic integrity and resulting leaks and later stricture formation [8, 15, 22, 30, 36, 42].

It has also long been known that an anastomotic leak increases the incidence of a significant stricture. Presumably, this results from several factors. A leak implies an area of necrosis and most commonly occurs in an anastomosis under tension. The inflammation produced by these factors will increase the stricturing tendency. A smaller leak will be treated by drainage and will fill in with time, but this process too will narrow the lumen and lead to stricturing. Finally, the presence of a leak restricts dilating and the stricturing tendency will not be countered. Over a few weeks, the stricture may become quite tight.

One of the important factors in healing is the adequacy of the blood supply to the tissues which must heal. A considerable amount has been written about the blood supply of the upper and lower esophageal segments. It is generally agreed that the great majority of the upper pouch blood supply is submucosal and not effected by dissection. Experience has confirmed this and the dissection of many upper pouches has failed to reveal any significant extrinsic blood supply and in no case in our experience was the esophageal tissue compromised. The upper pouches prepared for an anastomosis uniformly look robust and well perfused.

The lower esophageal segment has been the source of considerably more controversy regarding its blood supply. These arterial vessels feed the lower segment in a similar fashion to that provided to the viscera by the abdominal aorta. These vessels are commonly observed during the dissection and recognized as part of the normal blood supply. The question often raised regards the safety of dividing these extrinsic vessels. Often, however, if the lower segment is short, the vessels arise more superiorly and course downward and even with pulling the segments together for the anastomosis; their presence will not hinder the anastomosis. For vessels that limit pulling the segments together, the issue of the necessity of these vessels becomes more important. Both experimental and personal observation, however, has supported the conclusion that the external arteries can be taken if necessary and a submucosal supply will be adequate. Again, no instance in approximately 200 cases was the appearance of the lower segment compromised by dividing extrinsic vessels nor did a resulting necrotic area produce an anastomotic leak. A well-done anastomosis seems to be the best way to accommodate tension and greatly reduce anastomotic leaks; nevertheless, strictures will occur.

Strictures: Bougienage and Balloon Dilation

37

Khalid M. Khan

Introduction

In adults, esophageal stenosis (narrowing) largely results from malignancy and from strictures due to peptic disease or surgical resection. In children, the main causes of esophageal stenosis are strictures due to ingestion of caustic substances, peptic disease, or after esophageal atresia (EA) repair.

Historically, the earliest treatments included periodic mechanical stretching of the esophagus with bougienage. Dilation is still the most common treatment for patients with esophageal strictures. Stenting can provide luminal structure while the stricture is dilated (discussed elsewhere in the book).

This chapter discusses bougienage and balloon dilation of strictures in children. No specific equipment has been developed for children, and hence, we detail how equipment and techniques can be borrowed from the practice in adults to safely perform dilation and bougienage in small children.

Etiology

Esophageal strictures are uncommon in children; there are no good data documenting the epidemiology of esophageal strictures in children. Worldwide, the most common cause of esophageal stricturing in children is ingestion of corrosives (typically, of alkali, found in household bleach) [1]. Foreign bodies—particularly certain tablets—can lodge in the esophagus, eventually causing strictures, and are reported in adults or children [2]. Ingested disc batteries typically in infants have been shown to cause major injury, even within a few hours of ingestion. Esophageal stenosis can occur after resection of part of the esophagus; the most common cause is primary repair of esophageal atresia (EA) with or without a tracheoesophageal fistula (TEF) [3]. Peptic esophagitis is a common cause of esophageal stenosis in adults. Both peptic esophagitis and stricture formation are much less common in children. In children, it is most commonly seen in children with neurodevelopmental dysfunction. The prevalence of strictures has markedly decreased as a result of potent acid reduction therapy.

Unlike the adult population where malignancy of the esophagus is increasing, tumors are rarely seen in children and are usually benign [4]. Injury from radiotherapy for esophageal and pharyngeal malignancies is also a cause of proximal esophageal strictures. A review of strictures in adults

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_37

noted that just over half are malignant [5]. Peptic strictures make up two thirds of the benign strictures followed by anastomotic strictures, radiation-induced strictures, and caustic strictures [6–8].

Eosinophilic esophagitis reported elsewhere in this book is increasingly reported in children and adults though exactly how often it causes a true stricture versus dysphagia from an induration and dismotility is not clear. Less common causes of esophageal stenosis in children include congential stenosis (also discussed elsewhere in the book) and rarely systemic sclerosis, epidermolysis bullosa, and, primarily in immunocompromised individuals, infection [9, 10].

Pathophysiology

Esophageal anatomy and function are discussed in detail in other chapters. In brief, it should be noted that the esophagus is a tube consisting of smooth and striated muscle caudally and a mucosal layer; it has no major serosal component. The upper esophageal sphincter (UES) and lower esophageal sphincter (LES) control the movement in and out of the esophagus. The unique function of the esophagus is to propagate food and fluid, through antegrade motility, into the stomach. Esophageal stenosis is therefore of major consequence.

The pathology of stricture formation is understood as a primary response to tissue injury, whether from disease, dissection, or mechanical, chemical, or radiologic insult. In the case of esophageal dissection and reanastomosis, healing is followed by deposition of collagen and consequent fibrosis. Ingestion of disc batteries results in chemical and electrical injury from the change in pH. Congenital stenotic lesions in the esophagus may contain tracheal cartilage [11]. Eosinophilic esophagitis and systemic sclerosis are characterized by marked infiltration, resulting in mural thickening and stiffness. Tumor can infiltrate, fill the lumen with growth, or compress by growth in the esophageal wall or from an external source.

Benign esophageal strictures are often classified as either simple or complex in the adult literature. Simple strictures are characterized by a short, ringlike area, without severe narrowing; the esophagus is fairly normal despite some anastomotic or peptic damage [12]. Complex strictures, in contrast, are refractory to treatment or recur even after being dilated and tend to be longer than 2 cm, angulated, irregular, and severely narrowed, with concentric cicatricial luminal fibrosis but no inflammation, and those close to the UES or LES resulting from radiation therapy [7, 8].

Surgical Anastomosis and Esophageal Atresia Repair

In the alimentary tract, establishing continuity with an end-to-end anastomosis is known to be a potential source of stenosis due to strictures and reduction of lumen size. It is, however, the only option when reestablishing continuity of the esophagus. We have focused on esophageal growth using mechanical traction to for repair of long-gap EA. We have noted, as others have as well, that a long gap that requires tension for primary repair has a greater probability of stricture formation [13, 14]. The tendency to develop strictures has also been associated with an esophageal anastomotic leak or fistula, gastroesophageal reflux, two-layer closure, and certain suture types [13]. The reported incidence varies from 30 % to 50 % in patients with EA; the variation is related to the number of patients with long gaps in any given population [14]. Brown et al. described the relationship between gap length and stricture formation: they found a stricture formation rate of 44 % in a group of infants with long gaps (>3 cm) but only 17 % in the group with short gaps (<1 cm) [15]. Another study determined that anastomotic tension increased the risk of esophageal stenosis by ninefold [13]. The exact pathobiology of stricture formation when tension is applied is not clearly understood. One reasonable possibility is that the blood supply may be compromised when significant tension is placed on the two esophageal ends, resulting in more extensive fibrosis. Of note, in our study of long-gap EA, we showed that esophageal tissue growth is possible when tension on

the esophagus is used to increase the length of the esophagus [14]. Furthermore, we showed that the lengthening of the esophagus does not result in mural fibrosis, but rather a normal mural structure—suggesting that tension may be able to stimulate mural esophageal growth [16].

Evaluation of the Esophagus

In older children and in adults, the typical symptoms of esophageal stenosis include dysphagia, which occurs when 50% of the lumen is narrowed [17]. Other symptoms include food sticking in the chest, chest pain with eating, and either eructation or vomiting of undigested food. In smaller children, reluctance to eat becomes likely; at all ages, weight loss can occur, despite a good appetite or adaptation of diet and eating habits. Respiratory symptoms are also possible, ranging from a cough to pneumonia; an inability to handle secretions implies a severe degree of stenosis.

For patients with symptoms of esophageal stenosis, the most relevant evaluation tool is an upper gastrointestinal contrast exam focusing on the esophageal phase. In patients after EA repair, we have found that instilling contrast directly to fill the esophagus is vital, in order to differentiate true strictures from esophageal dysmotility and to avoid incomplete evaluation from poor filling of the esophagus. The choice of contrast may be determined by the likelihood of other problems, such as the risk of aspiration and the possible presence of fistula in the esophagus.

Cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is useful for evaluation of esophageal masses. Endoscopy is essential in evaluating the possibility of reflux-related esophagitis, along with a contrast exam, pH determination, and an impedance study for evaluation of gastroesophageal reflux. We have also used endoscopy for sizing the strictured area and assessing esophageal length; the presence of a hiatal hernia and the esophageal histology results will help diagnose eosinophilia. High-resolution endoscopic ultrasonography (EUS) can help define the length of the fibrous scar and the extent of eosinophilic thickening of the esophagus [18].

As a component of the differential diagnosis of patients with esophageal symptoms, an assessment of esophageal motility may be prudent, especially if the diagnosis is unclear. Such an assessment is the standard method of diagnosing achalasia of the lower esophagus. In a study of symptomatic patients with eosinophilic esophagitis, the investigators used a pull-through balloon technique to identify the area needing dilation [19]. If the etiologic diagnosis of congenital esophageal stenosis is unclear, EUS is useful in differentiating tracheobronchial remnants from fibromuscular stenosis [18, 20].

Management of Esophageal Strictures

The principle of nonsurgical treatment of enteric strictures has been based on application of luminal circumferential force, to disrupt fibrous tissue that constitutes the stricturing process [7, 21]. The configuration of the force can be tangential, shearing, or direct—depending on the instrument used [21]. Electrocautery can be used to ablate tissue or to excise fibrous tissue, with injection of steroids and application of mitomycin C used as adjuncts to reduce the possibility of stricture recurrence [22]. High-dose systemic steroids have been shown to be useful for preventing stricture formation after extensive mucosal resection of Barrett's lesions [23].

To treat patients with stenotic esophageal lesions, the usual timing of intervention is determined by the development of symptoms. However, the need for intervention can be anticipated in some circumstances, such as after an anastomosis has been created or after ingestion of a corrosive substance. In our patients with long-gap EA, we have hypothesized that the risk of stricture formation is high and that the timing of esophageal dilation should preempt severe stricture formation [24]. Conversely, other investigators managing EA have found it better to wait and see if symptoms develop; their practice is clearly still the standard when managing

the typical anastomosis, both in children and adults [1]. Similarly in treating adults with benign lesions, opinions also differ: some prefer intervening early, but others favor allowing a scar to be established before disrupting it [24]. In a study of balloon dilation of post-anastomotic strictures, early dilation was associated with less subsequent dilation [25].

Bougies and Balloons

The concept of bougienage dates back to the Middle Ages when candle wax, bone, silk, and cork were used to deal with food impaction.

The last 50 years have seen a number of developments in the clinicians' ability to dilate. Mercury-filled dilators, most notably the Maloney dilator, have been shown to be highly effective; they can be used blindly and even for self-bougienage [21]. Currently, the most common method used in the United States is a system of long, tapered radiopaque, polyvinyl hollow tubes such as the Savary-Gilliard system (Cook Endoscopy, Winston-Salem, NC) [12]. Regardless of the make, bougies come in a range of diameters up to around 20 mm; the extent of dilation is aimed at restoring the normal diameter of the esophagus.

Balloons constructed from polyethylene or related materials that can fit through endoscopic channels or over a guidewire are an alternative to bougienage. They come in a range of lengths and diameters. The balloons can be employed endoscopically or radiologically and expanded using contrast to ensure accurate positioning. In contrast to bougies which produce a shearing force, balloon dilators deliver a radial force, resulting in a simultaneously applied dilating force across the entire length of the balloon and thus the stricture [6, 8].

Technical Considerations

In adults, dilation with a bougie device can be performed blindly. But the typical dilation is more safely managed using radiography or endoscopy, with or without placement of a guidewire, with the patient under sedation. The size of the lumen that is aimed for varies, but 15–20 mm is necessary for symptomatic relief in adults.

To minimize the risk of perforation, 3 mm of dilation in a single session, with a limit to a diameter of 15 mm, has been advocated in adults, and multiple sessions may be necessary for symptomatic relief [12, 26]. A stricture can be considered refractory to dilation if a diameter of 14 mm cannot be reached during five sessions at 2-week intervals and recurrent if a satisfactory luminal diameter (14 mm) cannot be maintained for 4 weeks [12, 26]. Tight strictures may require redilation at frequent intervals, while rings and webs can be disrupted relatively easily with a larger diameter balloon [12, 27]. In patients with achalasia of the distal esophagus, the principle is to use a large balloon to split the muscular layers. The length of time that a balloon should be inflated is not agreed upon. It ranges from short bursts of 20–30 s to maintaining inflation for several minutes.

As advocated for complex benign strictures in adults, we recommend fluoroscopy and endoscopy in pediatric patients with benign strictures [1]. In infants, bougienage is often performed blindly after EA repair or during procedures involving long strictures from caustic ingestion. In certain patients recovering from caustic ingestion, long-term care has involved antegrade and retrograde dilation, often self-performed [28, 29]. We would add a note of caution when using tapered bougies in small children with a Nissen fundoplication: the bougie often needs to be driven down into the stomach, so the fundoplication may be inadvertently dilated, especially if the stricture is close to LES.

No balloons have specifically been created for pediatric patients; however, esophageal balloons can be used in older children without difficulty. In infants, the standard endoscope diameter may be too large for the esophagus, so we use a smaller-caliber endoscope typically 5–6 mm diameter. These scopes have a channel of only 2 mm which is too small to pass endoscopic balloons. We therefore pass the dilator alongside the endoscope and position it under direct vision.

In small children, esophageal balloons should be used with caution: the infant esophagus is roughly the same as the length of standard esophageal balloon and the balloon may inadvertently disrupt the UES or LES or fundoplication similar to the use of tapered bougies. Measurement techniques can be used to estimate the length of the esophagus before dilation. We have adapted to using shorter balloons designed for the pylorus and the colon that are about 5 cm in length (Fig. 37.1). The smaller length, however, poses the risk that the balloon will slip and hence lose position. The length of the balloon is also important when it comes to dilating a particularly angulated area: balloons are designed to expand in a linear fashion and may disrupt the adjacent mural structure, and polyvinyl tapered dilators may be the safest option.

In the most severe strictures and those affecting the cervical esophagus, a combination of antegrade and retrograde endoscopy has been described in adults with very tight strictures [30, 31]. We have used dual endoscopic access to the proximal and distal end of the stricture, by accessing a gastrostomy with a small scope (Fig. 37.2). A guidewire can be passed using fluoroscopic guidance; even a precut knife can be used to provide a small access hole in the stricture [32].

Outcomes

Objective outcome measures of dilation include improvement of symptoms, the need for redilation, and, in patients with benign strictures, the number of dilations necessary. In adult patients with peptic strictures, symptomatic response rate is 100 %, even though up to 80 % of them may need redilation in the subsequent year; moreover, the need for a second dilation is predictive of the need for further dilations; this is similar to postanastomotic strictures [25]. The use of acid blockers and especially proton pump inhibitors has reduced the restricture rate.

In a randomized prospective study of patients with peptic esophageal strictures, both polyvinyl bougies (Savary-Gilliard) passed over a guidewire and through-the-scope balloons were effective in relieving dysphagia, but the balloons may have had a long-term advantage [33]. In a long-term study of bougie versus balloon dilation, the investigators initially found an increased duration of symptom relief at 5 months with bougies, but

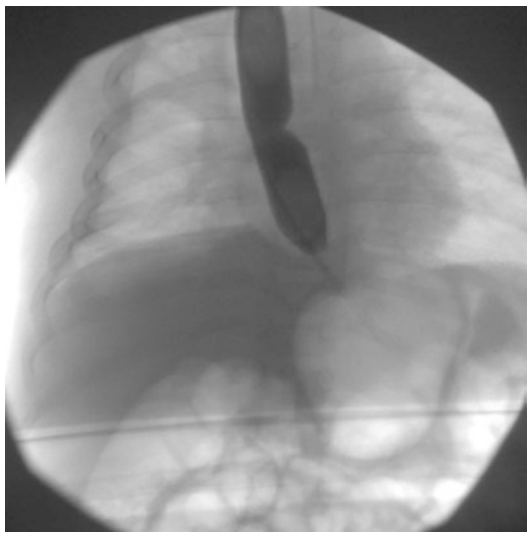

Fig. 37.1 Balloon dilator used in an infant. Note the proportionally larger diameter of the balloon to the thorax. The lower end is sitting above the esophagogastric junction. The patient is monitored for airway compression throughout the procedure

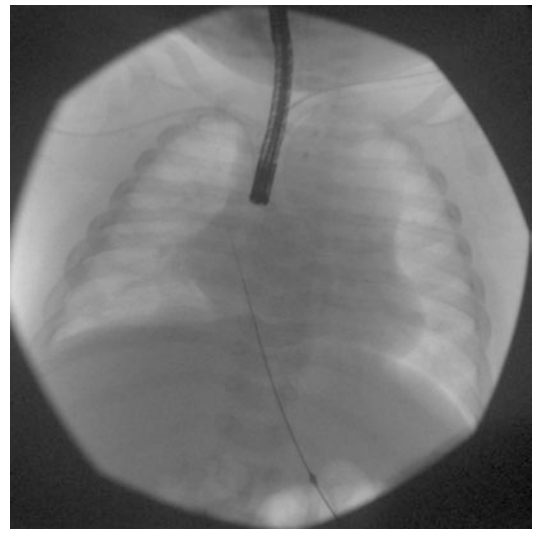

Fig. 37.2 Shows the relationship between the endoscope and a balloon dilator advanced through the gastrostomy site during retrograde balloon placement

at 1 year, there was no difference [34]. In a study of patients with peptic strictures and Schatzki rings, Scolapio et al. observed no differences between Savary-Gilliard versus balloon dilation in the relief of dysphagia or in the need for repeat dilation [26]. An advantage of Savary-Gilliard dilators is that they are reusable [4].

In children, there has been extensive use of bougienage for corrosive injury. Particularly long segments should be dilated with bougienage, and retrograde dilation and self-dilation with bougies is well described [35]. In one series, early dilation was associated with fewer complications than delayed dilation [36]. Similarly Contini et al. [37] found that those referred late had more complications and required more dilations. A study of balloon dilation for corrosive injury in children showed adequate palliation but no avoidance of surgery [38]. A study of long-term outcome of peptic strictures found that recurrent dilation was a predictor for the need for surgery [39]. Ultimately, these data indicate that the degree of fibrosis as the major determinant for the need for repeat dilations.

Bougienage has been shown to be effective in strictures that develop after EA repair, with an 87 % success rate reported in one series [13]. A single balloon dilation has been shown to be successful in one third to 100 % of patients [3, 40–42]. Koivusalo et al. found that a wait-and-see policy based on clinical indications was superior to routine dilations; over 50 % of their patients did not require dilations at all [43]. Most of the above studies did not include a large number of long-gap EA patients that have the greatest chance of recalcitrant strictures. In a retrospective pediatric study, balloons were more effective than bougienage and required fewer dilations [3].

The efficacy of dilation seems to be limited, and with a significant chance of esophageal rupture in congenital strictures that include cartilage, surgical resection may need be considered in such patients [44].

Adjuvant Therapy

Steroid injection into a fibrotic stricture has been shown to reduce stricture recurrence; 4-quadrant injection of diluted triamcinolone acetonide with a sclerotherapy needle was effective in 71 patients with various types of benign esophageal strictures [45]. In a randomized study of triamcinolone with dilation versus dilation alone, the interval between balloon dilations was increased with steroid injection [46]. A similar protocol that added antacid therapy with steroids further reduced the redilation rate and without perforation [47]. High-dose dexamethasone has proven to reduce the number of dilations required [48]. Ultimately, the effectiveness of steroids is likely to be related to the degree of inflammation [12]. In contrast, mitomycin C reduces the risk of stricture formation by reducing fibrotic tendency [22].

Complications

The risks and benefits of dilation—including those related to endoscopy, radiation, anesthesia, and existing comorbidities—must be explained to the patient and/or parent in order to obtain informed consent. The contraindications are relative and include a compromised airway, bleeding potential, and the general condition of the patient to undergo procedures and to blind bougienage include mucosal bridging, pseudodiverticuli, fibrotic shelves, as well as those described as complex benign strictures.

Esophageal dilation should be discussed with the patient and/or parent prior to the procedure using the best available data to estimate risk and benefit. Antibiotic prophylaxis is recommended in high-risk patients undergoing stricture dilation as there is an increased likelihood of bacteremia with dilation of tight strictures [49].

In adults, the most frequently reported complications of stricture dilation include perforation, hemorrhage, and bacteremia [50, 51]. The risk of perforation increases with larger, more sclerotic, or angulated strictures; with more aggressive dilation; after radiotherapy and with the preexistence of large hiatal hernias. Aggressive dilation of eosinophilic esophagitis lesions also risks the possibility of perforation. In a retrospective analysis of mercury-filled bougies, wire-guided polyvinyl bougies, and through-the-scope balloon dilators in adult patients, 4 perforations were noted in 348 procedures, and all of these were from blind dilation

of complex strictures with a mercury device [51]. A review of 251 procedures comparing the Savary-Gilliard system versus balloons also found no difference in complication rates [26]. Similarly an early prospective study of bougies versus balloons in adults found no difference between the two methods [52]. The investigators estimated a serious complication (perforation) rate of 0.4 % and minor complication rate of 4 %, the majority of the latter with repeated bougienage. Overall there is no significant difference between the two methods [5, 34]. A study of the degree of mural disruption with balloon dilation found that 21 % of patients experienced esophageal ruptures, mostly intramural tears; most of the injuries to the esophagus were not clinically relevant [53]. The cervical esophagus and the area immediately above the stricture are usually the sites of perforation.

Repeated dilation of corrosive ingestion was associated with a perforation rate of 17.4 % in one series from Turkey [54]. Other series describing dilation of strictures in children have noted perforation rates less than 3 % after balloon dilation and under 10 % for bougienage [3, 55–57]. Thus, balloon dilation may be preferable in children with simple strictures. In small children, the procedure is invariably performed under general anesthesia, so potential complications of anesthesia have to be anticipated. Anesthesiologists should keep in mind the possibility of hemodynamic instability and of endotracheal tube tip obstruction by the inflated balloon and anesthesiologists should safeguard the airway against blood, secretions, and radiopaque fluid during esophageal balloon dilation [58]. Mediastinal compression during the procedure should be identifiable and corrective action taken [3].

Summary

Esophageal strictures are uncommon in children. Noninvasive management of esophageal strictures is based on the same principles in adults and children though there is much less published literature in pediatric practice. Nevertheless, bougies and balloons can be effectively used to manage benign esophageal strictures in children.

The Dynamic Stent in the Treatment of Oesophageal Strictures

38

Luigi Dall'Oglio

Introduction

Conservative management of cicatricial oesophageal strictures (OS) includes oesophageal dilations and pharmacological therapy. Balloon dilation or endoscopic bougienage is the traditional treatment for OS. Safety and success rate, the optimal duration and the type of dilation remain controversial with a well-known risk of stricture relapse [1, 2]. Oesophageal perforations during endoscopic dilations of caustic stenosis are reported in as much as 15–20 % of patients in large series [3].

Oesophageal stents became popular in the last decade for the treatment of benign OS. Stenting represents a new strategy in order to avoid multiple dilations due to stenosis relapse; it is less invasive than surgical replacement procedures and recurrent endoscopic dilations. Several authors described their experience with different types of stents: silicon stent [4], self-expanding covered stent-Polyflex-Rush [5, 6], retrievable covered self-expanding metal stents designed for tracheo-bronchial use [7], polytetrafluorethylene stent [8], silicon stent [9, 10] and self-expandable biodegradable stent [11].

One advantage of stents is the potential for oesophageal function to be maintained. Stents may have two different mechanisms of action to achieve this; one type of stent, such as Polyflex or self-expanding metal stents, allows the passage of food inside the stent [5–7], while in the second type, i.e. the dynamic stent discussed here, food passes between the stent and the oesophageal wall [1, 8–10]. We have previously demonstrated effectiveness and safety of our custom silicone stent either for the number of dilations or for the duration of the treatment, in comparison with the traditional strategy of repeated oesophageal dilations [1, 9]. More recently, we have demonstrated success of the dynamic effect of our stent in caustic and post-oesophageal atresia strictures [10].

Stent Use in Children

Broto et al. [6] published a series of ten patients with recalcitrant strictures who were managed by a self-expanding silicone/polypropylene oesophageal stent (Polyflex). The stent was kept in place for 20–133 days and allowed normal feeding, and its tolerance was excellent. In this study, five patients were completely cured with a follow-up from 4 to 19 months. Stenting treatment reduced the treatment time and avoided the repeated anaesthesia sessions necessary for dilations. This stent represented an improvement in the treatment of children with benign OS because of its tolerance by patients and their families. The

absence of the NGT seemed to be very important; however, the risk of stent migration and adhesion was significant [12]. In his review, Kramer compared published series that included paediatric patients that had undergone stent treatment [12]. The migration rate was reportedly 10–29 % for the expandable stents and 0–5 % for other intraluminal stents, like the dynamic stent. Effectiveness of the expandable stents was reported in 50 % and 85 % of the patients, respectively. In series describing the use of expandable stents, De Peppo, Atabek and Mutaf [8, 9, 13] reported healing of the strictures with intraluminal stents in 96 %, 72 % and 69 % of patients. We interpret these reports as suggesting that the dynamic effect of food passage between the stent and the oesophageal wall allows for the improvement of oesophageal motility in addition to preventing stricture recurrence. In our last publication about dynamic stents [10], we reported good results in 88.6 % of the patients. The reduction of the stricture healing rate, in comparison to our previous paper [9], is due to the enrolment, from other referral centres, of very severe OS cases in which the stent had been used as rescue therapy before surgery.

The Dynamic Stent

The custom stent is built coaxially over a 12–14-Fr nasogastric tube (NGT) that helps to maintain the correct position. We use slices of silicone tubes (Penrose Drainage Redax S.r.L. Mirandola, Mo, Italy) that overlap each other to reach the desired diameter and length (Fig. 38.1). The custom silicon stent, which has a 6.5, 8.5, 10.5 or 12.5 mm external diameter according to the patient age and stricture length, is tailored to exceed the length of the stricture by at least 2 cm to avoid displacement of the stent above or below the area of interest [10]. The two stent ends are tapered for its easy introduction and to allow the food passage between the stent and the oesophageal wall. Instead of the silicone slices, a radio-opaque band is used to improve the radiological image during the insertion procedure and to evaluate the stent position; two metallic clips are affixed at the extremities. The patented commercial version of the dynamic stent will have the opportunity to vary the rigidity of the stent itself.

How the Dynamic Stent Is Used

The dynamic stent placement requires an experienced endoscopic team and a meticulous attention to all phases of our protocol. Endoscopic procedure is performed under general anaesthesia with tracheal intubation. We use standard videoendoscopes (GIF-XP160, GIF N180 and GIF-Q165; Olympus Europe). A straight-tip stiff guide wire (Amplatz Super Stiff, 0,035 in, Boston Scientific, MA, USA) with a semi-rigid tip is inserted through the stricture in to the stomach under spot fluoroscopy. Subsequently, oesophageal dilations are performed with an endoscope balloon dilator (TTS Microvasive, Boston Scientific from 10 to 12 mm in diameter) or Savary-Gilliard dilators (5, 7, 9, 11 and 12.8) (Cook Medical, Bloomington,

Fig. 38.1 The dynamic stent in the custom version. The two extremities are tapered for easy insertion and food passage around the stent

IN, USA) to obtain an adequate oesophageal calibre that would allow stent placement, of the desired size. Either the proximal or distal ends of the stricture are marked with a cutaneous marker (Fig. 38.2). After the dilation, accurate endoscopic evaluation of the oesophageal wall is performed with water injection and the aspiration of blood and mucus. We rule out oesophageal perforation with water-soluble contrast medium injected through the endoscopic channel with air under pressure (Fig. 38.3). A minimal perforation does not represent a contraindication to stent placement. The stent is then inserted through the mouth, over the guide wire, and its correct position is radiologically confirmed. The nasogastric tube of the stent is then passed backward through the nasopharynx and out of the nose, to which it is fastened. To avoid the distal displacement of the stent, a transverse silicone bar is affixed to the nasogastric tube outside the nose (Fig. 38.4). The patient receives a standard antibiotic prophylaxis, post-operative sedation and i.v. omeprazol treatment (1 mg/kg/day).

On the first post-operative day, an oesophagram (Fig. 38.5) with water-soluble contrast medium is performed, and, in the absence of leakage, oral, cold soft feed is started. In the absence of a perforation, the patient receives dexamethasone (2 mg/kg/day) for 3 days, progressively reduced and stopped in 6 days. Drooling and retching are always present on the first day after stent placement but resolve spontaneously, and all patients are generally able to resume a normal diet. In a few days, patients are gradually encouraged to eat normal food. We suggest solid food if the child is able to handle it. Patients are allowed to graduate from semi-liquid to soft or normal food (such as meat, pasta and pizza) according to their age, psychological condition and the characteristics of the stricture. The ability to eat normal food represents a very important and positive prognostic factor. Early resumption of oral feeding may be effective in

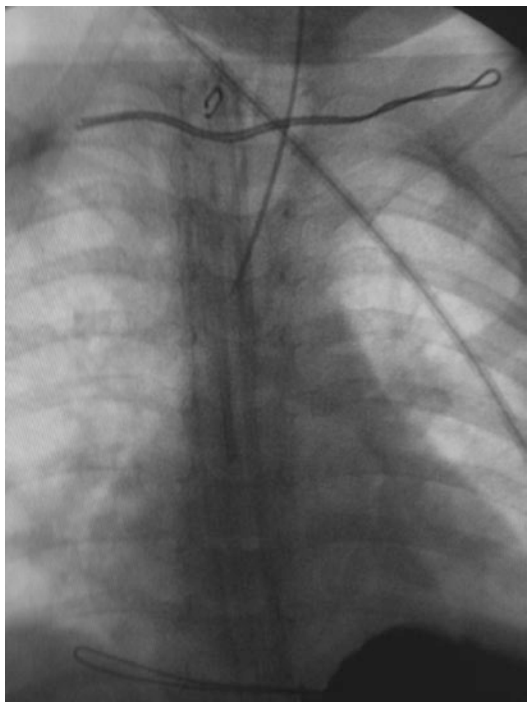

Fig. 38.2 Cutaneous marks at the stricture extremity, endoscopically and radiologically evidenced

Fig. 38.3 Contrast and air are injected through the endoscope suction channel to rule out possible oesophageal perforation. Here a normal oesophagogram

Fig. 38.4 The silicon bar affixed on the nasogastric tube, just outside the nostril, to avoid the distal stent dislocation

helping oesophageal plasticity and may therefore reduce scar development: the dynamic effect of this stent.

The stent is removed by the mouth after at least 40 days under general anaesthesia with endoscopic control of the oesophageal wall. In some cases, for logistical reasons, due to the distance from the hospital, the stent was removed later without complications. Extrapolating from the experiences of Attabek and Mutaf [8, 13], who left stents in place for 9–14 months, and our results showing a good stent tolerance, we now suggest leaving the stent in place for 2 months.

One month after stent removal, a barium swallow is performed to evaluate both the oesophageal lumen and the motility of the oesophageal wall. In case of partial stricture relapse it is likely to be less of a problem than before the stent treatment, and we advocate that the patient undergo monthly dilations. Gastro-oesophageal reflux disease (GORD) plays an important role in the scarring process and needs to be ruled out before considering a second stent. Reflux is often clinically not evident and Nissen fundoplication can positively change the patient clinical course. In case of early stricture relapse, especially if the stricture length is unaltered we would consider a surgical option rather than repeated dilations or a second stent. Psychological, social and logistical issues play an important role in this difficult choice and full counselling with the patient and parents is necessary. In case of recurrent strictures >2 cm in length, patients need a re-stenting procedure. Treatment is considered effective when patients are able to eat solid or semi-solid foods without dysphagia and when radiological studies show the resolution of the stricture.

Fig. 38.5 The oesophagogram performed in the first day after stent insertion. The water-soluble contrast medium passes around the stent that appears in the correct position in relative to the cutaneous marks

During follow-up, all patients are investigated for GORD. For the first 5 years after stenting, patients have 24-h pH-monitoring sessions and oesophageal biopsies to rule out GORD and oesophageal dysplasia every 2 years. Subsequently, the patients will have examinations on the basis of clinical evolution, with

endoscopy and biopsies performed every 5 years at minimum.

Stent Indications

Following our results demonstrating a reduction in both the number of dilations and the duration of treatment [1, 8], in caustic OS, the dynamic stent represents our treatment of choice. In these patients, we insert the stent, if it is possible and safe, after the first dilation. In post-surgical OS, it is well known that only one or two dilations may be required to resolve the stricture and related symptoms and so we place the stent only after at least five dilations. In strictures that follow oesophageal atresia repair, before considering stent insertion, it is mandatory to rule out vascular anomalies, such as an aberrant right subclavian artery; vascular anomalies are not rare in oesophageal atresia patients. There have been reports of subclavian-oesophageal fistulas [14], with severe gastrointestinal bleeding, in patients treated with a stent and with an undetected vascular anomaly.

Results of Dynamic Stenting

In Table 38.1, we have summarized our experience in the treatment of OS with the dynamic stent: The mean length of the strictures was 5.4 cm (range, 1–11.5 cm). Forty (50.6 %) patients underwent several oesophageal dilations (mean, 5.1; range, 2–26) before stent placement. We performed 114 stent placement procedures in 91 patients. Stents were removed after a mean of 39 days (range, 15–65 days). In 80/91 patients (87.9 %), the custom stent was effective in achieving resolution of the stenosis and relief of dysphagia with normal food swallowing.

Table 38.1 Results of 91 oesophageal strictures treated with the dynamic stent from 1988 to 2012

Effective 80/91 (87.9 %)
Caustic 56/62 (90.3 %)
Post-anastomotic 21/26 (80.7 %)
Actinic 2/3 (66.6 %)
Ineffective 11/91 (12 %)
Caustic 5/62 (8.6 %)
Post-anastomotic5/26 (19.2 %)
Actinic 1/3 (33.3 %)

A total of 45/91 patients (49.4 %) received only one dilation contemporary to the stent placement and no post stent removal dilations. All of these patients were caustic, in many cases (24 %) previously treated with several dilations without clinical improvement at referral centres.

The custom stent was found to be ineffective in 11 patients (12 %): 5 with caustic strictures, 5 post-surgical strictures and 1 actinic stenosis. All of these patients successfully underwent surgical treatment, except two cases that only underwent dilations.

Of the 80 patients successfully treated with oesophageal stenting, 45 (56 %) did not require further dilations on long-term follow-up (median, 12 years and 4 months; range, 6 months to 24 years). In the other 35 patients, a mean of 6 dilations (median, 3; range, 1–33) were required after stent removal. Fourteen children (17 %) required more stents (mean, 2.7; range, 1–4) and dilations (median, 4.5; mean, 6.6; range 1–29) after stenting to achieve complete resolution of the strictures.

Eight patients were affected by double strictures, seven caustic ingestion cases and in one case of post-surgical stenosis. In all but one of these cases, complete resolution of the stenosis was achieved with the dynamic stent. In two patients, premature stent removal was required due to respiratory distress for acute reflux laryngitis in the pre-omeprazole era, and four subsequent dilations were necessary to obtain resolution of the stricture.

The oesophageal atresia anastomotic stricture group, from 1992 to 2012, comprised 387 patients (mean age 38.6 months; range: 3–125 months), some referred from other hospitals. A total of 1,583 endoscopic dilations were performed (mean, 4 dilations; range: 1–24). Oesophageal stenting was performed in 26 (6.7 %) of the 387 patients for failure of endoscopic treatment.

On follow-up of these anastomotic strictures, mean 5.4 years (range 6 months to 20 years) in

21/26 cases (80.7 %), the stent was effective with complete resolution of oesophageal stricture. In 5/26 (19.2 %) cases, a surgical procedure was necessary after stricture relapse. Stricture resection with jejunal interposition and oesophageal re-anastomosis were performed in one case and in four cases, respectively. In these patients, we obtained shortening of the stenotic area with the stent; therefore, in four out of five cases, it was possible to perform an easy oesophageal anastomosis after the stricture resection. Two patients (9.5 %) had severe dysphagia due to pronounced oesophageal dysmotility with consequent nutritional support through gastrostomy.

Severe symptomatic GORD represents an important problem in patients with OS. It was diagnosed in 15/26 (71.4 %), post-anastomotic strictures, in 14/62 (22.5 %) caustic strictures and in 1/3 actinic strictures; therefore, a Nissen fundoplication was performed.

Fig. 38.6 This x-ray shows an oesophageal perforation with the stent in the correct position. The Replogle double-lumen suction 10 Fr drainage is at the perforation level for optimal suction

Complications

We observed two major complications being fistulas and perforation: subclavian-oesophageal fistulas with severe gastrointestinal bleeding in a patient with unknown aberrant right subclavian artery [14]. The patient underwent surgical correction with a patch repair and, after the second bleeding, with a graft substitution placing the graft anterior to the oesophagus.

Oesophageal perforation related to endoscopic dilation, which varied in severity, was observed in six patients. One patient died after incurring several systemic complications. In a second child, a percutaneous drainage of a mediastinal abscess was performed, and the stent was removed; after clinical resolution of this complication, the patient underwent a second stent with stricture healing. In a third child, a double-lumen 10 Fr suction tube was inserted in the oesophageal lumen alongside the stent at the level of the perforation, to obtain full suction (Fig. 38.6) with full recovery from the perforation. In the remaining three children, the minimal perforation spontaneously resolved with the stent in place. In patients with oesophageal perforation, dexamethasone therapy was started only after the perforation had sealed. Drooling and retching were always present on the first days after stent placement, but they resolved spontaneously, and all patients were able to resume a normal diet.

With respect to minor complications, we observed partial displacement of the stent in 15/114 (13 %) stent placements. In one case of proximal dislocation above the stricture due to post-operative retching, the stent was substituted with a longer one. In the other 14 cases of partial distal dislocation, due to food passage and incorrect fixation of the transverse silicone bar attached to the NGT outside the nose, the stent was correctly positioned again with simple traction on the NGT and the silicone bar was positioned more distally than before, thereby avoiding recurrence of this problem. In two more cases, the stent migrated into the stomach because of an incorrect stent fixation to the coaxial nasogastric tube. The stent was endoscopically recovered and substituted.

During the long-term follow-up, 30 patients (37.5 %) underwent Nissen fundoplication for severe GORD resistant to proton-pump inhibitors. None of the patients with endoscopic follow-up presented with oesophageal mucosal dysplasia or Barrett's oesophagus.

In summary, the dynamic stent represents an excellent alternative to tubular luminal stents and can reduce the morbidity from recurrent balloon dilations and potentially reduce the number of patients that need to go to surgery.

Mitomycin C Application on Caustic Esophageal Strictures

39

Khaled Mohamed El-Asmer,
Mohammed Abdel-Lalif Ayad,
and Alaa Fayez Hamza

Introduction

Benign esophageal stricture in children is a common complication owing commonly to gastroesophageal reflux, esophageal surgery, and ingestion of corrosive agents [1]. Management of esophageal stricture is controversial between centers, and there is no standard protocol for management worldwide; however, it is almost agreed that endoscopic dilatation is the first line of treatment trying to preserve the native esophagus [2]. However, some cases are resistant to frequent endoscopic dilatation, and, therefore, another treatment modality is indicated such as esophageal stenting or surgical intervention. Among these strictures caustic one are the most difficult to be managed with high incidence of recurrence, and most of these children referred eventually for esophageal replacement procedure [2–5].

Background/History

Many researchers directed their effort to find adjuvant treatment to improve the results of endoscopic dilatation for resistant esophageal strictures. Several agents had been tried experimentally to inhibit new collagen formation and so preventing esophageal stricture recurrence, but none had been effective for clinical application [6].

Recently mitomycin C (MMC) – an antibiotic isolated from *Streptomyces caespitosus* that has significant antineoplastic and anti-fibrotic properties – was proved to reduce scar formation in animal studies [6]. Clinically, MMC started to be applied in many ophthalmological procedures, e.g., pterygium surgery and glaucoma and lacrimal duct surgery which proved to be effective in decreasing rate of recurrence and postoperative scarring [7, 8]. Then otolaryngologist started to apply MMC widely in their field that achieved good results in preventing recurrence when added to usual management of laryngotracheal stenosis, after surgical correction of choanal atresia and other different surgical procedures [8–11].

Experimentally mitomycin C application was effective in preventing strictures following caustic esophageal injury in rats in a duration and dose-dependent manner [6]. In the past few years, some case reports were published on the use of MMC topical application on esophageal strictures with promising results [12–16].

Evaluation/Indications

Management of esophageal strictures usually requires multiple endoscopic dilatation sessions for prolonged period of treatment reaching in

DOI 10.1007/978-3-642-11202-7_39

some resistant cases up to 2 or 3 years. This long period of management and repeated dilatations have its psychological, social, and economic drawbacks on the child, parent, and medical society, and still there is high incidence of recurrence especially for those with caustic strictures [17, 18]. That is why the use of MMC as adjuvant to endoscopic dilatation could be of a great value as cost-effective modality in managing these patients.

Although MMC can adversely cause tissue sloughing and necrosis, bone marrow suppression, alopecia, nausea, and vomiting when administered intravenously or at high doses, topical applications in concentrations up to 0.4 mg/ml have been tried safely on esophageal strictures without local or systemic adverse effects with follow-up periods of up to 5 years [16].

Importantly, it must be emphasized that MMC has the theoretical risk of causing secondary malignancy in the long term [19]; however, in the early experience of MMC application in ophthalmological procedure, there were no malignancies had been reported in 870 pterygium cases in which MMC concentration of 0.4 mg/ml was applied and followed up for 10 years [7].

Treatment

MMC Dose and Concentration

Although the proper dose is not well studied yet, MMC concentration of 0.4 mg/ml that is to be applied topically on stricture site for 5 min shows to be effective and safe in short-term follow-up in our experience. Some authors reported the use of higher concentration up to 1 mg/ml without apparent side effect [12, 20]; however, further studies with long-term follow-up are needed to declare the most effective and safe concentration to be used on esophageal mucosa.

Application Technique

Topical MMC application is done after esophageal dilatation in the same session. The best is to apply the drug exactly on the area of denuded mucosa at stricture site after dilatation without touching normal adjacent mucosa with the applicator. There are many reported techniques for MMC application on esophageal wall; the classic first described one was by delivering a piece of gauze or cottonoid sponge soaked with MMC using a grasper forceps through rigid esophagoscope to the stricture site and to be applied sequentially on the four quadrant of the esophageal lumen. Although this way was easily practiced, it was difficult to control the precise application of the MMC to the site of the stricture only without unintentional exposure of normal esophageal mucosa to MMC, and also it was not applicable for long strictures.

At pediatric surgery department, Ain Shams University, Egypt, a modified technique was described using an applicator that was designed to match each stricture length individually for each patient. This was done using rigid esophagoscope and nelaton catheter as follow:

Nelaton Catheter Preparation

A nelaton catheter (size 10 FG) is prepared by wrapping a piece of cotton around its tip and circulating its terminal pores. This piece of cotton is secured in position using 3-0 silk suture; this fixation is done to secure the cotton piece from slippage during application. The length of the cotton piece is tailored according to the stricture length. Next, in vitro, the catheter is introduced inside the esophagoscope till the whole cotton wrap appears from its distal end, and then a mark is placed on the part of the catheter that just appears out from endoscope (catheter mark), to be sure during application that the whole cotton piece is applied on esophageal wall beyond the endoscopic distal end as the vision will be obscured by applicator during its introduction through rigid endoscopy.

Application Procedure

1. Esophageal dilatation – under general anesthesia and endotracheal intubation – using flexible endoscopy and wire-guided Savary-Gilliard dilators to appropriate size for each patient.
2. Reintroduction of flexible endoscope to accurately assess the site of the stricture (its distance from upper incisor) and its length in centimeter.

3. Marking the rigid esophagoscope with small adhesive tape at a point that is at equal distance to that measured by flexible endoscope corresponding to the site of beginning of the stricture (endoscopy mark). That is not to advance rigid endoscope beyond beginning of stricture which is more friable after dilatation to decrease incidence of perforation.
4. Introduction of rigid esophagoscope under vision till the endoscopy mark reaches the upper incisor. We confirm that we are at the beginning of the stricture by visualizing the denuded mucosa at stricture site after dilatation.
5. Introduction of the nelaton catheter inside the esophagoscope till the catheter mark is just at proximal end of esophagoscope. Now the cotton piece is just accurately applied on the stricture site.
6. Injection of 5 ml of the prepared MMC solution inside the lumen of nelaton catheter, that made the cotton piece soaked with the solution. This was left applied in place for 5 min.
7. Withdrawal of the catheter inside the esophagoscope not to expose proximal esophageal mucosa to MMC, followed by withdrawal of endoscopy.
8. Postoperative chest X-ray was done after complete recovery for exclusion of iatrogenic perforation.

Other authors reported different techniques by which MMC drug delivery was done through gastrostomy site with combined use of flexible endoscopy and/or fluoroscopy; however, it is to some extent a sophisticated technique, only applicable for patients with preexisting feeding gastrostomy, and it is hardly to be applied for long stricture [14–16].

Results

In pediatric surgery unit, Ain Shams University, MMC has been applied on caustic esophageal strictures of variable length on two clinical trials.

The first trial is a double-blinded randomized placebo-controlled trial on localized caustic esophageal strictures (<3 cm in length), wherein 40 patients were included in this study and were randomized into two groups, 20 patients in each group. Both groups were scheduled for regular endoscopic dilatations "session every 2 weeks for 3 months and then session every month for another 3 months"; assessment of stricture length was done in the first session, and MMC/placebo application was done in the second session, and subsequently the next scheduled sessions were done only if patient is symptomatic at its scheduled time. Assessment of patients after 6 months of drug/placebo application revealed that 16 out of 20 patients (80%) in MMC group had complete resolution of dysphagia after one session of MMC application and this raised to 18 patients (90%) after second application that was done after 6 months from first application, and this was compared with placebo group where only 7 out of 20 patients (35%) were resolved from dysphagia after 6 months of management. And it is remarkable that this significant difference in success rate between two groups was achieved with significant less mean number of dilatation sessions needed for MMC group (3.85) as compared to the placebo group (6.9). These patients are free of dysphagia for 9–36 months of follow-up with no recurrence.

The second trial was done on another group of patients (21 patients) with long caustic esophageal stricture (>3 cm and up to 8 cm in length) which resulted in resolution of dysphagia in 16 patients (76% success rate). Although these long strictures needed more dilatation sessions as compared to localized strictures and MMC was applied on multiple sessions (two to six times), however, these patients were previously referred for esophageal replacement due to failure of esophageal salvage by regular endoscopic dilatation.

Conclusion

According to these data, topical MMC application should be added to any standardized protocol for esophageal stricture management, as it markedly improves the response to endoscopic dilatation achieving a better quality of life for these

patients by preserving their native esophagus and decreasing the need for esophageal replacement procedures with its associated morbidities and mortalities.

Future Directions

Further studies are justified to investigate the proper dose and duration of MMC application as well as the number of application sessions that could be performed for each patient. Although this new treatment modality looks so promising in changing the quality of life for these patients with esophageal strictures, caution must be taken as regards its unjustified use as long-term adverse effect of topical MMC application on esophageal wall has not been studied yet.

40 Reoperations After Esophageal Atresia Repair (for Significant Leaks, Recurrent Fistulas, Strictures, Residual Tracheal Pouches, Large Diverticula, Partially Intrathoracic Stomachs, and Failed Repairs)

John E. Foker

Introduction

Reoperation may be needed for a number of reasons following repair of esophageal atresia (EA) with or without a tracheoesophageal fistula (TEF). Although not all complications require reoperation, one may be desirable either because of the severity or to bring the problem to a close if nonoperative treatment has been unsuccessful. The judgments about the severity of the problem or the risk of reoperation will vary considerably among practitioners, consequently, so will treatment plans. For many surgeons, a reoperation understandably seems daunting and clearly requires experience and a center that is able to support complex procedures. Currently, there is a lack of clear definitions and guidelines for what deserves reoperation; nevertheless, with these variables in mind, we will present our approach for significant complications which we believe justify an operative solution.

Reoperation may solve the problem more quickly and effectively than other approaches, and this chapter will discuss why and how they are done. Among the significant complications of EA repair, the literature reports an anastomotic leak rate of up to 25% and a recurrent TEF (recTEF) incidence of up to 15% [1–6]. Postoperative anastomotic strictures are also common although the frequency has not been established because, to some degree, it is a subjective diagnosis without an agreed-upon definition. These problems as well as residual tracheal pouches, diverticula from a previous myotomy, and a partially intrathoracic stomach from whatever cause often deserve reoperation. The literature has shown that the significant early complications are more frequent in repairs of long-gap EA (LG-EA); however, even apparently successful short-gap repairs may have chronic problems worthy of reoperation [1–14].

From the literature, the majority of leaks apparently heal spontaneously, but some do not and may require reoperation to close a chronic lesion. A recTEF, in contrast, is unlikely to heal on its own because a mucosa-lined track usually forms which prevents spontaneous closure. Several endoscopic methods to treat a recTEF including stripping off the mucosa

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_40

and/or plugging the track with various materials have been described [15]. Success, based on the patients referred to us, is unpredictable and the recTEFs often persist. Furthermore, a stricture in combination with either a leak or a recTEF presents an even more difficult problem because the usual methods of dilating the stricture will also likely keep either the anastomotic hole or the recTEF open. For these problems, reoperation will often be the best solution.

There are several other lesions following an EA repair which may be best treated by a reoperation. Occasionally, a residual pouch left in the tracheal membranous septum at the site of a lower segment fistula may enlarge, collecting mucous and bacteria which produce symptoms [12]. Although attempts to reduce the pouch have been made endoscopically, at present, a reoperation will likely be more successful [16].

Two other problems which result from techniques used to facilitate an anastomosis are a diverticulum from a circular myotomy or reflux from a partially intrathoracic stomach. Doing one or more myotomies or pulling the stomach part way up through the hiatus to allow a primary anastomosis in a longer-gap defect may have seemed like a good idea at the time; however, there may be unfavorable consequences. A myotomy may result in a large unsupported diverticulum which hinders food passage, continues to enlarge, and may even cause airway problems [13, 17]. For a partially intrathoracic stomach with the GE junction is in the chest, whether high or low, it is subjected to negative pressures, and significant reflux is predictable as are the consequences. These are difficult and reliably progressive problems which are very unlikely to be effectively treated without a corrective operation.

Most structural complications, with the exception of some anastomotic leaks, are unlikely to resolve without intervention and left untreated, usually produce significant symptoms. Consequently, for persistent problems resistant to nonoperative strategies, the indications for a reoperation will include large anastomotic leaks, recurrence of a TEF, a membranous tracheal pouch, significant GER, a recalcitrant stricture which does not relent with dilations and/or short-term stent placement, a large esophageal diverticulum, or a partially intrathoracic stomach. These are often complicated clinical situations and may require some combination of esophageal, tracheal, stomach, and diaphragm repair.

Reoperations, however, with predictable, often "dense" adhesions, the uncertain quality of the tissues to be repaired, and a lack of experience with difficult reoperations all may temper the surgeon's enthusiasm. The trepidation about reoperation may lead to a continued search for other solutions, to the detriment of the patient. Consequently, sending a patient with a significant chronic problem to a center where sufficient experience and expertise exists will make sense [11].

Reoperation, as a result, will fall to some surgeons, and the purpose of this chapter is to describe the surgical details which should aid in carrying out repeat thoracotomies with successful repair of the problems encountered.

The Surgical Technique for Reoperations

Timing of the Reoperation

The timing of the reoperation in relation to the previous thoracotomy or laparotomy will affect the ease of reentry. If the reoperation is done within about 10–12 days after the previous operation, reentry through the interspace and dissection throughout the pleural space will be relatively easy. Increasingly after this time and until at least 5–6 weeks later, the neovasculature that accompanies adhesion formation will insure blood loss during reoperation. After about 6 weeks' time, the vascularity will have largely regressed and, as the adhesions become filmy in nature, bleeding during reoperation will be less.

The Incision, the Interspace, and the Dissection

With the patient in a straight lateral position, perhaps tipped a little forward, the previous skin incision is usually reopened which will allow

access to virtually any interspace. Presumably, the original opening was correct for the initial lesion, and the recurrent problem will likely be in the same area and related to its repair. The same interspace is usually also reopened, but if one needs to be higher or lower inside the chest, a different interspace can be chosen. Admittedly, it will often be easier to enter through another interspace; however, the more interspaces entered, the greater the potential for fusion of multiple ribs, one of the causes of thoracic deformity [18].

A redo thoracotomy is more difficult for several reasons. Entering an interspace for the second or third time often means encountering fused ribs unless a piece of folded thin Silastic sheeting has been left between them. The rib fusion may be so dense that an osteotome will be required to separate them to gain entrance into the chest cavity. Only one corner of the osteotome should be used at a shallow angle to limit the depth of the cutting surface and avoid incising the adherent lung below.

Once the intercostal division is underway, the assistant elevates and pulls the ribs apart with two vein retractors, sturdy tissue hooks or similar instruments, creating a potential space which allows the lung to be dissected off the chest wall ahead of the osteotome. The dissection will be carried anteriorly and posteriorly in the line of incision and also superiorly and posteriorly to open the pleural space. The separation of the lung from the chest wall should be done as broadly as possible to avoid the disadvantages of working down in a tunnel. Elevating the rib cage, as described, makes the dissection easier, and at some point, a small chest retractor can be placed and it too can be elevated.

Carrying Out the Dissection

The general principle that will greatly aide achieving the preoperative goals will be to take down essentially all adhesions between the lung and the chest wall and, more posteriorly, with the esophagus. Depending on the location of the lesion and the size of the patient, it may not be necessary in a larger patient to take down all the adhesions medially between the lung and diaphragm.

The adhesions between the lung and parietal pleura are best taken down broadly and sharply under direct vision unless they are very filmy. The temptation will be to lyse as few adhesions as possible and go directly to the presumed site of the problem, whether it is esophageal or airway or both. This approach unfortunately results in a long, relatively narrow tunnel with the problem at the bottom. Effective repair, however, requires both good visualization of the lesion and mobility of the tissues to be brought together for closure. Consequently, dissecting the lung free and separating it from the esophagus will be important to success.

As noted, the dissection should proceed broadly anteriorly, superiorly, and inferiorly to prepare for the important posterior dissection. Then, lifting up the lung brings the dissection as much as possible up into the area of the incision and aids the lysis of the posterior adhesions by putting them on stretch. The lung can be elevated by using a small round peanut sponge held by a clamp, and, as the dissection progresses, a clamped larger tonsil or thumb sponge can be used to help separate the structures. In general, elevating the lung and bringing it and other structures up anteriorly rather than pushing them downward and medially will facilitate the dissection as it proceeds posteriorly. Elevation will create a potential space between structures which becomes realized as the dissection proceeds.

Completely freeing up these structures has at least two advantages. The nature of the problem will be better revealed, allowing lesions, such as fistulas to more remote parts of the bronchial tree, to be easily found. Secondly, and importantly, it will also provide the necessary mobility for effective esophageal and tracheal repairs. These repairs are much more difficult when the problem is seen at the bottom of a deep hole and hindered by the constraints of surrounding tissues and scarring. With experience, the dissection, which may seem daunting initially, becomes more straightforward and can be reliably done in reasonable time. This experience, nevertheless, will more likely be acquired at a center specializing in these problems.

