Contents

Evidence Based Cardiology CD Rom

Features

***Evidence-based Cardiology* PDF eBook**

- bookmarks and hyperlinks for instant access to all chapters and topics
- searchable
- requires Adobe Acrobat Reader, free download available on the CD Rom, or from http://www.adobe.com/products/acrobat/readstep2.html

***Evidence-based Cardiology* PDA edition – sample chapter**

- a free sample chapter from the forthcoming PDA edition. Works on all Portable Digital Assistants – Palm/Pocket PC/Psion etc.
- Requires Mobipocket Reader, free download available on the CD Rom, or from http://www.mobipocket.com/en/DownloadSoft/DownLoadReaderStep1.asp

BMJ Books Catalogue

- Instant access to BMJ Books full catalogue, including an order form

Also included – instant access to the *Evidence-based Cardiology* update website and regularly updated information on all BMJ Books Cardiology titles.

Note: the *Evidence-based Cardiology* PDF eBook is for search and reference only and cannot be printed. A printable PDF version and the full PDA edition can be purchased from http://www.bmjbookshop.com.

Instructions for use:

The CD Rom included with *Evidence-based Cardiology* should start automatically upon insertion into any PC running Microsoft Windows. The menu screen will appear and you can then navigate by clicking on the headings and icons. If the CD does not start automatically, or if you wish to use again after previously quitting, browse the CD Rom using Windows Explorer and double click the heart-shaped icon.

Troubleshooting:

Some users may receive the following error message: "A required .DLL file, MSUBVM60.DLL, was not found". If this or any other error message is received, please update your system by browsing the CD Rom with Windows Explorer and double-clicking the file "setup.exe". Once this installation process is completed, restart your PC and try again. If you continue to experience difficulties, or if you are using an alternative operating system, we can give you access to an identical electronic version of the text as well as the sample PDA Edition chapter via the internet. Please send proof of purchase to the following address, with a letter advising your email address and the problem you have encountered:

Preface to the Second edition

"Where is the knowledge in all that information?
Where is the wisdom in all that knowledge?"
W H Auden

The recent proliferation of carefully controlled large scale clinical trials, their meta-analyses and selective observational studies has contributed to the remarkable strides made in the management of cardiovascular disease. One of the prophesies stated in the first edition of this textbook has come to pass – namely, that management guided by external evidence is an evolving process as newer and more effective treatment modalities come to light. While successful as a critical approach for managing patients, evidence-based medicine is nevertheless a work in progress which, if allowed to rest on its laurels, will "by nature be threatened with impending obsolescence". In addition to keeping abreast of new information, there is a need to integrate and distill the information into coherent recommendations. Authors were therefore instructed to provide their recommendations including those based on qualitative judgments. The recognition of new developments in a rapidly changing dynamic field combined with the overwhelmingly positive worldwide response to the first edition have prompted the publication of this second edition.

This edition is again dedicated to providing a comprehensive compendium of best evidence for the diagnosis and management of a wide variety of cardiovascular disorders. To avoid critical information gaps as meaningful new data emerge, the text contains several new features. Because our concepts of what constitutes evidence-based medicine is subject to change we have included a completely revised introductory chapter. Appended to the printed text is a CD Rom that permits ready access to new information and periodic updates by way of a dedicated and active website. In addition, there will be available a compact hand-held (PDA) version of the text. There are new chapters on clinical trials and meta-analysis; fetal origins of cardiovascular disease; genetics; diet and cardiovascular disease; obesity; and cardiopulmonary resuscitation. Several chapters have been completely rewritten and most have undergone substantial revision. Finally, the layout of the text has been reformatted for better handling, portability, readability and affordability.

In preparing this edition the editors and contributors have subscribed to the principle that the best external evidence found in these pages are not to be considered as hierarchical choices but rather should be used judiciously with other forms of evidence be they pathophysiologic, observational or experiential. No effort has been spared in the preparation of this edition and to this end invaluable assistance has been accorded us by Judy Lindeman at McMaster University and Mary Banks and Christina Karaviotis at BMJ Books.

Preface to the First edition

> "… if a man declares to you that he has found facts that he has observed and confirmed with his own experience, be cautious in accepting what he says. Rather, investigate and weigh this opinion or hypothesis according to requirements of pure logic, without paying attention to this contention that he affirms empirically."
>
> MOSES MAIMONIDES. *ca.* 1195

Thus did the great physician Maimonides make a plea for an evidence-based approach to medicine by admonishing his followers to seek common ground between objectivism and empiricism. If Maimonides had lived in the year 1785, he would likely have read William Withering's *An Account of the Foxglove*; a compendium of Withering's personal observations on the clinical effect of the digitalis leaf. At first blush, Maimonides would cry foul at such flagrant empiricism, demanding to know the whole of the inception cohort. It turns out that Withering, instead of selecting specific cases which would have "… spoken strong in favour of the medicine, and perhaps been flattering to my own reputation" went on to say in his Preface "I have therefore mentioned every case in which I have prescribed the foxglove, proper or improper, successful or otherwise …" thus heralding a genuine, albeit retrospective, cohort study. It took 212 years before Withering was ultimately vindicated by the results of the first large scale randomized placebo controlled trial of digoxin (*N Engl J Med* 1997; **336**: 526). Sixty-eight hundred patients with congestive heart failure, in sinus rhythm, were randomized to receive digoxin (avg dose 0·25 mg/day) or placebo in addition to ACE inhibitors and diuretics. Over a three-year period there was no statistical difference in overall mortality but digoxin proved to be effective in reducing hospitalizations due to worsening heart failure.

The advent of large scale prospective randomized clinical trials has strengthened the external evidence upon which management decisions can be made with some confidence. We have come to rely on so-called external best evidence as critical guideposts for establishing minimal criteria for treatment of many cardiovascular disorders. In the process, some myths based on putative mechanisms have been dispelled while insights into the efficacy of new treatments have been more rapidly facilitated. On the other hand there is a danger of righteous complacency which, if unchecked, could lead to a slavish dependency on statistical bottom lines and, ultimately, to "cook book" medicine. It is the intent of this textbook to present a proper balance between "objectivism and empiricism". In this regard, the very first chapter begins by defining the practice of evidence-based cardiology as "… integrating individual clinical expertise with the best available external clinical evidence from systematic research".

The textbook has four principal components. An introductory general section addresses important topics in clinical epidemiology, as applied both to the bedside and to a population. This section includes: critical appraisal of data; clinical trials methodology; quality of life measurements; health economics; and methods of decision analysis, all in the context of current clinical practice. Next follows a section on preventive strategies based on evidence that should enable the practicing physician to advise, with confidence, on risk factor modification and quality of life issues for selected patients. There follows a section on a broad range of specific cardiovascular disorders that highlight management issues based on current best evidence. Finally, the section on clinical applications is an attempt to put a clinical face on evidence derived from population statistics through the use of "live" clinical cases. Here, an attempt is made judiciously to couple external evidence with clinical expertise and a sound knowledge of cardiovascular pathophysiology. There is understandably a wide range of the kinds of evidence available to support different practices and treatments. The editors have chosen not to constrain the authors into rigid and uniform formats for each chapter. While several of the chapters have the level of evidence/recommendations graded, or key messages highlighted, a uniform format would not have been appropriate for every chapter.

This textbook is designed for a wide audience. Since cardiovascular disease comprises more than fifty percent of adult medicine, there is something here for everyone in clinical practice and at all levels of medical undergraduate and postgraduate training. Its emphasis on practical applications of research methodology and critical appraisal of data covering a cross-section of clinical topics should invite interest among those engaged in population studies, biostatistics, clinical epidemiology and health economics as well as those involved in healthcare decision analysis, quality assurance committees and stakeholders responsible for healthcare planning.

Because this textbook relies so heavily on current best evidence, it is by nature threatened with impending obsolescence. To ensure that this does not happen, the editors, in concert with the publisher, have agreed to issue up-dates periodically in the form of special supplements or updated editions, so that the text can be continually revised in accordance with emerging relevant data. In this context, it is well to bear in mind that good science always proceeds hesitantly through a series of tenuous conclusions. And so any recommendation made on the basis of available best evidence is subject to revision as we probe deeper into the mysterious nature of disease processes. One may ask of the large scale clinical trial "Why did it require more than 10,000 patients to show incontrovertible evidence that the experimental drug is effective?" Aye, there is the scientific question!

The editors wish to acknowledge the herculean efforts of Catherine Wright and Karin Dearness who kept everyone on track and offer a special appreciation to Mary Banks for her editorial expertise, patience and support.

Glossary

Abbreviations commonly used in this book

ABI	ankle brachial pressure index
ACC	American College of Cardiology
ACE	angiotensin-converting enzyme
AED	automated external defibrillator
AF	atrial fibrillation
AHA	American Heart Association
AMI	acute myocardial infarction
APSAC	anisoylated plasminogen streptokinase activator complex
APTT	activated partial thromboplastin time
ARR	associated risk reduction
AS	aortic stenosis
ASD	atrial septal defect
ASMR	age standardized mortality rate
BBB	bundle branch block
BMI	body mass index
CABG	coronary artery bypass grafting
CAD	coronary artery disease
CBVD	cerebrovascular disease
CCB	calcium-channel blockers
CCU	coronary care unit
CEE	conjugated equine estrogen
CHD	coronary heart disease
CHF	congestive heart failure
CI	confidence interval
CK-MB	creatinine kinase MB isoenzyme
CPP	coronary perfusion pressure
CPR	cardiopulmonary resuscitation
CT	computerized tomography
CYA	cyclophosphamide
DA	dopamine
DALY	disability adjusted life years
DHP	dihydropyridines
DM	diabetes mellitus
DVT	deep vein thrombosis
ECG	electrocardiogram
EEG	electroencephalogram
EGF	epidermal growth factor
EMF	endomyocardial fibrosis
EOA	effective orifice area
EPS	electrophysiologic studies
FGF	fibroblast growth factor
FS	fractional shortening
GPI	glycoprotein inhibitor
HCM	hypertrophic cardiomyopathy
HDL	high density lipoprotein (HDL_2)
HMG-CoA	3-hydroxy-3-methylglutaryl-coenzyme A
HOCM	hypertrophic obstructive cardiomyopathy
HRT	hormone replacement therapy
IC	intracoronary
ICD	implantable cardioverter defibrillator
ICH	intracerebral hemorrhage
IDC	idiopathic dilated cardiomyopathy
IDL	intermediate density lipoprotein
IE	infective endocarditis
IFN-γ	interferon gamma
IGF	insulin-like growth factor
IGT	impaired glucose tolerance
IL	interleukin
IM	intramuscular
INR	international normalization ratio
IQR	interquartile range
IV	intravenous
LAE	left atrial enlargement
LBBB	left bundle branch block
LDL	low density lipoprotein
LDL-C	low density lipoprotein cholesterol
LMWH	low molecular weight heparin
Lp(a)	lipoprotein
LQTS	long QT syndrome
LV	left ventricular
LVE	left ventricular enlargement
LVEF	left ventricular ejection fraction
LVH	left ventricular hypertrophy
MCP	monocyte chemoattractant protein
MHC	major histocompatibility complex
MHS	Milan Hypertensive Strain
MI	myocardial infarction
MPA	medroxyprogesterone acetate
MRI	magnetic resonance imaging
MUFA	monounsaturated fatty acid
NA	not available
NHLBI	National Heart Lung Blood Institute
NINDS	National Institute of Neurologic Disease and Stroke
NNT	number needed to treat
NSAIDs	non-steroidal anti-inflammatory drugs
NSTEMI	non-ST-segment elevation myocardial infarction
NYHA	New York Heart Association
OR	odds ratio
P	probability
PAI	plasminogen activator inhibitor
PCI	percutaneous coronary intervention
PCR	polymerase chain reaction
PDGF	platelet derived growth factor
PE	pulmonary embolism
PET	positron emission tomography
PPCM	peripartum cardiomyopathy
PSVT	paroxysmal supraventricular tachycardia
PTA	percutaneous transluminal angioplasty
PTCA	percutaneous transluminal coronary angioplasty

PUFA	polyunsaturated fatty acid
PVC	premature ventricular complex
RCT	randomized controlled trial
RFLP	restriction fragment length polymorphisms
ROSC	return of spontaneous circulation
RRR	relative risk reduction
rtPA	recombinant tissue plasminogen activator
RV	right ventricular
RVEF	right ventricular ejection fraction
RVF	right ventricular enlargement
RVH	right ventricular hypertrophy
SAECG	signal-averaged ECG
SC	subcutaneous
SK	streptokinase
SMC	smooth muscle cells
SFA	saturated fatty acid
SFA	superficial femoral artery
STEMI	ST-segment elevation myocardial infarction
TEA	thromboendarterectomy
TEE	transesophageal echocardiography
t-FA	*trans* fatty acid
TGF	transforming growth factor
TIA	transient ischemic attack
TIMI	Thrombolysis in Myocardial Infarction
TMP	TIMI myocardial perfusion
TNF	tumor necrosis factor
TNK	tenecteplase
tPA	tissue plasminogen activator
TTE	transthoracic echocardiography
UK	urokinase
v	versus
VF	ventricular fibrillation
VPD	ventricular premature depolarization
VSD	ventricular septal defect
VT	ventricular tachycardia
VTE	venous thromboembolism
VUI	venous ultrasound imaging

Grading of recommendations and levels of evidence used in *Evidence-based Cardiology*

GRADE A

Level 1a Evidence from large randomized clinical trials (RCTs) or systematic reviews (including meta-analyses) of multiple randomized trials which collectively has at least as much data as one single well-defined trial.

Level 1b Evidence from at least one "All or None" high quality cohort study; in which ALL patients died/failed with conventional therapy and some survived/succeeded with the new therapy (for example, chemotherapy for tuberculosis, meningitis, or defibrillation for ventricular fibrillation); or in which many died/failed with conventional therapy and NONE died/failed with the new therapy (for example, penicillin for pneumococcal infections).

Level 1c Evidence from at least one moderate-sized RCT or a meta-analysis of small trials which collectively only has a moderate number of patients.

Level 1d Evidence from at least one RCT.

GRADE B

Level 2 Evidence from at least one high quality study of non-randomized cohorts who did and did not receive the new therapy.

Level 3 Evidence from at least one high quality case–control study.

Level 4 Evidence from at least one high quality case series.

GRADE C

Level 5 Opinions from experts without reference or access to any of the foregoing (for example, argument from physiology, bench research or first principles).

A comprehensive approach would incorporate many different types of evidence (for example, RCTs, non-RCTs, epidemiologic studies, and experimental data), and examine the architecture of the information for consistency, coherence and clarity. Occasionally the evidence does not completely fit into neat compartments. For example, there may not be an RCT that demonstrates a reduction in mortality in individuals with stable angina with the use of β blockers, but there is overwhelming evidence that mortality is reduced following MI. In such cases, some may recommend use of β blockers in angina patients with the expectation that some extrapolation from post-MI trials is warranted. This could be expressed as Grade A/C. In other instances (for example, smoking cessation or a pacemaker for complete heart block), the non-randomized data are so overwhelmingly clear and biologically plausible that it would be reasonable to consider these interventions as Grade A.

Recommendation grades appear either within the text, for example, **Grade A** and **Grade A1a** or within a table in the chapter.

The grading system clearly is only applicable to preventive or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or pathophysiologic.

Part I

General concepts and critical appraisal

Level 4 Evidence from at least one high quality case series.

GRADE C

Level 5 Opinions from experts without reference or access to any of the foregoing (for example, argument from physiology, bench research or first principles).

A comprehensive approach would incorporate many different types of evidence (for example, RCTs, non-RCTs, epidemiologic studies, and experimental data), and examine the architecture of the information for consistency, coherence and clarity. Occasionally the evidence does not completely fit into neat compartments. For example, there may not be an RCT that demonstrates a reduction in mortality in individuals with stable angina with the use of β blockers, but there is overwhelming evidence that mortality is reduced following MI. In such cases, some may recommend use of β blockers in angina patients with the expectation that some extrapolation from post-MI trials is warranted. This could be expressed as Grade A/C. In other instances (for example, smoking cessation or a pacemaker for complete heart block), the non-randomized data are so overwhelmingly clear and biologically plausible that it would be reasonable to consider these interventions as Grade A.

Recommendation grades appear either within the text, for example, **Grade A** and **Grade A1a** or within a table in the chapter.

The grading system clearly is only applicable to preventive or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or pathophysiologic.

1 What is evidence-based cardiology?

PJ Devereaux, R Brian Haynes, Salim Yusuf

Introduction

In 1836 the editor of the *American Journal of Medical Sciences*, Elisha Bartlett, heralded a study as "one of the most important medical works of the present century, marking the start of a new era in science".[1] What evoked such praise and suggested a paradigm shift was Dr Pierre Louis' systematic collection and numerical presentation of data on bloodletting. Louis adopted a baconian approach of collecting vast amounts of data on a large number of patients (by the standards of the early 1800s), which allowed him to systematically evaluate the efficacy of bloodletting. Louis argued that large numbers of patients and enumeration were necessary to equalize differences between treatment groups, as "by so doing, the errors (which are inevitable), being the same in two groups of patients subjected to different treatment, mutually compensate each other, and they may be disregarded without sensibly affecting the exactness of the results".[2] Louis subsequently went on to state: "a therapeutic agent cannot be employed with any discrimination or probability of success in a given case, unless its general efficacy, in analogous cases, has been previously ascertained", and thus, "without the aid of statistics nothing like real medicine is possible".[3]

The prevailing concept of illness at the time was that the sick were contaminated, whether by some toxin or contagion, or by an excess of one humour or another. This understanding of illness contained within it the idea that these states were improved by opening a vein and letting the sickness run out. Louis' finding that bloodletting hastened the death of the ill was a bombshell. George Washington had 2·4 liters of blood drained from him in the 15 hours prior to his death: he had been suffering from a fever, sore throat and respiratory difficulties for 24 hours.[4] Some have stated that in this way Washington was murdered.[5–7]

Although this is a relatively recent example, the plea for comparative evaluation was mentioned as early as the Old Testament. Throughout history there have been repeated exhortations to quantify medical or health problems and to compare outcomes in patient groups managed differently, with the goal of setting state policy or assisting individual physicians.

In this chapter we will discuss what evidence-based medicine is, and then discuss an approach to evidence-based decision making. We will use a clinical case to highlight the components of this approach, which include clinical state and circumstances, patients' preferences and actions, research evidence, and clinical expertise. At the end of the chapter we will review the application of these components of evidence-based decision making as they apply to our patient, and provide a decision aid that can be used in such a case.

What is evidence-based medicine?

Although the foundations for evidence-based medicine were laid over several centuries, an explicit philosophy, with its attendant concepts, definitions and models, has been largely developed as a formal doctrine over the last few decades. Evidence-based medicine is about solving clinical problems. Initially, the focus of evidence-based medicine was largely to find the best objective quantifiable research evidence relevant to the particular problem, and to apply that evidence in resolving the particular issue.[8] This early focus de-emphasized "intuition, unsystematic clinical experience, and pathophysiologic rationale as sufficient grounds for clinical decision making" and stressed "the examination of evidence from clinical research".[9] Subsequent versions have emphasized that research evidence alone is never sufficient to make a clinical decision.[10] Research evidence by itself rarely tells us what to do in individual situations, but rather it provides useful information that allows us to make more informed decisions. Clinicians must always view evidence in the context of the individual patient, and then weigh the potential benefits versus the risks, costs and inconveniences. Ideally the patient's values and preferences take precedence[10] (Figure 1.1).

Figure 1.1 is based on the first edition of *Evidence-based medicine*[11] and was published in an editorial that appeared in *ACP Journal Club* and *Evidence-Based Medicine* in 1996, along with the definition: "Evidence-based medicine is the conscientious and judicious use of current best evidence from clinical care research in the management of individual patients".[12] The editorial also included the caveat that the definition of evidence-based medicine would evolve as new types of information emerged, and would therefore be continuously refined. The concepts of evidence-based

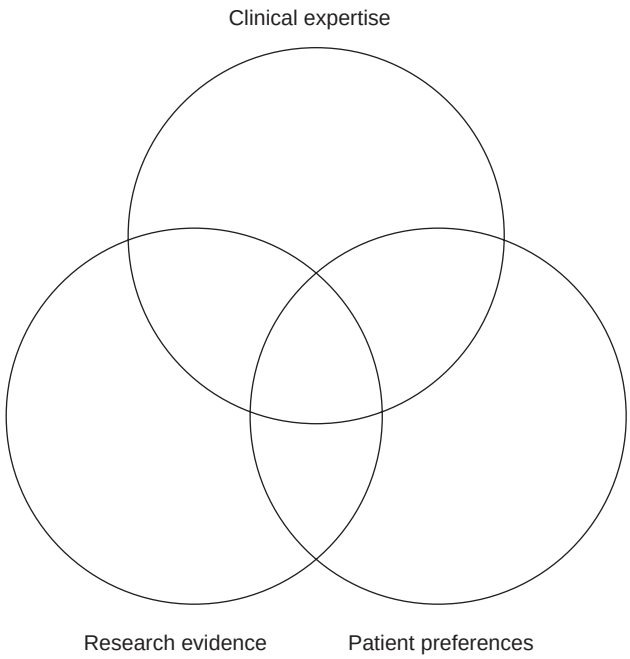

Figure 1.1 Early model of the key elements for evidence-based clinical decisions

medicine have evolved considerably and the initial model has recently been enhanced,[8] especially for what is meant by clinical expertise and the additional consideration of clinical situation and circumstances. In the next section we use this new model of "evidence-based clinical decisions" to help resolve a common clinical scenario.

Approach to evidence-based clinical decision making

New model for evidence-based clinical decisions (Figure 1.2)

Figure 1.2 depicts the evolution of the model for evidence-based clinical decisions,[8] which has more recently been redefined as "the integration of best research evidence with clinical expertise and patient values".[13] This model represents a desirable approach as to how all clinical decisions should be made. However, we acknowledge that, at present, many clinical decisions are not made in this way. For instance, at present, clinicians' individual preferences (as distinct from clinical expertise) often play a large role in their actions, leading to large "practice variations" in managing similar cases. When faced with critically ill patients with identical circumstances, different clinicians may, according to their preferences, institute aggressive life-prolonging interventions or withdraw life support.[14] Our model acknowledges that patients' preferences should be considered first and foremost, rather than clinicians' preferences, whenever it is possible to do so.

In Figure 1.2, the "clinical state and circumstances" of the patient replace "clinical expertise" as one of the key elements in clinical decisions, "patient preferences" is expanded to include patients' actions, and this element is reversed in position with "research evidence", signifying its frequent precedence. Integrating all three aspects requires judgment and clinical expertise, thus constituting a fourth overarching element. We will describe each of the components, and the role of clinical expertise in integrating them.

Clinical state and circumstances

A patient's clinical state and circumstances often play a dominant role in clinical decisions. Clinical trials provide us with results reflective of the average patient within the treatment groups of the trial, but rarely is a patient in

Clinical scenario

A family physician refers a patient requesting your input on the issue of antithrombotic therapy. The patient is an 80 year old man with a history of hypertension who 10 months ago, on routine examination, was diagnosed with atrial fibrillation. The patient suffered a major gastrointestinal bleed, requiring hospitalization, urgent endoscopy, and a transfusion the day after his atrial fibrillation was discovered (the patient had not started any antithrombotic therapy prior to his bleeding episode). He had, however, been receiving a non-steroidal anti-inflammatory drug (NSAID) for osteoarthritis. The patient has been free of any gastrointestinal symptoms since his bleed and has successfully avoided using an NSAID by using acetaminophen. Eight months earlier the patient's echocardiogram demonstrated normal valvular and left ventricular function and a left atrial measurement of 6·5 cm. Based on the duration of atrial fibrillation and the size of his left atrium, you decide that cardioversion is not an option. The patient is very worried about having a stroke, as his wife was left dependent on him for 2 years prior to her death following a major stroke. The referring physician, who recently had a patient who suffered a serious gastrointestinal bleed while on warfarin, is very concerned about the risk of bleeding, given this patient's age and recent history of gastrointestinal bleeding.

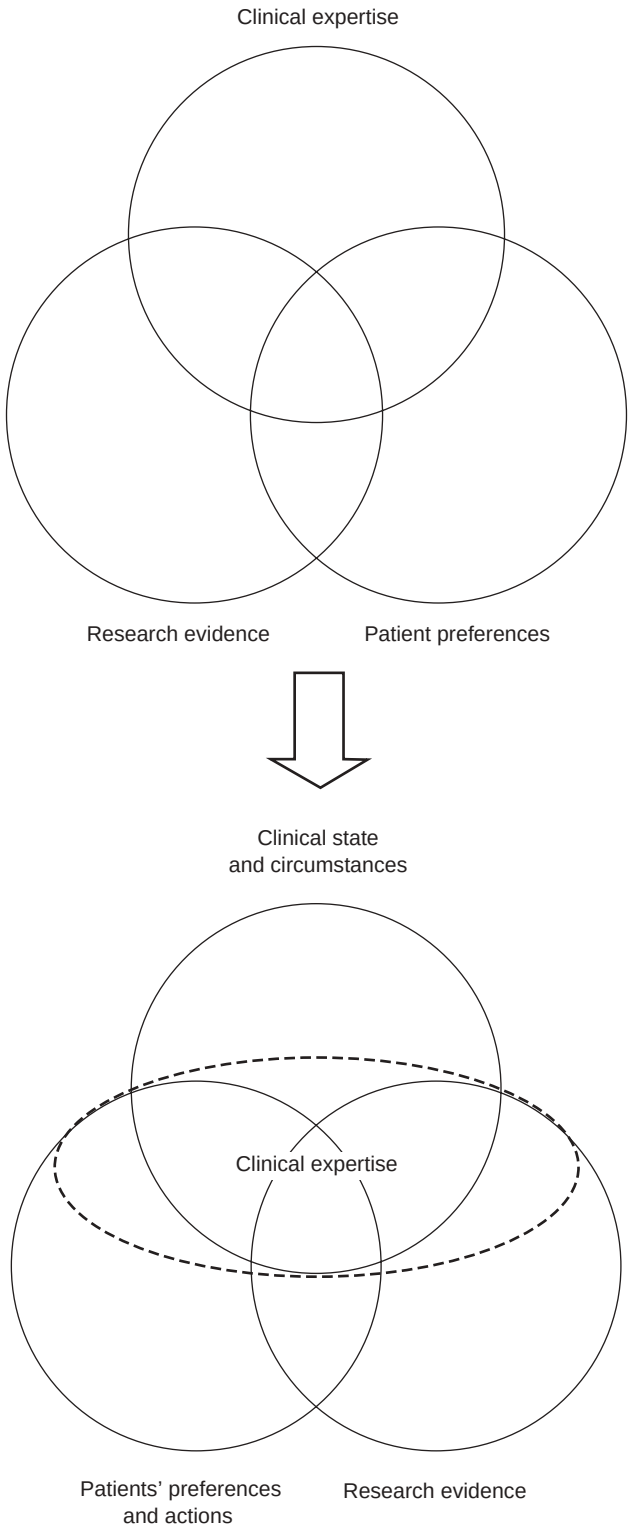

Figure 1.2 Evolving model for evidence-based clinical decisions

clinical practice the same as the average patient from a clinical trial. Individual patients have unique characteristics that typically put them at lower or higher risk of the outcome or treatment side effect than the average patient in the trial. As such, optimal clinical decisions should be individualized to the patient's clinical state. A patient who is at very high risk of a future vascular event, but at low risk of any complication from a drug (for example, a patient with a low density lipoprotein value of 8·0 mmol/l post myocardial infarction and no contraindication to statin therapy), or conversely a patient who is at low risk of the outcome and high risk of a treatment's complications (for example, a 40 year old man with atrial fibrillation without any associated stroke risk factors who has experienced a recent major gastrointestinal bleed), may find their clinical state dominating the clinical decision making process.

It is notable that the circles of clinical state and circumstances and research evidence overlap. Frequently research evidence can inform us about the influence of the clinical state and circumstances. Considering our patient, the pooled data from five randomized controlled trials (RCTs) evaluating the efficacy of warfarin in patients with non-valvular atrial fibrillation (NVAF) demonstrated an average annual stroke rate of 4·5% and a major bleeding rate of 1% in patients not receiving antithrombotic therapy.[15] The investigators who combined the five RCTs used the control patient data to develop a clinical prediction tool to estimate the annual risk of stroke. Independent risk factors that predicted stroke in control patients were increasing age, a history of hypertension, diabetes, and prior stroke or transient ischemic attack (TIA).[15] Our patient's annual risk of stroke is predicted to be about 8%, which is higher than that of the average control patient in the five RCTs, whose annual stroke rate was 4·5%.[15] Similarly, a clinical prediction tool has been developed for predicting the risk of major bleeding (defined as the loss of two units of blood within 7 days, or life-threatening bleeding) while taking warfarin therapy.[16] Independent risk factors that predict major bleeding in patients taking warfarin include age >65, history of stroke, history of gastrointestinal bleeding, recent myocardial infarction, anemia, renal failure and diabetes. (Note that many of the factors that predict a higher risk of stroke also increase the risk of bleeding.) Our patient's annual risk of major bleeding of 8% also differs from that of the average patient receiving warfarin in the five RCTs, whose annual risk of major bleeding was 1·3%. We are unaware of any clinical prediction tool for predicting major bleeding while taking aspirin, and the atrial fibrillation trials had inadequate power to estimate this. However, based on the results of the meta-analysis by the antithrombotic trialists' collaboration, we would expect aspirin to increase the risk of major bleeding from 1% to about 1·3% on average.[17]

The clinical circumstances in which you and your patient find yourselves (for example, your ability to administer and monitor a treatment) may be very different from those of an RCT. For example, the patient may not be able to obtain frequent tests of the intensity of anticoagulation. However, for a patient with the same clinical characteristics, we can frequently optimize clinical circumstances to decrease the risk

of an outcome or treatment side effect. For example, we can decrease the risk of bleeding due to warfarin therapy by more intensive monitoring. Thus, an "evidence-based" decision about anticoagulation for a patient with atrial fibrillation is not only determined by the demonstrated efficacy of anticoagulation and its potential adverse effects,[18] but will vary based on the patient's clinical state and according to individual clinical circumstances.

Patients' preferences and actions

Patients may have no views or, alternatively, unshakable views, on their treatment options, depending on their condition, personal values and experiences, degree of aversion to risk, healthcare insurance and resources, family, willingness to take medicines, accurate or misleading information at hand, and so on.[8] Accordingly, individuals with very similar clinical states and circumstances may choose very different courses of action, despite being presented with the same information about the benefits and risks of an intervention.

For our patient with NVAF, research evidence informs us about the differing preferences of patients and their physicians for antithrombotic therapy in atrial fibrillation when they weigh the competing risks of stroke and bleeding.[19] In this study,[19] participants (that is both physicians and patients) reviewed flip charts describing in detail the acute and long-term consequences of a major and minor stroke and a major bleeding event. Participants were instructed that the likelihood of a minor or major stroke was equal. The participants then underwent a probability trade-off technique which determined the minimum number of strokes that needed to be prevented before the participant felt antithrombotic therapy was justified (this value was determined for both warfarin and aspirin), given the associated increased risk of bleeding, costs and inconveniences. The same technique was also used to determine the maximum number of excess bleeds the participant would consider to be acceptable with antithrombotic therapy (determined both for warfarin and aspirin), given the benefits in terms of stroke reduction with this therapy. This study demonstrates significant variability between physicians and patients in their weighing of the potential outcomes associated with atrial fibrillation and its treatment. Patients required less stroke reduction and were more tolerant of the risk of bleeding than physicians. For example, on average, patients were willing to accept the risk of 17 extra major bleeding events in 100 patients over a 2 year period if warfarin prevented eight strokes among these 100 patients. Physicians, however, were only willing to accept 10 major bleeding events for the same level of benefit. Furthermore, physicians varied significantly in how much bleeding risk they thought was acceptable for a given stroke reduction associated with an antithrombotic agent. Hence different physicians would make very different recommendations to the same patient with identical risks of bleeding and stroke. This underscores the importance of having patient values and preferences drive clinical decision making. It is the patient who is at risk of the outcome and so, when willing and able, they should be the one to weigh the potential benefits versus the risks, costs and inconveniences.

There is debate regarding the optimal way to elicit and incorporate patient preferences into clinical decision making. One method is to discuss the potential benefits and risks with a patient and then qualitatively incorporate your impression of the patient's preferences into the clinical decision. Alternatively, at least two quantitative approaches exist: decision analytic modeling and probability trade-off technique. In a decision analytic model, a standard gamble, time trade-off or visual analog scale technique is used to determine the utility (patient value/preference) of the various outcomes. This information is then fed into a decision tree that includes the probabilities of the outcomes for all clinical decisions being considered. Using the decision tree, calculations are undertaken to determine what course of action optimally fits the patient's preferences. The probability trade-off technique presents patients with the probabilities for the various interventions being considered and then asks them to make a decision based on this information. This allows a direct and quantitative incorporation of the patient's preferences.

Proponents of decision analytic modeling question whether patients can understand probabilities to allow the appropriate incorporation of their preferences. Proponents of probability trade-off techniques wonder if a measure of utility (that is preference) in the absence of probabilities is meaningful. Only one study has directly compared decision analytic modeling with a probability trade-off technique.[20] This study focused on the primary prevention of stroke and myocardial infarction with aspirin therapy in elderly patients. Both methods (that is decision analysis and probability trade-off) were performed on all patients at separate times. This study demonstrated that treatment recommendations varied significantly, depending on which method was used. After patients were presented with their individual treatment thresholds as determined by both methods, over twice as many stated they would base their preferences on the results of the probability trade-off as opposed to the decision analysis.[20] Further research is needed to determine which of the models better represents patients' self-interests.

Regardless of what their preferences may be, patients' actions may differ from both their preferences and their clinicians' advice.[21] For example, a patient may prefer to lose weight, quit smoking and take their medications as prescribed, but their actions may fall short of achieving any of these objectives. Alternatively, they may follow the treatment as prescribed, even if they resent its imposition, adverse effects and costs. Unfortunately, clinicians' estimates of their patients' adherence to prescribed treatments

have no better than chance accuracy.[22] Thus, physicians' decisions for care will better meet the model's specifications if they are able to assess whether their patients will follow, or are following, their prescriptions.[22]

We recognize that at present patients' preferences are rarely formally incorporated in clinical practice. This may be related to lack of physician training in these approaches, a reluctance to tread unfamiliar ground, and also in many circumstances the lack of accurate quantitative information on risk and benefits, as well as clinical risk prediction tools. However, this is likely to change rapidly as clinical models can be derived from large databases and handheld computers can be utilized to quantify risks and benefits at the bedside.

Research evidence

We support a very broad definition of research evidence, namely, "any empirical observation about the apparent relation between events".[23] In keeping with this definition, research evidence includes everything from the unsystematic observation of a single physician to a systematic review of large RCTs. Not all evidence is created equal, and hence there is a hierarchy of evidence that varies depending on whether one is addressing a diagnostic, prognostic or therapeutic decision. We will focus on the hierarchy of evidence for therapeutic decisions (Box 1.1).[23]

Box 1.1 Hierarchy of evidence for treatment decisions*

Coherence of evidence from multiple sources
Systematic review of several well designed, large randomized controlled trials
Single large randomized controlled trial
Systematic review of several well designed small randomized controlled trials
Single small randomized controlled trial
Systematic review of several well designed observational studies
Single observational study
Physiologic studies
Unsystematic observation from a physician

* This hierarchy cannot be rigidly adhered to. At times a single observation may be very powerful (for example, defibrillation for ventricular fibrillation), or observational studies may provide unequivocal evidence (for example, smoking cessation and lung cancer). However, in most cases where treatment effects may be moderate, outcomes variable or the clinical course unpredictable, the proposed hierarchy is useful.

All evidence has value, and the best evidence available in the hierarchy should be given appropriate consideration, even if not at the top of the hierarchy. Therefore, the unsystematic observations of colleagues should not be dismissed when no higher level evidence exists. Indeed, unsystematic observations can lead to many important insights, and experienced clinicians usually develop a respect for the insights of their astute colleagues. However, it is equally important to recognize that unsystematic observations are commonly limited by the small number of observations, variability in outcomes, lack of objectivity, and the difficulties in integrating (for example, taking into account the natural history of a disorder, placebo effect, and a patient's desire to please) and drawing inferences from observations.[24]

All evidence has limitations. Although the majority of advances in medicine are initially uncovered through individual observations, physiologic studies, observational studies or randomized controlled trials evaluating surrogate endpoints, there have also been several extremely misleading findings that have, at times, resulted in harm. It is important to remember that contradictory results across studies on the hierarchy of evidence table are not isolated to one or two instances (Table 1.1).

Perhaps the most powerful example is the story of antiarrhythmic therapy. Despite encouraging evidence that encainide and flecainide could prevent premature ventricular beats, a large RCT demonstrated a higher mortality rate with these drugs than with placebo, such that these drugs resulted in an extra death for every 20 patients treated with encainide or Flecainide.[39] It is estimated that more Americans were killed by these drugs than died in the Vietnam War.[40]

Ideally, we would have evidence from all levels of the hierarchy and the evidence would be coherent across all levels. This would represent the most persuasive evidence. However, this rarely happens, as even RCTs may by chance frequently demonstrate contradictory findings, especially when they are small. Therefore, physicians should always aim for the highest level of evidence for clinical decision making. Clinicians can still make strong inferences, particularly when there is evidence from a systematic review of several well designed large RCTs, or simply a large single pragmatic RCT. The RCT is such a powerful tool because randomization is our only means to reduce bias in treatment comparisons by controlling for unknown prognostic factors.[41] Therefore, RCTs have the potential to provide the most valid (that is likelihood that the trial results are unbiased) estimates of treatment effect.[42] Furthermore, large RCTs with broad eligibility criteria enhance the generalizability of their findings.

An *n* of 1 randomized controlled trial is an RCT where individual patients are randomized to pairs of treatment periods, such that they receive the experimental treatment during one period and a placebo during the other.[43] Both patients and healthcare providers are blind to which period is the experimental and which the placebo. Patients continue undergoing pairs of treatment periods until they and the healthcare providers become convinced that the experimental intervention either does or does not work.[43] The advantage of an *n* of 1 RCT is that it provides evidence directly from the patient. However, this method is applicable only in a disease state that has limited fluctuation, and

Table 1.1 Some examples of contradictory results across studies at various positions in the hierarchy of evidence

Results from lower level evidence	Results from higher level evidence
Milrinone demonstrated improvement in left ventricular function during exercise[25]	A large RCT[26] and meta-analysis of several RCTs[27] demonstrated a 28% relative increase in mortality with milrinone compared to placebo
An observational study of extracranial to intracranial bypass surgery suggested a "dramatic improvement in the symptomatology of virtually all patients" undergoing the procedure[28]	A large RCT demonstrated a 14% relative increase in the risk of fatal and non-fatal stroke in patients undergoing this procedure compared to medical management[29]
A meta-analysis of 16 cohort studies and 3 cross-sectional angiographic studies (including studies of women with known coronary artery disease) demonstrated a relative risk of 0·5 (95% CI 0·44–0·57) for coronary artery disease among women taking estrogen[30]	A moderate-sized secondary prevention RCT did not demonstrate any reduction in coronary heart disease events but did demonstrate an increase in thromboembolic events in patients receiving estrogen.[31] Preliminary reports from an ongoing very large RCT (Women's Health Initiative) indicate an increased risk of MI and strokes in the first 2 years of estrogen therapy[32]
A secondary analysis of an RCT suggested that lower doses of ASA were associated with a higher risk of perioperative stroke and death in patients undergoing carotid endarterectomy[33]	A large prospective RCT showed a higher risk of perioperative stroke, myocardial infarction or death with high-dose ASA[33]
A physiologic study demonstrated that β blockers result in a decline in ejection fraction and increases in end-diastolic volume in patients with prior myocardial infarction[34]	A meta-analysis of 18 RCTs[35] and 3 large trials (CIBIS−2,[36] MERIT-HF[37] and COPERNICUS[38]) in patients with heart failure found a 32% relative risk reduction in death in patients receiving β blockers

for treatments that can be crossed over (for example, short-acting medical treatments rather than surgery) and which are targeted at symptom relief and quality of life, as opposed to serious outcomes such as myocardial infarction and death. Even then, *n* of 1 RCTs are not feasible for many patients because of lack of infrastructure to support them, such as a pharmacy that is able and willing to provide matching placebos. Also, short-term symptomatic effects of treatments may differ from their long-term effects, so that *n* of 1 trials may provide misleading answers. Similarly, if side effects occur only after prolonged treatment (for example, during to drug accumulation, as with amiodarone), then short-term crossover studies (which is what *n* of 1 trials are) may not identify the full risks associated with a treatment. As such, there has been limited implementation of *n* of 1 RCTs in cardiology, but they represent a unique opportunity (when possible and applicable) to obtain individual patient level evidence.