Dissection of the Esophagus and Airway

With the lung essentially completely mobilized, it can be elevated and retracted medially revealing the esophagus and much of the posterior (membranous) aspect of the airway. The area of the anastomosis is usually the site of the problem whether it is a leak, a stricture, or the presence of a recTEF, and the dissection will be easier if this site is not approached first. A relatively normal portion of the esophagus, usually closer to the diaphragm, is chosen and dissected free (at least the anterior surface), and, if helpful, a loop is passed around it. The posterior and medial adhesions to the esophagus will also be put on stretch by the loop making them easier to divide. The looped esophagus is pulled toward the surgeon allowing its contour to be visualized and the surface followed precisely up to the problem area, avoiding a new injury to either esophagus or airway.

A fistula into the airway, whether proximal or distal, will become obvious by the air leak when it is divided. A recTEF in a larger patient may not require full mobilization of the esophagus if the communication is small; nevertheless, the entire anterior surface should be free for a tension-free closure of the esophageal end of the fistula. A stricture alone or in combination with a recTEF, however, will require complete and extensive mobilization of the esophagus to enable a well-constructed anastomosis to be created after the resection.

Nonoperative Closure of Anastomotic or Post-dilation Leaks

From literature reports, many esophageal leaks close spontaneously with adequate chest tube drainage, but sometimes they do not and a procedure may be required to close the hole and allow feeding to begin. Several endoscopic methods have been used and are usually the first approach if the hole is not large. The endoscopic results so far have been variable and success is generally inversely related to the size of the hole. As with any new technique, however, improvement can be expected.

Through the endoscope, the edges of the hole may be clipped together, and this is most likely to be successful if the hole is small or a vertical split as might occur after a dilation. Larger holes or those with edges that cannot be pulled together easily by clips will be unlikely to benefit from this technique and might be made worse by the effort.

Another endoscopic approach is the short-term placement of covered stents which allow closure to take place. Because these stents have had some success, they will likely be used increasingly in the future as more experience is gained. Stents also have the advantage of holding the lumen open while the hole closes and may limit the consequences of the stricturing tendency present early after completion of the anastomosis. A stricture may still form after stent removal, however, which poses a difficult problem because of the presence of the healed leak site with its potential for reopening if dilations are used. In this case, reoperation with the excision of both the stricture and leak site will be the best solution.

Finally, it has been claimed that a nasogastric tube can be placed down the esophagus and guided out the hole into the cavity providing a form of internal drainage. The abscess cavity may close down satisfactorily, which would allow the tube to be slowly withdrawn; nevertheless, this procedure would only be used in very unusual circumstances. No reports of the use of this technique have appeared in the pediatric literature.

In summary, each of these endoscopic techniques has succeeded and each has failed. Predictably with experience and better techniques, success will come more frequently; nevertheless, there will be leaks that require reoperation.

Suturing Techniques for Leaks or the Difficult Anastomosis

The repair of a leak will obviously be influenced by the size of the hole which will usually be either at the anastomotic site or a longitudinal split from dilation. With the lung mobilized and

retracted, the leak site will be exposed. An effective repair will require joining viable, full-thickness esophageal walls trimmed of any obviously infected, necrotic tissue. The suturing techniques will be similar to those used for a first time primary anastomosis. For larger holes, whose closure will be under tension, the intraoperative technique of gradually bringing the edges together to allow closure can be used. All the sutures for closure are accurately placed and tagged (Fig. 40.1). When all are placed, the sutures are crossed and used to gradually pull the edges together. When the edges are touching and held in position, individual sutures are tied off tension with the knots brought down carefully, keeping the edges in apposition.

Alignment of the esophageal wall edges to promote accurate healing is very important for successful closure of a hole or for the creation of an anastomosis. If the edges are not aligning well, then suturing techniques can be used to overcome the malalignment. Lembert-type stitches in which the very edge of the mucosa is caught by the suture will align the walls (Fig. 40.2). If one edge is turned up or down, angling of the needle as it passes through the wall will help correct this by lowering or raising the edge. The needle is held by a Castro-Vejho needle holder, which can be used like a pen to compose the anastomosis and make up for alignment deficiencies between the two ends. By angling the needle during placement of the stitch to include more outer wall and less mucosa will depress the edge of the esophagus (Fig. 40.3a, c). Similarly, angling the needle to include less wall near the outer surface and more on the mucosa side, it will elevate the cut edge of the esophagus (Fig. 40.3b, d). Careful sewing techniques such as these will align the edges of the esophagus for a successful closure of a defect or to produce a well-constructed anastomosis (Fig. 40.3c, d).

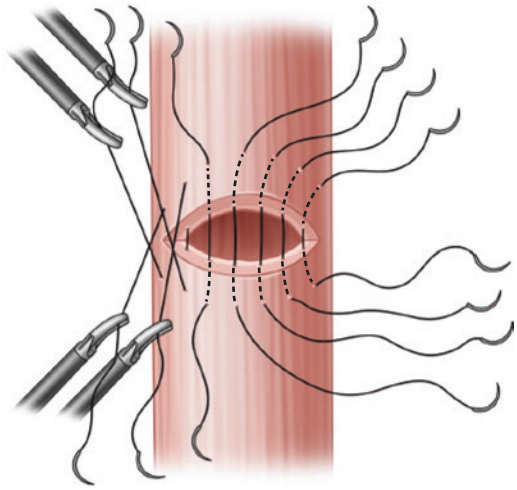

Fig. 40.1 Closure of an esophageal leak using preplaced, full-thickness sutures

The Recurrent Tracheoesophageal (Airway) Fistula

The literature indicates that in about 5–15 % of repaired EA cases, a fistula will later develop between the esophagus and the airway [1, 2, 4]. Most commonly, this is a recurrence of the original fistula between the lower esophageal segment and the back of the trachea or the proximal right main stem bronchus as found in the common form of EA (type C). Typically, recTEF becomes apparent within a few months of the original repair.

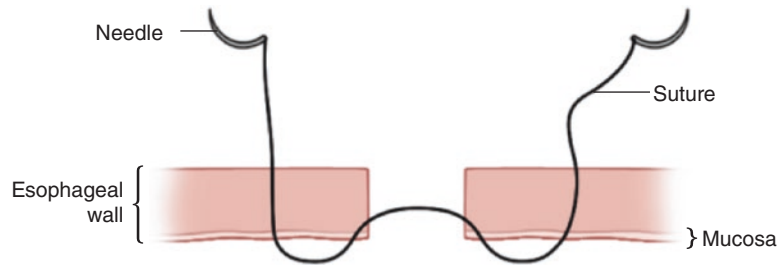

Fig. 40.2 Lembert stitch used to align the mucosal edges of the esophagus

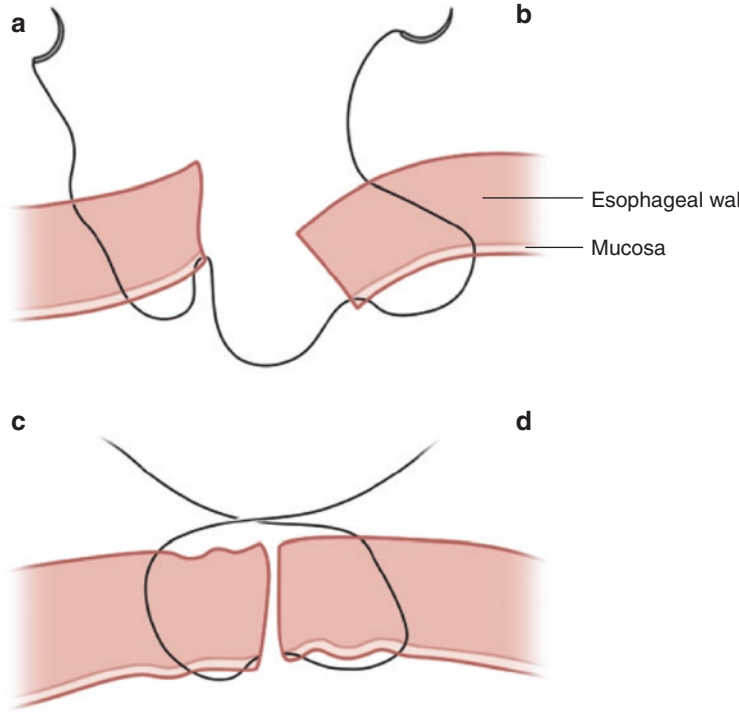

Fig. 40.3 Esophageal wall alignment disparity corrected by using angled needle and suture placement. (**a**) A wider tissue bite on the outer surface of the esophagus and narrow on the mucosal side will drop the edge and align as shown. (**b**) A narrower tissue bite on the outer wall and a wider bite at the mucosal side will elevate the cut edge. (**c**, **d**) When tied, the sutures placed as described above align the cut edges to promote accurate healing

The mechanism of recurrence presumably relates to the esophageal anastomotic line and the repair site of the airway being close together and vulnerable to the microabscesses which may appear in suture lines. An abscess will tend to migrate to a cavity, a lumen, or the outside. In the cases of the recTEF, the abscess migrated in order to drain, both into the trachea and back into the esophagus. Rarely, a similar inflammatory mechanism with a different location may result in the fistula entering the left main stem bronchus.

A recTEF is usually signaled by coughing, significant aspiration episodes, and pulmonary infections. In general, the more proximal and larger the TEF, the easier are the diagnosis and location established [4, 15, 19, 20]. The more distal recTEFs tend to be smaller and often require a careful contrast study to demonstrate a communication with the airway and provide an explanation for the pulmonary symptoms. The partial outlining of the distal trachea by an esophagram, done without spill over from above, satisfactorily confirms its presence and may identify the location. A fistula into a smaller bronchus can cause continued contamination of the airway; however, demonstrating it and localizing the site preoperatively can be difficult (Fig. 40.4). A small blush of contrast material from the esophagus into the lung field will establish the cause of the pulmonary

Fig. 40.4 X-ray showing a wire, which does not demonstrate the precise location of the airway entrance of a recurrent tracheoesophageal firstula (*arrow*)

problems, but may not provide much information on the location of the fistula into the airway.

When a fistula between the esophagus and airway is suggested because of the signs and symptoms and has been confirmed by a blush of contrast, the question becomes one of treatment. A recTEF, or even a de novo TEF, will pose problems and a conservative approach is unlikely to be effective [4, 19, 20]. The recTEF will soon be lined with mucosa which tends to preserve the lumen and prevent spontaneous closure. Furthermore, the presence of both a TEF and an accompanying stricture creates a difficult problem because adding dilations may also enlarge the TEF or at least keep it open.

The Later Appearing, More Remote Recurrent Tracheoesophageal Fistula

A smaller percentage of fistulas, however, occur at sites remote from the original TEF or develop following an EA repair even though none was present originally. The more distal airway fistulas may be less clear as to their cause, but likely began with a small abscess where the lung was adherent to the esophagus. Although the process may begin more peripherally near the surface of the lung, it can still find its way into a segmental bronchus and produce problems (Fig. 40.4).

In one case, a previously asymptomatic patient developed an occasional cough, not related to drinking liquids, 8 years after an uncomplicated repair of pure EA (type A). Contrast material injected into a small esophageal opening flowed through the peripheral lung parenchyma in an irregular path until it reached a small bronchus. The irregular path through the lung slowed the drainage of liquids; consequently her cough was sporadic and did not appear to be triggered by drinking.

Presumably, the recTEF began with the formation of an abscess in the peripheral part of the right lung which was adherent to the esophagus after the two earlier thoracotomies for the growth procedure. Again, the abscess migrated both to the esophagus and eventually to a small bronchus. Treatment required a reoperation with simple closure of the small esophageal opening and a more generous over sewing of the adherent pulmonary end. With a relatively small area of very chronic pneumonia adherent to the esophagus, it may be desirable to remove this portion of lung.

Nonoperative Methods to Close the Recurrent Fistula

The operative treatment of a recTEF may seem daunting because of predictable adhesions obliterating the pleural space and, often, because of its uncertain location. Consequently, a number of endoscopic methods have been devised to strip the mucosa and close the track, but these may not work and even might make the hole larger [15]. The methods range from laser treatments to plugging the fistula with artificial tissue membranes. More recently, tissue sealants in combination with the temporary placement of covered stents in the esophagus at the site of the fistula have achieved some successes with the more proximal recTEFs. The tissue sealants and implants do not seem to make the situation worse; however, they have not been reliable, are expensive, and may only delay resolution of the problem. Once the recTEF is established, the mucosa-lined fistulas resist closure and endoscopic procedures may not suffice for closure and reoperation will be necessary [15]. Other nonoperative methods of fistula closure will continue to be sought, however, and may, eventually, prove to be satisfactory and reliable.

Localization of the Fistula

If the fistula is a recurrence of the original TEF from the lower segment of esophagus (type C), its identification in the membranous portion of the trachea is reassuring as to where it will be at reoperation. For a fistula into the right main stem bronchus or even further out, the possibility of identifying and localizing it by bronchoscopy becomes progressively less even though the esophageal opening may be found. Because a TEF occasionally occurs more distally, it is

useful to understand how the TEF can be effectively located and treated despite the uncertainty and apparent difficulty it presents.

When the fistula can be visualized by bronchoscopy and an operative repair is planned, it has been frequently recommended that a catheter or wire be placed across the fistula to aid in locating it during the operative procedure [4, 19–23]. Although many surgeons have followed this advice which seems to have logic on its side, we have not found it either necessary or even helpful. The bronchial end of a distal fistula which is producing symptoms and problems, moreover, may be difficult to locate preoperatively by endoscopy causing consternation and even leading to the conclusion that "nothing more can be done." Beginning in Minnesota, where we were referred many recTEF cases and, more recently, in Boston where even a larger number have been treated, the operative approach to be described effectively revealed fistulas of any location and size without wire localization and allowed reliable closure.

Reoperation for Recurrent TEF

The operative approach is designed to insure the esophageal-airway fistula is found and divided no matter how small in size or distal in location. Once divided, this technique also maximizes the likelihood of a satisfactory repair with little chance of another recurrence. To accomplish these goals, the reoperation begins by opening the previous incision and dissecting the lung free, virtually to the diaphragm, so it can be elevated and the esophagus located. After the esophagus is first reached, usually well below the anastomotic site, the dissection follows the surface of the esophagus superiorly up into the thoracic inlet which will necessarily divide the recTEF. The separation of the lung and airway from the esophagus will efficiently reveal the divided fistula by the bubbling with ventilation at the site of the bronchial communication. Complete separation of the esophagus and the airway will also allow both ends of the fistula to be repaired under better visualization and, importantly, with less resulting tension imposed by inflexible, scarred surrounding structures.

The only fistula that could be missed by this technique would be in the cervical region; however, in this location, the preoperative studies would have identified it and the approach would be by a neck incision. And, although approaching a recTEF from the left side has been advocated, full mobilization of the structures would be made much more difficult by this approach which encounters the aorta [24].

The holes in a recTEF are typically small. A single generous, horizontal mattress suture should straddle the hole and incorporate almost the full wall up to the submucosa. When tied carefully, but not too tightly, the suture will provide a secure closure. A second more widely placed stitch can be used to reinforce closure but it must be tied even less tightly.

Another advantage of generous mobilization of the esophagus and tracheobronchial tree is that after the recTEF has been divided and repaired at each end, the two suture lines tend to lie some distance apart, further diminishing the chance of recurrence. If the two suture repairs remain close together, however, two or three relatively superficial sutures can be placed in the esophageal wall and posteriorly into the chest wall fascia to roll the esophageal closure further away from the tracheal repair.

As with the anastomosis, we believe the use of nonreactive sutures will minimize the inflammatory response. A simple repair using fine nonabsorbable monofilament sutures which are the least reactive material will minimize the occurrence of small abscesses. The choice between fine monofilament absorbable and nonabsorbable sutures will be made by the surgeon, but we have settled on the least reactive. Even absorbable sutures set up some local reaction with hydrolysis which helps make the case for a fine, nonabsorbable monofilament suture. Braided sutures are even more prone to microabscesses and silk sutures which are inherently very reactive would be the worst choice.

A 6-0 suture should be satisfactory for closure of the small fistulas. The knot should begin with two similar throws so it can be carefully tightened to bring the tissues together before a squaring throw locks it. The knot should be only

composed of four to five throws, and back pulling on the last throw will further lock the knot. The ends should be cut short to minimize the adverse effects of the suture material. These steps are done to minimize the occurrence of small abscesses which can enlarge and migrate toward the lumens of the trachea and esophagus, producing the dynamics which will result in a recTEF. This operative technique has been used successfully and without later recurrence in 38 consecutive cases in Minnesota and Boston where recTEF is a problem commonly referred for treatment [25].

A case has also been made in the literature for inserting tissue such as intercostal muscle or pleural or pericardial flaps between the suture lines to reduce the possibility of another recurrence. Again, although this may appear to be a helpful idea, the reported results seem no better than repairs without a flap and, compared to our experience, not as good [23, 26]. Any mobilization of flap tissue, moreover, may produce areas of necrosis and/or foster formation of microabscesses which add to the potential for a recTEF.

In summary, reoperation for a recTEF requires extensive mobilization and elevation of the lung and airway of the esophagus. This frees up a generous amount of the esophageal surface which will divide the connection and allows easy visualization of the holes, extensively mobilizing the esophageal wall so that an accurate and effective closure can be carried out. The tracheal repair should neither reduce the lumen size nor leave behind an unsupported pouch which may increase in size, harbor infection, and promote refistulization.

Strictures

As noted, clinical judgments about the severity of a stricture vary, but our definition has been that any visible anastomotic narrowing on a contrast study is at least a mild stricture. Even a mild stricture will likely produce some degree of dysphagia and perhaps episodes of food sticking. To function normally, the esophagus will need to be supple enough to allow the passage of solids of a larger diameter than the lumen collapsed at rest. Without distensibility, even a mild narrowing will limit the passage of some solids and be unpleasant for the patient. If a stricture is considered significant only when the lumen is clearly narrowed, patients with a lesser but real stricture will have to compensate by eating small bites of solids, with careful chewing to avoid food being caught at the site.

These two viewpoints are at the ends of a spectrum on how strictures are judged and treated. Because there is no agreed-upon definition of what constitutes a significant stricture, variation in the diagnoses and recommended treatments will continue to exist. The methods and vigor of the treatment will vary both from the judgments of the stricture and the experience and capability of those dealing with them. Mild strictures may not be addressed beyond the early postoperative period as the patients seem to be "doing well," and, as a probable consequence, dysphagia is very common even in adults who have had the common-type C EA/TEF repair in infancy [9, 10].

We believe a successful outcome of EA repair, however, does not include dysphagia, and these symptoms deserve evaluation and treatment. Dilations and, more recently, stent placement remain the first line of stricture treatment. The Minnesota experience has suggested relatively early, and frequent dilations seem more likely to encourage the stricturing tendency to relent rather than beginning dilations after more severe symptoms develop and the stricture is tighter [27, 28]. A more severe stricture will require more vigorous dilations, stirring up the mechanisms which lead to this problem.

Strictures, however defined, occur more commonly following repairs of longer-gap EA under tension and in patients with continuing gastroesophageal reflux (GER) [1, 2, 27–29]. The presence of GER will also be a persisting obstacle to effective stricture treatment, and, because late dysphagia is so common, the problem and treatment of strictures will be presented in detail.

Resection of Short Strictures

A variable of importance is the length of the stricture. Although most anastomotic strictures are relatively short and can be resected, the more recalcitrant ones may be relatively long making operative treatment including resection with primary anastomosis more difficult. For long strictures, the principle of growth induction by axial tension has been used to allow staged resection and eventual primary esophageal repair.

For relatively short, recalcitrant strictures, there are two operative options which preserve the esophagus. The first and most straightforward method is complete excision and reanastomosis. Even for a stricture length of 1.5 cm, however, complete excision will leave a gap of at least 4 cm after the ends retract, increasing the difficulty of the reanastomosis. This predictable situation is why surgeons may resort to a pull-up procedure for even a modest sized stricture. In experienced hands, however, resection and primary anastomosis keeping the GE junction below the diaphragm can be reliably accomplished and will prove to be increasingly beneficial over the succeeding years (Fig. 40.5a, b).

When making the decision to resect a stricture, several considerations should be kept in mind. The extent of the fibrous stricture may be longer than anticipated which, together with the retraction of for the divided esophagus, might make the resulting gap much longer than anticipated. The reoperation therefore should be approached in a flexible manner which does not prevent an eventual primary esophageal anastomosis and avoids a shift to a "rescue" gastric interposition. Finally, the entire stricture must eventually be resected; otherwise, the symptoms will persist and little will have been gained.

If there is uncertainty about the actual length of the stricture, the flexible approach would be to divide the esophagus in the center of the stricture and then systematically resect more until the surgeon believes that no more can be taken without

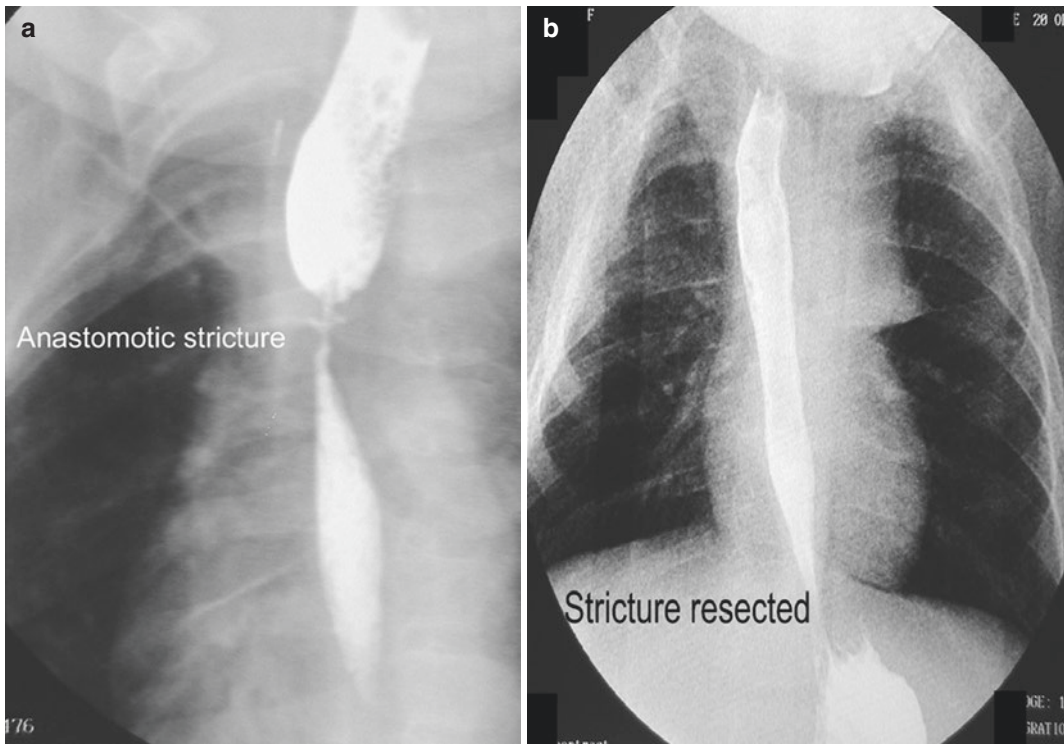

Fig. 40.5 Resection of a recalcitrant esophageal stricture. (**a**) Contrast study showing a 2 cm long anastomotic stricture. (**b**) Following complete resection and reanastomosis, the esophagus is of uniform caliber

jeopardizing the ability to accomplish an anastomosis. Once the esophagus has been divided and at least a portion of the stricture has been resected, there are three general possibilities for completion of the operation: (1) do a primary anastomosis even if the stricture has not been completely resected and plan on a second resection to remove the remainder in 7–10 days (2) close the ends or at least close the lower end and bring out a spit fistula, or (3) bring up an interposition graft. Only the first result, however, would be a completely acceptable outcome.

Resection of a stricture should be done carefully so that a primary anastomosis remains possible. A partial resection should be done initially and then more taken if an anastomosis under tension can still be accomplished. Sutures can be placed through the cut ends, tagged, and crossed to limit retraction. Under very special circumstances, the stricture can be 75–80% resected, leaving a strip of back wall, which will somewhat limit retraction and may add a sense of security. A complete resection of the stricture will be more desirable.

With more experience and careful attention to the details of creating an anastomosis, complete resection of a relatively short stricture will be reliably done. For longer strictures, a primary anastomosis will still be possible after using growth induction as part of a staged resection.

Stricturoplasty (Vertical Incision for a Short Stricture)

The second method, applicable for a relatively short lesion, consists of a longitudinal incision through the stricture with transverse closure. Although this will have the apparent advantage of largely eliminating the effect of retraction and preserving the back of the wall, it poses difficulties and leaves the original stricture in place, affecting perhaps 60–70% of the eventual circumference. To effectively relieve the stricture, the longitudinal incision must extend well above and below it; otherwise, even a transverse closure will not open up the lumen satisfactorily. It is the length of the vertical incision that determines how much the stricture will be opened. The upper and lower ends of the vertical incision will be brought together as the middle point of the transverse closure and consequently this distance may be much greater than the ends following a simple excision. The mid portion of the closure, therefore, may be under significant tension and difficult to bring together. This consideration limits this approach.

To accomplish this approach, after a suitably long opening has been made, closure begins by placing a suture at the midpoint on each side of the longitudinal incision. These sutures are tagged and pulled laterally to set up the transverse closure (Fig. 40.6a). Additional sutures to accomplish the transverse closure are placed, tagged, crossed, and put under increasing traction to bring the edges together. This method will be satisfactory if the mid-

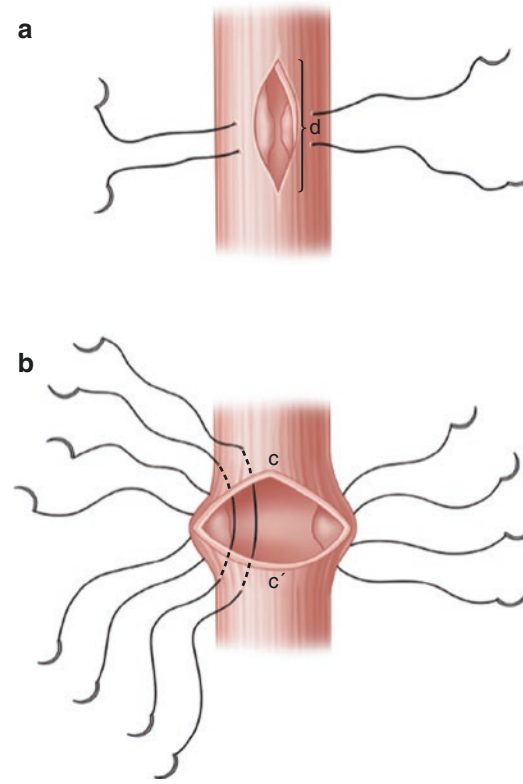

Fig. 40.6 A vertical stricturoplasty to treat an esophageal stricture. (**a**) A vertical incision divides the stricture. Midpoint sutures are placed to begin the horizontal closure. (**b**) Suture closure of the now horizontal opening. The upper and lower ends form the midpoint of the closure

points are not too far apart (Fig. 40.6b). Once the midpoints are essentially in apposition, the tying can proceed from laterally to medially on each end until the closure is complete. In this approach, a complete, full-thickness esophageal repair is desirable to avoid the use of a patch to complete the closure. The use of tissue patches to widen the lumen has been reported, and although colon patches will open up the area, their wall strength may not be adequate over the long term and a diverticulum may form [30]. Once formed, a diverticulum will have a tendency to enlarge, compounding the problem.

In summary, this technique of a longitudinal incision with transverse closure may appear useful under certain circumstances. In general, however, despite its initial appeal, it will only be workable for short strictures which are usually better served by resection.

Longitudinal Stricturoplasty

Another technique has been described which features a long incision through the fibrous portion of the stricture but only down to the mucosal layer [31]. The result resembles a pyloromyotomy for hypertrophic pyloric stenosis with mucosa bulging out between the edges of the split stricture. Given the probable need for a fundoplication and the sporadic contractile function of the lower esophagus following EA repair, the outpouching mucosa may begin to expand because of the slow emptying. Once the mucosa has begun to enlarge, the outpouching may continue to increase in size. Follow-up studies are not available in the literature; however, it does not seem likely that this method will provide a satisfactory long-term solution.

Residual Tracheal Pouch

If the tracheoesophageal fistula in the common form of EA (type C) is not repaired flush with the tracheal wall using tissue of good holding power, a pouch may develop. The pouch will tend to retain mucous and bacteria, leading to aspiration and other symptoms [12–16]. Although the natural history of these residual lesions from an EA/TEF repair is variable, because the pouches are relatively unsupported, they will often continue to enlarge, increasing the problem. Only local scarring associated with the original repair might impede this progression; consequently, when symptoms appear, the likelihood is that they will only increase in size and reoperation will eventually be needed.

To close the pouch, an essentially complete dissection is carried out and the lower trachea and esophagus separated. Because the wall of the diverticulum will be thin and easily entered, its location should be determined as the dissection proceeds superiorly. The light from a fine bronchoscope in the pouch usually provides the necessary information to safely continue the dissection upward.

Once the pouch has been dissected out and the esophagus retracted away, the decision on the specifics of the repair can be made. The repair will be carried out in a vertical direction and individual sutures on each side of the pouch should include a rim of the membranous septum. Although the membranous septum is relatively thin, the tissue is stronger than that of the residual pouch and a vertical closure will heal well and solve this problem. A vertical repair is desirable because the tracheal cartilages will prevent a horizontal closure of even a medium-sized defect.

The size of the pouch will affect the method of repair. If the pouch is small, endoscopic closure may suffice [16]. Larger pouches will likely require reoperation [12]. If the pouch is too big to be simply reefed up as the sutures are tied, it should be unroofed to leave less tissue folded into the closure itself; otherwise, later remodeling and regression of the wrapped up tissue might leave loose sutures and increase the potential for recurrence. There are no established guidelines; however, if the pouch is large and it appears too much tissue will be incorporated in the repair, a portion should be excised. These are the general principles; nevertheless, this repair is not without potential difficulties.

Fig. 40.7 Repair of an esophageal diverticulum. (**a**) Contrast study of an esophageal diverticulum. (**b**) Following esophageal growth and excision of diverticulum, a normal caliber esophagus was achieved

Esophageal Diverticulum

Following one or more circular myotomies, the unsupported mucosal wall of the esophagus will tend to enlarge, interfering with the esophageal emptying, and may even become a significant mass in the mediastinum impinging on the airway and causing ventilatory problems (Fig. 40.7a) [13, 17].

Repair requires reestablishment of a full-thickness esophageal wall; however, simple excision of a large diverticulum followed by anastomosis of the esophageal ends may be difficult. Given the tendency of the esophagus to retract, the excision of a 3–4 cm long diverticulum may result in a 6–8 cm gap between the esophageal ends and preclude an anastomosis. This variation of the long-gap problem can be remedied by first inducing growth of the esophagus above and below the diverticulum. Horizontal mattress sutures of 5-0 pledgeted Prolene are placed in the esophageal wall above and below the diverticulum, crossed and anchored either into the paraspinal ligaments or into the chest wall on the other side of the diverticulum. When these sutures are tied, the diverticulum will collapse and the normal esophagus will be stimulated to grow (Fig. 40.8). This approach uses the basic principles of axial tension to stimulate growth combined with not entering the esophageal lumen until one is ready for a primary anastomosis. After 5–7 days of this form of internal traction, a primary esophageal anastomosis will be much easier to achieve (Fig. 40.7b).

When the upper and lower portions of the esophagus are sufficiently close for a full-thickness anastomosis, then the diverticulum can be treated in one of two general ways. If the diverticulum was large, it is better excised. Generous suture

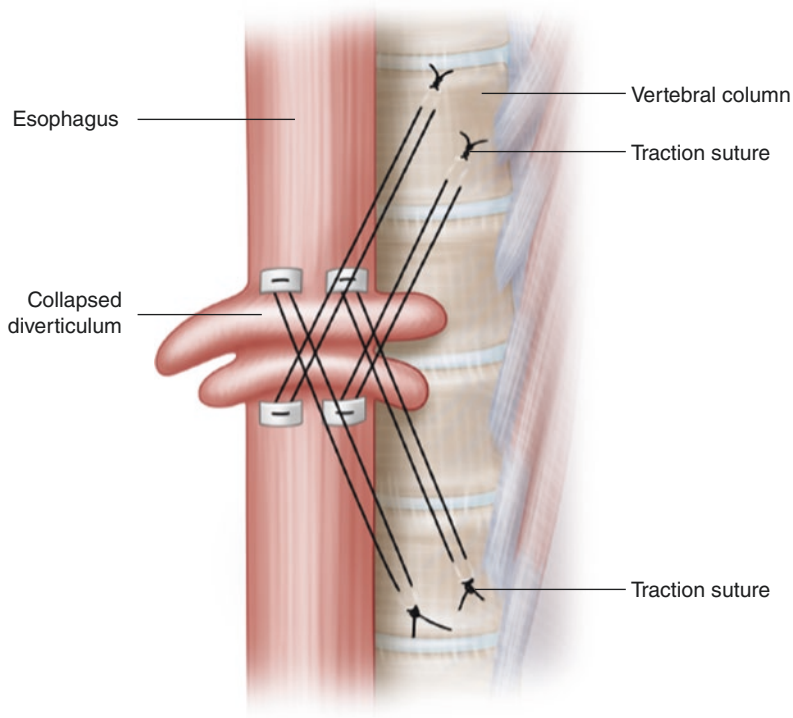

Fig. 40.8 Diagram of a diverticulum collapsed by sutures with resulting axial tension on the normal upper and lower esophagus inducing growth

bites are taken for the reanastomosis and placed in a Lembert fashion to bring the mucosal edges together (Figs. 40.2 and 40.3). In some cases of a relatively small diverticulum, however, the mucosa may be imbricated carefully with the sutures not entering the lumen. In this situation, the mucosal folds, if relatively small, can be expected to remodel and regress. The holding power will come from generous tissue bites in the esophageal wall as in any anastomosis.

By using one of these methods, a very satisfactory repair can be achieved. This overall approach will have the substantial long-term benefit of avoiding an interposition graft.

The Partially Intrathoracic Stomach

Whether by design to allow a primary anastomosis, or as a consequence of a large esophageal hiatus, from the result of traction sutures used to induce lower esophageal growth or from an esophageal anastomosis under significant tension, the GE junction and part of the stomach may be above the diaphragm. This configuration is detrimental for the long term because it insures GE reflux with its long-term adverse consequences. For the short term which may be 1 or even 5 or even 10 years, this problem may be treated in a symptomatic degree by antacid therapy; nevertheless, the effects of chronic bile reflux will prove to be increasingly detrimental, making unlikely the goal of 70 good years [31]. This unsatisfactory sequence of events will likely also be seen following gastric pull-up procedures, but the return to the abdomen in these cases will require a jejunal interposition to restore continuity.

The difficulty in correcting the partially intrathoracic stomach will be in rough proportion to how much is above the diaphragm. If the stomach has been brought up through the hiatus to allow an esophageal anastomosis, a significant amount may be in the chest. Even an unplanned hiatal hernia, however, may be relatively large and pose problems. Anatomic and physiologic correction

will require bringing the GE junction at least 2 cm below the diaphragm, and the esophagus will likely be "too short" for this to be easily accomplished causing a similar deficiency problem as found in long-gap EA.

Two methods have been used by us to return the GE junction below the diaphragm. The first is relatively straightforward and consists of full mobilization of the esophagus and placing a 3-0 monofilament suture superficially around the GE junction. The GE junction can usually be identified by surface characteristics of the esophagus in contrast to the stomach, as well as the presence of a branch from the vagus nerve which crosses the GE junction transversely along with a vein. This localization is important so that the subsequent wrap is around the esophagus and not the upper stomach. With downward traction on the 3-0 Prolene suture, and continued freeing up of the esophagus as it is pulled downward, the GE junction may be brought far enough below the diaphragm to allow a proper fundoplication to be done (Fig. 40.9). After reducing the hiatal opening and completing the wrap, the 3-0 Prolene suture is removed.

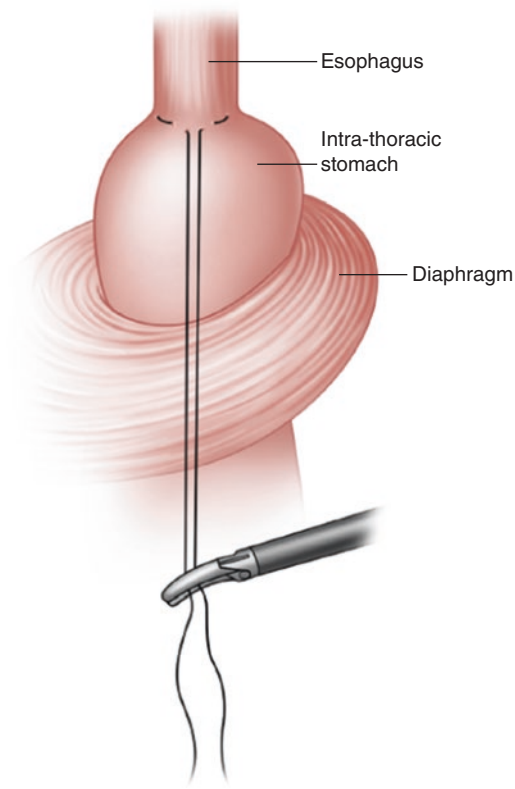

Fig. 40.9 Diagram of pulling down an intrathoracic stomach

Sufficient mobilization of the esophagus may also require reopening the thoracotomy incision and, although this increases the magnitude of the operation, we believe that a partially intrathoracic stomach is so detrimental over the decades that the combined incisions are more than justified to return the GE junction to the abdomen where it belongs.

The second method has not been described to our knowledge and may seem to be unorthodox; however, it is relatively straightforward and effective. This technique can be successfully used when the GE junction cannot otherwise be brought below the diaphragm.

The concept is simple enough. If the GE junction can't be brought below the diaphragm, the diaphragm can be moved above the GE junction (Fig. 40.10). Normally, the diaphragm dips downward posteriorly with the esophageal hiatus located well below the apex. The diaphragm can be detached along its posterior aspect, and when a sufficient length has been freed-up, it is anchored higher on the chest wall, well above the GE junction with nonabsorbable pledgeted horizontal mattress sutures (usually 4-0 Tevdek). The edge of the diaphragm will need to be split at an angle for a short distance which will place a strip of muscle between the esophagus and the posterior chest wall. The diaphragm will be closed around the esophagus to fashion a new hiatus. The innervation of the diaphragm is from the phrenic nerve which fans out from its central location; therefore, detaching the diaphragm posteriorly will not interfere with function.

This operative maneuver is not difficult, and small, posterior remnants of the crura may be left behind in the abdomen which will indicate the previous location of the esophageal hiatus. With the diaphragmatic opening higher on the esophagus, a fundoplication can be carried out in the usual fashion with the wrap and GE junction within the abdomen (Fig. 40.10).

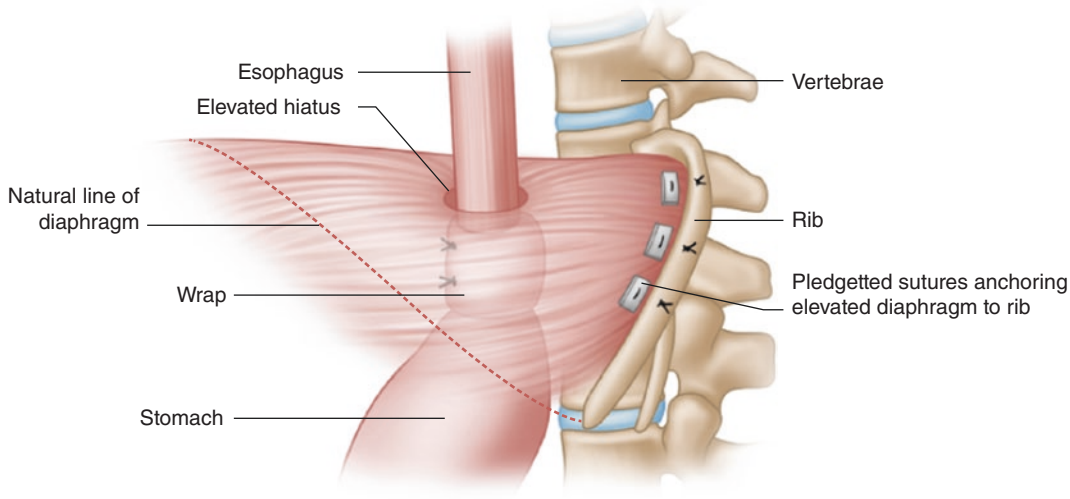

Fig. 40.10 Diagram of moving the diaphragm upward

In contrast to these methods, a partially intrathoracic stomach is in adults commonly treated by a Collis procedure in which the upper stomach is cut downward in the line of the esophagus and the resulting piece of greater curvature used to complete a type of fundoplication below the diaphragm. Obviously, this leaves the true GE junction in the chest along with the length of stomach which remains above the fundoplication. Although this may seem to provide a solution, the presence of gastric mucosa in the chest and the frequent lack of an effective pressure zone producing a physiological GE junction means acid production and reflux will continue to occur. For the long term, this situation will likely be very detrimental, and even the short-term results have been unsatisfactory [32].

Growth Procedure Following Previous Attempts at Repair of Esophageal Atresia

A patient who has had a failed EA repair which has included several operations may have little remaining esophagus. The choice will be between an interposition graft and a growth procedure. Although the prospect for a growth procedure can be daunting, it may still be possible to locate sufficient esophagus to produce an effective growth response, leading to a primary repair with the GE junction below the diaphragm. In such a case, the less desirable interposition may be avoided (Fig. 40.11a, b).

Summary

Reoperation, as discussed in this chapter, may be the best solution to a difficult and persistent problem. Avoiding a reoperation may have its appeal, but postponing effective treatment in these situations may be quite detrimental to the patient. The technical details for the successful treatment of several problems are presented, and, where a significant esophageal gap may result from the procedure, the methods to induce sufficient growth are also discussed. Reoperation, however, requires experience and may be best undertaken at a suitable center, where the approach can be adequately carried out.

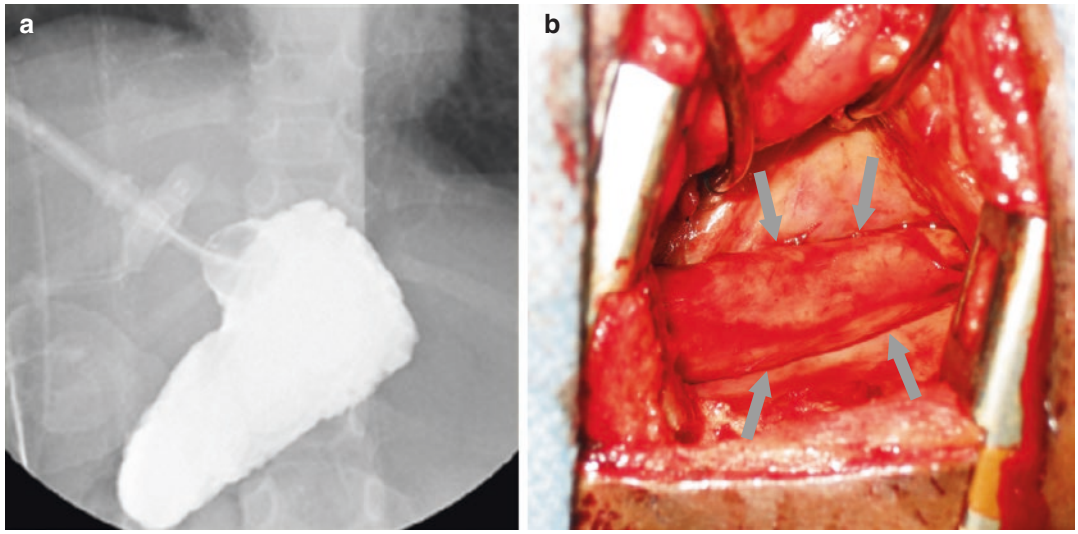

Fig. 40.11 Growth procedure following multiple operations for EA: (**a**) gastric contrast study of a 2-year-old who after eight operations, including cervical esophagostomy revisions, appeared to have completely lost her lower esophagus. The gap length to the upper pouch was 16.5 cm. (**b**) At laparotomy, a nubbin of the esophagus was found, and by axial tension, a very satisfactory lower esophagus was grown. The *arrows* indicate the edges of the new lower esophagus. After a primary esophageal repair, she eats normally

Growth Induction to Treat Long Esophageal Strictures

41

Tara C. Kendall Krosch and John E. Foker

Introduction

Esophageal strictures are a frequent consequence of the repair of esophageal atresia (EA), especially in the case of long-gap EA (LGEA). The principal method of treatment has been esophageal dilation, previously with rigid dilators, but now balloon catheters are commonly used [1–8]. More recently, removable stents and injections with mitomycin C or steroids have also been used to inhibit stricture recurrence, but the rate of their successes in children has not yet been determined [9–14]. Despite treatment which may include frequent dilations, injections, and removable stent placement, in some patients significant complications occur or the stricturing tendency remains active with continuing dysphagia [15–17].

Resection of the stricture followed by primary anastomosis of the normal esophageal tissues could solve the problem and provide the greatest benefit. The difficulties of this procedure, however, are well known and begin with a redo thoracotomy and takedown of extensive adhesions (see Chap. 40: "The Redo Operation"). A stricture, moreover, does not end sharply and typically tapers; therefore, a complete resection usually must extend further than expected. In addition, once resected, the esophageal ends will retract, making the resulting gap much longer than anticipated and the repair daunting.

Stricture resections, nevertheless, have been attempted, and the resulting dismaying gaps have led to additional maneuvers to make an anastomosis possible. Esophageal myotomies have been used or part of the stomach has been brought up into the chest to close the gap and allow an anastomosis. An alternative approach has been to incise the stricture longitudinally; however, the longer the lesion the less likely the obstructive effects will be relieved. Because of the anticipated difficulties, long strictures have often led directly to interposition grafts, typically of the stomach or colon, to bridge the gap after resection. These solutions, however, all have drawbacks which tend to increase with time. Because of these significant shortcomings, we have used growth induction to treat long, resistant strictures and end up with the long-term benefits of a true primary repair.

Principle of the Procedure

The basic principle of treating long strictures by resection is the same as for primary repair of LGEA; tension is created to provide the growth signal in the normal portions of the esophagus.

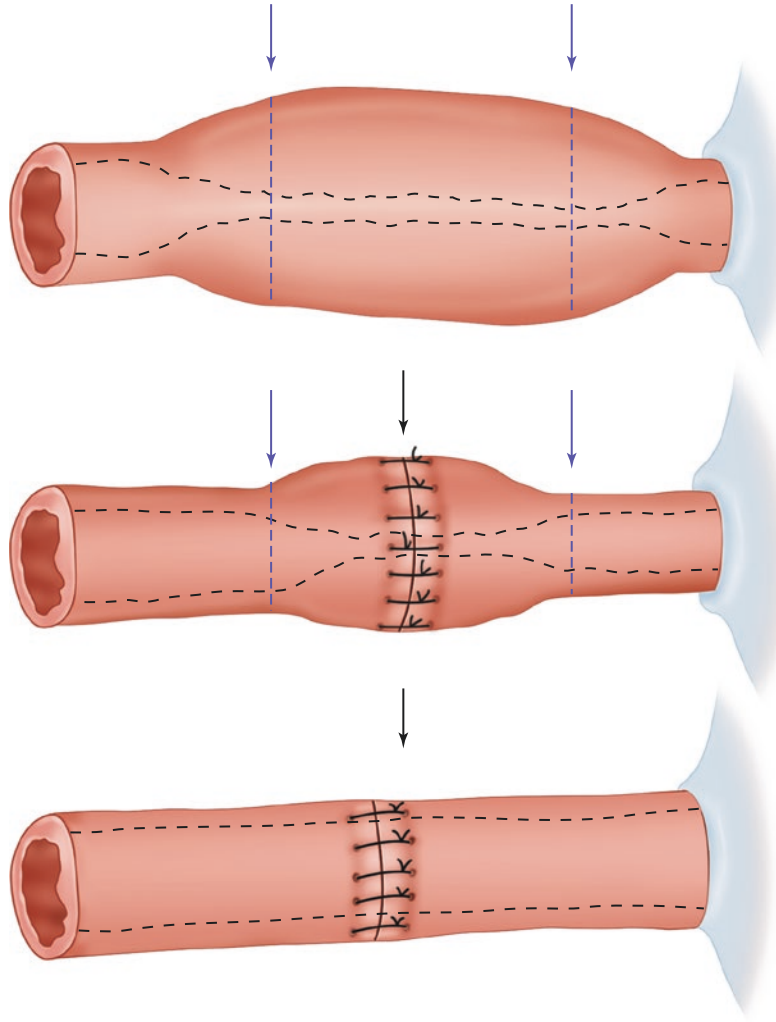

Fig. 41.1 Diagrammatic representation of a staged resection of a long esophageal stricture, in this case, a fibromuscular stenosis (see also Fig. 41.2). The resection begins in the middle of the stricture. A sufficient amount is removed so the resulting anastomosis will be under moderately severe tension which will induce the normal portions of the esophagus to grow. About 7–9 days later, another resection is done and, in this illustration, the remainder of the stricture is removed. We have used up to four resections to remove a long (12.5 cm) stricture. Although a well-constructed anastomosis is required, the tension reliably induces growth of the normal esophagus and will fill the gap caused by the resection

When the growth response is sufficient, a true primary repair becomes possible using only native esophagus. The difference between the two situations is that by resecting the stricture, a long gap is created, while for the LGEA lesions, it already exists. The growth signal, however, is basically the same although it is renewed in different ways to produce sufficient growth to bridge a long gap.

For a stricture too long to be completely excised and still allowing a true primary anastomosis, growth is induced by resecting it in stages. A section is removed from the middle of the stricture which leaves a long but manageable gap and two open esophageal ends. The new anastomosis will necessarily be under tension which provides the growth signal to the esophagus above and below the stricture (Fig. 41.1).

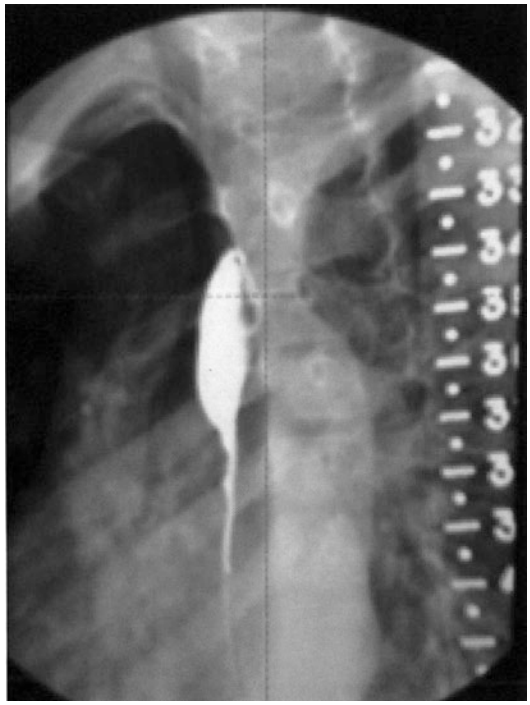

Fig. 41.2 Radiograph of a 6-year-old male with a long congenital (fibromuscular hypertrophy) stricture. He had never eaten solid foods and even the swallowing of liquids was a laborious process. Although three resections were used to completely remove the 6.5 cm stricture, two might have been sufficient. The first two resections were done only 3 days apart, and there had been insufficient time to maximize the growth response; therefore, the second resection was smaller

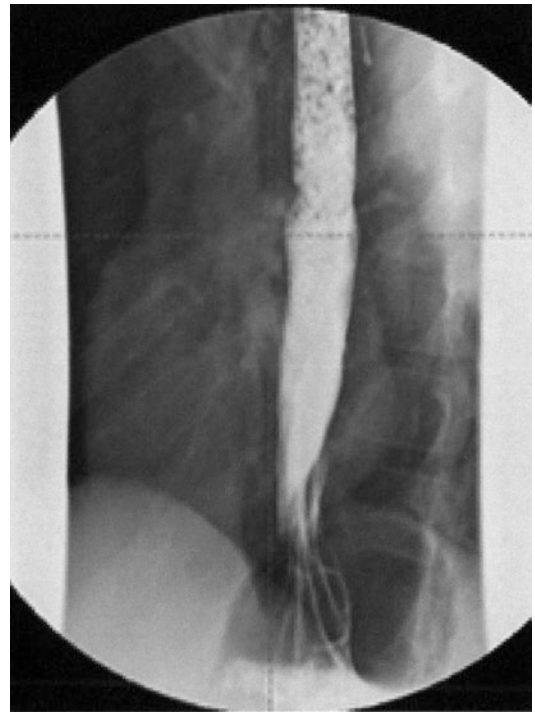

Fig. 41.3 After three resections of the fibromuscular stenosis, complete excision was achieved and the resulting esophagram was quite satisfactory. The patient is in boarding school and now eats the standard meals without difficulty or symptoms of dysphagia

This approach, however, requires a well-constructed esophageal anastomosis that will withstand significant tension and provide the axial force which will induce growth in the normal portions of the esophagus. By proceeding in stages, even long strictures can be successfully resected, leaving an intact esophagus with the GE junction below the diaphragm. A staged stricture resection, therefore, will solve the problems often associated with other methods to relieve a longer stricture. Even though this approach seems formidable, in practice it is straightforward, and the relief of a resistant and troublesome stricture pays considerable long-term benefits. Rather than being a solution that likely will deteriorate with time, it should be durable if the predictable postoperative issues, especially gastroesophageal reflux (GER), are also effectively treated (Figs. 41.2, 41.3, 41.4, and 41.5).

The Staged Operative Approach for Long Strictures

Through a posterior-lateral thoracotomy, which will usually be a reopening of a previous incision, the lung is dissected free and the esophagus mobilized completely (see Chap. 40: "The Redo Operation"). Once the esophagus is freed up, the stricture should be apparent although sometimes it is not, and a large red rubber tube or an endoscope passed from above will be helpful in finding it.

At the first operation, the surgeon should remove as much stricture as felt to be consistent with being able to create a primary anastomosis, necessarily under tension. The first operation will

Fig. 41.4 An esophagram of this 2.5-year-old male shows a long (12.5 cm) and very tight stricture after ingesting lye in his home country 5 months earlier. The contrast study also shows a very short distal segment of normal appearing esophagus entering the stomach. A similar length was present proximally in the cervical esophagus, although not seen on this frame. Multiple dilations had been carried out with no result except a perforation and significant mediastinitis. After arrival in Minnesota, the choice presented was between a staged resection and an interposition graft (jejunum), and the former was chosen. Very helpful to accomplishing a staged resection was the very thick wall of the stricture area. Despite the obvious inflammation, loss of the mucosal layer, and breakdown of the normal esophageal wall structure, the tissue strength was more than adequate to allow an anastomosis under significant tension. Although the mucosa had been largely destroyed, and the lumen very narrow, it was sufficient to allow the passage of saliva which made the time between resections tolerable

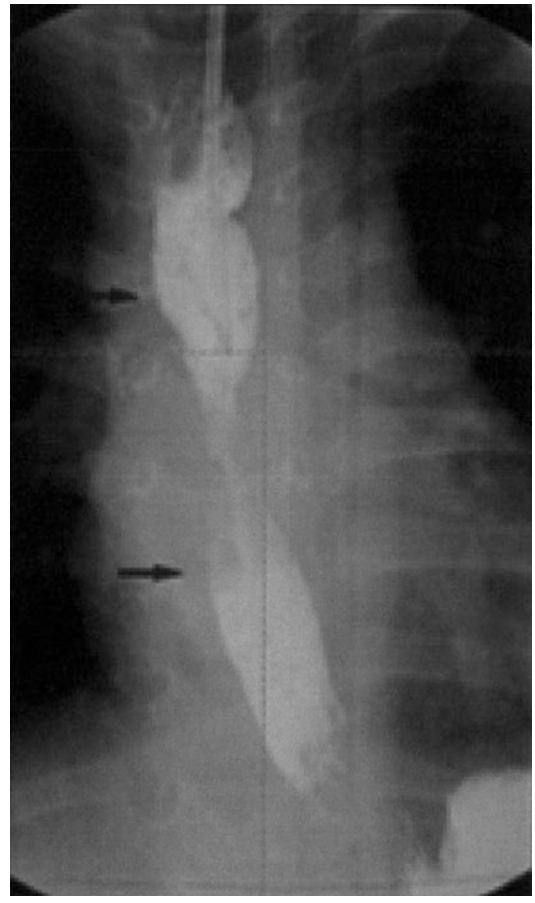

Fig. 41.5 After two resections, an esophagram showed a much shorter but still substantial area of stricture (*arrow*). The length of normal esophagus above and below the stricture has obviously grown considerably

require judgment because with retraction, the gap will become longer, and if too much is taken, the anastomosis may not seem possible and this approach will be abandoned.

The tension of the anastomosis provides a single stimulus which dissipates as growth occurs over the next several days. After about 7–9 days, essentially all the tension-induced growth will have taken place and another partial resection and anastomosis can be carried out. Within this time frame, vascular adhesions will not have formed and the repeat thoracotomies will not be difficult. Re-resections are approached through the same incision, and reentry can be made easier with the placement of very thin silastic sheeting in the rib interspace after each operation. Our practice is to not pull the ribs tightly together with pericostal sutures which

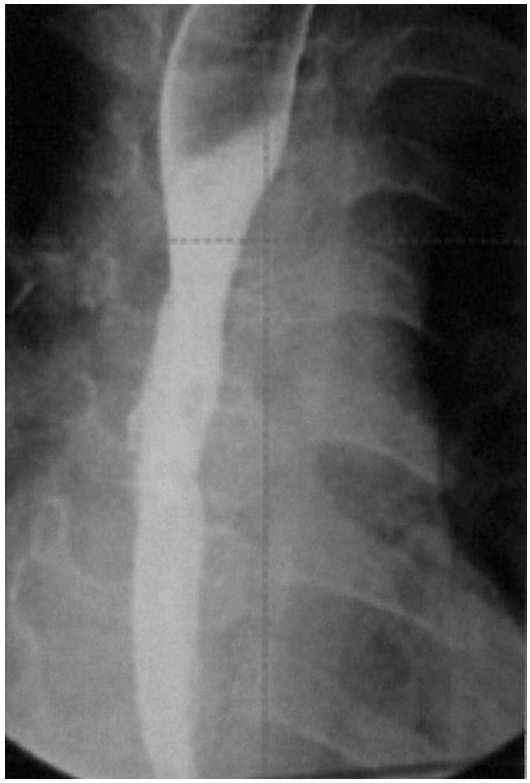

Fig. 41.6 After two more resections, the esophagram looked essentially normal, and following a fundoplication, he began a normal diet for the first time. The follow-up history is noteworthy. He and his father wished to return home after the last resection and before the dilations were completed. Consequently, he developed a short but resistant stricture and about 1 year later returned to Minnesota where the stricture was resected. After three dilations, he returned home where his subsequent course has been excellent. Follow-up endoscopy at age 15 revealed a normal appearing esophagus. Recently he has entered the KSA Air Force Fighter Pilot Training Program, something which would have not been possible with a colon or stomach interposition graft. Although this approach required several operations, the outcome has been excellent as is the long-term outlook

leaves a normal intercostal space and helps prevent fusion of the ribs. The number of resections required to remove the entire stricture will depend on its length and the experience of the surgeon.

At each stage the middle portion of the stricture is resected (Fig. 41.6). The amount removed will be decided by the surgeon, but, in general, after a 2–3 cm resection, retraction will result in a 4–5 cm gap, and a primary anastomosis will be under moderately severe tension. The technical details of completing an anastomosis under tension have previously been described (Chap. 25: "Growth Induction and the Flexible Approach"). Briefly, the back rows of sutures are placed taking generous tissue bites and then individually tagged. The sutures are crossed and, with continuous traction, the esophageal ends are slowly brought together. Because the anastomosis will be under tension and the esophagus not easy to turn, the back row will be tied on the inside. While maintaining tension on the crossed, untied sutures, one suture pair is selected and tied off tension which should prevent it from pulling through the tissues. When tying, the first two throws are not squared so the knot can be cinched down carefully to just bring the tissues into apposition without making the suture too tight and causing necrosis. The third throw is squared which will lock the knot. The suture material we use is typically 5-0 monofilament polypropylene, chosen because of its nonreactivity and its ability to slide easily through the tissues.

Treatment After the Last Resection

Fibroblasts produce anastomotic healing, and therefore, some degree of contraction occurs naturally at the circular repair site. This tendency will be increased by anastomotic tension and GER, both very likely to be present. Once the resections have been completed, a contrast esophagram is done 2–3 weeks later followed by evaluation with endoscopy. Evaluation for GER at about the same time has also been part of the treatment plan, and often, a fundoplication will be necessary.

Esophageal dilations are routinely performed, and if done early and frequently, they seem to more reliably cause the stricturing process to relent and achieve a durable result. The dilations have usually been started within 2–4 weeks of the final resection and done at 1–2-week intervals. With early treatment, only one to six dilations have been needed for a stable esophageal caliber. If begun later, after significant narrowing has occurred, the patients may again develop a fairly resistant stricture requiring many additional dilations or even resection.

Results of Stricture Resections

In our series of stricture resections at the University of Minnesota, up to four resections in the case of a 12.5 cm lye stricture were required to remove all involved tissue. Of the 19 stricture patients, 5 required 2 or more resections. For the other 14 patients, intraoperative traction accomplished bringing the ends together for a true primary repair (see Chap. 25: "A Flexible Approach to Long-Gap EA"). The growth response following an anastomosis under tension will essentially be completed within about 7 days, and reoperation will be easily done within about 10–12 days from the previous one. The next best time for the next resection would be 4–6 weeks later when the adhesions will be more filmy and less vascular. In this series, subsequent resections have been done from 1 week to 2 months after the previous resection, and the time interval resulted from a variety of factors. Some patients, for example, if they were handling secretions well, were discharged between resections which led to longer intervals.

A follow-up was completed at our institution for 12/19 patients from 0.7 to 7 years after completion of the stricture resections. All patients had fundoplications, usually before the stricture resection. The patients with the lye and congenital strictures, however, had the fundoplication after the stricture resections were completed. Endoscopy was completed in 12 patients and no residual strictures were seen. Mild reflux esophagitis on biopsy was found in 3/12, with the remaining having normal esophageal mucosa. Five patients remained on anti-reflux medications, although three out of five had no reflux symptoms. As is the case in EA repairs, after the stricture resections, usually no peristaltic motion existed below the anastomotic line and the esophagus emptied by sporadic uncoordinated contractions and the effects of gravity. Nevertheless, all patients were eating a normal diet, appropriate to their age. There were no reports of diet restrictions, dysphagia symptoms, or aspiration events.

Discussion and Conclusions

There is considerable variability in treatment of strictures across institutions, and few long-term data are available to provide guidelines. When the strictures are resistant to treatment, then resection and repair would appear to be the best option toward achieving this goal. This approach allows for the growth and utilization of esophageal tissue to make up the defect after resection which avoids the complications of various other replacement techniques. Importantly, once an essentially normal esophageal configuration has been achieved and reflux controlled, it is likely that these repairs will remain stable and should provide for the many long years of function that is necessary for the effective treatment of children. Because this is a relatively new approach, however, follow-up data are still needed.

This favorable outcome is in distinction to either the partial or complete gastric pull-ups or a colon interposition where the adverse consequences increase with time. With the stomach and GE junction, completely or partially in the chest, reflux becomes obligatory and little can be done about it. Either cervical or thoracic esophagitis will result even if the gastric mucosa becomes atrophic or large amounts of proton pump inhibitors are given. The reflux typically contains bile which has been shown to be the major cause of damaging effects [18]. A host of other problems will also be present ranging from anemia to reduced weight gain to aspiration and chronic pulmonary problems. For the colon, the organ dilates producing increasing difficulties from chronic aspiration, dysphagia, and difficulties in clearing food from the aperistaltic segment. The problems with these interpositions are discussed more fully in the chapters on their long-term results.

The resection of strictures described may require a technically more difficult operation than an interposition graft and even two or more resections to solve the problem. Although this may seem to be an elaborate overall approach,

the goal is for 70 good years without significant related problems, and our results suggest this is the most effective way to achieve it.

The Esophagogastric Junction, Reflux, and Esophageal Atresia

42

Khalid M. Khan

Introduction

The lower esophageal sphincter (LES) is charged with maintaining a gating system that allows passage of ingesta into the stomach and, at the same time, acts as a barrier to reflux of gastric contents. Anatomically, the LES is a thickening of the circular muscle at the distal end of the esophagus, which itself is a tube that is under tension (Fig. 42.1). The LES interacts with the adjacent diaphragm to maintain integrity and pressure differences between the abdominal and chest cavities; this relationship also plays a role in relaxing the sphincter mechanism to allow normal passage of food boluses. The maintenance of the closed or tonic state of the LES is a property of its intrinsic structure and physiology. The major response of the LES is to relax when a swallow is performed, allowing aborally propagated food boluses to enter the stomach. While the typical terminology is that the sphincter "relaxes," muscular contraction is involved in opening the sphincter [1].

In patients with esophageal atresia (EA) with or without a tracheoesophageal fistula (TEF), primary structural defects may exist in the organization of the LES in addition to a shortened esophagus and the primary defect and fistula. The mechanism that facilitates opening of the LES as a response to a swallow may be intact prior to EA repair despite the esophageal defect. Long-gap EA is usually associated with extreme shortening of the lower esophagus; in such extreme cases, the LES may be the only appreciable lower remnant.

Surgery to achieve a primary repair of EA may have an impact on the mechanism by which the LES opens, by disrupting the vagus nerve. To perform a primary repair of long-gap EA, tension is necessarily applied to the lower esophagus; as a result, the LES may be lifted into the thoracic cavity, thereby compromising the role of the diaphragm in the maintenance of LES continence. Our own practice has been centered on the use of esophageal traction to achieve primary repair of long-gap EA and referrals from outside institutions arrive at various stages or EA repair or failed repair [2]. A large proportion of our patients have pure EA without a distal or proximal fistula where the lower esophageal pouch may be severely diminished (Fig. 42.2). We have used traction as a method to grow the esophagus and therefore be able to perform a primary repair with the goal of always using the patient's own esophagus [3]. Application of tension via traction to the lower esophageal pouch over several days clearly has an effect on the location of the LES with loss of the normal angle of His as the stomach is pulled upward.

Gastroesophageal reflux (GER), a recognized problem in patients with EA, is more likely after long-gap EA repair [3, 4]. Relocation of the stomach into the abdomen and/or a Nissen fundoplication may be necessary to reestablish anatomic integrity (as well as treat the GER).

In the first half of the chapter, normal LES structure and function and the mechanisms for common abnormalities of the LES are reviewed, while in the second half of the chapter, these mechanisms are used to explain the LES structure, function, and mechanism of GER in patients with EA.

Structural Anatomy

Morphologically, the gastrointestinal tract changes from a tubular to saccular form at the transitional zone between the esophagus and

stomach called the esophagogastric junction (EGJ). At this point, the mucosal epithelium changes from stratified squamous to simple columnar. In the chest, the esophagus is subjected to negative pressure generated by respiration, whereas in the abdominal cavity, the stomach is exposed to positive pressure.

Anatomically, at the tenth thoracic vertebral level, the esophageal body enters the hiatus in the right crus of the diaphragm and ends in the LES, which is immediately above the EGJ. The phrenoesophageal ligament (which originates from the transversalis fascia of the diaphragm) inserts on the lower esophagus and aids in the fixation of the LES; the LES lies above and up to 2 cm below the diaphragm (Fig. 42.1).

Structurally, the lower esophagus has smooth muscle in two muscular layers: the thicker muscularis propria and the inner muscularis mucosae. The outer layer (propria) is much thicker; it is described as having a longitudinal outer and circular inner layer (Fig. 42.1). The esophagus is kept in tension between the EGJ and the upper esophageal sphincter: transection of the normal esophagus will result in retraction of both ends. The primary neural supply of the LES is via the vagus nerve. Between the longitudinal and circular smooth muscle layers of the muscularis propria lies the Auerbach's (myenteric) plexus; farther in, the Meissner's plexus lies in the submucosa and is primarily sensory. In the esophagus, the intramural density of ganglion cells increases aborally and is maximal just above the LES [1]. Please also see Chap. 35 for histological variations of the neuronal and muscular components of the esophagus in patients with EA.

The function of the esophageal muscle differs in the esophagus (versus in the LES), but the anatomic movement in the muscle fibers is the same. To achieve muscle contraction by shortening of the muscle, the fibers are arranged obliquely and cross each other. The angle at which muscle fibers cross determines their function; in the body of the esophagus, fibers cross at an angle of more than 45° and the resulting motion is propagation of food boluses downward [1]. At the LES, fibers cross at an angle of less than 45° and contraction pulls the LES open [5].

Like the muscle of the body of the esophagus, the LES maintains spontaneous muscle activity, allowing it to remain contracted without fatigue [1]. The force generated to keep the LES closed is not as strong as the force of a true occluding sphincter; nonetheless, the LES is able to keep acid out of the esophagus, most of the time, in the physiologically normal state.

A number of structures come together at the esophageal hiatus to create the complex occlusive function of the LES system [6]. It consists of the muscular elements of the diaphragm, ligaments, and the LES itself (Fig. 42.1).

The second part of the sphincter mechanism of the lower esophagus is the diaphragm. The crural diaphragm develops from the dorsal mesentry of the esophagus and is innervated from the costal diaphragm. Humans are able to swallow only if the crural muscles relax sufficiently during the passage of food boluses [7]. It can be shown that electromyographic activity in the diaphragmatic crural muscles stops during the swallowing process and that, simultaneously, the esophageal hiatus widens, allowing food to pass. The converse, i.e., tightening of the crura does not appear to contribute to the normal LES closed state [1]. However, tightening of the crura does contribute to LES pressure during inspiration and with increased abdominal pressure from maneuvers such as coughing; such additional pressure may be as much as 150 mmHg [8]. This section of the diaphragm encircles the LES, which can freely slide within the hiatus.

A third mechanism that helps prevent regurgitation is the natural angle of the esophagus as it becomes the stomach. The angle of His creates a valve-like effect that protects against GER (Fig. 42.1).

Physiology

In adults, the LES is characterized manometrically as a high pressure zone of 3–5 cm long that marks the lowest extreme of the esophagus. The proximal LES border is up to 2 cm above the squamocolumnar junction; more than half of the LES lies in the abdominal cavity. The LES is tonically closed with a resting pressure of

10–30 mmHg, although a pressure as low as 5 mmHg is enough to maintain function [6]. The area is differentiated from the esophagus above it by muscular, neuronal, and biochemical characteristics. Per radiologic assessment, it is an area of thickened muscle; it cannot be easily palpated in an operative field as a characteristic area, but it can be dissected in an autopsy specimen. Yet when examined on a computed tomography-position emission tomography (CT-PET) scan, the LES displays a very high signal [1]. The density of circular fibers of muscle increases progressing caudally from about 3 cm above the EGJ. The result is progressive thickness until the terminal portion of the esophagus, with an increase in the number of asymmetric inner muscles of the circular muscle layer of the muscularis propria [9]. The muscles on the side of the lesser curvature of the stomach retain their configuration and form the short muscle "clasps," whereas the muscles on the side of the greater curvature become the "oblique gastric sling" fibers [10]. This muscular asymmetry results in similar asymmetry of the intraluminal pressure zone. This pressure zone is affected by myectomy and by displacement the LES upward into the thoracic cavity. But, in experimental models, dissection of the phrenoesophageal membrane had no effect on LES pressure (Fig. 42.1). Clasps have significant tone at rest and a poor response to cholinergic stimuli; in contrast, sling fibers have little resting myogenic tone, but respond well to cholinergic stimuli (also see next section for a description of neural innervation) [11]. Resting tone therefore is primarily maintained by the unique properties of clasps—a combination of the properties of the muscle itself and neural excitation. The circular muscle maintains most of its elevated myogenic tone by entry of extracellular calcium through the L-type channels [12]. These channels are most abundant in clasps; less expression of such channels is seen in sling fibers.

The circular fibers of clasps are highly innervated by inhibitory motor neurons that release nitric oxide (NO); sling fibers have few such neurons [13]. NO is the major inhibitory neurotransmitter that mediates neurogenic smooth muscle relaxation in the gastrointestinal tract; it accounts for 34 % of all neurons in the myenteric plexus and is the most abundant neurotransmitter found in the LES [14]. The gastric sling, especially the left lateral part on the posterior side, is innervated mainly by cholinergic fibers; it has an alternative calcium-handling source, whether for resting tone maintenance or contraction [15]. In the resting state, this area demonstrates the highest manometric pressure [16]. Therefore, part of the resting tone is due to acetylcholine (ACH) release from excitatory neurons [17]. The balance between inhibitory and excitatory neural influence and myenteric NO appears to regulate LES tone.

All swallows are followed 1 to -2 s later by a drop in LES pressure, which lasts for several seconds; however, not all swallows create propagating motor activity in the esophageal body (Fig. 42.3). The process in the LES is a combination of cessation of tonic contraction and inhibition of the muscle by inhibitory neurons that are both nonadrenergic and noncholinergic (NANC). As noted above, there is vagal and peripheral control of the LES [17]. Peripheral control is related to postganglionic cells that mediate LES relaxation via the release of NO and, to an extent, vasoactive intestinal polypeptide (VIP) [18]. With vagal control, the fibers that supply the LES likely enter the musculature above the lower third of the esophagus; highly selective vagotomy in this area does not affect LES resting pressure or LES relaxation, and the effect of cholinergic stimulation is retained.

LES pressure exhibits diurnal variation. It is highest at night and lowest after meals— timed with motor activity of the stomach in reacting to food (especially fat), circulating peptides, and hormones. In healthy volunteers, the administration of cholecystokinin (CCK) results in LES relaxation [19]. Hormones have different effects depending on their site of action (such as pre- or postganglionic) and can act in more than one place. For instance, in cats, CCK stimulates inhibitory nerves that mediate physiologic LES relaxation (an indirect effect); it also has a direct excitatory effect by stimulating excitatory receptors in LES musculature, the overall effect being LES relaxation [20].

Manometry and Impedance

Contrast radiography has always been the first-line diagnostic test for disorders of the esophagus and LES. It is very sensitive for morphologic abnormalities as well as for normal anatomy. Manometry has been the most discriminative test of esophageal and LES function; more recently, impedance has been combined with manometry to simultaneously evaluate the relationship between bolus transit and esophageal pressure. Electrical impedance of the surface epithelium of the esophagus is reduced with passage of food boluses [1]. As the bolus is transported downward in the esophagus, its arrival at any point is preceded by an increase in luminal pressure, indicating an increase in esophageal wall tension [21]. As the bolus is transported distally, toward the stomach, the decrease in impedance becomes is prolonged.

The increase in pressure opens the esophageal lumen and produces a peristaltic wave as the wall tension rises, correlated with an axial lengthening of the esophagus (Fig. 42.3) [22]. This mechanism explains why a correlation between bolus transit time and pressure amplitude cannot be established in impedance and manometry recordings [22]. In the distal esophagus, impedance remains low for an extended time, during which the LES system is opened to allow the bolus into the stomach (Fig. 42.3). A relatively new technique to visualize esophageal pressure is high-resolution manometry (HRM) [23, 24]. HRM uses a large number of closely placed side holes or solid-state pressure transducers. It allows a more detailed view of pressure in the LES.

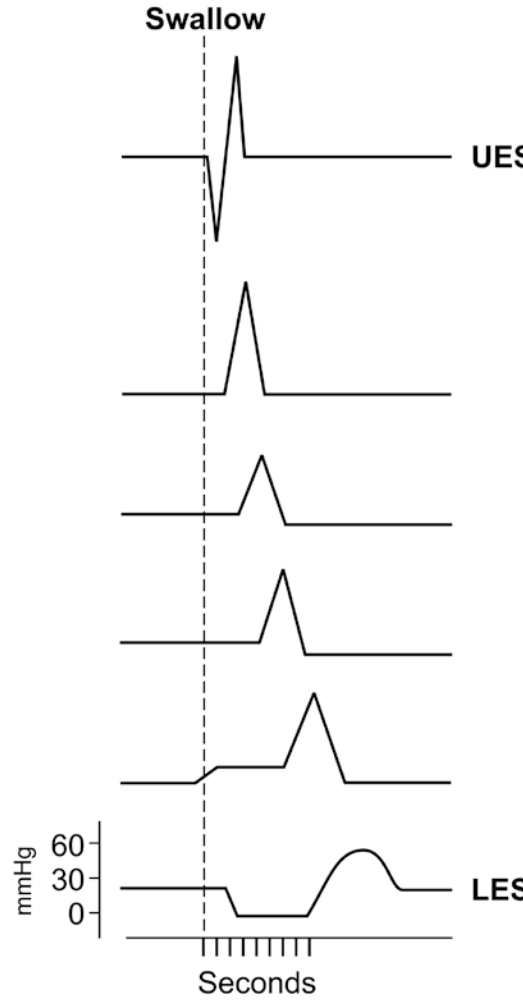

Fig. 42.3 Normal propagating manometric pressure wave through the esophagus. *UES* upper esophageal sphincter, *LES* lower esophageal sphincter

Transient Lower Esophageal Sphincter Relaxation

Other than gating the entry of food into the stomach, the LES system is most significant for producing GER, especially GER disease (GERD). Transient LES relaxation (TLESR), the hallmark of GER, is characterized as a sphincter relaxation that is not induced by swallowing. But TLESR is actually a physiologic process that occurs about three to six times per hour [25]. It is considered the normal mechanism that enables venting of gas from the stomach (i.e., belching) [26]. The subcardiac gastric region has the lowest threshold for triggering TLESR, so is likely the region primarily responsible [27]. Distention of the stomach caused by intragastric air and food triggers TLESR [17–20, 28]. Foremost, TLESR involves relaxation of the LES by activation of inhibitory neurons in the myenteric plexus by the vagus [29]. Suppression of crural motor activity results in relaxation of the crural diaphragm [29]. Similarly, lower esophageal peristalsis is suppressed. Contraction of the

distal esophageal longitudinal muscle leads to esophageal shortening [29]. During TLESR, longitudinal muscle contraction occurs in the distal esophagus, progressing retrograde; such contraction may be more forceful than the normal longitudinal muscle contraction associated with a swallow [30]. The sensory part of this reflex involves a signal from the stomach projected to the brain through afferent sensory fibers of the vagus [31]. The relaxation of the crural diaphragm that occurs simultaneously with LES relaxation is also mediated through vagal afferents [32]. The motor signals to the LES and crural diaphragm are conducted through the efferent motor tract of the vagus [33]. These signals are relayed to the myenteric plexus, from which they are distributed throughout the esophageal body and LES [33]. A number of peripheral factors have also been shown to trigger TLESR [34]. Overall, this reflex acts as a protective mechanism by preventing accumulation of excess amounts of gas in the stomach [6].

TLESR accounts for more than two-thirds of acid reflux episodes and is the main mechanism leading to acid reflux [6]. Yet most studies show a similar rate of TLESR in healthy individuals and in patients with GERD [35]. Thus, a greater proportion of TLESR is associated with GER in GERD patients [36]. An additional factor that facilitates reflux during TLESR in GERD patients (as compared with healthy controls) is a slightly higher trans-sphincteric pressure gradient before and during TLESR, caused mainly by an increase in intragastric pressure [37]. Furthermore, the pressure gradient is greater during TLESR accompanied by acid reflux [37]. Increased compliance of the LES in GERD patients has also been documented [38]. Increased compliance of the GEJ was found in GERD patients with hiatal hernia as well as in patients without hiatal hernia [38]. In symptomatic GERD patients without hiatal hernia and normal subjects, it was noted that GERD patients show a more distensible GEJ compared with controls [39]. Both primary peristalsis and more commonly secondary contractions are the motor event terminating GER episodes [40].

Pathologic GER is known to occur in particular patterns. One study found that, postprandially, the rate of GER episodes increased up to seven times [41]. That increase was related to a fivefold increase in the rate of TLESR and to an increase in the proportion of TLESR accompanied by GER [41]. The mechanism responsible for the postprandial increase in TLESR likely involves an increase in proximal gastric volume, activating tension receptors in the proximal stomach, yet the percentage of TLESR associated with acid reflux does not relate to proximal gastric volume [37].

Another pattern of significance for GER is nocturnal reflux, nocturnal GER events often occur when the patient is awake or arouses from sleep and not necessarily, while LES pressure is low during sleep [42]. Other mechanisms (such as straining and coughing) are responsible for the remaining GER episodes and are important in patients with severe disease associated with a hiatal hernia.

Despite the frequency of TLESR, additional mechanisms can protect against GER. In the fasting state, LES relaxation induced by pharyngeal stimulation is not associated with inhibition of the crural diaphragm or with acid reflux [6]. Postprandially, few of the pharyngeal stimuli result in crural diaphragm inhibition; GER was found only when LES relaxation was associated with crural inhibition [6]. Thus, simultaneous diaphragm inhibition and LES relaxation are necessary in order to generate GER.

Hiatal Hernia

In patients with a hiatal hernia, the LES cannot anatomically be kept closed in a coordinated fashion. The EGJ is transposed into the chest, thereby shortening the esophagus. The LES is rendered incompetent as a result of loss of tension in the esophagus; such tension is necessary to maintain LES form [1]. By the same mechanism, esophageal motility is reduced in GERD patients. The LES may not open properly in about 4% of GERD patients [43]. The relationship between TLESR in patients with a hiatal hernia is not clear [44]. TLRSR is less important for reflux in GERD patients with (versus without)

a hiatal hernia; only 40 % of acid reflux episodes are associated with GER [44]. Reflux in patients with a hiatal hernia is more often related to low LES pressure or to straining during periods with low LES pressure and otherwise normal LES relaxation [44]. As noted above, compliance of the EGJ in GERD patients with a hiatal hernia is increased.

Surgery for Gastroesophageal Reflux

A fundoplication is the standard surgical intervention for GERD patients and is effective in reducing GER (whether involving acid reflux or not) [45]. The mechanisms for its effectiveness are not clearly understood. When a hiatal hernia is repaired, the EGJ and part of the LES system are reconstituted. Transposition of the herniated stomach back into the abdomen reestablishes the stretch of the esophagus and therefore the occlusive state of the LES [1]. By definition, a fundoplication wrap decreases the distensibility of the EGJ but also that of the upper gastric cavity [46].

The effect on the gastric cavity appears to be more complex. One study showed that proximal gastric compliance was not significantly different in patients who underwent a fundoplication, in GERD patients, and in healthy controls [47]. Furthermore, although vagal damage is a concern with surgery, a fundoplication was shown to increase gastric emptying, with vagal damage in only 10 % of patients [48]. Moreover, a fundoplication decreases the rate of TLESR [49]. And the proportion of TLESR associated with reflux also decreases after a fundoplication [49].

The Closed Lower Esophageal Sphincter Achalasia

Achalasia, which means “inability to relax,” is the best known disorder that affects the LES as a primary problem. In reality, the term is a misnomer at some levels because the LES is unable to contract its muscle wall and thus unable to open [1].

Idiopathic achalasia involves Auerbach’s plexus and is characterized by an absence of ganglion cells in the involved portion of the esophagus [50]. Ganglion cell degeneration is prominent in the early years of achalasia, with progressive loss of neurons [51]. Absent or incomplete relaxation of the LES is secondary to defects in the postganglionic neurons; such neurons may be reduced in number, absent altogether, or normal but functionally abnormal, or they may terminate without more proximal connections [52]. In some patients, the intramural ganglion cells are diminished to a lesser extent in the LES [53]. In others, they are missing in the body of the esophagus as well as in the LES. Although propulsive waves are no longer detectable in patients with achalasia, spontaneous activity may cause pronounced hypertrophy of the muscle wall of the esophageal body, where there are many ganglion cells. The LES is the only segment of the esophagus that does not undergo hypertrophy, likely because it has only a few ganglion cells.

Achalasia can have a number of different causes [1], which may be the reason for the heterogeneous impedance manometry measurements in such patients [54]. The classic findings are increased LES pressure with incomplete relaxation or opening of the LES and loss of distally propagating contractions. The disorder is progressive. In a study of children whose achalasia was diagnosed by barium swallow and by absence of peristalsis per manometry, 57 % of them had normal LES pressure, 13.8 % had no LES relaxation, and 87 % had some LES relaxation [55]. In a study of adult patients without peristalsis, 81 % of them had incomplete LES relaxation and 19 % had intermittent normal LES relaxation [56].

Clinically, dysphagia and respiratory problems are typical. The esophagus eventually distends distally, because of the presence of food over the long term. Interventional treatment with sphincteric botulinum toxin injection, pneumatic balloon dilation, and myectomy can be effective. If medical management is preferred, the use of nitrates and calcium channel blockers can also be effective.

The Lower Esophageal Sphincter in Esophageal Atresia

Limited data have been published on LES anatomy or function in EA patients. A preoperative study of EA patients, with or without a TEF, found abnormalities of the myenteric plexus [57]. Similarly, in an animal model of EA, multiple anomalies in the vagus and its innervation were reported [58]. However, we previously demonstrated that at least the gross morphology of the LES is well preserved even when the lower esophagus is extremely short (Fig. 42.2). A manometric study of 20 neonates before EA repair showed that the LES was 8–14 mm long: in 84 % of the patients, LES pressure ranged from 22 to 35 mmHg; in 16.7 %, LES pressure was low; and in 8.4 %, LES relaxation was incomplete [59]. Another preoperative manometric case study of long-gap EA showed peristaltic contractions in the proximal esophagus that appeared to be propagated into the distal esophageal pouch, culminating in normal LES relaxation [60, 61].

Atresia Repair and the Lower Esophageal Sphincter

Some authors have argued that damage to the vagus and/or its branches during surgical repair may cause the motor defects in EA patients, including the discoordination of the LES (see next several section for details) [60–62]. One of the most compelling findings in support of that argument came from the preoperative data from Shono et al. mentioned above [60, 61]. EA repair was followed by abnormal motility and LES relaxation, suggesting that the abnormal motility seen after the typical EA repair may be the result of denervation from intraoperative mobilization. In contrast, an experimental canine study found that cervical vagotomy had no significant effects on the LES, despite a low resting LES pressure, thoracic disruption of the vagus or esophagus, resection of the esophageal branches of the vagus, and phrenic nerve resection [63].

In an esophageal transection model in rats, Montedonico et al. [64] looked at the difference between primary EATEF repair and long-gap EA. Using pull-through perfusion manometry, they measured LES pressure, crural sling pressure (CSP), and the length of the intra-abdominal segment of the esophagus (LIAE) (Fig. 42.1) in 20 rats before and after resection of 15 mm of the cervical esophagus (and in eight controls before and after esophageal transaction). In the 20 rats, mean LES pressure decreased from 44.9 ± 17.4 to 30.9 ± 12.3 mmHg and mean LIAE from 17.9 ± 2.8 to 15.8 ± 2.4 mm. But in the eight controls, LES pressure and LIAE did not significantly change. CSP did not change significantly. Montidonico et al. concluded that postoperative reflux in EA patients might be, in part, caused by damage to the vagus and/or its branches.

Dutta et al. reported similar findings in a case-control study of 27 children (mean age, 30 months) after EATEF repair [65]. Postoperatively, mean LES pressure was lower in the study patients (12.2 ± 6.8 mmHg) than in the controls (16.8 ± 4.3 mmHg). Mean LES pressure was 12.0 ± 7.1 mmHg in the study patients with no GER; 12.3 ± 3.7 mmHg, mild GER; 11.0 ± 5.7 mmHg, moderate GER; and 6.9 ± 5.6 mmHg, severe GER.

According to these studies, postoperative LES pressure at rest does tend to be low in EA patients, possibly related to disruption of LES physiology during repair. Yet low LES pressure does not appear to account for the symptoms described in children. The lack of a relationship between LES pressure and GER was also supported by a study of 20 children (mean age, around 111 months) whose GER was improved by a fundoplication; despite signs and symptoms of GER and esophageal manometric abnormalities, their postoperative LES pressure was normal [66].

Manometrically the LES of the EA patient behaves somewhat similar to achalasia. Swallows may be propagated in the proximal portion of the esophagus in the normal manner in some individuals and we have found the manometric force generated to be pronounced. There is no propulsive pressure change in the distal esophagus only simultaneous contractions that are variable in amplitude but generally of low amplitude. There is no relaxation of the LES to swallows and as

mentioned above the resting LES pressure may be reduced.

Hiatal Hernia After Esophageal Atresia Repair

The potential for a hiatal hernia as an iatrogenic phenomenon of EA surgery is understandable especially in long-gap patients, in whom tension is necessary to achieve primary repair. In our patients that undergo traction of the lower esophageal pouch for several days the EGJ can be transported cranially and the normal configuration and relationship with the angle of His is lost until a fundoplication is performed (Figs. 42.2 and 42.4). A study using esophageal manometry to evaluate LES function and motility of the esophagocardiac region found that patients who underwent operations for pure atresia and non-EA patients with hiatal hernias considered to have GER showed reduced LES pressure and LES length and esophagocardiac motor abnormalities [67]. LES pressure, length, and motility of the esophagocardiac region improved in patients who underwent an antireflux operation.

Hiatal hernia as a late complication is also likely related to growth of the individual [68]. It is a common finding in adults who, as children, underwent EATEF repair. One study of adults (mean age, 36 years; range, 21–57 years) found symptomatic GER in 34 %, and endoscopic findings included a hiatal hernia in 28 % [4].

Fig. 42.4 Endoscopic view of the esophagogastric junction (EGJ) after EA repair having undergone traction in an infant. The EGJ is pulled upward and has lost the normal configuration. The patient subsequently underwent a Nissen fundoplication

Gastroesophageal Reflux After Esophageal Atresia Repair

GER is universally reported as a problem after EATEF repair [68–73]. An Australian long-term follow-up study showed that older symptomatic patients had a high risk of complications: 63 % had reflux symptoms and 19 % had severe symptoms [68]. Another long-term study of 227 EA patients, spanning more than two decades, found GER in 127 patients (58 %); 56 patients (44 %) required an antireflux procedure [74]. In a series of 31 EATEF patients for whom medical treatment was unsuccessful, 14 patients (45 %) underwent a Nissen fundoplication [75]. A study of adults found that GER was a common problem that impaired quality of life in 30 % of patients [69]. Tovar et al. found major symptoms and acid clearance problems related to ineffective peristalsis in the distal esophagus in relation to GER [70].

Long-term follow-up of children after EA repair has revealed disordered esophageal motility in almost all of them [68–74, 76]. Apart from low LES pressure and lack of propagating motility, esophageal contractions are simultaneous and weak, especially in the lower esophagus [62, 65, 76]. Low LES pressure in such patients has been associated with more severe reflux and aspiration pneumonia [65]. However, no correlation has been found between pulmonary problems and the presence of GER, esophagitis, or esophageal dysfunction [74, 77].

Fundoplication After Esophageal Atresia Repair

There are few data on medical treatment of GER in EA patients and none specifically aimed at identifying specific pharmacological regimens. It would be reasonable that the patients are treated in a simi-

lar manner to the general population of reflux patients. In most series of EA patients, significant proportions undergo fundoplication and this may be up to 50% [75]. In the case of long-gap EA, a fundoplication is often necessary early after EA repair, to restore the EGJ in the abdominal cavity. It has been argued that, when the EGJ is displaced, simply restoring it in the abdominal cavity without a fundoplication should be adequate to treat GER [1]. The reasoning is that the shortened esophagus that has lost its natural tension is once again placed under tension and the configuration of muscle fibers is reestablished and therefore the function of the sphincter is restored [1, 78]. This method (simply restoring the EGJ in the abdominal cavity) has been used extensively with good success even when compared with a fundoplication though not in the EA population [78].

To an extent, simply restoring the EGJ in the abdominal cavity may have some advantages for EA patients. In the study by Curci et al. discussed earlier, of the 14 patients (out of 31) who underwent a Nissen fundoplication, five had prolonged dysphagia requiring supplemental gastrostomy feeding [75]. Of those five patients, four underwent postoperative manometry and extended pH monitoring, which revealed normal LES pressure (greater than 15 mmHg), normal pH results, and marked esophageal dysmotility. Curci et al. postulated that the fundoplication created a mechanical obstruction for those patients with a dyskinetic esophagus that cannot generate the pressure to open the LES. To avoid such a complication, they advised deferring antireflux surgery, if possible, in those patients with GER and marked esophageal motility abnormalities. Marked esophageal motility abnormalities are also a universal feature of EA repair, so no operation is ideal. In our long-gap EA patients, almost all of whom had a fundoplication, we noted that normal feeding patterns did subsequently develop [79].

Mechanism of Esophageal Reflux in Patients with Esophageal Atresia

Symptoms of GERD and esophagitis are common in patients with a history of EA [68]. The typical mechanism of pathologic GER however may not apply to EA patients. Studies are lacking that demonstrate TLESR, whether physiologic or pathologic, EA patients. Our present understanding of TLESR and LES abnormalities in EA patients suggests that TLESR does not occur because of the lack of an intact vagal feedback for generating TLSER. Nevertheless, both GER (as demonstrated by pH studies) and esophagitis are prevalent in EA patients and appear to be major issues when they become adults. If the original defect was long-gap EA, the problems and symptoms appear to be worse. A number of factors clearly play a role. First, a hiatal hernia not only from tension during EA repair but also the result of constant upward movement of the LES with growth and development, perhaps related to unequal growth of the esophagus versus the rest of the body. Secondly the compliance of the LES is likely reduced and as noted above the LES pressure may be low. Finally refluxed gastric contents cannot be cleared from the lower esophagus by the normal secondary peristalsis. As noted these pathological features apart from the last one are affected by fundoplication and this may account for the positive response seen in EA patients to fundoplication. Caution needs to be exercised given that the LES is somewhat like achalasia and a tight fundoplication may make esophageal clearance worse.

Summary

The LES is morphologically normal in patients born with EA, despite the type of lesion or the length of the gap. The LES has the potential to function; however, after EA repair, the LES does not open normally and may be displaced into the chest and cannot naturally relax. GER in such patients is related to this hiatal hernia and to the poor clearance of the lower esophagus of acid refluxate. TLESR, as a mechanism for GER, is less clear in the absence of normal vagal feedback and it is yet unclear as to whether it occurs in patients with a history of EA repair. The fundoplication wrap does improve GER but can be to worsen the obstruction that naturally exists in the LES of such patients, but it remains the only method for treating GER.

43 Management of Gastroesophageal Reflux After Esophageal Atresia Repair

Janine N. Pettiford and Daniel J. Ostlie

Introduction

Gastroesophageal reflux (GER) in infants, also known as chalasia of infancy, represents a common physiological phenomenon during the first year of life [1–3]. Regurgitation occurs more than once a day in 60–70 % of 3–4-month-old infants and decreases to approximately 20 % in infants between 6 and 7 months of age. By 10–12 months of age, less than 10 % of infants experience regurgitation [4–6].

Gastroesophageal reflux disease (GERD) is one of the most common gastroenterological disorders in infants and children and continues to pose complex diagnostic and management problems. GERD is defined as involuntary passage of gastric contents into the esophagus that leads to symptoms or tissue damage.

GER can be categorized as either physiologic or pathologic. Physiologic, or functional, GER is a regurgitation that leads to no sequelae, and thus patients do not suffer complications related to the reflux. These patients have no underlying predisposing factors or conditions for GER and experi ence no growth or developmental delays. They are often referred to as "happy spitters" and usually don't require pharmacologic treatment [1, 4, 7]. In contrast, children with pathologic GER usually experience complications from the reflux. These patients may develop malnutrition, failure to thrive, esophagitis, or respiratory disorders, as well as complications including esophageal strictures and Barrett's esophagus [1–3, 8–11].

GER in the pediatric population is characterized as immaturity of the lower esophageal sphincter (LES) [9]. The LES functions as a barrier between the esophagus and the stomach by preventing reflux [7]. It has been shown that in infancy and childhood, the LES transiently relaxes leading to reflux of gastric contents [3, 12]. During swallowing, food is propagated down the esophagus via esophageal peristalsis. The most distal portion of the esophagus lies in the abdomen, and food enters the stomach upon relaxation of the LES. This portion of the esophagus, known as the abdominal esophagus, is pivotal in preventing reflux. It is often referred to as the high-pressure zone because it denotes the location of the LES. Initially described in 1956, this high-pressure zone is composed of and influenced by many factors such as an adequate intra-abdominal esophageal length, the presence of the phrenoesophageal ligament, a

DOI 10.1007/978-3-642-11202-7_43

normal functioning diaphragm, and an appropriate gastric emptying. Anatomic or other abnormalities of these components can predispose to GERD. In adults, studies have shown that individuals with 1 cm or less of intra-abdominal esophagus are more prone to reflux when compared to those with an intra-abdominal segment longer than 3 cm [13]. An increase in intra-abdominal pressure due to poor gastric emptying has been found to increase the number of reflux episodes and contribute to incompetence of the LES [14]. Additionally, it has been shown that reflux symptoms usually occur when sphincter pressures drop to less than 5 mmHg [7, 15, 16]. Unrelated to the above noted factors, the supine position may also predispose to reflux [10].

Reflux Strictures

Fortunately, GERD in infancy and childhood usually becomes less evident with age [9, 17]. Unfortunately, the long-term complications of GERD in infants and children can result in esophageal strictures and, in more complicated cases, Barrett's esophagus [6, 9, 11]. In a strict sense, an esophageal stricture is defined as a long-standing narrowing of the esophagus, usually due to scarring, and is commonly caused by acid irritation [6, 18]. In the context of children with esophageal atresia, an anastomotic stricture is generally present at the time of repair and may progress due to GERD.

Risk factors associated with severe GERD, and possible stricture formation during infancy and childhood, include neurological impairment, esophageal atresia/tracheoesophageal fistula (EA/TEF), and chronic lung disease [1]. The most common acquired causes of esophageal stricture are ingestion of corrosives, GERD, and after repair of esophageal atresia. Symptoms are generally gradual in presentation, with initial difficulty in tolerating solids, and followed by intolerance to liquids [9].

The incidence of an esophageal stricture secondary to untreated GERD varies from 15 to 30 % [9]. In infants and children, the mean age at presentation is 5.5 years. Studies used to diagnose reflux esophagitis in infants and children include barium esophagram at the time of an upper gastrointestinal radiographic series and esophagoscopy with biopsy. For peptic strictures greater than 10 mm, the barium esophagram is more sensitive. The barium esophagram is also superior in diagnosing achalasia and diffuse esophageal spasm, although esophageal manometry is necessary for definitive diagnosis. The gold standard for identifying mucosal disease caused by GERD is endoscopy and biopsy [10, 18]. This allows for a complete evaluation of the esophagus and, more importantly, exclusion of malignancy [6, 7, 9]. 24-h pH probe monitoring and impedance studies have also been useful in confirming GERD secondary to acid reflux and to distinguish GERD from eosinophilic esophagitis [6, 7, 10, 12].

Management of esophageal strictures varies widely among institutions. A number of management strategies are possible and include bougienage and medical therapy, fundoplication without dilatation, preoperative esophageal dilatation followed by fundoplication with intraoperative and postoperative dilatations, and resection with interposition grafting or primary anastomosis [8, 16]. In contrast to adults where the usual esophageal dilatation is endoscopic dilatation, in the pediatric population, the usual approach is balloon dilatation, bougie dilation, or operation [8]. Dilations are usually ineffective if reflux is not treated. Factors that impact the success rate of dilation include age of presentation, location of the stricture, degree of tightness, length of stricture, number of strictures, and previous failures. Operative repair is recommended in patients who fail nonoperative management [8, 9, 11].

Complications Following EA Repair

EA was first described in the seventeenth century as a congenital interruption of the esophagus. It took almost 250 years before Haight successfully

repaired a baby in 1941 with EA/TEF in a single-stage operation [19].

The incidence of EA is reported as 1 in 2,500–3,000 births [20]. The survival of children with EA/TEF has improved significantly over the past 40 years and currently is greater than 95 % [20, 21].

The most common postoperative complication of EA repair is an anastomotic stricture, which occurs in 18–50 % of patients [11, 22, 23]. Factors leading to development of a stricture include the gap length, anastomotic tension, anastomotic leak, GERD, and possibly a two-layer anastomosis. The most common presentation is intolerance to feeding. When an infant or child develops new symptoms of feeding intolerance after EA repair, an esophagram should be obtained to evaluate the esophageal anastomosis. When present, an anastomotic stricture appears as an abrupt change in esophageal caliber at the anastomosis (Fig. 43.1).

The initial management of esophageal strictures after EA/TEF repair is esophageal dilation. We prefer to utilize balloon dilation as it allows for gradual and progressive dilation under fluoroscopy. Additionally, by using contrast to fill the balloon, the length of the esophageal stricture can be determined [22, 23]. Fortunately, most esophageal strictures can be managed with dilation, although some require multiple dilations for resolution. Rarely, the anastomotic stricture is recalcitrant to dilations, usually because of its length or density. In these circumstances, resection with a primary anastomosis or esophageal replacement may be needed.

Recurrent TEF is seen in up to 10 % of patients and usually occurs weeks to months after the initial repair [24]. These patients are often premature with a lower than expected birth weight or an anastomosis complicated by leak [20, 24]. When a recurrent TEF develops, babies present with reflux, pneumonia, or symptoms of tracheomalacia. As with strictures, the diagnosis can often be confirmed on an esophagram which will show contrast entering the trachea through the fistula. Initial management is conservative with cessation of oral feeds and administration of antibiotics if pneumonia has developed [24]. After stabilization, the recurrent TEF can be addressed.

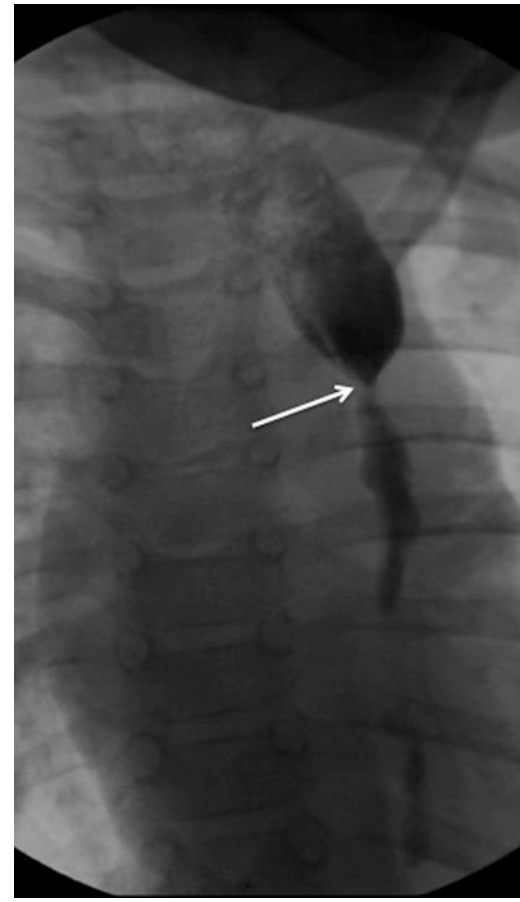

Fig. 43.1 This esophagram in an infant after esophageal atresia repair shows an anastomotic stricture (*arrow*)

Anastomotic leaks are not uncommon and can occur in up to 15 % of patients. The leak is usually identified several days after operation [22]. Babies most frequently present with an increase in chest tube drainage. However, they can present with pain, distress, and sepsis. Treatment is usually supportive as most leaks will close without operative intervention with adequate drainage.

Other complications following EA repair include GERD, dysphagia, pulmonary infections, asthma, and tracheomalacia [20, 21, 25, 26]. Later complications encountered are Barrett's esophagus, tracheomalacia, esophageal dysmotility, feeding problems, scoliosis, and, rarely, esophageal carcinoma [20, 25].

Anti-reflux Procedures and Lower Esophageal Motility

Prior to the 1990s, the majority of patients with GERD were treated with an operation due to lack of good medical therapy. Recently, fewer anti-reflux procedures are being performed due to improved pharmacotherapeutics and lifestyle modifications (i.e., dietary changes and sleep position) [4, 6, 9, 10]. Presently, anti-reflux procedures should be considered in patients who have failed medical management, patients on prolonged medical management, patients with complications due to GERD (i.e., esophageal strictures, esophagitis, Barrett's esophagitis, and pulmonary infections), or patients with symptoms and neurologic disorders [6].

Currently, the laparoscopic Nissen fundoplication is the most common procedure performed in both adult and pediatric populations for treatment of GERD [4, 15, 17]. Since the early reports of laparoscopic fundoplication in the early 1990s, significant advancements have occurred in the surgical approach in infants and children. Currently, laparoscopic Nissen fundoplication improves symptomatic disease in over 95 % of children and carries a morbidity rate of less than 5 % and a mortality rate less than 1 % [15, 17].

Regardless of the type of anti-reflux procedure performed, it is important to create an adequate length of intra-abdominal esophagus, accentuate the angle of His, increase the pressure barrier at the esophagogastric junction, and approximate the crura. These maneuvers should increase the resistance of retrograde flow across the lower esophageal sphincter due to an elevated residual lower esophageal sphincter pressure [7, 12, 17]. Techniques other than Nissen's have also been described and include the Thal procedure (anterior 180° fundoplication), Toupet operation (posterior 270° fundoplication), Watson fundoplication (anterior 120 fundoplication), and the Boix-Ochoa technique (restoration of intra-abdominal esophagus and recreation of the angle of His).

In a recent multi-institutional prospective, randomized trial, the effect of disruption of the phrenoesophageal membrane during laparoscopic Nissen fundoplication in relation to subsequent wrap herniation and the development of a hiatal hernia was evaluated [27]. It was shown that patients who did not have the phrenoesophageal membrane divided had a significantly lower likelihood of developing postoperative transmigration of the wrap (8 %) compared to those that underwent complete mobilization of the esophagus (30 %). Hence, it is now recommended not to extensively mobilize the intra-abdominal esophagus and not to divide the phrenoesophageal membrane (Fig. 43.2) [27].

It has been suggested that patients with esophageal dysmotility, including infants with EA/TEF, will benefit from a partial wrap, thus decreasing the risk of postoperative dysphagia secondary to distal esophageal obstruction created by the wrap in the face of inadequate esophageal motility [7]. Many surgeons prefer a partial, usually anterior, fundoplication via a laparoscopic or open approach in babies requiring fundoplication after EA/TEF repair. At our institution, these patients undergo a laparoscopic Thal fundoplication.

Laparoscopic Thal Fundoplication

The infant is placed at the foot of the operating table and positioned in the frog-leg position. A nasogastric tube (NGT) should be inserted to

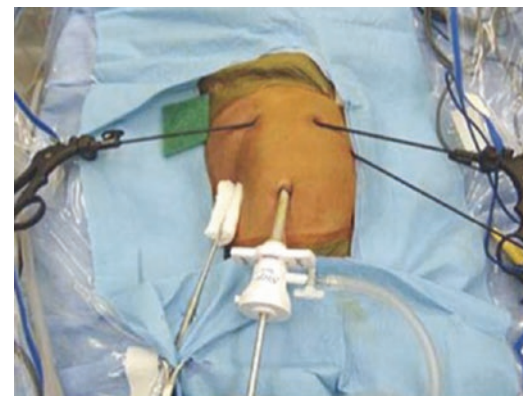

Fig. 43.2 This photograph depicts the placement of the umbilical cannula for the operating telescope and 3 mm instruments through stab incisions for a laparoscopic fundoplication

decompress the stomach prior to beginning the procedure. If a gastrostomy button is present, we remove it prior to prepping the abdomen. After prepping, we place a small piece of gauze and a Tegaderm (3M, Maplewood, Minn) over the gastrostomy site, and the patient is draped in the standard fashion.

A 5 mm cannula is inserted through the umbilicus for a 45° telescope. A 3 mm liver retractor is introduced in the right upper/mid-abdomen to retract the liver anteriorly. Atraumatic 3 mm instruments are placed in the right lateral epigastrium and left lower epigastrium for retraction and dissection. Generally, a 3 mm Maryland dissector is positioned in the left upper epigastrium (Fig. 43.3). Regarding incisions, we employ the transabdominal stab incision technique whenever possible in which only one cannula is utilized in the umbilicus [28].

The operation is begun using electrocautery to divide the short gastric vessels along the upper one-third of the length of the greater curvature. The left diaphragmatic crus is identified followed by the creation of a small retroesophageal window using blunt dissection, with care taken to not disrupt the phrenoesophageal membrane. Attention is then turned to the gastrohepatic ligament, which is divided with electrocautery. The right diaphragmatic crus is now identified, and the small retroesophageal window that was begun on the left side is completed using electrocautery and blunt dissection. Again, it is important not to disrupt the phrenoesophageal membrane during this portion of the procedure. Once the retroesophageal window has been created, if a hiatal hernia is found, the esophagus can be brought into the abdomen and the crura reapproximated with a 2-0 silk suture, incorporating a small portion of the posterior wall of the esophagus.

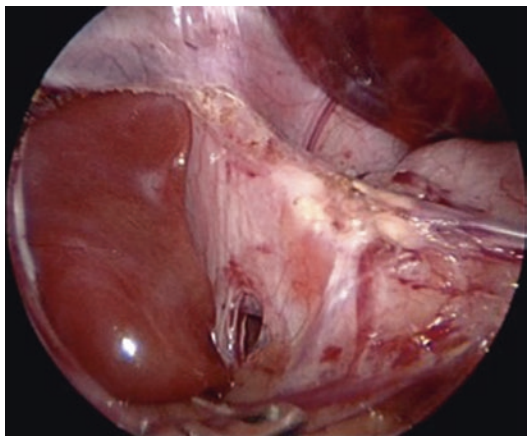

Fig. 43.3 The dissection of the posterior esophageal window is complete. Note the phrenoesophageal membrane has not been disrupted. The esophagus has been gently mobilized into the abdomen, and the crura are ready to be reapproximated posterior to the esophagus

Attention is now turned to creating the anterior fundoplication. An adequate anterior fundoplication should encompass at least 270° of the esophagus. A Thal fundoplication is initiated at the angle of His where the greater curve of the stomach is sewn to the left posterolateral aspect of the esophagus. We use 2-0 silk suture for this approximation, but any nonabsorbable suture can be used. Sequential interrupted sutures are then placed from the greater curve of the stomach progressing up the posterolateral esophagus, until the left crural-esophageal junction is reached. Generally, only three or four interrupted sutures will be needed to create the left side of the fundoplication (Fig. 43.4a). Sewing the fundus of the stomach to the anterior esophagus and diaphragm using interrupted sutures creates the anterior aspect of the fundoplication. The suture line should be performed in a manner that would follow a reverse C (Fig. 43.4b).

The right side of the fundoplication is formed by continuing to sew the fundus of the stomach to the right posterolateral esophagus using interrupted sutures, until the esophageal-gastric interface is reached (Fig. 43.4c).

Regarding other fundoplication options, it is reasonable to perform a “floppy” laparoscopic Nissen fundoplication. The technique for laparoscopic Nissen fundoplication has been extensively described and will not be reiterated here. Many infants who require a fundoplication will also require assistance with enteral feeding due to poor oral intake. When a gastrostomy is needed, we perform a laparoscopic gastrostomy as initially described by Georgeson [29].