Considering our case of the patient with NVAF, the highest level of evidence comes from a systematic review of all the RCTs that have evaluated antithrombotic therapy in patients with atrial fibrillation.[18] This study demonstrates that warfarin reduces the relative of stroke (ischemic and hemorrhagic) by 62%, and aspirin by 22%.

Considering the risk of bleeding associated with warfarin therapy, there is an RCT that demonstrates a 50% decrease in the risk of bleeding if a patient is willing to undergo education, training and self-monitoring of prothrombin time.[44]

Clinical expertise

Evidence-based decision making requires clinical expertise to establish and balance the patient's clinical state and circumstances, preferences and actions, and the best research evidence. Before a therapeutic decision can be considered, clinical expertise is required to get the diagnosis and prognosis right. As shown above, clinical prediction tools can be extremely helpful in determining a patient's prognosis, but they are unlikely to eliminate the need for sound clinical judgment acquired through clinical experience. Sizing up the clinical circumstances has never been more challenging, as commonly there exist several potential interventions, some of which require technical expertise for their effective and safe delivery. Getting the evidence right requires the skill to identify, evaluate and apply the evidence appropriately. Communicating with patients has always been considered important. This takes on greater importance as there is a growing desire on the part of patients to be involved in decisions relating to their health. Expertise is required to provide patients with the information they need, to elicit their preferences, and to incorporate those preferences into the decision.

Currently there is no consensus on how this information should be presented to patients and how their preferences should be incorporated. However, we know that information should not be presented in relative terms (for example, warfarin will decrease your risk of stroke by 62%) because

patients assume their baseline risk is 100% even when they are instructed it is not.[45] A recent systematic review of RCTs that compared decision aids (that is interventions designed to help people make specific choices among options by providing information on those options and outcomes relevant to the patient's health) to traditional ways of involving/informing patients in decision making[46] demonstrated that decision aids, as opposed to usual care, improved the average knowledge scores of patients for the options and outcomes by 20% (95% CI 13–25), reduced decisional conflict scores (that is patients felt more certain, informed, and clear about values in their decision), and increased patient participation in decision making.[46] Where available, decision aids provide a potential means to facilitate information presentation, incorporation of preferences, and participation in the decision-making process.

The varying roles of the components of evidence-based clinical decisions

Depending on the circumstances, any of the circles in the new model could predominate. Varying the size of the circles to reflect their actual contribution to the clinical decision could portray this visually. Sometimes the clinical state or circumstance dominates the clinical decision. For example, a patient who is at very high risk of an outcome and low risk of a complication may have their clinical state dominate the decision-making process. A patient living in a remote area may not have access to anticoagulation monitoring, and this would probably dominate the decision-making process. Patient's preferences can be so strong that they act as the driving factor in the decision-making process. For example, some patients will not take blood products regardless of the clinical situation. Research evidence can be the main factor in decision making when the benefit of an intervention is moderate to large in size and the risk of treatment small, as with β blocker therapy in patients post myocardial infarction, ACE inhibitors in coronary artery disease or heart failure, or cholesterol lowering with statins. Finally, clinical expertise can predominate, especially when it is related to technical capabilities.

Application to our patient

For our patient the evidence would suggest an 8% annual risk of stroke and 1% risk of major bleeding without any antithrombotic therapy. With warfarin therapy we would expect the annual risk of stroke to decrease to 3% and the risk of major bleeding to increase to 8%. This latter could be reduced to 4% if the patient were willing to undergo self-monitoring of their prothrombin time and an education program, as discussed above.[44] With aspirin therapy we would expect the annual risk of stroke to decrease to 6% and the risk of major bleeding to increase to 1·3%.

As discussed above, there is no consensus on how to present this information to our patient or how to incorporate his preferences. We have provided a decision aid for patients that describes atrial fibrillation (Table 1.2), a major and minor stroke (Table 1.3), a severe bleed (Table 1.4), and a probability trade-off for no treatment, aspirin and warfarin therapies (Figure 1.3). The descriptions of major and minor stroke and a severe bleed are slight modifications of the descriptions developed and tested by Man-Son-Hing and colleagues.[47] We have also individualized the probability trade-off for our patient, with the knowledge that he would undergo self-monitoring of his prothrombin time if he decided to take warfarin therapy (Figure 1.4).

Once this evidence-based clinical decision is reached our job is not over. The patient will need monitoring to ensure he is able to follow through on his clinical decision. One advantage of the decision aid provided (including his individualized probability trade-off) is that the patient can take the information home and does not have to rely on his memory to recall the facts discussed during your meeting.

Table 1.2 Atrial fibrillation: the most common disorder of the heartbeat

Risk	Chances of developing atrial fibrillation increase with age and it occurs in approximately 10% of all people above the age of 75
Physical symptoms	Irregular and usually rapid beating of the heart, sensed as a fluttering in the chest. Some patients feel no symptoms and are unaware that they have atrial fibrillation
Complications	Stroke • Atrial fibrillation increases the risk of a clot developing in the heart. This clot can be swept up towards the brain, causing a stroke • The chance of developing a stroke with atrial fibrillation increases with either age greater than 65 years, high blood pressure, diabetes, heart failure, or a history of strokes or "mini-strokes" • The risk of developing a stroke with atrial fibrillation varies, depending on how many of these risk factors you have
Treatment	• There are medications that thin the blood, which help to prevent clots and therefore stroke • Because the blood is thinned there is an increased risk of bleeding

Table 1.3 ☹ Strokes ☹ can be minor or major in severity. If you have a stroke as a result of atrial fibrillation, your chance of having a minor or major stroke are equal

	Minor stroke	Major stroke
Physical symptoms	You suddenly cannot move or feel one arm and one leg	You suddenly are unable to move one arm and one leg You cannot swallow
Mental symptoms	You are unable to fully understand what is being said to you You have difficulty expressing yourself	You are unable to understand what is being said You are unable to speak
Pain	You feel no physical pain	You feel no physical pain
Recovery	You are admitted to hospital Your weakness, numbness and problem with understanding improve, but you still feel slightly weak or numb in one arm and one leg You are able to do almost all of the activities you did before the stroke You can function independently You leave the hospital after 1 week	You are admitted to hospital You cannot dress The nurses feed you You cannot walk After 1 month of physiotherapy you are able to wiggle your toes and lift your arm off the bed You remain this way for the rest of your life
Further risk	You have an increased risk of having more strokes	Another illness will probably cause your death

Table 1.4 ☹ Severe ☹ bleeding while taking warfarin or ASA: an example of a stomach bleed

Physical	You feel unwell for 2 days, then suddenly you vomit blood
Treatment	You are admitted to hospital You stop taking warfarin or ASA A doctor puts a tube down your throat to see where you are bleeding from You receive sedation to ease the discomfort of the test You do not need an operation You receive blood transfusions to replace the blood you lost
Recovery	You stay in hospital for 1 week You feel well at the end of your hospital stay You need to take pills for the next 6 months to prevent further bleeding After that you are back to normal

Bleeding from the stomach is the most common type of serious bleeding while taking warfarin or ASA; however, rarely other serious forms of bleeding can occur, such as bleeding within the head after a fall.
Warfarin or ASA can also cause minor bleeding, including bruising and nose bleeds.
Taking warfarin can mean costs and inconvenience to yourself and family. For example: need for blood tests; parking/transportation; cost of warfarin.
Taking ASA can mean costs to yourself.
For example: cost of ASA.

Limitations of evidence-based clinical decision model

This model does not consider the important roles that society, governments or healthcare organizations can play in decision making. We deliberately restricted ourselves to decisions made by patients and their healthcare providers to allow a focused exploration of the issues involved in their immediate decision making process. However, a healthcare organization may pre-empt these decisions. For example, not funding primary percutaneous transluminal coronary angioplasty in acute myocardial infarction can have an enormous impact on health outcomes, and will impose a clinical decision on all patients and physicians by eliminating this option. Physicians will have to factor in such issues when considering their patient's clinical circumstances.

Without any blood thinning medication

Conclusions

The foundations for evidence-based medicine have been established over the centuries but the specific philosophies, concepts, definitions and models have essentially evolved over the past few decades. Evidence-based medicine is about solving clinical problems. Evidence-based decision making depends upon utilizing clinical expertise to integrate information about a patient's clinical setting and circumstances with the best research evidence while incorporating the patient's preferences and actions.

2 A critical appraisal of the cardiovascular history and physical examination

Akbar Panju, Brenda Hemmelgarn, Jim Nishikawa, Deborah Cook, Allan Kitching

There have been numerous technological advances made in the diagnosis and treatment of cardiovascular disease. In spite of this, a carefully conducted clinical examination remains the cornerstone in the initial assessment of the patient with known or suspected cardiovascular disease. Before conducting further laboratory or radiologic diagnostic tests, clinicians implicitly consider each piece of historical information and each finding from the physical examination as a diagnostic test that increases or decreases the probability of the possible diagnoses. The competency and accuracy of the clinical examination is therefore crucial, for it serves as the basis for our judgment regarding not only diagnosis, but prognosis and therapy as well.

This chapter is not intended to provide details of how to perform a cardiovascular history and physical examination, and should be read in conjunction with standard textbooks on cardiology to obtain such information. Instead, we will provide the reader with the tools to identify those features of the history and physical examination reported in the literature which are the most reliable and valid in assessing a patient with cardiovascular disease. We will focus on strategies to locate literature on the clinical examination, as well as guidelines to assess the quality of those studies. These techniques will then be applied to three common features of the cardiovascular history, namely chest pain, dyspnea and syncope, as well as common features of the physical examination, including assessment of the apical impulse, the third heart sound, central venous pressure, systolic murmurs, blood pressure and arterial pulse. We would also encourage the reader to access The Rational Clinical Examination series published in the *Journal of the American Medical Association* for further reviews on various aspects of the cardiovascular physical examination.[1–9] The following topics will be covered in this chapter:

- Strategies used to locate literature on clinical examination
- How to critically appraise this literature
- Application of the above in the cardiovascular history (chest pain, dyspnea, syncope)
- Application of the above in the cardiovascular physical examination (apical impulse, central venous pressure, systolic murmurs, blood pressure, arterial pulse).

Strategies used to locate literature on clinical examination

There are no validated strategies for locating precise and accurate information on obtaining a cardiovascular history and conducting a physical examination. A proposed strategy for searching the MEDLINE database is summarized in Box 2.1. This is the method suggested for authors of the Rational Clinical Examination series appearing in the *Journal of the American Medical Association*.[10] The first terms capture the clinical topic of interest by specifying the disease or presentation or function/dysfunction being sought. The second group of terms seeks clinical skills articles. The third group of terms is intended to find articles of high methodologic quality. An efficient strategy to locate high-quality articles would be to combine the first two groups of terms with "diagnosis (pre-exploded)" to maximize sensitivity, or with "sensitivity (textword)" to maximize specificity. This is an extension of the method suggested by the ACP Journal Club for finding high-quality articles on diagnostic tests in general.[11]

Box 2.1 Search strategy for clinical skills articles using MEDLINE

Group 1 terms

Term(s) for clinical entity of interest (for example, syncope, myocardial infarction) combined with (AND)*

Group 2 terms

- Physical examination (exploded; in title, abstract or subject heading)
- Medical history-taking (exploded)
- Professional competence (exploded)
- Diagnostic tests, routine
- Combined with (OR)*

Group 3 terms

- Sensitivity and specificity (textword; exploded)
- Reproducibility of results
- Observer variation
- Decision support techniques
- Bayes' theorem

*AND and OR represent Boolean terms (symbolic representation of relationships between sets) for combining items.

Any comprehensive search for relevant articles should include a review of reference lists from the articles found and

review articles on the topic, as well as textbooks on clinical examination, and advice from clinicians interested in clinical examination.

How to critically appraise the literature on clinical examination studies

Having located articles on the cardiovascular clinical examination, one must carefully review each study to establish its validity, or accuracy, prior to deciding whether the results obtained will aid in establishing or ruling out a particular diagnosis. We propose a strategy for evaluating the literature on clinical examination based on a framework developed for the *Users' Guides to the Medical Literature* series.[12] In assessing the validity of the study, and interpreting the results, the following points should be considered.

- Are the results of the clinical examination study valid?
    1. Was there an independent blind comparison with a reference (gold) standard of diagnosis?
    2. Was the clinical feature evaluated in an appropriate spectrum of patients (like those in whom it would be used in clinical practice)?
    3. Was the reference standard applied regardless of the result of the clinical feature?
    4. Were the methods of performing the clinical features described in sufficient detail to permit replication?
    5. Was there a description of the experience of the individuals doing the examination?
- What were the results?
    1. Are likelihood ratios for the results presented, or data necessary for their calculation provided?
    2. Has there been consideration given to reproducibility, precision, and disagreement?

The application of the initial five guides will help the reader determine whether the results of the study are likely to be valid. If the results are deemed to be valid, the reader can then go on to interpret the results presented, of which the likelihood ratio (LR) is the most important index in determining how good a particular diagnostic test is. The likelihood ratio is the probability that the results of a test would be expected in a patient with, as opposed to one without, the target disorder.

The application of these techniques for critically appraising the cardiovascular history and physical examination will now be described.

Clinical features in the cardiovascular history

Chest pain

There are many causes of chest pain, including both cardiac and non-cardiac conditions, as outlined in Figure 2.1.

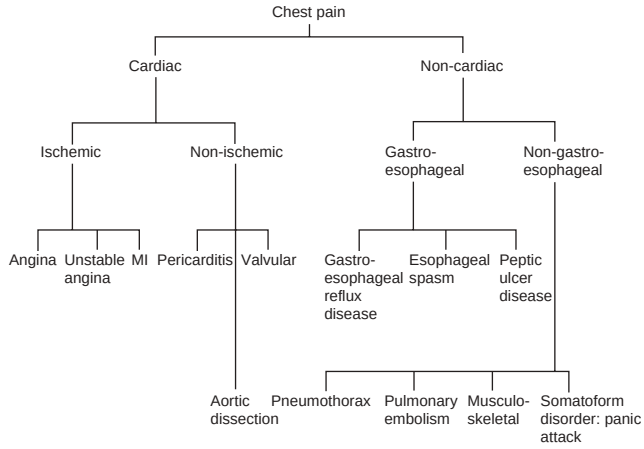

Figure 2.1 Cardiac and non-cardiac conditions presenting with chest pain

Elucidating the cause of the pain is important for both management purposes and prognosis. To ensure that the appropriate intervention is undertaken in the clinical setting, it is useful to classify patients presenting with chest pain into three categories:

1. Patients with myocardial infarction
2. Patients with myocardial ischemia but no infarction
3. Patients with non-cardiac chest pain.

The characteristics of the chest pain may help differentiate patients into the appropriate category. To identify features of the pain that might aid in classifying patients into category 1, myocardial infarction, we undertook a review of the literature using a search strategy similar to that outlined in the first section above. Relevant articles identified from this search were critically appraised using criteria outlined in the previous section. For the sake of relevance and clarity we have chosen to present only the results of those features in which a likelihood ratio of at least 2·0 or greater, or 0·5 or less, was obtained. The five studies that meet this criterion provide the best available evidence for identifying features of chest pain which aid in the diagnosis of myocardial infarction.

As outlined in Table 2.1, the features of the pain that increased the probability of a myocardial infarction included radiation, pain in the chest or left arm, and chest pain described as the most important symptom. Chest pain radiation was the clinical feature which increased the probability of a myocardial infarction the most, with a widespread distribution of pain being associated with the highest likelihood ratios. In particular, chest pain radiating to the left arm was twice as likely to occur in patients with rather than without an acute myocardial infarction, whereas radiation to the right shoulder was three times, and radiation to both the left and right arm seven times, as likely to occur in such patients. The quality of the pain, including pain described as squeezing or pressure, added little to establishing a diagnosis of myocardial infarction, with likelihood ratios of less than 2.

Table 2.1 Features of chest pain that increase the probability of a myocardial infarction

Clinical feature	References	LR (95% CI)
Chest pain radiation:		
(R) shoulder	Tierney *et al*[14]	2·9 (1·4–6·0)
(L) arm	Berger *et al*[13]	2·3 (1·7–3·1)
both (L) and (R) arm	Berger *et al*[13]	7·1 (3·6–14·2)
Pain in chest or (L) arm	Pozen *et al*[15]	2·7*
Chest pain most important symptom	Pozen *et al*[15]	2·0*

Abbreviations: CI, confidence interval; LR, likelihood ratio
*Data not available to calculate CIs.

Features of the chest pain that decrease the probability of myocardial infarction, and which therefore would be useful in ruling out a myocardial infarction, are outlined in Table 2.2. Pleuritic or positional chest pain, as well as chest pain described as sharp or stabbing, decrease the likelihood of a myocardial infarction. In addition, chest pain reproduced by palpation on physical examination was also associated with a low probability of myocardial infarction.

Table 2.2 Features of chest pain that decrease the probability of a myocardial infarction

Clinical feature	References	LR (95% CI)
Pleuritic chest pain	Tierney *et al*,[14] Lee *et al*,[16] Solomon *et al*[17]	0·2 (0·2–0·3)
Chest pain sharp or stabbing	Tierney *et al*,[14] Lee *et al*[16]	0·3 (0·2–0·5)
Positional chest pain	Lee *et al*,[16] Solomon *et al*[17]	0·3 (0·2–0·4)
Chest pain reproduced by palpation	Tierney *et al*,[14] Lee *et al*,[16] Solomon *et al*[17]	0·2–0·4*

Abbreviations: CI, confidence interval; LR, likelihood ratio
*In heterogenous studies the likelihood ratios are reported as ranges.

The precision in obtaining a chest pain history was addressed by Hickman and colleagues,[18] who assessed the interobserver agreement in chest pain histories obtained by general internists, nurse practitioners, and self-administered questionnaires for 197 inpatients and 112 outpatients with chest pain. The agreement between two internists for seven of the 10 items, including location and description of the pain, as well as aggravating and relieving factors, was substantial (κ, a measure of chance-corrected agreement, was 0·50–0·89). Agreement was slightly lower between internist and questionnaire, and between the nurse practitioners and internists, with the lowest level of agreement between nurse and questionnaire. Features of the chest pain associated with a lower probability of myocardial infarction, namely pleuritic, positional and sharp chest pain, were typically associated with a modest level of agreement for all comparisons (κ 0·26–0·62).

Although cardiac catheterization remains the definitive diagnostic procedure for allocating patients to category 2 – that is, the presence of myocardial ischemia or coronary artery disease – the character of the chest pain has also been identified as one of the most important clinical features in establishing the diagnosis of coronary artery disease.[19] The combination of typical angina and a long duration of symptoms was particularly predictive of severe disease. Although this study was undertaken in a very select group of patients (those who underwent cardiac catheterization), similar results were obtained from outpatients referred for non-invasive testing.[20] After smoking, typical angina was the variable most strongly associated with significant coronary disease (defined as >75% luminal narrowing of at least one major coronary artery). Subjects with typical angina were 13 times more likely to have significant coronary disease than those without.

There are many causes of non-cardiac chest pain, as outlined in Figure 2.1, and each condition has its own characteristic features and associated symptoms. It is beyond the scope of this chapter to identify all these conditions.

Dyspnea

Dyspnea, defined as an uncomfortable awareness of breathing, is a common complaint of both in- and outpatients. Cardiac and pulmonary causes of dyspnea are most common, with congestive heart failure, asthma and chronic obstructive pulmonary disease accounting for most complaints.[21] However, standard textbooks of internal medicine list over 30 different etiologies for dyspnea,[22] often with multiple etiologies explaining a patient's symptoms. It is often taught that the cause of dyspnea, of either the heart or the lungs, can be differentiated at the bedside by thorough history-taking. Unfortunately, such strategies to diagnose a cardiac cause for the breathless patient have been incompletely studied.

Zema and coworkers[23] looked at the value of symptoms as predictors of left ventricular systolic dysfunction in 37 patients with a clinical diagnosis of chronic obstructive pulmonary disease (COPD). Eliciting a symptom of dyspnea on exertion predicted depressed left ventricular systolic function with a sensitivity of 100% and a specificity of 20%. The symptom of orthopnea generated a sensitivity and specificity of 71% and 65%, paroxysmal nocturnal dyspnea 47% and 75%, and ankle edema 41% and 75%, respectively. All features were associated with a likelihood ratio of 2 or less. In general the study was well conducted, but the value of the results to the practicing clinician must be questioned. First, the symptoms of shortness of breath attributed to the heart

were only considered in the context of impaired left ventricular (LV) systolic function. It is now generally agreed that abnormalities in LV diastolic function also cause symptoms of dyspnea. A better gold standard would perhaps have been radionuclide ventriculographic evidence of both LV systolic and diastolic dysfunction. The generalizability of the results is also lessened by the fact that their definition of heart failure was a left ventricular ejection fraction (LVEF) <50%, when in fact the target for treatment of patients with heart failure is most often an LVEF of <40%. Finally, the study was performed in patients who first had a clinical diagnosis of COPD, when patients present with many causes of shortness of breath, not just COPD.

In summary, therefore, specific features when elicited in a patient presenting with a complaint of dyspnea are of limited usefulness in making a definitive diagnosis of impaired LV function.

Syncope

Little detailed evidence exists for either individual or clusters of clinical examination findings in the evaluation of syncope. In a prospective study of 433 syncopal patients presenting in a university setting (emergency, in- and outpatients), the history and physical examination were found to identify 55% (140) of the 254 causes ultimately found.[24] Many of the non-cardiac causes of syncope in this study were defined in clinical terms, and so provided the "diagnostic standard" for classification. The three most common non-cardiac causes were "orthostatic hypotension" (systolic drop of more than 25 mmHg, or drop of more than 10 mmHg to less than 90 mmHg with symptoms), "situational" (situations included cough, micturition and defecation, and required appropriate timing and no other identifiable cause) and "vasovagal" (requiring a precipitating event and premonitory symptoms), representing 31%, 26% and 25%, respectively, of identifiable causes of syncope overall.

Follow-up of the cohort demonstrated a 5 year mortality of 50·5% for cardiac versus 30% for non-cardiac or 24% for unknown causes. This provides some independent validation for the clinical classification criteria.

There is a need for further work in this area, particularly in developing and validating practical clinical tools to screen for psychiatric causes, to distinguish patients who will benefit from electrophysiologic testing, and to predict those who will have a positive tilt-table test.

Clinical features in the cardiovascular physical examination

Apical impulse

The apical impulse was first described by William Harvey in 1928[25] and is one of a number of palpable precordial pulsations reflecting the underlying movement of the heart and great vessels. Many criteria exist defining the normal location, size and character of the apical impulse, and many generations of medical students have been taught that an "abnormal" apical impulse may assist with the diagnosis of left ventricular enlargement and/or hypertrophy. It is only recently that evidence has been published to support these claims.

The relationship between the location and size of the apical impulse and LV size, as determined by two-dimensional echocardiography (gold standard), was evaluated by Eilen and colleagues.[26] An apical impulse lateral to the midclavicular line, defined as half the distance between the tip of the acromion process and the sternal notch, was a sensitive (100%) but not specific (18%) indicator for LV enlargement, with a likelihood ratio of only 1·2. Identification of the apical impulse <10 cm from the midsternal line was just as sensitive (100%) but only marginally more specific (33%). An apical diameter of <3 cm was a good indicator of LV enlargement, with a sensitivity of 92% and a specificity of 75%, and was almost four times as likely to occur in patients with, as opposed to those without, LV enlargement (LR=3·7).

O'Neill and coworkers[27] examined the relationship between the location of the apical impulse and the presence or absence of cardiomegaly on chest *x*-ray (defined as a cardiothoracic ratio greater than 50%). An apical impulse lateral to the midclavicular line had a sensitivity of 57%, a specificity of 76%, and a likelihood ratio of 2·4 for identifying cardiomegaly. Identification of the apical impulse >10 cm from the midsternal line was slightly more sensitive (78%) but considerably less specific (28%), and added little to establishing the diagnosis (LR=1·1). The results of this investigation must be accepted with caution, as the gold standard used in this case was chest *x*-ray, which is not a sensitive or specific marker of LV enlargement. Therefore, the validity of this gold standard must be questioned. This was, however, one of the few studies that also evaluated the variation between observers (interobserver variation) in the clinical assessment of the apical impulse, and reported good agreement on apex palpability (κ=0·72) and moderate agreement on degree of apex displacement (κ=0·56) between two physicians.

Eagle and coworkers[28] examined several clinical features in 125 inpatients with a variety of cardiac and non-cardiac diagnoses in an attempt to determine which features best predicted LVEF. In general, physician estimates of LVEF were good, with 56% being accurate within 7·5% of measured value; 27% of physicians overestimated and 17% underestimated the LVEF. Multiple regression analysis identified three clinical features most predictive of LVEF, including S_3 gallop, hypotension, and sustained LV apical impulse (defined as a palpable impulse greater than two thirds the ventricle systole).

In summary, the location, size and character of the apical impulse may be used to assess LV size, LV function and

cardiomegaly, either alone or in combination with other clinical features or simple diagnostic tests. However, a number of limitations exist, including the fact that a palpable impulse may only be found in approximately 50% of patients. In addition, the high sensitivity but low specificity associated with determining the location and size of the apical impulse make it a better test for ruling out rather than ruling in LV enlargement, which is good for screening but has limited usefulness at the bedside.

Third heart sound

Few studies have assessed the reliability and validity of detecting a third heart sound on physical examination. The studies that have been conducted suggest that the agreement between observers with respect to the presence of a third heart sound is low or moderate at best.[29–31] In one study, cardiologists, internists and residents in internal medicine examined 46 patients for the presence or absence of a third heart sound.[30] The overall interobserver agreement was poor, with a κ of only 0·18. A somewhat better agreement for the presence of a third heart sound was achieved in an earlier study by two internists and two cardiologists, with a κ of 0·40.[31] The evidence regarding the validity of the third heart sound is even more limited. Using a computerized phonocardiogram as a gold standard for the presence of a third heart sound, Lok *et al*[30] report positive and negative predictive values for identifying a third heart sound of 71% and 64%, respectively.

Although the reliability and validity of this physical examination finding may be limited, the detection of a third heart sound on physical examination may have important prognostic implications. Drazner and colleagues[32] performed a retrospective analysis of 2569 patients with symptomatic heart failure enrolled in the Studies of Left Ventricular Dysfunction treatment trial. In multivariate analyses adjusted for other markers of severity of heart failure, a third heart sound was associated with an almost 50% increased risk of hospitalization for heart failure, or death from pump failure.

Central venous pressure

The right internal jugular vein lies directly in line with the right atrium and acts as a manometer, displaying changes in blood flow and pressure caused by right atrial filling, contraction and emptying. Elevated jugular venous pressure reflects an increase in central venous pressure (CVP).

The reliability and validity of the clinical assessment of CVP have been assessed in a limited number of studies. In one study, medical students, residents and attending physicians examined the same 50 ICU patients and estimated their CVP as low (<5 cm), normal (5–10 cm) or high (>10 cm).[33] Agreement between students and residents was substantial (κ 0·65), agreement between students and attending physicians was moderate (κ 0·56), and agreement between residents and staff was modest (κ 0·30). Possible causes for disagreement include positioning of patients, poor lighting, difficulty in distinguishing carotid from venous pulsations, and variation in pressure with respiration.

As regards the relation between clinical assessments of CVP and the gold standard of simultaneous pressure measurements through a central venous catheter, one study[34] used an attending physician, a fellow, a medical resident, an intern and a student to predict whether four hemodynamic variables, including CVP, were low, normal, high or very high. The sensitivity of the clinical examination at identifying low (<0 mmHg), normal (0–7 mmHg) or high (>7 mmHg) CVP was 33%, 33% and 49%, respectively. The specificity of the clinical examination at identifying low, normal or high CVP was 73%, 62% and 76%, respectively. In another study, Eisenberg and colleagues[35] compared clinical assessments with pulmonary artery catheter readings in 97 critically ill patients. Physicians predicted CVP correctly only 55% of the time, more frequently (27%) underestimating than overestimating (17%).

Clinical assessments of a high CVP increase the likelihood that the measured CVP will be high by about fourfold; conversely, clinical assessments of a low CVP make the probability of finding a high measured CVP extremely unlikely (LR= 0·2).[33] The data demonstrate that clinical assessments of a normal CVP are truly indeterminate, with likelihood ratios approaching 1; such estimates provide no information because they neither increase nor decrease the probability of an abnormal CVP. Apart from less observer variation, CVP estimates are most accurate in patients breathing spontaneously.

The precision of the abdominojugular reflux test has not been reported, but its results will vary with the force of abdominal compression. Although this is an insensitive way to diagnose congestive heart failure, the specificity of the test is high.[36,37] Moreover, the positive likelihood ratios (6·4 when diagnosis was based on a clinical–radiographic score, and 6·0 when diagnosis was based on emergency room physician judgment) indicate that this is a useful bedside test.[1]

Systolic murmurs

Etchells and colleagues[2] have published a thorough review of the clinical examination for systolic murmurs. This included a systematic review of the literature and grading of the quality of the original articles. Quality was assessed by the sample size and recruitment (consecutive versus convenience) and whether comparison with the diagnostic standard was done independently and blindly.

Useful data for ruling aortic stenosis in or out are given in Tables 2.3 and 2.4. The reliability of the examination by cardiologists for late peaking murmur shape is good (κ 0·74), for the presence of murmurs is fair to moderate (κ 0·29–0·48),[2] but for other maneuvers may be poorer.[38]

Table 2.3 Features of the clinical examination that increase the probability of aortic stenosis

Clinical feature	LR*
Slow rate of rise of carotid pulse	2·8–130
Late peaking murmur	8–101
Soft or absent second heart sound	3·1–50

*LR, likelihood ratio: range of point estimates from original studies cited
Data from Etchells *et al*[2]

Table 2.4 Features of the clinical examination that decrease the probability of aortic stenosis

Clinical feature	LR*
Absence of a murmur	0
No radiation to right carotid artery	0·05–0·10

*LR, likelihood ratio: range of point estimates from original studies cited
Data from Etchells *et al*[2]

Studies of the clinical examination for other etiologies of systolic murmur were also reviewed but tended to be of lesser quality than those addressing aortic stenosis.

Subsequent to their original work,[2] Etchells and colleagues have gone on to develop a two-stage prediction rule for moderate–severe aortic stenosis (defined as an average valve area of less than or equal to 1·2 cm^2 or a peak gradient at or above 25 mmHg).[39] In this rule a murmur not radiating to the right clavicle was associated with a likelihood ratio of 0·1 (95% CI 0·02–0·44), significantly reducing the likelihood of aortic stenosis. If the murmur did radiate to the clavicle, the presence of 0–2 associated findings increased the likelihood ratio to 1·76 (95% CI 0·9–2·9), and 3–4 associated findings resulted in a likelihood ratio of 40 (95% CI 6·6–239), suggesting that the diagnosis of aortic stenosis is supported by a greater number of associated findings. The associated findings were reduced carotid volume, slow carotid upstroke, reduced second heart sound intensity, and murmur intensity in the second right intercostal space as loud as or louder than in the fifth left intercostal space.

Etchells and colleagues[2] point out that the majority of studies of this topic have used cardiologists as observers. The performance of non-cardiologists appears to be less accurate when studied. Further work, like their own, using a broader range of clinicians and patients, is needed to discover the value of the clinical examination in more general settings.

Blood pressure

An extensive review of the technique, reliability and validity of blood pressure (BP) measurement has been provided by Reeves.[3] As outlined in the review, two important sources of variation in BP measurement include the patient and the examiner. Random fluctuation in BP over time has been documented by the SD of readings, with a minute-to-minute variation of about 4 mmHg systolic and 2–3 mmHg diastolic, and day to day variation of 5–12 mmHg systolic and 6–8 mmHg diastolic. With respect to the examiner as the source of variability, differences of 10–8 mmHg by both physicians and nurses in routine medical practices have been noted.

Intra-arterial blood pressure measurement has been used as the gold standard to assess the accuracy of indirect BP measurement. With the indirect BP the phase I Korotkoff, or first audible sound, appears 15–4 mmHg below the direct systolic BP, whereas phase V, or disappearance of all sounds, appears 3–6 mmHg above the true diastolic BP in adults. Other factors that affect the accuracy of the indirect BP measurement, resulting in both an increase and a decrease in systolic and/or diastolic measurements, are outlined in Tables 2.5 and 2.6.

Table 2.5 Factors associated with an increase in blood pressure

Factor	Magnitude, SBP/DBP (mmHg)
Examinee	
Pseudohypertension	2–98/3–49
"White coat reaction" to physician	11–28/3–15
"White coat reaction" to non-physician	1–12/2–7
Paretic arm (due to stroke)	2/5
Pain, anxiety	May be large
Acute smoking	6/5
Acute caffeine	11/5
Acute ethanol ingestion	8/8
Distended bladder	15/10
Talking, sighing	7/8
Setting, equipment	
Leaky bulb valve	>2 DBP
Blocked manometer vents	2 to 10
Examination	
Cuff too narrow	−8–+10/2–8
Cuff not centered	4/3
Cuff over clothing	5–50
Elbow too low	6
Back unsupported	6–10
Arm unsupported	1–7/5–11
Too slow deflation	−1–+2/5–6
Too fast deflation	DBP only
Parallax error	2–4
Using phase IV (adult)	6 DBP
Too rapid remeasure	1/1
Cold season (*v* warm)	6/3–10

Abbreviations: DBP, diastolic blood pressure; SBP, systolic blood pressure
Data from Reeves *et al*[3]

Table 2.6 Factors associated with a decrease in blood pressure

Factor	Magnitude, SBP/DBP (mmHg)
Examinee	
Recent meal	−1–1/1–4
Missed auscultatory gap	10–50 SBP
High stroke volume	Phase V can=0
Habituation	0–7/2–12
Shock (additional pseudohypotension)	33 SBP
Setting, equipment	
Faulty aneroid device	Can be >10
Leaky bulb	≥2 SBP
Examiner	
Reading to next lowest 5 or 10 mmHg or expectation bias	Probably ≤10
Impaired hearing	SBP only
Examination	
Left *v* right arm	1/1
Resting for too long (25 min)	10/0
Elbow too high	5/5
Too rapid deflation	SBP only
Excess bell pressure	≥9 DBP
Parallax error (aneroid)	2–4

Abbreviations: DBP, diastolic blood pressure; SBP, systolic blood pressure
Data from Reeves *et al*[3]

Arterial pulse

Few studies have been undertaken to assess the reliability and validity of features of the arterial pulse in the cardiovascular examination, despite numerous descriptive accounts of its variability in different clinical conditions. Case series indicate that details regarding the presence and quality of the arterial pulse are more sensitive markers of coarctation of the aorta than aortic dissection. Absent femoral pulses or a femoral/brachial pulse discrepancy in patients was associated with a sensitivity of 88% in the diagnosis of coarctation of the aorta in patients less than 6 months of age.[40] Similar results were obtained for patients diagnosed with coarctation after 1 year of age, where weak or absent femoral pulses were associated with a sensitivity of 85%.[41]

The sensitivity of the presence and quality of the carotid, subclavian and femoral pulses in establishing a diagnosis of both proximal (primary tear in the ascending aorta with or without involvement of the arch, De Bakey classification type I and II) and distal (primary tear in the descending thoracic aorta, De Bakey classification type III) aortic dissections are outlined in Table 2.7. Proximal dissections were primarily associated with an absence or decrease in the brachiocephalic vessels, whereas distal dissections almost exclusively involved the femoral arteries.

Table 2.7 Sensitivity of the arterial pulse in the diagnosis of aortic dissection

	Aortic dissection (%)	
References	**Proximal***	**Distal†**

Spittell *et al*[44**]	9·0	2·4

* De Bakey classification type I and II.
† De Bakey classification type III.
§ Absence or decrease in amplitude of carotid, subclavian or femoral pulse(s).
** Absence of palpable carotid, subclavian or femoral pulse(s).

Features of the arterial pulse may also be used to determine the presence of valvular heart disease. As reported by Etchells *et al*,[2] features of the arterial pulse, including rate of rise of the carotid pulse, apical carotid delay and brachioradial delay, all increase the likelihood of establishing the diagnosis of aortic stenosis (Table 2.8).

Table 2.8 Features of the arterial pulse that increase the probability of aortic stenosis

Clinical feature	LR*
Slow rate of rise of carotid pulse	2·8–130
Apical carotid delay	∞
Brachioradial delay	6·8

* LR, likelihood ratio: range of point estimates from original studies cited.
Data from Etchells *et al*[2]

The diagnostic value of the pedal pulse examination, as an aid to establishing the diagnosis of peripheral arterial disease, has also been studied.[45] In this review the absence of both the dorsalis pedis and posterior tibial pulses was a powerful predictor for the presence of vascular disease (defined as an ankle-to-arm systolic pressure index of <0·9), with likelihood ratios ranging from 9·0 to 44·6. The presence of a femoral arterial bruit was also a strong indicator of disease, with likelihood ratios of 4·7–5·7.

Heart rate is another important component of the cardiovascular examination. The accuracy of the assessment of heart rate may be affected by both the site (apical or radial) as well as the counting interval (15, 30 or 60 seconds). With a regular rhythm, radial 15 second counts were the least accurate for both resting and rapid heart rates, whereas the 30 second counts were found to be the most accurate and efficient for rapid rates.[46] With the irregularly irregular rhythm of atrial fibrillation, however, the apical method and 60 second count have been reported to be the most accurate, with site being a more important source of error than

counting interval.[47] Using the ECG as the measure of true heart rate, the mean radial error for all counting intervals was 19·5 beats per minute, which was significantly higher than the mean apical error of 9·7 beats per minute.

Although the pulse in atrial fibrillation is typically described as "irregularly irregular", Rawles and Rowland,[48] using computerized analysis of R–R intervals and pulse volumes in patients with atrial fibrillation, disputed this assumption. In an assessment of 74 patients with atrial fibrillation they reported a non-random sequence of R–R intervals in 30%, and the presence of pulsus alternans in less than half (46%). The authors concluded that patterns of regularity of the pulse are common in patients with atrial fibrillation.

Summary

Despite the frequency with which details of the history and physical examination are used to establish or rule out a particular cardiovascular condition, there is a very limited amount of data available to support the reliability and validity of these features. The one component of the cardiovascular history which has been studied is that of chest pain in the diagnosis of myocardial infarction. Features of chest pain, particularly pain that has a wide distribution of radiation, increase the probability of myocardial infarction, whereas chest pain that is pleuritic, sharp or stabbing, positional or reproduced by palpation, decreases the probability of myocardial infarction.

The reliability and validity of various features of the cardiovascular physical examination have also received little attention in the literature. Of those that have been studied, the apical impulse has been shown to be a sensitive but nonspecific marker of LV size, which makes it useful for ruling out, rather than ruling in, LV enlargement. Clinical assessment of elevated CVP has been shown to be associated with a fourfold likelihood that the measured CVP will be high, with the abdominojugular reflex being a useful bedside test to assist in the diagnosis of congestive heart failure.

Of the cardiac murmurs, aortic stenosis has been studied the most thoroughly. Features of the clinical examination that increase the probability of diagnosing aortic stenosis include slow rate of rise of the carotid pulse, late peaking murmur, and soft or absent second heart sound. Conversely, absence of a murmur or no radiation to the right carotid artery or clavicle were features associated with a decreased probability of aortic stenosis. Recent work would suggest that the presence of an increased number of associated findings increases the likelihood of aortic stenosis.

A number of features have been shown to influence the accuracy of the indirect assessment of BP, including those related to the examinee, the examiner, the setting and equipment, and the examination itself. Assessment of the arterial pulse in diagnosing coarctation of the aorta and aortic dissection has been limited to case series, therefore estimates of sensitivity only are available. Features of the arterial pulse have been shown to be relatively sensitive markers for coarctation of the aorta and for chronic lower extremity ischemia, but less so for aortic dissection. Finally, both counting interval and site (radial versus apical) have important implications on the accuracy of heart rate assessment.

As is evident from the information presented, unfortunately, for a variety of reasons, research on clinical examination has lagged behind basic science and therapeutic research. So far, clinical examination is identified as the "art" of medicine, and by incorporating an evidence-based approach one can make clinical examination the "art and science" of medicine.

3 Obtaining incremental information from diagnostic tests

Raymond J Gibbons

Consider the following case history. A 75 year old male presents with a history of exertional chest pain. The patient describes substernal chest pain that he perceives as a "pressure sensation" occurring when he walks too fast, uphill, or in the cold. It is relieved by rest within a few minutes. On two recent occasions, he tried a friend's nitroglycerin tablets, and obtained even more rapid relief of his symptoms. His symptoms have never occurred at rest. The patient has a history of diabetes mellitus, hypertension, and hypercholesterolemia. He smokes one pack of cigarettes a day. Several male family members died of coronary artery disease before the age of 60. The patient underwent carotid artery surgery a year ago for treatment of transient ischemic attacks.