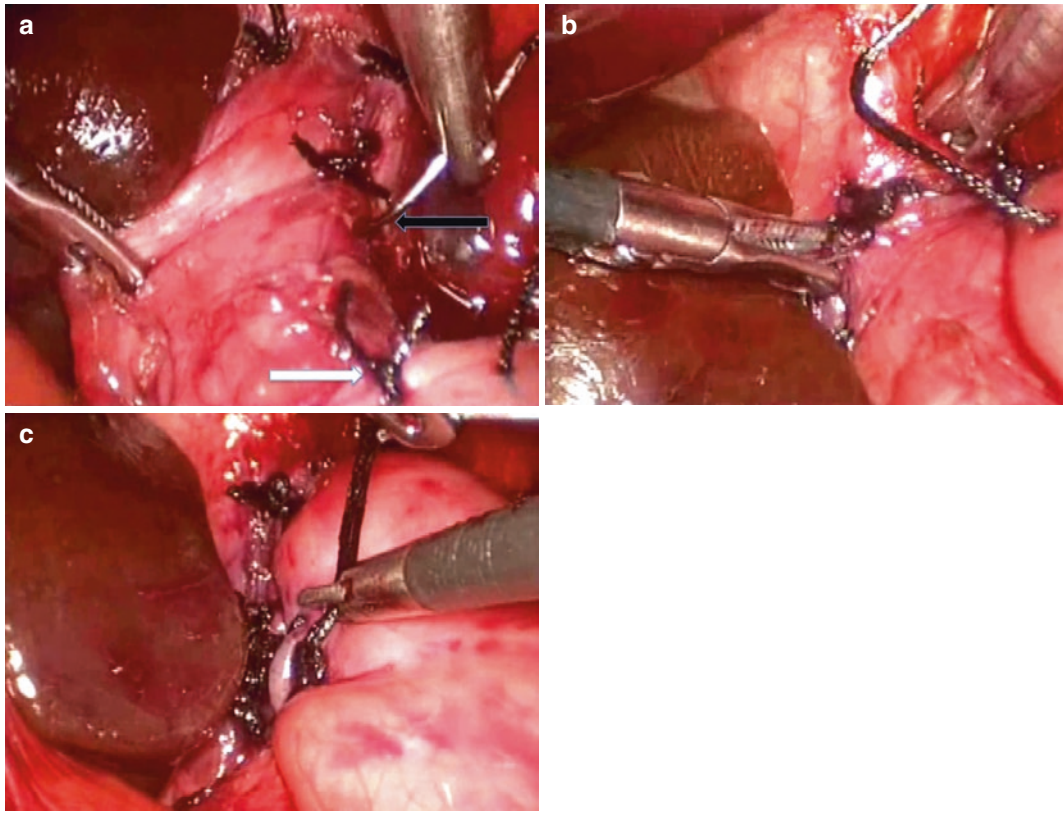

Fig. 43.4 The left side of the Thal fundoplication is being created using interrupted sutures that approximate the greater curve of the stomach to the left posterolateral esophagus from the angle of His (*white arrow*) to the diaphragmatic hiatus (*black arrow*) (**a**). Esophagocrural sutures have been placed to aid in the prevention of wrap migration. In the center (**b**), the anterior portion of the fundoplication has been created by sewing the anterior fundus to the anterior esophagus and diaphragm using interrupted sutures. On the right (**c**), the right side of the fundoplication is being completed. The interrupted sutures are placed from the fundus to the right posterolateral aspect of the esophagus

Outcomes/Complications

In a recent experience at our hospital with 99 patients undergoing both open repair and thoracoscopic repair of EA/TEF, 26 (26%) required fundoplication. All patients underwent an anterior Thal procedure via either an open or laparoscopic approach, and all patients had improvement in their GERD symptoms.

It has been shown that patients undergoing laparoscopic fundoplication have comparable results to the open operation and have a shorter hospital stay. The anti-reflux medications can generally be stopped within 1 month. The most common complications associated with fundoplication post EA/TEF repair are bloating, retching, dysphagia, atelectasis, pneumonia, and wound infection. Late complications include bowel obstruction, wrap failure, and herniation of the wrap [7, 15].

When seen, boating or retching usually occurs shortly after the fundoplication. Unless the infant has an associated neurologic disorder, these symptoms are often related to gas bloat. Dysphagia is more commonly associated with a complete fundoplication and is rarely seen with a partial anterior fundoplication. The concern regarding esophageal dysmotility and subsequent dysphagia in these EA patients is the most common reason many surgeons prefer a partial fundoplication to a complete fundoplication. Wrap dehiscence or migration generally occurs later

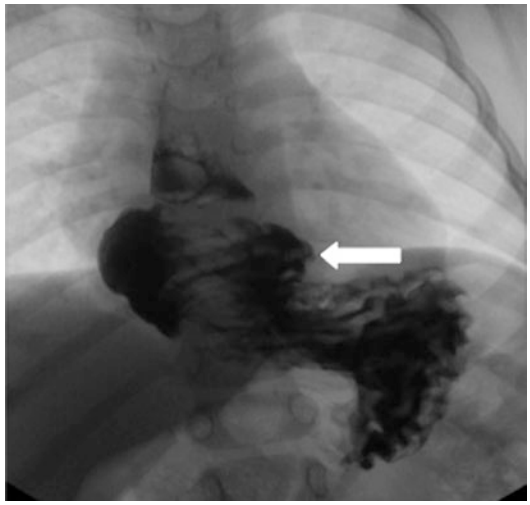

Fig. 43.5 This upper gastrointestinal contrast study reveals a fundoplication that has migrated through the esophageal hiatus (*white arrow*), resulting in recurrent GERD symptoms

and will present with recurrent GERD symptoms or new onset of retching. Upper gastrointestinal contrast evaluation should be obtained and will provide the critical information about the integrity or location of the wrap (Fig. 43.5). As noted, minimal esophageal mobilization will significantly decrease this risk of wrap migration.

The Stomach and Esophageal Atresia Repair

44

Khalid M. Khan

Introduction

Esophageal atresia (EA) with or without a tracheoesophageal fistula (TEF) is an abnormality of embryologic differentiation. There are a range of phenotypes, and EA-TEF is associated with developmental anomalies in other organ systems. The gastric cavity is intimately related to the esophagus anatomically and functionally. In clinical practice gastric morphological anomalies are not reported in patients with EA, and there is little discussion on gastric function. In this chapter we examine clinical and experimental data that includes the stomach in patients with EA. Gastric neuromuscular development during embryogenesis, electrophysiology, and gastric function after EA repair are reviewed in relation to EA-TEF and EA without TEF. The effects of EA repair surgery and fundoplication on gastric function are examined and whether there is an impact of this on long-term outcome of patients with EA.

Embryology

The relationship between the esophagus and stomach is an example of the coordinated function that characterizes the alimentary tract. The smooth sequential movement of the upper intestinal tract is made possible by their common origins. The embryology of the foregut is discussed elsewhere in this book. In brief the primitive foregut gives rise to the pharynx, respiratory tract, esophagus, stomach, and proximal duodenum. Differentiation of the stomach commences around 7 weeks of gestation. The gastric cavity and esophagus therefore develop in concert during embryologic differentiation of the foregut. While the precise event or sequence of events that lead to the various EA defects is not defined, there is data that shows anomalies of the sonic hedgehog and related signaling pathways are involved [1]. The same pathways are involved anatomically and functionally in the normal foregut [2]. Furthermore atretic malformation of segments of the alimentary tract distal to the stomach is associated with the EA-TEF spectrum [3].

Gastric Anatomy at Birth

During fetal growth functional maturity of the alimentary tract involves the flow of amniotic fluid, and in utero foregut obstruction leads to abnormalities of fluid volume [4]. The most

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_44

common form of EA comprises a blind-ending upper esophageal pouch and a TEF to the lower esophageal end so that fluid can flow via the tracheal fistula into the distal esophagus and therefore the remainder of the alimentary tract. In EA without a TEF to the distal esophageal pouch, amniotic fluid cannot flow through to the lower esophagus and stomach, and therefore development of the stomach can potentially be affected in such cases. Indeed diminished or absence of air in the stomach is a radiological feature for the diagnosis of pure EA [5].

Sase et al. examined fetal gastric volume using ultrasound [6]. Women with normal singleton pregnancies between 18 and 39 weeks of gestation were included in their study. Gastric measurements were also performed in 13 fetuses with digestive tract obstruction. While the cases of EA were not defined in terms of the presence or absence of a fistula, the gastric area ratio was below the 95 % confidence interval for the predicted value in all five fetuses with EA and greater than the 95 % confidence interval for the predicted value in 7 of 8 with duodenal atresia or distal intestinal tract obstruction. While it is reasonably assumed that amniotic fluid has a role to play in the development of the gut, there has been no systematic study on the development of the stomach and gastric anatomy in patients with EA. Indirect evidence comes from an investigation of the neurohistopathology of the lower esophagus, gastroesophageal junction, and gastric cardia associated with EA. Nakazato et al. used a microdissection technique to study the upper gastrointestinal tract of five patients with EA-TEF prior to surgical repair [7]. A looser than normal Auerbach's plexus configuration was present in the distal esophagus, and the nerve plexus was abnormal in the gastric fundus of all the patients. The authors concluded that the findings suggest the existence of congenital functional impairment of the upper gastrointestinal tract in patients with EA-TEF, due to abnormal development of the myenteric plexus. In contrast to this, a report in which the authors utilized a manometric approach to examine the lower esophageal sphincter (LES) prior to EA repair showed that the relaxation of the LES was normal in response to contractions in the upper esophageal pouch suggesting that the neurophysiology of the gastroesophageal junction is normal in these patients [8, 9]. Our series of patients comprises the largest group of EA patients without a distal TEF undergoing primary EA repair [10]. We have also noted that in cases of pure EA where there is almost no discernible length to the distal esophageal pouch (Fig. 44.1), the LES can still be visualized as a distinct structure (Fig. 44.2). Furthermore we have assessed the stomach visually and with contrast to define gastric anatomy and noted that the dimensions of the gastric cavity have not been compromised in typical cases of EA without a distal TEF (Fig. 44.3) [10]. Conversely a report on nine babies with pure EA, albeit over a decade ago, noted that after initiation of gastrostomy feeds, seven (78 %) developed gastric complications, including two posterior gastric perforations (one fatal). The authors proposed that the high complication rate was due to a small, abnormal stomach that was vulnerable to damage by operative trauma and the effects of handling large volumes of feed. They hypothesized that the stomach is abnormal because it has not been exposed to the maturing effects of amniotic fluid in utero [11].

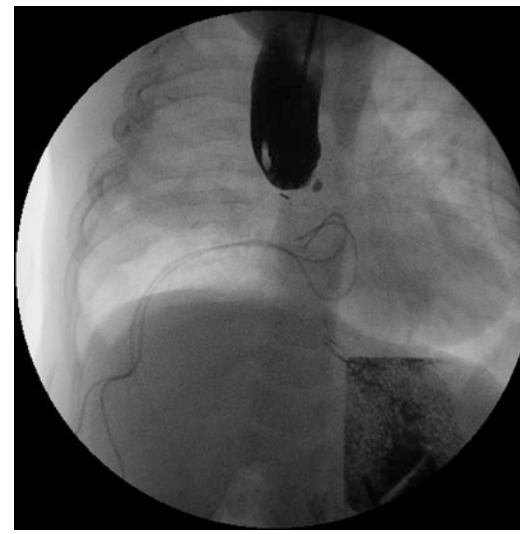

Fig. 44.1 An extremely short lower esophageal remnant that cannot be easily seen even when a probe is used to distend the area of the stomach in a case of pure esophageal atresia. The gastric volume is not diminished

Gastric Electrophysiology

The electrical activity of the stomach was first defined almost a century ago. There is a consistent pattern whether recorded from the serosal or mucosal surface of the stomach or the skin surface [12]. The characteristic electrical activity comprises slow waves of three cycles per minute (cpm) or 0.05 Hz. This is driven by pacemaker cells high on the greater curvature and is an inherent property of the smooth muscle of the stomach and related to cell membrane permeability changes and movement of sodium – interstitial cells of Cajal have been defined as the primary pace setting cells of the gastrointestinal tract [13]. Spikes waves correspond to action potentials of muscular contractions. A maturation pattern of the gastric electrical activity has been demonstrated dependent on the gestational age; a normal electrical rhythm can be detected during early gestation [14, 15]. Chen and McCallum reported that normal slow-wave frequency in the EGG was related to normal gastric motility and that abnormal slow-wave frequencies were associated with motility disorders [16]. Dysrhythmias have been reported in patients with pseudo-obstructive disorders with associated gastric dysfunction suggesting that disordered gastric electrical activity is a sign of intrinsic neuropathic disorders of the gut [3]. Surface skin recording or electrogastrography (EGG) and its uses in clinical practice are discussed in detail elsewhere in this book. Patients with EA have been studied using this technique. In a study of 16 EA patients in comparison to controls, the authors found a wide frequency distribution with two individuals showing tachygastria (frequency ≥5 cpm) and another two demonstrating bradygastria (frequency <2 cpm) [12]. The authors postulated that the wide range suggests that there is an electromechanical dissociation that results in abnormal gastric contractions. In a similar study by Yagi et al., 13 children with a history of EA repair underwent EGG, 5 of whom demonstrated abnormalities [17]. The dysrhythmias continued in the postprandial period and were persistent in 3 of 5. The authors concluded from this that there must be a congenital neuronal defect associated with these findings in patients with EA. In support of this hypothesis, there is evidence to show that the smooth muscle cells of the stomach can exhibit an abnormal slow-wave frequency after inhibition of cholinergic activity [18]. Gastric dysrhythmias are suggested to cause antral dysmotility by inhibiting the strength of

Fig. 44.2 The appearance of the lower esophageal sphincter in the case from Fig. 44.1

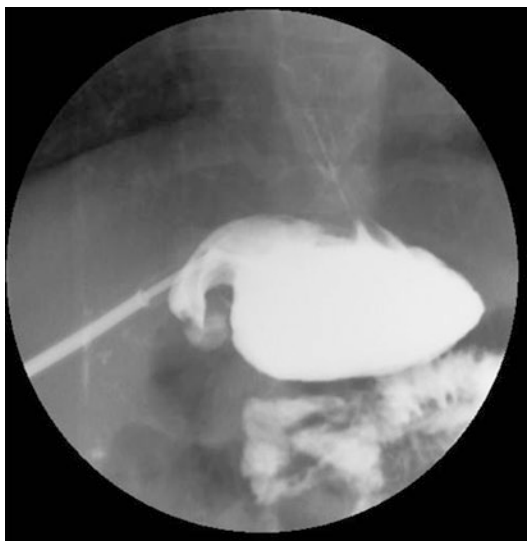

Fig. 44.3 Contrast study after esophageal atresia repair and fundoplication in a case of pure esophageal atresia; the gastric volume does not appear to be diminished

contractions or reducing aboral propagation of contractions [19]. In a study by Bokay et al., there was a significant increase in bradygastria and decrease in tachygastria in the postprandial from the preprandial period in patients with a history of EA repair in comparison to controls [20]. Abnormal EEG patterns were present in 11 of 15 of the EA patients, while in 12 of 15 some clinical evidence of gastroesophageal reflux (GER) had been noted, and 60 % of the EA patients showed reflux on esophageal pH monitoring. There was no difference in the distribution of gastric myoelectrical activity between those with and without esophageal reflux on pH monitoring either before or after a meal. The authors of this study hypothesized that the significant increase in bradygastria and decrease in tachygastria in the postprandial period indicate that the myoelectrical response to ingested meals is sluggish [20]. The lack of a relationship between symptoms and abnormal myoelectrical activity evident in this study was a feature of the studies of Cheng et al. and Yagi et al. In particular there is no clear association between the presence of GER and abnormalities of gastric slow waves from these studies.

Gastric Function

There are limited data on the mechanical function of the stomach after EA repair. Investigators have focused on the stomach mainly to try and explain upper digestive symptoms that are reported in patients after EA repair in children and adults [21]. Gastric emptying by scintigraphy is the gold standard for the study of gastric function [21, 22]. It was first described by Griffith et al. in 1966 and is now used routinely in adult and pediatric patients to assess gastric emptying of solids and liquids [22]. Jolly et al. used scintigraphy to assess liquid-phase gastric emptying as well as GER in children after EA repair [3]. The authors noted that gastric emptying delay and GER were related to the use of tension on the esophageal ends in achieving primary EA repair. In a study by Montgomery et al. using a mixed meal comprising of pancakes in older children gastric emptying was abnormal in two of ten children with GER [23]. Romeo et al. examined gastric emptying in patients who had EA repair in childhood, 60 % of whom had symptoms of dyspepsia and dysphagia [24]. They found longer gastric emptying times in EA patients compared to controls with overt gastric delay in 4 of 11 patients using solid-phase emptying. The authors concluded that delayed gastric emptying is common and may be responsible for GER in EA patients. Our own data (unpublished) has been based on long-gap EA patients [10]. We examined liquid-phase gastric emptying in nine infants with only one showing delay (gastric emptying half-life – T ½ of >90 min); all our patients had undergone a fundoplication. In the most recent publication on the subject by Caldaro et al., 12 of 39 patients with EA exhibited delayed gastric emptying [25]. The possibility of gastric emptying delay as a cause of significant GER though elegant is not clear from the pediatric data. In a study by Aktas et al., gastric emptying times did correlate with the degree of scintigraphically assessed GER in infants [26]. In children with severe neurological injury from birth (cerebral palsy), gastric emptying times were found to be the same in patients with pathological GER diagnosed with pH monitoring and control patients [27]. Gastric emptying, foregut dysmotility, and GER often coexist. This has been noted in specific patient groups such as the abovementioned children with neurological injury [28], as part of morphological syndromes and foregut anatomical disorders. Manometric study of gastric motility in EA patients was conducted by Romeo et al. in the study of EA patients discussed above [24]. The investigators were able to recognize the features of the migrating motor complex in the interdigestive phases: phase I, a quiescent period; phase II consisted of irregular motor activity; and phase III a period of coordinated contraction. Three peristaltic wave types (I, II, and III) cycle were also identified. In 5 of 11 patients, the duration of the third phase and the frequency and amplitude of the peristaltic waves were abnormal. The authors found that antral hypomotility was due to increased duration of the third fasting phase and to reduced amplitude of type III

peristaltic waves. The significance of the findings was less clear in that two patients with GER were symptomatic and had delayed gastric emptying and abnormal gastric manometry, two others with delayed gastric emptying and abnormal manometry had no symptoms, and one patient had manometric abnormality but without major symptoms or gastric emptying problems. The authors noted that the alterations observed had some similarities with those observed in patients with primary or secondary dyspeptic syndromes. As noted above antral dysmotility may be a feature abnormal slow-wave activity [20, 29]. It could be postulated that foregut dysmotility gives rise to gastric emptying delay which in turn results in GER. In addition primary repair of EA could potentially involve disruption of the vagus nerve further complicating the etiological relationship between electrophysiology, manometry, and symptomatology in these patients [30].

Fundoplication

Gastroesophageal reflux is a common sequel to congenital disorders of the foregut. In one study almost all patients treated for EA developed GER [31]. Not surprisingly therefore most case series of EA patients show that a proportion of children undergo fundoplication [32]. Fundoplication in children with preexisting upper gastrointestinal dysmotility may however be problematic. In a series of children evaluated for symptoms of upper gastrointestinal motor dysfunction having undergone fundoplication for severe GER symptoms were unchanged or worsened after fundoplication [33]. The outcome of fundoplication may be specifically related to gastric motility. Loots et al. examined dysphagia after fundoplication and found that children who developed postoperative dysphagia were those with preoperative gastric emptying delay as compared to children without gastric emptying problems [34]. Conversely mean gastric emptying time was shown to be reduced in patients after undergoing Nissen fundoplication [35]. The acceleration in gastric emptying after fundoplication was elaborated to represent a shift toward normal gastric emptying times in the vast majority of patients in one study [36]. This would imply that while post-fundoplication symptoms may develop in patients with preoperative gastric emptying delay, ultimately gastric emptying may be improved in this group. The findings in relation to post-fundoplication gastric emptying are however not consistent. In a study of children undergoing Nissen fundoplication for GER, the investigators were able to demonstrate reduction in gastric compliance, an increase in minimal gastric distending pressure, exacerbation of the sensation discomfort with gastric distension, and yet no effect on gastric emptying [37].

Patients with EA are likely to need a fundoplication if tension is necessarily applied to the esophageal ends to achieve primary anastomosis [19]. Wheatley et al. described wrap disruption and recurrent reflux in 33 % of a pediatric population treated for EA [38]. The authors theorized that upward tension on the wrap owing to the presence of a shortened esophagus probably predisposed these patients to an increased frequency of fundoplication failure. Snyder et al. also concluded that the same factors responsible for the development of reflux in children with EA (poor acid clearance, altered motility, esophageal shortening) may contribute to the higher failure rate [39]. The authors showed that a complete or Nissen fundoplication failed twice as commonly as partial wrap fundoplication.

Apart from failure of the fundoplication, there are other consequences to a Nissen fundoplication in patients after EA repair. In the study by Curci et al. of 14 of 31 patients who underwent a Nissen fundoplication, dysphagia requiring supplemental gastrostomy feeding became an issue in 5 [32]. Of those five patients, four underwent postoperative manometry and extended pH monitoring, which revealed normal LES pressure, normal pH results, and marked esophageal dysmotility. The authors postulated that the fundoplication created a mechanical obstruction for those patients with a dyskinetic esophagus that cannot generate the pressure to open the LES. Other investigators have also concluded that particularly in children with EA, fundoplication cannot be considered a procedure

without complications and that problems resulting from disturbed gastric and esophageal motility should not be underestimated [40]. As discussed above fundoplication is inevitable in cases of long-gap EA where significant tension is necessary for primary repair, and, as noted by Esposito et al., dysphagia occurs independent of the anti-reflux mechanism adopted and that dysphagia especially when associated with respiratory symptoms may be a consequence of the primary dysmotility of the esophagus that typifies EA [41]. In our true long-gap EA patients, fundoplication was always performed after EA repair, and we have shown that the children are able to develop normal feeding milestones [42].

Long-Term Outcome

The most commonly reported long-term problem after EA repair is GER [43–48]. An Australian long-term follow-up study showed that older symptomatic patients had a high risk of complications: 63 % had reflux symptoms and 19 % had severe symptoms [43]. Another long-term study of 227 EA patients, spanning more than two decades, found GER in 127 patients (58 %); 56 patients (44 %) required an anti-reflux procedure [49]. Similarly in a series of 31 EA patients treated for GER 14 patients (45 %) required a Nissen fundoplication [32]. A study of adults found that GER was a common problem that impaired quality of life in 30 % of patients [44]. Tovar et al. showed symptoms were related to reduced acid clearance as a result of ineffective peristalsis in the distal esophagus in relation to GER [45], and as discussed above disordered esophageal motility is known to be a constant feature of the repaired esophagus in EA and therefore poor esophageal clearance [43–50]. Apart from low LES pressure and lack of propagating motility, esophageal contractions are simultaneous and weak, especially in the lower esophagus [20, 50, 51]. Low LES pressure in such patients has been associated with more severe reflux and aspiration pneumonia [52]. However, no correlation was found between pulmonary problems and the presence of GER, esophagitis, or esophageal dysfunction [49, 53].

Summary

The available data on gastric pathophysiology in the setting of EA is limited but does allow some conclusions to be drawn. It can be reasonably argued that the foregut neurophysiology may not be normal at birth at least in a proportion of EA patients; however, the genetic data which is largely based on animal models does not allow us to differentiate between the known human phenotypes. At birth the morphology of the stomach is not greatly altered in EA-TEF, and there is insufficient data to suggest gastric volume is reduced in cases of EA without TEF. Gastric emptying delay can be a problem in patients and may contribute to GER. The etiology of gastric delay may involve antral hypomotility related to congenital neuronal disruption in some patients. The effect of EA surgery and possible injury to the vagus nerve can be considered as contributing to gastric emptying delay. Tension applied to the esophagus affects the gastric cardia, and fundoplication is known to have an effect on gastric physiology though how this affects patients with EA is less clear. Our own findings based on long-gap EA patients along with other data indicate that indeed a small proportion of children consistently demonstrate abnormalities of gastric function; however, this does not account for the proportion of patients with a history of EA-TEF repair that expresses upper gastrointestinal symptoms. Apart from GER there is evidence to show that the upper digestive and pulmonic symptomatology is related to poor clearance from the esophagus and may be the major factor to consider in adults who present with esophagopulmonic symptoms.

45 Learning to Eat After Esophageal Atresia Repair: In Infancy and Childhood

James Brudney

Once the esophagus has been surgically connected, the next steps in the progression for the child to eat orally begin. Focusing on eating will be the charge of the speech therapist, a specialist with extensive knowledge and experience dealing with feeding difficulties in infants and children. The therapist brings an understanding of the swallow mechanism, feeding skill development, and infant/child development to the therapy process. He will lend his expertise to the well-being of the child to develop the most carefully planned feeding program. The child and parents are at the center of this program, which combines the child's past experiences, the parents' beliefs and expectations, and following the child's lead. The therapist melds these components with his own knowledge to visualize a course with the desired outcome of eating. The course is determined by information gathered in the evaluation, knowledge of normal feeding development, and understanding how the repair process interferes with the normal development of the child. Three primary areas are examined in the evaluation to identify where the child is starting on the spectrum of developmental feeding skills. The areas include oral motor skills [1–5], sensory integration [6, 7], and physiological function. Throughout the course of treatment, there will be many questions raised by the parents, and the quality of the answers will influence the treatment outcome. Their buy-in to therapy is mandatory for success. Education and participation of parents in the therapy program will help address many questions such as: will my child ever eat? How long will it take my child to learn to eat? Parents base so much hope upon the initial answers to these two questions. The therapist's responses to these questions can set the entire tone for the duration of treatment. Many therapists would acknowledge that working with children after repair of esophageal atresia presents the most challenging collection of issues related to eating for the speech therapist.

Normal Development

Understanding the normal feeding development in newborns and their progression of skills from birth to toddler-hood is crucial for the feeding therapist [1–5]. The therapist's decisions should be guided by reference points like child's skills, the understanding what is expected and what are red flags and what skills are to develop next. A newborn baby begins life with certain "prefeeding" reflexes of rooting, sucking, and swallowing. These reflexes emerge around 28 weeks' gestation. At 34–36 weeks' gestation, the fetus begins to coordinate a rhythmic

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_45

suck-swallow-breathe pattern in anticipation of feeding moments after birth. The first month of life is about eating and gaining weight to sustain life, using the pre-wired reflexes in response to repeated bodily cues, classic conditional learning. For example, say, an infant performs 50–75 SSB cycles while eating 2 oz of milk each feeding eight times daily. That works out to 400–600 cycles/day and 12,000–18,000 cycles the first month. That is a staggering amount of practice in the first month of life. Chances are the baby will be eating more than 2 oz at the end of the month. In months 2 through 6, the infant refines the suck-swallow-breathe pattern to accommodate numerous changes occurring during this period including increase in oral secretions, integration of the sucking reflex where sucking becomes an intentional act, and reabsorption of the fat pads in the cheeks creating more space orally. From 7 to 12 months, the gag reflex is less strong as more textures are introduced, and tooth eruption gives the infant new sensory receptors. Alternate feeding positions (being more upright), adapting to spoon presentations of puree consistency, and the emergence of independent feeding behaviors increases as the child transitions to more mature eating skills.

During the second year of life, many gross motor and fine motor advances facilitate increased eating independence [8, 9]. Thoracic stability and head control are stronger allowing the child to use his arms and hands more effectively to reach for items and explore them orally through the many sensory receptors of the mouth and hands. A controlled bite on soft solids appears mixed with a phasic bite and sucking marking the development of cerebellar control through graded movements. Simultaneously, food consistencies expand with hard and soft solids, thicker puree, and mixed textures leading to growing oral motor control and sensory tolerance. Their diet repertoire is transforming, and soon they will be sharing the same food choices as their parents. Appreciating the skills and developmental changes a typical child encounters across the first 24 months of life magnifies the challenges which lie ahead for child with esophageal atresia.

Realities of Repair

Medical intervention for esophageal atresia children is very intrusive on the child's overall development, especially feeding skills. The hospitalization sets the child up for delays with so many skills by the time they leave the hospital connected and ready to return home. Discharge from the hospital varies greatly depending upon type of repair. A primary repair of the esophagus implies one surgery to connect the two ends of the esophagus. Recovery is usually short, and feeding therapy proceeds over the next several months as weaning from tube feedings encourages hunger cues and motivation to eat. A two-stage repair will prolong the process by weeks because of the additional procedures and time needed to prepare the esophageal ends for attachment [10]. In the intermediate procedures, traction on the ends of the esophagus is placed to promote growth. During this time, the child is sedated and paralyzed to prevent complications. This down time disrupts a critical point of development for early sensory skills, oral motor skills, and learning opportunities from daily routines. The child misses out on how to manage one's environment when stressors are encountered, responds to stressors in inappropriate manners, and cultivates incorrect associations with typical newborn stimuli. Stressors present before repair include frequent oral suctioning to manage oral secretions which are not removed by the nasal catheter which courses down into the blind upper esophageal pouch. The noise of the suction and tape on the face to secure the catheter are noxious irritants to the child. After repair, the child is weaning from narcotics making them more irritable, the gut is slow to wake up after surgery, and the persistent intrusion of caregivers visually puts the child in a defensive demeanor. Oral aversion is a frequent end result of the medical intervention shown by the refusal of the child to all stimuli near the face, mouth, or lips and an extreme behavioral response characterized by gagging, crying, fighting to turn away, blocking with hands to avoid the presentation or approach. In the course of recovery, the healing process in the esophagus causes strictures and scarring which narrow the inner diameter of the esophagus and prevent movement

through the tube. Compounding the narrowing is the lack of peristalsis along the esophagus. Gravity becomes the source of motion. Dilatations break down the scarring tissue and expand the opening of the tube, but with a price. The child is intubated each time and reinforces the established negative associations during a time when therapy is attempting to establish new, positive oral associations. The dilatations are necessary for the long-term function of eating. In addition, feeding tube schedules diminish hunger cycles, and missed opportunities to foster sensory integration through holding and swaddling add to the harsh environment. However, experience amassed over 13 years of treating children with long-gap esophageal atresia (5 cm and greater in length) and with short-gap atresia has shown that therapy can directly change the development of these children. They can learn positive oral experiences, learn to manage their environmental stressors with appropriate responses, and learn to eat. The path will be different from typically developing children, but the outcome is expected to closely align with their peers. There has been recent validation of these expectations from a longitudinal study looking at the eating skills of 40 long-gap children after repair compared with a control group of like peers typically developing [11]. The study concluded that the long-gap children catch up to their peers with eating skills without significant limitations.

Approaches for Treatment

No single approach or method has been proven to be the most effective with all children in helping them to learn how to eat after repair for esophageal atresia. So many variables play into the decisions regarding approaches to take with each child. Many of the variables have been previously discussed in the chapter, related to the perspective of the child, the parents, the medical history, and the course of intervention and duration. Often times a combination of strategies from different methods may benefit the child, forming the crux of the program for the child. A popular method of feeding therapy used with children 15 months and older is the Sequential Oral Sensory feeding program created by Dr. Kay Toomey, a psychologist [12]. This approach is helpful in addressing many different feeding problems. The Sequential Oral Sensory (SOS) feeding program is a noninvasive developmental approach to feeding. It focuses on increasing a child's comfort level exploring and learning about the different properties of foods, including texture, smell, taste, and consistency. The SOS approach allows a child to interact with food in a playful, non-stressful way. It follows the steps to eating, beginning with the basic ability to tolerate food in the room, in front of the child, touching, and eventually tasting and eating foods. Parent education and involvement is an important part of this feeding approach [13–14]. A therapist works directly with the parents while they are watching each feeding session to learn this approach to feeding. Parents learn to identify physical signs and "body language" to identify when the child is overstimulated and to assist with setting up the home program.

A case in point, I worked with a 4-year-old girl status post long-gap esophageal atresia repair that came to the initial evaluation and sat at the table to discuss what we would do during her visit. Stating she was OK with the process, I began to prepare the space to explore some sample foods to see what kind of skills she possessed and where were the barriers or walls that kept her from eating. At the sight of seeing foods which were outside of her comfort zone (i.e., yellow, white, or light orange), she began to gag and wretch and vomit tube feedings. Once the food was removed from sight, then she was able to calm herself. Her defenses were so high that the sight of food made her exhibit severe negative behaviors. Over the course of 6 weeks in intensive therapy (2–3 visits weekly for 45–60 min sessions), the girl learned to make positive associations with food, not see it as threatening and could begin to respond to her own cues of hunger and pleasure with food. Parents were intimately a part of therapy, participating in the program at therapy and then repeating the episodes with food at home to generalize skills for the girl across setting. She is an example of an extreme case of aversion to eating, but the walls or barriers were very apparent. Any food

which fell outside of her repertoire of "safe" foods was considered threatening and triggered such an extremely inappropriate response that set her back for progressing with eating. When she began to learn that all foods were safe, she could begin to explore them in different ways, the walls came down, and the eating increased over time. After 3–4 months of continuing the treatment program at home with family, the girl was able to get the g-tube removed and continues to eat a typical adolescent diet with no limitations or restrictions.

A preferred method for infants involves a natural learning technique in which the therapist facilitates learning through the typical environmental stimuli from the caregivers and expected development. Reinforcement is provided to the child along with the cues and opportunities which will elicit the reflexive responses expected from their developmental age. For example, the rooting reflex in a 3-month-old infant can be a helpful response to incorporate into therapy as a way to increase sucking behavior after prolonged intubation in a 3-month-old male infant. Therapy can build off this reflex to set in motion providing positive oral experiences. As an infant, their long-term memory is not established, and new experience can become their new history. In contrast, an 8-month-old female infant with prolonged intubation needs a different strategy. The root reflex has been integrated, and sucking may not provide any interest to her. A different strategy is taken based upon what this child demonstrates in oral skills and defensive behaviors. Perhaps she will bring toys to her mouth and bite on them and explore them lingually, but she will not let others present anything to her face, refusing to accept touch or even kisses from her mother, let alone food in her mouth. Identifying the starting point of treatment helps the therapist lay out a "road map" of sorts for the parents to follow and bridge their understanding of what the child will need to reach the goal to eat.

Evaluation

The involvement of speech therapy begins when the major medical issues have been resolved following repair. The child is evaluated by the speech therapist and focuses on three primary areas of concern, involving oral motor skills, sensory integration skills, and physiological function. Findings from these three areas create the foundation for the child's therapy program. The evaluation may originate with any one of the three areas, often decided by how the child initially responds to the new therapist approaching. If the child cries, fusses, or turns away upon approach, these could signal fear which often indicates a lack of trust. Without trust in the caregivers, the child will always shut down, and therapy will fail. Trust building can start with providing positive interactions with the child, such as swaddling, rocking, or hand and foot massage. Success with these calming strategies can be passed onto parents and staff to provide additional positive interactions outside of therapy. The multiplicity of procedures and interventions to repair the child's anatomy come at a cost to their internal state regulation or sensory integration.

Most children are bombarded with repeated aversive stimulation for which they generate misaligned or inappropriate responses. Aversive stimulation can range from lying on the back in extension without boundaries and oral suctioning to feeding tubes and oxygen lines taped across the face, to IV lines and boards taped on the arm. These necessary actions occur at a critical period of learning for the child and result in misinterpreted signals and an inappropriate response. During assessment, the therapist is watching how the child is coping in their current environment. If doing poorly, the therapist needs to try some strategy to bring about improvement in the child's internal state control. Some strategies may include turning lights off, using quiet talking, and providing confinement or boundaries with swaddling, blanket rolls, or side lying. Changes in the child are noted by quiet breathing, increased sucking, less fussing, closing eyes, and overall less fidgeting. With these changes, the therapist may move to elicit nonnutritive sucking to create improved state regulation.

For example, a 3-month-old female has been held infrequently on a pillow throughout her hospitalization due to multiple lines, tubes, and cords attached to her body, and parents have

been scared to hold her since she always cries or screams when she is moved. Being held is normally a preferred activity that infants respond to with cooing, calming, and falling asleep. In this case, her response to the stimulation, even her interpretation of what's happening, is inappropriate. To help her learn new responses and improve her appraisal of what caregivers are providing, she needs positive nurturing interactions. These events will encourage trust building through the calming and comforting experiences. Swaddling is an ideal strategy to initiate with this infant during therapy. In addition, less crying eases the parents' apprehension with holding her and raises their comfort and confidence level with their child. As trust builds, the child reduces her resistance and engages in more activities. Internal self-regulation strategies are valuable to getting performance from the child. These strategies can be adjusted for the older child based upon developmental levels. Occupational therapists are a great resource for learning more about the techniques on sensory integration.

Achieving some state regulation is critical to progressing to the second important area, oral motor skills. Assessing oral motor skills examines the basic anatomy of the face, cheeks, lips, tongue, and palate along with complexity of muscle tone, range of movement patterns, timing of movements across the structures, respiratory coordination, and swallowing [13–15]. The therapist looks at the sensory sensitivity of the oral system and how reactions to stimuli affect the ability of the child to manage responses to stimulation. The therapist takes an inventory of the skills demonstrated to identify where the child falls in comparison to his or her age-based peers. Is the child latching and grooving her tongue to a gloved finger or pacifier? Can nonnutritive sucking be elicited and sustained? Can the child take tastes of water or formula from a pacifier or gloved finger? Can the child coordinate suck-swallow-breathe from a bottle? Is the child's breathing pattern prohibiting the child from swallowing? Is the child swallowing safely, showing overt signs of aspiration? These are standard questions in an oral motor assessment for all infants and children. Unfortunately, EA children often give more complicated answers which generate additional questions. Nonetheless, the answers to these questions direct the therapist in their treatment plan. Secondly, they provide a starting point for education to help the parents begin to learn meanings behind the cues from their child. Every child has a different starting point based upon their experiences, behavioral responses, and skills. Interpreting the meaning of these behaviors will provide insight into how we can help them overcome the negative associations, learning a new set of positive experiences with appropriate responses.

While assessing the oral motor skills, the therapist is watching the responses to the interactions. How does the child react with touch to her face and lips? Does she gag, wretch, and drop her saturation level? Is she swallowing her oral secretions effectively or is suctioning needed every 15–20 min by staff? Are the secretions passing through to the stomach? Does she allow massage on her hands or will she grasp and hold onto objects? Will she bring anything to her mouth independently? Is she hypersensitive in her gag with touch to her mouth or with anything that comes near it? Does the child use gagging behavior to escape oral activities? Does the child cry or turn away? Does the child block with their hands any movement toward the face? These types of responses are learned reactions to intrusions that have not been soothing, nurturing, or comforting and have ultimately led to negative associations. With toddlers, these behaviors can be more dramatic and more challenging to overcome.

The third area of importance is the physiological function of the GI system. How does any swallowed liquid or food move through the esophagus into the stomach? Is there any peristalsis seen on the UGI studies? Does the esophagus dilate greater superiorly to the anastomosis site causing blockage and retrograde movement of the bolus? The retrograde movement can present as reflux symptoms clinically and turn the child off from any oral intake. Function refers to the mouth-esophagus-stomach-intestine relationship. What are the signals or messages the child is receiving that would turn him or her off from eating or elicit refusal with easier tasks like tasting drops of water or formula while sucking on a pacifier or gloved finger,

swallowing secretions. If the body is saying, "don't take any drink, it will make me vomit" or "I'm not hungry, I don't want to drink," then what do these cues or signs look like to the caregiver so that they know when it's not OK to push. Does it mean that when the esophagus is narrowed, the bolus gets stuck at the anastomosis and reflux occurs? Knowing the function of the repaired anatomy gives us information about fluids moving through the tube.

Beneficial information can be obtained from repeated UGI studies showing the surgical site, any narrowing related to scarring, the esophageal function superior and inferior to the anastomosis site. Dilatation procedures occur regularly following connection of the esophagus as a means to reduce and prevent excessive scarring and stricturing of the esophagus. Each time the child has a dilatation, asking how significant the narrowing at the anastomosis may shed light on how the child is reacting to food or drink in therapy. It is therapeutically significant if the dilatation opens the esophageal anastomosis to 10–14 mm every 2 weeks and then is scarred down to an opening of 6–8 mm diameter 2 weeks later. The passage of fluids through the esophagus is greatly reduced and can explain why the child may start out willing to taste formula but then stop after 3–4 swallows, becoming irritable with arching and twisting and crying. The child may resort to nonnutritive sucking (NNS) with a pacifier and resting several minutes. NNS can promote esophageal peristalsis, making the child feel better and interested in trying tastes again. Strictures cause increased gagging with secretions, refusal with all oral tastes, reflux symptoms, and cause the child to shut down in therapy. The function of the anatomy provides more clues and explanations to understand what drives the child's responses. An "ah ha" moments in therapy arise when the child is seen days after dilatation and is more interested in taking tastes of milk without gagging, vomiting, or stopping after 3–4 swallows. Seeing these kinds of changes clinically and knowing the physiological function help the therapist correlate what's happening with the tastes after swallowing. Adjustments are made to the treatment plan accordingly and education continues with the parents about relation of the esophagus and eating.

Therapy

Much of the knowledge and expertise with helping children learn to eat stems from watching their cues, their behavioral responses to the presentations of food and drink [16, 17]. How they react to your requests and what signals their body is giving them arise from knowing the physiological process that is occurring when they swallow the food and the drink that enter the esophagus. Do they turn a certain way, to the right to trigger Sandifer's reflex or arch, or turn red faced and whine, all signs of reflux which we know every child will exhibit as a result of the anomaly of esophageal atresia.

In many ways, the evaluation is similar to a trial run for therapy, finding out what works and what does not work. Therapy sessions become a process of taking steps forward and sometimes back stepping when necessary. The forward steps increase positive experiences with oral activities which will foster the child's curiosity toward greater exploration, facilitate skill development, and synch up natural physiological cues with developmental feeding skills. To this end, the child learns to pursue drink and food from an internal motivation, hunger. Along the way, cognitive connections are made between hunger and food. The session begins with a mini reevaluation to see how the child is tolerating the current level treatment. The session progresses by challenging the child to try more tastes, or new volumes, or different foods without falling apart and resulting in negative responses. The child must direct the therapy through his or her reactions to new presentations. Pushing too hard and too fast will only cause to child to step backward and shut down.

Therapy sessions have another purpose: to teach parents how to create a positive environment around meal time and integrate new skills learned in therapy on a daily basis in the home setting, giving them practice with supervision to carry out sessions at home. The incorporation at home helps the child generalize the new skills and supports learning in more natural settings. At some point in therapy, the child begins to make connections for learning on their own, and the natural learning of skills will take over for the child allowing them to advance without therapy. A skilled therapist is

always asking the question of when is it time to wean treatment and let the child go it alone. Parents are capable of supporting and guiding the child to the next skill level because of their education, their understanding of the skill developmental, their ability to read cues, and their support and belief in the child to succeed.

As the child begins to increase their intake orally, the focus of therapy turns to reduction of g-tube dependence to promote increased hunger. Promoting hunger without sacrificing weight gain is a fine balance since each works against the other causing prolonged dependence on tube feedings. During this critical period of growth for the child, the primary concern is always the growth of the brain and body for overall development, even if it means delaying individual feeding skill development. The first 2 years of life is the window for brain growth and development in the child. Individual skills can still be learned after that time, but the brain is set. Many issues arise with tube feedings. Children will start out with continuous feedings which diminish any hunger and reduce their desire to feed. Progressing to bolus feedings helps put the child on a cycle of hunger and satiation, a typical pattern of infants and children. Bolus feeds are consolidated volumes given over reduced time allowing for periods of nonfeeding. The transition from continuous feeds to bolus feed can take weeks and is driven by the child's tolerance with faster feeds. Once bolus feeds have been achieved, withholding feedings may become a strategy to increase oral feedings, only when the child is doing well on the growth chart. If they are behind, as many EA children are, it will be necessary for the child to get adequate calories for growth and having involvement with a dietitian to monitor adjustments with feeds, formula selection, and growth tracking. These issues will persist beyond the point when therapy is finished and managed by the pediatrician until no longer a concern.

Conclusion

For every therapist working with EA children, there are two difficult questions that will be asked by parents and are nearly impossible to answer accurately. It's important that the therapist is ready to face them when they are raised in conversation. The first question is, will my child learn to eat? It is a crystal ball question with so many variable factoring into the equation. There are some indicators which help in answering, including diagnoses, syndromes associated with the EA, neurological involvement, and overall developmental progression of the child. The more contributions from these variables, the greater the challenge eating becomes. The second question is, how long will it take my child to learn to eat? From experience with numerous EA children repaired, parents are told to expect 6 months to a year after discharge from the hospital to be working on feeding issues and weaning from g-tube feedings. It helps prepare the parents for a long road to recovery yet gives them hope for their child. As discussed earlier in the chapter, feeding a child is the essence of nurturing the child, and when that function is missing, parents question their value as a parent. Restoring that precious value for parents is a bonus therapists receive with guiding the child on the path to eating.

The Airway: Nerves, Malacia and Life-Threatening Events

Apparent Life-Threatening Event (ALTE) in Infants with Esophageal Atresia

46

Francesco Cozzi and Denis A. Cozzi

Introduction

It is to Cameron Haight's credit that he was the first surgeon who successfully accomplished in 1943 a primary esophageal anastomosis in a baby born with an esophageal atresia and a distal tracheoesophageal fistula [2]. Less attention has been devoted to the description by Robert Mercer of the stormy postoperative course of this patient, who on the 12th postoperative day developed recurrent episodes of stridorous respiration coming on during or shortly after feeding. On the 47th postoperative day, one of these episodes was characterized by severe respiratory distress after feeding; the supervening cyanosis was followed by "a respiratory arrest during the expiratory phase." Resuscitation was successfully carried out [4].

Subsequently, many authors have used a variety of terms to describe a similar episode characterized by a respiratory arrest in infants with esophageal atresia (Table 46.1). In 1996, we proposed to call these episodes "apparent life-threatening event" (ALTE) [42]. This term was coined by the members of the National Institutes of Health Consensus Development Conference on Infantile Apnea and Home Monitoring to describe an episode that appears life threatening to the caregiver. These episodes can occur during sleep, wakefulness, or feeding. Gastroesophageal reflux is one of the identifiable conditions that can cause ALTE [11].

After Haight's report, survival rate following primary repair of esophageal atresia has progressively improved, so that today the mortality has been reduced to an insignificant proportion. Improved survival has resulted in an increasing awareness of short- and long-term postoperative complications. ALTE represents one of the most severe complications because in several patients it has progressed to sudden death [15, 21, 25, 26, 34, 37, 38].

We previously described the clinical and physiological manifestations of respiratory distress in infants with esophageal atresia. In this section, 65 years after its first description [18], we will focus attention to our knowledge on ALTE in infants with repaired esophageal atresia.

Pathophysiology

In 1945, Mercer concluded that the syndrome he described was due to an excessive activity of a vagal reflex causing "a laryngeal spasm and a cardiac and respiratory arrest in expiration." In his view the vagal reflex was initiated by stimulation of sensory endings of the pharynx because

Breath holding spell [15]
Apneas, malaises [25]
Apneic episodes life-threatening anoxic spells [26]
Respiratory arrest [29]
Dying spells [32]
Death attacks [33]
Near miss sudden death [35]
Near fatal events [39]
Apparent life-threatening event (ALTE) [42]

ALTE came on during or shortly after feeding. The possibility that the stridor was due to a congenital anomaly was ruled out because the larynx was normal at laryngoscopy. The possibility that the ALTE was due to anoxia was excluded because of the rapidity with which cardiac and respiratory arrest developed following the onset of laryngeal stridor. Therefore, laryngeal stridor and respiratory arrest in expiration were better explained on the basis of a neurogenic reflex [4].

In 1954, Allen et al. reported clinical observations suggesting that the syndrome of inspiratory laryngeal stridor associated with ALTE described by Mercer in an infant with esophageal atresia may occur also in infants with tracheal stenosis or in otherwise normal infants. In an infant without esophageal atresia, tracheal stenosis was documented by a tracheogram and by a bronchoscopy, which revealed a 50 % reduction of the size of distal tracheal lumen. Tracheal narrowing was considered to be due to a congenital weakness of the tracheal walls, more than to a compression of a left innominate artery arising from a dextroposed aortic arch. Actually, division of the left subclavian artery and suspension of the innominate artery were not followed by relief of symptoms. Allen et al. described also in infants with esophageal atresia an ALTE not associated with inspiratory stridor but observed after a blood transfusion, or after the passage of a string for future esophageal dilatations, or after the introduction of a bronchoscope, or after regurgitation. The conclusion was that in infants with or without esophageal atresia, ALTE with or without inspiratory stridor was due to an overactive vagal reflex [20].

In 1963, Fearon and Shortreed noticed that the clinical manifestations of respiratory distress associated with ALTE of some infants with esophageal atresia were not different from those of some infants with a tracheal compression by various congenital vascular anomalies. They speculated that the respiratory problems were due not only to a neurogenic mechanism but also to tracheal compression between a dilated esophagus posteriorly and an anomalous mediastinal vessel anteriorly. They pointed out that the stridor may be biphasic, that is, both inspiratory and expiratory. The intrathoracic tracheal compression was considered responsible for the airway obstruction in expiration, whereas inspiratory stridor was attributed to an associated laryngomalacia [16].

Actually, patients with a variable obstruction of the thoracic trachea have a greater difficulty in breathing out than in breathing in, because the negative intrathoracic pressure during inspiration tends to enlarge the tracheal lumen, whereas during expiration the positive intrathoracic pressure tends to increase the obstruction. Conversely, patients with a variable obstruction of the upper airway have a greater difficulty in inspiration than in expiration because during the inspiration the atmospheric pressure around the cervical airway exceeds the intratracheal pressure that becomes negative below the obstruction and tends to aspirate the tongue, which may obstruct the pharyngeal and laryngeal airways [3, 22].

Fearon and Shortreed described also what they called "reflex apnea," that is, an ALTE not associated with respiratory distress but initiated by a bulky bolus of food in the esophagus or accumulation of secretions in the tracheobronchial tree. In some patients, the "reflex apnea" was initiated by stimulation of the area of tracheal compression during tracheobronchoscopy. Reflex apnea was considered an indication for surgical relief of tracheal compression to interrupt some reflex arch [16].

During the 1970s, attention was drawn to the concept that in infants with repaired esophageal

atresia, tracheomalacia, that is, a weak tracheal wall, may be a major factor responsible for the collapse of the thoracic trachea [25–28]. The temporal correlation with feeding was explained by considering that the dilated upper esophagus, filled during swallowing or after a gastroesophageal reflux, increases the compression of the malacic trachea against the anomalous vessel anteriorly [27, 32]. A further step in the understanding of ALTE pathogenesis in infants with esophageal atresia was the finding that transcutaneous monitoring of PO2 during feeding in infants with a history of ALTE showed a significant hypoxemia [32]. This finding supported the previous concept that not a vagal reflex but severe hypoxemia due to tracheal obstruction can be responsible for ALTE [27]. In this view, tracheopexy serves to relieve the tracheal obstruction.

Southall et al. have studied the mechanism responsible of ALTE in a large series of infants with recurrent cyanotic attacks, including three infants with repaired esophageal atresia [12, 31, 34, 36]. All three infants with repaired esophageal atresia had recurrent episodes of ALTE without evidence of associated obstructed inspiratory effort. One patient previously underwent an aortopexy and a fundoplication; another underwent an aortopexy, and the last one underwent a tracheostomy for acute airway obstruction considered to be the cause of ALTE. In these three patients, surgery reduced or had no impact on the frequency and severity of ALTE without respiratory distress [34, 36]. In one of these patients, the first event detected before ALTE by the parents and hospital staff was an audible grunting, followed by the onset of cyanosis within 5–10 s. By 20 s the patient was deeply cyanosed and seemed unconscious [34]. As previously pointed out [4], Southall et al. concluded that the rapid onset of cyanosis cannot be explained by a simple upper airway obstruction. Actually in infants in whom an airway obstruction was imposed by maternal smothering, arterial hypoxemia sufficient to produce cerebral anoxia was delayed for 60–72 s [35]. In addition, an upper airway obstruction was not considered to be the cause of ALTE because ALTE continued despite nasotracheal intubation in one case or tracheostomy in another case [34, 36]. In their view, the rapid desaturation was due to a sudden right-to-left intrapulmonary shunt, "sudden atelectasis braking syndrome," brought about by an exaggerated expiratory effort, by "prolonged expiratory apnea," and/or by low lung volume brought about by abnormal surfactant [31]. Support for the concept of a right-to-left shunt is due to a sudden lung collapse that comes from the autopsy findings of an infant with esophageal atresia, who was found dead in the incubator on the third day after primary anastomosis: postmortem examination showed only the presence of widespread pulmonary atelectasis [17].

Vagal reflexes from lung mecanoreceptors play an important role in the organization of active expiration [9]. This is a breathing strategy adopted by infants with a low lung volume. An active interruption of expiratory flow by glottis adduction associated with a positive expiratory pressure (equivalent of Valsalva's maneuver) serves to maintain patency of alveoli by forcing gas retrogradely into the peripheral airway; grunting is the clinical manifestation of an active expiration. An abnormal response to this protective lung reflex may provide an explanation for the "prolonged expiratory apnea" and for the respiratory arrest in expiration [9]. Accordingly, Southall postulated that the surgical repair of esophageal atresia may damage the autonomic innervation of the lung with the result that abnormal lung reflexes may be responsible of the prolonged expiratory apnea. Iatrogenic damage of autonomic innervation of the lung may also interfere with an abnormal synthesis of lung surfactant which may result in a low lung volume [12]. The main criticism to this concept is that in infants with esophageal atresia, ALTE may occur even before the surgical repair [37]. In addition, ALTE is a manifestation of a more general dysautonomia affecting multiple vagal target sites [37, 48].

During the last 40 years, our group has contributed to the understanding of the pathogenesis of ALTE associated with respiratory distress [7, 14, 37, 41, 42, 44, 45, 48]. In 1977, the senior author speculated that in infants with esophageal atresia, the pathogenesis of ALTE may be similar

to that of life-threatening apnea in infants with choanal atresia, or Pierre Robin syndrome, or hypertrophied adenoids and sleep apnea [7]. In this view, the life-threatening apnea was sustained by an obstruction of the upper airway caused by a backward aspiration of the tongue. This functional obstruction of the pharynx was originally described by Pierre Robin in infants with micrognathia and called "glossoptosis" [1]. In Pierre Robin view, the backward displacement of the tongue was a mechanical consequence of a short mandible. Our physiological studies supported the concept that glossoptosis was the consequence of strong aspirating forces brought about by strong inspiratory efforts [7].

Subsequent clinical and physiological studies suggested that even mild inspiratory efforts, brought about by simple rhinitis if not counterbalanced by an appropriate reflex activity of upper airway dilating muscles, may cause an inspiratory collapse of the laryngeal and/or pharyngeal airways [14]. Therefore, in infants with different types of upper airway anatomical or inflammatory narrowing, the important pathogenetic factor for upper airway inspiratory collapse to occur appears to be a disorder of the autonomic control of the upper airway dilating muscles.

The concept of a developmental delay of autonomic control of respiration is supported by the findings of our studies on breathing patterns in some infants with esophageal atresia associated with ALTE and inspiratory dyspnea [37, 41]. The mild inspiratory load imposed by tilting the infant from the lateral to the supine position was not followed by an appropriate reflex activity of upper airway dilating muscles because it resulted in a sharp reduction of the inspiratory airflow despite a marked increase of inspiratory effort (Fig. 46.1). This obstructive hypopnea was accompanied by an audible inspiratory stridor [37].