On the basis of his age, gender, chest pain description, and risk factors, this patient is highly likely to have significant obstructive coronary artery disease (CAD). The added, or incremental, value of any stress test for the diagnosis of the presence of disease in such a situation is very small. Out of 100 patients with this presentation, perhaps only one or two will not have obstructive CAD. The potential contribution of stress testing is therefore restricted to only these one or two patients.

This example demonstrates the importance of the concept of incremental value for diagnostic tests. In the current era of healthcare reform, it is no longer sufficient that a test simply provide "more information". The more appropriate current questions are:

- how much information does the test provide, and
- at what cost?

Increasingly, tests are also required to have a demonstrable impact on critical nodal, or decision, points with respect to patient management.

The demonstration of the incremental value of diagnostic tests requires rigorous methodology. The principles of the required methodology should be credited primarily to Dr George Diamond and his colleagues at Cedar Sinai Medical Center in Los Angeles.[1–3] First and foremost, such an analysis should reflect clinical decision making. Since clinical assessment is performed before any diagnostic tests, and usually at lower cost, parameters available from this assessment should be considered separately without any information from subsequent testing. The analysis should preferably focus on hard, demonstrable end points such as significant obstructive CAD, severe (three vessel or left main) coronary artery disease, myocardial infarction, or death. Although alternative end points, such as functional impairment, unstable angina, and the need for revascularization, are often included to increase statistical power, such end points have major limitations with respect to reversibility, subjectivity, and definite impact on patient outcome. The analysis should create appropriate models that include all available important variables. An experienced clinician always takes the patient's age, gender, and history into account in making his or her clinical decision regarding patient management, even when testing results are available. These important clinical parameters must therefore be included in any final model that reflects the clinical decision making process. The analysis must demonstrate that the additional information is statistically significant in an appropriate patient population. Analyses that demonstrate additional information in older, "sicker" inpatient populations should not be casually extrapolated to younger, "less sick" outpatients in whom testing is customarily performed. Finally, the test must provide information that is clinically significant and cost effective. In very large patient samples, differences that have little, if any, clinical significance for individual patient management may emerge as statistically significant. The potential impact on patient management in *some* patients must compare favorably with the incremental cost of the test in *all* the patients who must be tested.

This chapter will attempt to elucidate this methodology using the published data with respect to the diagnosis of significant obstructive CAD, non-invasive screening for severe CAD, and patient outcome. All of these examples are drawn from the arena of ischemic heart disease, because this entity is a predominant feature of clinical practice in cardiology, and the published literature is voluminous and extensive. However, the same principles apply to other disease entities, both cardiac and non-cardiac.

Clinical assessment

As outlined above, the initial step in any analysis designed to demonstrate incremental value is the consideration of all

the information available prior to performance of the test. This will always include the results of the history and physical examination, and may sometimes include the results of other tests already performed. This section focuses on the information available from clinical assessment.

Diagnosis of coronary disease

As demonstrated by the earlier example, clinicians often encounter patients with chest pain and suspected CAD. The ability of clinical assessment to predict the likelihood of significant obstructive CAD has been demonstrated in numerous studies. The likelihood of significant disease based on clinical assessment is appropriately labeled the "pretest probability", in statistical terms.

Age, gender, and the patient's chest pain description are the most important clinical parameters for estimating the likelihood of CAD.[4] Older patients, men, and patients with chest pain that is typical, or classic, for angina pectoris are more likely to have coronary disease. Although multiple different systems have been used to classify chest pain, the simplest and easiest was proposed by Diamond.[5] He suggested a classification based on three elements – substernal location, precipitation by exertion, and relief by rest or nitroglycerin. If all three elements are present, the chest pain is classified as "typical angina". If two elements are present, the chest pain is classified as "atypical angina". If only one or none is present, the chest pain is classified as "non-anginal chest pain".

Table 3.1 shows published estimates of pretest probability on the basis of age, gender, and chest pain description.[4] It is obvious that there is a very wide range of pretest probability, ranging from 1% for a 35 year old woman with non-anginal chest pain to 94% for a 65 year old man with typical angina. Note that a 50 year old man with atypical angina has about a 50% probability of disease.

A more comprehensive attempt to consider all clinical characteristics, including risk factors for atherosclerosis, was published from the Duke University Medical Center databank.[6] In addition to the three parameters previously discussed, this analysis found that evidence for previous infarction, smoking, hyperlipidemia, ST and T wave changes on the resting electrocardiogram (ECG), and diabetes were all highly significant predictors of the presence of coronary artery disease. Figure 3.1 shows a published nomogram for men that incorporates all of these parameters. Careful inspection of this figure demonstrates that the impact of the clinical parameters other than age, gender, and chest pain is variable. ECG and historical evidence of previous infarction have a major impact, diabetes and ECG ST-T changes have a modest impact, and lipids and smoking have a minimal impact. For example, a 50 year old male with atypical angina has a 46% pretest probability of disease in the absence of smoking, hyperlipidemia, or diabetes, a 48% pretest probability in the presence of both smoking and hyperlipidemia, and a 65% pretest probability if he has diabetes as well. In the presence of ECG Q waves and a history of MI, his pretest probability exceeds 90%.

Non-invasive screening for severe coronary artery disease

Not surprisingly, clinical parameters are also very important in estimating the likelihood of severe (three vessel or left main) CAD.[7] The same parameters that are most important for predicting the presence of disease – age, gender, and chest pain description – remain important. In addition, diabetes mellitus and history or ECG evidence of myocardial infarction are also very important. The simplest approach for estimating the likelihood of severe disease was published by Hubbard *et al.*[8] They assigned one point each for: male gender; typical angina; history and ECG evidence of myocardial infarction;

Table 3.1 Pretest probability of coronary artery disease

Age (years)	Pretest probability (%)							
	Asymptomatic		Non-anginal chest pain		Atypical angina		Typical angina	
	F	M	F	M	F	M	F	M
30–39	<1	2	1	5	4	22	26	70
40–49	1	6	3	14	13	46	55	87
50–59	4	9	8	22	32	59	79	92
60–69	8	11	19	28	54	67	91	94

From Diamond and Forrester.[4] Reprinted by permission of the *New England Journal of Medicine*, and Diamond GA. A clinically relevant classification of chest discomfort. *J Am Coll Cardiol* 1983;**1**:547–75

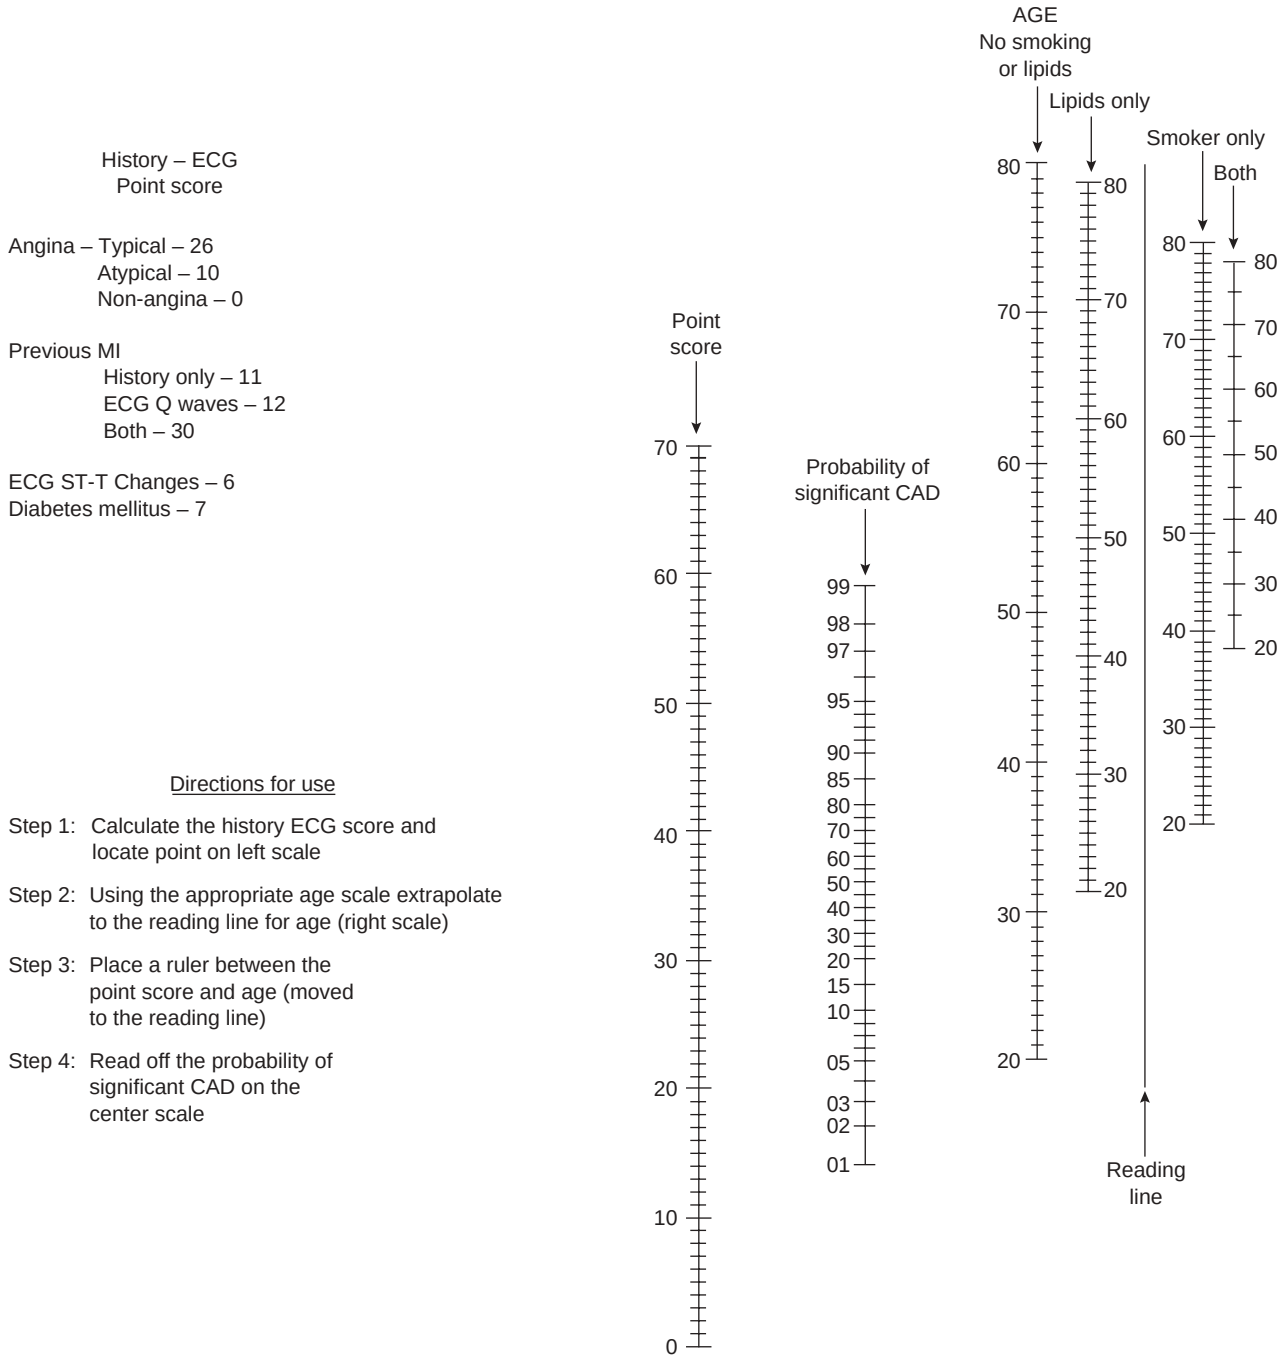

Figure 3.1 Nomogram for predicting the probability of significant coronary artery disease (CAD) in men. ECG, electrocardiogram; MI, myocardial infarction. (After Pryor *et al.*[6]) Example: A 50 year old, white male with atypical angina and diabetes mellitus, but no ECG ST changes, previous MI, smoking, or hyperlipidemia. Point score on left scale = 10 + 7 = 17. Appropriate reading line on right labeled "no smoking or lipids". Connect age 50 on this reading line to point score of 17 with a straight edge. This intersects the middle line at 60, indicating that this is the percentage probability of significant CAD.

diabetes; and insulin use. Thus, the point score had a minimum value of 0 and a maximum value of 5. Figure 3.2 shows a nomogram for the probability of severe CAD based on age and this point score. It is quickly apparent that age is an extremely important parameter for predicting severe disease.

A more comprehensive analysis on a larger number of patients was published from the Duke University Medical Center databank.[9] In addition to the five parameters already mentioned, these workers found that the duration of chest pain symptoms, other risk factors (blood pressure,

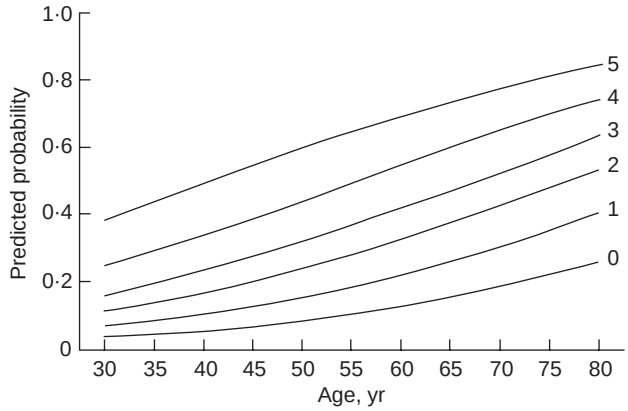

Figure 3.2 Nomogram showing the probability of severe (three vessel or left main) coronary artery disease based on a 5 point score. One point is awarded for each of the following variables – male gender, typical angina, history, and electrocardiographic evidence of MI, diabetes, and use of insulin. Each curve shows the probability of severe coronary disease as a function of age. (From Hubbard *et al*,[8] with permission.)

hyperlipidemia, and smoking), a carotid bruit, and chest pain frequency were also important determinants of the likelihood of severe CAD. However, the magnitude of their additional effect was modest.

Prediction of patient outcome

The ability of clinical assessment to predict patient outcome has been demonstrated in numerous previous studies. The largest and most important of these came from the Duke University databank[10] and the Coronary Artery Surgical Study Registry.[11] Many of the same parameters that predict the presence of disease and the presence of severe disease are also associated with adverse patient outcome. Age, gender, chest pain description, and previous myocardial infarction all have independent value in predicting patient outcome. In addition, history and physical examination evidence for congestive heart failure, history and physical examination evidence of vascular disease, unstable chest pain characteristics, and other ECG findings, such as ST-T wave changes, left bundle branch block, and intraventricular conduction delay, all have prognostic value. It is not generally appreciated how well clinical parameters perform in this regard. The Duke group reported that 37% of the patients undergoing stress testing at their institution had a predicted average annual mortality of 1% or less over the next 3 years, on the basis of clinical assessment.[11]

Several studies have shown that a normal resting ECG, and the absence of a history of prior infarction, predict a normal ejection fraction with 90% confidence,[12,13] and therefore a favorable prognosis.[14–16]

Approaches to the assessment of incremental value

Once the information available from clinical assessment (and other tests already performed) has been considered, there are a variety of conceptual and statistical approaches that can be employed to assess the incremental value of the test in question. This section will present examples of three such approaches.

Diagnosis of CAD

The application of multiple different stress tests for the diagnosis of coronary artery disease has been extensively studied. The most common approach used in this setting to demonstrate the incremental value of a new test employs Bayes' theorem.[17] This theorem indicates that the likelihood of disease following testing (post-test probability) can be calculated from the test characteristics (sensitivity and specificity) and the pretest probability. This calculated post-test probability is often plotted graphically as a function of pretest probability (Figure 3.3).

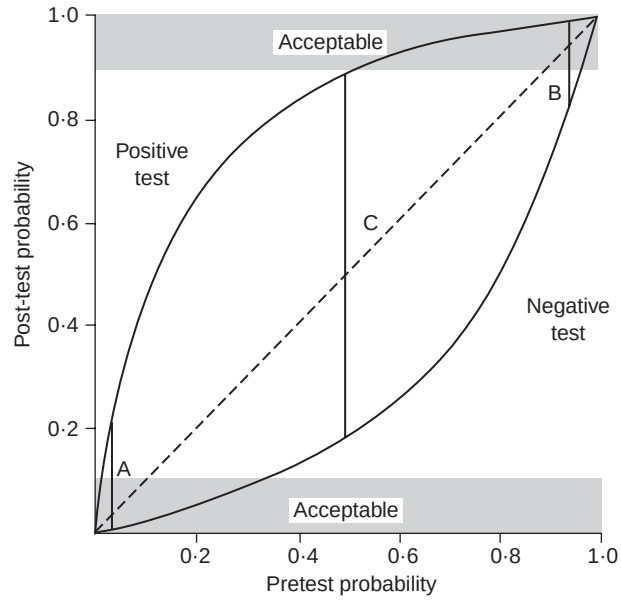

Figure 3.3 Relationship between pretest probability and post-test probability. The solid curves for positive and negative tests are plotted for a test with 80% sensitivity and a 90% specificity. Post-test probabilities that are acceptable for diagnosis (90% and 10%) are shown in the shaded zones. Line A represents a patient with a very low pretest probability; line B, a patient with a high pretest probability; line C, a patient with an intermediate probability. (Modified from Berman DS, Garcia EV, Maddahi J. Thallium-201 scintigraphy in the detection and evaluation of coronary artery disease. In: Berman DS, Mason DT, eds. *Clinical nuclear cardiology*. New York: Grune and Stratton, 1981, with permission.)

In Figure 3.3, the pretest probability is shown on the *X*-axis and the post-test probability is shown on the *Y*-axis. The dotted line represents the line of identity. The vertical distance from this line to the upper solid curve represents the increase in the probability of disease as a result of positive test. In analogous fashion, the vertical distance from this dotted line to the lower solid curve represents the decrease in probability as a result of a negative test. The solid vertical lines describe three different clinical situations.

Line A represents a patient with a very low pretest probability, such as a 40 year old woman with non-anginal pain. A negative test changes probability very little. A positive test increases probability somewhat, but the post-test probability remains well under 50%, and the test is most likely a "false positive".

Line B represents a patient with a high pretest probability of disease, such as a 65 year old man with typical angina. A positive test will increase the probability only slightly. A negative test will decrease the probability of disease somewhat, but the post-test probability remains substantially greater than 50%, so that the test is most likely a "false negative".

The final situation (line C) represents a patient with an intermediate probability of disease, such as a 50 year old male with atypical angina. A positive test in such a patient would increase the probability of disease substantially to near 90%. On the other hand a negative test would decrease the probability of disease substantially to approximately 18%.

Thus, it is evident that the incremental value of diagnostic testing is greater in patients with an intermediate probability of disease, a principle that is broadly recognized.[17]

However, it is also recognized that this kind of analysis has a number of limitations. The single curves for positive and negative tests do not take into account the degree of test abnormality. The test results are therefore better displayed for a whole range of values for a parameter that helps distinguish normal from abnormal. The best known example of this would be the magnitude of ST segment depression on treadmill exercise testing.[18] In addition, multiple other parameters are reported during a treadmill exercise test, which help to distinguish severely abnormal tests from only mildly abnormal tests.[19] Ideally, all of these parameters would be incorporated into a single "score" and a series of curves would be plotted.

Next, construction of such curves relies on the premise that the sensitivity of tests will be identical for any population of patients with disease regardless of disease prevalence. This assumption is usually invalid. As demonstrated in the previous section, those parameters which help to identify the presence of disease also help to identify the presence of severe disease. In general, the sensitivity of most tests is greater in patients with more severe disease. It is therefore quickly evident that sensitivity would be expected to vary with the prevalence of disease. This point has been demonstrated by several investigators,[20] and provides justification for the use of logistic regression analysis for diagnostic purposes.[21] Despite these limitations, bayesian analysis serves as a useful framework for understanding the potential incremental value of diagnostic tests.

Post-test referral bias, also known as work up bias or verification bias, occurs whenever the results of the test in question influence the subsequent performance of the "reference" test (sometimes referred to as the "gold standard"). This bias has been recognized for more than 20 years.[22] An early survey of the literature on exercise testing showed that only 2 of 33 studies avoided this bias.[23] The recognition of the importance of this phenomenon was emphasized in a landmark paper in 1983, which described the "declining specificity" of radionuclide angiography as a result of this bias.[24] More than 10 years ago, a monograph from the Institute of Medicine emphasized this well established concept.[25] The key question to ascertain whether postreferral bias is present is "did the results of the test being evaluated influence the decision to perform reference standard?".[26]

Although this bias potentially occurs for any diagnostic test, it is particularly important for non-invasive diagnostic tests for CAD. Patients with positive non-invasive tests are often referred to coronary angiography (the "reference" test). In contrast, patients with negative tests are often sent home without coronary angiography. The effects of this preferential referral to coronary angiography are to markedly decrease the observed specificity of the test in question and modestly increase its sensitivity.

The clearest solution to the problem of post-test referral bias is to avoid it completely by studying patients in whom the decision to proceed with the "reference" test is made before the performance of the diagnostic test in question.[25] For the diagnosis of CAD, this standard is incredibly difficult and rarely achieved. A more feasible alternative is the mathematical correction of sensitivity and specificity for post-test referral bias using one of two published formulae and information about all of the patients who were studied using the diagnostic test in question and did not proceed with coronary angiography.[27,28] There are a number of published studies demonstrating the effect of these corrections on the observed test performance for exercise electrocardiographic testing,[29] exercise echocardiography,[30] and exercise Single Photon Computed Tomography (SPECT) perfusion imaging.[31] Correction for referral bias markedly increases the specificity and modestly decreases the sensitivity of these tests. As a result, the predictive value of a positive test is improved, but the predictive value of a negative test decreases. It is generally difficult to confirm the validity of these corrections. However, a carefully designed prospective study of exercise echocardiography in women has now reported sensitivity and specificity values that are very close to those reported after correction for referral bias.[32]

Post-test referral bias has numerous important implications for the interpretation of the diagnostic literature.[32] Many of the reported sensitivity and specificity values are very likely to be erroneous.[32] Widespread misconceptions exist regarding gender differences in test performance. The post-test probability of CAD is higher for either a positive or negative test than that which would be calculated from Bayes' theorem using the reported values of sensitivity and specificity.[31]

Non-invasive screening for severe CAD

The incremental value of testing for the diagnosis of severe CAD has been studied using both bayesian analysis and logistic regression analysis. When the latter analysis is conducted properly, all of the previously discussed clinical parameters that are associated with severe coronary disease are incorporated into a model that is used to predict the probability of severe CAD. The output of such a model is a probability that ranges between 0 and 1. It is critically important that these candidate variables be "forced" into the model, even if they are statistically insignificant in the population under study. Most study populations are too small to have adequate power to detect the true significance of these variables, which has been demonstrated in very large subsets. For example, age should always be forced into such models, even if it does not appear to be significant in the particular population in question, because there is abundant evidence that it should always be considered (and indeed usually is by clinicians).

Using this approach, a second model should then be constructed which includes all of the clinical parameters, as well as pertinent new parameters from the test in question. If these parameters have statistical significance independent of the clinical parameters, the test has incremental value. This approach is demonstrated in Table 3.2, which shows the improvement in the logistic regression model for severe CAD reported by Christian *et al*,[16] when the exercise test was added to clinical parameters, and when thallium imaging parameters were added to clinical and exercise parameters. An alternative approach is to construct the receiver operating characteristic (ROC) curves, which display sensitivity and specificity as a function of the predicted probability of severe disease (the output of a logistic regression model). The area under the ROC curve can then be compared between the model that incorporates clinical parameters,

Table 3.2 Logistic regression multivariate analysis: prediction of three vessel or left main (coronary artery) disease

Model	Direction	Odds ratio (95% CI)	*P* value
Clinical			
Diabetes mellitus	Present	2·0 (1·3–3·1)	0·001
Typical angina	Present	2·3 (1·4–3·9)	0·001
Sex	Male	3·2 (1·4–4·0)	0·007
Age[a]	Older	1·4 (1·1–1·9)	0·01
$\chi^2 = 31{\cdot}3$			
Clinical and exercise			
Diabetes mellitus	Present	1·9 (1·2–3·0)	0·005
Typical angina	Present	1·9 (1·1–3·3)	0·02
Sex	Male	2·3 (0·9–5·3)	0·07
Age[a]	Older	1·2 (0·9–1·7)	0·16
Magnitude of ST depression	More	1·5 (1·3–1·8)	<0·001
Peak heart rate × peak systolic blood pressure[b]	Lower	0·9 (0·86–0·95)	<0·001
$\chi^2 = 65{\cdot}0$			
Clinical, exercise, and thallium-201			
Diabetes mellitus	Present	1·9 (1·2–3·0)	0·004
Typical angina	Present	1·8 (1·1–3·2)	0·03
Sex	Male	2·2 (0·9–5·3)	0·07
Age[a]	Older	1·2 (0·9–1·7)	0·17
Peak heart rate × peak systolic blood pressure[b]	Lower	0·9 (0·86–0·95)	<0·001
Magnitude of ST depression	More	1·4 (1·2–1·7)	0·001
Global T1-201 score (delayed – after exercise)	Higher	1·1 (1·0–1·1)	0.02
$\chi^2 = 70{\cdot}4$			

[a] Increments of 10 years (each 10-year increase in age increases the odds of severe disease 1·4-fold).
[b] Increments of 1000 units.

and the model that incorporates clinical parameters and the new test parameters. Methods are available for determining the statistical significance of changes in the area under these two ROC curves.[33] An example of this approach is shown in Figure 3.4, taken from Christian *et al*[16] The clinical significance of these differences in the models (assessed by either χ^2 analysis or ROC curves) is discussed later.

Prediction of patient outcome

The demonstration of incremental prognostic value for diagnostic tests is obviously extremely important for clinical decision making. It requires strict adherence to the rigorous standards that were outlined previously. In general, very few of the published studies demonstrating prognostic value of diagnostic tests meet the strict criteria necessary to demonstrate *incremental* prognostic value for these tests. The statistical model most often used for this purpose is a linear proportional hazards, or Cox, model.[34] When strictly applied, all the previous information available to the clinician, either from clinical assessment or previous testing, should be incorporated into a linear proportional hazards model that predicts time to an event. Once again, parameters that have been clearly demonstrated in larger populations to be significant must be "forced" into such models to make sure that their contribution is not neglected. The events in question should preferably be hard end points such as death and myocardial infarction. As previously mentioned, unstable angina and the need for revascularization are alternative end points that are often included to enhance statistical power, but these have major limitations.

One of the best examples of a rigorously constructed analysis demonstrating incremental prognostic value was published by Pollock *et al* in 1992.[35] They tested the association between various combinations of variables, and time to death or myocardial infarction, in a linear proportional hazards model using the χ^2 statistic. Clinical and exercise variables were significantly better than clinical variables alone. Similarly, a model that added thallium redistribution to clinical and exercise variables was significantly better than the combination of clinical and exercise variables.

Another example of such a rigorous analysis was that reported by Christian *et al*[6] in patients with a normal resting electrocardiogram. Using a similar approach, these investigators reported that a model adding thallium variables to clinical and exercise variables did not add significantly to the model using clinical and exercise variables. Thus, in the subset of patients with a normal resting ECG, Christian *et al*[16] were unable to confirm the findings of Pollock *et al*[24]

Clinical significance and cost effectiveness

Even when statistically significant incremental value has been demonstrated for a diagnostic test using appropriate rigorous methodology, the clinical significance of the findings must be equally rigorously examined. The two fundamental issues that should be addressed are the actual impact of this incremental value on clinical decision making and, where possible, cost effectiveness. The principles of decision analysis pertinent to the first criterion will be presented in much greater detail in Chapter 7. The available published data on diagnostic testing in coronary disease that will be presented here use only rudimentary concepts with respect to decision analysis. Formal cost analysis also requires understanding of a much greater body of published knowledge, which will not be presented here. The examples presented will again be very rudimentary, but demonstrate the principle.

Diagnosis of CAD

The clinical significance of diagnostic testing can best be understood in terms of decision making thresholds. From the standpoint of diagnosis, a test will be useful primarily if it moves a significant number of patients from an "uncertain" pretest probability to an "acceptably certain" post-test probability. The exact criteria, or threshold, to be used in these classifications are clearly a matter of judgment; many investigators have chosen post-test probabilities of less than 10% and greater than 90% as criteria for definitive diagnosis.[36] Thus, non-invasive testing will be useful for diagnosis if it moves a reasonable number of patients into the shaded zone shown in Figure 3.3.

Although treadmill testing has clear incremental value for diagnosis, particularly in patients with intermediate pretest probability, as discussed earlier, its ability to move patients across such thresholds of probability appears to be very limited. Goldman *et al*[37] examined the ability of treadmill

Table 3.3 Effect of treadmill exercise test results in moving patients across various diagnostic thresholds

Threshold probability	Patients moved across (*n*)	Correctly moved	Incorrectly moved	Net increase in diagnoses (correct-incorrect)
0·10	8	6	2	4
0·90	53	33	20	13
Either 0·10 or 0·90	61	39	22	17 (5%)

From Goldman *et al*,[37] by permission of the American Heart Association, Inc.

exercise variables to classify 329 patients with CAD. Their results are summarized in Table 3.3. The pretest model was very powerful, as it classified 84% of the patients correctly. Table 3.3 shows the number of additional patients classified correctly for given thresholds of probability. For example, if 10% was considered an acceptable threshold to "rule out" CAD, eight of 324 patients were moved across this threshold, but only six were moved correctly. Similarly, for a 90% threshold to "rule in" CAD, 53 patients were moved across this threshold but only 33 were moved across correctly. As a result, the net total number of patients who were correctly moved into the diagnostic zone in Figure 3.3 was only 17, or 5% of the patient population. Thus, the clinical significance of the incremental value provided by the treadmill test appears to be very limited.

Similar rigorous analyses have been published for radionuclide angiography.[38] The results of one of these are displayed in Figure 3.5. The study group excluded men with typical angina over the age of 40 in order to eliminate most patients with a high pretest probability. Logistic regression models developed on a retrospective population were applied prospectively to a group of 76 patients. As demonstrated in Figure 3.5, eight (11%) of the 76 patients could be classified with 90% certainty on the basis of clinical variables alone. Following radionuclide angiography, 24 patients (32%) could be classified directly. Thus, the incremental value of exercise radionuclide angiography in moving patients across clinically meaningful decision thresholds appeared to be much greater than for the treadmill exercise test, as 21% of the patients were correctly classified by the radionuclide angiogram.

Similar findings have been reported for planar thallium imaging.[39,40] Unfortunately, no rigorous analyses are available for either SPECT imaging or sestamibi imaging, primarily because post-test selection bias has greatly limited the feasibility of such studies in the current era.

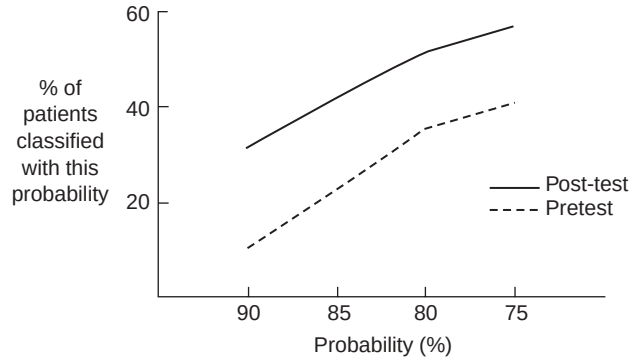

Figure 3.5 Percentage of patients classified with a given probability of coronary disease before and after exercise radionuclide angiography. The prospective study group of 76 patients excluded males of 40 years or older with typical angina. (From Gibbons *et al*,[38] with permission.)

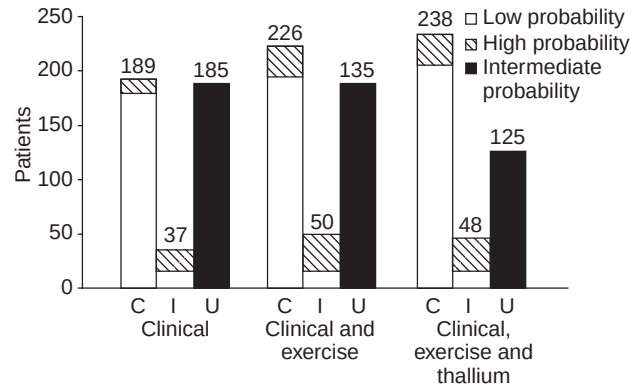

Figure 3.6 Correct (C), incorrect (I), and uncertain (U) classification of patients with three vessel or left main coronary artery disease by the use of logistic regression multivariate models. Low, intermediate, and high probability defined using: clinical variables only; clinical and exercise variables; clinical, exercise, and thallium-201 variables. (From Christian *et al*,[16] with permission.)

Non-invasive screening for severe CAD

The same threshold approach has been applied to the non-invasive identification of severe CAD. Here the ability of tests to move patients across somewhat different thresholds of probability, as assessed by logistic regression models, has been tested. Christian *et al*[16] defined a low-probability group for severe CAD as $<0{\cdot}15$, a high-risk group as $>0{\cdot}35$, and an intermediate group as 0·15–0·35. These thresholds were chosen to correspond to earlier work from Duke University reporting on the utility of the early positive treadmill test.[41] Figure 3.6 shows the results that were

obtained using this approach. Using clinical parameters alone, 189 patients (46% of the study group) were correctly classified as low or high probability. Thirty-seven patients (9%) were incorrectly classified as low or high probability. The remaining 185 patients (45% of the study group) had an intermediate probability, and were therefore in an uncertain category. The addition of exercise parameters correctly classified an additional 37 patients at the expense of 13 additional incorrect classifications, for a net of 24 additional correct classifications (6% of the study group). The addition of thallium parameters led to 12 additional correct classifications, and two fewer incorrect classifications for a net increase of 14 correct classifications (3% of the study group). These workers then used Medicare reimbursement figures to calculate the cost per additional correct classification. For exercise testing, the cost per additional correct patient classification was $1524. For thallium scintigraphy, the cost was $20 550 per additional correct classification.

Thus, this analysis demonstrated that the clinical impact was modest, and the cost was high, when thallium imaging was used in patients with a normal resting ECG to try to identify patients non-invasively with severe CAD. Although thallium scintigraphy clearly had statistically significant incremental value, it did not appear to be cost effective for this purpose.

Prediction of patient outcome

The issues of clinical significance and cost effectiveness are particularly pertinent to the application of diagnostic tests for the prediction of the patient outcome. These applications often involve relatively low-risk patient groups with few subsequent events. Tests applied to the entire population may identify a subset of patients who are at considerably increased risk.[42,43] These results will be highly statistically significant, and generate very impressive *P* values and risk ratios. However, it must be recognized that the absolute rate of events often remains too low in the high-risk patient subgroup to be clinically meaningful, and the cost of this identification is often therefore prohibitive when viewed on a per event basis.

This concept was nicely demonstrated in a study by Berman *et al*[44] on patients with a low clinical likelihood of CAD studied by SPECT sestamibi. During 20 months of follow up, only patients with an abnormal sestamibi study suffered death or myocardial infarction. This difference was statistically highly significant ($P = 0 \cdot 007$). However, this increment in prognostic value was clearly not cost effective, as noted by the authors. Although the cost analysis by the authors was quite detailed, the cost ineffectiveness of this approach is readily apparent with very simple analysis. The 107 patients in the high-risk group suffered only three events during 20 months of follow up. In order to identify the high-risk group, testing was required of 548 patients. Using a Medicare reimbursement figure of $700 per test,[16] more than $383 000 of testing would be required to identify the high-risk cohort. The cost of testing alone would therefore exceed $127 000 per possible event prevented. This simple analysis ignores the additional costs that would accrue from the subsequent cardiac catheterizations and coronary revascularizations that would be necessary in the high-risk group in order to attempt to prevent the three events. (There is obviously no certainty that the three events could actually be prevented by revascularization.)

Similar analyses have been published for screening in asymptomatic individuals. As a general principle, it should be recognized that non-invasive testing for the assessment of prognosis is far less cost effective in subsets of patients at intrinsically low risk.

Conclusion

Clinicians should recognize that an evidence-based approach to the evaluation of the incremental value of diagnostic tests is not simple or straightforward. Unfortunately, it is far easier for both clinicians and investigators to use simple, less rigorous, approaches that appear to demonstrate important incremental value for each new diagnostic test. Although convenient, such approaches lead to incorrect conclusions, and generally overestimate the added value of each new testing modality. The examples presented in this chapter should provide a framework for thinking clinicians to evaluate better new publications on new diagnostic tests. However difficult these analyses may be, and however disappointing the results, the escalating costs of healthcare demand an approach of rigorous methodology and thoughtful analysis to make certain that the *incremental* value of a diagnostic test is not only statistically significant, but clinically significant and cost effective.

4 Clinical trials and meta-analysis

Colin Baigent

Introduction

Although large effects on survival arising from certain treatments may occasionally be obvious from simple observation (as, for example, when cardioversion for ventricular fibrillation avoids otherwise certain death), the vast majority of interventions have only moderate effects on major outcomes and hence are impossible to evaluate without careful study. Enthusiasm for the biologic foundations of a particular therapeutic approach often leads to exaggerated hopes for the effects of treatment on major clinical outcomes. These hopes may be based on dramatic laboratory measures of efficacy, or on the types of surrogate outcome that are commonly studied before drugs go into Phase III or IV studies: for example, a drug may almost completely prevent experimental ischemia progressing to infarction, or practically abolish experimental thrombosis. However, these large effects on surrogate end points very rarely translate into large effects on major clinical outcomes: the overwhelming message from two decades of clinical trials in cardiology is that the net effects of most treatments are typically moderate in size.* This chapter explains why large-scale randomized evidence, either in a single "mega-trial" or in a meta-analysis of similar trials, is generally an absolute requirement if such moderate effects on major outcomes are to be characterized reliably.

It is important to appreciate that progress in cardiologic practice, and in the prevention of cardiovascular disease, has been and remains dependent on the availability of large-scale randomized trials and appropriately large-scale meta-analyses of such trials. In the management of acute myocardial infarction (MI), for example, these methods have helped to demonstrate that fibrinolytic therapy,[1–3] aspirin,[1,3,4] angiotensin-converting-enzyme (ACE) inhibitors[5–7] and β-blockers[8] all produce net benefits which, although individually moderate in size, have together produced a substantial improvement in the prognosis of acute MI. Similarly, the demonstration that ACE inhibitors produce moderate reductions in the risk of death and in the rates of hospitalization for worsening heart failure,[9] and that the addition of digoxin further reduces the need for recurrent hospitalization,[10] has improved the prognosis of congestive heart failure.

Clinical trials: minimizing biases and random errors

Any clinical study whose main objective is to assess moderate treatment effects must ensure that any biases and any random errors that are inherent in its design are both substantially smaller than the effect to be measured.[11,12] Biases in the assessment of treatment can be produced by differences in factors other than the treatment under consideration. Observational (that is non-randomized) studies in which the outcome is compared between individuals who received the treatment of interest and those who did not, can be subject to large biases.[13] Instead, the guaranteed avoidance of biases requires the proper randomized allocation of treatment and appropriate statistical analysis, with no unduly data-dependent emphasis on specific subsets of the overall evidence (Table 4.1).[12]

Avoidance of moderate biases

Proper randomization

The fundamental reason for random allocation of treatment in clinical trials is to maximize the likelihood that each type of patient will have been allocated in similar proportions to the different treatment strategies being investigated.[14] Proper randomization requires that trial procedures are organized in a way that ensures that the decision to enter a patient is made irreversibly and without knowledge of the trial treatment to which a patient will be allocated. In situations where the next treatment allocation can be deduced by those entering patients, decisions about whether to enter a

* For rare adverse effects, however, there may be large proportional differences between one treatment and another, or between treatment and control. For example, some non-steroidal anti-inflammatory drugs may substantially increase the risk of gastrointestinal bleeding. Rare adverse effects with extreme relative risks can often be recognized reliably by careful clinical observation, or by other non-randomized methods, and such relative risks are sometimes best quantified in case–control or cohort studies.

Table 4.1 Requirements for reliable assessment of MODERATE treatment effects[11,12]

1. *Negligible biases*
   (that is guaranteed avoidance of MODERATE biases)
   - Proper RANDOMIZATION (non-randomized methods cannot guarantee the avoidance of moderate biases)
   - Analysis by ALLOCATED treatments (that is an "intention to treat" analysis)
   - Chief emphasis on OVERALL results (with no unduly data-derived subgroup analysis)
   - Systematic META-ANALYSIS of all the relevant randomized trials (with no unduly data-dependent emphasis on the results from particular studies)
2. *Small random errors*
   (that is guaranteed avoidance of MODERATE random errors)
   - LARGE NUMBERS (with minimal data collection as detailed statistical analyses of masses of data on prognostic features generally add little to the effective size of a trial)
   - Systematic META-ANALYSIS of all the relevant randomized trials

particular patient may be affected, and those allocated one treatment might then differ systematically from those allocated another.[15] In the Captopril Prevention Project (CAPPP) trial,[16] for example, envelopes containing the antihypertensive treatment allocation could be opened before patients were irreversibly entered into the study. Highly significant differences in pre-entry blood pressure between the treatment groups, which were too large to have been due to chance, may well have been the result of this design weakness.[17]

Intention to treat analysis

Even when studies have been properly randomized and well conducted, moderate biases can still be introduced by inappropriate analysis or interpretation. One well recognized circumstance is when patients are excluded after randomization, particularly when the prognosis of the excluded patients in one treatment group differs from that in the other (such as might occur, for example, if non-compliers were excluded after randomization). This point is well illustrated by the Coronary Drug Project, which compared clofibrate versus placebo among around 5000 patients with a history of coronary heart disease. In this study, patients who took at least 80% of their allocated clofibrate ("good" compliers) had substantially lower 5 year mortality than "poor" compliers who did not (15·0% *v* 24·6% respectively; $P = 0{\cdot}0001$). However, there was a similar difference in outcome between "good" and "poor" compliers in the placebo group (15·1% *v* 28·3%, respectively; $P < 0{\cdot}00001$), suggesting that "good" and "poor" compliers were prognostically different even after allowing for any benefits of actually taking clofibrate.[18] If there is really no difference in outcome between two treatments, then the least biased assessment of the treatment effect is that which compares all those allocated to one treatment versus all those allocated to the other (that is an "intention to treat" analysis), irrespective of what treatment they actually received.[19]

Because some degree of non-compliance with allocated treatments is unavoidable in randomized trials, intention to treat analyses will obviously underestimate the effects produced by full compliance. However, "on treatment" analyses, which compare effects among compliant patients with those in non-compliant patients, are potentially biased, and it is more appropriate to calculate an "adjustment" based on the level of compliance and then to apply this to the estimate of the treatment effect provided by the intention to treat comparison.[20] For example, in a meta-analysis of the randomized trials of prolonged use of antiplatelet therapy among patients with occlusive vascular disease, the average compliance 1 year after treatment allocation seemed to be around 80%.[4] Application of this estimate of compliance to the proportional reduction of about 30% in non-fatal MI and stroke estimated from intention to treat analyses of these trials suggests that full compliance with antiplatelet therapy produces reductions in risk of about 35–40%.

Dangers of data-dependent emphasis on particular results

In the medical literature a particularly important source of bias is unduly data-dependent emphasis on particular trials or on particular subgroups of patients. Such emphasis is often entirely inadvertent, arising from a perfectly reasonable desire to understand the randomized trial results in terms of who to treat, which treatments to prefer, or disease mechanisms. However, whatever its origins, selective emphasis on particular parts of the evidence can often lead to seriously misleading conclusions. This is because the identification of categories of patients for whom treatment is particularly effective (or ineffective) requires surprisingly large quantities of data. Even if the real sizes of the treatment effects do vary substantially among subgroups of patients, subgroup analyses are so statistically insensitive that they may well fail to demonstrate these differences. On the other hand, if the real proportional risk reductions are about the same for everybody, subgroup analyses can vary so widely just by the play of chance that the results in selected subgroups may be exaggerated. Even when highly significant "interactions" are found, they may be a poor guide to the sizes (or even the directions) of any genuine differences, as the more extreme such results may still owe more to chance than to reality. This is particularly the case when such interactions have emerged after an overzealous examination of multiple

subgroups. For example, in the large Second International Study of Infarct Survival (ISIS-2), the 1 month survival advantage produced by aspirin was particularly clear (804 vascular deaths among 8587 patients allocated aspirin *v* 1016 among 8600 allocated placebo; proportional reduction of 23% (SD 4); $P < 0{\cdot}000001$).[1] When these overall results were subdivided by the patients' astrological birth signs, however, no fewer deaths were observed with aspirin than with placebo among patients born under Libra or Gemini (Table 4.2). Although few doctors would consider such analyses to be valid, similarly unreliable conclusions based on "exploratory" data-derived subgroup analyses are widely reported in medical journals and at scientific meetings, and may well have adverse consequences for patient care.

An example of how such subgroup analyses resulted in inappropriate management of patients is provided by the early trials of aspirin for the secondary prevention of stroke. Here, emphasis on the results in men led to a situation where, for almost 20 years, the US Food and Drug Administration approved this use of aspirin only for males; more recent evidence shows this to have been mistaken.[4] A further example is provided by the large Italian GISSI-1 trial comparing streptokinase versus control after acute MI. The overall results favoured streptokinase, but subgroup analyses suggested that streptokinase was beneficial only in patients without prior MI. Fortunately, the GISSI investigators were circumspect about this "finding",[2] and their caution turned out to have been wise, as a subsequent overview of all the large fibrinolytic trials showed that the proportional benefits were similar, irrespective of a history of MI.[21] Many thousands of patients with a previous history of MI might well have been denied fibrinolytic therapy, however, if the apparent pattern of the results in the GISSI-1 subgroups had been believed.

A similar bias may arise in a situation where several studies have addressed much the same therapeutic question but only a few of them are chosen for emphasis. This could be a source of serious bias, as chance fluctuations for or against treatment might affect this choice. It is therefore more appropriate to base inference on a meta-analysis of results from all relevant randomized trials (or, at least, on an unbiased subset of the relevant trials, such as all trials above a certain minimum sample size).[22,23] One additional advantage of such an approach is that such meta-analyses will also minimize random errors, because far more patients (and most importantly, more events) will be available for analysis. The separate trials might well be heterogeneous, but with careful interpretation of such heterogeneity it is often possible to enhance understanding of particular clinical questions.[24] Occasionally, when detailed information on individual patients is available within a really large meta-analysis that includes several thousand major outcomes, such as death[21] or cancer recurrence,[25] it may be feasible to identify particular groups of individuals in whom the benefits or hazards of treatment really are especially great. (Where it has been possible to establish cooperation between trialists before any of the trial results are known, having just a few prespecified subgroup hypotheses can provide some protection against unduly data-dependent emphasis on particular results in a large meta-analysis.[26])

Avoidance of moderate random errors

Small trials may produce false negative results

Whereas the avoidance of moderate biases requires careful attention both to the randomization process and to the analysis and interpretation of the available trial evidence, the avoidance of moderate random errors requires large numbers of events. Because major outcomes such as death may affect only a small proportion of those randomized, very large numbers of patients often need to be studied before the results can be guaranteed to be statistically (and hence medically) convincing. For example, the early trials of intravenous fibrinolytic therapy for acute myocardial infarction were individually too small to provide reliable evidence about any moderate effects of this treatment on mortality, although several did identify an increased risk of serious bleeding. As a result, fibrinolytic therapy was not used routinely until the GISSI-1[2] and ISIS-2[1] "mega-trials" provided such definite evidence of benefit that treatment patterns changed rapidly.[27] It is worth noting, however, that GISSI-1 and ISIS-2 both included more than 10 000 patients and 1000 deaths, but had they only been one tenth as large the observed reduction in mortality would not have been conventionally significant, and would therefore have had much less influence on medical practice.

Table 4.2 Unreliability of "data-dependent" subgroup analyses: ISIS-2 trial of aspirin among over 17 000 patients with suspected acute myocardial infarction[1]

Astrological birth sign	Vascular death by 1 month		*P* value
	Aspirin	Placebo	
Libra or Gemini	150 (11·1%)	147 (10·2%)	0·5
All other signs	654 (9·0%)	869 (12·1%)	<0·0001
Any birth sign	804 (9·4%)	1016 (11·8%)	<0·0001

Small-scale meta-analyses may be unreliable

Because meta-analyses are appearing in medical journals with increasing frequency it is useful to be able to judge the reliability of such reviews – and, in particular, the extent to which confounding, biases or random errors could lead to mistaken conclusions. (In randomized trials, "confounding" exists when a comparison of some particular treatment in one group versus a control group involves the routine coadministration in one group, but not the other, of some cointervention that might affect the outcome.) To avoid any possibility of confounding, and to avoid any flexibility in the question of which trials to consider, meta-analyses should generally include only unconfounded properly randomized trials. The main problems that then remain are those of biases and random errors.

Two types of bias could affect the reliability of a meta-analysis: those that occur within individual trials, and those that relate to the selection of trials. More empirical research into the numerous biases that can occur within randomized trials would be valuable. However, it is clear from existing studies that, for example, inadequate concealment of the likely treatment allocation does quite often result in exaggerated estimates of treatment effect,[28] and that the inappropriate postrandomization exclusion of particular patients is common.[29] Such defects have unpredictable consequences for particular trials, however, and no generalizations about the likely size, or even direction, of the resultant biases are possible.

A further problem involves the process of identifying all relevant trials. Unfortunately, the subset of trials that are eventually published (and hence which are conveniently available) is often a biased sample of the trials that have been done. Trials may well be more likely to be submitted for publication if their results are strikingly positive than if they are negative or null.[30–33] Such "publication bias" can, along with other sources of bias, produce surprisingly impressive looking evidence of effectiveness for treatments that are actually useless.[34] The particular circumstances in which publication bias has contributed to producing misleading estimates of treatment are difficult to identify, and it is still more difficult to generalize about the exact size of any such bias when it does occur.

The problem of incomplete ascertainment is likely to be particularly acute within small meta-analyses that contain no more than a few hundred major outcomes and which consist mainly of small published trials. This is because results from trials with only a limited number of end points are subject to large random errors, and such trials are therefore particularly likely to generate implausibly large effect estimates. If publication bias then results in emphasis on the more promising of these small trial results, the resulting summary odds ratios are likely to be unreliable.[35] Hence, unless the particular circumstances of a small-scale meta-analysis suggest that publication bias is unlikely, it may be best to treat such results as no more than "hypothesis generating". On the other hand, a thoroughly conducted meta-analysis that in aggregate contains sufficient numbers of major outcomes to constitute "large-scale" randomized evidence[4,21,25] is unlikely to be materially affected by publication bias and, provided there are no serious uncontrolled biases (see above) within the individual component trials, is likely to be fairly trustworthy – although, even then, inappropriate subgroup analyses may generate mistaken conclusions.

Large-Scale Randomized Trials

Trials of the effects of treatments on major outcomes can only be made large if they are kept as simple as possible. In particular, as many as possible of the main barriers to rapid recruitment need to be removed. An important way in which trial design can facilitate this is to limit the amount of information that is recorded. For example, data recorded at baseline can often be restricted to important clinical details, including at most only a few major prognostic factors and only a few variables that are thought likely to influence substantially the benefits or hazards of treatment. Similarly, the information recorded at follow up need not be extensive and can be limited largely to those major outcomes that such studies have been designed to assess, and to approximate measures of compliance. (Other outcomes that are of interest but which do not need to be studied on such a large scale may best be assessed in separate smaller studies, or in subsets of these large studies when this is practicable.) Likewise, complicated eligibility criteria, inappropriately detailed consent procedures[36] and unnecessarily extensive auditing of data can all prevent the recruitment of large numbers of patients. Furthermore, if trials are complex they are likely to involve a high cost per patient, which again tends to limit their size. Either way, complexity is rarely a virtue in trials designed to assess major outcomes, whereas simplicity can sometimes lead to the rapid randomization of very large numbers of patients, and to results that change clinical practice within very short periods of time.[1,27]

The "uncertainty principle"

For ethical reasons, randomization is appropriate only if both the doctor and the patient feel substantially uncertain as to which trial treatment is best. The "uncertainty principle" maximizes the potential for recruitment within this ethical constraint (see Box on p 38).

If many hospitals are collaborating in a trial then wholehearted use of the uncertainty principle encourages clinically appropriate heterogeneity in the resulting trial population, and in large trials this may add substantially to the practical value of the results. Among the early trials of

The "uncertainty principle"

A patient can be entered if, and only if, the responsible physician is substantially uncertain as to which of the trial treatments would be most appropriate for that particular patient.

A patient should not be entered if the responsible physician or the patient is, for any medical or non-medical reason, reasonably certain that one of the treatments that might be allocated would be inappropriate for this particular individual (in comparison either with no treatment or with some other treatment that could be offered to the patient in or outside the trial).[37]

fibrinolytic therapy, for example, most of the studies had restrictive entry criteria that precluded the randomization of elderly patients, and so those trials contributed nothing of direct relevance to the important clinical question of whether treatment was useful in older patients. Other trials that did not impose an upper age limit, however, did include some elderly patients, and were therefore able to show that age alone is not a contraindication to fibrinolytic therapy.[21]

Thus, homogeneity of those randomized may be a serious defect in clinical trial design, whereas heterogeneity may be a scientific strength: after all, trials do need to be relevant to a very heterogeneous collection of future patients. The "uncertainty principle" not only ensures ethicality and clinically useful heterogeneity, but also is easily understood and remembered by busy collaborating clinicians, which in turn helps the randomization of large numbers of patients.

Can observational studies substitute for large-scale randomized trials?

As the resources will never be available to design large, simple trials to address all the questions of clinical interest, there have been several recent suggestions that observational studies might be able to provide reliable estimates of the effects of particular treatments. Non-randomized studies do not necessarily provide inaccurate estimates of the effects of treatments, but the point is that they cannot be **guaranteed** to produce reliable estimates because of biases that are inherent in their design. It may well be difficult or impossible to avoid such biases, or to adjust fully for their effects.[38] When non-randomized studies suggest that certain treatments have surprisingly large effects, such findings are often refuted when those treatments are assessed in large randomized trials.[39] For example, the claims of hazards with digoxin in heart failure,[40] based on non-randomized evidence, were not confirmed by the very large randomized DIG (Digitalis Investigation Group) trial.[10] Even if non-randomized comparisons happen to get the right answer then nobody will really know that they have done so. Thus non-randomized studies are of little practical value if the primary aim is to assess moderate treatment effects (whether beneficial or adverse) on major outcomes.

Summary

Many interventions in cardiological practice produce only moderate effects on major outcomes such as death or serious disability. However, even a moderate effect of treatment, if demonstrated clearly enough for that treatment to be widely adopted, can prevent disabling events or death in substantial numbers of people. Moreover, if – as in the treatment of acute myocardial infarction – more than one moderately effective treatment can eventually be identified, then the combination of two or three individually moderate improvements in outcome may collectively result in substantial health gains. In some instances sufficient information is already available from large-scale randomized trials – or, better still, from meta-analyses of those trials – to allow the balance of risk and benefit of particular treatments to be defined for particular patients. But many important questions have still not been answered reliably, and there remains a need for many more large "streamlined" megatrials, and meta-analyses of such trials, to help resolve some of the outstanding clinical uncertainties in the management of cardiovascular disease.

5 Finding current best evidence to practice evidence-based cardiology

Dereck L Hunt, K Ann McKibbon, R Brian Haynes

Staying current with new diagnostic tests, treatments, and other clinically useful new knowledge in a rapidly evolving field such as cardiology requires effort. Fortunately, this once daunting task is becoming more feasible because of new evidence-based information resources and the steady advance of information technology into clinical settings. This chapter will review ways to find current best evidence for the care of patients with cardiac problems, including both solving patient problems as they arise, and keeping up with new evidence that is ready for application in clinical practice.

The patients whom we see on a daily basis provide an excellent stimulus to staying current. They may have clinical problems that we are unfamiliar with, or that we have not recently reviewed. They may also present us with information from the media or friends to evaluate, or ask us questions that we need to research before answering. Depending on the type of center in which we work, our colleagues, teachers, and students may also ask questions or provide suggestions, making us realize that our knowledge may be "time-challenged".

To become proficient in responding to such challenges (also known as "learning opportunities"), we can make use of a growing array of specialized information resources, aided by information technology that can bring access to our fingertips, almost wherever we may be. To illustrate how patient contacts can provide us with the stimulus to keep up to date and be aware of new evidence, consider the following scenarios.

1. During your outpatient clinic, you see a 56 year old woman who recently became your patient after she moved to your community. She has been diagnosed as having an idiopathic dilated cardiomyopathy and had an echocardiogram 6 months ago that revealed a diffusely enlarged left ventricle with no segmental abnormalities. The ejection fraction was estimated to be less than 30%. You review her current condition and note that her symptoms are controlled on an angiotensin converting enzyme (ACE) inhibitor, digoxin, and a diuretic. Still, she complains of fatigue and dyspnea on moderate exertion. Before leaving, she asks if you can recommend any other medications that would help.
2. Later that day, you pass through the emergency department where an emergency physician happens to notice you. She has been working up a 65 year old man who presented with a swollen left calf. He had an ultrasound that confirmed the presence of a deep venous thrombosis. The patient is anxious to return home because his wife is ill and requires care. The emergency physician is interested in your opinion on the use of low molecular weight heparin for the treatment of deep venous thrombosis in outpatients.

These questions are consistent with the common information needs of physicians. For internists, questions arise at a rate of two questions for every three outpatients seen[1] and five questions on average for every inpatient.[2] No one knows whether cardiologists confront similar numbers of questions, but no professional discipline studied to date is immune from the need to address unanswered questions to keep up with the advance of knowledge.

How would you address each of the questions raised by the clinical scenarios? The possibilities include using an electronic bibliographic database such as MEDLINE, a specialized abstract journal like *ACP Journal Club* or *Evidence-Based Cardiovascular Medicine*, a current textbook, or the Cochrane Library. We will consider the strengths and weaknesses of these resources and apply them to the clinical problems.

MEDLINE

MEDLINE is a huge, multipurpose database of medical literature citations and abstracts produced by the US National Library of Medicine (NLM). It includes citations to almost all important clinical studies, and also a much larger volume of non-clinical studies and articles. Few other resources currently rival this scope. Accessing MEDLINE is relatively easy.[3–5] CD Rom based systems, online systems, and, most importantly, internet access are all available. Examples of CD Rom systems include OVID, Aries, SilverPlatter, and DIALOG. Online access by modem is available through vendors such as PaperChase and HealthGate.[6] Internet access is readily available (see Medical Matrix (http://www. medmatrix.org)

and Dr Felix's Free MEDLINE Page (http://www.beaker.iupui. edu/drfelix) sites for locations that offer MEDLINE access). Some of these MEDLINE systems have user fees but, at least at present, free access is available from many, led by the NLM PubMed (http://www.ncbi.nlm.nih.gov/PubMed/) internet site. This site features the earliest MEDLINE access to newly published articles and point-and-click search strategies that improve the yield of clinically useful studies on the cause, course, diagnosis, and treatment of clinical problems.

If ready access is one of MEDLINE's strengths, the skills needed to rapidly and dependably locate high quality articles that specifically address a clinical question are a weakness. A working knowledge of MEDLINE searching terminology and searching strategies is essential. Luckily, most hospital and university libraries offer training courses for MEDLINE. The NLM has also established a set of eight regional medical libraries that are charged with providing access and training for all US health personnel (+1-800-338-7657). Physicians in the UK can call the Health Care Information Service (+44-207-412-7477) for similar information, while Canadians can call the Canada Institute for Scientific and Technical Information (+1-800-668-1222).

Turning to our initial scenario, we are interested in locating information about new medical therapies for patients with idiopathic dilated cardiomyopathy. Also, it would be wise to focus initially on treatments that already have been adequately tested in well-designed clinical trials.[7] While it may be interesting to read about new medications that are being designed and tested at the laboratory level, or are undergoing early human testing, this information will not be immediately applicable in our clinical practices.

Turning to MEDLINE for assistance, we might begin searching by using a medical subject heading (MeSH) for congestive heart failure. MEDLINE indexers choose appropriate terms from a thesaurus of 14 000 specific terms and 18 000 synonyms for content and methodology. Unfortunately, these terms are not always intuitive (for example, β blockers indexed as adrenergic β antagonists). Therefore, it is often necessary to search through the MeSH vocabulary before carrying out a search. The software for all search systems includes MeSH, so it is quite easy to search for appropriate terms. For our topic, a search for CONGESTIVE HEART FAILURE leads to HEART FAILURE, CONGESTIVE.

Depending on the topic and the scope that you are interested in covering, you may also want to take advantage of two additional features of MeSH headings. Because many articles deal predominantly with two or three topics, the NLM will indicate these topics for each citation by designating them as major subjects of the article. Limiting your search to articles in which the search term has been designated as the major subject heading will be beneficial if you retrieve too many citations from using the search term without "majoring" it. Sometimes, though, you can miss important studies this way. A trial and error approach may be needed to retrieve the best studies.

"Exploding" is another useful feature of MEDLINE MeSH indexing. When articles are indexed, they are classified according to the most specific MeSH heading available. Thus, if you wish to identify all articles that deal with congestive heart failure, including those with more specific MeSH terms such as congestive cardiomyopathy, then you can do so by searching with the term EXPLODE HEART FAILURE, CONGESTIVE.

If you are searching for a topic that has not been well indexed, you may want to take advantage of textword searching. Using this approach, you are simply asking MEDLINE to search the titles and abstracts of all the citations for any occurrences of a certain sequence of letters, such as "dilated". This approach is particularly useful for new drugs or concepts that have not yet been incorporated into MeSH. MeSH is updated annually, but the lag can be considerably longer for certain terms.

If several different endings to a word may have been used, and you wish to identify them all, you can use "truncation", using the "*" symbol. For example, if you asked for RANDOM*, MEDLINE would search for RANDOM, RANDOMIZATION, RANDOMIZED, RANDOMISATION, RANDOMISED, and RANDOMLY. Be careful with truncation. The term "salmon*" retrieves not only the fish but salmonella as well! Some systems may use symbols other than "*", such as ":" or "?".

Returning to identifying new therapies for patients with significant left ventricular dysfunction, EXPLODE HEART FAILURE, CONGESTIVE is a good start, but we need to narrow in on treatments that have been tested in well-designed studies. Luckily, a number of methodological search strategies have been tested and validated for retrieving sound studies for questions relating to therapy, prognosis, etiology or cause, and diagnosis (Box 5.1).[8,9] Alternatively, you can search for a systematic review of studies. Research is currently ongoing to establish the best approach to identify systematic reviews and meta-analyses.[10] For our current search, limiting the citations to systematic reviews and meta-analyses seemed like a reasonable first step. A simple but not fully validated strategy to identify systematic reviews and meta-analyses is to identify all citations in which the publication type is designated as meta-analysis (note that in addition to indexing articles according to subject, the NLM also indexes citations according to "publication type"). Over 40 publication types are recognized, including "meta-analysis", "randomized controlled trial", and "review"), as well as citations that include the phrase "meta-anal*" as a textword, and citations that are designated as reviews in the publication type section, but also have the textword "MEDLINE" in their abstract. Putting this all together yielded the search strategy in Box 5.2 using PubMed.

Box 5.1 Optimal search strategies for identifying studies relating to treatment, diagnosis, prognosis, or etiology using MEDLINE

Treatment	
Best single term:	clinical trial.pt. ("pt" indicates publication type)
Combination of terms with best specificity:	placebo:.tw. ("tw" indicates textword) OR double.tw. AND blind:.tw.
Combination of terms with best sensitivity:	randomized controlled trial.pt. OR random:.tw. OR drug therapy (as a subheading of the subject) OR therapeutic use (as a subheading of the subject)
Diagnosis	
Best single term:	explode diagnosis
Combination of terms with best specificity:	explode "sensitivity and specificity" OR predictive.tw. AND value:.tw.
Combination of terms with best sensitivity:	explode "sensitivity and specificity" OR explode diagnosis (as a subheading of the subject) OR sensitivity.tw. OR specificity.tw. OR diagnostic use (as a subheading of the subject)
Prognosis	
Best single term:	explode cohort studies
Combination of terms with best specificity:	prognosis OR survival analysis
Combination of terms with best sensitivity:	incidence OR explode mortality OR follow up studies OR prognos:.tw. OR predict:.tw. OR course:.tw. OR mortality (as a subheading of the subject)
Etiology or cause	
Best single term:	risk.tw.
Combination of terms with best specificity:	cohort studies OR case–control studies
Combination of terms with best sensitivity:	explode cohort studies OR explode risk OR odds.tw. AND ratio:.tw. OR relative.tw. AND risk:.tw. OR case.tw. AND control:.tw.

Based on Haynes *et al*[8] and Wilczynski *et al*[9]

Box 5.2

1.	Heart failure, congestive	41 251	(PubMed automatically explodes MeSH terms)
2.	Meta-analysis[pt]	6123	(pt indicates publication type)
3.	Meta-anal*[tw]	9683	(tw indicates textword)
4.	Review[pt] AND medline[tw]	5156	
5.	#2 OR #3 OR #4	16 637	(the "OR" means that all citations in either #2 or #3 or #4 will be included)
6.	#1 AND #5	141	(the "AND" means that only citations that occur in both #1 and #5 will be identified)

Looking at the titles and abstracts of these articles, you find that one is a meta-analysis on β blockers, and the abstract suggests that these medications are almost certainly beneficial. You decide to go to the library to retrieve this paper,[11] and then to critically appraise it using the guidelines for a systematic review.[12]

Many alternative ways exist for conducting a MEDLINE search, including the one just displayed. Unfortunately, because no perfect recipe exists, what works well in one situation may not work as well in another. Combining an appropriate content term (HEART FAILURE, CONGESTIVE, in this case) with methods terms for reviews (as above) or

for sound study designs (as in Box 5.1) is a good place to start. It also has to be considered, however, that such searches are bound to take some time. This is because of the general nature of this huge biomedical research database: it is so large and comprehensive that even the extensive indexing and care that is taken in preparing it are insufficient to guarantee quick and accurate retrieval for clinical uses. Fortunately, many vendors have developed specialized subsets of MEDLINE for clinical use in cardiology. For example, Aries (http://www.kfinder.com) offers a cardiovascular disease subset (CardLine) on compact disc that you can subscribe to yourself. Instead of having 1 full year of MEDLINE on each CD Rom disc, these subsets provide journals and citations relating to a specific field for inclusion. For example, CardLine has cardiology citations from MEDLINE for the 10 most recent years on one disc.

Specialized clinical information resources

While large electronic bibliographic databases such as MEDLINE can be very helpful, they can also be very frustrating or overwhelming because of the different ways that articles can be indexed and because of the vast array of preclinical and non-clinical literature that is included. MEDLINE serves many user groups besides clinicians (basic scientists and other researchers, educators, librarians, journalists, etc.). An alternative is to use a resource that includes only methodologically sound and clinically relevant articles, such as *ACP Journal Club* (American College of Physicians (ACP-ASIM)), for internal medicine and its subspecialties, *Evidence-Based Medicine* (for all major specialties; from ACP-ASIM and from the BMJ Publishing Group), and the cardiology journal *Evidence-Based Cardiovascular Medicine* (published by Churchill Livingstone). These are available in both paper and electronic versions. In addition to including only methodologically sound articles[13] and presenting the results using a structured abstract format, these journals also include a commentary written by a clinical expert, designed to put the study findings into clinical context.

Searching *ACP Journal Club* (www.acpjc.org) using the text phrase "low molecular weight heparin" locates several relevant references, including one directly on target.[14] This report summarizes the findings of two randomized controlled trials comparing intravenous heparin administered in hospital with subcutaneous low molecular weight heparin administered at home, and both found that outpatient therapy was as safe and effective as inhospital management.

Other resources

The Cochrane Library is an increasingly valuable source of evidence summaries and trials of healthcare interventions. This new electronic database is updated quarterly and contains the collected work of the Cochrane Collaboration, an international voluntary organization that prepares, maintains, and disseminates systematic reviews of randomized trials of healthcare interventions. Available on CD Rom and via the internet (http://www.cochranelibrary.com), the Cochrane Library consists of three key sections for locating clinical evidence: the Cochrane Database of Systematic Reviews (CDSR), the Database of Abstracts of Reviews of Effectiveness (DARE), and the Cochrane Controlled Trials Registry (CCTR). The CDSR consists of the full reports of Cochrane Collaboration systematic reviews as well as protocols for ongoing systematic reviews. DARE is produced by the UK National Health Services Center for Reviews and Dissemination located at the University of York. It contains citations to many non-Cochrane systematic reviews, and includes structured abstracts for many of them. The CCTR is a growing collection of over 320 000 citations to therapeutic intervention trials.

Searching the Cochrane Library is relatively easy and requires only entering a word or short phrase. The Library automatically searches all three sections for any relevant reviews or citations. Applying this to our scenarios, searching using the term "dilated cardiomyopathy" in Cochrane Library 2001, Issue 4, yields numerous citations: three citations to completed reviews in the CDSR, seven citations in the DARE, and 267 citations in the CCTR. The Cochrane reviews address the role of anticoagulation, antiplatelet agents, and digoxin in patients with a cardiomyopathy, and the structured abstracts within the DARE include a meta-analysis of β blocker studies.[15] Doing a similar search using the term "low molecular weight heparin" locates numerous references including a Cochrane review entitled "Home versus in-patient treatment for deep vein thrombosis".[16] This systematic review was updated in February 2001 and identified the two studies that were found earlier using *ACP Journal Club*.

Textbooks

At this point, you may be thinking about your textbooks. What role do these have in clinical practice and in particular with respect to staying current? Textbooks remain an important resource for clinicians in terms of anatomy and pathophysiology, the basics of practice that usually do not change very quickly, except perhaps for molecular biology. They also provide descriptions of the classic presentations of numerous disease conditions and review important aspects of the history, physical examination, and diagnostic testing. By reviewing conditions that may present with similar findings, a good textbook can also help to broaden the differential diagnosis in more complex cases. These references may also describe medication adverse effects and pharmacokinetics, and

may include historical perspectives and practical suggestions to assist in patient management.

Textbooks, however, are seldom explicit about the quality or currency of evidence used in recommendations for management. Also, there is often a passage of 3 or more years between updates of specialty textbooks, and new studies may have been published in the interval. Particularly for rapidly evolving aspects of management such as laboratory diagnosis and therapeutics, print textbooks simply cannot be trusted. Fortunately, we are now seeing the emergence of CD-ROM and Internet versions of textbooks with regular updates, such as UpToDate[17] and *Scientific American Medicine* (SAM).[18]

The internet

This brings us to the world wide web, an increasingly useful resource for locating current information, and one that our patients are accessing at an increasing rate. We have already mentioned how MEDLINE, *ACP Journal Club* and the Cochrane Library can be accessed over the web. A rapidly growing number of journals are also available online. A few examples include the *New England Journal of Medicine* (http://www.nejm.org), *Annals of Internal Medicine* (http://www.acponline.org), *JAMA* (http://jama.ama-assn.org), *BMJ* (http://www.bmj.com), and *The Lancet* (www. thelancet. com). A number of cardiology textbooks are also available over the internet, as are many clinical practice guidelines. Two websites that have extensive cardiology sections are the Medscape (http://www.medscape.com) and Medical Matrix (http://www.medmatrix.org) sites.

Journals and browsing to keep up to date

We have focused to this point on looking for evidence when it is needed. If the search is successful, the evidence can be applied immediately and this can be a powerful learning experience. But what if we don't search for evidence because we don't know that we are out of date? A complementary strategy is needed, browsing the medical literature regularly in one way or another. The difficulty is that so many journals include articles relevant to cardiology that it is impracticable to review them all. One of the best solutions is to subscribe to a journal such as *Evidence-Based Cardiovascular Medicine* that continuously scans a wide range of journals in a systematic way, according to explicit criteria, and includes structured abstracts and commentaries on methodologically sound and clinically relevant studies.

Conclusion

In summary, while the time that we devote to updating ourselves with new developments is limited, a growing number of easy-access resources are available so that we can use this time effectively. MEDLINE is more readily available now than ever, and is seeding the development of specialty-specific collections. Journals that abstract only high-quality, clinically relevant articles are appearing, and systematic reviews are becoming the norm. Internet-accessible textbooks that are regularly updated are also becoming available. Applying these resources to clinical care on an ongoing basis after appraising the quality of information and considering how it relates to our individual patient's circumstances can lead to improvements in the quality of care we provide.

Key points

- New resources are rapidly emerging that make keeping up to date with clinically significant developments in cardiology easier than ever.
- Large bibliographic databases, such as MEDLINE, are becoming more accessible to practicing physicians, and search strategies for locating high quality studies are now available.
- Specialty journals, such as *Evidence-Based Cardiovascular Medicine*, that identify and abstract methodologically sound and clinically relevant studies, also facilitate the ongoing process of staying current.

6 Understanding concepts related to health economics

Mark Hlatky

Introduction

Economics is concerned with how to allocate scarce resources among alternative uses efficiently and effectively. It is a fundamental principle of economics that resources are limited relative to human wants, and that those resources have alternative uses.[1] Consequently, when people say that the cost of health care has grown too high, they mean that the quantity of resources flowing toward medical care has grown to the point where additional funds cannot be spent on other things that society values, such as education, public safety, environmental protection, public works, pensions for the retired or disabled, or assistance to the poor. The fact that most people put a very high value on health does not mean that they are willing to provide limitless resources to medical care. Indeed, even the goal of improving health and longevity may also be served by non-medical expenditures on programs such as nutritional supplements, a safe and clean water supply, police and fire protection, or safety improvements to roads, as well as by medical expenditures.

The cost of medical care has been rising steadily for the past 50 years, but it has only been in the past decade that the level of expenditures became so large as to cause alarm among policy makers, payers, and the general public (Table 6.1). The steady expansion of health care has now begun to meet substantial resistance in the large industrial countries, and new policies and payment mechanisms have been introduced to contain the rising cost of medical care. As a consequence, physicians must now consider cost as they design programs to prevent, diagnose, and treat disease. Cardiovascular diseases consume a large share of health care resources (Table 6.2), so cardiovascular specialists must be particularly knowledgeable about health economics. This chapter will attempt to outline the major principles of health economics relevant to cardiovascular medicine. First, some general concepts of health economics will be presented. Second, methods to identify and compare the costs of cardiovascular interventions will be described. Finally, the principles of cost effectiveness analysis will be discussed.

Table 6.1 US national healthcare expenditures, 2000

Category	US$ ($\times 10^9$)	Percentage
Hospital care	412·1	32
Physician services	286·4	22
Other professional services	99·0	8
Drugs, supplies	171·5	13
Nursing home care	92·2	7
Home health care	32·4	2
Other personal health care	36·7	3
Administration	80·9	6
Public health	44·2	3
Research	25·3	2
Construction	18·6	1
Total	1299·5	100

General concepts

Various societies have adopted different systems to pay for health care, and these systems reflect societal values and the historical experience within each country. The United Kingdom has a national health service, Canada has national health insurance, France and Germany have public/private financing for health care, and the United States has a perplexing and rapidly evolving patchwork of public and private health insurance systems. These are very different systems to finance health care, and yet each is faced with the same issues of how to allocate the limited resources available to best provide health care. Each country is also facing the same steady rise of healthcare costs, despite the wide differences in the ways they finance health care.

Provision of cardiovascular services requires resources in all societies, irrespective of the method of financing or delivering health care. Coronary bypass surgery, for example, is very resource-intensive, with the operation requiring cardiac surgeons, a cardiac anesthesiologist or anesthetist, a perfusionist, several nurses, and considerable quantities of specialized supplies and equipment. Postoperative care also requires skilled nurses and physicians, with support from specialized supplies, equipment, and facilities. Each health professional involved in cardiac surgery spends the scarce resource of time to care for the patient – time that could be put to other valuable uses, such as care for other patients. The drugs used, the disposable supplies, the operating room equipment, even the hospital building, all cost money. All of these are true costs to the system, even if the coronary bypass operation is performed "for free" – that is, without charge to the patient. The scene in the operating room, the postoperative recovery areas, and the hospital wards is much the same in the United Kingdom, Canada, France, Germany, and the United States despite the different ways these societies pay for medical care. The resources used in the care of patients, and the increasing sophistication of that care, drive healthcare costs up in each of these countries, irrespective of the way such care is paid for.

Another basic concept of economics is the so-called "law of diminishing returns". This concept is illustrated in Figure 6.1, in which the quantity of resources used in health care is plotted on the horizontal axis, and the resulting health benefits on the vertical axis. In the case of the patient with an acute myocardial infarction, for example, survival would be improved as more resources are applied, such as prehospital transportation, electrocardiographic monitoring, access to defibrillation, and a competent team to deliver coronary care. Outcomes might be further improved by reperfusion therapy, but with a greater increment in survival from using a cheaper, basic approach (streptokinase, for example) relative to no therapy, than from more expensive alternatives (such as tissue plasminogen activator (tPA) or PTCA). The extra benefit from adding even more aggressive care will be smaller still, and at some point the patient may be harmed by overly aggressive care. Helping physicians define the optimal point on this curve (Figure 6.1) is one of the goals of economic analysis.

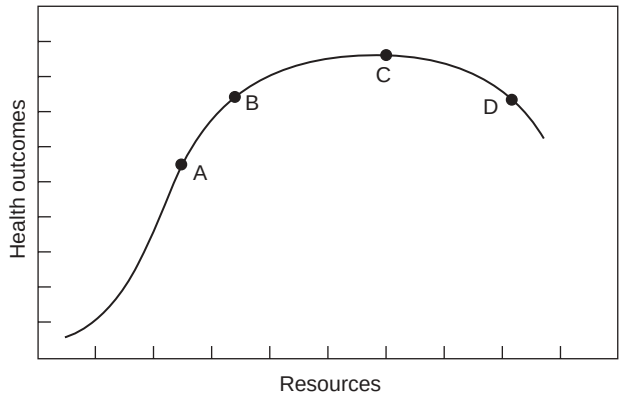

Figure 6.1 General relationship between increasing healthcare resources (horizontal axis) and health outcomes (vertical axis). At point A, outcomes are improving rapidly with increased resources and treatment is cost effective. At point B, outcomes are still improving with increased resources, but at a rate that is not cost effective. At point C, increased resources are no longer improving outcome (that is, "flat of the curve"), and at point D increased resources actually lead to worse outcomes, through iatrogenic complications and overtreatment.

Determination of costs

The cost of producing a particular healthcare service can be defined in a variety of ways. The cost of performing a coronary angiogram can be used as a specific example that will illustrate the various aspects of cost and how the cost might be measured. Performing a coronary angiogram requires a variety of resources, including radiographic equipment, trained personnel (including an angiographer and technical assistants), and specialized supplies such as catheters, radiographic contrast, and sterile drapes. The equipment needed is very expensive to purchase, and the healthcare facility where it is installed may require special renovations to assure proper radiation shielding and adequate electrical power. The capital cost for a coronary angiography laboratory will be considerable, perhaps $2–3 million, depending on the type of equipment purchased. The laboratory will have a physical lifespan of perhaps 7–10 years, although technologic innovations may lead to replacement of the equipment before the end of its physical lifespan. The cost of building an angiography suite represents a large *fixed cost* for coronary angiography, a cost that is roughly the same whether the laboratory performs 200 or 2000 angiograms per year. The cost per case is lower in the high volume laboratory, however, because the fixed equipment costs can be spread over more cases. Thus, if the equipment costs

$2·5 million and has a useful life of 10 years, the prorated share of fixed costs for each patient in the low volume laboratory performing 200 cases per year is

$$\text{Fixed costs/case} = \frac{\$2\,500\,000}{(200\ \text{cases/yr})(10\ \text{years})} = \$1250/\text{case}$$

whereas in the high volume laboratory (2000 cases per year) the prorated share of fixed costs per case would be

$$\text{Fixed costs/case} = \frac{\$2\,500\,000}{(2000\ \text{cases/yr})(10\ \text{years})} = \$125/\text{case}$$

Procedures that have high fixed costs will be performed with greater economic efficiency in centers that have sufficient volume to spread those fixed costs over a larger number of individual patients. (There may be additional advantages to larger procedure volumes as well, since the technical proficiency is higher and clinical outcomes of many procedures are usually better when performed in higher volume clinical centers.)[2–4] Procedures with lower fixed costs will have a smaller effect of volume on costs.

In contrast to the fixed equipment costs, the cost of supplies consumed in performing coronary angiography varies directly with the volume of cases performed, and the supply cost per case will be fairly constant irrespective of the volume of cases performed (apart from the small effect of discounts available to large volume purchasers). The cost of laboratory staff falls in between these two extremes, in that the hours worked in the catheterization laboratory by technical staff can be varied somewhat according to the volume of cases performed, but some staff effort is required regardless of patient volumes, such as supervisors.