Recurrent episodes of functional upper airway obstruction usually cause an alveolar hypoventilation characterized by hypoxemia and hypercapnia. However, infants with esophageal atresia [44], like those with choanal atresia or congenital micrognathia [14], often show a blood gas derangement characterized by hypoxema without hypercapnia. The most frequent chest films findings are the presence of some atelectatic areas of the lung associated with other hyperinflated areas of the lung [14, 44]. Normal perfusion of hypoventilated areas of the lung may explain the hypoxemia. The hyperventilation of some other areas of the lung may explain the normocapnia.

In our series of patients with esophageal atresia or choanal atresia, or congenital micrognathia, the requirement of oxygen concentration in the inspired air to maintain an oxygen blood concentration between 60 and 80 mmHg was often surprisingly high considered the limited extent of chest films

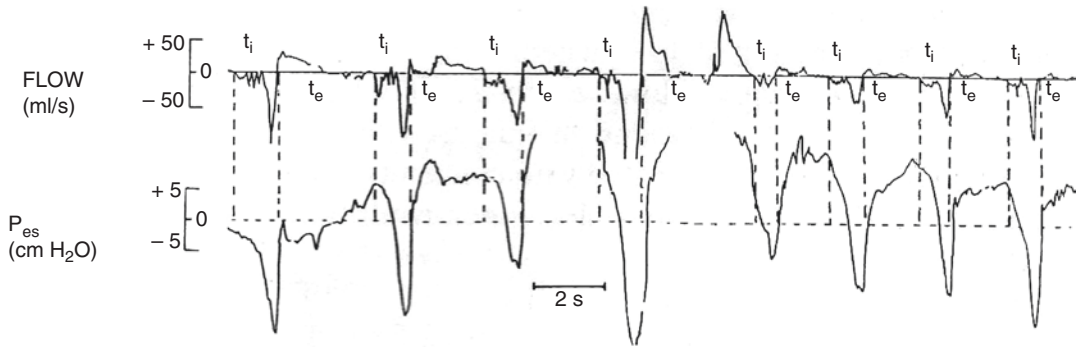

Fig. 46.1 Infant with esophageal atresia and distal tracheoesophageal fistula. The postural respiratory loading imposed by tilting the infant from the lateral to the supine position resulted in a retarded and reduced inspiratory flow despite increased inspiratory efforts (obstructive hypopnea). Note: the obstructive hypopnea is followed by prolongation of the expiratory time and interruption of the expiratory flow associated with positive expiratory pressure. Ti and Te: inspiratory and expiratory time, respectively

opacities. Consequently, patients breathing at high oxygen concentration in the inspired air develop a considerable alveolar-arterial oxygen difference (Fig. 46.2). The best explanation of these findings is that the upper airway functional obstruction associated with variable anatomical airway narrowing causes the development of a lower airway instability due to ventilation/perfusion inequalities and an intrapulmonary right-to-left shunt. Actually, oxygen, compared with other gases, is more rapidly absorbed from the alveolus. Therefore, alveolar hyperoxia due to an increased delivery of oxygen converts into atelectasis those segments of the lung with a low ventilation to perfusion ratio where the absorption exceeds the rate of delivery of oxygen [14, 44].

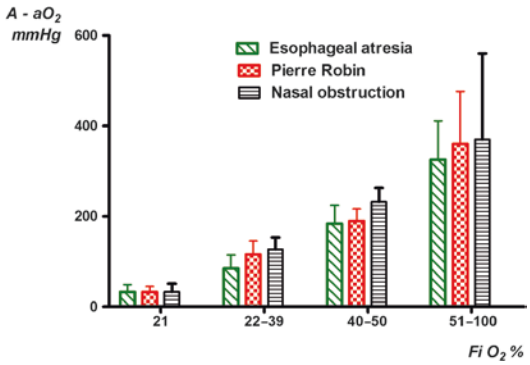

Fig. 46.2 In infants with different anatomical causes of upper airway obstruction, greater pressure of inspired oxygen (FiO2) results in large alveolar-arterial oxygen difference (A-aO2), suggesting intrapulmonary right-to-left shunt

Accordingly, in two infants with repaired esophageal atresia, who presented with recurrent ALTEs percutaneous arterial PO2 and PCO2 measurement while breathing 100 % oxygen administered in a plastic hood showed only moderate increase in PO2 and normal PCO2 (Fig. 46.3). The two infants showed no blood gas derangement and, on chest films, no lung opacities. These findings are consistent with the development of a considerable right-to-left shunt caused by absorption collapse of some hypoventilated areas of the lung. The breathing oxygen test returned to normal shortly after glossopexy, a surgical procedure which serves to stabilize the upper airways [42, 45]. These findings allow us to exclude the presence of an extra-pulmonary right-to-left shunt and suggest that the lower airway instability was sustained by recurrent episodes of obstruction in the upper airway [42].

In our series of infants with different types of upper airway anatomical narrowing, the correlation between upper and lower airway instabilities was also indicated by our studies of the breathing patterns, showing that obstructive apneas (Fig. 46.1) as well as central apnea (Fig. 46.4) were immediately followed by an active expiration, which is the breathing strategy adopted in presence of a lower airway instability due to a

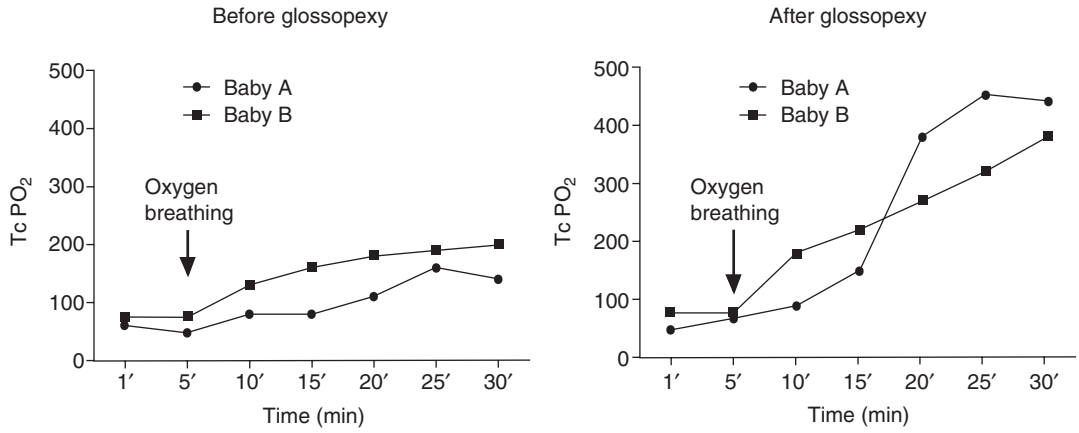

Fig. 46.3 Breathing oxygen test in two infants with repaired esophageal atresia. Note: development of a relevant right-to-left shunt (15–20 %) before glossopexy; normal breathing oxygen test shortly after glossopexy

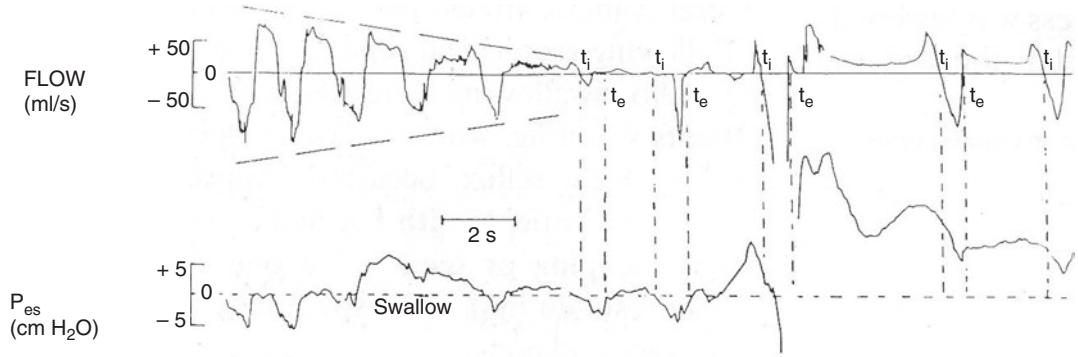

Fig. 46.4 Infant with esophageal atresia and distal tracheoesophageal fistula. Swallowing is associated with a parallel reduction of inspiratory flow and inspiratory efforts (central hypopnea). Note: central hypopnea is followed by grunting expiration. Ti and Te: inspiratory and expiratory time, respectively

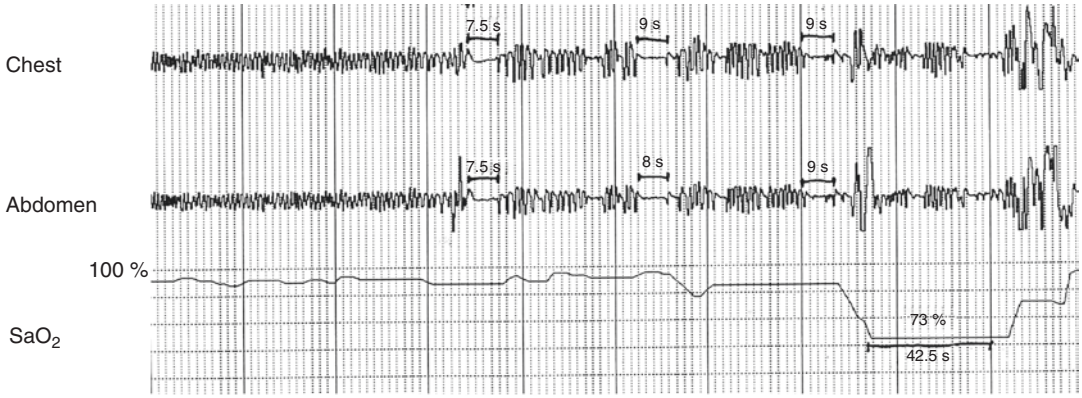

Fig. 46.5 Infant with esophageal atresia with feeding gastrostomy and continuous suction of the blind upper esophageal pouch. Accumulation of saliva in the upper pouch is followed by periodic breathing. Note: repetitive apneic pauses of similar short duration are followed by a sudden and severe desaturation suggesting a right-to-left shunt, due to developing microatelectasis

low lung volume [37, 45] (Fig. 46.1). These findings suggest that not only obstructive but also central apneas may be responsible of lower airway instability. Repetitive central apneas hypopneas may cause a progressive fall in lung volume resulting in a sudden and severe desaturation probably due to the development of alveolar collapse and right-to left shunt [48] (Fig. 46.5).

The respiratory status we found in infants with an inspiratory obstruction associated with various congenital anomalies of upper airways is quite similar to the respiratory status found in infants with inspiratory stridor caused by inflammatory upper airway obstruction. In infants with epiglottitis, radiologic and gas exchange abnormalities, similar to those we found in our series of patients with various upper airway congenital anomalies, were considered to be the consequence of an increase in lung water [8, 13, 24]. During phases of moderate inspiratory respiratory distress, interstitial flooding causes peribronchial edema, small airway closure, and military atelectasis [13, 24]. This segmental collapse of dependent zones of the lung is not detected on conventional chest films [10] and may be responsible for the modest ventilation/perfusion mismatch with hypoxemia. Arterial PCO2 may be normal because of compensatory hyperventilation of uninvolved pulmonary segments. This pathophysiological mechanism may

well explain the hypoxemia without hypercapnia and with clear chest films.

According to Costigan et al. [13], during phases of more severe inspiratory distress, a widespread alveolar flooding causes major atelectasis, which is visible on chest films. Accordingly, in our series of patients, lung opacities frequently cleared up on subsequent films, indicating lung collapse more than consolidation [14, 37, 44]. In addition, the "butterfly pattern" frequently found on chest films is consistent with the diagnosis of pulmonary edema [44]. Actually, postmortem examination of the child who died during a cyanotic episodes following food bolus impaction in the esophagus showed only pulmonary edema [34].

To investigate whether feeding, gastroesophageal reflux, tracheomalacia, and upper airway instability are independent or interrelated factors, we studied the clinical manifestations of patients with esophageal atresia treated with a cervical esophagostomy and/or a gastrostomy [48]. The presence of a gastrostomy and a blind lower esophageal stump rules out the putative pathogenetic role of gastroesophageal reflux as well as the role of feeding. The cervical esophagostomy rules out the putative pathogenetic role of tracheal stenosis. In our study, eight of nine patients with a feeding gastrostomy and with a continuous suction of the blind upper esophageal pouch presented with ALTEs either associated or not with signs of airways obstruction. Subsequently, for the presence of respiratory problems, five of the nine patients underwent an esophagostomy. In addition the other six patients underwent an esophagostomy as a primary procedure. Of the 11 patients with a cervical esophagostomy and a feeding gastrostomy, 5 presented signs of airways obstruction without ALTE and 6 ALTE without signs of airways obstruction. Trigger factors of respiratory distress and central and/or obstructive ALTE were upper respiratory tract infections, swallowing, crying, anesthesia, sedation, and sleeping. These findings strongly suggest that feeding, gastroesophageal reflux, and tracheomalacia may trigger ALTE but are not essential for ALTE to occur. In our opinion, the principal pathogenetic factor seems to be a development delay of the respiratory control. Feeding, gastroesophageal reflux, and tracheomalacia, like many other trigger factors, probably offer evidence of an underlying dysautonomic problem [48].

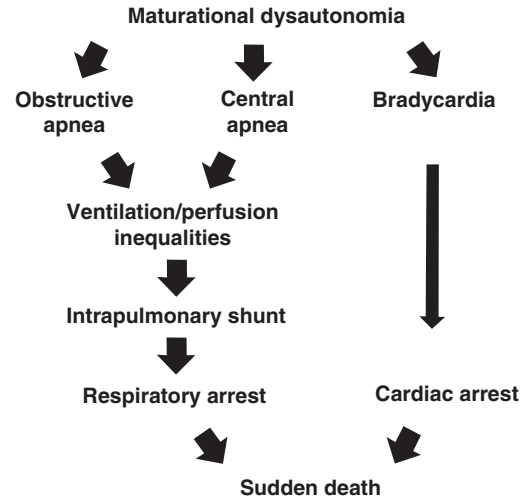

Fig. 46.6 Putative respiratory and cardiac pathways for apparent life-threatening event and sudden death in infants with esophageal atresia

In few reported cases, a different pathogenetic mechanism of ALTE has been documented, that is, a primary reflex bradycardia followed by cardiac arrest [21, 23, 30, 37]. The vagus nerve has a depressant action on the sinus pacemaker; hypersensitivity of this inhibition reflex may cause a cardiac arrest; the consequent circulatory failure causes cerebral anoxia which may progress to ALTE and even to sudden death [21]. Probably, the condition of cardiac arrest due to an overactive vagal reflex is largely overlooked [23, 30]. Actually, the diagnosis can be made with certainty only in infants on continuous cardiac activity monitoring.

On the basis of available evidence, we suggest that in infants with EA, the pathogenesis of ALTE and sudden death may be considered as a cascade reaction (Fig. 46.6). Babies born with esophageal atresia may present a development delay of the regulation of respiratory and cardiac functions. The dysfunction of respiratory control causes obstructive and/or central apneas/hypopneas that in turn cause ventilation/perfusion inequalities, intrapulmonary shunt, severe hypoxemia, and

eventually a respiratory arrest. The dysfunction of cardiac rhythm may cause bradycardia and eventually cardiac arrest. Both respiratory and cardiac arrests may progress to sudden death.

Clinical Manifestations

In infants with esophageal atresia, the prevalence of ALTE is difficult to determine because the differences between respiratory distress and ALTE or between cyanotic attacks and ALTE are most often not specified. In addition the prevalence of ALTE not treated by surgery is usually not reported, and the choice to treat ALTE surgically is subjective. In a series of 148 patients with esophageal atresia treated at The Hospital for Sick Children, Great Ormond Street, London [33], 21 infants developed "significant gastroesophageal reflux sufficient to cause life-threatening episodes" (18 %), and 19 infants presented "tracheomalacia severe enough to cause serious respiratory embarrassment" (16 %). In our own series of cases with esophageal atresia, we found a prevalence of 30 %, life-threatening episodes requiring resuscitation, including ALTEs that resolved spontaneously [37]. Similarly, in a series of 371 patients treated at the Pediatric Surgical Center of Amsterdam [46], 87 patients presented recurrent respiratory problems (32 %). These data, taken together, suggest that in infants with esophageal atresia, ALTE is a frequent complication.

Three different clinical forms of ALTE have been described. The most frequent reported clinical form, originally described by Mercer, is characterized by recurrent episodes of upper airway obstruction which precede ALTE. We described in the chapter on choanal atresia the clinical manifestations of the respiratory distress. Often the inspiratory dyspnea is associated with signs of expiratory dyspnea, which may simulate an asthmatic attack [41]. Characteristically, ALTE is observed after the first few months of life. The reason for this late presentation is considered obscure [32]. Probably, these clinical findings support the concept that recurrent episodes of upper airway obstruction causes a pulmonary status which subsequently predispose to ALTE [44].

The other clinical form of ALTE is characterized by a respiratory arrest not associated with signs of inspiratory efforts (central apnea). This form was originally described by Allen et al. [20]. Subsequently, Fearon and Shortreed called "reflex apnea" an ALTE induced under light general anesthesia when a bronchoscope was passed through the compressed area of the trachea [16]. In an infant with repaired esophageal atresia, this form of ALTE has been reproduced by inflating a latex balloon within the upper third of the esophagus [36]. In an infant with long-gap esophageal atresia, before the continuity of alimentary tract was established, we observed that the accumulation of saliva in the upper pouch caused periodic breathing associated with significant desaturation (Fig. 46.5) [48]. ALTE induced by a bolus of food impacted within the upper esophagus may progress to sudden death [34, 37].

ALTE without inspiratory efforts most often occurs after crying rather than swallowing [37]. In our experience, this form of ALTE is most often triggered by upper respiratory tract infections; other favoring factors are sleeping, sedatives, and anesthesia [48]. Also this form of ALTE has a late presentation and is preceded by recurrent episodes of apnea without inspiratory efforts [37, 48]. Central apnea, especially if occurs during sleep, may easily be overlooked even if associated with desaturation.

The third clinical form is characterized by an ALTE sustained by a reflex bradycardic arrest. In 1959, Bauer et al. described in an infant, who had a thoracic transposition of the stomach to bridge the gap of an esophageal atresia without tracheoesophageal atresia, an episode of bradycardia with sinoatrial block and appearance of a slow AV rhythm. This infant died in the 34th postoperative day during one of these cyanotic episodes. At autopsy, the vagus nerve was found to be compressed in the upper chest by a dilated stomach. It was thought that the severe bradycardia was brought about by stimulation of vagus nerve due to gastric distension [21].

Very few cases with this form of ALTE have since been described [23, 30, 37]. These patients

may become symptomatic at "different stages of development" but usually are diagnosed during first admission for a direct stimulation of the thoracic vagus nerve [21, 30, 37]. However, an ominous fetal bradycardia may be detected during the last weeks of gestation or during delivery, requiring an emergency caesarean section [37]. One patient with repaired esophageal atresia presented a reflex bradycardic ALTE at the age of 2 years, when she was eating some solid food [23]. One of our patients presented a reversible bradycardic cardiac arrest probably sustained by a mechanical manipulation of the nerve vagus during primary esophageal repair. Subsequently, this patient presented two new cardiac arrests requiring a cardiac message during esophageal dilatation under general anesthesia given through a tracheal tube [37]. Another of our patients with esophageal atresia had a bradycardic arrest during esophageal dilatation under general anesthesia. In addition, this patient at the age of 4 years presented an episode of ALTE triggered by a mild frightening injury [48].

In infants with esophageal atresia, ALTEs are very often associated with other dysautonomic features including oropharyngeal dysphagia, regurgitation, vomiting, hyperhidrosis, hyperthermia, and bradycardia [37, 48]. In addition, nearly all patients present the characteristic seal-like bark cough due to the associated tracheomalacia. Main complications of infants with glossoptosis syndrome include failure to thrive, cor pulmonale, and asphyxic brain damage [14].

Evaluation and Surgical Management of Underlying Disorders

In infants with esophageal atresia, the underlying disorders currently considered to be surgically correctable causes of ALTE include gastroesophageal reflux, tracheal compression/tracheomalacia, and upper airway instability.

Gastroesophageal reflux is usually diagnosed with radiological investigations and esophageal pH probe monitoring. In infants with repaired esophageal atresia, the occurrence of gastroesophageal reflux is rather frequent. In a series of 120 patients, routine pH measurement showed gastroesophageal reflux in 53 patients (41 %); failure of medical therapy was the indication for surgical antireflux procedure in 41 (77 %) patients [46]. The other characteristic of gastroesophageal reflux in infants with repaired esophageal atresia is that only half of the patients improved after fundoplication mainly for the presence of respiratory symptoms, or emesis, or failure to thrive [40, 43]. There are a few reports regarding specifically the results of surgical treatment of gastroesophageal reflux to prevent recurrent ALTE; available data suggest that fundoplication appears to be an effective method for preventing recurrent ALTE [28, 29].

Tracheomalacia can be diagnosed on clinical grounds from the presence of the typical brassy cough. However, the severity of tracheomalacia must be assessed by means of a bronchoscopy in a patient breathing spontaneously. The well-accepted treatment of tracheomalacia is aortopexy [19, 26, 27]. Splinting of the trachea may be an alternative but does not reverse ALTE. In infants with esophageal atresia, the results of tracheopexy for ALTE are usually considered good [38, 39, 46]; however, in a minority of cases, ALTE may persist after aortopexy [36, 38, 47].

If gastroesophageal reflux and tracheomalacia coexist, the decision to proceed with tracheopexy or fundoplication is usually based on the impression of each surgeon. Before taking the decision, it is of paramount importance to exclude the presence of a concomitant recurrent tracheoesophageal fistula. To evaluate the results obtained when tracheomalacia and gastroesophageal reflux coexist, Nasr et al. reviewed the experience at the Hospital for Sick Children of Toronto. Of 288 patients with esophageal atresia, 22 developed a severe respiratory distress which was related to tracheomalacia or gastroesophageal reflux. Severe respiratory distress included pneumonia (two cases), blue spells (ten cases), and ALTE (ten cases). Thirteen infants had an aortopexy or a tracheal splint. Of these, seven patients (including three with ALTE) improved, and six (46 %) required subsequent fundoplication for ongoing respiratory problems. Nine infants had an initial

fundoplication. Of these, six patients (including two with ALTE) improved, and three required an aortopexy or a tracheal splint for ongoing respiratory problems. Overall, nine patients (including five patients with ALTE) improved only after the second procedure [47].

The diagnosis of upper airway instability may be made on a clinical ground. The presence of inspiratory efforts with poor or absent air entry, usually associated with a clear chest X-ray, is a clinical manifestation of partial or total upper airway obstruction (obstructive apnea or hypopnea). On examination, glossoptosis and inspiratory retractions of the soft part of the neck (especially suprasternal notch) are usually observed. The inspiratory efforts are very often associated with inspiratory stridor or noisy inspiration. The additional clinical signs of functional inspiratory obstruction include open-mouth breathing and head extension (opisthotonus). The severe phases of inspiratory dyspnea are associated with signs of expiratory obstruction including grunting/wheezing and ballooning on expiration of cheeks and soft part of the neck. In infants with esophageal atresia, the expiratory dyspnea is conventionally attributed to tracheomalacia. However, an active expiration, that is, adduction of the vocal cords associated with a positive expiratory pressure, may contribute to the clinical manifestations of a functional expiratory obstruction (equivalent of Valsalva's maneuver). The sign of an active expiration is prolonged expiration associated with grunting. Grunting may simulate a wheezing but may be easily differentiated because grunting is loudest over the neck, whereas wheezing is loudest over the thorax. In infants with ALTE, grunting should be considered a clinical manifestation of lower airway instability until otherwise proved. In some infants with esophageal atresia, the recurrent episode diagnosed as "bronchiolitis" or as "asthmatic attacks" [28] may be sustained by a not recognized active expiration [42].

To document the frequency and the severity of central and obstructive apneas especially during sleep, polysomnography can be a useful investigation. The site of functional upper airway obstruction can be documented with the use of cineradiography. Endoscopic examination of the upper airway during spontaneous breathing may document the diagnosis of pharyngomalacia (glossoptotic pharyngeal obstruction) or laryngomalacia. As the presence of a lower airway instability in our opinion should prompt a treatment of the associated upper airway instability, we have found useful to document the presence of areas of ventilation/perfusion inequalities with the aid of 100 % O_2 breathing test. Having the patient to breathe oxygen for up 20–30 min, a sample of arterial blood is obtained for PaO_2 and hemoglobin concentration determinations. The ratio of right-to-left shunt flow to total systemic blood flow may be calculated.

The presence of an elevated right-to-left shunt allows one to identify those patients who are susceptible to ALTE for the development of lung collapse (Fig. 46.3).

In infants with Pierre Robin syndrome, ALTEs have been successfully treated by lip-tongue adhesions (glossopexy) [5, 6]. Similar good results have been obtained by glossopexy in infants with esophageal atresia and ALTE [42, 45]. These good results, as those reported after fundoplication or after aortopexy, may be only temporary and not casually related with surgery, because ALTEs tend to disappear spontaneously. However, the rapid improvement of clinical manifestations related to upper and lower airway instabilities and the rapid improvement of blood gas derangements (Fig. 46.3) strongly suggest that glossopexy stabilizes the upper and lower airways. For those infants who do not solve the problem of ALTE with a glossopexy, mandibular distraction may avoid glossoptotic pharyngeal obstruction. If necessary, tracheostomy will prevent episodes of recurrent upper airway obstruction. As in infancy, tracheostomy has a relevant morbidity, a less invasive alternative can be aortopexy or fundoplication performed with the rationale to avoid the additional respiratory load imposed by tracheomalacia or by gastroesophageal reflux [48].

Acknowledgments We wish to thank Dr. S. Frediani for his help and comments in the preparation of this chapter.

New Insights and Applications in the Treatment of Nerve Injuries

47

Alison K. Snyder-Warwick, Andrew Yee, and Susan E. Mackinnon

Introduction

Peripheral nerve injuries can have devastating functional consequences. Particularly in the pediatric population, nerve injuries may have negative implications on growth, mobility, and quality of life. While prevention is the most effective treatment for injury, nerve pathology pervades all age groups and all subspecialties. Peripheral nerve disorders may result from mechanical, infectious, iatrogenic, immunologic, oncologic, and traumatic etiologies. Cosmesis has psychosocial importance, but restoration of function is paramount in planning nerve reconstructions. Historically, treatment of peripheral nerve injuries had limited application and suboptimal results. While the advancement of microsurgical technique as well as our understanding of nerve injury and regeneration has led to improved technical ability to repair nerve pathology, the slow rate of neuroregeneration has limited the results of treatment of proximal nerve injury. The last decades of work have helped shape the novel concept of treating proximal peripheral nerve injuries with a distal reconstruction via nerve transfers. This chapter reviews special considerations specific to nerve injury in the pediatric population, the mechanisms of neuroregeneration, obstacles in muscular reinnervation after injury, and modern approaches to the treatment of peripheral nerve injuries in children.

Nerve Injuries in Children

Pediatric patients possess extraordinary healing potential. Peripheral nerve surgeons have long held the belief that identical peripheral nerve injuries have much better prognosis in children compared to adults [34], and scientific data are now available to support this clinical observation. After crush injury, immature rats demonstrate less functional impairment at 2 weeks when compared to identically treated adults [4]. Immature nerves regenerate faster [62], with some reports describing rates of up to five times the rate of adult peripheral nerve regeneration [76]. Neonatal experimental models have also demonstrated greater maintenance of somatotopy and improved target specificity of neuroregeneration compared to adults [1]. In addition, the distances required for nerves to regenerate in order to achieve target reinnervation are smaller compared to those in adults. All of these factors result in reduced time to reinnervation, and the importance of this timing will be discussed in relation to the muscular motor end plates in a later section. Rapid reinnervation of target

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_47

muscle results in improved functional outcomes. Children also demonstrate greater cortical and neuronal plasticity [47, 90] and are therefore better able to adapt not only to altered patterns of peripheral innervation but also retraining that may be required as a result of reconstructive techniques.

Despite these advantages, treatment of peripheral nerve injuries in children also presents challenges. The physical examination and diagnosis of nerve injuries in children can be difficult if the patient is young and unable to follow commands. Examination is based largely on observation of posture and abdominal and thoracic symmetry with breathing (in the case of the phrenic nerve) [11, 94], spontaneous activity, and reward-based prompting for the child to reach for objects, both with and without the assistance of gravity. Depending on the diagnosis, nerve injury may also be quite painful, and care should be taken to control pain and minimize undue stress as much as possible. Patients should be examined in a comfortable setting, such as a parent's lap or while playing. Pain control should not be ignored. Because of communication barriers due to developmental stage, the treating physician should maintain a high index of suspicion for injury and discomfort. In addition, rehabilitation presents additional challenges for the child that cannot yet follow instructions. Therapy can be based on motivators, such as visually stimulating toys, and is a team endeavor involving the physician, therapist, and caregiver.

Peripheral Nerve Fiber and Fascicular Anatomy

Knowledge of normal peripheral nerve anatomy and physiology is an imperative prerequisite to managing peripheral nerve injuries. Peripheral nerves are comprised of mature axons that are encapsulated by Schwann cells and are either myelinated or unmyelinated (Fig. 47.1). Unmyelinated fibers are composed of several axons, surrounded by a Schwann cell and its dual layer basement membrane. The axons of myelinated nerve fibers are also surrounded by a Schwann cell, which instead forms a multi-laminated myelin sheath. Individual myelinated nerve fibers and groups

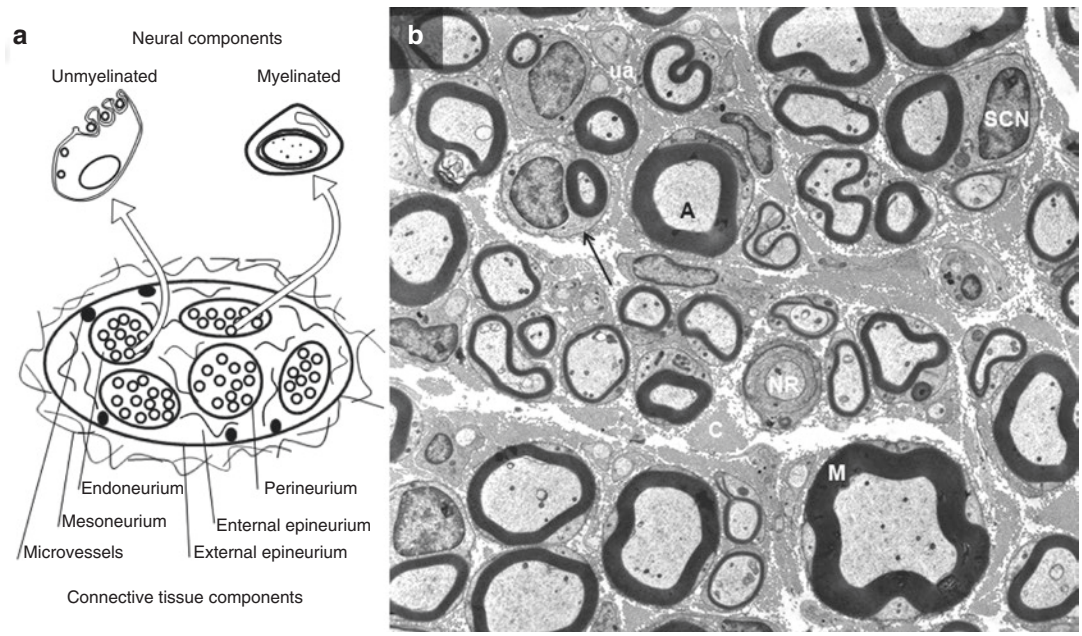

Fig. 47.1 Normal peripheral nerve morphology. (**a**) The peripheral nerve is composed of neural and connective tissue components. The nerve fiber is either unmyelinated or myelinated. (**b**) An electron microscopy image of a population of myelinated and unmyelinated nerve fibers. *M* myelin, *A* axon, *SCN* Schwann cell nucleus, *arrow* double basement membrane, *C* endoneurial collagen, *ua* unmyelinated axon, *NR* node of Ranvier (Uranyl acetate, 4750× magnification)

of unmyelinated fibers are surrounded by a Schwann cell-derived double membrane of basal lamella.

Surrounding the individual myelinated nerve fibers and groups of unmyelinated nerve fibers are thin collagen fibers known as the endoneurium. These myelinated and unmyelinated nerve fibers collect together to form a fascicle, and fascicles are bound by a discrete connective tissue sheath called perineurium. The connective tissue that surrounds the individual fascicles is termed the internal (intrafascicular) epineurium, while the connective tissue that surrounds the entire nerve is termed the external (extrafascicular) epineurium. A loose areolar tissue that surrounds the nerve and extends from the epineurium to the surrounding tissue is known as the mesoneurium. The mesoneurium is continuous with the perineurium and is critical in longitudinal gliding of the nerve.

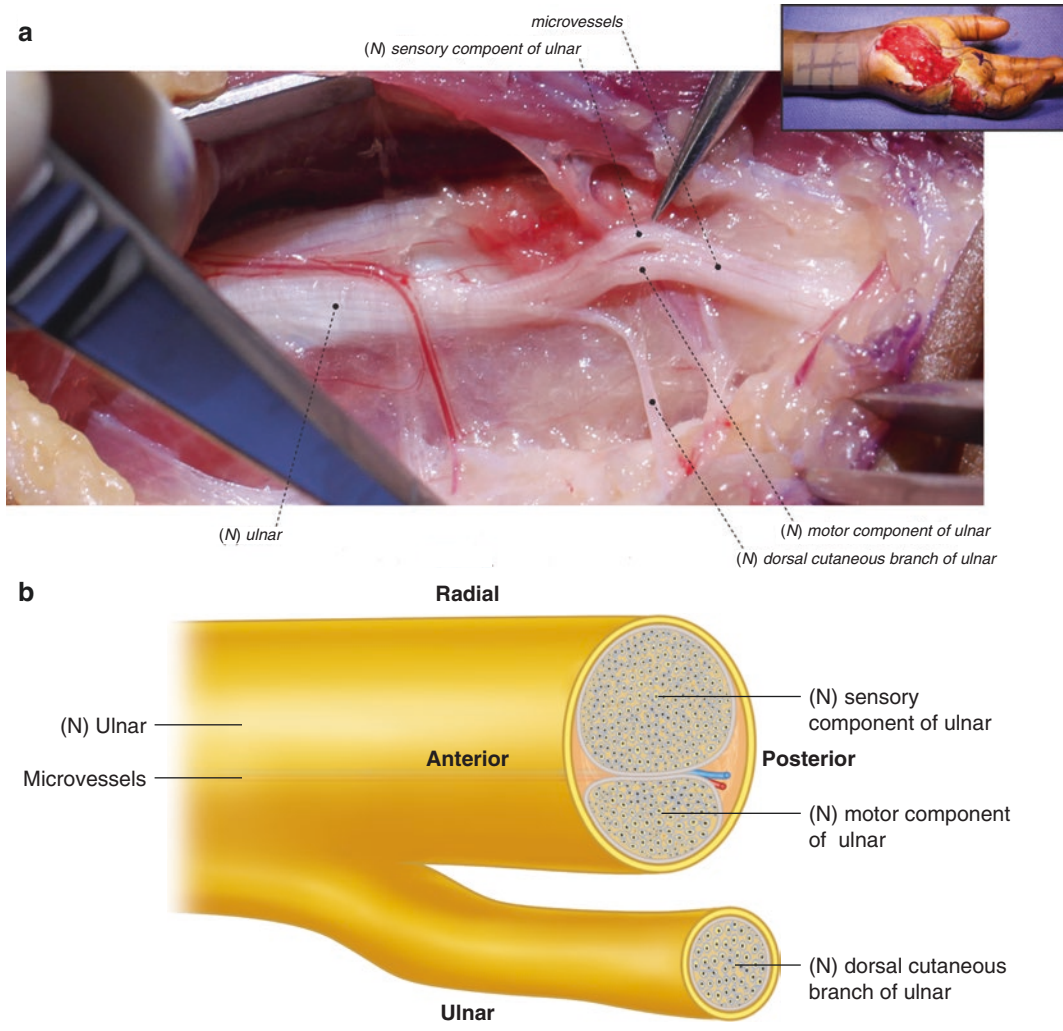

Fig. 47.2 Internal topography of the ulnar nerve in the forearm (**a**). Knowledge of internal topography of peripheral nerves is critical for nerve repair to optimize the specificity of modality- and function-matched reinnervation. As an example (**b**), the ulnar nerve in the forearm has three components. The sensory component is found on the radial half of the ulnar nerve. The motor component is found adjacent and ulnar to the sensory component. This component becomes the deep motor branch distally. The dorsal cutaneous branch is found ulnar to the motor component and branches distally to innervate the ulnar dorsal cutaneous aspect of the hand. *N* nerve

There are three basic types of fascicular nerve patterns: monofascicular with just one large fascicle, oligofascicular consisting of a few fascicles, and polyfascicular consisting of many fascicles of varying sizes. In relation to the extremities, monofascicular patterns are found in the proximal extremity with each fascicle consisting of a mixture of motor and sensory fibers. There is considerable plexus formation among fascicles in the proximal extremity. This pattern decreases as the nerve travels distally becoming polyfascicular in the distal extremity and further differentiates into motor and sensory components [39, 95].

Knowledge of the internal topography of peripheral nerves directs the proper alignment of fascicles during nerve repair to optimize the specificity of modality- and function-matched reinnervation (Fig. 47.2). Mismatched modality and/or function in nerve repairs dramatically downgrades the outcome following nerve reconstruction. This topographical knowledge has resulted predominantly from intraoperative electrical stimulation of nerves to identify specific motor and sensory components [14]. Electrical stimulation has been a viable tool not only in identifying and confirming the internal topography of a nerve but also to confirm function or loss of function after nerve injury.

Mechanism of Neurodegeneration and Neuroregeneration

The neuronal response to injury depends on a number of factors which include mechanism of injury, patient age, and the injury proximity to the cell body. The mechanism that regulates the cell body response, axonal projection, and terminal synaptogenesis of a single neuron after injury is thought to be regulated locally. As a result, compromise to a proximal compartment may not spell demise to the distal compartment. This "compartmental view of neurodegeneration," as termed by Gillingwater and Ribchester [24], is used to describe the multilevel response to peripheral nerve injury. The most devastating level of injury to a motor neuron is proximally either by avulsion, direct lesion, or other injuries [46, 48], which results in the death of the individual neuron. Proximal neuronal injury is devastating in neonates with demise of up to 60–70 % of involved motor neurons reported in the murine model [3, 55, 86, 87]. Currently, the reconstruction of choice for proximal nerve injuries is distal nerve transfer.

Wallerian degeneration is a process that occurs at the distal segment of an injured nerve fiber. This process is described as Schwann cells, fibroblasts, myocytes, and injured axons expressing a host of neurotrophic factors in response to injury as the degrading neural elements are phagocytosed [2, 24, 25, 28, 35, 36, 53, 75, 79]. Proximal axonal injuries and avulsions lead to injury-induced cell death with loss of the cell body and its projections. The cell body is maintained following a distal axonal injury with preservation of its regenerative potential [17]. The distal axonal segment to the injury undergoes Wallerian degeneration. In situations of prolonged denervation of 6 months or later, Schwann cells in the distal nerve segment provide less trophic support and may even undergo apoptosis [73]. This may explain impaired nerve regeneration following delayed nerve injury repair.

Recovery following peripheral nerve injury is influenced by the relative distance of the injury to the cell body and is characterized by the specific changes both proximal and distal to the site of injury [22]. Following injury, the proximal axons retract a variable distance and undergo a brief dormant phase, during which molecular signaling cascades are initiated and neurotrophic factors are shuttled, before the formation of a regenerating unit [26]. The regenerating unit elongates with a single parent axon and sprouts multiple daughter axons, having an appearance of a hydra [20]. In myelinated nerve fibers, axons sprout from the gap between myelin sheaths, also known as nodes of Ranvier, and progress to their motor or sensory targets. Nerve fibers regenerate at a rate of ~1 mm daily or ~1 in. per month. Schwann cells have a pro-regenerative phenotype that is critical in remyelinating and guiding axons to their appropriate targets along residual endoneurial tubes known as bands of Bungner [29, 33, 40, 41, 51, 54, 80]. Once an axon projecting from

the regenerating unit attaches to its target and forms a functional synapse, the remaining daughter axons are "pruned back," creating a one-to-one relationship between the neuron and end organ.

Classification of Nerve Injury

Classification of peripheral nerve injuries and knowledge of the degree of nerve injury are critical both for prognosis and surgical planning when determining potential for nerve reconstruction [71]. The three categories of nerve injury (neurapraxia, axonotmesis, and neurotmesis) were first described by Seddon in 1943 and were later expanded in 1951 by Sunderland using five degrees of nerve injury [31, 72]. Mackinnon popularized the sixth degree of injury to describe mixed-degree injuries, which encompass two or more injury patterns at the same level of disruption (Fig. 47.3) (Tables 47.1 and 47.2).

Neurapraxic (first-degree) injury is an ischemic injury which may have segmental demyelination, but no interruption of the continuity of

Table 47.1 Historical classification of nerve injuries

Seddon	Sunderland (degree)	Mackinnon
Neurapraxia	I	VI degree
Axonotmesis	II	Mixed injury pattern
	III	
Neurotmesis	IV	
	V	

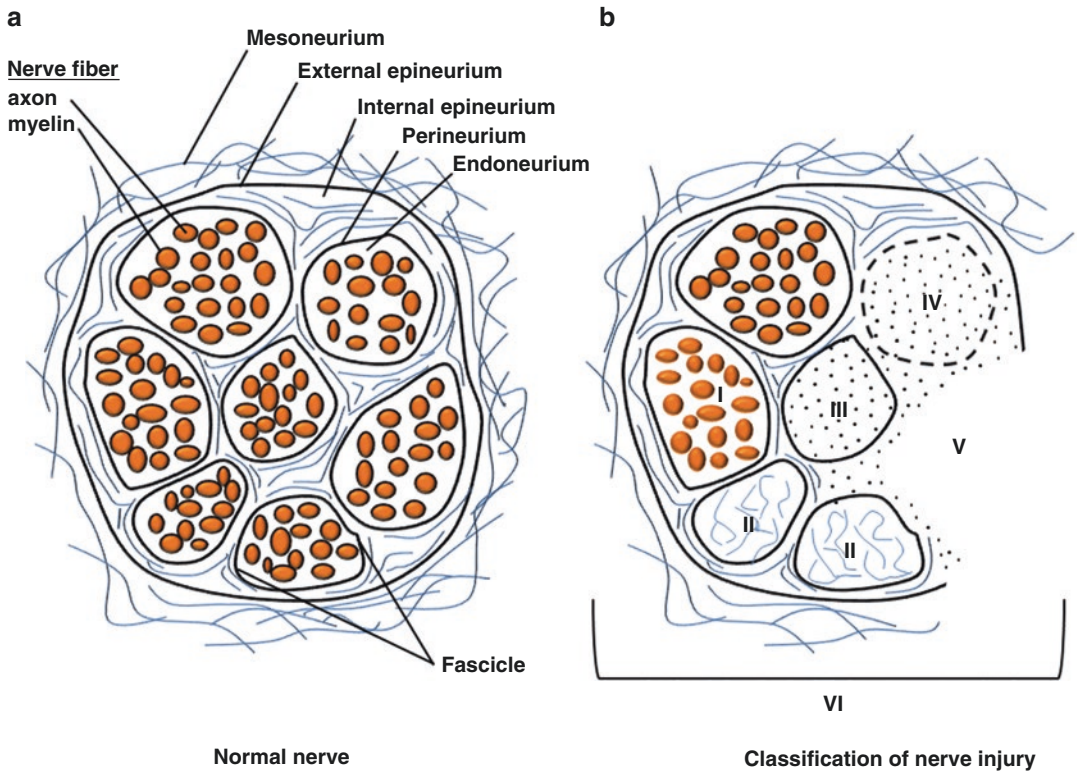

Fig. 47.3 Degrees of nerve injury. (**a**) Cross-sectional diagram of a normal nerve and its neural and connective tissue components. (**b**) Classification of nerve injury in a cross-sectional diagram. Normal nerve fascicle is found in the top left. First-degree (*I*) injury is neurapraxia with segmental demyelination. Second-degree (*II*) injury is axonotmesis that involves the axon and myelin. Third-degree (*III*) injury is injury to the axon, myelin, and endoneurium. Fourth-degree (*IV*) injury is neurotmesis with an injury to the axon, myelin, endoneurium, and perineurium. Fifth-degree (*V*) injury is a nerve that is not in continuity and is transected. Various normal and injury patterns within the nerve are considered sixth-degree (*VI*) injury

Table 47.2 Classification and management of nerve injuries

Degree of injury		Histological changes					Tinel's sign		Recovery	Rate of recovery	Surgical management
		Myelin	Axons	Endo-N	Peri-N	Epi-N	Present	Advancement			
I	Neurapraxia	+/–					–	–	Complete	Up to 12 weeks	–
II	Axonotmesis	+	+				+	+	Complete	1″ per month	–
III		+	+	+			+	+	Varies[a]	1″ per month	+/–
IV	Neuroma in continuity	+	+	+	+		+	–	None	None	+
V	Neurotmesis	+	+	+	+	+	+	–	None	None	+
VI	Mixed injury (I–V)	Various fibers and fascicles demonstrate various pathological changes					+	+/–	Some fascicles (II, III)	Depends on injury (I–V)	+

N neurium (e.g., *Endo-N* endoneurium)

[a]Recovery can vary from excellent to poor depending on the amount of scarring and the motor versus sensory axon misdirection to target receptors

axonal or connective tissue. A localized conduction block is present in this injury. Since the axons are not injured, recovery can be expected in up to 12 weeks with remyelination of axons. Tourniquet palsies are typically acute conduction blocks and recover within 12 weeks. In chronic nerve compression or radiation neuritis, a permanent conduction block may exist.

Axonotmetic (second-degree) injury is described by the disruption of axons, but with intact connective tissue sheaths. The axon segment distal to the injury undergoes Wallerian degeneration. In this type of injury, the connective tissue sheaths are uninjured and recovery will be complete with an expectant rate of nerve fiber regeneration of ~1 in. per month. The progress of regeneration can be followed by a Tinel's sign. However, motor recovery will be incomplete and adversely affected in circumstances where the distance from the nerve injury to the motor end plates results in prolonged denervation. In terms of management, first- and second-degree injuries are managed conservatively.

Axonotmetic (third-degree) injury is characterized by fibrosis in the endoneurium that prevents regeneration of some injured axons. This may lead to incomplete or mismatched end-organ innervation and may require decompression of scar tissue or areas of entrapment to optimize recovery. The recovery with decompression is uniformly better than that seen with a repair or graft reconstruction, unless it is associated with severe causalgia.

Neurotmesis (fourth-degree) injury represents an in-continuity neuroma with no potential for spontaneous recovery. The entire population of regenerating axons proximal to the injury is blocked by scar tissue. Neuroma excision with an end-to-end or graft repair is indicated in this type of injury. Neurotmesis (fifth-degree) injury is a complete transection of the nerve fiber which includes both axons and all connective tissues. This type of injury is the most severe and mandates surgical repair.

Sixth-degree injury describes nerve injuries demonstrating two or more degrees of injury at the same level of disruption. This injury pattern is the most challenging since it requires treating each injury pattern uniquely based on degree of injury. Reconstructions of these injuries require a high level of judgment and technical skill in order to protect and not downgrade uninjured fascicles or those that have recovery potential while reconstructing the fourth- and fifth-degree injury components.

Background and Considerations in Motor Nerve Reconstructions

For motor reconstruction, knowledge of the anatomy and physiology present at the muscle-nerve interface, in addition to the nerve itself, is critical in understanding and treating peripheral nerve injuries. The motor end plates provide the communication of the nerve to the muscle. Their presence is imperative; they are the adaptors that allow continuity of the circuit. Without the motor end plates at the neuromuscular junction, functional innervation is absent. In the normal state, there is a physiologic cycle of denervation and reinnervation occurring at the skeletal muscle, due to synaptic instability and axonal dropout. These transient periods of denervation are completely ameliorated by rapid reinnervation that follows. It is only with prolonged denervation that pathologic changes occur within the muscle [50].

In the setting of denervation, changes occur not only in the nerve but also in the newly denervated muscle, and this sequence of events is termed denervation atrophy. Immediately following nerve injury, proteases associated with the ubiquitin-proteasome pathway cause myofibril reabsorption, myosin and actin filament catabolism, decreased muscle cell size, and increased collagen deposition in the extracellular space. With prolonged time of denervation and increased loss of myofibrils, myocytes may undergo a process similar to apoptosis. These changes do not occur uniformly throughout the muscle, and fiber-type grouping may occur with reinnervation [50]. There is a loss of capillaries, which over time may result in large proportions of the muscle becoming avascular [6]. Simultaneously, the muscle environment is optimized for reinnervation. Acetylcholine receptors and neural cell adhesion molecules are upregulated diffusely across the muscle, a state similar to that in embryogenesis. These factors help to guide ingrowth of the motor axon, and once the regenerating nerve has reached the muscle target, a neuro-

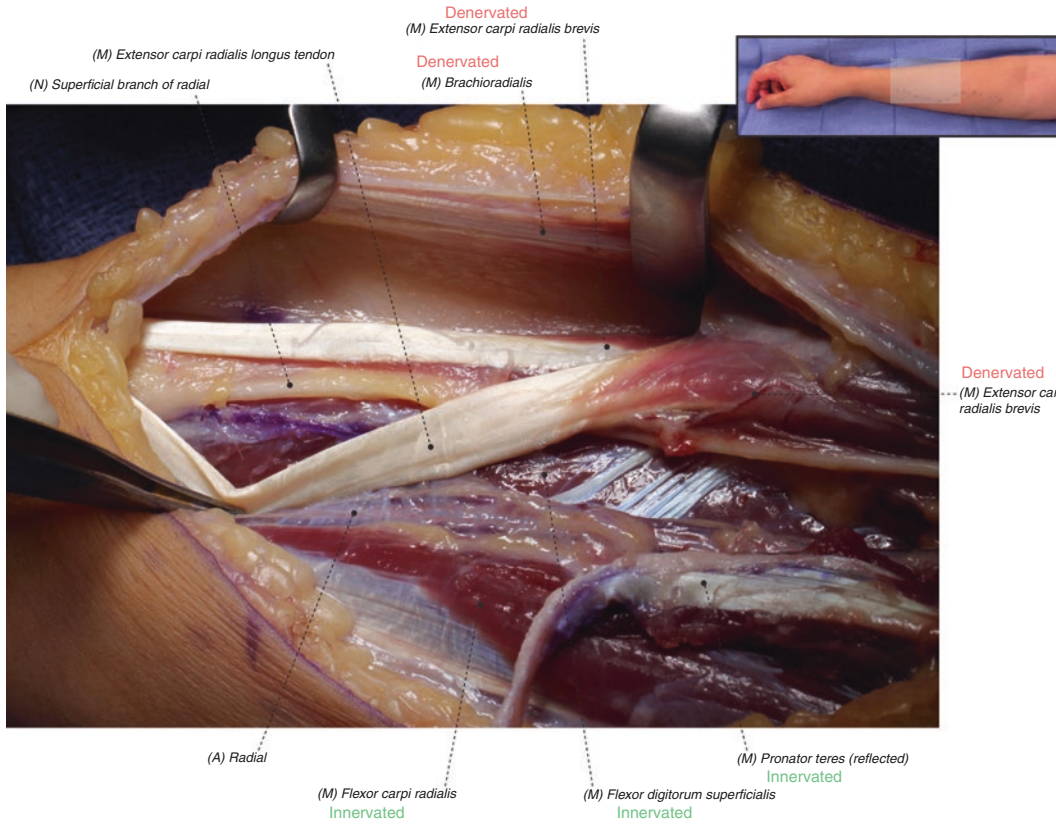

Fig. 47.4 Appearance of prolonged denervation in muscles. Denervated muscles atrophy as time elapses following nerve injury and take on a pale appearance with signs of fatty infiltration. This patient had complete radial nerve palsy following a humeral fracture, and a median to radial nerve transfer was performed 6 months following the injury. The radial-innervated muscles, specifically the extensor carpi radialis brevis, have a discolored appearance when compared to the functional median-innervated muscles following 6 months of denervation. (*N* nerve)

muscular junction is formed, and acetylcholine receptors and neural cell adhesion molecules are once again expressed only in the vicinity of the motor end plate [50]. With denervation atrophy, loss of muscle cross-sectional area corresponds with decreased contractile force, and with prolonged denervation, myofibril disorganization and collagen replacement result in decreased specific force capacity [45]. Unfortunately, deficits in specific force are permanent. With denervation, there is decreased muscle power, increased time to peak contractile force and to relaxation, and reduced speed of contraction [50].

Muscle reinnervation occurs following axonal regeneration, synaptogenesis, and resumption of contractile function. A reduction in the number of regenerating motor axons, however, results in deficits in muscle force [11, 50] as well as changes in gross appearance with pale color and significant atrophy (Fig. 47.4). With increasing periods of denervation, the embryonic-like state of high affinity between the regenerating nerve and muscle diminishes. Eventually, the muscle becomes refractory to synaptic formation; it can never be reinnervated, regardless of neuroregeneration. It is this time sensitivity to motor reinnervation that is integral to reconstructive planning for motor recovery. The location of the nerve lesion may preclude optimal or even feasible functional motor recovery via traditional methods. Denervation greater than 12–18 months is often considered the upper limit of this timeline depending on the patient's age. Proximal nerve lesions that are a long distance from their motor target may preclude primary muscle reinnervation given the known rates of neuroregeneration. If a nerve regenerates

in an adolescent at a rate of 1 mm daily, a lesion that is 50 cm from its motor target may have a diminished or absent functional result, particularly if time has passed since the onset of injury before presentation to the peripheral nerve surgeon.

Sensory reinnervation is not limited by such time constraints as motor end plates are not involved in sensation. Sensory reconstruction may be performed at any time and may traverse any distance due to the lack of time constraints.

Types of Pediatric Peripheral Nerve Injuries Specific to the Thorax

Pediatric peripheral nerve injury may result from numerous etiologies, as previously outlined. Specific to esophageal disorders and treatment, pediatric surgeons may encounter stretch injuries to the brachial plexus, phrenic nerve injury, brachial plexus tumors, brachial plexus birth-related palsy, positioning injuries with compression on the ulnar or peroneal nerves, thoracic outlet syndromes, intercostal neuromas and post-thoracotomy pain, and recurrent laryngeal nerve injury. One of the most devastating peripheral nerve injuries in children is injury to the brachial plexus. As this injury is more common than other etiologies of nerve injury at an incidence of ~1.5 injuries per 1,000 live births [18] and the majority of the pediatric peripheral nerve literature relates to this topic, many examples in this chapter will use this clinical problem. Brachial plexus injuries also clearly illustrate some of the challenges in peripheral nerve reconstruction: proximal injuries that are far from their end targets, nerve gaps, and loss of critical function.

History of the Treatment of Pediatric Nerve Injuries

Pediatric peripheral nerve injuries have been described since antiquity. Albrecht Durer, a German painter of the Renaissance, depicts the classic waiter's tip position of the arm that is characteristic of Erb's palsy in two of his famous works, one being in an infant [84]. Brachial plexus injury related to birth trauma is one of the more common pediatric peripheral nerve injuries and was first described by William Smellie in 1768 [91]. Wilhelm Erb described paralysis of C5 and C6 in 1874 [16], but it wasn't until 1903 that the first operative treatment for birth-related brachial plexus palsy was reported by Kennedy. His technique involved neuroma excision and direct suture repair of the ensuing nerve defect via immobilization of the head to the shoulder to facilitate nerve coaptation. He describes three cases and recovery of arm abduction and elbow flexion in the patient with longest follow-up (9 months) [65]. Reports of disappointing results following operative intervention for obstetrical brachial plexus palsy in the early twentieth century [42, 63] led to a period of nonoperative management for many decades. After brachial plexus injury, the resultant muscle imbalances and abnormal mechanics may lead to growth inequities, bony deformities, joint contractures, and osteopenia. The advancement of microsurgical techniques as well as improved understanding of neural anatomy and pathophysiology brought a renewed interest in operative intervention for pediatric brachial plexus injuries in the 1970s. Multiple classification systems of injury have since been proposed, and a plethora of literature exists describing suggestions for improved techniques, optimal surgical timing, and methods of enhancing regeneration.