Hospital overhead is also a real cost, but one that is less directly linked to any one medical service or procedure. Hospitals must pay for admitting offices, the medical records department, central administration, the laundry service, the cafeteria, housekeeping and utilities, to name just a few areas. These costs cannot be tied easily to the coronary angiography procedure in the same way as the cost of the catheters or radiographic contrast. Most facilities assign a share of these costs to patient care services according to a formula such as the step down method. Discussion of specific methods to allocate hospital overhead is beyond the scope of this chapter, but can be found in several articles and books.[5,6]

The overall effect of procedure volume on the cost per case is illustrated in Figure 6.2. In general, the cost per case declines as more cases are performed, up to the limit of the facility's capacity (for example, 2000 cases). If volume increases further, more facilities must be built, increasing the cost per case, as more fixed costs are spread over a few more patients. Figure 6.2 also illustrates the distinction between concepts of "marginal cost" and long run "average cost". The marginal cost is the added cost of doing one more case. In an already equipped and staffed coronary angiography laboratory, the marginal cost of performing one more procedure is just the cost of the disposable supplies consumed in the case: the catheters, radiographic contrast, and other sterile supplies. In the example of Figure 6.2, the marginal cost is $250 per case. The marginal cost is lower than the average cost per case ($375 per case), which also includes a prorated share of the salaries of the laboratory staff, depreciation of the laboratory equipment costs, and the facility's overhead costs.

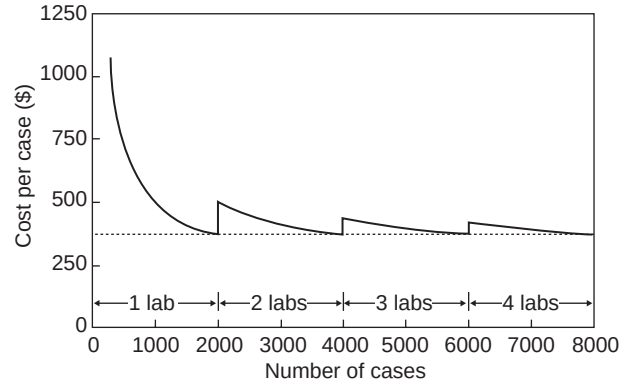

Figure 6.2 Cost per case for coronary angiography as a function of clinical volume. Assumes fixed costs per laboratory of $250 000 per year, and marginal (that is, variable) costs of $250 per case. When volume reaches 2000 cases per year in a laboratory, the model assumes an additional laboratory will be built. The dotted line indicates the "long run average" cost per case of $375.

Costs *v* charges

Costs and charges are related but distinct concepts. The cost of a medical service represents the value of the resources required to produce it. The charge for a service is a specific form of reimbursement to healthcare providers in a fee-for-service healthcare system. The cost and charge for providing a service should be quite close to one another in a competitive economic market. The reason is simple: if one provider charged an amount much higher than it actually cost to provide a service, a competitor could offer the same service at a lower price and still come out ahead. Conversely, if a provider charged less than the costs of production, the provider would lose money. These basic economic principles have not applied very well to medical care, at least until recently, because medical care has not had significant competition on prices.

In regulated or non-price competitive healthcare systems, the charge (price) for a service need not bear a close relationship to the cost of producing a service. Hospitals might choose to set high prices for some services, such as coronary bypass surgery, and use the excess revenues to subsidize other services that were less well reimbursed, such as the emergency department or, in academic centers,

medical education, and research. With greater price sensitivity on the part of healthcare payers, the subsidization of one medical service with the proceeds of another service has been sharply curtailed. While this trend has had the positive effect of bringing an element of economic reality to medicine, it has also caused dislocations and considerable harm as worthwhile endeavors have lost the funding they previously enjoyed from cross-subsidization. In the long run, medical education, clinical research, and services to uninsured or poorly insured patients should receive direct funding to replace the indirect funding by cross-subsidies, but in the transition these endeavors have been threatened due to loss of a traditional funding base.

Estimation of costs

The cost of providing a specific service, such as coronary bypass surgery, can be established in several alternative ways. In principle, one valid way to measure cost would be to identify a competitive market for medical service, and note the charge (price) for coronary bypass surgery in that market. While competitive market pricing might work well for commodities such as consumer electronic devices or farm products, it is not well suited to medical care, where there are few competitive markets. An alternative method to measure cost is to take note of the charge for a service, and apply correction factors to estimate cost more accurately. A third method to estimate costs is to examine in detail the resources used to provide a service, and apply price weights to the resources used:

$$\text{Cost}_j = \sum_i (\text{Quantity})_{ij} \times (\text{Price})_{ij}$$

The use of these different approaches to cost determination is illustrated by a study that estimated the costs savings achievable by substituting coronary angioplasty for coronary bypass surgery.[7] In that study, hospital billing records were used to construct resource consumption profiles for patients undergoing either angioplasty or bypass surgery for the treatment of stable angina. A microcosting approach was then applied to the resource consumption profiles, with the cost of a specific resource (for example, an electrocardiogram) defined either as the cost of supplies only (marginal cost or variable cost) or as the cost of supplies, personnel and equipment, but omitting overhead (average direct cost). Charges on the billing record for a service were also converted to costs by two different correction factors, also known as ratios of cost to charges. One cost–charge ratio included all direct costs of providing a service (supplies, personnel, and equipment), but omitted hospital overhead (for example, medical records, laundry, utilities, administration). The second cost–charge ratio allocated a share of hospital overhead to each service in addition to its direct costs.

As shown in Table 6.3, the cost savings attributable to substitution of angioplasty for bypass surgery varied considerably according to how costs were defined. The lowest cost savings are evident when only marginal costs are included, and fixed cost and overhead excluded. The average direct cost difference is intermediate in value, and comparable estimates of this cost savings were obtained from the use of resource consumption profiles and cost weights (method 2) or the cost-to-charge ratio method that omitted overhead (method 3). Finally, the inclusion of overhead (method 4) led to the highest absolute difference in costs.

The differences in cost as estimated using these methods is directly related to the issue of how the information is to be used or, put another way, depends on the answer to the question, "cost to whom?". A hospital manager might be most interested in the marginal cost of procedures (method 1) in looking at the effect of adding or subtracting a small number of cases to the volume performed in an institution. Under a fixed budget for cardiac services, for instance, the effect of substituting angioplasty for bypass surgery may be small, given that the personnel, equipment, and overhead are largely fixed. Performing a few extra procedures with existing facilities adds very little cost from the perspective of the

Table 6.3 Effect of different definitions of cost on the savings possible by substitution of coronary angioplasty for bypass surgery

Definition of cost	PTCA cost ($)	CABG cost ($)	Difference ($)	PTCA/CABG ratio (%)
Variable cost only	2672	4607	1935	58
Average direct cost				
By microcosting	4073	8666	4593	47
By ratio of cost-to-charges	4935	10 281	5346	48
Average cost + overhead	7530	15 367	7837	49
Charges	9556	19 644	10 088	49

Source: adapted from Hlatky *et al*[7]

head of a clinical service or a hospital manager. They may even be willing to perform a modest number of additional cases at a reimbursement level below their actual average cost, but above marginal cost, in order to increase volume and spread their fixed costs over more patients. Thus, marginal or variable costs are quite relevant to decision makers within the institution providing a service.

The perspective of a policy maker or health planner includes a longer time horizon and the possibility of adding or subtracting substantial volumes of clinical services. From this perspective, no cost is truly fixed, for personnel needs can be adjusted, and the number of facilities providing a service can be altered. This perspective is a broader one, and the costs considered are therefore more inclusive. For most policy level discussions, long run average cost is the most relevant measure.

International perspectives

With the advent of large multicenter clinical trials that enroll patients from several countries, interest has developed in cost comparisons between countries for the same service. Cost estimation as part of large randomized trials will enhance clinical decision making, for the randomized design is the strongest way to compare all outcomes of therapeutic alternatives, including cost. Extension of cost comparisons across national borders introduces a number of technical and conceptual issues that deserve discussion.

Different countries measure cost in their respective national currencies, so that readers in another country need to convert between units (for example, pounds sterling or euros to US dollars). These conversions can be done using currency exchange rates, or the closely related purchasing power parity factors. The differences between countries in units of measurement are important, but this issue is fairly simple to address.

A more thorny issue in international comparisons is differences in the relative prices of the resources used to provide a service and differences in resource profiles used to provide a service. Thus, if the cost of service *j* is defined as

$$\text{Cost}_j = \sum_i (\text{Quantity})_{ij} \times (\text{Price})_{ij}$$

then cost may differ among countries due to either differences in the quantity of resources used to provide a service, price differentials for the same resources, or both. A specific example will help illustrate these concepts (Table 6.4). Care of a patient with acute myocardial infarction given thrombolysis includes the cost of the drug, the cost of basic hospital care, and the cost of additional tests and treatments in the convalescent phase. Table 6.4 presents hypothetical costs of basic care in two countries, with monetary values expressed in dollar units for simplicity. The costs of drugs in Country 1 are higher than in Country 2, where drug prices are strictly regulated. The time spent by the hospital staff to care for the patient are quite similar in Country 1 and Country 2 (50 hours per patient for Treatment A and 54 for Treatment B, a difference due to lower complication rates with Treatment A). The average hourly compensation for hospital staff is, however, higher in Country 2, so that total personnel costs are higher as well. Thus, both cost savings and the relative costs of Treatment A and B are different in these two healthcare systems, due to different prices for the same resources used to care for a myocardial infarct patient.

There may also be differences in the level of resource use between countries, especially for discretionary procedures such as coronary angiography. Suppose that the use of Treatment A cuts the use of coronary angiography by one third, partially offsetting the higher cost of the drug. If, however, the baseline rates of angiography are different between countries, the cost implications of reducing angiography by one third in each country will be quite different (Table 6.5). A reduction by one third in the high rate of angiography in Country 1 (from 60% to 40%) provides a $200 cost offset per patient, whereas a reduction by one third in the low rate of angiography in Country 2 (from 20% to 15%) provides only a $50 cost offset per patient.

International comparisons of the cost of therapies can thus be affected by (a) differences in resource use patterns that reflect differences in practice style and the organization

Table 6.4 Effect of differences in medical prices on costs of alternative treatments

	Country 1		Country 2	
	Tx A	Tx B	Tx A	Tx B
Drug ($)	2000	200	1500	150
Nursing hours	50	54	50	54
Nursing wages ($)	30	30	35	35
Total ($)	3500	1820	3250	2040
Cost savings (A−B) ($)	1680		1210	
Cost ratio B/A	52%		63%	

Abbreviation: Tx, treatment

Table 6.5 Effect of differences in resource utilization on costs of alternative treatments

	Country 1		Country 2	
	Tx A	Tx B	Tx A	Tx B
Drug/nursing ($)	3500	1820	3250	2040

of medical care, and (b) by differences between countries in the prices attached to specific resources, such as healthcare wages, drugs, and supplies. Data from cost studies can be most readily applied in different practice environments if the study provides information on both resource consumption patterns and price weights attached to the specific resources used, as well as a summary cost measure. This detail is needed for readers to understand the applicability of the cost findings to their own practice settings.

Cost effectiveness analysis

The cost of providing a particular medical service can be measured, but determination of whether the service provides good value for the money spent is a more difficult judgment. Cost effectiveness analysis is a method of weighing the cost of a service in light of the health effects it confers in an attempt to facilitate the ultimate value judgment about whether the service is "worth" the cost.

Cost effectiveness analysis is one of several alternative analytic methods, each with its own strengths and limitations.[5] If two alternative therapies are either known to yield identical results or can be shown to be clinically equivalent, they can be compared on the basis of cost alone. This form of analysis, which is termed "cost-minimization analysis", is particularly appropriate to commodities such as drugs, supplies, and equipment that can be expected to yield equivalent results when applied clinically. In such situations, the relative costs of the alternatives become the predominant consideration.

Many alternative therapies are known to differ both in clinical outcomes and in cost. In this situation, both the difference in cost and the difference in effectiveness of the therapeutic alternatives must be measured and weighed against each other. When the effectiveness on intervention is measured in clinical terms (for example, lives saved, years of life added), the analysis is termed "cost effectiveness". If the clinical measures of effectiveness are translated into monetary units, the term "cost–benefit analysis" is applied. Cost–benefit analysis has been used to guide public policy in areas outside of medicine, such as in the construction of transportation systems or whether to remove or reduce environmental exposures. Cost–benefit analysis measures the effects of programs in monetary terms, so that net cost (in dollars) can be compared with net benefits (in dollars). Since there is great reluctance on the part of physicians and health policy makers to assign a dollar value to saving a life or improving a patient's function, cost effectiveness analysis rather than cost–benefit analysis has been applied predominantly to medical problems.

Cost effectiveness analysis was first applied to medical programs only 25 years ago[8,9] and has since been widely used.[10–12] The principles of cost effectiveness analysis for medical programs have recently been examined in detail by a Task Force convened by the United States Public Health Service.[13–15] A group of experts attempted to establish consensus on a number of methodologic issues, with the goal of standardizing the technical aspects of cost effectiveness analysis among studies, thereby enhancing their comparability. The principles articulated by this group are reasonable, and should guide this important field in its next 20 years.

A basic principle of cost effectiveness analysis is that the analysis should compare alternative programs, and not look at any single program in isolation. Thus, a drug to treat life-threatening arrhythmias might be compared with placebo, or an implantable cardioverter defibrillator might be compared with a drug. In essence, cost effectiveness analysis must always answer the question "cost effective compared with what?".

Another principle is that the costs included in cost effectiveness analysis should be comprehensive. The cost of a specific therapy should include the cost of the intervention itself (for example, thrombolytic therapy for acute myocardial infarction) and the costs of any complications the therapy induced (for example, bleeding), less any cost savings due to reduction of complications (such as, heart failure). The need for other concomitant therapy should also be included, which is particularly important when assessing the cost effectiveness of screening programs or diagnostic testing strategies.

The length of follow up should be sufficient to include all relevant costs and benefits – such as readmissions to the hospital due to treatment failures. Non-monetary costs directly related to the medical intervention should also be included, such as the cost of home care by the patient's family, since omission of these costs would bias assessments toward programs that rely on unpaid work by family members or volunteers. Other costs not directly related to the intervention, however, such as the patient's lost wages or pension costs, are omitted by convention from the measured costs in a cost effectiveness analysis.

Another important issue in cost effectiveness analysis is the perspective taken by the analysis. There is general agreement that the analysis should include all relevant costs, regardless of who pays them. This principle is known as "taking the societal perspective", and it assures a complete accounting of costs in the analysis. A hospital, for instance, may not care about the out of pocket costs paid directly by the patient, but these are real costs and should be considered in the analysis.

Medical costs may accrue over long periods of time, especially in preventive programs or the treatment of chronic disease. Time scales of more than a year or so bring up two related but distinct issues – inflation and discounting. The nominal value of any currency changes over time; a dollar in 1977 had more purchasing power than a dollar in 1997. Studies conducted over long time periods will need to correct for the changing value of currencies, typically by application of the Consumer Price Index (or the GDP deflator). Application of the Consumer Price Index removes the effect of inflation, but does not address the separate issue of time preference for money. Even in a country free of inflation, citizens would prefer to receive $100 today than a promise they will be paid $100 in a year. One might have to promise to pay more money in a year, say $103, to compensate for the delay. The same is true in health programs: we would prefer to be paid today instead of in the future, and we would also prefer to pay our obligations in the future rather than today. Use of a discount rate provides a way to correct for the lower value of future costs relative to current costs. The technical experts' consensus is that future costs should be discounted at a rate equivalent to the interest paid on safe investments such as government bonds in an inflation-free environment, or about 3% per year. The effect of alternative discount rates between 0% and 5–10% per year should also be checked to document the sensitivity of the analysis to future costs.

In summary, a cost effectiveness analysis should include all medical costs, including those of complications of therapy and adverse effects prevented. The study should be of sufficient duration to measure all relevant costs and benefits of the treatment. All costs and benefits should be included, regardless of who bears or receives them. In studies covering more than a year or so, corrections should be made for inflation, and 3% per year discount rate should be applied to follow up costs.

Measuring effectiveness

The effectiveness of an intervention in practice can be measured in a variety of ways, with different outcome measures most appropriate for specific applications. Physiologic end points are often used in clinical trials, with the result of therapy assessed by a laboratory measure such as millimeters of mercury for blood pressure or episodes of non-sustained ventricular tachycardia on an electrocardiographic monitor. Laboratory measures are useful in judging the physiologic effects of therapy and its mechanism of action, but these surrogate markers may not predict the ultimate effect of therapy on mortality and morbidity, as vividly illustrated by the results of the Cardiac Arrhythmia Suppression Trial (CAST).[16] Physiologic end points are also tied closely to one specific disease, making comparisons against other benchmark therapies difficult. The patient and public are most concerned with the effect of therapy on survival and on their ability to function – that is, upon the length of life and the quality of life. A common denominator measure of effectiveness is thus the life years of expected survival, or the quality adjusted life years (QALYs). This measure is relevant to patients and to the public and can be applied to virtually any therapy.

Mortality is a common end point in clinical trials, and leads directly to the measure of life years of survival. The mean life expectancy of a cohort of patients is equal to the area under a standard survival curve. The difference in life expectancy between two therapies is therefore equal to the difference in the areas under their respective survival curves. Since many clinical studies do not follow patient cohorts long enough to observe complete survival times for all patients, some assumptions and modeling of long-term survival may be needed to estimate the full survival benefit of therapy for a cost effectiveness analysis.[17]

Improvement in quality of life is often as important to patients as reducing mortality, and it is often the main goal of therapies, such as the relief of disabling angina or improvement in exercise tolerance. A quality of life measure can be translated into a scale that ranges from a low of 0·0 (the worst possible health state, usually taken as death) to 1·0 (perfect health). This quality of life measure is multiplied by the length of time a patient spends in the health state to yield a quality adjusted life year (QALY). Thus:

$$\text{QALY} = \sum_{i} Q_i \times t_i$$

where QALY = the quality adjusted life years, Q_i = the quality factor for follow up period "i" and t_i = the length of time spent in period "i". This equation shows that the effectiveness of a treatment, as measured in QALYs, can be improved

by either enhancing the patient's quality of life (Q_i) or the patient's length of life (t_i), or both.

Calculation of cost effectiveness

After the costs of therapy and the medical effectiveness of therapy have been assessed, cost effectiveness (CE) can be calculated as:

$$\text{CE ratio} = \frac{\text{Cost}_2 - \text{Cost}_1}{\text{QALY}_2 - \text{QALY}_1}$$

where Cost_1 and Cost_2 represent the costs of program 1 and program 2, respectively, and QALY_1 and QALY_2 represent the effectiveness of programs 1 and 2, respectively.

There are several implications of using this formula. First, cost effectiveness ratios that are positive (that is, >0) result if and only if one alternative has both higher cost and greater effectiveness – that is, $\text{Cost}_2 > \text{Cost}_1$ and $\text{QALY}_2 > \text{QALY}_1$ (or the reverse: $\text{Cost}_2 < \text{Cost}_1$ and $\text{QALY}_2 < \text{QALY}_1$). Cost effectiveness ratios of <0 are not generally important for decision making, since they arise only when one alternative has both lower costs and greater clinical effectiveness than the other (for example, $\text{Cost}_2 > \text{Cost}_1$, and $\text{QALY}_2 < \text{QALY}_1$). In this case, program 1 is superior in all respects: it has better outcomes and lower cost than program 2, and thus is said to "dominate" the alternative. The decision of which program to recommend is therefore simple.

Another important implication of the formula used to calculate cost effectiveness is that the ratio is undefined when the two alternatives provide equal outcomes, since when $\text{QALY}_2 = \text{QALY}_1$ the denominator in the cost effectiveness ratio is equal to zero. The implication is that when the difference in outcomes between two programs is negligible, cost effectiveness analysis is unnecessary, and the choice between two alternatives can be based on cost alone (that is, cost minimization analysis is more appropriate than cost effectiveness analysis).

Most commonly, one of two therapeutic alternatives has higher costs and greater effectiveness, and use of the formula yields a cost effectiveness ratio greater than zero. One treatment may have a cost effectiveness ratio of $5000 per year of life saved, and another might have a ratio of $75 000 per year of life saved. Since it is problematic to assign a dollar value to life, interpretation of these ratios is best made by consideration of benchmarks – other generally accepted therapies that serve as a rough gauge to an "acceptable" cost effectiveness ratio. Renal dialysis is a form of therapy that most people would consider expensive, and yet dialysis is an intervention that the USA and most other industrialized countries provide as a life saving therapy. The end stage renal disease program in the USA costs about $35 000 a year per patient, and if this therapy were withdrawn the patient would die. Thus, renal dialysis has a cost effectiveness ratio of $35 000 per year of life saved (or if one considers the reduced quality of life for a dialysis patient, perhaps $50 000 per quality adjusted year of life saved). Therapies with cost effectiveness ratios considerably more favorable than renal dialysis (that is, $<$$20 000) would be considered very cost effective, whereas therapies with cost effective ratios much higher (say $>$$75 000) would be considered too expensive.

Different societies may come to different conclusions about the level of cost effectiveness they consider good value. Wealthy countries with high per capita incomes are more willing to pay for expensive therapies than are poor countries. For instance, the percentage of gross domestic product and per capita health spending in Eastern Europe is much less than in Western Europe or North America, and these countries have not chosen to provide expensive services such as bypass surgery as readily or as frequently.

Decisions about funding programs might be more equitable and rational when guided by the relative cost effectiveness of programs. When studies use similar methods to measure cost and effectiveness, cost effectiveness ratios can be compared to rank the economic attractiveness of alternatives. Tables comparing various treatments, such as Table 6.6, have been termed "league tables" because of their similarity to the athletic league standings published in newspapers. Given the uncertainty inherent in measuring cost and effectiveness of medical interventions, and the methodologic variations among studies, only relatively large differences in cost effectiveness ratios should be considered significant. Thus, a program with a cost effectiveness ratio of $5000 per life year added is much better than one with a ratio of $30 000. Programs with ratios of $25 000 and $30 000 are so close that no firm conclusion about the relative values should be drawn.

Patient selection and cost effectiveness

Drugs and procedures in medicine are applied to different patient groups for different clinical indications. The medical effectiveness of therapies varies considerably according to patient selection. Cholesterol lowering therapy, for instance, will extend the life expectancy of a patient with multiple cardiac risk factors more than it will for a patient with the same cholesterol level and no other cardiac risk factors. Coronary bypass surgery provides greater life extension to a patient with left main coronary artery obstruction than it does to a patient with single vessel disease.[18] The cost effectiveness ratio for these therapies will therefore vary among patient subgroups due to the impact of patient characteristics on the clinical effectiveness of therapy, which forms the denominator of the cost effectiveness ratio. Similarly, the cost of a particular therapy may also vary according to patient characteristics, since the therapy itself may be more

Table 6.6 Cost effectiveness of selected cardiovascular therapies

Strategy	Patient group	Cost effectiveness[a]
Lovastatin	Post MI Men 45–54 Chol ≥ 250	Saves dollars and lives
Enalapril	CHF EF < 35%	Saves dollars and lives
Radio frequency ablation	WPW, post cardiac arrest	Saves dollars and lives
Physician counseling	Smoking	$1300
β blocker	Post-MI High-risk	$3600
CABG	Left main CAD Severe angina	$9200
β blocker	Post-MI Low-risk	$20 200
Lovastatin	Primary prevention Men 55–64 Chol > 300 Three risk factors	$20 200
tPA	Acute MI	$32 800
ICD	Sustained VT	$35 000
CABG	Two vessel CAD Angina	$42 500
Lovastatin	Primary prevention Men 55–64 Chol > 300 No other risk factors	$78 300
Exercise ECG	Asymptomatic 40 year old men	$124 400
CABG	Single vessel CAD Mild angina	$1 142 000
Lovastatin	Primary prevention 35–44 year old women Chol > 300 No other risk factors	$2 024 800

[a] $ values, dollars per year of life added.

or less expensive according to different patient subgroups, or the likelihood of costly complications may be higher or lower in different groups of patients.

The clinical effectiveness of a therapy is generally the most important factor determining cost effectiveness. The reason for this importance is (a) that clinical effectiveness of a therapy generally varies more among patients than does the cost of therapy, and (b) the value of the cost effectiveness ratio is more sensitive to changes in the denominator (effectiveness) than to changes in numerator (cost). In the last analysis, a therapy must be clinically effective before it can be cost effective. Cost effectiveness analysis relies more on the assessment of medical effectiveness than it does on determination of cost.

Diagnostic tests and cost effectiveness

Cost effectiveness analysis has been applied primarily to assess specific therapies or therapeutic strategies, for which it is natural to measure effectiveness in terms of patient outcome. The principles of cost effectiveness can be extended to analyze screening tests and diagnostic strategies as well, but some additional factors must also be considered.

Therapies are expected to improve patient outcome *directly*, by intervening in the pathophysiology of disease processes. In contrast, a diagnostic test is expected to provide the physician with information about the patient, which in turn is expected to improve management and thereby *indirectly* improve patient outcome. The value of a test is therefore linked closely with patient selection for therapy, and the value of testing may well change as new therapies are developed, or alternative tests become available.

The information provided by a test may be used in different decisions, and the test may be more or less useful in these different settings. An exercise electrocardiogram, for example, can be used as a diagnostic test for coronary disease, a prognostic test for patients with recent myocardial infarction, a monitoring test to assess the effect of antiischemic therapy, or even as a way to establish target heart rates for an exercise training program. The efficacy and cost effectiveness of applying the exercise electrocardiogram will be different for these varied uses of the information provided by the test. The value of the test will depend on the indication for which it is used, much as the value of a β blocker will vary whether it is used to treat hypertension or as secondary prevention after a myocardial infarction.

The same test (for example, the exercise ECG) applied for the same purpose (such as diagnosis of coronary disease) will provide more information in some groups of patients than in others. As discussed elsewhere in this book, a diagnostic test provides more value if used when the pretest probability of disease is intermediate than when the pretest probability is either very high or very low. The test has the most value when the result is likely to change the estimated probability of disease such that clinical management is changed. Tests that never change patient management cannot change patient outcome, which is the "bottom line" in assessing cost effectiveness.

Conclusions

Economic analysis is designed to assist decisions about the allocation of scarce resources. Physicians now must address the cost implications of clinical decisions, and be aware of the effects on scarce resources. Economic efficiency is but one of many goals, however, and issues of fairness and humaneness are also central to medical care, and must be considered as well.

7 Introduction to decision analysis

Kevin A Schulman, Henry A Glick, Allan S Detsky

The concept of evidence-based medicine challenges physicians to improve their use of the medical literature to guide their decision making in specific clinical settings. The concept is discussed extensively throughout this book. However, there are circumstances in which clinical trials do not address all of the issues of interest to a clinician. This may be because the trials do not compare the risks and benefits of all relevant treatment alternatives, or because the trials lack important data on the outcomes and costs of therapy. In these cases, researchers and clinicians are developing analytical strategies to improve their ability to synthesize the available information from the clinical literature and to help resolve these unanswered questions. One method of achieving this synthesis is the use of decision analysis, a set of mathematical strategies for aggregating information, making issues related to clinical decisions explicit, and solving for an optimal strategy under the constraints of the analysis. This decision analysis is a framework that can be used in the analysis of clinical problems as well as in economic analysis (see Chapter 6).

Decision analysis has been available to cardiologists for over 20 years.[1–3] In that time, the techniques have become more sophisticated and begun to address a broader range of questions.[4–6]

The goal of this chapter is to introduce the reader to some of the basic concepts of decision analysis and to review its use in the cardiovascular literature. For more specific information about the concepts or methods of decision analysis, the reader is referred to several excellent summary articles[2–11] or to one of the major texts in the field.[12–14]

Examples of decision analysis

In this section we present two examples of the use of decision analysis, a clinical example and an economic example. These are provided to demonstrate the steps involved in developing a decision analysis. As will be clearly demonstrated, decision analytic models must simplify reality in order to structure the problem and analysis. Although our examples are extremely simplified to illustrate the steps involved in decision analysis, many models in the clinical literature offer more complex depictions of clinical reality.[16–22,26,27,36,40,41,53–58]

Steps in decision analysis

1. Identify the strategic options.
2. Draw the tree (structure of outcomes).
3. Determine the probabilities.
4. Determine the relevant outcome measures (effects, utility, survival, costs).
5. Evaluate the tree.
6. Make a structured analysis of the problem.
7. Develop a conclusion.

A comparative clinical analysis: warfarin *v* aspirin for atrial fibrillation

For patients with non-valvular atrial fibrillation, both warfarin and aspirin have been shown to reduce the risk of stroke.[28–35] However, the effectiveness and side effects of these two treatments can vary substantially. As there has been no randomized trial of aspirin and warfarin for stroke prevention, decision analysis has been used to identify the clinical outcomes resulting from treatment with each medication.[36]

Step 1: Identify the strategic options

In terms of therapeutic benefit, patients who receive either warfarin or aspirin experience a reduction in the risk of stroke. However, patients receiving these therapies also experience risk of bleeding complications. Both stroke and hemorrhage can be either fatal or non-fatal.

Step 2: Draw the tree

Based on these facts, we can graphically depict the issue using a decision tree (Figure 7.1). The tree is displayed so that the decision of interest is on the left side of the diagram, while the strategies to be compared are in the center, and the outcomes of those strategies are on the right. There are several pieces of information included in this simple figure.

In the decision tree a choice is represented by a square, also called a "decision node". In this example, the decision node represents a choice between warfarin and aspirin. Once a decision is made, patients experience the potential

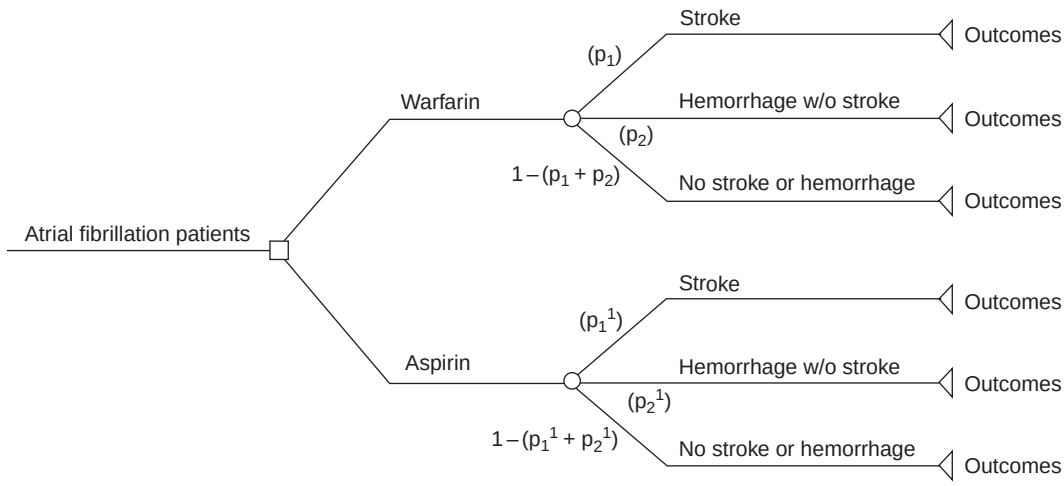

Figure 7.1 A decision tree for a comparative clinical analysis: warfarin *v* aspirin for atrial fibrillation

for different clinical events (stroke or hemorrhage). These decisions and their subsequent clinical events are represented by lines or "pathways" running through the tree diagram. Figure 7.1 contains six possible pathways: warfarin with stroke; warfarin with neither stroke nor hemorrhage; warfarin with hemorrhage but without stroke; aspirin with stroke; aspirin with neither stroke nor hemorrhage; and aspirin with hemorrhage but without stroke.

After the initial treatment decision between warfarin and aspirin has been made, subsequent outcomes occur with a defined probability such that all of the potential treatment outcomes are represented by the treatment pathways. The individual patient's achievement of a given treatment outcome (for example stroke or no stroke) is not a decision: it is, instead, a chance occurrence, where the "chance" event is represented by a circle in the decision tree.

The final treatment outcomes for each pathway are represented by triangles. These figures represent the outcomes of each treatment strategy. One, two or more outcomes can be expressed for each pathway (survival, quality adjusted survival, or costs).

Step 3: Determine the probabilities

Once a tree has been developed to depict a clinical problem, the next step is to begin to develop the data required to complete the analysis. In our example, we must identify the probability of stroke for patients in our two treatment categories and identify the potential risk of bleeding complications associated with each therapy.

Rates of stroke without therapy, outcomes of stroke, and stroke risk reduction with prophylaxis with aspirin or warfarin can be estimated from clinical trials or epidemiologic studies.[36] Rates of major hemorrhage associated with warfarin and aspirin therapy, and the outcomes of such an event, can be estimated in the same fashion.[36] However, in pooling these various data sources, investigators are left with a degree of uncertainty about these estimates. Sensitivity analysis, a method for assessing the impact of uncertainty in data analysis of clinical problems, will be discussed later, but it is an integral component of most well constructed decision analytic models.

Step 4: Determine the relevant outcome measures (effects, utility, survival, costs)

For this analysis, quality adjusted survival will be the primary outcome measure. Other possible outcome measures include event-free survival or simple survival. Analysis of quality adjusted survival uses estimates of patient preferences for a variety of possible health states for patients with stroke. Patient preferences are a measure of health-related quality of life, or utility, as defined on a 0–1 scale, in which 0·0 represents the worst imaginable health state and 1·0 denotes the best imaginable health state. Quality adjusted survival is the product of the expected survival of patients and their preferences for the different health states resulting from a stroke or hemorrhage. These data can be estimated from expert opinion, as reported in the medical literature, or derived from patient interviews.[37] Calculation of quality adjusted life years (QALYs) is described in greater detail elsewhere.[9]

Step 5: Evaluate the tree

Once data have been compiled for the specified model parameters, the next step is to analyze the tree. This requires the calculation of the expected value for each pathway of the tree. For both warfarin and aspirin therapies, the expected value of the outcome (effects, utility, survival or costs) is a weighted average of all possible treatment outcomes. This weighted average is calculated as the product of

the value of each terminal node and the probabilities of the occurrence of that node (the product of the probabilities of achieving that node). The value of each node is then summed to result in the weighted average value for the treatment (for example, the outcome for warfarin would be the weighted average of the products of the probability of stroke while taking warfarin and the outcome for stroke ($P1 \times O1$), the probability of hemorrhage without stroke while taking warfarin and the outcome for hemorrhage without stroke ($P2 \times O2$), and the probability of no stroke or hemorrhage and the outcome for no stroke or hemorrhage $\{(1 - [P1 + P2]) \times O3\}$).

A more complicated decision analysis proceeds in stepwise fashion for each set of probabilities and outcomes. This is called folding back the tree. The net result is an assessment of the outcomes for the two treatments, warfarin and aspirin. Other techniques can be used to solve more complicated problems, for which there are many branches of each tree – for example, when the risk of stroke or hemorrhage is related to the duration of treatment. (These methods are based on the probability of moving between health states over time. Analysis can also be based on "state transition models" or Markov models.)

For clinical analyses, decision trees allow an incremental analysis of the treatment benefits of one medical therapy compared to another. They are used to compare the expected utility for each branch of the tree to pick the best treatment option. The best option is the one with the highest value in terms of clinical effects (survival or utility) or the one with the smallest value in terms of cost. An incremental analysis assesses the additional benefits gained from one treatment and, thus, differs from a calculation of the absolute benefit of a treatment.

Step 6: Structured analysis of the problem

Finally, the primary analysis having been completed, investigators should examine uncertainty in their estimates using a technique called sensitivity analysis. By recognizing that a decision tree can suffer from uncertainty in the probability of each treatment strategy, investigators can ask how the results might change were the possibilities of stroke or hemorrhage to increase or decrease by 10% for each treatment arm. In a sensitivity analysis, the investigator recalculates the results of the model to address the robustness of the analysis to changes in the model specification.

Step 7: Conclusion

This decision analysis was structured to compare the outcomes of two strategies for the treatment of stroke prophylaxis – warfarin and aspirin. Such an analysis allows for an assessment of the clinical benefits of the two strategies, incorporating both the differences in risk reduction of stroke and the differences in hemorrhage resulting from the prophylactic treatment. The analysis would end with an estimate of the quality adjusted survival resulting from each treatment strategy. The results could reveal that warfarin is superior to aspirin, that aspirin is superior to warfarin, that the treatments are comparable, or that there is not enough information from which to draw a firm conclusion. The analysis would also address how sensitive the analysis was to differing model parameters. This could help define areas for further research to resolve outstanding issues in the clinical assessment.

A cost effectiveness analysis: implantable cardiac defibrillators

At present there is a great deal of debate about the most appropriate treatment of patients with arrhythmias, especially about whether implantable cardiac defibrillators (ICDs) will reduce cost and mortality for high-risk patients. Early clinical trial results address mortality issues related to the use of ICDs in high-risk populations.[38] However, there remains a great deal of concern about the findings of the study and the robustness of its results.[39] Although decision analysis cannot answer the clinical questions regarding ICD use, these techniques have been used to model the costs and effects of ICD insertion to estimate the potential cost effectiveness of this therapy, given current estimates of ICD clinical effectiveness.[40,41] To understand the decision analysis approach to this question, we will review the clinical issues and then build a decision analytic model to formalize the question.

High-risk patients experience an increased incidence of sudden cardiac death.[42] One new technology, the ICD, has been proposed as a means of reducing the incidence of sudden death in cardiac patients.[38,43–48] Patients who choose to receive this therapy must undergo a surgical procedure and maintain the device over the remainder of their lifetime.

Step 1: Identify the strategic options

In terms of treatment benefit, patients who receive an ICD have the potential for a different survival probability than patients who do not receive an ICD. From a cost perspective, patients receiving an ICD bear the additional cost of the device itself, as well as the future costs of maintaining it.

Step 2: Draw the tree

Based on this discussion, we can graphically depict the issue using a decision tree (Figure 7.2). There are four possible pathways in this figure: ICD with sudden death; ICD without sudden death; no ICD with sudden death; and no ICD without sudden death. In this simple model we consider only two health states: sudden death and no sudden death.

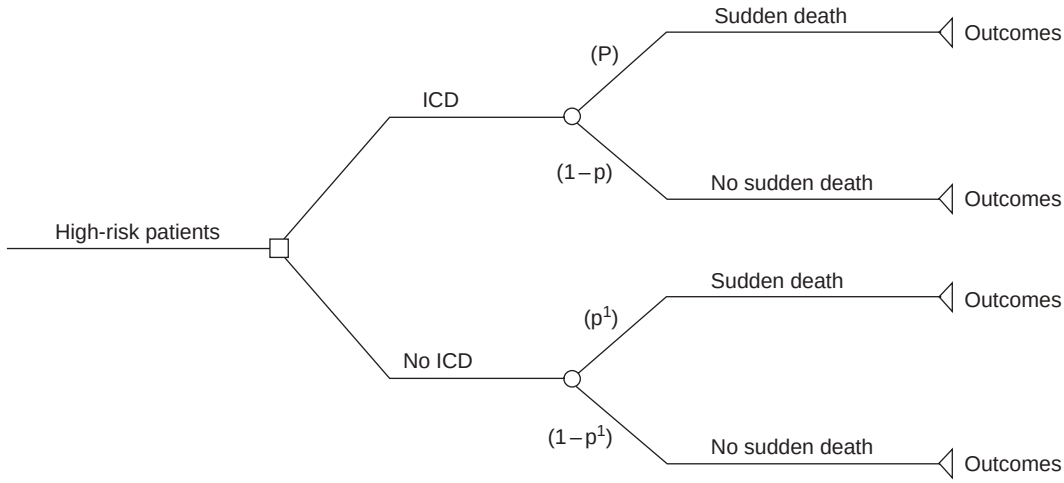

Figure 7.2 Decision tree for a cost effectiveness analysis: ICD to reduce incidence of sudden death in cardiac patients

Step 3: Determine the probabilities

Estimates of the possibility of sudden cardiac death for high-risk patients are available in the medical literature and in trials of ICDs.[43–49] Estimates of the probability of sudden death for patients receiving an ICD are available from the MADIT Study[38] or may be estimated based on clinical trial protocols for expected treatment benefits.[41] The quality of the evidence from these data sources can vary. Data from the literature on non-ICD patients, the probability of sudden death without an ICD, come from observational studies, whereas data on ICD patients come from a controversial randomized controlled trial. Thus, there is some uncertainty about these estimates.[10]

Step 4: Determine the relevant outcome measures (effects, utility, survival, costs)

Treatment benefits can be expressed in terms of survival (years of life gained) or in terms of quality adjusted survival (QALYs). Calculation of these benefits proceeds as outlined in the stroke example.