Management of Peripheral Nerve Injuries

The modern approach to treatment of peripheral nerve injuries in children is similar to that in adults and is based upon the classification of the injury. Knowledge about the natural history of nerve injuries is important to prevent unnecessary interventions, provide patient education, and optimize outcomes. Classification of the injury, therefore, is an important initial task in the management of pediatric nerve injuries. Sunderland described five degrees of nerve injury [72], and Mackinnon emphasized a sixth degree, as outlined in an earlier section. First- through third-degree nerve injuries are typically managed without surgical intervention as they demonstrate

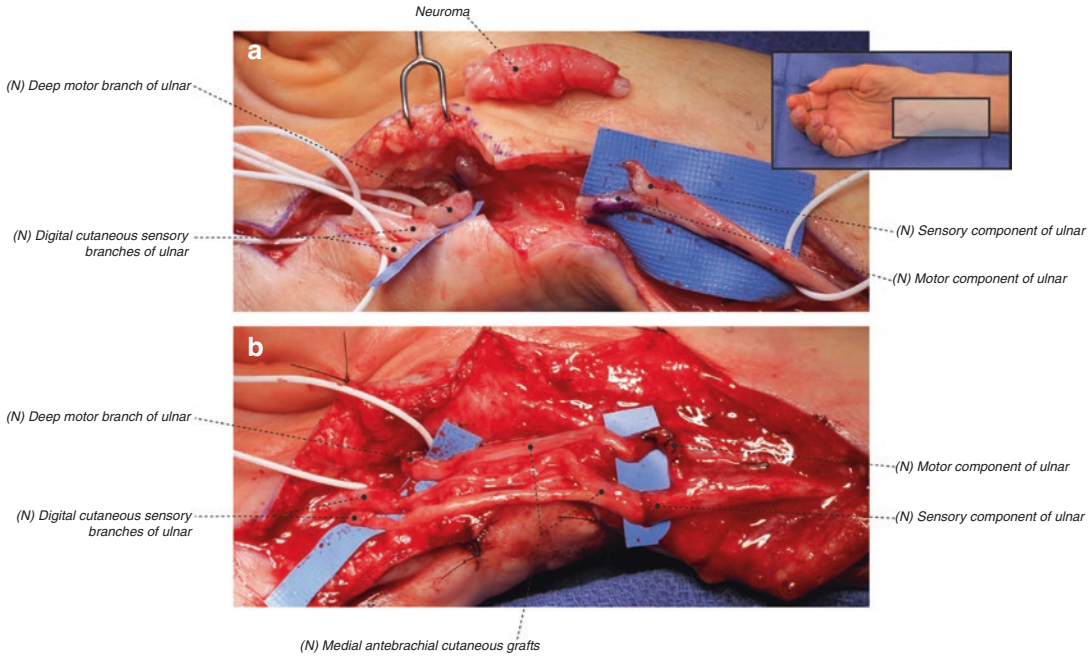

Fig. 47.5 Tension-free nerve repairs and matching motor/sensory modalities are essential concepts for successful nerve reconstruction. (**a**) The removal of a failed primary nerve repair introduced a large ulnar nerve defect. (**b**) The large ulnar nerve defect was reconstructed with three medial antebrachial cutaneous (MABC) cable nerve grafts. A single MABC graft was used to reconstruct the deep motor branch. Two MABC grafts were used to reconstruct the superficial sensory branches. Tension-free repairs occurred with modality and fascicular alignment. (*N* nerve)

complete or near complete recovery. Occasionally third-degree injuries may demonstrate incomplete recovery and may require surgical intervention to optimize results. Fourth- and fifth-degree injuries, however, will not spontaneously recover and do require surgery for optimal recovery. Sixth-degree nerve injuries represent a mixed picture, and the need for surgical intervention depends on the specific involved injury and recovery over time (Table 47.2). Physical examination is paramount, but electrodiagnostic studies may also provide useful information regarding the level of injury. Other imaging modalities, such as diaphragmatic ultrasound or MR myelogram, may augment diagnosis in specific cases.

The goals of nerve reconstruction are to provide restoration of function in as safe, complete, and rapid manner as possible while minimizing any donor site morbidity. To achieve these goals, reconstructions must be appropriately planned and performed using meticulous surgical technique. Nerve coaptations should always be without tension (Fig. 47.5). Nerve grafting is preferable to direct coaptations performed under tension or apposition via postural modifications. In addition, the injury should be clearly identified. Elegant nerve reconstructions performed within the zone of nerve injury have no functional value.

Management of peripheral nerve injuries may involve options such as behavior modification, nonoperative supportive management, decompression, neurolysis, primary repair, excision of lesion and interpositional nerve grafting, tendon transfers, joint fusion, stimulation, and nerve transfers. The specific technique used is dependent upon multiple factors including the location of the injury; the distance from the target; the presence of associated injuries including life-threatening or systemic disease or injury, adjacent vascular injuries, or complex soft tissue wounds; the time since the injury occurred; and the availability of donor tissues. The specific algorithms for treatment selection have been previously described [12, 38, 71, 82] and are not the focus of this review.

The outcomes of peripheral nerve reconstruction also depend on a multitude of factors, including patient characteristics, type and location of the injury, timing of intervention, and type of repair performed. An area that consistently demonstrates disappointing results involves injuries that occur distant from their end target. These reconstructions are typically performed with nerve grafting. The operations are lengthy, require donor nerves, and may require several years to achieve only modest recovery. The main explanation for suboptimal results relates to the time required for neuroregeneration to reach the target. Often motor end plates are lost and sensory recovery is delayed. In addition, the reconstruction may be limited by the amount of expendable nerve graft that is available. These are several of the challenges that have limited functional outcomes in peripheral nerve reconstruction for decades, and it is because of these limitations that new techniques have been developed.

Theory and Principles of Nerve Transfer

Nerve transfer offers an alternative approach to nerve reconstructions that otherwise may result in suboptimal function utilizing traditional techniques. Nerve transfers utilize redundant, expendable innervation to convert a more proximal injury to a more distal injury, one that is close to the end target. The specific functional deficit is identified and reconstructed. In a recent meta-analysis comparing treatment of adult upper trunk brachial plexus injuries with nerve transfers or nerve grafting, improved functional results for elbow flexion and shoulder function were noted in the nerve transfer group [23]. Nerve transfers dramatically decrease the time necessary for motor and sensory reinnervation, thus preventing loss of motor end plates, speeding recovery, and providing improved functional outcomes.

Indications for nerve transfer include proximal nerve injuries, an inadequate proximal nerve stump (thereby rendering traditional nerve grafting impossible), unacceptable time for regeneration (either due to distance to target or delayed presentation), and scarring that would prohibit safe dissection at the zone of injury. Nerve transfers permit dissection away from the site of original injury, in a field of unscarred tissue that facilitates ease and perhaps quality of the reconstruction. In addition, nerve transfers allow reconstruction of function without downgrading any regenerating function that exists, such as in the setting of sixth-degree nerve injuries.

Increased knowledge of internal nerve topography has facilitated the technique of nerve transfer. Laboratory studies have also demonstrated the safety of internal nerve dissection permitting the delicate isolation of specific nerve fascicles [14]. Nerve transfers require the availability of redundant, expendable donor nerves near the site of the denervated target (motor end plates or sensory receptors). For example, in the setting of a proximal ulnar nerve injury, traditional nerve grafting would result in little to no recovery of intrinsic motor function of the hand. Distally, however, the AIN branch to pronator quadratus can be transferred to the deep motor branch of the ulnar nerve to optimize motor recovery [60, 94]. Intraoperative electrical stimulation is used to confirm nonfunction of the injured nerve and to delineate motor targets of specific nerve fascicles in the potential donor to ensure redundancy prior to harvest. Donor sensory fascicles must innervate noncritical regions of sensation. Donor nerves should be purely motor or purely sensory depending on the function being reconstructed. Ideally donor nerves possess functional synergy to the function being reconstructed, similar axon number, and an appropriate size match. Unlike tendon transfers, nerve transfers are appropriate in the setting of joint stiffness. Motor and sensory reeducation is critical in the postoperative period to optimize function [12, 19, 71, 83, 94]. Several nerve transfers are now regularly utilized by our group and are summarized in (Table 47.3).

End-to-Side Nerve Transfer

A specialized type of nerve transfer is the end-to-side (ETS) technique. ETS nerve transfer is a technique where the distal end of a transected injured (recipient) nerve is reinnervated by coapting it into the side of an intact functional (donor)

Table 47.3 Nerve transfer options for various injured nerves in the upper extremity

Injured nerve	Impaired function	Donor nerve	Recipient nerve
Restoration of motor function			
Spinal accessory	Shoulder elevation and abduction	Medial pectoral, C7 fascicle	Spinal accessory
Long thoracic	Scapula stabilization, forward abduction	Medial pectoral, thoracodorsal, intercostal	Long thoracic
Suprascapular	Shoulder abduction, external rotation	Branch of spinal accessory	Suprascapular
Axillary	Shoulder abduction	Medial triceps branch of radial, medial pectoral	Deltoid and teres minor branches of axillary
Musculocutaneous	Elbow flexion	FCU fascicle of ulnar, FCR/FDS fascicle of median	Biceps brachii and brachialis branches
Triceps brachii	Elbow extension	FCU fascicle of ulnar, thoracodorsal	
Radial	Wrist and finger extension	FCR, FDS ± PL	ECRB branch and PIN
Pronator teres	Forearm pronation	FCU, FDS, FCR, ECRB	Pronator teres
AIN	FDP finger flexion, thumb flexion	Brachialis, FDS, supinator, ECRB	AIN
Median	Thumb opposition	AIN (pronator quadratus branch)	Recurrent (thenar) branch of median
FPL	Thumb flexion	FDS	FPL
Ulnar	Hand intrinsics	AIN (pronator quadratus branch)	Motor component of ulnar (DMBU)
Restoration of sensory function			
Median (C5, 6)	C5, 6 distribution	3rd webspace fascicle of median	1st webspace fascicle of median
Median	1st, 2nd, 3rd webspace, median palmar aspect of hand	Dorsal cutaneous branch of ulnar	1st webspace fascicle of median
Ulnar	Ring and small finger, dorsal and ulnar palmar aspect of hand	3rd webspace fascicle of median	Sensory component of ulnar
Radial sensory	Radial aspect of hand	LABC	Radial sensory

FCU flexor carpi ulnaris, *FCR* flexor carpi radialis, *FDS* flexor digitorum superficialis, *PL* palmaris longus, *ECRB* extensor carpi radialis brevis, *PIN* posterior interosseous nerve, *AIN* anterior interosseous nerve, *FPL* flexor pollicis longus, *DMBU* deep motor branch of ulnar nerve, *LABC* lateral antebrachial cutaneous nerve

nerve (Fig. 47.6). This technique was first described in the late 1800s and subsequently reintroduced in the early 1990s as published reports in peer-reviewed literature [49, 52, 56, 57, 88, 89]. Since then, the clinical use of the ETS nerve transfer has been a controversial topic in peripheral nerve surgery [57, 81, 96] due to the numerous contradictory studies.

On review of the literature, there are two concepts related to ETS nerve transfer and axonal sprouting: "regenerative sprouting" and "spontaneous collateral sprouting" [61]. The first, "regenerative sprouting," describes the concept where axons reinnervating the recipient nerve are derived from sprouts of regenerating units in response to axonal injury. This concept of sprouting with injury is widely accepted in the community. However, the second concept of "spontaneous collateral sprouting" is the source of controversy. This concept describes axons collaterally sprouting spontaneously without injury from the nodes of Ranvier.

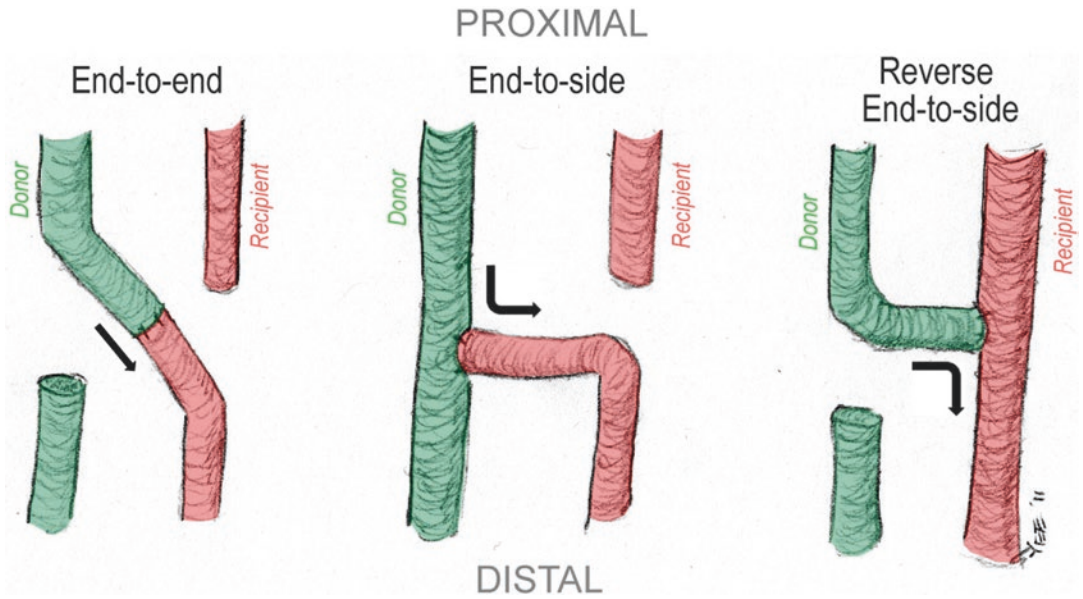

Fig. 47.6 Types of nerve transfer coaptations. Three nerve transfer coaptations currently exist: end to end (ETE), end to side (ETS), and reverse end to side (RES). ETE is the standard coaptation for restoring critical function and directing the maximum number of fibers from donor into recipient nerve. ETS is the distal segment of the recipient nerve being coapted to the side of the donor nerve. RETS is the proximal end of the donor nerve being coapted to the side of the recipient nerve. The *arrow* describes the direction of nerve regeneration

Some studies have shown evidence that suggests ETS nerve reconstruction results in collateral sprouting in sensory nerves [8, 25, 30, 77, 78]. This phenomenon is seen in patients recovering sensation over time following a donor nerve harvest that results in a sensory deficit. By contrast in motor nerves, there is evidence that motor axons will sprout only if injured [30]. Clinically, this specific phenomenon is seen in our hypoglossal-facial experience and in a specific nerve transfer for shoulder reconstruction [70]. Even if the donor nerve requires an axotomy injury, this may not significantly impact its function due to the redundancy and plasticity of donor nerve motor end plate innervation [27, 30, 61, 66–69].

The ETS nerve transfer may be a viable reconstructive alternative in specific circumstances where other reconstruction options are unavailable. These circumstances can include restoration of noncritical sensation, donor sensory nerve deficits, and select motor injuries where an axotomy injury to facilitate regenerative sprouting in the donor nerve will not cause a significant motor deficit. In the situation of a motor reconstruction, an ETS nerve repair is essentially a form of nerve transfer where axons are diverted through a modest neurectomy within a single fascicle of the donor nerve. The size of the neurectomy determines the amount of regenerative sprouting while limiting the donor deficit. Clinically, we have reported functional motor recovery after an ETS nerve transfer [70] and continue to utilize this technique in a specific shoulder reconstruction. In this report, a compression injury is made proximal to the coaptation site in addition to the axotomy to facilitate a regenerative nerve front. For sensory reconstruction, the ETS nerve repair occurs via a perineural window in the donor nerve. The size of the perineural window dictates the amount of collateral sprouting [93].

Another situation where ETS nerve transfer may be clinically relevant is in the context of harvesting donor sensory nerves and neuropathic pain. Dorsi et al. [13] describe two possible sources of neuropathic pain in nerve injuries: neuroma for-

mation of the distal end of the proximal nerve and collateral sprouting from adjacent sensory territories into the distal injured sensory nerve (Fig. 47.7). While neuroma pain is managed with neuroma resection and proximal intramuscular transposition, hyperalgesia pain from collateral sprouting can be managed with an ETS nerve repair. The theory is that by providing regenerative nerve fibers to innervate the distal portion of the injured sensory nerve, collateral sprouting at the source of hyperalgesia pain is prevented. We have seen these techniques successfully manage injury-induced neuropathic pain.

Reverse End-to-Side Nerve Transfer

Another special technique of nerve transfer is the reverse end-to-side (RETS) reconstruction. In a RETS nerve transfer, an expendable donor

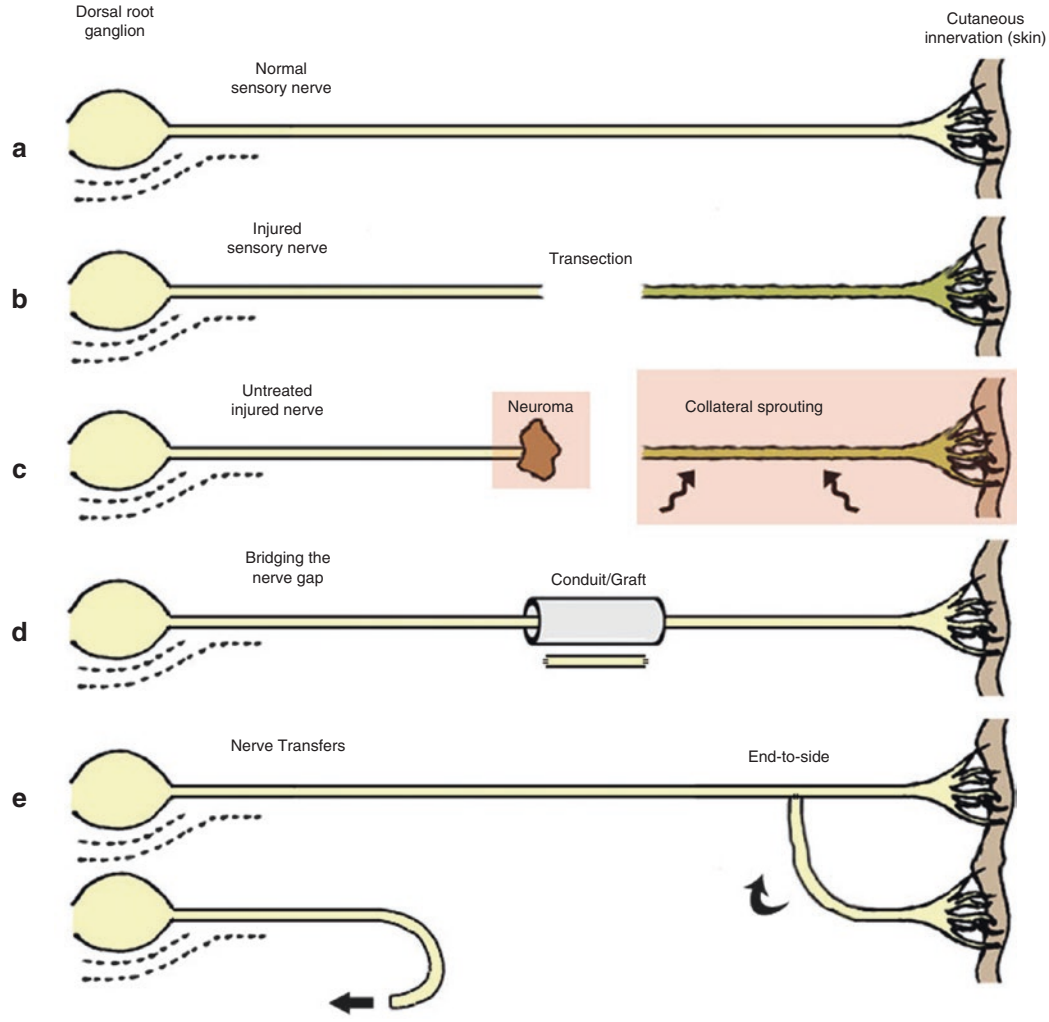

Fig. 47.7 Strategies for pain management from neuroma formation and hyperalgesia. Pain related to nerve injury can originate from two sources: neuroma formation at the distal stump and hyperalgesia due to collateral sprouting form adjacent sensory territories. (**a**) Normal sensory nerve. (**b**) Injured sensory nerve with transection injury and Wallerian degeneration in the distal nerve segment. (**c**) Pain resulting from neuroma formation and collateral sprouting. (**d**) One type of strategy is to bridge the gap with a graft or conduit. (**e**) Another strategy is to transpose the proximal end of the nerve into the muscle to prevent neuroma formation. An end-to-side nerve transfer into an adjacent sensory nerve is performed to prevent hyperalgesia

nerve is transected distally, and the distal (donor) end is transferred to the side of the intact injured nerve close to the target muscle via a perineural window (Fig. 47.6). The advantages of the RETS nerve transfer are to provide additional motor axons to "supercharge" the regenerating nerve as well as provide early muscle reinnervation (preventing loss of motor end plates) by "babysitting" the target muscle until the native axons regenerate from proximally.

In the case of significant proximal nerve injuries that occur distant from the target muscle with minimal to no chance of functional recovery, an end-to-end motor nerve transfer can be used to restore prompt motor reinnervation [10, 12, 74, 83]. The appropriate surgical management for nerve injury distant from the target muscle, however, is less clear. In this scenario, the expected functional recovery after traditional nerve grafting techniques is fair, but not excellent, as functional recovery from nerve regeneration is dependent on the relationship between the time elapsed from injury and the distance to the target muscle [83]. This scenario is also considered to be a "gray area" between proximal and distal injuries where indications for distal nerve transfers or primary repairs are less clear. RETS nerve transfer may serve as a technique to approach this type of scenarios and achieve optimal results.

Published data on RETS nerve transfer are relatively scarce. Isaacs et al. (2008) described successful donor motor axon regeneration through a RETS coaptation resulting in successful target muscle reinnervation, but dependent upon injury to the recipient nerve with resultant muscle denervation [37]. Fujiwara et al. [21] later augmented a primary repair with the RETS nerve transfer and found improved motor and sensory functional recovery in RETS augmentation than transection and repair alone. Finally, Isaacs et al. [37] performed a similar study in the tibial and peroneal nerves except with the addition of preferential electrical stimulation. They demonstrated significant target muscle reinnervation in both the donor and recipient native nerves. Although these studies provided supportive evidence for the RETS nerve transfer, they lacked reliable negative controls of injury without repair. The importance of this negative control addresses the superlative regenerative capacity of the rodent model and prevents a false positive [9]. This is an important consideration in the rodent model when translating to humans with slower regenerative capacity.

Recently, Kale et al. [43] published a study from our institution that presents a model of RETS that comprehensively evaluates the surgical technique in a rodent. This study boldly suggests that the RETS technique can result in an equivalent number of donor motor axons as the standard end-to-end (ETE) nerve transfer. This finding is supported by fluorescent microscopy results (Fig. 47.8). Potentially, these results suggest that in the clinical setting, the RETS nerve transfer could replace the ETE nerve transfer in cases where any potential for native axonal regeneration exists. However, further investigation is ongoing to determine the mechanism and utility of the RETS nerve transfer.

To further describe the utility of the RETS nerve transfer, Kale et al. [43] also presented in their study a case report of a successful reconstruction of an ulnar nerve deficit following a failed ulnar nerve transposition. The patient presented with a 4-month history of severe ulnar nerve deficit following failed transposition, which included intrinsic hand wasting. He was reconstructed by revision of the ulnar nerve transposition and augmentation with the RETS anterior interosseous to ulnar motor nerve transfer. Twelve months postoperatively, he has recovered excellent ulnar intrinsic function, which is unseen in revision ulnar nerve transposition cases, as results are typically fair. Due to this excellent clinical finding, we have adopted the RETS nerve transfer to augment recovery of ulnar intrinsic muscles after ulnar nerve injury secondary to recurrent cubital tunnel syndrome. On several occasions, we have seen early recovery within months postoperatively and excellent intrinsic muscle recovery long term. Essentially for these ulnar nerve case scenarios, we are creating a Martin-Gruber anastomosis in the distal forearm.

Our encouraging results with RETS in the adult population have prompted its use in appro-

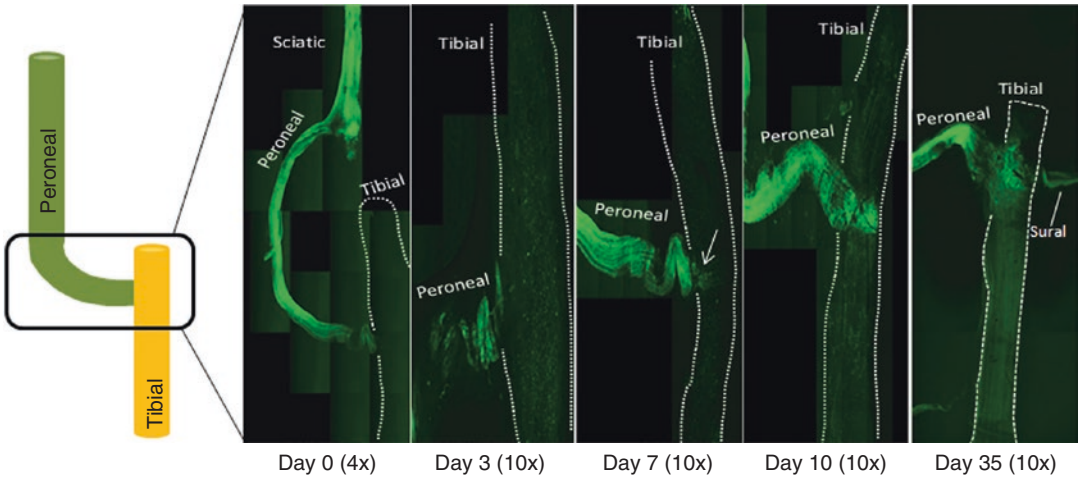

Fig. 47.8 Confocal imaging of the reverse end-to-side nerve transfer coaptation site. The schematic (*left*) displays the area of interest for the composite images acquired with confocal microscopy (*right*). Axonal infiltration across the reverse end-to-side coaptation was noted as early as 7 days after surgery in the rodent model (*white arrow*). Regeneration into the recipient distal tibial nerve stump was robust 35 days after surgery. An adjacent sural side branch is seen in the 35th day image. *Dotted lines* outline the tibial nerve (Reprint from Kale et al. [43], with permission from Elsevier)

priate clinical scenarios in the pediatric population as well. We were called to assist intraoperatively with an iatrogenic phrenic nerve injury during thymectomy to treat refractory myasthenia gravis in a 16-year-old female. Appropriate exposure was obtained via a right anterior thoracotomy (Fig. 47.9a). Although we were expecting the injury to require a nerve graft (Fig. 47.9b), a tension-free primary suture coaptation was achieved after extensive mobilization of the phrenic nerve (Fig. 47.9c). Because the injury was over 7 cm proximal to the diaphragm (Fig. 47.9d), the RETS technique was used to supercharge diaphragmatic innervation from the sixth intercostal nerve. The neurovascular bundle to the sixth intercostal space was dissected intrathoracically (Fig. 47.9e). An epineurial window was made in the phrenic just proximal to the diaphragm; the sixth intercostal nerve was then transected and coapted to the phrenic at the epineurial window (Fig. 47.9f). The patient has recovered well, now 5 months postoperatively, and reports less shortness of breath compared to her preoperative state, which may be related to the myasthenia treatment. The theory, again, was to attempt to preserve the motor end plates to the diaphragm and decrease the time to motor reinnervation.

Another application of the RETS technique in our clinical pediatric practice is reconstruction of the deep motor branch of the ulnar nerve in a 9-year-old female, 5 months after she sustained a proximal radius and ulnar fracture that was managed nonoperatively. The patient had noted immediate numbness in the ulnar nerve distribution at the time of the fracture. She had ongoing sensory recovery, but wasting of the intrinsic muscles. Electrodiagnostic studies were consistent with ulnar neuropathy. At the time of ulnar nerve decompression in Guyon's canal at the wrist, intraoperative electrical stimulation of the deep motor branch demonstrated no motor function. The deep motor branch was then reconstructed with the pronator quadratus branch of the anterior interosseous nerve in a RETS fashion. At 10 months postoperatively, the patient has regained normal intrinsic hand function, indicating complete motor reinnervation of the muscles innervated by the deep motor branch of the ulnar nerve (Fig. 47.10). The distal reconstruction was able to preserve the motor end plates in the ulnarly innervated intrinsic hand muscles to improve the functional outcome.

Nerve Transfer Outcomes

The concept of nerve transfer was proposed as early as 1913 [32]. With increased reports of the shortfalls of traditional reconstructive techniques in certain clinical scenarios, as well as the difficult application of allotransplantation, nerve transfers have become increasingly utilized and accepted.

Nerve transfer outcomes in adults have been reported extensively in the literature [7, 15, 92]. Due to increasing popularity of this technique in recent years, results from the adult population no longer have to be extrapolated to the pediatric

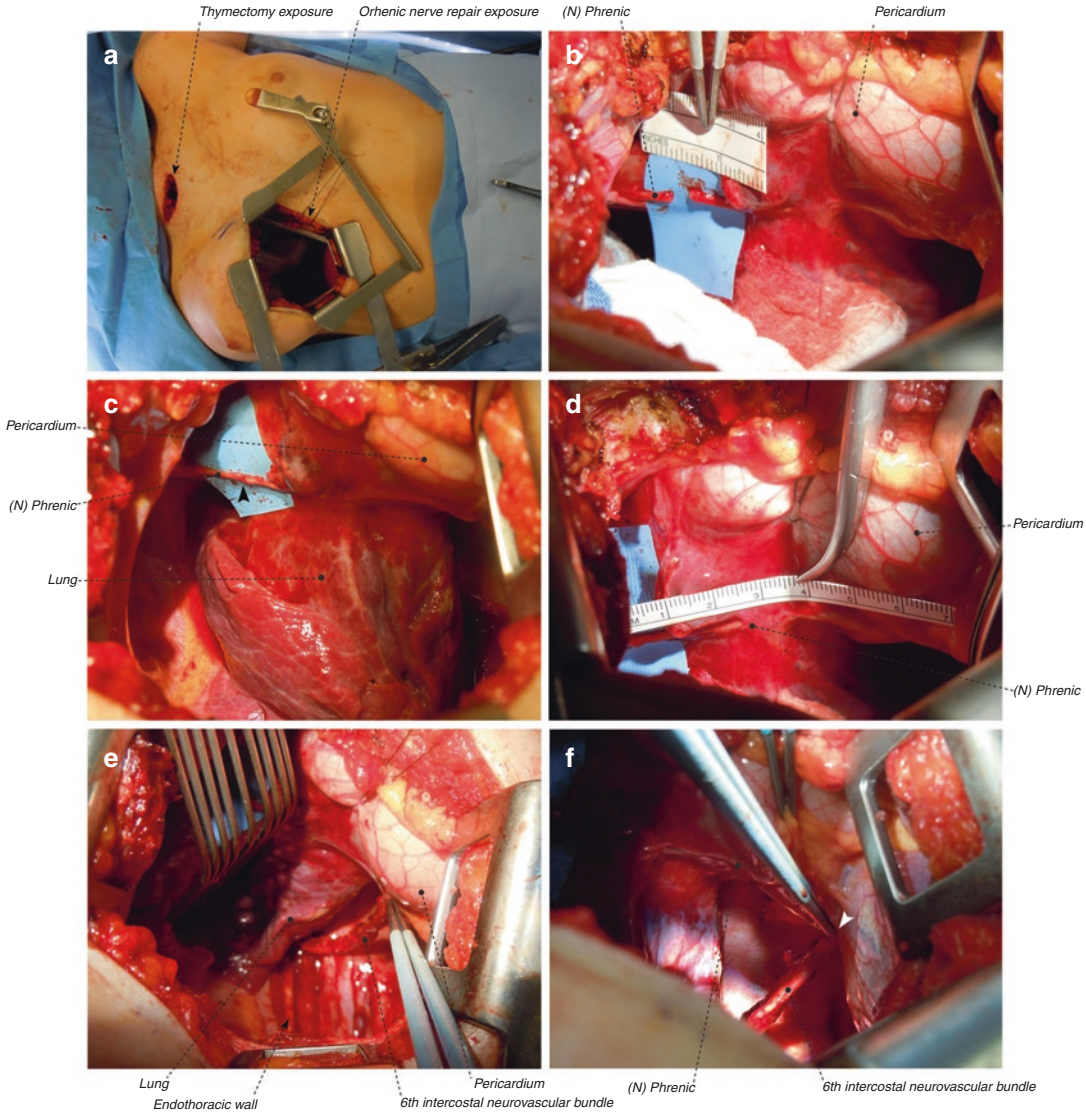

Fig. 47.9 Reverse end-to-side (RETS) sixth intercostal to phrenic nerve transfer following an iatrogenic phrenic nerve injury. (**a**) The phrenic nerve was injured during thymectomy to treat myasthenia gravis in the neck exposure. A right anterior thoracotomy was performed to access the phrenic nerve for the RETS nerve transfer. (**b**) The phrenic nerve was found completely transected. (**c**) A tension-free repair was completed on the phrenic nerve. (**d**) The injury occurred 7 cm from the diaphragm. (**e**) As result, the sixth intercostal neuromuscular bundle was harvested. (**f**) Following, the sixth intercostal nerve was transferred via RETS technique to the phrenic to augment the proximal primary repair. (*N* nerve)

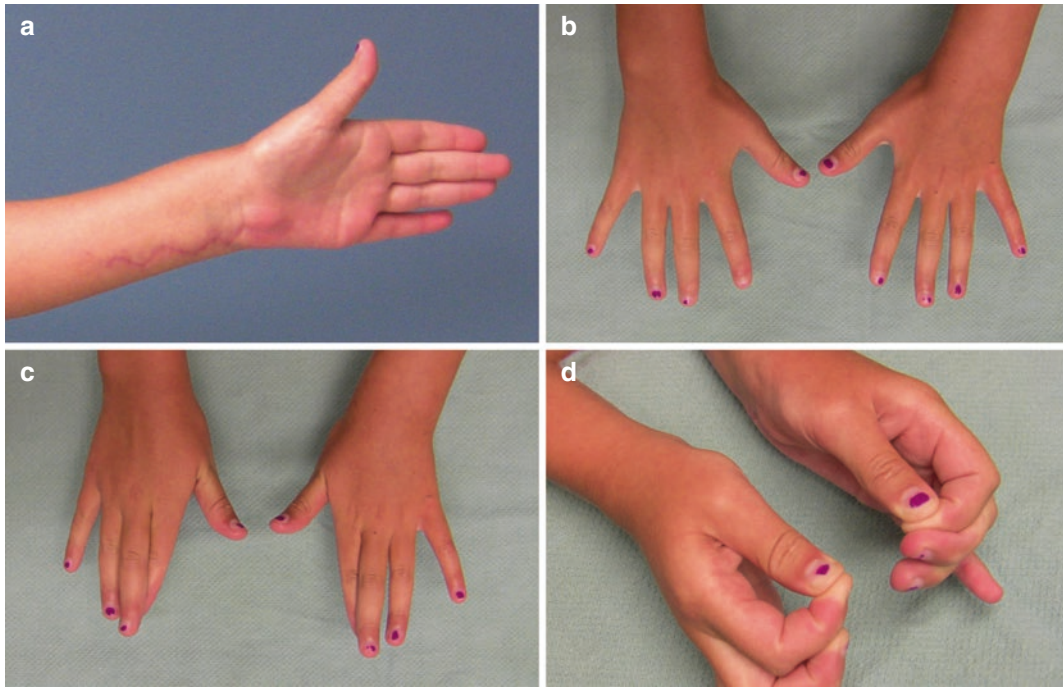

Fig. 47.10 Outcome following reverse end-to-side (RETS) anterior interosseous to ulnar motor nerve transfer. A nine year-old female sustained proximal radius and ulnar fractures and demonstrated ulnar nerve injury with wasting of ulnar intrinsic muscles and loss of ulnar nerve sensation. While she showed sensory recovery, the RETS anterior interosseous to ulnar motor nerve transfer was performed to augment the proximal motor nerve regeneration to her ulnar intrinsic muscles. (**a**) Ten months post-operative results showed significant recovery of ulnar intrinsic muscles. Her incision is well-healed. (**b**) Significant wasting is not seen in the left hand. (**c**) The patient was able to cross her fingers. (**d**) The patient did not display Froment's sign

population. Outcomes after nerve transfer in the pediatric population have been encouraging. Much of the reconstructive focus has been to reestablish biceps function. After transfer of two to three intercostal nerves to the musculocutaneous nerve for biceps reinnervation in patients with birth-related brachial plexus palsy, Kawabata et al. [44] reported 84 % of the patients achieved M4 biceps strength. They noted that recovered strength diminished with increasing age at the time of surgery. Two different groups have reported good to excellent results after performing Oberlin's transfer (ulnar nerve FCU fascicles transferred to nerve to the biceps) in pediatric patients. Al-Qattan [58] reported restoration of normal biceps function in two of two patients 5 months after transfer. Noaman et al. [59] noted recovery of good to excellent biceps function in five of seven children who had undergone an Oberlin transfer. Blaauw and Slooff [5] described outcomes after a series of 25 patients had undergone medial pectoral nerve transfer to the musculocutaneous nerve for restoration of biceps function in the setting of brachial plexus palsy. They noted complete reinnervation of the biceps muscle in most cases by 6 months after surgery. Over a mean follow-up of 70 months, 17 patients achieved excellent function and 5 patients displayed fair function. There were two complete failures due to disruption of the coaptation. They noted their selection of the medial pectoral nerve due to its increased number of motor fibers compared to intercostal nerves. Reconstruction of external shoulder rotation has also been applied to the pediatric population. Pondaag et al. [64] performed suprascapular neurotization to achieve infraspinatus reinnervation either by grafting of C5 or accessory nerve transfer. Their results showed only 17 of 86 patients (20 %) recovered greater than 20° of external shoulder rotation, and 41 % of patients were incapable of any shoulder rotation, regardless of the type of reconstruction performed. They did not,

however, dissect the suprascapular nerve to the level of the suprascapular notch, and this could be a confounding factor. They did note that patients compensated well to effectuate good function. Improved results were seen when the spinal accessory nerve was transferred to the suprascapular nerve in children who had spontaneously recovered shoulder and arm function, except for shoulder external rotation, following birth-related brachial plexus injury. Functional exorotation was achieved in 52 of 54 children, and external rotation exceeded 20° in 39 of 54 patients. Shoulder abduction also improved in half of the patients [85].

Conclusions

While pediatric peripheral nerve injuries are relatively uncommon, their effects can be life-altering. Treatment options continue to evolve as knowledge regarding the anatomy, topography, and physiology of the peripheral nervous system matures, as do technology and approaches to restoring function. In recent years, nerve transfers have improved previous shortcomings of our treatment armamentarium. Injuries that are far from the end target can be managed more efficaciously by converting them to a distal reconstruction, borrowing expendable nerves to reestablish critical function. This not only speeds reinnervation, thereby preserving motor end plates and improving function, but also allows reconstruction of previously untreatable lesions or of patients who have a delayed presentation. In addition, reconstruction away from the site of initial injury may provide for a safer outcome for the patient in cases of extensive scarring near important structures. Critical outcomes analysis and scientific endeavors will continue to progress the treatment of pediatric peripheral nerve injuries.

Tracheomalacia and the Effective Aortopexy

48

John E. Foker, Abby C. Meyer, and Frank Rimell

Introduction

A soft trachea (tracheomalacia) is susceptible to collapse, creating variable degrees of ventilatory distress and producing symptoms from the barky cough common in esophageal atresia (EA) patients to life-threatening difficulties in breathing. The symptoms are roughly proportional to the severity of the tracheomalacia (TM) and range from increased work of breathing, stridor, wheezing, failure to thrive, recurrent pneumonias, severe respiratory distress, apnea, bradycardia, cyanosis, to sudden ventilatory arrest [1–7].

Many tissues and organs, such as muscle and bone, react to stress, pressure, and other biomechanical stimuli with hypertrophy and increased density to counteract these forces. The trachea and bronchi, however, do not strengthen to resist external and internal pressures, but, rather, lose the tissue components which produce structural rigidity. Collapse can then occur with the negative intraluminal pressure of inspiration or from forces and structures external to the trachea during expiration, usually the innominate artery and its origin off the aorta.

TM, as a result, is found in a variety of conditions including EA and certain types of congenital heart disease, most notably the absent pulmonary valve syndrome or with vascular rings which put external pressure on the airway [1–13]. In EA, the frequently large upper pouch puts pressure posteriorly on the trachea, compressing it against the innominate artery, likely causing the tracheomalacia [13]. As a result, both the cartilage and myoelastic elements do not have normal structural rigidity. When the upper pouch does not have a decompressing fistula, it will be larger and more likely to produce significant tracheomalacia.

The pressure can also come from vascular structures such as enlarged pulmonary arteries or an entrapping vascular ring [8, 9]. Again, the external pressure almost paradoxically causes weakening of the cartilage and the tendency to collapse. TM may also be produced by prolonged intubation while on the ventilator [7, 14]. Consequently, pressure either

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_48

from outside the trachea or from within will decrease tracheal structural rigidity [7, 14]. In addition, primary TM may occasionally occur without apparent etiology.

The seriousness of TM in some cases has led to increasing awareness of the condition and advances in diagnostic techniques and treatment in children [5, 7, 15–17] (see Chap. 46). As suggested by the variation in signs and symptoms, TM exists in a spectrum of severity, and the mode of treatment will depend on the clinical consequences. Recently a classification of TM severity as determined endoscopically has been proposed based on the amount of collapse and loss of luminal area. This classification, with experience and refinement, may prove useful [18].

For mild cases, treatment begins with good nutrition, adequate calcium supplementation, and removal of the stimuli producing the TM. With time, the trachea should firm up and improve the situation. Ideally, this will be sufficient, but it may not be and an operative procedure will be needed. Whatever the treatment selected, good nutrition and a positive calcium balance which would include vitamin supplements should be emphasized as part of the regimen.

With more significant TM, the symptoms become more severe as does the difficulty breathing. At the severe end of the spectrum, TM can interfere substantially with ventilatory mechanics and produce apneic episodes, a form of an acute life-threatening event (ALTE). Because air hunger quickly leads to increased inspiratory and expiratory efforts with more collapse, the patient's condition may quickly deteriorate and lead to a near death experience or even become fatal (see Chap. 46). For these patients, an effective operative treatment would prevent significant collapse, and its value would be easily justified.

The situation for the intubated patient with TM is more complicated, and the decision must be made whether to move toward weaning and eventually attempt extubation or accept the much slower process of tracheal firming while still intubated. With an indwelling tube, the trachea may have difficulty in stiffening up and progress will be very slow. Effective surgical treatment (an aortopexy) may however greatly hasten extubation and, with it, discharge from the hospital despite persistence of the TM.

Operative Approaches for Tracheomalacia

Several operative approaches have been described beginning with the first solution used: a tracheostomy and indwelling tube to prevent collapse. A tracheostomy and cannula, however, bring a number of undesirable consequences and should only be done in the most difficult of circumstances and will not be considered further here. Another approach has been to firm up the trachea internally by stents or externally by cartilage grafts [19, 20]. The former method is prone to severe complications, and the latter, although elegant, is difficult and involved technically. Consequently, the most commonly used operative solution is the aortopexy, the simplified name which often includes additional vessels besides the aorta. An aortopexy does not treat the TM directly but prevents collapse by elevation of any vessels impinging on the trachea anteriorly. In some cases, fixation of the posterior extent of the trachea and even the tracheal membrane itself posteriorly to the prevertebral fascia will allow the anterior vessel elevation to more effectively round up the trachea and prevent collapse. Which components of the aortopexy will be used will largely be determined by bronchoscopy. Primary collapse of the trachea itself will increase the importance of the anterior elevation of the vessels, while encroachment of a redundant posterior membrane may make adding fixation valuable to the aortopexy.

The majority of patients with significant tracheomalacia also have anomalies of the esophageal atresia spectrum. With only the "barky cough" of the typical post-repair EA patient, nothing further will need to be done, and the situation will improve with time. For significant TM, however, with severe difficulties in breathing and near coaptation seen endoscopically, an aortopexy is typically done to round up the trachea and hinder collapse. In these cases, the innominate artery is usually the offending vessel, with variable contributions by the neighboring area of the aorta and the pulmonary arteries. The aortopexy may also include elevation of these vessels to obtain adequate relief as determined by the bronchoscopy findings. When the trachea is very soft and the tissues between it and the innominate artery are not

strong enough to insure the trachea is adequately rounded up, the rings themselves may also need to be suspended to prevent collapse.

For tracheobronchomalacia from cardiac causes, operative treatment includes removing the deleterious pressure effects of the impinging vessels and also rounding up the trachea to limit collapse with expiration and inspiration by some variation of an aortopexy [8, 9, 11, 21]. The absent pulmonary valve syndrome, as will be discussed, is probably the congenital heart defect that is best known to produce TM [9]. Vascular rings if present are divided and the arteries rotated or elevated away by the aortopexy sutures. Vascular rings may also be associated with tracheal stenosis, but, in many cases, only TM may be the result.

For infants having significant acute spells or requiring ventilator support and intubation because of TM, serious consideration should be given to an operative solution. Carefully done, an aortopexy has a considerable potential to eliminate or, at least, greatly reduce the severity of these spells at a low risk. For patients on the ventilator primarily because of TM, the benefit will likely include a relatively quick extubation and removal from the ventilator, ending the deleterious consequences and considerable expense of being ventilator bound or ending up with a tracheostomy.

Principles of an Aortopexy

For the recommendation of an aortopexy, the TM symptoms should be considered a significant problem and deserving of operative treatment. For infants without significant vascular anomalies such as the EA/TEF patient, the vessels, including the innominate artery, are normal in position and size, and it is the soft trachea which cannot resist the presence and pressure of the artery as well as the excursions of the mediastinum. Because of the TM, the presence of the artery collapses the airway enough to set up the possibility of cycles of increasing difficulty breathing with the consequent air hunger producing more vigorous ventilatory efforts with additional tracheal collapse. For these cases of severe TM with apparent vascular compression of the airway, the operation will necessarily have two considerations. First, the arteries producing the vascular compression are moved, and second, if the TM is severe enough, the trachea itself must be rounded up by elevation anteriorly and fixation posteriorly if the relief of the vascular impingement does not produce the desired effect.

The direction of compression can be lateral as well as in the anterior-posterior plane. Examples of lateral tracheal compression and tracheomalacia include vascular rings, large pulmonary arteries, and even a descending aorta that is displaced medially and pushed anteriorly by the vertebral bodes [8–10]. For these patients, systematically removing the different components of vascular compression is part of the operative treatment. The effect of the various maneuvers can be determined by directly observing the result through the bronchoscope during the effective aortopexy procedure that will be described.

Several aortopexy approaches have been described in the literature with differing incision sites and, therefore, varying views of the offending vessels with some differences in effectiveness and durability of the procedure. The operations have included both open and thorascopic techniques and the differences also affect the end result.

Our operative procedure, which will be described in detail, gains access to the upper mediastinum with the patient slightly head-up with the neck extended and supine with bronchoscopy available to evaluate the result. The innominate artery and, if necessary, other arteries (e.g., pulmonary arteries, branches of the aorta) will be pulled forward by sutures into the wall of the vessel and anchored into the posterior fascia of the sternum and proximal portions of the ribs. The vessels that need to be elevated will vary and the aorta will not always be included.

It must be emphasized that no dissection is carried out between these vessels and the tracheobronchial tree so that these tissues serve to pull the anterior surface of the airway forward. It is also important to not dissect behind the trachea so that tissue holds the posterior wall of the airway in place when the anterior wall is pulled forward and the trachea is rounded up. These form the basic principles of an effective aortopexy.

The Vessels Producing the Airway Compression

Typically in the EA patient who has a left aortic arch, it is the innominate artery crossing over the mid to lower portion of the trachea that is the principal offending collapsing the soft airway. As noted, other vessels may be involved particularly when there are also vascular anomalies in the area or in the presence of congenital heart disease. The complexity of the vascular structures and impingement may vary considerably as will the degree of TM. As detailed, an analysis of the vessels and the structures impinging on the airway as necessary should be carried out by scan (CT or MRI) and echocardiography. Bronchoscopy during the aortopexy will be of most value as it will reveal the requirements of an effective operation. Direct elevation of the vessels during the procedure will allow the effects to be observed.

The effect of the innominate and neighboring arteries can be demonstrated by several methods; however, we have relied on bronchoscopy to definitively reveal the location and degree of obstruction at the time of aortopexy. This method of assessment has the considerable advantage that the area of collapse is revealed and the effect of the aortopexy can be directly determined. Pulling forward the innominate artery as well as its aortic origin should round up the trachea and allow visualization of the main stem bronchi. With the benefit confirmed, the elevation of the vessels can be secured and the operation completed.

Aortopexy Operations

Several techniques for an aortopexy have been described [1, 7, 9, 21–34]. The important consideration in the aortopexy is to bring the vessels forward in an even way so that the elevation rounds up not only the central portion of the airway but also keeps open both main stem bronchi. Whether or not this is accomplished depends, at least in part, on the incisional site. The trachea and proximal bronchi are in the midline directly in back of the sternum. If the incision for the aortopexy is either to the right or left of the sternum, the elevation on that side will be satisfactory although it may be at the expense of the lumen of the opposite main stem bronchus. The far side cannot be easily reached by a right- or left-sided approach, and compression of the opposite main stem bronchus may not be relieved and possibly even made worse by the aortopexy. All of the lateral approaches have this potential shortcoming, and, at the end of the procedure, bronchoscopy with the patient supine should be done to assess the consequences for the opposite main stem bronchus.

Commonly cited operative approaches utilize right or left anterior thoracotomies or an incision through the bed of the third rib. In some techniques, Dacron patches or tissue flaps are also used to enhance the aortopexy and even do away with the aortic sutures [24, 29]. A minimally invasive technique has also been used approaching from either the right or left intercostal area. For these thoracoscopic approaches, the same caveats pertain about achieving a symmetrical aortopexy. The less graceful suture placement and the large needles used in thoracoscopic procedures, moreover, would seem to make the risk of bleeding greater [32, 33]. Certainly, it seems apparent to the thoracoscopic surgeon that the risk is greater; consequently, the stitches are few, are placed more superficially, and are more likely to pull out, and symptoms recur [32].

To address the asymmetrical elevation that may occur with either a right- or left-sided approach, a manubriotomy through a low collar incision was used which allowed direct access into the anterior mediastinum [34]. This provided equivalent exposure to the partial sternotomy approach, made a symmetrical elevation of the vessels possible, and produced an effective result. Simple sutures were placed in the superior aspect of the aortic wall without pledgets, however, which might make them more prone to pull through. Finally, a full midline sternotomy has been used in two cases, but a complete sternal split is unnecessary and certainly enlarges the operation [31].

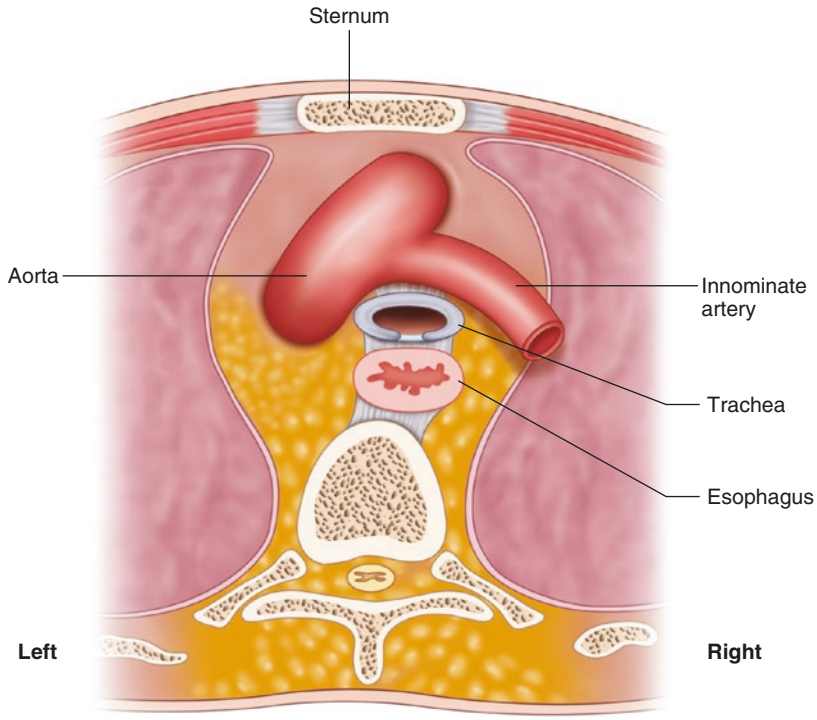

Fig. 48.1 Elevation of the vessels. The partial sternotomy approach provides direct exposure of the innominate artery, ascending aorta, and the main pulmonary artery. In most cases, the innominate artery courses across the soft trachea and becomes a significant contributor to the airway obstruction. Elevation of the innominate artery and, to some degree, the right-hand side of the upper ascending aorta relieves the obstruction by rounding up the trachea making it no longer subject to collapse. In other approaches to an aortopexy, simple sutures are typically placed through the anterior high point of the upper ascending aorta and then to the back of the sternum resulting in a rounding up of the trachea and relief of symptoms. If the approach is either from the right or left, there are several potential drawbacks to this method. If bleeding occurs, it may be difficult to reach and control. By the partial sternotomy approach, the vessels are directly accessible, and, if bleeding occurs, it can be more directly controlled. Also, from a more lateral approach, the elevation of the aorta may not be straight anterior and may roll somewhat to the opposite side and tends to be impinged on the main stem bronchus if the elevation is not even and favors the side of the approach. With the patient supine and the use of intraoperative bronchoscopy, the consequences for both main stem bronchi can be readily seen, and if they are still impinged upon, then elevation of the pulmonary artery and/or the pericardium itself should relieve the problem. Elevation is accomplished by placing pledgeted horizontal mattress sutures on the lateral aspect of the innominate artery and the ascending aorta as shown. The sutures are then placed in the posterior sternal fascia, and the effect of elevation can be readily determined by bronchoscopy. If bleeding occurs, the suture can be removed and the site controlled with an additional U-shaped suture

An Effective Aortopexy

The Operative Approach

In order to fulfill the basic principles of the operation and address some of the problems which arise with the procedures cited, we have used a limited midline approach to provide excellent access and facilitate an effective aortopexy. A short transverse incision is made slightly above the manubrial-sternal angle (Fig. 48.1). A low collar neck incision could also be made in the skin lines; however, it will require a somewhat longer opening for equal access to the anterior mediastinum [32]. The manubrium is split in the midline which allows direct access to the thymus and the vessels lying beneath it (Fig. 48.2). The bony incision is readily made and gentle, and

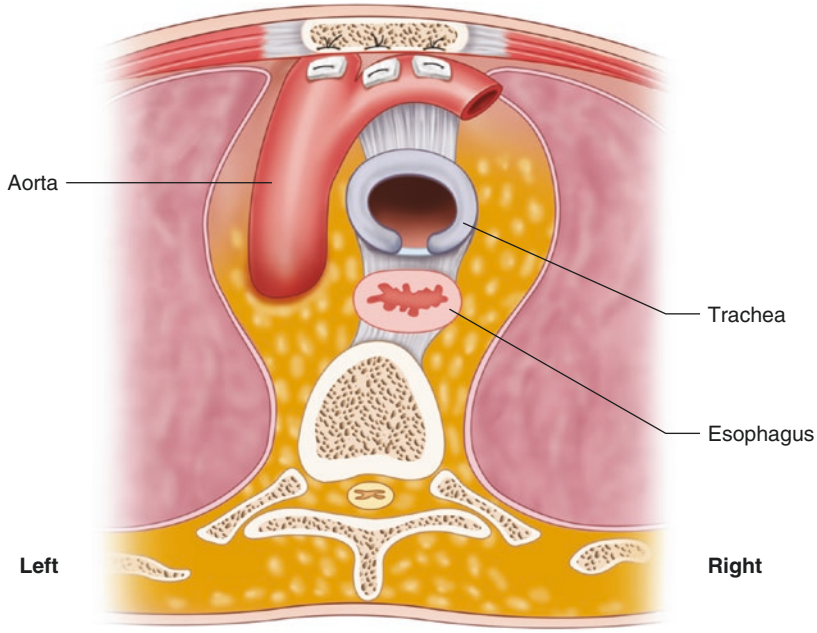

Fig. 48.2 A short (3 cm) transverse incision is made at the level of the manubrial-sternal junction. A partial sternotomy beginning at the sternal notch is carried down to just past the junction which will provide very adequate exposure. The right lobe of the thymus can be moved, or removed if necessary, which will reveal the upper part of the pericardium. A vertical incision in the pericardium and tacking the edges apart laterally will reveal the ascending aorta, innominate, and main pulmonary artery. This exposure, along with simultaneous bronchoscopy, will allow the effects of elevating the innominate artery and neighboring portion of the ascending aorta to be determined. If necessary, the pulmonary artery or the pericardium itself can be elevated. This information will allow for both a more precise placement of the sutures and effective aortopexy to be accomplished

progressive spreading with a small sternal retractor provides excellent exposure. Surgeons will utilize the incisions with which they are familiar and most pediatric surgeons have done few, if any, sternotomies. Most have access to colleagues, however, who are familiar with this approach and could provide help in carrying out the partial sternotomy.