Estimates of treatment costs often must be developed from primary sources (for example, hospital accounting departments), from standard price lists for specific costs,[50] from literature reviews, or from expert opinion. Costs included in these models can include direct medical costs (the costs of medical care, such as hospital or physician costs), direct non-medical costs (the costs patients incur in receiving medical care services, such as the cost of transportation to a physician's office), indirect costs (the costs of morbidity or mortality related to disease), or intangible costs (the costs of pain and suffering related to disease).[51,52]

Step 5: Evaluate the tree

Once the data are available for all of these model parameters, the next step is to analyze the tree. For economic analyses, decision trees allow an incremental analysis of the treatment costs and benefits of one medical therapy compared to another in a cost effectiveness analysis. The incremental cost effectiveness of therapy A compared to therapy B is defined by the following formula:

$$\text{Cost effectiveness of treatment A} = \frac{(\text{Cost}_A - \text{Cost}_B)}{(\text{Effects}_A - \text{Effects}_B)}$$

where Cost_A is the cost of treatment A, Cost_B is the cost of treatment B, Effects_A are the effects of treatment A, and Effects_B are the effects of treatment B.[52] Decision trees may also allow enumeration of the costs and consequences of different treatments without comparing the costs and effects of treatment in a cost effectiveness ratio.

Step 6: Structured analysis of the problem

Sensitivity analysis would be conducted to assess the impact of uncertain values on the model. For example, because there was uncertainty in the probability of each treatment strategy, how would the results change if the possibilities of sudden death were increased or decreased by 10% for each treatment arm? Similarly, how would the results differ if ICD costs were increased or decreased by 10%? In a sensitivity analysis, the investigator recalculates the results of the model to address the robustness of the analysis to changes in the model specification.

Step 7: Conclusion

This decision analysis was structured to assess the cost effectiveness of a new therapy for the treatment of patients at high risk for sudden cardiac death. It would conclude with an estimate of the incremental effects of ICD therapy in years of life gained per patient, the incremental costs of ICD treatment per patient, and an estimate of the cost effectiveness of

ICD therapy for patients evaluated in the model. The paper would also address how sensitive the analysis was to different model parameters. This sensitivity analysis could help define areas for further research to resolve outstanding issues in the clinical assessment.

Applications of decision analysis to cardiology

The above examples offer a simplified explanation of some of the basic components of decision analysis. They also illustrate the issues that must be addressed before using the results of a decision analysis to guide clinical decision making. As when reviewing clinical trials, clinicians must assess whether the population considered in the decision analysis model is relevant to their own population. The reader must consider the strength of the evidence available to the investigator in developing the model to understand the strength of the recommendations resulting from the model. This includes not only whether the evidence was based on randomized controlled trials or on observational studies, but also whether the original studies included detailed information required by the model (for example, in the stroke analysis, whether the clinical studies reported both hemorrhage and stroke rates for the study's patients). Finally, the reader should consider the model used by the investigator to determine whether it was constructed appropriately and considered all relevant comparisons.[1,5] The models below that use lower-quality data or evidence should be considered exploratory analyses, not definitive evidence. As such, they also should be interpreted as potential rationale for future studies. Likewise, decision models that project results to new time periods, new populations and new interventions – even those that use A1a-grade evidence – should be viewed only as exploratory analyses.

Decision analysis has been used extensively in cardiology over the past several years (Table 7.1). These examples include articles from a MEDLINE search of decision analysis and cardiology from 1993 to 2001. Issues addressed have included the use of specific technologies, such as ICDs for patients at risk for sudden death, as well as specific diagnostic or pharmacologic products for defined populations of patients (for example, treatment of high blood cholesterol), and the assessment of patient management strategies for defined populations of patients (for example the selection of patients for placement on a cardiac transplant list). Each of the analyses listed in Table 7.1 will be reviewed in this section.

Table 7.1 Use of decision analysis in the cardiovascular literature

Clinical issue	Efficacy data	Cost data	Sensitivity analysis	Source	Evidence grade*
New technologies					
Inpatient ICD placement	Observational study; utility not assessed	Hospital charges; literature review for resource use data	Yes	Kupersmith *et al*[16]	B4
Outpatient ICD placement	Literature review for survival and utility estimates	Hospital and claims data; literature review for resource use data	Yes	Owens *et al*[41]	A1c
Treatment strategies for WPW syndrome	Literature review; expert opinion; authors' estimates for utility data	Cost-accounting data for 13 patients at one study center	Yes	Hogenhuis *et al*[17]	B4
Specific products					
Low *v* high-osmolality contrast media	Literature review; authors' estimates for utility data; patient survey for intangible cost estimates	Resource use from a clinical trial; literature review; costs from Canadian hospital	Yes	Barrett *et al*[18]	A1c
Simvastatin, high cholesterol	Clinical trial data; utility not assessed	Resource use from clinical trial; costs from hospitals in Sweden; employment status from clinical trial	Yes	Johannesson *et al*[19]	A1a

Table 7.1 ***Continued***

Clinical issue	Efficacy data	Cost data	Sensitivity analysis	Source	Evidence grade*
Pravastatin, high cholesterol	Clinical trial data from 2 studies; utility not assessed	Literature review and expert opinion for resource use data; costs from aggregate US hospital data	Yes	Ashraf *et al*[20]	A1c
Captopril, acute MI	Clinical trial data; utility data from 82 patients	Resource use from subset of study patients; costs from US Medicare reimbursement rates	Yes	Tsevat *et al*[21]	A1a
Estrogen replacement	Literature review; utility not assessed	Not assessed	Yes	Zubialde *et al*[22]	B2
Streptokinase *v* tPA, suspected MI	Literature review, including utility data	Resource use estimated; drug and hospital cost data from Ireland	Yes	Kellett *et al*[26]	A1a
Warfarin *v* quinidine *v* amiodarone, acute atrial fibrillation	Literature review and expert opinion, including utility data	Not assessed	Yes	Disch *et al*[27]	A1a
Warfarin *v* aspirin, stroke prophylaxis	Literature review; utility data from study of 74 patients	Resource use estimated; costs from literature review, Medicare data, and survey of pharmacies	Yes	Gage *et al*[36]	A1a
Preoperative coronary angiography and revascularization, non-cardiac vascular surgery	Literature review; utility not assessed	Literature review	Yes	Mason *et al*[55]	A1a
Treatment strategies					
CCU admission	Cohort study; utility not assessed	Hospital charges from the cohort adjusted to costs	Yes	Tosteson *et al*[56]	B4
Emergency medical services	Literature review; utility not assessed	Analysis of existing EMS program in Canada	Yes	Nichol *et al*[57]	B4
Cardiac transplantation selection	Transplant registries	Not assessed	Yes	Stevenson *et al*[58]	B4
Aortic valve replacement				Wong *et al*[59]	B4
Medical *v* surgical therapy for chronic stable angina	Expert guidelines, randomized trials, and meta-analyses; utility not assessed	Not assessed	Yes	Kwok *et al*[61]	A1a
Strategies for hypoplastic left heart syndrome	Literature review and data from 231 patients; utility not assessed	Not assessed	Yes	Jenkins *et al*[62]	B3

Table 7.1 *Continued*

Clinical issue	Efficacy data	Cost data	Sensitivity analysis	Source	Evidence grade*
Electrocardiogram algorithm to predict myocardial infarction	Retrospective cohort study; utility not assessed	Not assessed	Yes	Shlipak *et al*[63]	B2

*Evidence grades for decision analysis are complicated by the many different sources of data used in constructing the analysis. Evidence grades here are based on the data for the most important component of the analysis for the clinical portion of the decision tree. Where sources of evidence for the analysis were from a variety of sources, two grades were assigned to reflect the differing quality of data available for the analysis (see Owens *et al*.[41] for an example of grades of evidence for data incorporated into a decision analysis).
Grade A: Decision trees with the primary effect estimate from a large, high-quality study (a randomized controlled trial with more than 500 patients), or decision trees with a formal meta-analysis for the primary effect estimate.
Grade B: Decision trees with the primary effect estimate based on literature review but without a formal meta-analysis for primary effect estimate; includes evidence from case series and randomized controlled trials with fewer than 500 patients.
Grade C: Decision trees with the primary effect estimate based on expert opinion.

Decision analysis evaluating new technologies

ICD placement

Over the past several years, investigators have attempted to calculate the cost effectiveness of the ICD in patients at high risk for sudden cardiac death. Recent evidence from the Antiarrhythmics versus Implantable Defibrillators Trial indicates a decrease of 27% in 2 year mortality with ICD.[15] Kupersmith *et al*[16] assessed ICD placement on an inpatient basis for patients with and without prior electrophysiologic (EP) studies. **Grade A1c** The investigators assumed an 84% improvement in life expectancy for patients undergoing ICD therapy based on a case series of 218 non-randomized patients who received an ICD when it was assumed that the patients would have died at the time of the first event (first shock or death). In this analysis, ICD patients had a mean life expectancy of 3·78 years, whereas EP-guided drug therapy patients had a mean life expectancy of 2·06 years. Total charges for these treatments were $146 797 for ICD patients and $93 340 for the EP-guided patients. The investigators found that the cost of ICD placement, including the cost of the device and the hospitalization, would range between $27 200 and $44 000 per year of life saved.

The investigators conducted an extensive sensitivity analysis around their cost data and around the period of replacement of the ICD generator. They found that the cost effectiveness of the therapy was sensitive to the magnitude of the clinical benefit of the therapy (this included the efficacy of the therapy, as well as the estimated life expectancy for the underlying population, as represented by ejection fraction). The model was less sensitive to the cost of ICD therapy. The authors concluded that ICD use was economically attractive, especially using endocardial lead placement (based on preliminary estimates of the cost of this new procedure).*

Owens *et al*[41] assessed ICD implantation on an outpatient basis using a decision analytic model. In this analysis, the investigators modeled the potential cost effectiveness of therapy, assuming in their principal analysis that the ICD led to a 20–40% reduction in mortality. **Grade A1c** The investigators found that the cost of patients receiving ICD therapy would be $88 400, and the cost of patients receiving amiodarone therapy alone would be $51 000. For high-risk

* There are four possible outcomes of a cost effectiveness analysis: (1) the intervention will save money and be more effective than the comparison; (2) the intervention will cost money and be more effective than the comparison; (3) the intervention will save money and be less effective than the comparison; and (4) the intervention will cost money and be less effective than the comparison.[51] The first outcome is the most preferred, and the intervention will always be adopted. The last outcome is never preferred, and the intervention will never be adopted. The second and third outcomes may be preferred at times, and the interventions may be adopted, depending on the relationship between the costs and effects of the intervention (the cost effectiveness ratio). The second outcome may be adopted if the intervention yields a great enough benefit for the additional cost (in the USA, an economically attractive intervention may be one that costs less than $50 000 per year of life gained, whereas some Canadian authors have suggested that therapies that cost less than CDN$100 000 might be economically attractive).[35,53] The third outcome may be adopted if the intervention yields a small enough reduction in outcomes for the reduction in cost (for example, the same Canadian authors suggested an economically attractive intervention might be one that saves more than CDN$100 000 per year of life forgone).[35,52]

patients, the investigators reported that ICD patients would have an estimated survival of 4·18 QALYs, whereas patients treated with amiodarone alone could expect a survival of 3·68 QALYs. Investigators found that the cost effectiveness of therapy ranged from $37 300 per QALY saved for high-risk patients, assuming a 40% reduction in mortality for patients treated with the ICD compared to those treated with amiodarone alone, to $138 900 QALYs saved for intermediate-risk patients and assuming a 20% reduction in mortality for patients treated with the ICD compared to amiodarone alone. They concluded that the use of an ICD will not be economically attractive unless all-cause mortality is reduced by 30% or more compared to amiodarone.

Alternative therapies for WPW syndrome

Hogenhuis *et al*[17] determined which of five management strategies should be used for the treatment of patients with Wolff–Parkinson–White (WPW) syndrome: observation, observation until cardiac arrest-driven therapy, initial drug therapy guided by non-invasive monitoring, initial radiofrequency ablation, and initial surgical ablation. The model included the risks of cardiac arrest, arrhythmia, drug adverse effects, procedure-related complications and mortality, and assumed that radiofrequency ablation had an overall efficacy of 92% in preventing cardiac arrest and arrhythmia. **Grade B4**

For survivors of a cardiac arrest, radiofrequency ablation offered additional survival at reduced cost compared to all other treatment strategies. For patients with arrhythmia without hemodynamic compromise, radiofrequency ablation resulted in a cost of $6 600 per QALY gained in 20 year old patients and $19 000 per QALY gained in 60 year old patients without hemodynamic compromise. For asymptomatic patients, radiofrequency ablation costs from $33 000 per QALY gained in 20 year old patients to $540 000 per QALY gained for 60 year old patients. The authors conclude that their analysis supports the practice of radiofrequency ablation in patients with WPW syndrome who survive cardiac arrest. For asymptomatic patients, however, the analysis supports the current practice of mere observation, given that radiofrequency ablation was economically unattractive in this population of patients.

Decision analysis in the evaluation of specific products

Decision analysis has been used extensively in the evaluation of specific clinical products, including contrast media and pharmaceutical products.

Contrast media

Grade A1c Barrett *et al*[18] developed a decision analytic model to assess the economic impact of low- and high-osmolality contrast media for cardiac angiography. Investigators assumed that low-osmolality contrast media reduced the risk of myocardial infarction and stroke. Reduction in the risk of specific clinical events with low-osmolality contrast media was assumed to be 0% in fatal events, 25% in severe events, 80% in moderate events and 10% in minor events. The investigators found that the incremental cost per QALY gained with these media was $17 264 in high-risk patients and $47 874 in low-risk patients for a third-party payer. From a societal perspective, the corresponding costs are $649 and $35 509. The authors report that these estimates were sensitive to cost of the contrast media and the total cost of contrast media used per patient. The authors also suggest that the model is extremely sensitive to changes in assumptions regarding the efficacy of low-osmolality contrast media for the prevention of severe reactions. To allow the reader to better understand the inputs of this model, the authors include a cost–consequence analysis of the program as a separate presentation in the results. The authors concluded that, in the context of restricted budgets, limiting the use of low-osmolality contrast media to high-risk patients is justifiable. The recommendation to limit use of this medium was also justified by the lack of clinical evidence that low-osmolality contrast media prevent severe or fatal reactions.

Cholesterol reduction

Several authors have used decision analysis to investigate the cost effectiveness of therapies designed to reduce high blood cholesterol.[54] Two recent studies use clinical trial data to assess the cost effectiveness of cholesterol reduction in secondary prevention of coronary artery disease. Johanneson *et al*[19] developed an analysis based on the Scandinavian Simvastatin Survival Study, which reported that, in patients with pre-existing coronary disease, reduction in blood cholesterol resulted in a 30% reduction in overall mortality based on a median follow-up of 5·4 years. **Grade A1a** The authors modeled the effects of 5 years of cholesterol-reducing therapy on patients' outcomes, using a model based on data reported from the trial. The costs of therapy were based on the assumption that the use of cholesterol-reducing agents would not entail any additional costs for patients with pre-existing coronary disease other than the cost of medication itself, and then used data on hospitalizations to estimate the direct medical costs incurred for the treatment of cardiovascular disease.

Interestingly, this model also included the indirect costs of medical care based on the employment status of patients in the trial. The investigators found that simvastatin treatment for 5 years in 59 year old patients with a history of heart disease and a pretreatment total cholesterol level of 261 mg/dl would have a net cost of $1 524, with 0·28 years of life gained, resulting in a cost per year of life gained of $5 400 for men, and a net cost of $1 685 with 0·61 years of life gained, resulting in a cost per year of life

gained of $10 500 for women. An analysis that included direct and indirect costs showed that cholesterol reduction leads to an additional $1 065 decrease in associated morbidity cost for men and an $876 reduction in associated morbidity cost for women. The analysis was somewhat sensitive to baseline cholesterol level and patient age at the initiation of treatment, to follow-up and screening costs and to the price of simvastatin. However, treatment remained economically attractive in all of these analyses. The model was somewhat sensitive to reduction in cardiovascular risk and the risk of mortality after coronary events. The authors concluded that in patients with coronary artery disease, simvastatin therapy is economically attractive among both men and women at the ages and cholesterol levels studied.

Ashraf *et al*[20] assessed the cost effectiveness of cholesterol reduction based on 3 year data from the Pravastatin Limitation of Atherosclerosis in the Coronary Arteries (PLAC I) and Pravastatin, Lipids and Atherosclerosis in the Carotids (PLAC II) studies. **Grade A1c** These trials reported no statistically significant decrease in all-cause mortality, but did report a decrease in the number of coronary events in men in the group receiving drug therapy to reduce high blood cholesterol. Therapy was estimated using a Markov model based on data from the Framingham Heart Study to estimate subsequent annual morbidity and mortality rates for patients with non-fatal myocardial infarction. Costs of therapy were based on the costs of drug therapy, and hospitalization costs were derived from the cost of treatment of myocardial infarction and from expert opinion on the frequency of medical events. Investigators found that cost per year of life saved due to secondary prevention was sensitive to a number of risk factors, but ranged from $7124 per year of life saved for a male patient with three risk factors, to $12 665 per year of life saved for a male patient with one risk factor. The model was sensitive to assumptions about efficacy of therapy and cost of services. It was also sensitive to patient characteristics, such as the number of risk factors of patients receiving secondary prevention. The authors conclude that pravastatin is economically attractive compared to other widely accepted medical interventions.

A potentially serious limitation of the Ashraf *et al*[20] analysis is its strategy of deriving costs for 3 years while projecting the effects over 10 years. Specifically, the authors project years of life saved by avoiding events in the first 3 years over the next 7 years. This potentially problematic practice of generating a differential time horizon should be avoided.

Postmyocardial infarction treatment

Tsevat *et al*[21] used decision analysis to assess the cost effectiveness of captopril therapy after acute myocardial infarction (MI). **Grade A1a** In this paper, the investigators used data from the Survival and Ventricular Enlargement (SAVE) trial, which demonstrated that captopril therapy reduced mortality in patients who survived MI. The effectiveness of therapy was modeled using a decision analytic model based on all-cause mortality within the clinical trial observation period and the projected clinical benefits over a patient's lifetime. This paper also incorporated data on quality of life from a subset of patients in the SAVE trial. Cost estimates for the model were based on a subset of 123 study patients for whom hospital data were obtained for all hospitalizations in the subset. The investigators used two projection methods, a limited-benefit model and a persistent-benefit model. The limited-benefit model was more conservative in that it assumed similar annual mortality rates between captopril and control patients beyond the clinical trial period. This analysis resulted in an estimated cost effectiveness for captopril therapy ranging from $60 800 per QALY for 50 year old patients to $3 600 per QALY for 80 year old patients. The persistent-benefit model was more optimistic in that it assumed that the clinical benefits observed in the trial persisted throughout each patient's lifetime. In this analysis, the cost effectiveness ratios were similar to those in the limited-benefit model for patients aged 60–80 years, but they were substantially better for 50 year old patients. In the sensitivity analysis, the models were most sensitive to the annual cost of captopril therapy. In addition, the persistent-benefit model appeared to be more "stable" than the limited-benefit analysis. That is, when the benefits persist, there are few changes to the values of other variables that would affect the resulting cost effectiveness ratios (owing to the magnitude of the benefit), whereas if the benefits do not persist, variations in other variables do have an effect. The investigators concluded that angiotensin converting enzyme inhibitor therapy with captopril was not only effective in improving survival after MI, but also moderately economically attractive.

Hormone replacement therapy

Zubialde *et al*[22] used a decision analytic model to assess gains in life expectancy resulting from the use of estrogen replacement therapy for postmenopausal women. Efficacy data for this analysis were obtained from a review of the literature which suggested that risk reduction with estrogen therapy for coronary artery disease was between 40% and 50%. **Grade B2** The model did not assume an increased incidence in breast cancer in the principal analysis, but it did include an increased incidence of endometrial cancer. Results of the analysis suggested that the benefit of estrogen and progesterone therapy in average-risk women aged 50 years at the time of therapy initiation was 0·86 years, with a range of 0·41–1·19 years, whereas therapy in average-risk women aged 65 years at the time of therapy initiation was 0·47 years, with a range of 0·21–0·66 years. The authors reported that the benefits of estrogen and progesterone therapy were similar to the gains from cholesterol reduction to

200 mg/dl and smoking cessation. The authors concluded that significant potential benefits in life expectancy in coronary artery disease reduction, combined with the osteoporosis prevention in symptom relief, would point to greater emphasis on postmenopausal estrogen use in appropriate patients. Since the report by Zubialde *et al*[22] hormone replacement therapy has undergone additional study. A growing body of literature suggests that its predicted effects have not been fully realized,[23,24] and the results of a recent polymorphism study have further complicated matters.[25] It bears repeating here that the reliability of a decision analysis is related directly to the quality of the data on which the analysis is based. The Zubialde analysis was based on the best data of its time, but superior data from clinical trials have since called the findings into question.

Thrombolytic therapy

Kellett *et al*[26] presented a paper on the use of thrombolytic therapy for patients with suspected MI. This assessed the use of two types of thrombolytic therapy, streptokinase and accelerated tissue plasminogen activator (tPA), on patients with suspected MI. **Grade A1a** The efficacy of the two therapies was based on reports from the medical literature. The authors assessed the clinical benefits of thrombolytic therapies for patients presenting with different likelihoods of MI, given their clinical and ECG findings, different age groups, and different probabilities of death given MI. Data on clinical efficacy for the two strategies were based on the GISSI-2, ISIS-3 and GUSTO trials. The authors suggested that, for patients with a 26% probability of MI (a group with chest pain and a history of coronary artery disease but a normal ECG), thrombolytic therapy would only be beneficial if the probability of death given an MI was 20% or greater. In contrast, for patients presenting with a probability of MI of 78% (chest pain plus ST or T wave changes), thrombolytic therapy would be beneficial for all patients except those over 80 years of age who had a probability of death given an MI of 2·5% or less. The authors conclude that, for a typical 60 year old man presenting 4 hours after the onset of symptoms with definite acute MI, treatment with streptokinase in addition to aspirin would gain 150 quality adjusted life days, whereas treatment with aspirin and accelerated tPA would result in 255 quality adjusted life days, compared to no thrombolytic therapy. Thrombolytic therapy is preferred over no thrombolytic therapy as long as the probability of stroke is less than 5% for streptokinase and 8% for accelerated tPA. The cost per QALY was estimated based on the probability of acute MI, the extra days of quality adjusted life, and the probability of death given an MI. The analysis was sensitive to estimates of efficacy for both streptokinase and accelerated tPA, as well as the probability of death given thrombolytic therapy. The authors conclude that decision analysis can be a useful bedside tool to guide thrombolytic therapy. It is important to bear in mind, however, that this decision model has not been tested on actual patients.

Management of atrial fibrillation

Dirsch *et al*[27] developed a decision analytic model to assess the outcomes of four treatment strategies for patients with acute atrial fibrillation undergoing cardioversion: warfarin therapy, quinidine therapy and low-dose amiodarone therapy. **Grade A1a** Efficacy was based on a review of the literature, including randomized controlled trials, observational studies, and expert clinical opinion when necessary. Investigators found that all four treatment strategies differed by 0·2 QALYs over patients' lifetimes, with 4·55 expected QALYs for patients who undergo no treatment after cardioversion and 4·75 expected QALYs for patients who undergo cardioversion with amiodarone. Use of warfarin and quinidine therapies yielded expected quality adjusted life benefits between amiodarone and no treatment. The model was sensitive to the annual rate of bleeding on warfarin, the annual rate of stroke for patients on warfarin, the annual rate of stroke for patients with atrial fibrillation, the decrement in quality of life associated with taking warfarin, and the excess mortality of quinidine and amiodarone. The authors conclude that cardioversion followed by low-dose amiodarone to maintain normal sinus rhythm appears to be a relatively safe and effective treatment for a hypothetical cohort of patients with atrial fibrillation.

Prophylaxis of stroke

Gage *et al*[36] developed a decision analytic model to assess the cost effectiveness of warfarin and aspirin treatment for prophylaxis of stroke in patients with non-valvular atrial fibrillation. The clinical efficacy of the treatment strategies was obtained from the published literature. **Grade A1a** The quality-of-life estimates for this study were obtained by interviewing patients with atrial fibrillation. Costs were also estimated from a literature review and from a survey of national pharmacies and laboratories. The authors found that, for patients with non-valvular atrial fibrillation and no additional risk factors for stroke, warfarin would minimally affect quality adjusted survival but increase costs significantly. For patients with non-valvular atrial fibrillation and one additional risk factor, warfarin therapy resulted in a cost of $8 000 per QALY saved compared to aspirin. The model was most sensitive to the rate of stroke if no therapy was prescribed, the effectiveness of aspirin, the rates of major hemorrhage, and the disutility of taking warfarin. The authors conclude that treatment with warfarin is economically attractive (has a low cost effectiveness ratio) in patients with non-valvular atrial fibrillation and one or more additional risk factors for stroke. However, in patients with non-valvular atrial fibrillation without other risk factors for stroke, the use

of warfarin instead of aspirin would add significantly to costs with minimal additional clinical benefit.

Preoperative cardiac revascularization

Mason *et al*[55] developed an analysis to determine whether preoperative coronary angiography and revascularization improved short-term outcomes in patients undergoing non-cardiac vascular surgery with three strategies. **Grade A1a** The first was to proceed directly to vascular surgery; the second was to perform coronary angiography followed by selective coronary revascularization prior to surgery and to cancel vascular surgery in patients with severe inoperable coronary disease; and the third was to perform coronary angiography followed by selective coronary revascularization, and to perform vascular surgery in patients with inoperable coronary artery disease. The literature was scrutinized for data on the efficacy of all three strategies. The authors found that proceeding directly to vascular surgery led to a lower morbidity and cost in the base-case analysis. The coronary angiography strategy led to a higher mortality of vascular surgery in patients with inoperable coronary disease, but to a lower mortality in operable patients who did not proceed to vascular surgery. The model was sensitive to the surgical mortality rates for both catheterization and the vascular surgical procedure. The authors concluded that decision analysis indicates that vascular surgery without preoperative angiography generally leads to better outcomes, and that preoperative coronary angiography should be reserved for patients whose estimated mortality for vascular surgery is substantially higher than average.

Use of decision analysis in treatment strategies

CCU admission

Tosteson *et al*[56] used a decision analytic model to identify cost effective guidelines for admission to a coronary care unit (CCU) for uncomplicated patients without other indications for intensive care. The probabilities of death, and minor, major and life-threatening complications were based on 12 139 emergency department patients who were enrolled in a multicenter chest pain study. Cost data were available from a subset of patients in the study admitted to one study center. Under the assumption that there is a 15% relative increase in mortality when patients with acute MI are admitted to the intermediate care unit instead of an intensive CCU, the authors found that costs per year of life saved for triage to the CCU varied markedly depending on the age of the patient and the probability of MI. For 55–64 year old patients with an emergency department probability of infarction of 1%, the cost per year of life saved was $1·4 million; but when the probability of infarction was 99%, the cost per year of life saved was $15 000. Admission to the intensive care unit was generally more costly for younger patients, and use of the CCU had a cost effectiveness ratio of less than $50 000 per year of life saved when the initial probability of acute MI was greater than 57% among patients 30–44 years of age, and greater than 21% among patients 65–74 years of age. The model was sensitive to the reduction of mortality associated with the use of the intensive care unit and to the costs of the intensive care unit. The authors conclude that the CCU should generally be reserved for patients with a moderate or high probability of acute MI, unless they need intensive care for other reasons.

Emergency medical services

Nichol *et al*[57] used a decision analytic model to assess the cost effectiveness of potential improvements to emergency medical services (EMS) for patients with out-of-hospital cardiac arrest. **Grade B4** The authors developed their analysis based on a review of the effectiveness of various emergency systems from an extensive meta-analysis, costing of each component of the EMS, and community characteristics and response times for EMS. The authors also modeled a one-tier system versus a two-tier system. In the one-tier system the response team is trained in advanced life support, and in the two-tier system the first response team is trained in basic life support and the second in advanced life support. The authors found that the fixed cost of the first tier of a two-tier EMS system was $651 129 for Hamilton, Ontario, with estimates of survival of 5·2% in the one-tier system and 10·5% in the two-tier system. They found that a 1 minute reduction in response time improved survival by 0·4% in a one-tier system and by 0·7% in a two-tier system. The authors found that a change from a one-tier system to a two-tier system would result in 0·19 QALYs saved and an incremental cost of $7 700 per patient, or a cost per QALY of $40 000. Improvement in a one-tier EMS system by the addition of more basic life support providers in the first tier would result in an incremental survival benefit of 0·40 QALYs, with an incremental cost of $2 400 or cost per QALY of $53 000. An improvement in response time in a one-tier system by the addition of more providers and ambulances would achieve an incremental survival benefit of 0·2 QALYs for a cost per QALY of $368 000. The authors performed an extensive sensitivity analysis based on a combination of the model's parameters. They concluded that the most attractive options in terms of incremental cost effectiveness ratios for an EMS program would be improved response time in a two-tier EMS system, or a change from a one-tier EMS system to a two-tier system. However, the authors were concerned about the poor quality of the data available for their analysis.

Heart transplantation

Stevenson *et al*[58] used a decision analytic model to determine optimal strategies for selecting patients for cardiac

transplantation. **Grade B4** The authors developed a model based on data from cardiac transplantation databases. The decision analytic model was developed to determine the size and outcomes of the waiting list population, depending upon different strategies for listing heart transplant candidates. They found that if current practices continued all hearts would be transplanted to hospitalized candidates and newly listed urgent candidates, and 3700 outpatient transplant candidates would be listed with virtually no transplantation unless they deteriorated to an urgent status. A decrease in the upper age limit for transplantation to 55 years would reduce the number listed each month by 30%. If this strategy were to be adopted, the waiting list would reduce to one third its current size, with 50% of all hearts being available for outpatient candidates. The authors conclude that immediate provisions should be made to limit candidate listing and revise expectations to reflect the diminishing likelihood of transplantation for outpatient candidates.

Surgery for aortic stenosis

Wong *et al*[59] used decision analysis to assess whether to recommend cardiac surgery for elderly women with aortic stenosis. **Grade B4** This analysis was based on a specific case of assessing the treatment choice for an 87 year old patient with severe aortic stenosis, three vessel coronary disease, depressed left ventricular function and moderately severe heart failure. Data for the analysis were based on the medical literature. Specific data elements included in the analysis were life expectancy with and without surgery for an octogenarian, morbidity and mortality associated with surgery, and quality of life with congestive heart failure. Sensitivity analysis assessed the sensitivity of the model to assumptions used in developing the analysis and assessed the impact of patients' risk preferences regarding treatment choice. The authors also modeled valvuloplasty compared to surgery. They found that life expectancy with surgery (5·0 QALYs) was greater than that for medical therapy (1·1 QALYs). (These gains in life expectancy are substantial. Most interventions reported in the medical literature yield incremental gains in life expectancy from 0·167 to 1·2 years of life.[60]) In sensitivity analysis, surgery still had the highest life expectancy until mortality from the procedure was greater than 70%. Valvuloplasty was the best strategy if the patient was not the best candidate for surgery or, perhaps, in cases in which the perioperative mortality rate was greater than 50%. They concluded that even in the later decades of life, aortic valve surgery is substantially preferable to medical therapy.

Treatment strategies for chronic stable angina

Kwok *et al*[61] used a decision analytic model to simulate a randomized controlled trial of coronary artery bypass graft surgery versus medical therapy for chronic stable angina. **Grade A1a** The authors developed a Markov model that incorporated current American College of Cardiology/American Heart Association guidelines, baseline data from a meta-analysis of randomized trials of the two therapies, and risk reduction data from randomized trials and meta-analyses. The outcome measures of interest were 5 and 10 year mortality, as well as incidence of non-fatal myocardial infarction. The authors conducted a base-case analysis of the two therapies, which they supplemented with annual fixed transition probabilities to account for a steady linear increase in mortality observed in the meta-analysis. They also conducted two subgroup analyses, one to examine 5 year mortality and infarction rates for patients with triple vessel disease, the other to examine the same outcomes for patients with impaired left ventricular function. In the base-case and subgroup analyses, the authors found that both therapies increased overall and infarction-free survival. The relative advantage of surgery over medical therapy found in this study mirrored the findings of previous trials. One-way and multiway sensitivity analyses yielded absolute differences of less than 2% for overall and infarction-free survival rates, except that use of the upper limit of aspirin therapy's relative reduction of myocardial infarction yielded a 3% increase in infarction-free survival among patients receiving medical therapy. The authors concluded that therapeutic advances have improved outcomes for both medical and surgical patients, as well as preserving the advantages of surgery, thereby confirming that the conclusions of previous bypass trials remain valid.

Treatment strategies for hypoplastic left heart syndrome

Jenkins *et al*[62] used a decision analytic model to determine the optimal treatment strategy for maximizing 1 year survival among patients with hypoplastic left heart syndrome. **Grade B3** Using data from the literature and from a data set of 231 patients treated at four US surgical centers, the authors obtained probabilities for the following treatment strategies: complete staged surgery; stage 1 surgery as an interim to transplantation; patient listing, then stage 1 surgery if no donor is found within 1, 2 or 3 months; and patient listing without surgery until transplantation. The authors conducted one- and two-way sensitivity analyses on all probabilities in the decision tree to determine the values at which the optimal treatment strategy would change. In the base-case analysis, transplantation within 1 month emerged as the preferred strategy, followed by staged surgery if no donor is available after listing the patient for 1 month. These results were sensitive to several probability thresholds, including stage 1 and stage 2 mortality rates, the surgical center's 3 month organ donation rate, and the transplantation mortality rate. Centers with high organ donation rates are best served by a strategy of listing without surgery

until transplantation. Those with low donation rates, however, should perform staged surgery. In two-way sensitivity analyses, the authors found that the highest 1 year survival rates were achieved with staged surgery; patient listing, then stage 1 surgery at 1 month; and listing without surgery until transplantation. The authors concluded that each surgical center can determine its optimal treatment strategy with an algorithm that uses the center's organ donation rates and stage 1 survival outcomes, as well as individual patients' risk factors for mortality and organ availability.

Use of electrocardiogram to predict myocardial infarction

Shlipak *et al*[63] used a decision analytic model to assess the clinical utility of a previously reported electrocardiogram (ECG)-based algorithm to predict myocardial infarction in patients with left bundle branch block (LBBB). **Grade B2** The authors developed probability data for their analysis by first conducting a retrospective cohort study of patients presenting with LBBB on their initial ECG. The subsequent decision analysis was performed to determine which of the following strategies would constitute optimal therapy: thrombolysis for all patients with LBBB; no treatment for these patients; or use of the ECG-based algorithm to screen patients for the appropriateness of thrombolysis. The authors found that the ECG algorithm had low sensitivity and would predict less than 10% of myocardial infarctions in patients presenting with LBBB and acute symptoms. As a screening test, the algorithm resulted in a survival rate less than that yielded by thrombolysis and similar to that yielded by no therapy. In one-way sensitivity analysis, thrombolysis was always the optimal strategy. In two-way sensitivity analyses thrombolysis was always preferred, unless the ECG-based algorithm had a sensitivity greater than 85%. If the ECG algorithm were used as a screening test for thrombolytic therapy, almost no patients with LBBB and myocardial infarction would receive the treatment. The authors conclude that the ECG algorithm is a poor predictor of myocardial infarction and that thrombolysis should be used for all patients with LBBB and symptoms of myocardial infarction.

Summary

Decision analysis offers powerful techniques to better understand uncertain clinical decisions in cardiology. Increasing use of these techniques has already shown them to be very valuable in clinical and policy decision making in a variety of settings. Decision analysis may be most useful when clinical trial data do not clearly answer the clinical issue; when the clinical trial concludes that there are differences in risks and benefits across two treatment groups; when the relevant outcomes were not collected as part of the clinical trial; or when the decision maker is concerned with both clinical benefits and costs. Readers of a decision analysis paper should consider the strength of the evidence underlying the analysis, whether the model was constructed appropriately from a clinical perspective, and whether all relevant comparisons were included in the model.[5,6]

Key points

- Decision analysis may be most useful when clinical trial data do not clearly answer the clinical issue; when the clinical trial concludes that there are differences in risks and benefits across two treatment groups; when the relevant outcomes were not collected as part of the clinical trial; or when the decision maker is concerned with both clinical benefits and costs.
- Sensitivity analysis is used to assess the impact of uncertainty on decision analytic models.
- In reviewing a decision analysis paper, the reader must assess whether the population considered in the model is relevant to the clinician's population, the strength of the evidence available to the investigator in developing the model, and whether the model used by the investigator is constructed appropriately by including all relevant comparisons.
- Decision analysis has been used to assess a wide variety of clinical issues in cardiology.

8 Assessing and changing cardiovascular clinical practices

C David Naylor, David A Alter

Research into cardiovascular clinical practice has grown early enormously in volume and sophistication since the early twentieth century, driven by the worldwide prominence of atherosclerotic vascular diseases. The sheer volume of research literature has made it virtually impossible for even a subspecialist to stay abreast of her/his field. There is insufficient time for any evidence-oriented practitioner to critically appraise the full array of individual studies relevant to practice, and a real risk that, as the years go by, his/her filtering of the literature will prove misleading.

One solution is for practitioners to rely increasingly on integrative reports. As documented throughout this volume, evidence on a particular clinical topic is often usefully compiled in published meta-analyses, decision analyses, or practice guidelines. These integrative reports synthesize the best evidence available from multiple research studies to help define what a practitioner ought to do when confronted with a particular clinical situation.

While information uptake from integrative reports is necessary to ensure that clinical care evolves in evidence-driven directions, it may not be sufficient. For decades, researchers have shown that the rates of provision of various cardiovascular services vary inexplicably across regions and among nations. Some of this variation is random; some represents reasonable disagreement in the absence of definitive evidence about best practices. However, when practices are examined more closely using explicit criteria for appropriateness of care, it has become clear that actual practice sometimes differs sharply from what the evidence suggests ought to be done, raising concerns about quality of care. Quality concerns are further galvanized by evidence that technical skill and patient outcomes vary among procedural specialists. Not surprisingly, then, concerns with costs and quality of care have led a growing cadre of researchers, clinical leaders, facility managers, third party payers, and public policy makers to examine what clinicians do, and to seek ways to change clinical practice.

Assessing and changing clinical practice is central to the discipline commonly known as health services research. This chapter accordingly provides an introduction to some of the key methods of health services research as applied to cardiovascular medicine and surgery.

By definition this chapter demands a different treatment than later chapters where it is possible to provide integrative summaries of evidence to inform contemporary practice or steer future research. Since our focus is on how evidence is translated into clinical action, it stands to reason that there will seldom be one "right answer". Practice will instead be shaped not just by evidence, but by values and circumstances or context. Thus, it is important for the reader to suspend judgment as to whether there is necessarily one right health system, or one right profile of services for all populations with a given cardiovascular condition. A corollary of this point is that hundreds of descriptive and analytical studies have been published in cardiovascular health services research, many of which are context-specific. Our hope is to use a small number of these studies to heighten the reader's understanding of analytical principles and general lessons. For consistency, the examples will relate to clinical management of coronary artery disease, not to primary and secondary prevention. However, the conceptual frameworks are applicable to all areas of cardiovascular care. It is hoped that the evidence-oriented reader will be able to generalize the methodological insights from this chapter to his/her particular clinical and research context.

The specific objectives of this chapter are three:

- to outline the challenges and opportunities in gathering evidence about how health care is delivered;
- to describe and provide illustrations of the various types of studies done to evaluate processes and outcomes of care; and
- to examine some of the interventions that can be undertaken to improve the quality of cardiovascular care.

Gathering evidence about health care: challenges and opportunities

Study designs

Randomized controlled clinical trials are the most rigorous tool for confirming causal relationships between a given outcome and intervention or factor. Most randomized clinical

trials are designed to test the efficacy of an intervention within a controlled and stable environment. In contrast, health services research focuses on assessing and improving the provision of care in usual practice settings. Observational studies of health services may be cross-sectional or cohort designs. Cross-sectional studies or survey designs offer convenient one-off snapshots of patient populations, providers, or practice settings. Disease- and procedure-specific inception cohorts have the advantage of delineating relationships of particular variables to outcomes over time.

Cross-sectional and cohort methodologies can also be combined in a single study. For example, Payne and Saul[1] undertook a mail survey of a random sample of 16 750 residents of the Sheffield (UK) region, and found that 4·0% of subjects had symptoms suggestive of angina pectoris. The prevalence of angina was significantly higher in neighborhoods with lower socioeconomic status, but these same areas had significantly lower rates of mechanical revascularization. In other words, variations in service profiles were inversely related to ecological markers of both population need and population deprivation – obvious grounds for concern about access or equity of services use. The authors went further, however, and used data linkage methods to determine procedures that were actually provided to individuals identified as having angina. In so doing, they effectively shifted from a cross-sectional study reliant on ecological inferences to a full-fledged cohort design. They found that among subjects reporting angina who lived in affluent neighborhoods, 11·2% had undergone procedures, as compared to 4·2% in less affluent areas ($P=0·03$). Similar socioeconomic-related disparities in cardiovascular processes of care have been well described in both private and publicly-funded healthcare systems.[2,3]

Intervention studies in health services research focus on effectiveness and efficiency rather than efficacy. Quasi-experimental designs and formal randomized clinical trials are brought into play to test interventions designed to improve care. However, for obvious reasons, it is often providers, clinics, hospitals, or regions that are randomized rather than patients.[4]

Whatever the internal validity of the design chosen, health services researchers face a recurrent challenge to prove the external validity of their work. Some of the published literature in health services research consists of local or regional quality assurance projects with uncertain generalizability, and evidence-oriented practitioners may not find these studies applicable in their own context.