Once the partial sternotomy has been made, the two lobes of the thymus are easily separated, and retraction or removal of one lobe reveals the innominate artery and the upper part of the ascending aorta. If needed for an effective aortopexy, the main and branch pulmonary arteries are also readily accessible and can be elevated [9]. Whether or not one opens the upper portion of the pericardium will depend on what is needed to complete the aortopexy although it does enhance the exposure.

A very important advantage of this approach is the ability to use bronchoscopy during the procedure to accurately assess the effect of the elevating sutures. With the patient lying flat, the endoscopist can see the airway without distortion and will be able to assess the effect of elevating the arteries on the trachea and both main stem bronchi. Initially, the likely offending vessels can be gently elevated with pickup forceps and the effect observed.

This operative approach provides even greater advantages when dealing with more extensive tracheobronchomalacia and more complex causes of compression by vascular abnormalities. In addition to elevating the innominate artery, the more proximal ascending aorta, pulmonary arteries, and even the pericardium itself can be brought anteriorly to round up the lower trachea and proximal main stem bronchi [8, 9]. The upper portion of the pericardium overlies the lower trachea and proximal main stem bronchi, and, therefore, elevation may be useful in opening these airway structures. Pulling upward on the pericardium at various points will allow the effect

to be determined via the bronchoscope and the permanent site for the sutures determined.

For some cardiac anomalies (e.g., absent pulmonary valve syndrome), the vascular abnormalities are usually repaired at the same time. In this case, the very large main pulmonary arteries which appear to be the cause of the tracheobronchomalacia would be reduced in size by reefing them up after the intracardiac repair is completed [9]. Before closure of the incision, elevating the pulmonary arteries will insure the airway is adequately rounded up. On rare occasions, elevating the superior and lateral aspect of the pericardium itself may also be useful to extend the effect of the aortopexy to include the main stem bronchi. Finally, if the trachea does not round up satisfactorily by elevating the vessels, monofilament sutures in each side of the anterior surface of the tracheal rings can be used to open the lumen.

Another maneuver that may provide help in EA patients following repair where there is no esophagus directly in back of the trachea is to tack the ends of the tracheal rings or even the posterior membrane directly to prevertebral fascia. Care must be taken with suturing the posterior membrane, however, to avoid an air leak. In addition, because the approach will usually be from the right side, the left main stem bronchus may not be opened adequately, and determining the effects of these sutures by bronchoscopy will be more difficult with the patient in the lateral position.

The Arterial Sutures

The arterial sutures are pledgeted to provide holding power and are placed in a horizontal mattress fashion on the lateral aspect of the vessels and then into the posterior fascia along each side of the sternum (Figs. 48.3). At this point, the sutures can be pulled up and the degree of relief of compression of the trachea and bronchi assessed.

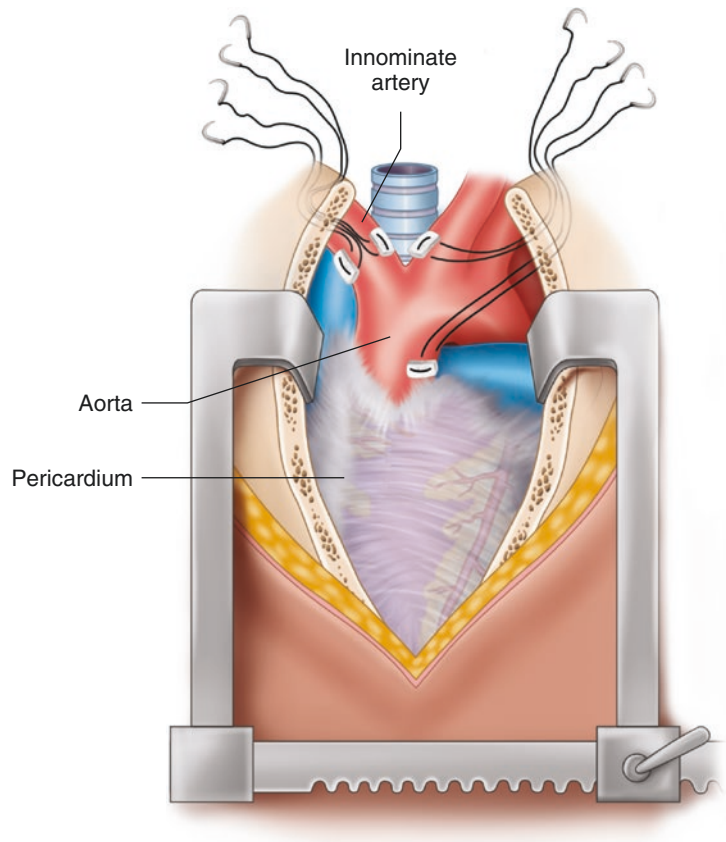

Fig. 48.3 The arterial sutures are pledgeted to provide holding power and are placed on the lateral aspect of the vessels and then into the posterior fascia along each side of the sternum

The sutures are carefully placed within the wall of the vessels while not entering the lumen. Because of the upward force on these sutures and vessels, if the lumen is entered, it would seem prudent to remove the suture and repair the vessel with a more superficially placed 6-0 or 7-0 Prolene suture if there is still bleeding. The suture material itself can either be a braided permanent polyester suture such as 4-0 or 5-0 Tevdek which has good strength and is mounted on a relatively small needle. A permanent monofilament such as Prolene could also be used and small pledgets fashioned and mounted on the suture. Either 4-0 or 5-0 monofilament suture will slide through the tissues of the vessel wall easily be amply strong. More care has to be taken, however, in the handling of the more brittle monofilament suture.

The sutures are then passed through the posterior fascia of the manubrium and sternum. Pledgets are usually not needed on this end because these tissues are sturdy. At this point, a small chest tube is brought up through the subxiphoid area and into the pericardial space just inferior to the elevating sutures. One or two sternal wires are placed and the ends tagged. A small piece of very fine silastic sheeting is cut to size and placed centrally between the back of the manubrium and overlying the vessels that will be elevated. The thin silastic sheeting will make a future sternotomy incision, if needed, easier and safer to accomplish. The sternal edges are then drawn together by the wires as closely as convenient to still allow tying of the elevating sutures. When this is done, the sternal wires are twisted together, and the remainder of the closure is carried out in the usual fashion.

This operative approach fulfills the basic principles of an effective aortopexy, and if more extensive elevation is required in complex cases, it can be accomplished. An important consideration is that because the elevation begins centrally and moves laterally along the course of the main stem bronchi, as needed, there will be no secondary kinking of these structures as might happen if they are relatively out of view of the surgeon and bronchoscopist.

Results

Aortopexy was first described by Filler et al. [1] and used initially to treat TM in EA patients. As with most operations, the approach and technical details have evolved and, presumably, improved with time. Our institutional experience began primarily with cardiac patients with varying degrees of secondary tracheobronchomalacia. Because a sternotomy was also utilized in these patients, a partial midline reopening created no additional problems. Moreover, because of the severity of the tracheobronchomalacia, bronchoscopy was often used which made clear the utility of being able to directly determine the effects of the aortopexy.

The EA population requiring aortopexy has grown steadily and includes patients referred for EA growth procedures, those with continuing tracheobronchomalacia problems, or following a failed aortopexy which has compromised the opposite main stem bronchus. The results reflect our increased understanding of the principles behind an effective aortopexy.

Very early on, three cases of severe TM with cardiovascular anomalies had a tracheostomy. Two of the tracheostomies were done before the referral for aortopexy, and the one done after this operation was because of continuing severe cardiac dysfunction. In our EA series, no patient has required a tracheostomy for TM and the only tracheostomy done was in a patient referred with bilateral recurrent laryngeal nerve damage and failed EA repair.

Recently a comparison of nonrandomized cases at another institution showed the partial sternotomy approach was more effective in relieving symptoms than thoracotomy or thorascopic approaches [7]. Furthermore, recurrence was very unusual presumably because of the more accurate suture placement under direct vision.

The aortopexy, as described, has proven very effective and, as opposed to the placement of a stent(s) or even a tracheostomy, should not produce later problems that may be difficult to solve. Consequently, we believe it can be recommended in cases with documented, significant TM, typically causing severe ventilatory problems and certainly for those experiencing near

death episodes (ALTEs). Because of the considerable benefit and low risk, this procedure has been requested when less extreme but still very stressful symptoms are present. Noisy breathing from tracheal collapse indicates a critical airway narrowing which will tolerate little further reduction in the opening as might occur during an upper airway viral infection. Certainly, it is difficult to predict when moderate ventilatory distress will quickly cycle into a significant apneic episode. For parents who have witnessed difficulty breathing and progression to apneic episodes in their babies, it will be very reassuring to have this problem effectively treated.

Summary

An aortopexy will be more likely to be effective, we believe, if the principles described are followed. A short upper sternal incision as described will reveal the offending vessels and allow them to be elevated in a symmetrical fashion without leaving a main stem bronchus comprised. The suspension of the vessels which cause the compression will round up the very soft tracheobronchial tree, and this can be confirmed by intraoperative bronchoscopy. If the cause of compression is more complex, a wider range of elevation using multiple sutures to other great vessels or even the pericardium can be easily carried out through this incision. Finally, if bleeding occurs, the vessels are well exposed and accessible. With this overall approach, the symptoms should be greatly reduced or eliminated and without later consequences for the patient's growth and development.

Thoracoscopic Aortopexy

49

Klaas(N) M.A. Bax

Introduction

Aortopexy was first described by Gross and Neuhauser in 1948 [1]. Gross used it for the treatment of tracheal compression what he and his radiologist Neuhauser thought was caused by an anomalous innominate artery. Much later Mustard et al. and Berdon et al. queried an abnormal origin of the innominate artery as the cause of the compression [2, 3]. They felt that the trachea was compressed by a normally placed innominate artery in the relatively "overcrowded mediastinum" of a small child. They thought that perhaps a degree of tracheal softening also played a role. In 1976 Filler et al. described three children with life-threatening events due to innominate artery compression after repair of esophageal atresia with distal fistula [4]. Slowly it was understood that rather an intrinsic abnormality an extrinsic compression of the trachea caused tracheal obstruction in the majority of patients after esophageal atresia repair [5]. Nowadays the term tracheomalacia (TM) is used and aortopexy has become the procedure of choice for the treatment of severe forms of TM [6].

Physiopathology

TM refers to a weakness of the trachea. The normal intrathoracic trachea dilates somewhat during inspiration and narrows with expiration as a result of differences between the intrathoracic and intraluminal pressures [7, 8]. In TM, this physiologic process is accentuated. The majority of cases of tracheomalacia are intrathoracic in nature; hence during expiration and particularly forced expiration or coughing, intrathoracic pressure is positive and the affected segment of trachea or bronchus narrows leading to wheeze [9]. In the less common case of cervical, extrathoracic TM, the collapse takes place during inspiration by transmission of the negative intrathoracic pressure, causing stridor. In esophageal atresia with distal fistula, there is a deficiency of cartilage, an increased width of the posterior membranous trachea, and an increased internal tracheal perimeter [10]. Malformed tracheal cartilage rings have also been found in the adriamycin tracheoesophageal fistula rat model [11]. In contrast to esophageal atresia with distal fistula, clinically important TM is rare in pure esophageal atresia [12], H-type tracheoesophageal fistula without atresia, and their combination [13].

In idiopathic TM or TM associated with compression, structural changes are less obvious but a decreased cartilage to muscle ratio seems common [14, 15]. Similar changes may be seen in children with sudden infant death syndrome [14].

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_49

It has been questioned whether such an enlargement of the trachea is a congenital or acquired event. The same applies to TM in adults [6].

TM may be localized to one portion of the trachea or may involve the entire trachea. The main stem bronchi may be involved as well in which case the term tracheobronchomalacia is applicable. The terms tracheomalacia and tracheobronchomalacia have been used interchangeably especially in studies regarding children [6]. Isolated weakness of the bronchi, bronchomalacia, is much rarer. In this chapter the term TM is also used to include tracheobronchomalacia.

Classification

There are different classifications of TM. Some authors classify TM on a basis of the extension into localized and extensive forms [16]. Others make a difference between primary and secondary malacia. For Benjamin primary TM comprises premature infants, otherwise normal children, and children with dyschondroplasia, while secondary TM comprises children with tracheoesophageal fistula, children with innominate artery compression, and children with compression due to a vascular ring, a congenital cyst, or a tumor [15]. Austin and Ali make a distinction between congenital and acquired forms, but consider TM in association with compression by anomalous great vessels as acquired [9]. Carden et al. make the same distinction and describe a long list of potential causes in both groups. They include TM in prematures in the congenital form, but consider TM associated with congenital anomalies of the great vessels as acquired. They also place TM associated with congenital cysts like bronchogenic cysts, enterogenic cysts, cystic hygroma, lymphatic malformations, and tumors like teratomas in the acquired group [6]. TM associated with bronchopulmonary dysplasia should not be part of the primary congenital form as bronchopulmonary dysplasia in the premature is caused by damage due to long-term endotracheal intubation and mechanical ventilation with volume and barotrauma. As stated earlier, many authors do not believe in tracheal compression by an abnormal origin of the innominate artery; they rather believe in an intrinsic weakness of the trachea [2, 3, 6, 15, 17–19]. Whether there is a cause effect relationship between aortic arch anomalies and tracheal softening is speculative. More likely are both expressions of one event.

Mair and Parsons proposed a major airway collapse classification MAC system based on histopathologic, endoscopic, and clinical findings of the flaccid airway [20]. MAC 1 represents congenital tracheal collapse without external compression; MAC 2 represents tracheal collapse caused by external compression, e.g., vascular anomalies, cysts, tumors, and thymic or thyroid gland enlargement; MAC 3 refers to acquired TM arising from prolonged ventilation, tracheotomy, or severe tracheobronchitis. They felt that the term TM should be reserved for cases with widening of the posterior wall with a ratio to the anterior cartilaginous wall of 2:1 (Table 49.1).

Incidence

The incidence of TM is not commonly reported. One study estimated it to be 1 per 1,445 infants [21]. In a retrospective study of 664 bronchoscopies in a university setting, 15,4 % of the children studied had TM [22]. In another retrospective study of 512 bronchoscopies, the incidence of primary airway malacia was estimated to be 1 in 2,100 children [23]. In the subgroup of children with idiopathic TM, 46 % had TM, 36 % tracheobronchomalacia, and 16 % bronchomalacia. In children under the age of 3 years, scheduled for bronchoscopy due to a history of recurrent respiratory distress, the incidence of TM seems double [20]. In a study of 50 infants with TM, ± 50 % had primary TM. Most of the children with secondary TM were premature babies requiring prolonged mechanical ventilation [22]. TM is becoming much more frequently recognized [6, 9], which is undoubtedly related to an increased awareness among clinicians and the better imaging techniques. The better the diagnostic tools, e.g., multidetector CT [24] and magnetic resonance imaging [25], the higher the incidence is likely going to be.

Table 49.1 Classification

Primary
Idiopathic (otherwise normal children)
Associated with other congenital anomalies
Esophageal atresia with distal tracheoesophageal fistula
Congenital tumors or cysts
Anomaly of the great vessels
Double aortic arch
Right aortic arch
Aberrant innominate artery
Aberrant right subclavian
Anomalous left pulmonary artery
As part of a syndrome or association
Antley-Bixler syndrome
Blackfan-Diamond syndrome
Brachman-de Lange syndrome
Campomelic syndrome (skeletal)
CHARGE syndrome (coloboma, heart, atresia of choanae, retardation of growth, genital hypoplasia, earanomalies)
Chondrodysplasias
Deletion 11p13, 12q, 22q11
DiGeorge syndrome
Ehlers-Danlos syndrome
Hallermann-Streiff syndrome (skeletal)
Kniest dysplasia
Larsen syndrome (skeletal)
Mucopolysaccharidoses (Hurler, Hunter)
Pfeiffer syndrome
Pierre-Robin sequence
Translocations 18–22
Trisomies 9 and 21
VACTERL association (vertebral, anorectal, cardiac, tracheal, esophageal, renal, limb anomalies)
Williams-Campbell syndrome (congenital bronchiectasis)
Secondary (previous normal trachea)
Prolonged intubation/ventilation
Tracheostomy
Tracheobronchitis
Polichondritis
Trauma
Secondary compression
Abscess
Left atrial hypertrophy
Tumor including goiter, thymic enlargement

Modified from Carden et al. [6]

In children with esophageal atresia with distal fistula, TM is invariably present as is witnessed by the barking noise that those children make during forced expiration [26].

Natural History

As TM may be part of many underlying conditions, a general prognosis regarding TM itself is difficult to give. In most patients with TM, however, symptomatology is mild and intervention is not required. Many references state that symptoms improve with age and that symptoms often resolve by 1 or 2 years of age [6]. Most references are, however, old. In a study regarding 17 patients with primary bronchomalacia, all improved with time but the three patients over 5 years of age reported limitation of vigorous exercise indicating that pathology does not disappear completely with time [27]. A lifelong decrease in exercise intolerance in idiopathic TM has also been suggested by others [23]. In TM associated with esophageal atresia with distal fistula, the typical cough persists throughout adulthood [28]. TM may cause significant morbidity. It may go unrecognized or may be misdiagnosed as asthma or other respiratory conditions [6]. Moreover non-diagnosed TM has been implicated in the pathogenesis of sudden infant death syndrome [14, 29, 30]. There is an important subgroup of patients, who present with life-threatening symptoms requiring immediate treatment. In esophageal atresia with distal fistula, this is estimated to represent between 10 % and 20 % [12, 30]. Several factors have been implicated in the acute life-threatening events. Tracheal obstruction during expiration is certainly one of them, but reflex apnea caused by irritation of the trachea by acid secretions and/or a bolus of feeding in the esophagus has also been suggested as a contributing factor [4, 15]. Gastroesophageal reflux is common both in idiopathic TM [31, 32] and in esophageal atresia [26, 33]. Gastroesophageal reflux seems an important cause of acute life-threatening events in children even without esophageal atresia [34]. Compression of the trachea by a bolus of feeding

in the upper esophagus has also been implicated in the symptomatology of children with repaired esophageal atresia and distal fistula [35], but the absence of TM in esophageal atresia without fistula contradicts this.

Symptomatology

Classically, the signs and symptoms of TM have been described as occurring not at birth but instead appearing insidiously during the first weeks or months after birth [32, 36, 37]. However this standard has been challenged in a recent study that noted signs and symptoms in 95 % of the cases of congenital TM at birth [20]. Patients with esophageal atresia with distal fistula have a noisy barking expiration, especially during crying, but sometimes even at rest [26]. Often there is wheezing. If the TM has an extrathoracic component, there may be inspiratory stridor as well. Feeding usually exaggerates symptoms. Often the child feels uncomfortable during feeding. As a result the child wants to cry, thereby increasing the intrathoracic pressure but at the same time compressing the intrathoracic trachea even further. The child wants to exhale but cannot. Clinically there is opisthotonus.

Intercostal and substernal retractions occur and there is nose flaring. The child becomes cyanotic, and when hypoxia has taken effect, the child relaxes and may start breathing again. During such a life-threatening episode, the child may aspirate. Primary gastroesophageal reflux with or without aspiration has also be held responsible for these events [38], and it remains difficult to be certain about the primary causative factor: gastroesophageal reflux or TM [31].

A severity rating score for TM has been proposed [15]:

Mild TM
: Children have respiratory difficulties associated with infectious processes such as croup or bronchitis. These children have often problems with retained secretions.

Moderate TM
: Children present with classic symptoms such as stridor, wheezing, recurrent respiratory infections, and even cyanosis with exacerbations.

Severe TM
: Children present with stridor during tidal breathing, marked sputum retention, upper airway obstruction, reflex apnea, and even cardiac arrest.

Diagnosis

Awareness of the possibility of TM and knowledge of its symptomatology are of course important. This applies especially for the idiopathic form. In a group of 96 outpatients with idiopathic TM, mean age at diagnosis was 5.2 years (range 0–16 years) [23]. Moreover TM was not suspected before bronchoscopy in half of the patients with idiopathic TM. While the association between esophageal atresia with distal fistula and TM is well known among pediatric surgeons, attributing the actual symptoms to TM and proper management is more of a problem as symptoms in patients with repaired esophageal atresia with distal fistula may also be caused by gastroesophageal reflux or recurrent fistula.

Many methods have been used to diagnose TM through the years.

Plain X rays have a low sensitivity [39]. CT scanning is gaining popularity. It has a high sensitivity, it allows for 3D reconstruction, and it is fast and does not require general anesthesia. The disadvantage is radiation exposure, but dose reduction schemes are being developed [19, 40]. MRI is the preferred method for evaluating external compression [25, 41, 42]. General anesthesia has, however, to be given, which is not without danger [43]. The use of imaging techniques will undoubtedly increase as technology evolves. They certainly will allow in the future for a dynamic evaluation of the trachea in small children despite their “uncooperativeness.”

At present, endoscopy of the airway still plays a crucial role in the diagnosis [6]. First of all it allows for the diagnosis of concomitant anomalies

of the upper airway such as tracheal stenosis [44]. For observing the dynamics of the TM, general anesthesia in spontaneously breathing infants is required. Nowadays flexible endoscopes are often used. A tracheal collapse of more than 50 % during expiration or coughing or a ratio of the cartilage to the membranous tracheal wall of more than 3:1 is considered diagnostic [15, 23]. Bronchoscopy is, however, an invasive procedure. It requires general anesthesia, but spontaneous breathing. Kamata et al. selected those patients for surgery in whom there was a 70 % collapse of the airway during mechanical ventilation without spontaneous breathing [45]. In three of the six patients with tracheobronchomalacia, a pexy of the pulmonary artery was added to the aortopexy and one of the patients with pure bronchomalacia had just a pulmonary artery pexy.

Aortic arch anomalies can be diagnosed antenatally [46]. Not all cases in this publication were symptomatic at birth: of the five cases with double aortic arch, one fetus was aborted, one was asymptomatic, and the remaining three underwent surgery; of the six cases with right aortic artery and aberrant left subclavian artery, five remained asymptomatic and one underwent surgery, and finally of the eight cases with left aortic artery and aberrant right subclavian artery, one fetus was aborted while the remaining seven cases remained asymptomatic.

Treatment

It has been stated over and over again that TM improves with time [6, 31] and that medical treatment suffices in the meantime in most cases. It should be realized however that TM does not only just cause obstruction of the intrathoracic trachea during expiration. Sputum retention due to impaired secretion clearance and ineffective cough may lead to tracheal mucosal metaplasia, reduced cilia, atelectasis, and/or recurrent pneumonia [15, 31, 32, 47].

There is general agreement that severe TM needs urgent treatment [6, 26, 48]. In one series of TM associated with esophageal atresia and distal fistula, indications for surgery were episodes of apnea and cyanosis 65 %, recurrent pneumonia 25 %, and worsening stridor 46 % [49]. When TM is associated with tracheal stenosis or anomalies of the great vessels such as a pulmonary sling, these anomalies have their own treatment plans with concomitant or later aortopexy [19, 50–55]. After double aortic arch correction, symptoms may persist in up to 30 % of the cases [56].

For TM itself, several treatment options are available [6], but there is an absence of evidence to support any of the therapies currently used for the management of primary tracheomalacia [57].

Treatment Options

Tracheostomy and Long-Term Ventilation

These techniques have been the mainstay of therapy for severe TM for many years. Tracheostomy causes, however, additional tracheal injury. In the 1990s the percentage of infants and children requiring tracheostomy for TM varied widely from 12 to 62 % [6].

Continuous Positive Airway Pressure (CPAP)

CPAP with or without tracheostomy is an effective treatment for moderate to severe TM [58]. The disadvantage of CPAP is that it usually requires a long treatment period and hospitalization. Moreover it is associated with a delay in the commencement of oral feedings, retardation of speech and language, and potential developmental delay [22, 59]. CPAP can be considered as an initial treatment [6].

Fundoplication

The association between TM and gastroesophageal reflux has been recognized for a long time. Especially in severe TM associated with esophageal

atresia, one has argued about the primary approach: fundoplication or aortopexy. In a series of 22 infants presenting with severe respiratory symptoms after esophageal atresia repair, 13 (59%) had an initial TM procedure, stent, or aortopexy [38]. Respiratory symptoms improved in seven. Six of the seven got a fundoplication and all six improved. Nine (41%) had an initial fundoplication with improvement of symptoms in six. The non improving patients had an aortopexy later on, with improvement in all. The authors do not choose between both approaches as a first. In contrast Corbally et al. choose aortopexy as a first [49], which seems reasonable, but no time should be lost embarking on a fundoplication when the aortopexy is not effective.

Splinting of the Trachea

There have been several attempts at external splinting of the trachea and bronchi, e.g., with pericardial patches [60], silastic-impregnated Marlex mesh [61, 62], and costal cartilage [63]. Even ceramic rings have been advocated at least in adults [64]. External splinting techniques have not gained popularity because of the magnitude of the operation, especially when a long segment is affected. There is also concern regarding the growth of the trachea, when these techniques would be used in children.

Stenting of the Trachea

Stents in children were used for the first time in 1995 [65]. Today a wide variety of stents have become available. There are mainly three different types: metal stents, silicone stents, and biodegradable stents [66, 67]. Stents have the advantage of immediate relief of the problem, but stent displacement, formation of granulation tissue, and difficulties in removal at least when metal stents are inserted have limited their use. Biodegradable stents seem to be the future, but clinical trials have not been conducted so far due to the very low incidence of very severe TM. Today stenting is regarded as an option when other treatment modalities have failed [19, 66, 67].

Slide Tracheoplasty

Removal of the affected trachea with slide tracheoplasty has been described in an infant with congenital tracheal stenosis and TM after esophageal atresia with distal fistula repair.

Aortopexy

Aortopexy has been carried out through several approaches. Gross used a left anterolateral approach; Filler et al. used a right posterolateral approach in their first case, but shifted to a left anterior thoracotomy in the third intercostal space in the cases to come [4]. Gross removed part of the thymus and sutured the adventitia of the innominate artery to the posterior periosteum of the sternum with fine silk sutures. A detailed description of the technique was published in 1982 by the Toronto group [5]. In two cases a retropleural approach was used. The left lobe of the thymus was removed and the aortic arch and branches were exposed. The plane between the aorta and trachea was left undisturbed so that the anterior tracheal wall would follow the aortic arch when sutured to the sternum. Three to four nonabsorbable sutures were placed through the adventitia and a portion of the media of the following vessels: (1) aortic arch, at the level of the lateral border of the innominate artery; (2) anterior wall of the innominate artery, 0.5–1 cm from its origin; (3) aortic arch, at the level of the medial border of the innominate artery; and (4) aortic arch, 0.5 cm medial to the previous suture. The anterior sternum was dissected free and the ends of the sutures passed through the sternum and tied. Relief of the anterior compression of the trachea was evaluated either perioperatively or at the completion of the procedure. Spitz described in 1986 the use of a Dacron patch in order to distribute the traction on the aortic arch over a larger area [68]. Aortopexy through an anterior right thoracotomy has been performed as well [69]. Vaishnav and MacKinnon proposed a cervical approach with split of the upper sternum [70]. Brawn and Huddart advocated aortopexy

through a median sternotomy, claiming better access [71]. Bullard et al. entered the chest through a mediastinal window by resecting the costal cartilages II and III on the left [72]. When the distance between the aortic arch and the sternum is too long, a pericardial flap can be used to decrease the distance [73]. Some authors use pledge-supported sutures [74].

All approaches mentioned so far were performed through a thoracotomy. Thoracoscopic aortopexy was reported for the first time by DeCou et al. in 2001 [75]. Since then several reports of thoracoscopic aortopexy have been published [76–80]. Schaarschmidt did one aortopexy from the right in a patient who had a previous aortopexy through a left-sided thoracotomy [79]. Kane used a right thoracoscopic approach primarily [81].

Technique of Thoracoscopic Aortopexy [82]

Tracheal intubation and ventilation in combination with CO_2 insufflation are used. The child is placed in supine position close to the left edge of a short table (Fig. 49.1a). The left chest is 15° elevated, and the table is put in 15° reverse Trendelenburg. The left arm is abducted along the head so that the left axilla is free. The child's head is positioned in such a way that an intraoperative tracheoscopy can be performed. The midsternal line is marked for future suture insertion (Fig. 49.1b).

The surgeon stands at the left side of the table with the cameraperson below him and the scrub nurse at the lower end of the table (Fig. 49.2). The key screen is placed in front of the surgeon at the right side of the table, next to the patient's head. When intraoperative tracheoscopy is planned, the display of the tracheoscopy should be visible by the surgeon.

Three cannulae are inserted (Fig. 49.3). The first one is a 3.8 or 6 mm one for a 3.3 or 5 mm 30° telescope. In children below 2 kg, the smaller telescope is used. The first cannula is inserted in the midaxillary line at the level of the nipple. After confirmation that the first cannula is in the thoracic cavity, CO_2 pneumothorax is started. A pressure of 5–8 mmHg and a flow of 0.1–0.5 L/min usually suffice. There may be initial desaturation, which is counteracted by releasing the CO_2 pneumothorax, and adjustment of the ventilator setting (higher frequency but lower tidal volume). Two 3.5 mm cannulae for 3 mm instruments are inserted in triangle configuration with the telescope cannula, one lower down but more anteriorly and one higher up in the axilla. All cannulae should have snugly fitting sleeves for fixation to the thoracic wall. Fixating sutures should not only include the skin but also the underlying thoracic wall.

A magnificent view of the upper anterior mediastinum is obtained (Fig. 49.4a). Care is taken not to injure the left phrenic nerve, which lies in front of the left pulmonary pedicle. The mediastinal pleura is opened longitudinally over the thymus and the thymic gland is mobilized anteriorly and posteriorly. After complete anterior and posterior mobilization, the gland can be pushed to the right, but removal of the left portion makes the procedure easier. The aortic root with pericardial reflection, aortic arch, and innominate artery are freed but the adventitia is left intact (Fig. 49.4b). The area to be suspended is rather the ascending aorta and innominate artery and then the arch itself. When the distance between the aorta and back wall of the sternum is too large, then a pericardial patch with its base at the pericardial reflection on the aortic root can be constructed, but in small children the pericardium easily tears.

Sutures are placed transsternally in and out through the same 2–3 mm transverse skin incisions but through slightly different tracks through the sternum in order to create a bridge for the sutures (Fig. 49.4c). The best position for the sutures is a position directly in front of the vessels to be suspended. For identification of the best place, a needle is inserted through the skin and sternum in the upper midline. When the needle is in good position, a small incision is made. For transsternal suturing a rather large needle is needed. We have used Ethibond® 3/0 on a FS-1 needle, but others have used other materials and brands including Prolene® [75], Ticron® [48],

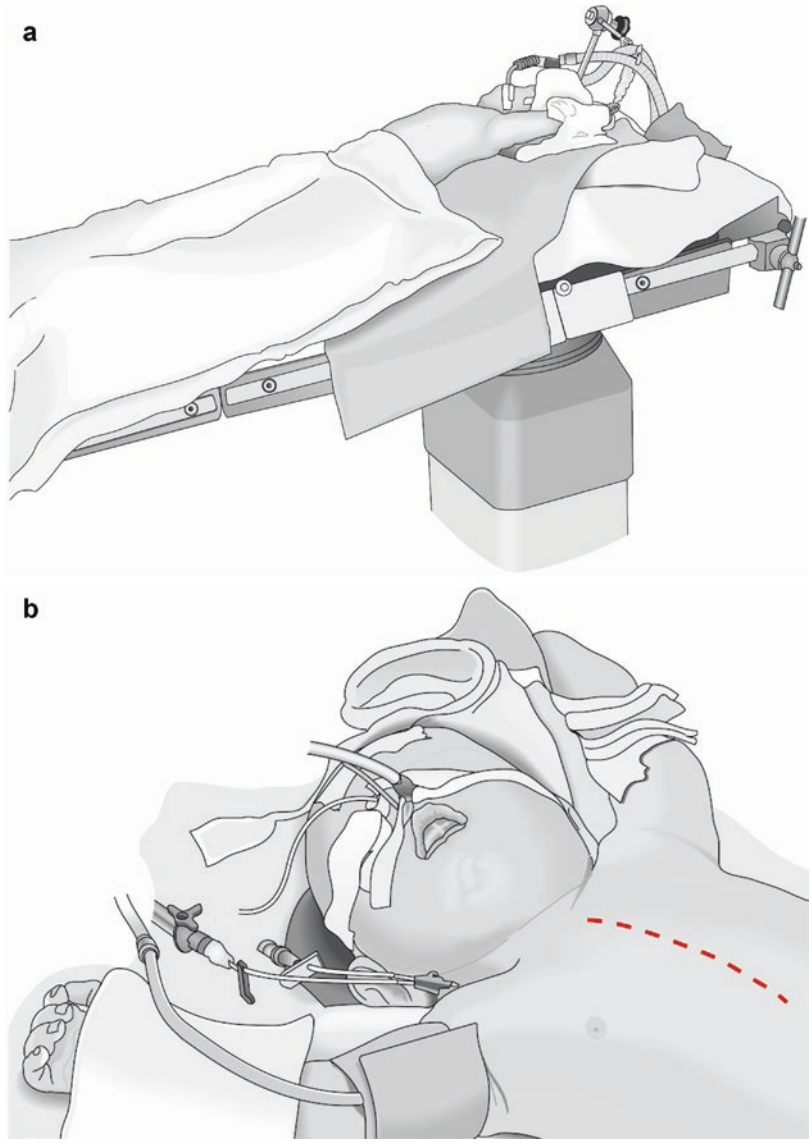

Fig. 49.1 (**a**) The child is placed in supine position close to the left edge of a short operating table (Reprinted with permission Bax and van der Zee [82]). The left chest is 15° elevated, and the table is put in 15° reverse Trendelenburg. The left arm is abducted along the head so that the left axilla is free. The child's head is put in such a way that an intraoperative tracheoscopy can be performed. (**b**) The mid-sternal line is marked for future suture insertion (Reprinted with permission Bax and van der Zee [82])

and silk [81]. The disadvantage of a large needle is its reduced maneuverability especially when the needle has been straightened. Moreover straightening of needles interferes with their design. For getting the needle out, a large-bore intravenous needle is passed transsternally through the same skin incision, but slightly more medial or lateral to the entrance of the suture so that a small bridge of sternum is between entrance and exit. The intrathoracic needle of the suture is then pushed into the intravenous needle and both are taken out en block (Fig. 49.4d). Getting a good bite of the adventitia of the aorta and innominate artery without taking the whole wall

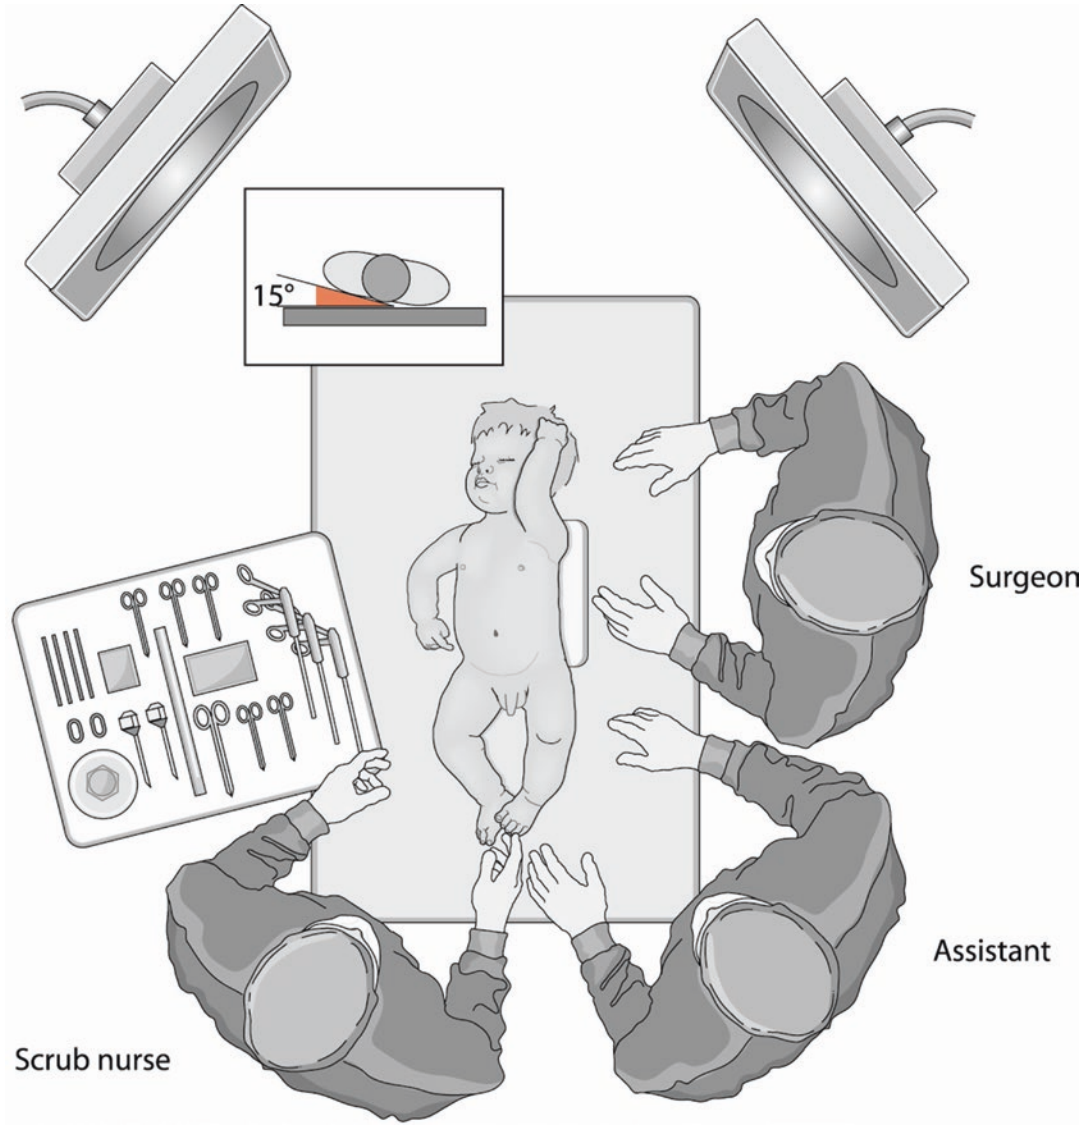

Fig. 49.2 The surgeon stands at the left side of the table with the cameraperson below him and the scrub nurse at the lower end of the table. The key screen is placed in front of the surgeon at the right side of the table, next to the patient's head (Reprinted with permission Bax and van der Zee [82])

is not simple, especially not with a large needle. Sutures with smaller needles can be used but these sutures should then be inserted through either a cannula or directly through the thoracic wall. The ends of these have then to be picked up transsternally with the use of nylon loops introduced through large-bore intravenous needles (Fig. 49.4e). At least three sutures should be placed, the first one at the pericardial reflection, a second one halfway the ascending aorta, and a third one at the takeoff of the innominate artery (Fig. 49.4c).

Perioperative tracheo-bronchoscopy has been advocated over and over again during the tying of the sutures, but TM is a dynamic event and spontaneous breathing is said to be important for evaluating TM. During aortopexy, however, children do not breathe spontaneously. Moreover the

child's position on the table during aortopexy is not ideal for a tracheo-bronchoscopy. Lastly, not much more than three of four sutures can be placed anyway. Dave and Currie, who published a series of 27 open and one thoracoscopic aortopexy, also have given up perioperative bronchoscopy [48]. During the tying of the sutures, care should be taken that the suspended vessels and especially the innominate artery do not kink. Pulse oxymetry of the right hand is helpful in this perspective. Pressing on the sternum during the tying of the sutures is advantageous as it decreases the distance between the sternum and the vessels to be suspended, thereby decreasing the likelihood of tearing out of the sutures.

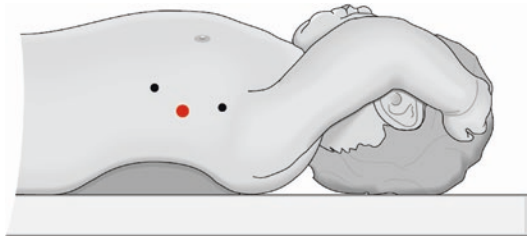

Fig. 49.3 Three cannulae are inserted. The first one is a 3.8 or 6 mm one for a 3.3 or 5 mm 30° telescope. In children below 2 kg, the smaller telescope is used. The first cannula is inserted in the midaxillary line at the level of the nipple. Two 3.5 mm cannulae for 3 mm instruments are inserted in *triangle* configuration with the telescope cannula, one lower down but more anteriorly and one higher up in the axilla (Reprinted with permission Bax and van der Zee [82])

At the end of the procedure, thymic tissue is removed when a partial resection has been undertaken. This can be done in a piecemeal fashion under vision with a mosquito inserted through one of the port sites. CO_2 pneumothorax is released, the lungs are expanded, and the skin incisions are closed with adhesive strips. A drain is not required when the procedure was smooth and lung trauma was avoided. Scars are minimal (Fig. 49.5).

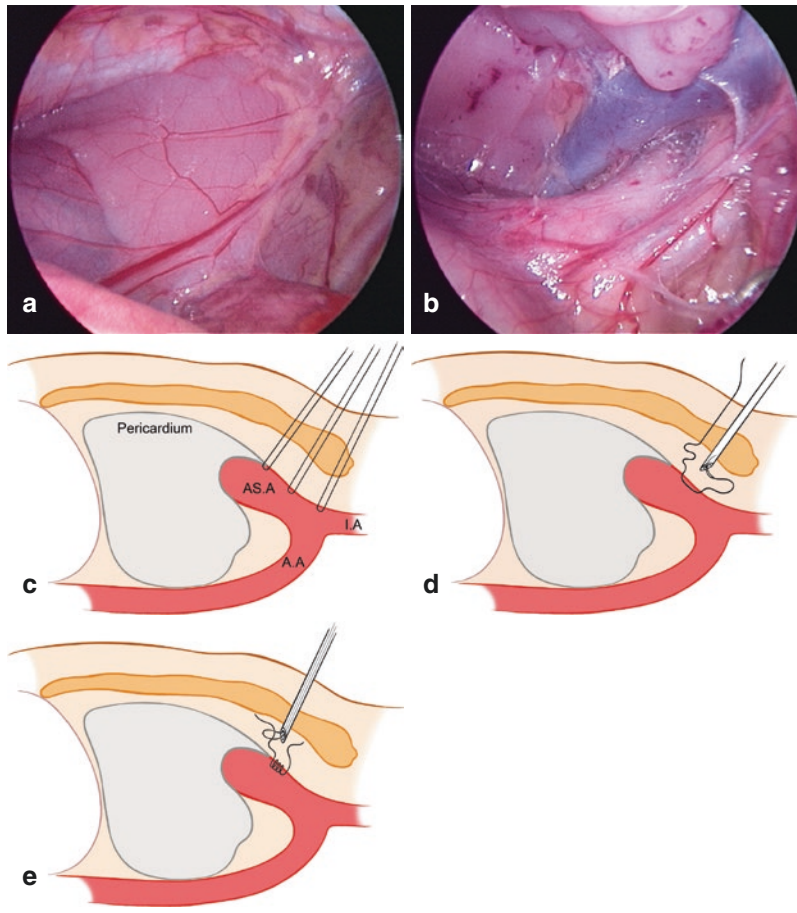

Fig. 49.5 The procedure results in minimal scars

Complications of Aortopexy

Massive hemorrhage due to tearing out of sutures that were inserted through the whole vessel wall has been described [71]. This can be avoided by meticulous placement of the sutures. Only bites of adventitia should be taken. It is stated that also part of the media should be included but this increases the likelihood of transarterial wall suturing. Phrenic nerve injury either transient or requiring plication of the diaphragm has been described [48, 74]. Postpericardiotomy syndrome and chylopericardium after aortopexy with pericardiotomy have also been described [83]. All these complications have been described after open aortopexy, but there is no reason why these could not happen after a thoracoscopic approach. Wound-related complications such as dehiscence have described after an open approach [74]. It is unlikely that these will occur when using a thoracoscopic approach.

Early Results of Aortopexy

When aortopexy is effective, detubation can be performed at the end of the procedure on the operating table or within a few days. The effectiveness of the procedure depends not only on the quality of the operation but also on whether the TM is idiopathic or not. In a series of 17 patients with idiopathic TM, aortopexy failed to relieve the symptoms in 10 of them (59 %) [31]. In contrast the same institution reported an 86 % improvement after aortopexy in series of patients with esophageal atresia [84]. In their series of 28 children with TM, 15 in association with esophageal atresia and 13 idiopathic, 26 responded well to aortopexy [48]. In TM in combination with esophageal atresia the success rate was 100 %; in idiopathic TM the success rate was 86 %. Recurrent chest infections and asthma-like symptoms however occurred in 25 % of the patients. In a series of 20 patients with TM, including five after esophageal atresia repair and two with double aortic arch, good long-term results with a mean follow-up of 7.8 years were obtained in 80 % of the cases [69].

Not many results after thoracoscopic aortopexy have been described. Van der Zee and Bax reported good results in four of six patients [80].

Fig. 49.4 (**a**) A magnificent view of the upper anterior mediastinum is obtained. The thymic triangle with sternum in front, phrenic nerve posteriorly, and pericardium distally is identified. The mediastinal pleura is incised over the thymus and the left thymic lobe is mobilized, pushed to the right or even better removed. (**b**) The ascending aorta with overlying pericardial reflexion and the innominate artery are identified. The adventitia is left intact. (**c**) Three nonabsorbable sutures are passed through small skin incisions through the sternum. The adventitia is taken in the sutures and the needles are passed back through the sternum parallel to the entrance passage and out through the entrance skin incisions. (**d**) Getting the suture needle out again is facilitated by passing a large-bore intravenous needle through the sternum parallel to the entrance trajectory and the suture needle is inserted into the tip of the intravenous needle. Both needles are then taken out en block. (**e**) Hitching the adventitia well, a smaller suture can be used. The ends of the suture can be taken out separately through the sternum using nylon loops inserted through large-bore intravenous needles

In two patients life-threatening events recurred after 2 and 4 weeks. Both patients had a repeat thoracoscopic aortopexy and did well afterward. Perger et al. reported about five patients, four of them having TM in association with esophageal atresia [78]. Two of them had a pneumothorax postoperatively. Symptoms resolved in all, but three out of the five kept on having respiratory infections.

Longer Term Results of Aortopexy

The contribution of aortopexy in the long-term results is difficult to determine as idiopathic TM and TM associated with esophageal atresia have a tendency to improve with time.

Conclusions

A higher awareness of TM will undoubtedly increase the diagnostic incidence of TM, especially of the milder forms. Tracheobronchoscopy remains an important diagnostic modality both for assessment of tracheal collapsibility during spontaneous breathing and for diagnosing associated anomalies of the tracheobronchial tree. High-quality imaging techniques like multidetector CT and MRI have become available. However general anesthesia is required for MRI and a CT scan exposes the child to radiation. Whether the use of such techniques is justified depends on the severity of TM.

There is no discussion that severe TM, and especially TM resulting in life-threatening events, should be treated aggressively. Thoracoscopic aortopexy is an excellent first treatment option. When it fails to resolve the symptoms, a laparoscopic fundoplication may be additionally needed. As thoracoscopic aortopexy is a much less invasive procedure than aortopexy through thoracotomy, its indications could be extended to moderate or even less severe forms of TM. Aortopexy, whether open or thoracoscopically, is not a panacea for all patients with TM. Stenting is an alternative, but not as a first treatment option.

Part X

Further Out from EA Repair: Functional Results and the Quality of Life

50 Long-Term Results: Prognosis, Developmental Milestones, and Quality of Life After Surgery for Esophageal Atresia

Daniel C. Aronson

Short-Term, Midterm, and Long-Term Prognosis

Over the last 70 years, the survival of patients with esophageal atresia has increased from 0 % to around 95 %. Today, mortality is largely determined by associated comorbidities, mostly the cardiac anomalies. The notion that a patient, who is discharged from hospital after successful reconstruction of an esophageal atresia, is definitely "cured" has been abandoned. Instead patients may be facing many long-term problems like feeding disturbances related to recurrent anastomotic stenosis, gastroesophageal reflux, and motility disorders. Additionally, respiratory problems, either caused by concomitant tracheomalacia or by gastroesophageal reflux with recurrent aspiration, are some of the important problems that mandate regular follow-up.

Respiratory problems in the first year of life may be caused by recurrent fistulas, gastroesophageal reflux, tracheomalacia, or associated anomalies such as laryngotracheoesophageal cleft. These must be promptly recognized and treated to prevent serious morbidity. For further information, we refer to previous chapters. Late mortality may be related to associate anomalies or may occur from late complications of the esophageal anomaly itself or of its treatment [1]. Even infants with a smooth initial course may eventually suffer sudden death related to tracheomalacia, gastroesophageal reflux, or food impaction in the esophagus [1, 2]. In many cases, respiratory problems tend to improve later in life, but up to 40 % of adults retain the typical barking cough of tracheomalacia and about 25–40 % continue to have respiratory problems such as recurrent wheeze, asthma, bronchitis, and pneumonia [3–5].

There has been much interest in late morbidity, which can be related to the esophageal anastomosis, to abnormal esophageal motility, to gastroesophageal reflux, and to respiratory problems [6–9]. Disturbed esophageal motility and concomitant gastroesophageal reflux have been the most troublesome problems, since this may cause strictures at the anastomotic site or at the lower esophageal sphincter. Abnormal esophageal motility contributes to long-term dysphagia in almost one third of the adult patients. This symptom is probably inadequately recognized, as some individuals are so adapted to their motility problem that they do not consider it to be abnormal [5]. A relationship between gastroesophageal reflux and Barrett's esophagus (intestinal metaplasia), esophageal adenocarcinoma, or squamous cell carcinoma has been reported [6, 7, 10, 11, 12]. However, the few described cases do not

H. Till et al. (eds.), *Esophageal and Gastric Disorders in Infancy and Childhood*,
DOI 10.1007/978-3-642-11202-7_50

unequivocally establish a relationship between esophageal atresia and the development of esophageal cancer.

Several studies have shown that gastroesophageal reflux and esophagitis persist in a significant number of adolescents and adults [5–8]. Since reflux and esophagitis may be obscure in patients with EA, the necessity for and the timing of a surveillance esophagoscopy have been under debate, especially in view of the potential development of Barrett's esophagus and esophageal cancer. Interval esophagoscopy has been recommended every 3–5 years [8]. However, not only the efficacy of screening but also its cost-effectiveness and the psychological aspects of implementation of a screening program must be taken into consideration, including subjecting (ex)-patients with minor or no complaints to invasive procedures under anesthesia [5].

Long-term growth and development have been reported to be within normal limits in most follow-up evaluations. A large proportion of patients are below the fifth percentile at 6 months of age but show catchup growth in almost all cases within the first 5 years of life [13].

Developmental Milestones

The dramatic improvements in the treatment of various congenital anomalies like esophageal atresia but also other chronic and even life-threatening diseases over the last few decades have lead to an increased survival of pediatric patients. The price of this success is a growing population of adults with a chronic condition. As a consequence, physicians will increasingly be confronted with young adults who have grown up with a chronic disease due to a congenital malformation. This requires physicians with special interest and knowledge of the implications of chronic pediatric disease, who can manage the transition from pediatric to adult medical care.

Children are continually developing via interaction with their environment. As Piaget and others demonstrated, their cognitive development progresses through a systematic and predictable sequence [14]. These norms are established for age, physical growth, and adaptive, cognitive, and social capacities and form a standard pattern of growth and evolution in healthy subjects with a normal mental development. Next to these steps in maturing, the achievement of developmental milestones in adolescence, such as the search for contact outside the family, or acquisition of independence, is essential to the adaptation to adult life. This is usually referred to as the "course of life" [15]. The impact of chronic diseases in childhood on the course of life is not yet fully defined. A chronic disease increases the individual's dependence on caregivers, decreases participation in peer-based or school-based activities, and hinders the achievement of developmental milestones [15]. This delay can be tested with a validated instrument called the Course of Life Questionnaire, developed to assess the course of life of young adults with a chronic disease thereby allowing comparison with healthy peers [16]. Items in this questionnaire relate to behavioral characteristics of certain ages, developmental tasks, and limitations children face growing up with a chronic disease. Most questions interrogate, whether the responder had achieved certain milestones or at what age they were achieved. Items are divided into five scales: autonomy development, psychosexual development, social development, antisocial behavior, and substance use and gambling. The only study done so far compared the course of life of a reference group of 508 healthy young adults with a group of 650 young adults with a chronic disease, all aged 18–30 years. The latter group was composed of 348 survivors of childhood cancer, 93 with anorectal malformations, 72 with Hirschsprung's disease, 61 with esophageal atresia, and 76 with end-stage renal disease [15]. In contrast to the other chronic diseases tested, only the course of life in the individuals who had been treated for esophageal atresia appeared to be as favorable as that reported by the control group and no delays in the domains tested were recognized. While factors such as coping with the disease, family functioning, and social support were not separately taken into account, this finding was explained by the authors by the fact that esophageal atresia is treated so early in life that it is not

experienced as a life-threatening disease. Affected individuals are therefore able to adjust to their condition and to participate normally in social activities. The authors of this study warn the reader that the course of life is measured in a retrospective manner, which limits the range of topics highlighted. In order to prevent bias due to inadequate memory, questions were factual and did not go further back to primary school.

Another study showed that most of the 119 adult individuals (16–48 years of age) with a reconstructed esophageal atresia were leading a normal life in regard to work or education. They were either employed and had finished high school (77 %) or were still in school full time (31 %) [5].