Data sources and collection

Health services researchers use both primary and secondary data sources. *Primary data* are collected by design to answer specific research questions, whereas *secondary data* are used for multiple purposes and their use for research purposes may be unplanned. Administrative databases designed for purposes of health service funding and administration are among the most common secondary data sources used in assessing clinical practice. Databases specifically constructed for ongoing epidemiologic surveillance of medical care, such as clinical registries, sit on the cusp between primary and secondary data, in that they are valuable for management and quality assurance, but are usually designed to meet specific research objectives as well.

Prospective primary data collection is costly but crucial for complex variables that are poorly covered in most secondary data sources – for example, patients' quality of life and psychosocial status. Retrospective primary data collection through chart reviews is also possible, but can be costly and time-consuming. It is best focused on routinely-recorded variables. For example, in charts of patients hospitalized with acute myocardial infarction (AMI), data on variables such as presenting symptoms, heart rate, blood pressure, ECGs, and cardiac enzymes are almost uniformly recorded. Absent primary data collection, there is always a risk that researchers will frame their questions around convenient access to data rather than addressing pressing issues.

Researchers often combine primary and secondary data collection, or incorporate multiple data sources to address specific research questions. For instance, a study may assess patients' short-term outcomes using self-administered health status questionnaires, and then track their subsequent use of health services and outcomes through administrative data. As an inexpensive solution to the limitations of single secondary databases, many researchers now link data across multiple administrative databases to provide better patient characterization and longitudinal follow up.[5] Finally, linkage of samples from randomized clinical trials to administrative databases is becoming more common both to provide accurate and cost efficient follow up of clinical trial populations and to enable comparison of the characteristics and outcomes of trial participants to the broader populations from which they are drawn.[6]

Data quality

Inaccurate measurement or recording is a particular concern when information comes from secondary data sources that are not designed for research or epidemiologic surveillance of medical care. For instance, Jollis *et al*[7] compared information about cardiac risk factors in an administrative database in patients undergoing angiography with information collected prospectively for a clinical database. A chance-corrected measure of agreement (kappa statistic) showed moderate to poor agreement as follows: hypertension (56%), heart failure (39%), and unstable angina (9%). Hannan *et al*[8] found similar discrepancies in comparing a cardiac surgery registry to an administrative database in New York State. While the accuracy of coding in

administrative databases appears to be improving over time,[9,10] significant undercoding of comorbidities still exists, especially among the elderly.[10,11]

As noted above, limited or inaccurate data in insurance databases or computerized hospital discharge abstracts may be supplemented or corrected by chart audits. A more efficient approach is to establish registries geared to measuring key patient characteristics, process-of-care elements, and relevant outcomes. Registries are proliferating in cardiovascular medicine and surgery, especially for acute ischemic syndromes and coronary surgery. This has led, however, to a new challenge – that is, agreement on a set of core data elements and definitions so that reliable comparisons can be drawn across registries from different jurisdictions.

Key measures

Processes of care

Process of care is an umbrella term, encompassing all inputs into the clinical encounter that are relevant to the effectiveness and efficiency of the service provided. Process measures of particular interest for this chapter are the clinical decision-making patterns of physicians and other health professionals, as these reflect the uptake and use of evidence from the literature of medicine. Other inputs may also be relevant, such as hospital staffing ratios and qualifications of providers. Not infrequently, researchers use characteristics of the admitting hospital as ecologic proxies for processes of care that may affect individual patients.[12–14] In this respect, hospital volumes for specific diagnoses or procedures are often taken as proxies for the expertise or experience of the relevant providers. Some measures are intermediate. Waiting times for services and lengths of stay, for example, are at once indicators of the process of care, and outcomes of interest to patients, professionals, and administrators alike.

Outcomes

The most important outcomes studies in cardiovascular care are conventional randomized trials used to test the efficacy of novel interventions, as described elsewhere in this volume. However, non-randomized outcomes studies have a role in assessing practice patterns. These studies allow for the evaluation of therapies and the natural history of disease in real-world settings.[15,16] In some cases where randomization is simply not feasible (for example, socioeconomic status as a factor in prognosis), they also allow us to isolate patient characteristics from process-of-care factors to help elucidate pathophysiologic mechanisms of disease.[17,18] Perhaps most importantly, a cardiovascular service may be provided to the right patient at the right time, and for the right reasons, but be delivered in a technically substandard fashion that leads to needlessly poor outcomes. Non-randomized outcomes studies are therefore useful indicators of quality of care for technically demanding services.[19]

Outcomes of interest, after Kerr White, can be conveniently remembered as the six "Ds": death, disease, dysfunction, disability, distress, and dissatisfaction.[20] The easiest outcomes for health services researchers to measure are those that are defined objectively and usually captured in large insurance databases or computerized hospital administrative data. These include death, routinely-coded complications following surgery, or hospital re-admissions. Linkage to vital status registries is also performed to track out-of-hospital deaths. Unfortunately, health services researchers have often failed to assess other outcomes, such as functional status, symptom relief, or overall quality of life, that are very important to patients and their physicians.[21]

Assessing processes and outcomes of care

Assessing processes of care

Descriptive studies

Health services research gained considerable momentum in the 1970s and 1980s from studies pioneered by Wennberg and Gittelsohn,[22,23] which documented unexplained geographic variations in rates of services. These early studies were a population-wide extension of research done in single hospitals or in public and private prepayment plans starting in the 1930s and showed variations in how different physicians managed apparently similar patients. However, Wennberg and coworkers coupled computerized systems of hospital discharge abstracts to census data and showed that citizens living in one area were significantly more or less likely to undergo certain procedures than those living in other areas. They also showed that greater variations were generally demonstrable when procedures were more discretionary or elective, or where there was uncertainty about the indications for the procedure or service of interest.[24,25] In these latter instances, values and circumstances apparently interact strongly with evidence in driving decisions about service provision.[26]

Such descriptive studies continue to appear in the health services literature. They involve simple rates or proportions, with various numerators and denominators. Possible numerators include primary care visits or encounters, specialized diagnostic and therapeutic services, composite measures of use, such as overall numbers of hospital bed-days used per 10 000 residents, or even mean expenditures per capita on health care for all types of services. Denominators may tally patients according to the clinics or hospitals that they use, or by their residency in a given geographic area. These two denominators may be melded into hospital market shares – for example, the total population living in an area where a specified percentage of all patients receive their cardiac care at the hospital of interest.

Several statistical summary measures are used in variations analyses.[27,28] Computational details and statistical properties of these measures are beyond the scope of this chapter. What matters is that the degree of variation should be both statistically significant and suggestive of meaningful differences from the standpoint of quality, accessibility, or efficiency of care provision. Thus, examination of the patterns of service and potential outcome implications is arguably more illuminating than the focusing on specific summary measures.

The interpretive challenges of such descriptive studies are illustrated by evidence assembled with clinical and/or administrative data showing sex differences in treatments for patients hospitalized with acute myocardial infarction (AMI).[29–31] Sex differences in care have been found in several nations, but the relationship between gender and service intensity is not consistent.[32–34] The debate about the gender gap in service intensity is likely to continue until there is clearer evidence from randomized trials to delineate whether and how men and women with otherwise similar cardiovascular disease should be managed differently.

Variations in processes of care have been well documented to extend beyond patient factors. As one example of this genre, Chen *et al*[35] documented significant interhospital variations in length of stay after AMI in Ontario. These variations persisted after adjustment for various factors such as coronary angiography on the index admission, patients' age and sex, and comorbidity as inferred from secondary diagnoses on discharge abstracts. In almost any jurisdiction and for almost any cardiovascular service where interpractitioner, interinstitutional, or interregional variations in patterns of service provision have been sought, they are demonstrable.

In sum, descriptive studies showing process-of-care variations are tantamount to screening tests in medical practice. They raise the possibility that there may be a problem with quality, efficiency, or accessibility. However, the finding of statistically significant variations is predicated on a null hypothesis that processes of care should vary no more than would be expected on the basis of the play of chance. Most such studies apply direct or indirect standardization to control for differences in the age–sex profile of the populations being compared, but may not consider myriad other sources of variation (Box 8.1). In response to that limitation, researchers may either develop evidence-oriented criteria to examine decision making at the level of the individual case, or try to link processes and outcomes of care in the same study as a means of inferring a causal connection. We examine both types of studies below.

Box 8.1 Sources of regional/institutional variation in service profiles

- Age and sex composition
- Age/sex specific disease incidence
- Random variation with time and place
- Availability and practice organization, such as
  - primary care
  - specialist services
  - hospital services/bed provision
  - overall funding levels
  - methods of payment
  - alternative services
- Referral patterns
- Practice styles of service providers
- Variations in patient expectations, demands, health education/behaviors
- Rates of previous service (for example, organ removal where relevant)

Criteria-based utilization analyses

Given the limitations of descriptive studies that delineate variations in processes of care, health services researchers have developed other methods to determine whether the right service is provided to the right type of patient for the right reasons at the right time and place. One approach is implicit reviews of case records, drawing on the individualized judgments of expert clinicians. Unfortunately, lack of standardization renders implicit reviews unreliable.[36,37] Explicit criteria, which form the basis for most process-of-care analyses in the literature, have the advantages of standardization and consistency, as well as transparency. Where necessary, trained staff can apply them retrospectively to medical records without a major time commitment from clinicians. These studies are described in America as "utilization reviews" and in the UK as "clinical audits".[38]

Process-of-care audits have the advantage of efficiency in comparison to outcomes studies as quality management tools. Bad outcomes caused by negligence and incompetence are (happily) rare. Technical competence does not necessarily equate with good judgment and appropriateness of service provision. Moreover, bad outcomes from *under*-treatment are hard to detect because the impact of modern cardiovascular care is often to make life only a little better on average for patients or to reduce their risk of otherwise rare events. For example, from overviews of randomized placebo-controlled trials we know that β blockers confer about a 25% *relative* reduction in mortality in the first year after a myocardial infarction. For a cohort of medium-risk patients, this equates to an *absolute* reduction in cumulative postdischarge mortality from 4% to 3%. To show such a mortality difference on a comparative outcomes audit of two practices (80% power, 2-sided alpha of 0·05), we require over 5000 patients per practice; but a 1% mortality difference presumes absolutely no use of β blockers in the practice with poorer outcomes. A more realistic assumption would be that about 70% of eligible patients receive β blockers in the practice with worse outcomes versus over 95%

in the exemplary practice. Based on the randomized trials, this equates to perhaps a 0·2% increase in mortality. To detect such a small difference in mortality would require over 100 000 patients per practice! In contrast, one could simply examine charts to see whether patients were getting β blocker prescriptions, versus 70% in the other practice, one would only need to examine about 75 charts in each practice for a reliable assessment.

This latter audit is simple in another respect. We can basically use randomized trial inclusion and exclusion criteria to decide who should be getting the drug, make sure there are no obvious contraindications or medication intolerances documented on the medical record, and tally whether patients are getting the treatment that they ought to be getting. In general, however, audits require close attention to the validity, application, and applicability of the criteria chosen (Box 8.2).[38]

Box 8.2 User's guide to appraising and applying the results of a process-of-care audit

- *Are the criteria valid?*
  - Was an explicit and sensible process used to identify, select, and combine evidence for the criteria?
  - What is the quality of the evidence used in framing the criteria?
  - If necessary, was an explicit, systematic, and reliable process used to tap expert opinion?
  - Was an explicit and sensible process used to consider the relative values of different outcomes?
  - If the quality of the evidence used in originally framing the criteria was weak, have the criteria themselves been correlated with patient outcomes?
- *Were the criteria applied appropriately?*
  - Was the process of applying the criteria reliable, unbiased, and likely to yield robust conclusions?
  - What is the impact of uncertainty associated with evidence and values on the criteria-based ratings of process of care?
- *Can you use the criteria in your own practice setting?*
  - Are the criteria relevant to your practice setting?
  - Have the criteria been field-tested for feasibility of use in diverse settings, including settings similar to yours?

Adapted from Naylor and Guyatt[38]

Validity of audit criteria

To be valid, the criteria must have a direct link either to improving health (as is obvious with β blockers for secondary prevention after AMI) or to lowering resource use without compromising health outcomes. There should be an explicit and sensible process to identify, select, and combine the relevant outcomes-based evidence.

The hierarchy of evidence outlined above by Kitching, Sackett and Yusuf applies here. Evidence from randomized trials is strongly preferred, but evidence from observational sources cannot be ignored. For example, from observational studies within trials, it is plain that the largest survival benefits with thrombolytic therapy are obtained when treatment is administered early.[39] It would be unethical to randomize patients to receive thrombolysis on a delayed or urgent basis to determine how large these effects are. Thus, guidelines now recommend that thrombolytic therapy be administered, wherever possible, within 30 minutes of a pateint's arrival to hospital.[40] Studies from America,[41] Canada,[42] the UK,[43] Italy,[44] and New Zealand[45] have all documented remediable problems with treatment delays in administering thrombolytic agents to eligible patients. All are classic examples of criteria-based audits.

If only some of the indications for a particular service under audit will be covered by high quality evidence, then weaker sources of evidence, inference, and expert opinion must often be brought into play, usually through formal panel processes. Such panels should include an explicit process for selecting panelists, and a sensible, systematic method for collating their judgments. In this respect, the RAND group has pioneered multispecialty panel methods that are widely emulated.[46–48] Scenarios are compiled that describe a potential indication for the procedure or clinical service in question. Each expert panelist independently rates hundreds of different case scenarios on a risk–benefit scale. Scenarios are re-rated at a panel meeting after patterns of interpanelist agreement and disagreement are shown anonymously and discussed. The final set of panelists' ratings then determines whether a given indication is deemed potentially appropriate, uncertain, or inappropriate.

With this method, it is not clear whether the appropriateness ratings for any given indication rest primarily on research evidence or inference, extrapolation, and opinion. The relative values placed on different outcomes are also unclear. For example, in randomized trials of CABG versus percutaneous transluminal coronary angioplasty (PTCA),[49–52] PTCA has a slightly lower early mortality, along with lower initial costs and more rapid recovery from the procedure. Longer term mortality data are similar, but CABG patients appear to achieve better symptom relief, have decreased use of medication, and require fewer subsequent procedures.[53] When an expert panel addresses the respective appropriateness of PTCA and CABG, the findings reflect these trade offs, but we cannot be sure that patients themselves would make the same choices. The conflation of facts and values in panel-based criteria is highlighted by studies showing that the nationality of a panel markedly affects the criteria and results of applying them to cardiovascular procedures (Table 8.1).[26,54] Indeed, available evidence would also suggest that hospital practice settings and resource availability influence panel-based criteria.[55] Nonetheless, the RAND methods compare very favorably with those used to create several utilization review tools now in widespread use.[38]

Table 8.1 Categorization of appropriateness of indications for cardiovascular procedures based on actual audits in the field: cross-national differences in expert panel assessments

Procedure	Location/sample	Year	*n*	Panel nationality	Appropriate	Uncertain	Inappropriate
Coronary artery bypass graft	USA, 4 hospitals in Washington State	1979–80	386	American	62	25	13
		1979–82		British	41	24	35
	UK, 3 hospitals in Trent region	1987–88	319	American	67	26	7
				British	57	27	16
	Canada, 13 hospitals in Ontario and British Columbia	1989–90	556	American	88	9	3
				Canadian	85	11	4
	USA, 15 hospitals in New York State	1990	1336	American	91	7	2
				Canadian	85	10	6
Coronary angiography	USA, 4 hospitals in Washington State	1979–80	376	American	50	23	27
		1979–82		British	11	29	60
	USA, Medicare beneficiaries in 3 states	1981	1677	American	74	9	17
				British	39	19	42
	UK, 3 hospitals in Trent region	1987–88	320	American	71	12	17
				British	49	30	21

				Canadian	51	39	10

Adapted from Naylor[26]
The data show the appropriateness ratings for sets of identical patient charts as described. Each set of charts was assessed according to criteria derived by expert panels based in the listed countries.

Application and applicability of the audit criteria

Application of explicit process-of-care criteria often rests on data derived from retrospective chart reviews by professional auditors. The audit process must therefore be reliable. Biases can be introduced through skewed sampling of practitioners, hospitals, and patients. Even a meticulous audit, however, may miss mitigating factors. Thus, in many instances, if the explicit review shows potential problems with the appropriateness of a service, the case is assessed by experienced clinicians to preclude "false positives".

It is also crucial that enough cases be reviewed to draw robust conclusions. For example, in one study, RAND researchers used explicit criteria to assess the appropriateness of PTCA in 1990 for 1306 randomly selected patients in 15 randomly selected New York State hospitals.[54] The inappropriate utilization rate varied by hospital from 1% to

9% ($P = 0{\cdot}12$). Differences of this magnitude, if real, could be important to patients, payers, and policy makers. Thus, this sample size may have been insufficient for the investigators to confirm important differences in quality among hospitals.

Although the task is subjective, end users must consider intangibles such as local medical culture and practice circumstances before accepting audit criteria that may not be relevant. The stronger the evidence on which the criteria are based, the less one needs to consider local factors; for example, few medical cultures would reject aspirin for AMI – a cheap and simple drug treatment that has been definitively proven to yield reductions in mortality. With weaker evidence and higher costs, however, the judgments are less straightforward.

Last, even if criteria are sufficiently valid and relevant, training times and other costs must be considered. Special logistical problems arise when criteria are used for concurrent case management rather than retrospective utilization review. Any errors associated with concurrent care management will have immediate consequences for individual patients and physicians. Nonetheless, many American hospitals already do a range of concurrent reviews.

The use of chart audits to infer appropriateness

Table 8.1 shows the proportion of appropriate, inappropriate, and "uncertain" indications for cardiac procedures as randomly audited in the USA, UK, and Canada.[26,56–58] Since all the procedures shown are used many times more often in the USA than in the UK, it seems almost paradoxical that the proportions of inappropriate cases are not much higher in the USA. The literature has suggested that relationships between appropriateness of care and cardiovascular service intensity are similarly weak within nations.[25,58–60]

However, two studies shed a slightly different light on this issue. The rates of all major coronary procedures in New York State, USA are about twice as high as in Ontario, Canada.[61] Figure 8.1 shows the relative rate of isolated coronary artery bypass surgery (CABG) for the two jurisdictions by age and anatomy. Overall, only 6% of CABG patients in Ontario versus 30% of patients in New York had limited coronary artery disease – one or two vessel disease without proximal left anterior descending (PLAD) involvement. However, more patients in New York had left mainstem disease (23% *v* 16%, $P < 0{\cdot}001$). In relative terms, the differences are most dramatic among elderly persons. For example, New York brings 17 times as many persons over the age of 75 to surgery with anatomic patterns of coronary disease that are not associated with life expectancy gains after CABG. Nonetheless, much of this extra use could pass an appropriateness audit, since 90% of the persons with limited coronary anatomic disease in New York had moderate to severe angina before surgery.[61]

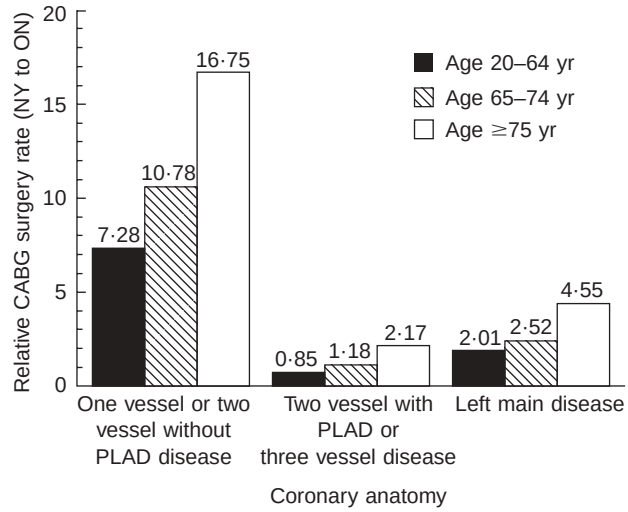

Figure 8.1 Relative rate of isolated CABG for New York State (NY) and Ontario (ON) according to age and disease anatomy. Adapted from Tu *et al*.[61] PLAD, proximal left anterior descending.

A reasonable inference is that major increases in capacity, and expansion of population-based services rates, are associated with *diminishing marginal returns*. The Canadian approach – fixed budgets in a universal health system, and "managed delay" with organized waiting lists[62] – seems to promote more efficient use of resources, with patients receiving surgery primarily if they are likely to have life expectancy gain. However, restricted use of coronary angiography leads to some implicit rationing that affects primarily the elderly, and a certain proportion of patients at all ages with left mainstem disease are not detected and/or do not undergo surgery.

A second study[63] of CABG develops this argument more strongly. Rather than using appropriateness criteria from an expert panel, Hux *et al* based their case-specific process assessments on a meta-analysis of randomized trials by Yusuf *et al*[64] Whereas the broad category of "appropriate" care as defined by expert panels includes a range of risk–benefit ratios, a trials-based assessment allowed estimation of the degree of potential 10 year survival benefit conferred by CABG surgery among patients for whom, by and large, it was appropriate. Hux *et al* found that only 6% of 5058 Ontario patients undergoing isolated CABG in 1992–93 fell in the low benefit category – that is, patients for whom there is no survival advantage from early CABG. However, the degree of anticipated benefit differed according to the center where surgery was provided. For instance, the proportion of patients in a high-benefit category ranged from 65·2 to 79·9% ($P < 0{\cdot}001$). Significantly more patients were in a high-benefit category in hospitals serving areas with lower population-based rates of CABG. Analyzing the data by site of residence, there was an inverse relationship between marginal degree of life expectancy gains and the surgical rates for each county.[63]

In sum, if one accepts that overtly inappropriate services are unlikely to be commonplace in any health system, the relationship between appropriateness of care and population-based services rates can be redefined. Rather than seeking to relate the prevalence of bad judgment to high service intensity, or decrying health systems with low service intensity for rationing care, researchers might better assess whether the marginal returns of other forms of cardiovascular care are indeed smaller in areas where those services are used more frequently. The policy decision then becomes one of trade offs: given competing demands on scarce healthcare resources, at what point do the marginal returns of particular cardiac services become low enough that further investment in those services cannot be justified?

Evidence-oriented clinicians must be positioned to contribute to these debates by marshaling comparative utilization data that help decision makers make explicit determination of the likely yields from funding different sets of cardiovascular and non-cardiovascular services. Arguably, they must also use these evaluative tools to safeguard their patients against inappropriate *underuse* of necessary services.

Again, explicit process-of-care criteria can be helpful. For example, analytical variations studies using American data have repeatedly shown that black and uninsured patients have lower coronary angiography rates than those who are insured.[65–67] Laouri *et al*[68] drew on audit data from four teaching hospitals in Los Angeles and assembled a cohort of 352 patients who met explicitly defined criteria for the necessity of coronary angiography as established by an expert panel. The patients were tracked forward for 3 months and, after adjustment for confounding factors, those managed in the public hospital system had a 35% rate of angiography versus 57% for private hospital patients ($P < 0{\cdot}005$).

Two recent studies incorporate appropriateness criteria to provide further evidence for underuse of coronary interventions. The first by Guadagnoli *et al*[69] examined variations in coronary angiography after AMI in approximately 50 000 elderly Medicare beneficiaries in the USA. Among those patients with ACC–AHA class 1 indications, coronary angiography was used less often among Medicare beneficiaries enrolled in managed-care plans than among those with fee-for-service coverage. Moreover, utilization rates among elderly patients with class I indications for angiography were low in both groups (37% *v* 46%), suggesting room for improving the care of such patients with acute myocardial infarction. In contrast, the rate of angiography use among those with ACC–AHA class III indications (where angiography was deemed not useful) was similarly low (13%) in both groups. The second prospective study applied appropriateness ratings for coronary revascularization procedures to 2552 patients identified at the time of coronary angiography for various indications. Among 908 patients with indications appropriate for PTCA, 34% were treated medically. Among 1353 patients with indications appropriate for CABG, 26% were treated medically. Relating processes to outcomes, the research team also found that medically-treated patients deemed appropriate for revascularization were more likely to experience adverse events downstream.[70]

The lesson, simply put, is that evidence must be sought for both inappropriate *overuse* and *underuse* of cardiovascular services in any and all healthcare systems.

Outcomes studies and process–outcome relationships

Types of outcome studies

Researchers, clinicians, and administrators alike are also drawing on outcomes with increasing frequency as a means of assessing quality of care. To repeat a point made earlier, various biases threaten the validity of inferences drawn from these non-randomized studies; but they have a useful role both in monitoring quality of care and as a source of evidence when randomization is not feasible or appropriate.

Just as studies in the 1960s and 1970s showed geographic and institutional variations in broad markers of processes of care, so also did the 1980s and 1990s see the publication of research demonstrating significant mortality differences across physicians,[71] hospitals,[72] regions,[73] and health systems.[74] The magnitude of mortality variations has been meaningful, even amongst relatively homogeneous groups of patients. For example, Tu *et al* demonstrated marked interhospital and interregional variations in 1 year risk-adjusted mortality rates for patients hospitalized between 1994 and 1997 in one Canadian province. Mortality ranged from 20·8% to 27·4% across regions, and from 17·6% to 32·3% across hospitals admitting 100 or more AMI cases per year.[75] Regional variations persist even in highly selected subpopulations of patients. Pilote *et al* demonstrated that 1 year AMI mortality rate across eight US census regions ranged from 8·6% to 10·3% among the population enrolled in GUSTO-1.[73]

As with descriptive studies of variations in process of care, these high-level outcomes studies function largely as screening tests: they often raise more questions than answers. Researchers use multivariate analyses to adjust for prognostic differences in the patient populations being compared. However, since patients are not randomized to different sites or regions, there is uncertainty about the extent to which unmeasured variation in patient characteristics accounts for the residual outcomes variation. Furthermore, the higher the level of comparison and the longer the follow up, the more uncertain the causal inferences become. Regional differences in long-term AMI outcomes, for example, may reflect genetic differences in populations, environmental factors, regional variation in health behaviors and socioeconomic status, as well as more conventional factors such as variations in processes of care

on the index hospitalization and follow up interventions (for example, revascularization or rehabilitation).

For convenience, we suggest that outcomes analyses in health services research can be classified variously as *quality-of-care screening studies* or *process/outcome hypothesis studies*.

Quality-of-care screening studies focus on outcomes to detect variations in quality of care. They are most powerful when applied to short-term outcomes that are closely tied to a particular episode of illness or procedure, and a provider or institution. In these circumstances, causal inferences are more straightforward. Their applicability is clearest for technically demanding procedures, such as PTCA or CABG, where variations in outcomes are taken as proxies for operator skill. However, even in such instances, other factors in pre- and perioperative care may be important. For relatively homogeneous diagnoses, outcomes studies may also sometimes be a useful screen to determine if detailed process-of-care analyses are required. For example, if inhospital mortality were found to be similarly low across a whole set of institutions, there would be little rationale for undertaking a major audit of processes of care.

Ultimately, the goal of such studies is to isolate one or more process-of-care factors that can be modified to lead to consistently better outcomes. Outcomes analyses may also be used to validate process-of-care criteria or their application, for example, the study of underuse of revascularization by Hemingway *et al* cited above.[70] In this sense there is overlap between the two categories of non-randomized outcomes studies. But an important distinction should also be drawn. Quality-of-care studies are concerned with the applicability of existing evidence in a particular context. Other outcomes studies may be initiated with a view to deriving or supporting generalizable hypotheses about the process–outcome relationship. They are poor cousins to randomized trials from the standpoint of strength of evidence. For true efficacy assessments, randomized trials are usually possible and always preferable, given the unavoidable biases of observational studies.[76] A poorly conducted non-randomized outcomes comparison for quality management purposes may at worst mislead patients and tarnish the reputation of a number of capable cardiologists or cardiac surgeons. A poorly conducted non-randomized outcome comparison of two treatments may, if taken seriously, misguide clinical practice worldwide.

That caveat aside, these process/outcome hypothesis studies can be useful to illustrate unanticipated harm from interventions, test the external validity of randomized trial results, generate hypotheses about interventions that may be worth testing with formal experimental designs, and, in special circumstances, provide an acceptable level of evidence for adopting a particular intervention.

There are many methods available for examining the relationship between processes of care and outcomes. The simplest method is to draw broad causal inferences using ecological comparisons, for example, correlating differences in processes and outcomes across two or more institutions or jurisdictions. However, the greater the difference between service settings being compared, the more difficult it is to be sure that patients were similar, or to isolate which aspects, if any, of the process of care relate to the outcomes observed. This is especially true when comparisons are made on a broad geographic footing between regions or countries in which populations and processes of care differ in many ways. In these latter comparisons, we are obviously veering away from the use of non-randomized outcomes data to benchmark technical quality of care for homogeneous procedures, and entering the more complex realm of process/outcome hypothesis studies.

This genre is typified by several studies[77–80] showing that Canadian patients have more symptoms, worse functional status, or higher death/re-admission rates after AMI than do American patients. The reasons for these differences, however, are unclear. For example, Mark *et al*[78] in a GUSTO-1 substudy found that, while rates of revascularization were much higher in the USA, Canadians drew their post-MI care more often from family physicians and general internists, while Americans relied more on cardiologists and received more cardiac rehabilitation services.[78] In other words, revascularization was only one factor among many that might explain differences in outcomes across two health systems.

In an effort to limit the effects of competing process factors, analysts have borrowed the concept of instrumental variables from econometrics.[81] This approach compares patients' outcomes according to some characteristic that sharply distinguishes the care of two or more groups of patients. Thus, one might attempt to elucidate the impact of differences in the rate of revascularization across hospitals with and without on-site interventional capacity. Alter *et al*[72] recently used such a design to show that hospitals with on-site revascularization facilities had a lower rate of non-fatal composite outcomes (recurrent cardiac hospitalization and emergency department visits), and were also 3·5 times more likely to refer patients to myocardial revascularization procedures. Yet, despite the markedly higher rates of invasive procedures, the non-fatal outcome advantages of invasive-procedure hospitals were actually explained by their teaching status!

In sum, given the relatively weak inferences possible from most observational studies of outcomes, alternative strategies for ensuring the quality of medical care should always be considered. It will often be feasible and more efficient to use randomized trials or meta-analyses of trials to establish optimal management strategies, and then ensure that quality of care is maintained by monitoring the process of care in that well-proven practices are consistently applied to eligible patients. On the other hand, for high volume and technically demanding procedures where reasonable risk

adjustment methods can be brought into play, outcomes measurement has merit for quality control so long as the results are interpreted carefully. Finally, studies aimed at delineating process–outcome relationships will continue to be valuable, but researchers and evidence-oriented practitioners alike will often find that the interpretation of the findings plunges them into a thicket of causes, effects, and epiphenomena.

Special challenges in non-randomized outcomes studies

In this section, we delve more deeply into some of the analytical challenges of non-randomized outcomes studies. Many types of biases have been described in the literature,[82,83] but selection bias is a recurrent concern whether one is comparing the outcomes of two cardiac surgeons, or using non-randomized data to develop hypotheses about the effectiveness of pharmacologic or non-pharmacologic therapies in real-world settings. Indeed, the ubiquity of selection bias in health services research arises from the fact that ordinary good judgment in practice inevitably means that there are systematic differences in the characteristics of patients who are selected for particular interventions as compared to those who are not.

Patients selected post-MI to undergo coronary angiography, for example, are often younger and healthier than other MI victims.[72,82] The survival benefits observed for those undergoing angiography may therefore be due to prognostic characteristics rather than to revascularization consequent upon angiography. This latter phenomenon is known as confounding and is a common result of selection biases. Confounding occurs when particular factors are associated with both a study (process) variable and the outcome of interest.

Researchers therefore routinely employ some form of multivariate analysis to adjust for imbalances in prognostic factors between groups under study. A complementary strategy is to confirm the consistency of the findings after restricting the analysis to a relatively *low*-risk subgroup of the patients being examined.[76] Eliminating patients in higher risk categories associated with more widely varying physiologic states increases the likelihood of a "level playing field" for comparisons.

For many common procedures and diagnoses, researchers can draw on validated prognostic indices and risk-adjustment algorithms as signposts in carrying out study-specific multivariate analyses. For frequently studied procedures such as CABG, major studies have tended to show relative consistency in the types of prognostic clinical factors that must be taken into account for risk adjustment purposes.[84] Not surprisingly, risk-adjustment models appear to perform somewhat better with clinical as compared to administrative data.[85] However, the key to predictive performance appears to be better data, not more variables. Studies have suggested that the accuracy of risk-adjustment models reaches a plateau after use of only a few key variables. Tu *et al*,[86] for example, examined risk-adjusted hospital mortality rates for CABG with multisite registry data. They determined that six core variables in a risk-adjustment model (age, gender, emergency surgery, previous CABG, LV dysfunction, left main disease) permitted modest discrimination between patients who did and did not die postoperatively (area under the receiver operating characteristic [ROC] curve = 0·77). Statistical performance improved only trivially with the inclusion of six additional characteristics, and the relative rankings in the risk-adjusted mortality rates between hospitals did not change. Notwithstanding these studies, the ultimate number as well as the type of clinical variables required in a risk-adjustment model will obviously depend upon the disease being assessed, the processes and outcomes of interest, and the unit of analysis (for example, risk-adjusted mortality rates per physician *v* per hospital).

Propensity scores can also be used to contain the impact of confounding.[87] This method reduces the entire collection of background characteristics into a single composite characteristic (that is, the propensity to receive treatment *v* no treatment), which is then used to subclassify patients further into categories of relative equal propensities. Accordingly, the case-mix composition of patients with similar propensities is balanced, and outcome differences can be directly compared between those receiving and not receiving treatment.

While not a solution for confounding *per se*, hierarchical statistical modeling has recently found favor as a useful analytical tool in outcome studies.[88,89] Data in health research frequently exist in an ordered hierarchical structure: that is, patients are managed by physicians who practice within hospitals. In contrast, traditional multivariate techniques ignore the natural hierarchy of data and treat each observation as if it were independent (Figure 8.2).

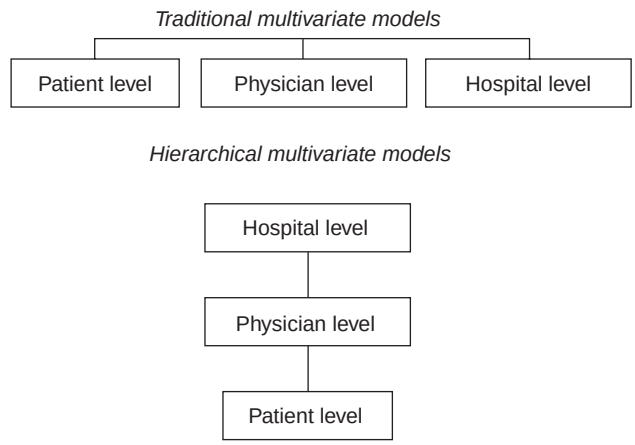

Figure 8.2 Schematic view of hierarchical *v* traditional models

The use of hierarchical modeling makes intuitive sense since patients may share higher-level characteristics, leading to observations that are not necessarily independent of one another. The existence of standardized inhospital processes of care (for example, treatment protocols and care maps) may result in greater homogeneity in treatments across patients admitted to a particular institution. Accordingly, the use of traditional multivariate analyses may lead to an artificially inflated number of independent observations and an underestimate in the magnitude of standard error and potential alpha error.[90]

While the embedding of multivariate analyses in a hierarchical structure has obvious advantages, neither this technique nor fastidious risk-adjustment methods can match the effectiveness of randomization when balancing the case-mix distribution between two groups, especially because researchers and quality-of-care evaluators are unlikely to know all the prognostic factors that interact with processes of care and may alter outcomes. Moreover, even if key prognostic confounders are known, they may not all have been measured or recorded accurately. Box 8.3 sets out some general principles that may be useful when researchers appraise non-randomized outcome studies.[38]

Box 8.3 User's guide to appraising an observational outcomes study

- Are the outcome measures accurate and comprehensive?
- Were there clearly identified, sensible comparison groups?
- Were all important determinants of outcome measured accurately and reliably?
- Were the comparison groups similar with respect to important determinants, other than the one of interest?
- Was multivariate analysis used to adjust for imbalances in patient prognostic factors and other outcome determinants?
- Did additional analyses (particularly in low-risk subgroups) demonstrate the same results as the primary analysis?
- Did any multivariate analysis take into account natural heirarchies in the data, such as clustering of patients within providers' practices and/or within institutions?

Adapted from Naylor and Guyatt[38]

Changing practice patterns

General considerations

Practices clearly change over time in response to published evidence. At times, these changes can be rapid and dramatic, particularly when an innovation is associated with overwhelmingly positive risk–benefit ratios and is feasible for large numbers of practitioners to adopt. This model of knowledge-based practice change is termed *passive diffusion*. Its impact is heightened by the extent to which the mass media pick up major medical advances, and by the marketing initiatives of drug and device manufacturers. However, as implied by studies showing unexplained and undesirable variations in practice patterns, the model of passive diffusion leads to inconsistent uptake of evidence into practice.

How, then, can evidence be incorporated into practice more consistently, and what happens when data are in hand showing either that practice departs sharply from what available evidence suggests should be the norm, or that technical competence is below standard? How can the gap between "is" and "ought" in medical care be closed? These questions relate to changing physician (and system) performance, and follow logically from work done to measure or assess practice processes and outcomes.

Although there is limited randomized evidence on this topic for specific aspects of cardiovascular care, a wealth of experience – some unhappy – has shown that direct incentives and disincentives, financial and otherwise, can have a major impact on practice. Bonuses are paid in American managed care organizations if practitioners meet certain financial and clinical performance targets. Within the UK National Health Service, meeting targets for prespecified preventive services leads to extra payments for general practitioners; and the new rating system for hospital trusts offers administrative autonomy and preferential access to capital funding as a reward for strong performance on measures of quality, accessibility, and efficiency. Simply shifting the mode of physician payment may be an effective way of modifying behavior. For example, exponents of fee-for-service remuneration of cardiovascular medicine and surgery argue that salary and capitation schemes impose a risk of underservicing. Critics of fee-for-service argue that it undervalues quality and cognitive services, and creates a conflict of interest that promotes the use of procedures. As to non-financial incentives and disincentives, the range of options includes merit awards, disciplinary proceedings, and litigation.

Arguably more relevant to the evidence-oriented practitioner is the available information on non-administrative mechanisms to improve physician performance that rely on voluntary knowledge- or information-based change. Such initiatives have the advantage of calling forward the better instincts of health professionals who, with few exceptions, seek first to serve patients as competently as possible.

Exponents of clinical guidelines initially believed that dissemination of guidelines might prove a key component in catalyzing knowledge-based improvements in physician performance.[91] Guidelines would usefully compile the totality of relevant evidence on several related aspects of a clinical condition, treatment, or procedure. The evidence-oriented practitioner would no longer have to comb through the clinical literature, critically appraise it, and keep the relevant materials at hand or in her/his memory. The guideline would instead provide a convenient source of definitive

evidence. Furthermore, because inference, expert judgment, values, and circumstances could be used in developing guidelines, clinicians would be able to rely on regionally-developed guidelines to navigate the many "grey zones" of clinical practice[26] where evidence alone was insufficient. Finally, guidelines could be developed, endorsed and disseminated by authorities with clinical credibility, lending weight to evidence that might otherwise appear rather impersonally in clinical journals.

Lomas[92] termed this latter approach the model of *active dissemination*, and criticized its prospects for success on the grounds that it ignored other factors in the practice environment, and presupposed that information acquisition alone leads to behavior change. The available evidence does suggest that there is some impact from more active approaches to informing and educating physicians about relevant clinical advances or guideline content.[93] However, the more passive the educational process, and the more removed it is from physicians' own practice context, the less likely it appears to succeed.

Researchers and administrators have accordingly developed an array of non-coercive interventions designed to improve physician performance (Box 8.4). In 1995 Davis *et al*[94] and Oxman *et al*[95] conducted systematic reviews of all the available controlled studies of the effects of these strategies on physicians' and other health professionals' performance. They included any strategy designed to persuade physicians "to modify their practice performance by communicating clinical information". Purely administrative interventions or financial and similar applied incentives and disincentives were excluded.