Quality of Life

The ultimate goal of treatment has moved from mere survival to alleviating symptoms and to improving quality of life. In the last decade, several study groups have therefore developed an interest in the influence of esophageal atresia and its long-term sequelae on the quality of life of surviving patients. Although before this époque several older studies mention quality of life after correction of esophageal atresia, most of these studies focus on the number of medical problems and on psychological development and not on quality of life per se [17–21].

Quality of life is studied by the use of standardized and validated quality of life questionnaires, comparing the quality of life of a certain patient group with healthy controls. Although definitions of quality of life vary widely, there is consensus about two central aspects. Firstly, quality of life should be assessed from the patient's perspective whenever possible. Secondly, quality of life should be regarded as a multidimensional construct incorporating at least three broad domains that can be affected by one's disease or treatment, including physical, mental, and social functioning [22, 23]. Most instruments in quality of life research can be classified as either generic or disease specific. The generic instruments are designed to measure all aspects of health and well-being regardless of the underlying disease and enable comparisons across different disease groups and with healthy reference groups. However, the generic instruments are limited as they do not measure aspects that are of particular relevance to specific disease groups, such as disease symptoms. Conversely, disease-specific measures examine the symptoms of specific disease groups and how they function. Various questionnaires are available to measure the generic or the disease-specific quality of life, and a choice is made by the study group, usually depending on the aim of the study and the age restrictions of the questionnaire [24]. Ideally, generic and disease-specific questionnaires are selected, and often, questionnaires that measure psychosocial functioning are added.

An example of a QoL questionnaire for adults is the 36-item Short Form Health Survey (SF-36), a widely used generic, validated questionnaire for health-related quality of life [25]. It contains scales of vitality, social functioning, emotional role functioning, and emotional well-being that make up the summary measure of mental health. Furthermore scales of physical functioning, physical role functioning, bodily pain, and general health perceptions make up the summary measure of physical health. Positive affect, an extra dimension of mental quality of life, can separately be measured by a Positive Affect Scale (PAS) [26, 27]. Examples of QoL questionnaires for children are the Child Health Questionnaire Child Form (CHQ-CF87) for children ≥10 years of age and the Child Health Questionnaire Parent Form (CHQ-PF50) for parents of children ≤13 years. These instruments use item scales for physical functioning, role functioning/emotional behavior, role function physical, bodily pain, general behavior, mental health, self-esteem, general health perceptions, family activities, family cohesion, and parental impact [28–30].

Examples of disease-specific quality of life instruments to assess symptoms and psychosocial functioning directly related to EA are Gastrointestinal Quality of Life Index (GIQLI) and the Respiratory Symptoms-Related Quality of Life Index (RSRQLI). The GIQLI is a 36-item questionnaire concerning four domains; physical

well-being, gastrointestinal symptoms, social well-being, and emotional well-being. Scores below a certain cutoff point indicate ongoing GI symptoms that can be further assessed by creating specific subdivisions for gastroesophageal reflux, functional gastrointestinal disorders, bowel function, etc. [31].

The RSRQLI has been developed by the pulmonologists and pediatric surgeons of the University of Helsinki [32]. The instrument was designed to measure the quality of life related to respiratory diseases through a 15-item questionnaire.

Many questionnaires measuring psychosocial functioning are available. To name a few that have been used in the literature reviewed, the Illness Cognition Questionnaire (ICQ) was developed to assess illness cognitions that reflect different ways of evaluating the inherently aversive character of a chronic condition [33]. It contains three scales, helplessness, acceptance, and disease benefits and as a supplement asks for the positive and negative influences of various aspects of disease on life [5, 33].

Self-esteem can be separately measured by the use of the Self-Perception Profile for Children (SPPC) which is a 36-item questionnaire designed for 8–12-year-olds [17]. Also instruments are available for the use of parents, such as the Child Behavior Checklist (CBCL) which tests behavioral and emotional problems of the child [34]. The Family Assessment Device (FAD) measures family functioning, and the Life Events Questionnaire (LEQ) has proved to be a reliable indicator of familial psychosocial stress [17, 35, 36]. The Rosenberg Self-Esteem Scale (RSES), the Beck Depression Index (BDI), and the Cohen's Test for Life Management Ability (CTLMA) have all been used in an attempt to define the negative impact of chronic diseases in childhood [32, 37].

To date, only six studies that have used standardized and validated quality of life questionnaires to study esophageal atresia patients are available. Unfortunately, the choice of questionnaire itself is far from standardized, which makes the comparison of the various studies complicated. In one of these studies, the quality of life for long-gap esophageal atresia patients is examined together with the functional results from eight patients after colon interposition [20]. Another study, from the same research group, examined the quality of life in 58 patients more than 20 years after correction of esophageal atresia [21]. These results showed "acceptable" quality of life after colon interposition and "excellent" quality of life after primary repair of esophageal atresia. A third study addressed the quality of life as medium-term outcome after primary and secondary gastric transposition for esophageal atresia in 28 patients with a mean age of 13 years [38]. Quality of life could not be completely compared to the quality of life of healthy individuals, since the GIQLI questionnaire had been modified to include more esophageal-specific items and exclude items inappropriate for the specific age groups tested. However, the mean scores of the individuals after primary gastric transposition remained within the 95 % confidence interval (CI) as compared to healthy individuals but were outside the 95 % CI after secondary gastric transposition [38]. The parental reports showed that children in both groups experienced difficulties in all aspects of eating, which affected their quality of life adversely. Patients after secondary gastric transposition experienced more disease-specific symptoms [38]. Koivusalo et al. [32] reported that the generic quality of life in most of the adults after esophageal atresia repair was no worse than that of the general population, but individuals with low health-related quality of life scores in the generic SF-36 questionnaires scored low in the disease-specific questionnaires (GIQLI and RSRQLI). GIQLI dimensions measuring gastroesophageal reflux were lower after esophageal atresia repair. Overall, in 15 % of patients, morbidity from esophageal functional disorders and/or respiratory disorders impaired health-related quality of life. Quality of life did not differ between different types of esophageal atresia or between the different types of esophageal reconstruction [32]. The study of Deurloo et al. [39] compared the generic quality of life after correction of esophageal atresia in a group of 16–48-year-olds with that of healthy controls and

found no differences in the overall physical and mental health. General health was reported to be worse in the 25 % of individuals that had persistent gastrointestinal complaints, e.g., dysphagia. Only 8 % of the patients indicated that they felt limited because of their reconstructed esophageal atresia. This subgroup of patients felt their quality of life to be significantly impaired in several dimensions. Overall, however, individuals at long-term follow-up after esophageal atresia correction perceived their quality of life to be good, although scores on the domains of general health and vitality were lower than healthy controls. Surprisingly, the presence of other congenital anomalies did not seem to influence the quality of life in this study group [39].

One study addressed the health-related quality of life in children and/or adolescents after reconstructed esophageal atresia among 37 patients aged 6–18 years and 24 parents [29]. In the individuals tested, most domains of the health-related quality of life assessment were comparable to healthy controls. But both the patients and the parents scored significantly lower on the domain general health perception. Specifically gastro-esophageal reflux symptoms reduced general health perception, as did older age at follow-up and concomitant anomalies. According to the parents, the esophageal atresia patients experience negative consequences in their daily life such as gastrointestinal symptoms. Effect sizes of this domain indicate a moderate-to-large clinical effect. Scores in the family activities domain showed that children and adolescents reported that their health did not limit or interrupt family activities nor was it a source of family tension. In fact, it may have even strengthened the relationships between family members.

In summary, two aspects of these quality of life studies are of great importance. In the first place, parents of newborns with esophageal atresia can be reassured that their child has a good long-term outlook and should be able to lead a normal life with normal developmental milestones. Secondly, health-care workers and parents should be aware that esophageal atresia-related symptoms have a negative influence on the health-related quality of life. Careful follow-up focused on diagnosing and treating these symptoms vigorously may further improve the long-term outcome on the quality of life.

Outcomes of Oesophageal Atresia Beyond Childhood: Helsinki Experience

51

Saara J. Sistonen, Mikko P. Pakarinen, and Risto J. Rintala

Introduction

Survivors of oesophageal atresia are reaching their adulthood in large numbers for the first time thus allowing assessment of true long-term outcome among these patients. Patients with repaired oesophageal atresia have significant gastro-oesophageal [1–5], respiratory [1, 2, 5–7] and musculoskeletal problems beyond childhood [2].

In 2003, we initiated a cross-sectional population-based follow-up study to evaluate late outcomes in adult patients, who had undergone neonatal repair of oesophageal atresia. We aimed to study oesophageal function and morbidity, oesophageal metaplasia and cancer, respiratory morbidity, and clinical characteristics of musculoskeletal anomalies, especially spinal defects, at adult age.

Patients and Methods

The original study population consisted of 588 patients treated for oesophageal atresia in the Children's Hospital, University of Helsinki, from 1947 to 1985. A total of 235 alive patients with their native oesophagus were included. Of the 235 contacted patients, 169 (72 %) responded. The first 101 (median age 36 years), who replied and agreed to participate, underwent clinical investigations. The clinical and demographical characteristics of the study group were statistically similar to those of non-participants (Table 51.9). All patients responded to a symptom questionnaire including questions about oesophageal, respiratory, musculoskeletal symptoms and quality of life (SF-36, GIQLI, RSRQLI). Age- and sex-matched healthy controls ($n = 287$) filled identical questionnaires. The study patients underwent upper gastrointestinal endoscopy with biopsies, oesophageal manometry, pulmonary function tests and full orthopaedic evaluation with radiographs. The incidence of cancer among oesophageal atresia patients was evaluated from population-based countrywide cancer registry that covers practically 100 % of all cancer cases.

Results

Survival

The survival with oesophageal atresia has dramatically improved since the beginning of its successful surgical treatment, being nowadays well over 90 % in dedicated centres [8]. Today, even most infants with very low birth weight and severe cardiac malformations survive due to improvements in surgery and in modern intensive care.

DOI 10.1007/978-3-642-11202-7_51

In the Children's Hospital, Helsinki University, Finland, mortality after oesophageal atresia repair has markedly decreased over the last decades (Table 51.1). In the early years, high mortality was associated with failure of surgical treatment, pneumonia, problems related to prematurity, and trisomies 18 and 21 with multiple anomalies. More recently, the main causes of death have been prematurity with low birth weight and trisomies 18 and 21 with major cardiac defects. Nowadays, nearly all patients will survive.

Table 51.1 Numbers of patients undergoing surgery for esophageal atresia and percentages discharged from hospital alive by year of operation in the Hospital for Children and Adolescents, Helsinki University, Finland, according to Louhimo [9] and our own work

Time-period	Number of patients	Survival (%)
1947–1956	100	19
1956–1960	100	43
1960–1965	101	56
1965–1971	101	70
1971–1978	100	85
1978–1985	86	85
1989–2007	89	97

Oesophageal Morbidity

Oesophageal atresia and its surgical repair disrupt the anatomy and innervation of the oesophagus, most likely contributing to oesophageal dysmotility. Oesophageal dysmotility predisposes to gastro-oesophageal reflux (GOR) and its complications. Significant GOR is a frequent finding after surgical repair of oesophageal atresia [2–5, 10–14], necessitating medical or surgical management in most children. Several recent endoscopic studies of adult oesophageal atresia patients have frequently demonstrated oesophagitis and intestinal metaplasia (Table 51.2), and even cases of oesophageal cancer (Table 51.3).

Oesophageal atresia is often associated with various oesophageal symptoms: regurgitation, heartburn, aspiration and dysphagia. Incidence of dysphagia ranges from 39 to 77 % and GOR from 17 to 63 % [2–5, 10–14, 22]. Most of these studies involved children and adolescents, but not adults. Typical late complications of the oesophageal anastomosis are oesophageal stricture in 30–56 % and recurrent tracheo-oesophageal fistula in 5–14 % [6, 7, 14, 23, 24]. Strictures are more common in patients with long-gap atresia

[6]. Persistent strictures are often associated with GOR [25] and thus require prompt antireflux treatment with fundoplication in addition to dilatations or stricture resection or both.

Oesophageal atresia is also associated with oesophageal dysmotility, low oesophageal distal wave amplitudes and non-propagating peristalsis of the oesophagus [10–12, 26]. Lack of distal oesophageal contractions correlates with the development of GOR [26], and patients reporting dysphagia often will have more disturbed motility and lower scores for quality of life [13].

In our population-based adult study, GOR occurred in 34 % and dysphagia in 85 % in patients post-oesophageal atresia repair versus 8 % and in 2 % in healthy controls ($p < 0.001$ for both). The endoscopic findings included hiatal hernia (28 %), Barrett's oesophagus (11 %), oesophagitis (8 %) and anastomotic stenosis (8 %). Three patients had an oesophageal diverticulum at the site of the anastomosis, and one recurrent tracheo-oesophageal fistula was found and treated successfully by bronchoscopy and laser. Histology showed oesophagitis in 25 % and epithelial metaplasia in 21 % (15 % gastric and 6 % intestinal metaplasia). All epithelial metaplasia were CDX2 positive, and those with intestinal metaplasia also demonstrated MUC2 positivity. Oesophageal metaplasia was associated with oesophagitis in 7 of the 21 patients. None of the patients had oesophageal dysplasia or carcinoma. The occurrence of pathological findings at endoscopy or histology had no correlation with symptoms of GOR or dysphagia. Patients with oesophageal columnar metaplasia had more anastomotic complications than do the rest of the patients (Table 51.4).

Oesophageal manometry demonstrated non-propagating peristalsis in most patients and ineffective distal oesophageal pressure in all. Manometrical abnormalities were significantly more common in those with epithelial metaplasia ($p < 0.02$) (Fig. 51.1).

Bars represent wave amplitudes of the oesophagus. The first column represents the minimum of normal values; the second, a median value for all patients; and the third, the value for patients with metaplasia. Normally, distal wave amplitudes grow stronger when moving from the proximal to the distal oesophagus. All adult patients with repaired oesophageal atresia had low distal wave

Table 51.4 Anastomotic complications

Complication	All ($n = 101$) N (%)	Metaplasia ($n = 21$) N (%)	p-value
Early stricture resection	4 (4)	3 (14)	0.06
Recurrent fistula	10 (10)	6 (29)	0.02
Late stricture	8 (8)	5 (24)	0.03
Long gap requiring myotomy	5 (5)	4 (19)	0.03

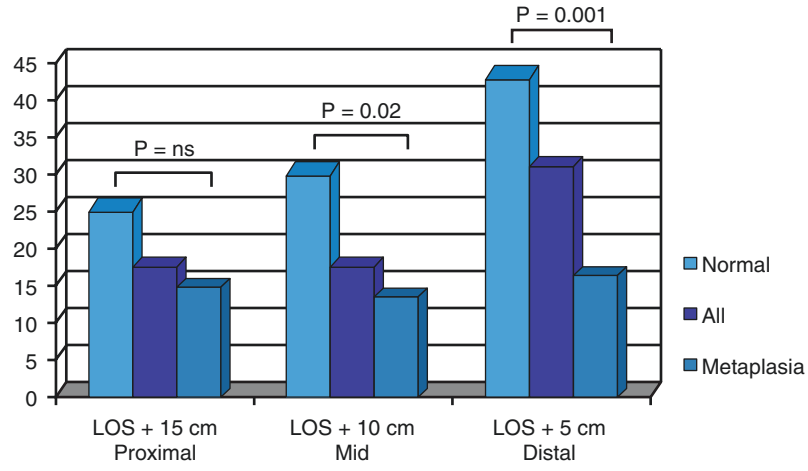

Fig. 51.1 Oesophageal distal wave amplitudes in the proximal, mid- and distal oesophagus

amplitudes, and patients with metaplasia even lower. In addition, none of the patients with epithelial metaplasia exhibited propagating peristalsis, and the difference between all patients and patients with metaplasia was significant ($p \leq 0.02$).

Anastomotic complications, age, low distal oesophageal pressure and defective peristalsis predicted development of epithelial oesophageal metaplasia (Table 51.5). Of the patients with epithelial metaplasia, 72 % were male, and 76 % were older than 30. The occurrence of epithelial metaplasia was associated with increasing age.

Cancer

Reports on oesophageal cancer among young adults with repaired oesophageal atresia (Table 51.3) arouse concern about risk for oesophageal cancer after repair of oesophageal atresia, and the necessity of long-term surveillance beyond childhood. Reflux oesophagitis and oesophageal columnar metaplasia are typical findings among oesophageal atresia patients and represent risk factors for oesophageal adenocarcinoma.

Despite high incidence of oesophageal metaplasia, none of the Finnish oesophageal atresia patients had oesophageal cancer. The number of person-years at risk was 8,034. Three patients had had cancer in other organ systems (SIR, 1.0; 95 % CI, 0.20–2.8); one had a lymphoma in the small intestine, one leukaemia and one uterine carcinoma. The overall cancer incidence was similar as in the general population. Our study showed that the statistical risk for oesophageal cancer after repair of oesophageal atresia was less than 500-fold than that of the general population.

Table 51.5 Multivariate logistic regression model for occurrence of oesophageal epithelial metaplasia

	OR (95%CI)	*p*-value
Early stricture resection	24.0 (2.3–260)	0.008
Recurrent fistula	24.0 (2.2–250)	0.009
Age >30 years	20.0 (1.3–310)	0.034
Long gap requiring myotomy	19.0 (2.0–180)	0.011
Late stricture	8.6 (1.7–45)	0.011
Distal wave amplitudes <25 mmHg	2.6 (0.68–10)	0.002
Non-propagating peristalsis	2.2 (0.43–11)	0.014

Respiratory Morbidity

Respiratory problems are also common in children and adolescents with oesophageal atresia and tracheo-oesophageal fistula [2, 6, 27, 28]. The occurrence of respiratory symptoms ranges from 33 % to 41 % [2, 5, 27–29]. Typical respiratory symptoms associated with oesophageal atresia include aspiration, failure to thrive, choking, wheezing, persistent cough, repeated respiratory infections and asthma [6, 27, 28, 30]. Wheeze occurs in approximately 37 % of the survivors of oesophageal atresia with no tendency to improve with age [8, 27, 29, 31]. Prevalence of doctor-diagnosed asthma during childhood and adolescence after repair of oesophageal atresia has been 12–29 % [5, 28–31]. Such a prevalence seems higher than in the general population of children (8.8 %) [28] and in adults (6 %) [32]. Approximately 10–20 % have severe tracheobronchomalacia with airway instability and collapse [8, 33]. Recurrent respiratory infections, persistent cough and wheeze are typical symptoms in childhood [27] and in adolescence [28], with a tendency to improve with age. However, repeated infections, aspiration and persistent tracheo-oesophageal fistula may result in irreversible lung damage with bronchiectasis and chronic pulmonary disease. Recurrent chest infections such as bronchitis and pneumonia occur in up to two-thirds of the survivors in the early years of life, but respiratory morbidity decreases in frequency and severity as the child reaches late adolescence [27].

In the few adult studies on oesophageal atresia patients, 33 % had respiratory symptoms [2, 5], and restriction was the main ventilatory defect [1, 2]. A strong connection exists between severity of GOR and persistence of respiratory symptoms among oesophageal atresia survivors. Although

such respiratory problems are common in children and adolescents, long-term outcomes beyond childhood have been unknown.

In our study, the patients had significantly more respiratory symptoms and infections as well as asthma and more often impaired respiratory symptom-related quality of life when compared to those of controls ($p \leq 0.002$) (Table 51.6). Among our adult oesophageal atresia patients, 11 % and 2 % of the controls had current respiratory symptoms ($p < 0.001$). Fifty-six percent and 70 % of the patients had a history of pneumonia and bronchitis (controls 20 % and 50 %, $p < 0.001$); 16 % of the patients and 6 % of the controls had doctor-diagnosed asthma ($p < 0.001$). Impaired respiratory-related quality of life was reported by 11 % of the patients but only in 6 % of the controls ($p < 0.001$).

Pulmonary function tests (Table 51.7) showed obstruction in 21 %, restriction in 21 % and both in 36 % of the patients. Only 20 % of the patients had normal pulmonary function. Bronchial hyperresponsivenes was detected in 41 % of the patients in histamine challenge test, and in 15 %, it was compatible with asthma. A total of 11 % had elevated exhaled nitric oxide levels indicating airway inflammation. Thoracotomy-induced rib fusions and surgical complications leading to GOR-associated oesophageal epithelial metaplasia were the most significant risk factors for restrictive ventilatory defect.

Of children and adolescents with repaired oesophageal atresia, restrictive pulmonary function occurs in 21–40 %, and obstructive PF in 12–54 % [28, 34–36]. The pulmonary function abnormalities did not correlate with current respiratory or oesophageal symptoms. The reason for pulmonary function abnormalities remains unclear, but it has been suggested that they were caused by permanent lung damage from recurrent aspiration in the patients' early years [2], by poor tracheal clearance leading to recurrent episodes of bronchitis or pneumonia leading to lung damage [30, 35] or by poor lung growth during infancy [36].

Prevalence of bronchial hyperresponsiveness in a general healthy population with normal lung volumes was 17 % [37]. Increased bronchial responsiveness has been described in 36 % of oesophageal atresia patients with tracheo-oesophageal fistula, reflecting sequelae of chronic lung disease from damaged epithelium in the airways [36]. Severe or moderate bronchial hyperresponsiveness is associated with a more restrictive ventilatory defect [28]. No correlation has emerged between increased bronchial hyperresponsiveness and history of doctor-diagnosed asthma or atopic eczema [28, 36].

Table 51.6 Self-reported incidence of asthma, allergy and respiratory symptoms of the participants with repaired oesophageal atresia ($n = 101$) and of the controls ($n = 287$)

Spinal and Other Skeletal Abnormalities

Reported incidences of vertebral and other skeletal anomalies in association with oesophageal atresia have ranged from 9 % to 24 % [23, 38–40]. The occurrence of musculoskeletal defects and scoliosis due to thoracotomy is even more common [41–43]. Many of the skeletal and hand anomalies are not evident in infancy and in childhood, and therefore, their real incidence and natural history remain unclear.

Table 51.7 Pulmonary function, bronchial hyperresponsiveness, exhaled nitric oxide and skin prick test among adults with repaired esophageal atresia ($n = 101$)

Variable	Result mean (range)	Abnormal (%)	Grade mild	Moderate	Severe

FVC forced vital capacity, *FEV1* forced exhaled volume in 1 s, *PD15FEV1* provocative dose of histamine causing a 15 % fall in FEV1, *Restriction* = FVC <80 % = Z-score ≤2.0, *obstruction* = FEV1/FVC <87 % = Z-score ≤2.0

In our adult study population, vertebral anomalies were detected in 45 %, most commonly in the cervical spine (in 38 % of the patients). Most of these were vertebral fusions in C2–3 and C6–7 (Fig. 51.2). The most significant risk factor for vertebral anomalies was any additional anomaly. Clinical and radiographical scoliosis was found in 56 % of the patients; the risk of significant scoliosis was 13-fold when compared with healthy population (Tables 51.8 and 51.9). Thoracotomy-induced rib fusion and other associated anomalies were the strongest predictors for scoliosis. The most common type of scoliosis was upper thoracic (in 31 %) (Figs. 51.2 and 51.3) and showed concavity towards the thoracotomy site. In most patients, the clinical course of scoliosis was mild and did not require bracing or spinal surgery. Radial ray anomalies were found in 25 % of the patients, of which most were thenar aplasias or hypoplasias. Few patients have had floating thumb that has been corrected successfully with pollicisation of the index finger. In the majority of the patients, the vertebral anomalies and radial ray anomalies were not detected or recorded during the initial management period and follow-up during childhood.

Fig. 51.2 Radiograph of cervical spine with multiple vertebral fusions and of severe thoracic scoliosis

Deformities of the chest wall and spine may result from associated vertebral and skeletal anomalies or be due to thoracotomy. Previous studies on patients with repaired oesophageal atresia have reported "winged" scapula in 24 % [45], anterior chest wall deformities in 20 % [45, 46] as well as rib fusion and female breast deformities. We found

TOF tracheo-oesophageal fistula, *VACTERL* vertebral defects, anal atresia, cardiovascular anomalies, tracheo-oesophageal fistula with oesophageal atresia, radial and renal dysplasia, limb defects

shoulder asymmetry in 80%, chest wall deformities in 15% and rib fusions in 30%. Shoulder asymmetry, "winged" scapula and limited motion of the right upper extremity result from paralysis of the latissimus dorsi muscle, and chest wall deformities from atrophy of the serratus anterior muscle, thoracotomy-induced rib fusions, scoliosis or other deformities of the thoracic cage (pectus carinatum or excavatum).

Quality of Life

The adult oesophageal atresia patients had more frequently impaired gastrointestinal (GIQLI<105 in 23% of the patients vs. 8% of controls) and respiratory-related (RSRQLI<45 in 12% of the patients vs. 2% of controls) quality of life in relation to controls ($p<0.001$). There was no difference in the total scores of disease-specific quality of life (GIQLI and RSRQLI) and in the overall health-related quality of life (SF-36) between the patients and controls.

In a previous study, adults with repaired oesophageal atresia achieved a gastrointestinal quality of life index (GIQLI) score similar to that of their general population-derived controls, and no difference in health-related quality of life, even though they had more dysphagia and GOR and a lower respiratory symptom-related quality of life [47]. In another study, one-third of the adult survivors have had negative effects of

Fig. 51.3 Radiograph of cervical spine with multiple vertebral fusions and of severe thoracic scoliosis

oesophageal atresia on their daily life, especially dysphagia, but their generic quality of life, as well as physical and mental health, was good [48]. Patients reporting dysphagia more often had disturbed motility and lower scores for quality of life [48]. In a third study, the GIQLI results were similar after primary anastomosis for oesophageal atresia to those of healthy controls [49].

Conclusions

Morbidity associated with oesophageal atresia is significant in adults. Oesophageal symptoms such as dysphagia and GOR were common as well as abnormal oesophageal histology. There was no association between oesophageal symptoms and histological findings. Surgical complications, increasing age and impaired motility predicted the occurrence of epithelia metaplasia. Oesophageal anastomotic complications appeared to further impair oesophageal motility and GOR; these predisposed to the development of epithelial metaplasia that commonly occurred (21%) among adults with repaired EA. However, we found no cases of oesophageal cancer among adult study population. The overall cancer risk of adults with repaired oesophageal atresia was similar to the general population. However, the study population was relatively young; therefore, continuing follow-up and further studies are required to clarify the risk of oesophageal cancer and also define guidelines for long-term endoscopic surveillance of adult oesophageal atresia patients.

Respiratory symptoms, asthma and infections were more common in oesophageal atresia patients than in the controls. Obstruction and asthma were common, but bronchial hyperresponsiveness and restrictive ventilatory defect increased in frequency with age. Thoracotomy-induced rib fusions and GOR-associated columnar metaplasia were the strongest risk factors for restrictive ventilatory defect. Impaired respiratory-related quality of life and respiratory-related morbidity extended into adulthood in significant number of patients.

Over half of the patients with repaired oesophageal atresia developed scoliosis. Risk factors for scoliosis were 13-fold after repair of OA in relation to the general population. Vertebral abnormalities, especially cervical anomalies, and radial ray anomalies were also common; most of these had not been detected earlier. However, the overall quality of life of the patients was comparable with healthy controls.

Surgical complications, patient age and impaired oesophageal motility were significant predictors of development of oesophageal epithelial metaplasia, suggesting that a tight primary oesophageal anastomosis and reoperations due to surgical complications further impair oesophageal motility, predisposing to epithelial metaplasia. Columnar epithelial metaplasia of

the oesophagus is a preneoplastic condition arising as a result of GOR, and it remains still unclear whether the presence of intestinal metaplasia is required for neoplastic potential [50]. The patients with epithelial metaplasia showed significantly lower median wave amplitudes in the distal oesophagus as well as decreased frequency of propagating peristalsis. Thus, primary anastomosis under considerable tension and the repeated, often extensive, surgical dissection during reoperations may result in additional neuromuscular damage and predispose to further impairment in oesophageal motility, GOR and subsequent development of oesophageal epithelial metaplasia. Although definitive recommendations concerning surveillance endoscopies cannot be given based on our study, screening endoscopy may be warranted after 30 years of age at least for patients with operative complications and long-gap EA.

The Minnesota Experience

52

Khalid M. Khan

Introduction

It is well known that the typical case of esophageal atresia (EA) which includes a tracheoesophageal fistula (TEF) is managed by a primary repair procedure soon after birth. Where the esophageal defect is long, a primary repair is not possible and a variety of alternatives have evolved. At the University of Minnesota, a unique procedure was developed over two decades ago as a direct response to the use of the stomach, colon, or small intestine to replace the esophagus and in the belief that the esophagus itself is the best conduit to the stomach. This procedure involved applying traction to grow the native esophageal ends to the point that a primary repair can be performed and has been used in infants with almost no discernible lower esophageal remnant. Here, we discuss the procedure and outcomes.

Background

Esophageal atresia is a congenital defect of the mid-esophagus that results in blind proximal and distal esophageal pouches that are evident at birth. In the most common variant accounting for around 70–80 % of cases, there is a fistula from the lower esophageal pouch to the trachea (type C) [1]. The length of the lower pouch is preserved as a result of tethering via the fistula to the trachea. Conversely, in infants born without a fistula to the lower end (type A or pure EA), the lower esophageal pouch is not well formed. As would be expected, the situation is similar when a fistula is present only from the proximal pouch to the trachea (type B). The most severe configuration of pure EA comprises an upper pouch that terminates in the neck and the lower segment remains below the diaphragm. In practice for the majority of type C cases with a short gap, primary repair is possible soon after birth. Gaps of 2.5–3 cm are considered long as primary repair in these cases is often not possible [2]. For the minority of patients with a miniscule lower segment that may only reach the diaphragm, a primary anastomosis is usually considered impossible [1–3].

Methodology to circumvent a long gap has included delaying the anastomosis so that some growth can occur with time. A myectomy of the circular muscle or formation of a rotating flap from the esophageal pouch has also been used to preserve the esophagus, while the miniscule lower pouch is often removed altogether and either the stomach, small bowel, or colon has been brought up to provide continuity with the upper esophageal pouch; the gastric cavity may be dissected longitudinally or including the fundus to provide a tube or pulled through the hiatus

relocating partially in the thoracic cavity [4–6]. More recent developments include transplantation, tissue engineering, and using stem cells to reconstitute the esophagus [7].

The Minnesota Method

While the University of Minnesota has a long history in the area of transplantation, thinking in regard to repair of long-gap EA was taken in a different direction by Dr. John Foker [1, 2]. He hypothesized that the knowledge that tissue has an ability to regenerate, grow, and develop given the appropriate stimulus should be applicable to the esophagus particularly in infants. At this age, there is continuing growth and therefore the possibility that this process can be enhanced. Indeed, delayed primary closure aimed to take advantage of this process. Traction was certainly known to be an effective method for expanding tissue particularly skin though it was not implicit for a complex structure such as a viscus. Foker proposed the application of traction directly to the esophageal ends as a simple technique that is possible only in the esophageal part of the alimentary tract because the esophagus is uniquely fixed at both ends.

Preoperative Assessment and the Esophageal Gap

Assessing the gap length is a prerequisite to deciding on appropriate treatment. The standard methodology to assess the gap between the two esophageal pouches involves radiographic imaging. An upper pouch fistula can be assessed with instillation of contrast though caution is necessary to prevent significant aspiration. The presence of a lower pouch fistula is signified by air in the stomach. The absence of air in the stomach requires assessment with contrast after a gastrostomy is fashioned. The true length of the lower segment and therefore the gap length do need to be explored, and we have typically performed contrast studies while distending the two pouches with probes to have a better understanding of how the two pouches may behave intraoperatively. Even on a posterior-anterior radiograph, there may be inaccuracy in assigning gap size, and vertebral body size is used as markers of length. Ultimately intraoperative assessment with and without tension applied to the esophageal ends is the best measure of the ability to perform a primary repair and has been fundamental to the algorithm that determines the need for traction (see below). Endoscopic assessment is part of the initial evaluation of the upper and lower esophageal pouches for occult fistula and integrity of both segments (Fig. 52.1).

The Surgery

The details of the method have been published previously [1–3]. In brief, the esophageal gap is first estimated using a contrast radiographic study. The initial operative procedure is posterior right thoracotomy between the fourth and seventh ribs. The two ends of the esophagus are assessed as to whether a primary anastomosis is possible. If an anastomosis cannot be formed, sutures with radiopaque markers are placed in the ends of the two esophageal segments and traction

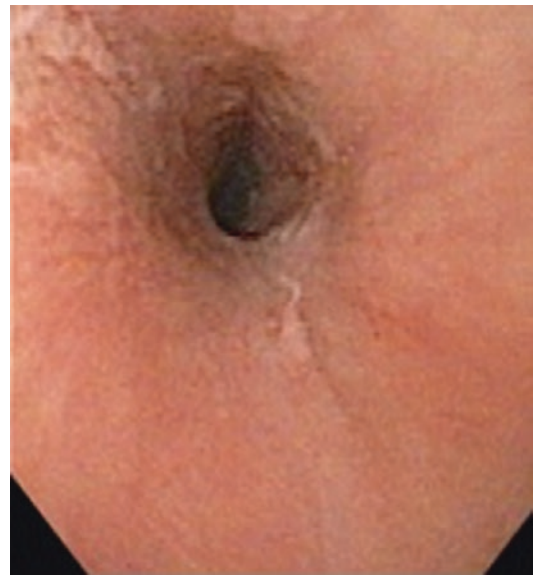

Fig. 52.1 Endoscopy through the gastrostomy site showing the appearance of the lower esophageal segment

is applied. For external traction, the sutures are crossed and brought out of the back above and below the incision and tied over silastic buttons (Fig. 52.2). The sutures are shortened up to three times per day and tension maintained until the two ends of the esophagus are seen to be close enough on a radiograph to attempt an anastomosis. Internal traction is considered for relatively smaller gaps for 3–4 days, and sutures are attached to the prevertebral fascia. Of note, the procedure was subsequently applied to long irregular caustic strictures facing the prospect of esophageal resection.

Along with the change in the radiographic appearance of the opaque markers at the tip of the esophageal segments, a reduction in the tension of the sutures signals the need to regularly tighten the traction sutures. Where there is doubt regarding slippage of the sutures, the intraoperative examination of the esophageal segments allows estimation of thickness, and endoscopy allows an examination of mucosal integrity. Furthermore, we have used ultrasound to examine the mural structure and found that it is maintained throughout the traction process [3, 8]. Of note, a separating barrier between the esophagus and the surrounding structures is placed to reduce adhesion formation. The almost constant traction applied to the esophageal segments likely also plays a role in minimizing adhesion with adjacent structures.

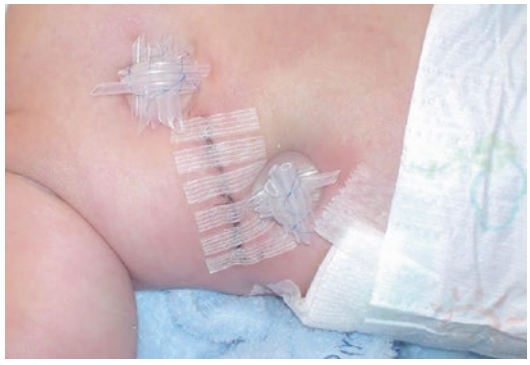

Fig. 52.2 Sutures attached to the esophageal ends are brought out of the back above and below the incision and tied over silastic tubes. The sutures are tightened frequently to maintain the tension on the respective esophageal ends

The Minnesota Series

The series comprised of patients mostly from outside of the state of Minnesota. After the initial success of the program, international referrals were also seen including the patients and the technique. Patients were in a variety of states that included having prior esophagostomy, colon interposition, and failed attempts at primary repair with a recurrent communication to the thoracic cavity. The majority of referrals were infants though those who had failed an attempt at delayed primary closure were often young children. Gaps of over 10 cm were recorded in these infants with the worse cases showing almost no recognizable lower esophageal segment. The breakdown of patients managed at the University of Minnesota by gap length is shown in Table 52.1. Of note, in the last decade, no patient has failed primary repair after traction despite gap length.

Perioperative Outcome

The extensive nature of the surgery typically means that the patient is not extubated immediately following the primary repair procedure. Anastomotic leaks are of the greatest concern following primary repair especially in our population given that the anastomosis is performed under tension. Table 52.2 outlines the problems that developed with using traction in patients with long-gap EA managed at the University of Minnesota.

A combination of contrast and endoscopy is routine to confirm adequacy of the anastomosis. Dilation is typically performed, “as needed” in

Table 52.1 Gap length of esophageal atresia cases managed at the University of Minnesota (1990–2007)

Long gap	2.6–3.4 cm	17
Ultra long gap	≥3.5 cm	70
	3.5–4.5 cm	(23)
	4.6–5.9 cm	(27)
	6.0–9.9 cm	(16)
	>10 cm	(4)
Total		87

≤3.5 cm	17/65	25 %
≥3.6 cm	68/70	97 %

the common case of EA-TEF; however, we have learned that anastomotic narrowing is inevitable, and therefore gentle dilation is performed at 3 weeks following anastomosis. This is repeated at 2–3 week intervals based on the anastomotic appearance itself. Typically between three and five sessions, it seems to be necessary to understand whether the anastomosis will relent, and increasing intervals between assessments tend to be confirmatory. The timing of dilations and the length of time necessary to achieve an adequate lumen cannot be predicted to develop a suitable protocol for all patients as each cased differs. For difficult cases, we have started to use stenting as a technique to reduce the need for dilations [9]. We begin feeding patients as soon as possible and despite some narrowing as the eating process itself serves to help the dilation process. Not surprisingly, the longest gaps have been the most challenging not only operatively but in the extent to which they stricture. Most of our patients with extremely long gaps undergo fundoplication as there is a natural tendency for the gastroesophageal junction to be pulled in to the diaphragmatic hiatus (Table 52.3). The fundoplication is also far from straightforward given that the gastroesophageal junction has to be reestablished in the abdominal cavity.

Results

The results of the Minnesota practice have been outlined in a number of publications that have focused on the various issues that have needed to be addressed during development of the program. The earlier descriptions were focused on surgical technique and thereby proof of principal [2]. Outcomes and the clinical progress of patients have been reviewed periodically. As expected in a patient group that is characterized with major non-EA-related comorbidities, deaths were recorded in patients managed at the University of Minnesota (Table 52.4). No deaths were however related to the management of the EA itself.

The successful early management of these cases is paramount for resuming a normal course to feeding and childhood development, and to this end, we have shown that despite delays in feeding, which in some cases was years, the feeding pattern can be established without resorting to unusual diets [10]. We have not noted any tendency to aspiration or sinopulmonary problems in the short term other than those with laryngotracheal clefts, though this is a possibility given the atonic nature of the lower esophagus. However, we would not expect this to be different to the standard EA-TEF repair. Table 52.5 shows our review of a proportion of the patients after 3 years, and Table 52.6 shows the most recent data. These data indicate that gastroesophageal reflux is a possibility in a proportion of patients. Of the more recent cases, comorbidities such as chronic lung disease related to prematurity were

noted to be an issue (Table 52.6). To put all of these follow-up issues in context, it has been well documented that even patients with delayed closure may have feeding problem, and feeding problems are not uncommon especially in patients with long-gap EA despite the type of management of strategy [11–15]. Furthermore, it has been previously shown that there is a significant chance of loosening of the wrap in patients who have undergone fundoplication after EA repair especially in long-gap EA cases [13].

The Role of the Foker Technique

Given the novel nature of the procedure described by Foker, there had to be a validation of the technique from sources other than our center, and after the initial reports, the technique has been attempted by others around the world [16]. There remains a debate as to the role of the procedure. We have argued that it represents the ideal treatment for long-gap EA. To preserve the esophagus has a number of advantages. Not only is there anatomical normalcy, but the physiological and psychological relationship to food is largely preserved. It should be appreciated that apart from the pleasure of it, eating defines growth, bonding, and socializing functions of normal development and life in general. The use of a flap or myotomy allows the continuity of the esophagus to be established; however, there is an obvious limitations to large or many myotomies in creating a mural weakness that may result in herniation of the mucosa to form diverticula. Similarly, the possibility of dissection of the pouch for elongation process has serious limitations particularly for long gaps, and similarly, a delayed repair is not likely to be possible in the truly long gap.

The concern regarding the long-term outcome in children is different to adult disease. As would be intuitive, patients undergoing gastric, colon, or jejunal transposing surgery cannot by definition eat normally [14]. The normal gastric reservoir is either bypassed or obliterated depending on the surgery. Furthermore, gastric transposition results in a conduit rather than a cavity. The issues with colon transposition further include a relatively atonic state, and the possibility of colon cancer cannot be excluded with time. Similarly, the exposure of the proximal esophagus to gastric acidity is a risk for Barrett's metaplasia. The clearance of the upper esophageal area is likely impaired in most of these circumstances though it is not known because of the small number if there is truly an adverse outcome.

The creation of a solution that will last a child's entire life has been the ultimate goal. We have always held to the notion that the comparison should be with alternatives for the management of long-gap EA and not to EA-TEF repair. Displacing any organ or tissue from its original location and function is likely to be a less than perfect solution particularly when it comes to the colon and gastric displacement. In the case of the former, we should acknowledge that colonoscopy or some form of surveillance is recommended after the age of 50 years in normal individuals in the United States, and therefore would need to be factored in. Furthermore, the loss of the normal position of the gastroesophageal junction is a major concern for intestinal metaplasia of esophageal tissue and is likely in the case of gastric transposition. Admittedly, our series lacks long-term data to quantitate any complications into adult life; however, the situation is not dissimilar with other organ use. This is partly as a result of the small numbers of such patients. Almost all of our EA patients undergoing traction required a Nissen fundoplication, and arguably a disruption of the lower esophageal sphincter mechanism after use of traction may be inevitable. A fundoplication after EA-TEF repair may result in short-term dysphagia related to the dysmotility of the lower esophageal segment [17].

Also a potential exists for missing feeding milestones following delayed EA-TEF repair [12]. We used questionnaires to assess the development of feeding skills [10]. Our findings are however unique, and long-gap EA serves as one of the few models for delayed initiation of feeding in human infants. In that regard, our findings indicate that biological feeding patterns are preserved despite significant delays in initiation of feeding. The findings are reassuring for parents of children with difficult EA-related problems.

In summary, the Foker procedure clearly has a role in the management of patients with long-gap EA. It is physiologically the most appropriate procedure and likely needs to be considered early and as a first option to derive the best results.

The Patient Perspective

The Minnesota approach to the management of EA had important implications for the families. The difficult problems of LG-EA, long strictures, and diverticula that were managed with the same principles in mind required a shift in thinking from one operation to at least two with a period of growth between them. The families had to consider the longer hospitalization than the one procedure usually required for creating an interposition graft—the alternative. Ultimately, what was of more importance in their decision, however, was the long-term benefit of one's own esophagus compared to a graft of the stomach or colon.

Parents that sought out the Minnesota program and traveled there for treatment created the program. They had access to information, first by an old-fashioned literature search for the first to come to Minnesota, soon followed by media publicity and the early age of the internet. Becoming informed is one thing; however, these early parents also needed to become their child's strong advocate and chose a new, and as yet unproven, treatment for LG-EA. Their choice often went against local medical advice; nevertheless, they were willing to travel great distances and spend considerable time in achieving the result they wished for their child. Consequently, they were the real heroes of the success of the Minnesota EA program. If these parents had not become advocates for their children, few operations would have been done at Minnesota, and surgeons elsewhere would not have noticed and continued using gastric or colon interpositions.

The first to arrive at the University of Minnesota were the "E" family—so termed for confidentiality purposes. Specifically for this section of the book, the mother recalled for us their story and accounts from other parents that she has contacted:

An ultrasound at 28 weeks into the pregnancy gave the diagnosis of EA. The local pediatric surgeons were sure a repair could be made shortly after birth; however, a study revealed LG-EA which precluded connecting his esophagus. We agreed to let him grow for 2 months to allow his esophageal ends to grow closer together she recalled. The gap widened, however, and we were given three choices for repair: gastric pull-up, colon interposition, or reverse gastric tube. These did not sound good and we began our research. Without the help of the Internet, we spent days pouring over books at the University Medical Library. Our research turned up an article written by Dr. John Foker which stated he had success in attaching the ends of EA patients even when the gap was very long. We placed a call and I informed him that our son had a gap of 5.5 cm and eight vertebral spaces. He told us he would do his best to get the ends together on the first try, but if he could not, he would perform a procedure (now known as the Foker Method) he devised for another boy just 2 months before. We waited another 2 months to see if the esophageal ends would grow; the hospital and our insurance company became impatient. During that time, we sought the opinions of five area surgeons and four of them told us the procedure would never work. Only one senior pediatric surgeon gave us his blessing and agreed to sign the paperwork needed to travel to Minnesota.

Our son was 2 months old when we arrived at the University of Minnesota Hospital, and 2 days later, the first stage was begun. Sutures were placed in the upper and lower esophageal ends, and after 10 days, his esophagus grew enough to

connect the ends. The weeks following included a Nissen fundoplication and were otherwise filled with recuperation, occupational therapy, speech therapy, and learning to eat. When we look back on our time in the hospital, it seems like a blink of an eye.

I have spoken with several families and was amazed to hear their stories which ended in Minnesota. No one had heard of Dr. Foker before our children were born, but we all came to the conclusion that the other options did not have the outcome we hoped for our child. Early on, we felt it was important to spread the good news. Our story was told on the evening news just as others who had driven to Minneapolis, unloaded their suitcases at the home of an aunt. Our story of success was also published in the Chicago-based support group, EA-TEF Child and Family Support Connection's newsletter. The Internet was new so I was pleasantly surprised to hear from families around the world that had read our story. They contacted me and told me they were thankful to hear about Dr Foker and his method.

One mother who had found my son's story on the EA-TEF website and decided on the Foker Method described how the local surgeon made the parents sign a legal document stating that the local hospital did not recommend the procedure and would not be held liable if they chose it against advice.

An Italian family recounted how they were told that their daughter would be "pretty normal" after a gastric pull-up or colon interposition. The mother wasn't willing to settle for "pretty normal." No one in Italy had heard about the Foker Method so the family petitioned their country's health system to fund the treatment in Minneapolis. Luckily, their doctors were very interested in the new procedure, and they arranged coverage by the national medical insurance. The parents invited a surgeon and anesthesiologist to join them in Minnesota to learn the technique. They accepted and the Foker Method has been performed several times in Napoli: the first center in Europe to use it.

A young man from England with a very challenging esophageal stricture demonstrated how this method was not just for infants with EA. He was born in London in 1995 with a long, severe stricture which limited him to liquids and gruels for the first 6 years of his life. After many dilations, they were referred to London's leading pediatric hospital, the Great Ormond Street Hospital (GOSH), and its top specialists. A course of dilations was prescribed, but unfortunately, the third one ruptured his esophagus. He was released after 3 weeks with the only option now being a gastric pull-up. His grandparents had a holiday home in Sanibel, FL, and by a stroke of fortune, there was a doctor from Minneapolis next door! He had heard of a local Minneapolis surgeon who had developed a new way to solve problems with the esophagus and gave them the contact information. They sent an email describing his problem. The answer was that although the growth procedure was designed for babies, it should work equally well for a child. They went back to GOSH to explain the proposed surgical treatment and were told they did not believe it was possible. It would go against all current thinking about being able to cut a section out of the esophagus and rejoin it without a lot of leakage. His mother refused to sign for a gastric pull-up. Their journey to Minnesota began without medical insurance to cover the treatment so they approached the, National Health Service (NHS) in the UK to see if they would provide funding. Because the procedure was not offered in the UK, they would only consider funding if the treatment were approved by NICE (National Institute of Health and Care Excellence). Without the support of the UK specialist, this was not forthcoming. His parents felt they had no choice but to go ahead. They spent 3 months in Minneapolis where a three-part operation over 14 days removed the long, thick, and tight stenosis. The center was taken out three times until the stricture was all removed. The principle was the same, the application just a bit different. On return to the UK, his mother continued her efforts to get the procedure recognized as an option for children suffering from LG-EA or other esophagus problems. She appeared on television and had several newspaper articles published. Eventually, it became accepted as a treatment option by NICE.

The last parents recalled how their son was born with EA in Boston in 2004. They had done some research on EA, but when they told their surgeon they wanted to opt for the Foker method, the response was "we're not going to do anything crazy." They spoke with another surgeon, Dr. Russell Jennings, at Boston Children's Hospital, and he facilitated the referral and accepted an invitation to fly to Minneapolis to learn the procedure.

All the families that recalled their experiences felt the Foker Method was the only procedure that offered a normal life for their children. Consequently as these stories illustrate, the parents that first brought their child to Minnesota had to overcome several layers of opposition. First, they had to research and determine that growing the esophagus was possible when only information and articles from Minnesota described this procedure and its success. Second, this required follow-up, more searching, and talking to other parents. Furthermore, the local doctors often advised against the growth approach. Finally, the families were dislocated and occupations disrupted. Clearly, the parents supported the growth procedure and described its success to others. Their efforts allowed the growth procedure and the Minnesota program to thrive.

Long-Term Follow-Up and Quality of Life After Gastric Transposition

53

Lewis Spitz and Lorraine Ludman

Introduction

While we certainly subscribe to the principle that "the child's own oesophagus is best" and that the oesophagus can be preserved in a majority of cases of oesophageal atresia [1–3], we remain concerned that in some cases repeated attempts to preserve the oesophagus may be to the detriment of the child and that their own oesophagus may be a liability. In many of these children, their entire infancy and early childhood have been dominated by endless attempts to preserve the native oesophagus at all costs. Replacement of the oesophagus represents an irreversible decision to abandon further attempts at salvage of the oesophagus.

The ideal oesophageal substitute should function as closely as possible to the original structure. The patient should be able to swallow normally, consume normal amounts, and should not experience any reflux symptoms. An additional requirement in children is that the substitute should continue functioning for many years without deterioration.

Satisfactory results have been reported for all forms of oesophageal replacement [4], although the numbers reported are mostly small and long-term data are scanty.

At Great Ormond Street Hospital for children, in London in the past 25 years, we have used gastric transposition almost exclusively for oesophageal substitution. One-hundred and ninety-two infants and children underwent gastric transposition for oesophageal substitution [5]. There were 116 male and 76 female patients undergoing the procedure at a median age of 2 years (range 7 days to 17 years).

The indications for oesophageal replacement are shown in Table 53.1. Ninety-four patients were referred from centres abroad (49 %), and 62 from centres within the United Kingdom (32 %), while the remaining 36 (19 %) received all their treatment at Great Ormond Street Hospital. In total, 156 (81 %) of our patients were referred for their replacement from other centres.

A prior colonic interposition had been unsuccessful in 17 patients, six had a partial gastric transposition, three each had had a Scharli-type procedure [6] or a reversed gastric tube oesophagoplasty, and one child had a failed jejunal interposition. Previous extensive surgical attempts to retain the original oesophagus had been carried out in a total of 69 (36 %) patients.

The method of replacement [7, 8] was via the posterior mediastinum using blunt dissection in 98 patients, while 90 patients required an additional lateral thoracotomy due to extensive mediastinal fibrosis secondary to the original injury (caustic, perforation) or to previous

Congenital stenosis	3
Congenital short oesophagus	1
Prolonged foreign body impaction	2
Diffuse leiomyoma	2
Inflammatory pseudo-tumour	1
Teratoma	1

attempts at oesophageal reconstruction. The stomach was placed in the retrosternal position in four patients, who previously had a failed colonic interposition placed in that site. A jejunal feeding tube was routinely inserted in patients who had not previously fed orally. A transanastomotic nasogastric tube was left in the intrathoracic stomach to provide postoperative gastric decompression. All patients with the exception of the first nine in the series were electively paralysed and mechanically ventilated for varying periods postoperatively.

Mortality: There were nine deaths in the series, a mortality rate of 4.6%. One child died intraoperatively from uncontrollable haemorrhage, five died in the early postoperative period from either respiratory (4) or cardiac (1) failure and three died over a year postoperatively, all of respiratory causes. Eight of these children had had complex courses prior to the transposition.

We believe that mortality can be reduced by submitting patients to oesophageal substitution earlier and refraining from endless attempts at oesophageal salvage. It is easy to become unduly focussed on saving the oesophagus at all costs, but repeated attempts at oesophageal salvage will substantially increase the operative difficulty encountered at the time of substitution procedure.

Anastomotic leakage at the oesophagogastric anastomosis in the neck occurred in 23 patients (12%), all except one of which closed spontaneously. The one child with a major disruption had a cervical oesophagostomy re-established. Secondary anastomosis was carried out uneventfully 6 months later. Four of these patients had undergone previous unsuccessful oesophageal replacement procedures (two colonic and two partial gastric transpositions), and nine had had multiple procedures carried out previously in an attempt to preserve their original oesophagus.

Anastomotic strictures developed in 40 patients (20%) all but three responding to endoscopic dilatations. In the three requiring stricture resection, the procedure was successfully completed via a cervical approach. In 17 cases, the original pathology was caustic oesophageal injury. Five children had previously undergone a colonic interposition.

Significant swallowing problems were encountered postoperatively in 55 patients (29%) half of whom had prolonged difficulties. Eighteen of these children had had major swallowing problems prior to the gastric transposition. The importance of sham feeding in maintaining a normal swallowing mechanism in infants having a cervical oesophagostomy for isolated oesophageal atresia where primary, or delayed, anastomosis is impossible cannot be overemphasised. The feeding difficulties can persist for many months during which enteral nutrition is provided by jejunal feeds, but improvement gradually occurs. It is important to persist with attempts at oral feeding and to try different consistencies of food. In the long term, the great majority of patients can eat and swallow normally. Although many prefer small frequent meals, those who have undergone oesophageal replacement in later childhood report a normal feeling of satiety after eating [2].

Respiratory problems: Reflux into the cervical oesophagus is common in the early months after gastric transposition. This can lead to regurgitation and aspiration especially in the recumbent position resulting in coughing episodes. It is recommended that the infant be propped up in bed and the older child sleeps on two or three cushions. The reflux may cause

mild oesophagitis for which an antacid should be prescribed.

Severe delay in gastric emptying occurred as a late complication in 16 (8.3 %) patients. Included among this group were three infants in whom an original pyloromyotomy was converted to a pyloroplasty and two who required a Roux-en-Y gastrojejunostomy. The delay in gastric emptying may be responsible for halitosis experienced by a few patients.

Dumping symptoms is frequently experienced in the early weeks postoperatively and usually responds well to simple measures such as small frequent meals, avoidance of sugar in the diet, the addition of starch as the main source of carbohydrate and separating the solid and liquid components of a meal. Dumping as a long-term problem only occurred in 2 % of cases but all eventually resolved.

Seven patients experienced problems with the jejunal feeding tube comprising leakage into the peritoneal cavity following traumatic re-intubation, volvulus, intussusception, internal fistula and adhesion obstruction.

Other complications included three infants with severe tracheomalacia, two of whom required aortopexy, two vocal cord paresis requiring temporary tracheostomy, two chylous effusions, two transient Horner's syndrome and one postoperative haemorrhage requiring re-thoracotomy.

The long-term outcome was considered excellent if the child had normal eating habits with the absence of symptoms. The result was considered good if the child had occasional dysphagia or had an altered eating habit such as a preference for a small, frequent meal. In 90 % of our patients, the long-term outcome was considered good to excellent in terms of the absence of swallowing difficulties or other gastrointestinal symptoms such as dumping or diarrhoea. Many patients prefer to eat small frequent meals. Unsatisfactory long-term outcome was present in eight patients (4.6 %), three of whom had chronic respiratory problems (CHARGE syndrome, laryngeal cleft, recurrent pneumonia). A poorer outcome was particularly associated with multiple previous attempts at oesophageal salvage. There was no evidence of deterioration in the function of the gastric transposition in 72 patients followed up for longer than 10 years.

Long-term nutritional and respiratory function [9]: Although the few children tested have a measurable respiratory compromise, they are generally asymptomatic.