There were 99 studies involving physicians and a further three on other health professionals' behavior. Most of the studies on physician performance focus on internists or family physicians, and specific cardiovascular studies are limited in number to date. Single-intervention studies had positive effects on process or outcome parameters in 49/81 (60%) of trials where they were applied. Short educational seminars or conferences and dissemination of educational materials (printed or in audiovisual format) were least effective of all the single-intervention modalities explored. This finding supports proponents of implementation as opposed to dissemination.

Simple audit-and-feedback studies had limited impact. However, it is important to distinguish the types of studies that fall into this category. For example, in randomized studies from the early 1980s, investigators showed that a computer-based monitoring system with reminders and feedback led to significantly better follow up and blood pressure control for patients with hypertension.[96,97] Two controlled studies by Pozen *et al*[98,99] showed that a point-of-service strategy to facilitate implementation of a predictive algorithm for chest pain diagnosis reduced inappropriate use of coronary care units. These studies can best be regarded as "reminder" studies because there is continuous feedback at point of service. Audit-and-feedback studies that appear to be ineffective are those where data are collected and cumulated about processes or outcomes, and fed back only intermittently to practitioners without mechanisms to ensure local buy-in, to address local barriers to change, or to rectify specific gaps in clinical knowledge that may be associated with aberrant practice patterns.

The latter distinction also highlights the fact that feedback can occur concurrently with service provision or retrospectively (that is, after the service has been provided). Concurrent audit and feedback arguably is taken to its

Box 8.4 Some methods used to alter physician performance/behavior

- **Education materials:** Distribution of published or printed recommendations, including practice guidelines and audiovisual materials or electronic publications.
- **Conferences:** Participation of healthcare providers in conferences, lectures, workshops, or traineeships outside their practice settings.
- **Outreach visits:** Use of a trained person who meets with providers in their practice settings to provide information. The information given may include feedback on the provider's performance.
- **Local opinion leaders:** Use of providers explicitly nominated by their colleagues to be "educationally influential".
- **Patient-mediated interventions:** Any intervention aimed at changing the performance of healthcare providers for which information was sought from or given directly to patients by others (for example, direct mailings to patients, patient counseling delivered by others, or clinical information collected directly from patients and given to the provider).
- **Audit and feedback:** Any summary of clinical performance of healthcare over a specified period, with or without recommendations for clinical action. The information may have been obtained from medical records, computerized databases or patients or by observation.
- **Reminders:** Any intervention (manual or computerized) that prompts the healthcare provider to perform a clinical action. Examples include concurrent or intervisit reminders to professionals about desired actions such as screening or other preventive services, enhanced laboratory reports or administrative support (for example, follow up appointment systems or stickers on charts).
- **Marketing:** Use of personal interviewing, group discussion (focus groups) or a survey of targeted providers to identify barriers to change and the subsequent design of an intervention.
- **Local consensus processes:** Inclusion of participating providers in discussion to ensure agreement that the chosen clinical problem is important and the approach to managing it appropriate.

Modified from Oxman *et al*[95]

administrative conclusion in utilization management programs that refuse to authorize payment for a cardiovascular procedure unless the patient meets certain criteria, or in mandatory second opinion programs. These types of programs were not included in the reviews by Davis *et al*[94] and Oxman *et al.*[95]

The methods that had the most consistent effects were: outreach visits including formal academic detailing and opinion-leader studies, where an educationally influential physician was nominated by local peers to be the vector for the information; physician reminder systems at point of service; and patient-mediated methods, including reminders or educational materials. If two or more modalities were combined, then the effects were greater – that is, combining two effective methods (for example, academic detailing with support from a local opinion leader) had more impact than combining two less effective methods (for example, audit-and-feedback combined with a one-day seminar). Multifaceted interventions showed the strongest effects, with 31 of 39 (79%) positively affecting processes or outcomes of care.

Davis *et al*[94] noted that most interventions appear to have a greater impact on process-of-care measures and other indices of physician performance, than on patient outcomes. They postulated that this may be because the clinical interventions themselves have limited impact (a rationale for the power argument given earlier), and because patients do not always accept physician recommendations. They also suggest that a recurring weakness in interventions designed to improve processes and outcomes of care is a failure to conduct a needs analysis that addresses barriers to change.

These systematic reviews of practice-change interventions do not provide definitive evidence about which behavior change interventions are most effective and efficient in particular contexts or clinical conditions. This is because the studies cover a wide range of clinical condition and provider groups, rendering inferences across studies difficult. As in any meta-analysis, cross-study inferences involve nonrandomized comparison with all their potential pitfalls. Furthermore, factorial designs in behavior changes studies have been more the exception than the rule, and it is therefore usually unclear as to which element(s) in a multifactorial strategy was (were) truly effective. Nonetheless, the evidence from controlled trials does suggest that practice changes are best achieved by combining credible evidence or information with active local strategies of implementation using multifactorial methods. Such multifactorial initiatives are further supported in a recent qualitative study examining factors leading to increasing β blocker use after AMI.[100] Hospitals with greater improvements in β blocker use over time, when compared to those having less or no improvement, were more likely to have shared goals, substantial administrative support, strong physician leadership advocating β blocker use, and incorporation of credible data feedback programs.

The case of outcomes report cards

The interest in outcomes measurement to assure technical competence has led to statewide initiatives whereby all cardiac surgery centers in New York and Pennsylvania, USA, are mandated to provide clinical data to permit compilation of publicly released mortality "report cards" on their CABG patients. (More recently, cardiovascular report cards have included interregional and hospital-specific AMI mortality rates, process indicators, (for example, evidence-based therapies and cardiac intervention rates post-AMI),[75,101] and patient satisfaction with hospital care.[102])

The CABG report cards provide a final case study that bridges some of the material presented above on outcomes assessment and behavior change. In New York between 1989 and 1992, inhospital postoperative mortality of CABG showed an unadjusted relative decline of 21%.[103,104] Patients were apparently becoming sicker in the same period, so that the risk-adjusted mortality decline was computed as 41%. Exponents of outcomes reporting claim that this improvement was catalyzed by a reporting system that provided relevant data to patients, administrators, and referring physicians.[103,104] There can be no doubt that the New York and Pennsylvania report cards have pinpointed problems with a few operators who had very poor technical outcomes. The key question is how much of the overall improvement in mortality can be attributed to public outcomes reportage.

Some critics contend that the trend is confounded by two factors. More assiduous coding of risk factors would artefactually increase the overall expected mortality, and surgeons could generate better mortality profiles by selectively turning down high-risk patients, even though such patients may have most to gain from CABG. There has indeed been a striking increase in the prevalence of various reported risk factors in the New York database since its inception. For example, prevalence of congestive heart failure rose from 1·7% in 1989 to 7·6% in 1991; renal failure rose from 0·4% to 2·8%, chronic obstructive pulmonary disease (COPD) from 6·9% to 17·4% and unstable angina from 14·9% to 21·8% in the same period.[105] As well, a survey[106] of randomly selected cardiologists and cardiac surgeons in Pennsylvania found that about 60% of cardiologists reported greater difficulty in finding surgeons who would operate on high-risk patients; a similar number of surgeons reported that they were less willing to operate on such patients. However, this type of survey is weak evidence for harm done by untoward case selection, and internal New York data do not support such a trend in the state.[107]

A more telling criticism is the fact that ecological correlations between falling mortality and initiation of reportage are tantamount to a case series in medicine. They provide weak and uncontrolled evidence for causation. In fact, the above-noted survey[106] of randomly selected cardiologists in Pennsylvania showed that most referring physicians did not

view the Pennsylvania guide as an important source of information because of concerns about inadequate risk adjustment, unreliable data, and the absence of indicators of quality other than mortality. Schneider and Epstein[108] later surveyed patients undergoing cardiac surgery in Pennsylvania to determine the impact of the statewide consumer guide to the performance of hospitals and individual surgeons. Only 12% of the patients were aware of the guide before undergoing a CABG, and less than 1% knew the correct rating of their hospital or surgeon or reported that such information had any meaningful influence on their selection of a provider for open-heart surgery.

It is perhaps not surprising that, more generally, a recent overview by Marshall *et al*[109] found little evidence for consumer-driven market shifts arising from public report cards about specific diseases or procedures. It appears more plausible that the publication of outcomes "report cards" facilitates change by sensitizing politicians, public servants, and the governing bodies of hospitals to the existence of outcome variations. For example, after the publication of the CABG "report card", New York State insisted on attainment of center-specific minimum case volumes before certifying any cardiac surgery program.

On the other hand, in the absence of any report cards, the drop in post-CABG mortality in neighboring Massachusetts[110] has rivaled that seen in New York and Pennsylvania. Technical improvements in surgery, together with closer quality monitoring at the institutional level, appear to be the primary reason for these improved outcomes.

Given what has been learned about physician behavior change, the controversy about the New York State and Pennsylvania programs is hardly surprising. These externally mandated experiments in outcomes assessment contrast with initiatives that involve influential professionals and promote local buy-in from the outset. O'Connor discusses elsewhere in this volume the successful regional collaboration for continuous quality improvement that was developed in northern New England by involving cardiac surgeons in a systematic examination and improvement of processes and outcomes of care.[111–113] In Canada, a similar cooperative venture exists through the Cardiac Care Network of Ontario, which draws together representatives of all major cardiovascular referral centers in the province.[114] Historically, confidential report cards on mortality and length of stay were generated for the chief of cardiac surgery and CEO (cheif executive officer) at each center, using risk adjustment algorithms coauthored by leaders of the Cardiac Care Network itself.[84] CABG outcomes in Ontario are comparable to those in New York and Pennsylvania. Moreover, as in Massachusetts, the trend to improved outcomes antedates the report card system.[115,116] Most recently, hospital-specific CABG outcomes in Ontario have been made available to the public.

In summary, the unresolved issues with public outcomes report cards include validity and reliability of the data and the risk adjustment algorithms, as well as inadvertent adverse effects (for example, avoidance of high-risk patients, and consumers' or referring physicians' focus on point estimates rather than statistically reliable ranges). Potential harm to the public from substandard technical competence must be weighed against needless patient anxieties and confusion, along with harm to skilled health workers and fine institutions caused by poorly founded and widely publicized inferences about inferior outcomes. Debate continues, but it is untenable to assume that all hospitals or providers are equally technically competent, and the public has an unequivocal right to receive reliable and current data on physician and hospital performance. Thus, the trend must inexorably be toward greater public reporting of both process and outcome indicators of quality of care. The challenges for evidence-oriented practitioners are to ensure that the right indicators are chosen, that reliable data are analyzed appropriately, and that responsible reporting mechanisms are developed.

Conclusions

Assessing cardiovascular practices involves observational methods that can focus on either processes or outcomes of care. Methodologies for process-of-care assessments range from simple descriptive studies revealing variations in practice, to highly sophisticated case-specific audits using explicit criteria. Process-of-care assessments are more efficient than outcomes assessments in many respects, and lend themselves to measuring both over- and underuse of necessary cardiovascular services, thereby shedding light on quality and accessibility of care.

Observational outcomes measurement is nonetheless useful in assessing provider or institutional quality of care for high volume and relatively homogeneous procedures where technical skill is a factor. These comparisons must be made with caution, given the inevitable influence of unrecognized confounding through selection biases inherent in routine practice. The use of well-validated risk adjustment algorithms is imperative to improve the chances that differences in outcomes arise from the technical quality of care provided, rather than from differences in prognostic characteristics of patients themselves. Observational outcomes studies can also be undertaken cautiously to illustrate unanticipated harm from interventions, test the external validity of randomized trial results, generate hypotheses about interventions that may be worth testing with formal experimental designs, and, very rarely, provide an acceptable level of evidence for adopting a particular intervention.

To reduce general inconsistencies in the uptake of evidence into practice, and to redress instances where process or outcomes of clinical care are measured and found wanting, several proven strategies are available. First, while new

evidence published in journals or distilled into educational materials and practice guidelines does change practice through passive diffusion, evidence is most likely to have an impact if actively disseminated and made relevant and salient locally to practitioners. Strategies to achieve this end include:

- reminder systems
- concurrent audit and feedback
- local outreach through academic detailing
- patient-mediated interventions
- local involvement of an educationally influential practitioner, and
- a local needs assessment with a consensus among providers on the issues as well as the barriers and facilitators to positive change.

In conclusion, the practitioner of evidence-based cardiovascular medicine and surgery is increasingly challenged to stay abreast of his or her field and to maintain technical competence in performing ever more exacting procedures. Information systems in practice can and will be re-engineered to be more conducive to evidence-based clinical decision making. However, it will also remain important to assess practice patterns on a systematic basis, to share that information with patients and providers, and wherever necessary, take steps to improve physician performance with a view to optimizing the quality, accessibility, and efficiency of cardiovascular care.

Part II

Prevention of cardiovascular diseases

Salim Yusuf, Editor

Grading of recommendations and levels of evidence used in *Evidence-based Cardiology*

GRADE A

Level 1a Evidence from large randomized clinical trials (RCTs) or systematic reviews (including meta-analyses) of multiple randomized trials which collectively has at least as much data as one single well-defined trial.

Level 1b Evidence from at least one "All or None" high quality cohort study; in which ALL patients died/failed with conventional therapy and some survived/succeeded with the new therapy (for example, chemotherapy for tuberculosis, meningitis, or defibrillation for ventricular fibrillation); or in which many died/failed with conventional therapy and NONE died/failed with the new therapy (for example, penicillin for pneumococcal infections).

Level 1c Evidence from at least one moderate-sized RCT or a meta-analysis of small trials which collectively only has a moderate number of patients.

Level 1d Evidence from at least one RCT.

GRADE B

Level 2 Evidence from at least one high quality study of non-randomized cohorts who did and did not receive the new therapy.

Level 3 Evidence from at least one high quality case–control study.

Level 4 Evidence from at least one high quality case series.

GRADE C

Level 5 Opinions from experts without reference or access to any of the foregoing (for example, argument from physiology, bench research or first principles).

A comprehensive approach would incorporate many different types of evidence (for example, RCTs, non-RCTs, epidemiologic studies, and experimental data), and examine the architecture of the information for consistency, coherence and clarity. Occasionally the evidence does not completely fit into neat compartments. For example, there may not be an RCT that demonstrates a reduction in mortality in individuals with stable angina with the use of β blockers, but there is overwhelming evidence that mortality is reduced following MI. In such cases, some may recommend use of β blockers in angina patients with the expectation that some extrapolation from post-MI trials is warranted. This could be expressed as Grade A/C. In other instances (for example, smoking cessation or a pacemaker for complete heart block), the non-randomized data are so overwhelmingly clear and biologically plausible that it would be reasonable to consider these interventions as Grade A.

Recommendation grades appear either within the text, for example, **Grade A** and **Grade A1a** or within a table in the chapter.

The grading system clearly is only applicable to preventive or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or pathophysiologic.

9 Global perspective on cardiovascular disease

K Srinath Reddy

Introduction

In the second half of the 20th century, cardiovascular diseases (CVD) became the dominant cause of global mortality and a major contributor to disease related disability. In the first half of the 21st century this pattern will become even more pervasive as the CVD epidemic accelerates in many developing regions of the world, even as it retains its primacy as the leading public health problem in the developed regions.[1–7]

In 2000, CVD accounted for 16·7 million deaths globally.[1] Coronary heart disease (CHD) and stroke were then leading contributors, with a death toll of 6·9 million and 5·1 million, respectively. According to estimates provided by the World Health Organization, in 1998 30·9% of all global deaths were due to CVD. Both men and women experienced these burdens, with CVD contributing to 28% of the deaths in the former and 34% of the deaths in the latter.[2] The low and middle income countries contributed 78% of all CVD deaths, and 86·3% of disability adjusted life year (DALY) loss attributed to CVD that year. Although these large absolute burdens reflect the large population sizes of the developing countries, proportional mortality rates of deaths attributable to CVD have also been rising in these countries, from 24·5% in 1990 to 28·5% in 1998. The relative importance of CHD and stroke vary across regions and from country to country. For example, more than twice as many deaths from stroke occurred in the developing countries as in the developed countries.[3] CHD was the dominant form of CVD in the developed countries, Latin America and India, whereas stroke was the leading cause of cardiovascular death in sub-Saharan Africa, China and other parts of Asia. Developing countries such as Argentina, Colombia and China now have CVD mortality rates higher than those of most other countries. Argentina currently exceeds many European and North American countries in its CVD mortality rate.[7]

The rise and recent decline of the CVD epidemic in the developed countries have been well documented.[8–11] The identification of major risk factors through population based studies, and effective control strategies combining community education and targeted management of high-risk individuals, have together contributed to the fall in CVD mortality rates (inclusive of coronary and stroke deaths) that has been observed in almost all industrialized countries. It has been estimated that, during the period 1965–90, CVD related mortality fell by 50% or so in Australia, Canada, France and the United States, and by 60% in Japan.[8] Other parts of western Europe reported more modest declines (20–25%).[8] The decline in stroke mortality has been more marked than the decline in coronary mortality. In the USA the decline in stroke mortality commenced nearly two decades earlier than that in coronary mortality and maintained a sharper rate of decline.[10] During the period 1979–89, the age-adjusted mortality from stroke in that country declined by about one third, and the corresponding decline in coronary mortality was 22%.[10] In Canada, Japan, Switzerland and the United States, stroke mortality has declined by more than 50% in men and women aged 65–74 years since the 1970s.[11] In Japan, where stroke mortality outweighs coronary mortality, the impressive overall decline in CVD mortality is contributed principally by the former.

However, recent trends in some of the developed countries have been of some concern. A flattening of age adjusted mortality rates for major cardiovascular diseases in the USA has been reported since 1990, with an especially well documented absence of a decline in stroke mortality since that year (Figure 9.1). This has been accompanied by

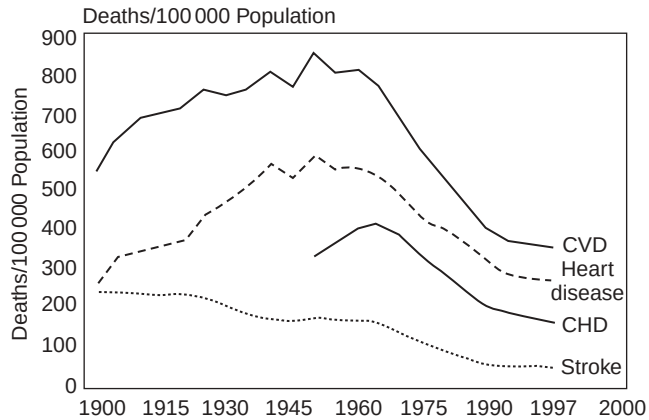

Figure 9.1 Age adjusted (to 2000 standard) mortality rates for major cardiovascular diseases in the United States from 1900 to 1997[12]

an increase in mortality from congestive heart failure. Lack of decline in incidence of CHD and stroke, fall in the rate of decrease in cardiovascular risk factor levels and rising levels of obesity since 1990 have all been incriminated as factors responsible for such a plateau effect on CVD mortality rates in the USA over the past decade.[12]

The discordant trend of rising CVD mortality rates in eastern and central Europe, however, is in sharp contrast to the decline in western Europe.[4] In countries such as Bulgaria and Hungary, CHD mortality rates are now the highest in the world in both men and women, and are still rising.[8] The average life expectancy in Russian males has fallen rapidly in recent years to below 60 years, a phenomenon to which rising CVD rates have contributed substantially.[13–15] Considerable variations in CVD mortality trends have been described across central and eastern Europe.[16] Whereas Poland has demonstrated a recent decline in CVD mortality, many other countries are still manifesting a rise. The 25% decline in CHD mortality observed in Poland during 1991–93 has been attributed to an increase in the consumption of fresh fruit and vegetables.[17]

Rheumatic heart disease (RHD) is also a major burden in the developing countries: it is the most common CVD in children and young adults. Although it is rare in the developed countries, at least 12 million persons are currently estimated to be affected by RHD globally.[2] More than 2 million require repeated hospital admission and 1 million will need heart surgery over the next 20 years.[2] Annually, 500 000 deaths occur as a result of RHD, and many poor persons, who are preferentially affected, are disabled because of lack of access to the expensive medical and surgical care demanded by the disease. The prevalence of RHD in the developing countries ranges from 1 to 10 per 1000 and the incidence of rheumatic fever ranges from 10 to 100 per 100 000, with a high rate of recurrence.

Early age of CVD deaths in developing countries

Although the present high burden of CVD deaths is in itself an adequate reason for attention, a greater cause for concern is the early age of CVD deaths in the developing countries compared to the developed countries. For example, in 1990 the proportion of CVD deaths occurring below the age of 70 years was 26·5% in the developed countries, compared to 46·7% in the developing countries.[4] The contrast between the truly developed "established market economies" (22·8% of CVD deaths <70 years) and a large developing country such as India (52·2%) was even sharper.[3] Therefore, the contribution of the developing countries to the global burden of CVD, in terms of disability adjusted years of life lost, was 2·8 times higher than that of the developed countries.

Epidemiologic transition and the evolution of the CVD epidemic

What is the "transition"?

The health status and dominant disease profile of human societies have been historically linked to the level of their economic development and social organization at any given stage. The shift from nutritional deficiencies and infectious diseases as the major causes of death and disability, to degenerative disorders (chronic diseases such as CVD, cancer, diabetes) has marked the economic ascent of nations as they industrialized. This has been called the epidemiologic transition.

The economic and social changes that propel this transition are related to a rise in per capita income; greater investments in public sanitation, housing and healthcare; assured availability of adequate nutrition; and technological advances in medical care. Life expectancy rises as causes of childhood and early adult mortality decline. This, in turn, leads to a decline in fertility. The age profile of the population changes from a pyramidal distribution dominated by the young to a columnar structure where adults and the elderly progressively expand their numbers. This has been described as the demographic transition. Because the disease profile is also linked to the age profile of the population, the health transition encompasses the effects of the epidemiologic and demographic transitions.

CVD profile at different stages of the epidemiologic transition

The model of epidemiologic transition originally described by Omran,[18] with three phases (the age of pestilence and famine; the age of receding pandemics; the age of degenerative and manmade diseases), was later modified to include a fourth phase, the age of delayed degenerative diseases.[19] Life expectancy increases progressively from around 30 years in the first phase to over 70 years in the fourth phase. The shift to a dominant chronic disease profile occurs in the third phase. As the average life expectancy exceeds 50–55 years, the proportionate mortality due to CVD begins to exceed that of infectious diseases.[20]

The transition occurs not only between the broad disease categories but also within them. The disease profile within CVD alters at each phase of the epidemiologic transition. In the first phase (the age of pestilence and famine), CVD accounts for 5–10% of deaths.[20] The major causes of CVD are, however, related to infectious and nutritional deficiencies. Thus, RHD and cardiomyopathies (for example, Chagas' disease) are the main CVD in this phase. Even as countries emerge from this phase, the residual burden of chronic valvular heart disease and congestive heart failure often remains for some time. These effects are still evident in sub-Saharan Africa and parts of South America and south Asia.[20]

In the second phase (the age of receding pandemics), the decline in infectious disease that accompanies socioeconomic development ushers in changes in diet. As the subsistence nutrition changes to more complete diets, the salt content of the food increases. Hypertension and its sequelae (hypertensive heart disease and hemorrhagic stroke) now affect the population, whose average age also has risen with increased life expectancy.[20] Some residual burden of RHD and cardiomyopathies is also evident. These non-atherosclerotic diseases contribute to 10–35% of deaths. This pattern currently prevails in parts of Africa, north Asia and South America.[20]

In the third phase (the age of degenerative and manmade disease), accelerated economic development and increased per capita incomes promote lifestyle changes in diet, physical activity, stress and addictions. A diet rich in calories, saturated fat and salt is accompanied by reduced physical activity through the increased use of mechanized transport and sedentary leisuretime pursuits. The metabolic mismatch leads to obesity, increased blood lipids, diabetes and elevated blood pressure. Tobacco consumption, especially cigarette smoking, starts as a pleasurable pastime and turns into a severe addiction. These factors result in the onset of clinically manifest atherosclerotic vascular disease (CHD, atherosclerotic stroke and peripheral vascular disease) at around 55 years of age. Such patterns first occur in the upper socioeconomic classes, who have disposable income to expend on rich diets, tobacco and transport vehicles. Several countries in South America and Asia currently manifest this pattern. As the epidemic advances further and involves all social strata, with homogenization of risk behaviors and risk factors across the population, the death toll of CVD rises to range between 35% and 65% of all deaths. This scenario is currently observed in eastern Europe.

In the fourth phase (the phase of delayed degenerative disease) a number of changes occur in the society to modify risk behaviors and reduce risk factor levels in the population. Health research augments the knowledge of CVD risk factors. The desire to reduce the adverse impact of CVD on individuals, as well as on the society, steer the community as well as the policymakers to apply this knowledge to disease prevention and health promotion. Community awareness through education, as well as its ability to exercise healthy choices through supportive regulatory measures, empowers its members to adopt healthier lifestyles. Saturated fat and salt consumption declines and leisuretime physical activity and exercise programs are avidly pursued. With concerns about the effects of active and passive smoking, tobacco consumption falls. Simultaneously, medical research makes available new technologies which are very effective in saving lives, modifying the course of disease and reducing the levels of risk factors. All of these changes, in unison, delay the onset of disease, lower the age standardized mortality rates and reduce the disability. The contribution of CVD to total mortality falls to 50% or below. These patterns are now established in most of North America, western Europe and New Zealand.[20]

Recent developments in some countries of eastern Europe, with sharp declines in life expectancy and other health indices, led to a fifth phase of health transition being postulated.[6] In this stage of "social upheaval and health regression" the CVD spectrum too may witness a reversal, with CHD and stroke occurring at younger ages, resulting in a fall in life expectancy as in Russia.

Variations in the transition

There are, however, variations on this theme. Even within Europe, for example, northern Europe and the Mediterranean countries have differences in CVD mortality rates which are better explained by cultural differences in diet than by the level of economic development.[21] Japan has so far avoided the CHD epidemic.[6] Whether recent changes in diet, with a rise in mean plasma cholesterol levels in the population, combined with high smoking rates, will lead to a major CHD epidemic in the future remains to be seen.

The question of "arrested epidemiologic transition" is also raised with respect to some of the developing countries. If poverty continues to be a major problem for them, will they experience the CVD epidemic in its full fury or will the pre-transitional diseases of nutrition and infection continue to occupy the center stage? Even now, there is evidence that the social gradient has begun to reverse for risk factor levels and even for morbidity measures in some populations in the developing world.[4] Unless economic development is greatly stunted in some countries, it is likely that the model of epidemiologic transition will be applicable to most of the developing countries.

The transition to the atherothrombotic phase of the epidemic may be preceded by a sharp fall in the burden of hemorrhagic stroke. The recent decline in CVD mortality reported from South Korea reflects such a fall in the contribution from hemorrhagic stroke, whereas thrombotic stroke and coronary heart disease have just begun to rise.[22] Whether adherence to traditional diets will result in a continued decline of CVD in South Korea, or CHD rates will rise further to push up the CVD mortality rates, remains to be studied. Cuba and Chile have also been cited as examples of developing countries with declining CVD mortality rates, despite high life expectancy. The model of "health transition", although very useful, is not immutable and is likely to vary according to both level of development and the nature of public health responses to social transition.

The model of health transition should also not lead to complacency regarding the high absolute burdens and early deaths in the developing countries. For example, even in a country in "early transition", such as Tanzania, the stroke mortality rate in the age group 15–59 years in rural and

urban areas is two to four times higher than that in the UK in a similar age group.[23]

Early and late adopters

The pace of epidemiologic transition will vary both between and within countries. Usually lifestyle changes towards risk-prone behaviors occur first in the higher socioeconomic groups and urban communities, for whom the innovations of modernity are more easily accessible and affordable. As these innovations diffuse and become routinely available at prices amenable to mass consumption, the poorer sections and rural communities also join the CVD bandwagon. Soon the awareness of CVD risks, as well as the economic independence to make healthy lifestyle choices in relation to diet and leisuretime exercise (along with the greater ability to access healthcare), moves the "early adopters" in the affluent and urban strata into a reduced risk zone. The burden of CVD is then largely concentrated in the lower socioeconomic groups and rural populations, who continue to practice high-risk behaviors and display elevated risk factor levels.[20] These "late adopter" groups also will slowly alter their behaviors, lower their levels of risk and reduce their burden of CVD as healthcare responses to the CVD epidemic become universally effective.

This is the evolutionary profile of the CVD epidemic, as evident from the analysis of mature epidemics in industrial nations and the advancing epidemics in the developing countries. Differences within and between countries, suggested by cross-sectional views at any point in this evolution, should not obscure the longitudinal perspective of an evolving epidemic in which most countries will traverse similar paths, albeit at different times determined by their pace of development. Global shifts in CVD risk factors and their reflection in global CVD trends indicate that all countries and communities have far more in common in terms of disease causation than the differences that demarcate them. The challenge of epidemiologic transition is not whether it will happen in the developing countries, but whether we can apply the available knowledge to telescope the transition and abbreviate phase three of the model in these countries.

Projections

The Global Burden of Diseases study[15] estimates that annual mortality from non-communicable diseases will rise from an estimated 28·1 million deaths in 1990 to 49·7 million in 2020. CVD, which accounts for a large proportion of these, will rise as a result of the accelerating epidemic in the developing countries. CHD will continue to be the leading cause of death in the world and, in terms of disability adjusted life years (DALY) lost, will rise from its fifth position in 1990 to top the DALY table in 2020.[15] Men as well as women in the developing countries will experience the largest rise in CHD and stroke mortality rates across the world (Table 9.1).

Table 9.1 Global % change in CHD and stroke mortality 1990–2020 (adapted from Murray and Lopez[3])

	CHD		Stroke	
	Men	Women	Men	Women
Developed countries	+48	+29	+56	+28
Developing countries	+137	+127	+124	+107
World	+100	+80	+106	+78

The profile of DALY loss attributable to CVD in 1990 in various regions of the world and the projected estimates for 2020 (Table 9.2) also indicate a large rise.[3] Among the developed countries, the sharp decline in the industrial nations is partly offset by the rise in the former socialist countries.

Table 9.2 Contribution of cardiovascular disease to DALY loss (percentage of total) (adapted from Murray and Lopez[3])

Region	1990 (%)	2020 (%)
World	10·85	14·7
Developed countries	25·7	22·0
Developing countries	8·9	13·8

Deaths attributable to tobacco, a risk factor for CVD and other chronic diseases, are projected to rise from 3·0 million in 1990 to 8·4 million in 2020. The largest increases will be in India, China and other developing countries in Asia, where tobacco-attributable deaths will rise from 1·1 million to 4·2 million in 2020.[24]

Mechanisms that propel a CVD epidemic in developing countries

Demographic changes due to the epidemiologic transition

A major public health challenge, identified by recent analyses of global health trends, is the projected rise in both proportional and absolute CVD mortality rates in the developing countries over the next quarter century. The reasons for this are many.[4] In the second half of the 20th century, most developing countries experienced a major surge in life expectancy. This was principally as a result of a decline in deaths occurring in infancy, childhood and adolescence, and was related to more effective public health responses to perinatal, infectious and nutritional deficiency disorders and to improved economic indicators, such as per capita income,

and social indicators such as female literacy in some areas. These demographic shifts have augmented the ranks of middle-aged and older adults. The increasing longevity provides longer periods of exposure to the risk factors for CVD, resulting in a greater probability of clinically manifest CVD events. The concomitant decline in infectious and nutritional disorders (competing causes of death) further enhances the proportional burden due to CVD and other chronic lifestyle related diseases.

The ratio between deaths due to pretransitional diseases (related to infections and malnutrition) and those caused by post-transitional diseases (such as CVD and cancer) varies among regions and between countries, depending on factors such as the level of economic development and literacy, as well as availability of and access to healthcare. The direction of change towards a rising relative contribution of post-transitional diseases is, however, common to and consistent among the developing countries.[25] The experience of urban China, where the proportion of CVD deaths rose from 12·1% in 1957 to 35·8% in 1990, illustrates this phenomenon.[26]

Population expansion and aging

Despite relative declines in fertility, the continuing growth of populations in the developing countries will also increase the absolute numbers at risk of CVD. The world population is expected to rise from 5·71 billion in 1995 to 8·29 billion in 2025. Combined with changes in the demographic profile, this will result in a large number of adults who are potentially vulnerable to CVD.

At present there are an estimated 380 million people aged 65 or more, including around 220 million in the developing countries. By 2020, the figures are projected to reach more than 690 million and 460 million, respectively.[2] In India, for example, the population is expected to rise from 683·2 million in 1981 to somewhere between 1253·8 and 1480·5 million in 2021. Simultaneously, the proportion of adults aged 35 years or above will rise from 28·4% of the population to 42·4%.[27]

Increased standard of living leading to deleterious health behaviors

A third reason to arouse concern is that, if population levels of CVD risk factors rise as a consequence of adverse lifestyle changes accompanying industrialization and urbanization, the rates of CVD mortality and morbidity could rise even higher than the rates predicted solely by demographic changes. Both the degree and the duration of exposure to CVD risk factors would increase as a result of higher risk factor levels, coupled with a longer life expectancy. The increase in body weight (adjusted for height), blood pressure and cholesterol levels in Chinese population samples aged 35–64 years between the two phases of the Sino-MONICA study (1984–86, 1988–89), and the substantially higher levels of most CVD risk factors in urban population groups compared to rural population groups in India, provide evidence of such trends.[26] The increasing use of tobacco in a number of developing countries will also translate into higher mortality rates from CVD, lung cancer and other tobacco related diseases, and undesirable alterations in diet and physical activity are also having adverse effects on cardiovascular health.

The global availability of cheap vegetable oils and fats has resulted in greatly increased fat consumption in low-income countries in recent years.[28] The transition now occurs at lower levels of the gross national product than previously, and is further accelerated by rapid urbanization. In China, for example, the proportion of upper income persons who were consuming a relatively high-fat diet (>30% of daily energy intake) rose from 22·8% to 66·6% between 1989 and 1993. The lower and middle income groups too showed a rise (from 19% to 36·4% in the former, and from 19·1% to 51·0% in the latter).[28] The Asian countries, traditionally high in carbohydrates and low in fat, have shown an overall decline in the proportion of energy from complex carbohydrates along with an increase in the proportion of fat.[28] The globalization of food production and marketing is also contributing to the increasing consumption of energy-dense foods that are poor in dietary fiber and several micronutrients.[29]

The rising tobacco consumption patterns in most developing countries contrast sharply with the overall decline in the industrial nations.[30] Recent projections from the World Health Organization suggest that by the year 2020 tobacco will become the largest single cause of death, accounting for 12·3% of deaths worldwide.[24] India, China and countries in the Middle Eastern crescent will by then have tobacco contributing to more than 12% of all deaths. In India alone, the toll attributable to tobacco will rise from 1·4% in 1990 to 13·3% in 2020.[24] A large component of this will be in the form of cardiovascular deaths.

Thrifty gene

A "programming" effect of factors promoting selective survival may also determine individual responses to environmental challenges and, thereby, the population differences in CVD. The "thrifty gene" has been postulated to be a factor in promoting the selective survival, over generations, of persons who encountered an adverse environment of limited nutritional resources.[31] Although this may have proved advantageous in surviving the rigors of a spartan environment over thousands of years, the relatively recent and rapid changes in environment may have resulted in a metabolic mismatch. Thus a salt-sensitive person whose forefathers thrived despite a limited supply of salt now reacts to a salt-enriched diet with high blood pressure. It has also

been hypothesized that populations subjected to food scarcity have undergone selection of a gene which increases the efficiency of fat storage through an oversecretion of insulin in response to a meal. Although this favors survival in a situation of low caloric availability, a current excess of caloric intake may lead to obesity, hyperinsulinemia, diabetes and atherosclerosis. Similarly, an insulin-resistant individual whose ancestors may have survived because a lack of insulin sensitivity in the skeletal muscle ensured adequate blood glucose levels for the brain in daunting conditions of limited calorie intake and demanding physical challenges, may now respond to a high-calorie diet and a sedentary lifestyle with varying degrees of glucose intolerance and hyperinsulinemia. Although such mechanisms seem plausible, their contribution to the acceleration of the CVD epidemic in the developing countries remains speculative.

Maternal–fetal exposures as a cause of midlife CVD

A recently reported association which, if adequately validated by the tests of causation, may have special relevance to the developing countries is the inverse relationship between birth size and CVD in later life.[32–38] The "fetal origins hypothesis" states that adverse intrauterine influences, such as poor maternal nutrition, lead to impaired fetal growth, resulting in low birthweight, short birth length and a small head circumference. These adverse influences are postulated to also "program" the fetus to develop adaptive metabolic and physiologic responses which facilitate survival. These responses, however, may lead to disordered responses to environmental challenges as the child grows, with an increased risk of glucose intolerance, hypertension and dyslipidemia in later life, with adult CVD as a consequence. Although some supportive evidence for the hypothesis has been provided by observational studies, it awaits further evaluation for a causal role. If it does emerge as an important risk factor for CVD, the populations of developing countries will be at an especially enhanced risk because of the vast numbers of poorly nourished infants born in the past several decades. The steady improvement in child survival will lead to a higher proportion of such infants surviving to adult life, when their hypothesized susceptibility to vascular disease may manifest itself.

Ethnic diversity

Although ethnic diversity in CVD rates, risk factor levels and risk factor interactions are evident from population studies, the extent to which genetic factors contribute is unclear. It is only after demographic profiles, environmental factors and possible programming factors are ascertained and adjusted for that differences in gene frequency or expression can be invoked as a probable explanation for interpopulation differences in CVD.[39] The extent to which chronic diseases, including CVD, occur within and among different populations is determined by genetic–environmental interaction, which occurs in a wide and variable array, ranging from the essentially genetic to the predominantly environmental. This is perhaps best illustrated by the knowledge gained from studies in migrant groups, where environmental changes due to altered lifestyles are superimposed on genetic influences. These "natural experiments" have been of great value in enhancing the understanding of why CVD rates differ among ethnic groups. The classic Ni-Hon-San study of Japanese migrants revealed how blood cholesterol levels and CHD rates rose from Japan to Honolulu and further still to San Francisco, as Japanese communities in the three areas were compared.[40] The experience gleaned from the study of south Asians, Chinese and Pima Indians further elucidates the complexities of ethnic variations in CHD.[41–43] The comparison of Afro-Caribbeans, south Asians and Europeans in the UK brought out the sharp differences in central obesity, glucose intolerance, hyperinsulinemia and related dyslipidemia between the three groups, despite similar profiles of blood pressure, body mass index and total plasma cholesterol.[44] However, urban–rural comparisons within India,[27] as well as migrant Indian comparisons with their non-migrant siblings,[45] reveal large differences in these conventional risk factors. Thus, where the environment is common but gene pools differ, the non-conventional risk factors appear to be explanatory of risk variance, whereas when the same gene pool is confronted with different environments, the conventional risk factors stand out as being of major importance.

To what extent ethnic diversity in response to CVD risk factors influences the course of the CVD epidemic in different developing countries remains to be studied. However, the experience of some of the migrant groups (for example, south Asians) portends severe epidemics in the home countries as they advance in their transition.

Strategies to deal with the coronary epidemic

CVD prevention

Evolving concepts of risk factors

Risk factor – Decades of research, embracing evidence from observational epidemiology and clinical trials, have demonstrated that CHD is multifactorial in causation. The term "risk factor" was first used in the context of CHD.[46] Several such risk factors have been identified, ranging from the established "major" factors such as smoking, elevated blood cholesterol and hypertension, to the recently investigated factors such as homocysteine and lipoprotein a. A risk factor must fulfill the criteria of causality: strength of association (high relative risk or odds ratio), consistency of

association (over many studies), temporal relationship (cause preceding the effect), dose–response relationship (greater the exposure, higher the risk), biologic plausibility, experimental evidence and, very importantly, evidence from human studies.

"Clinical" v "prevention" norms – The need to make "clinical" decisions related to the management of these risk factors led to a definition of threshold levels of risk and practice guidelines. These "clinical norms" erroneously came to be identified, by the health professionals as well as the community, as also representing the prevention norms. The former are defined by evidence of benefit exceeding risk when an intervention reduces a risk factor below a particular level (the net benefit being demonstrated in clinical trials specifically designed for that purpose). The latter, however, are usually identified from observational studies (long-term longitudinal prospective studies of large cohorts) and denote the optimal values of the risk factor at which the risk of developing disease is minimal.

The targeting of individuals is promoted by the "clinical" approach of healthcare providers, who seek to identify persons at "high risk" of disease or its outcomes for intensive investigation and intervention. Thus thresholds are defined to categorize persons with "high cholesterol" or "high blood pressure" and to implement individualized control strategies. Attention and action above this threshold often contrast with indifference and inertia below it.

As trial evidence is gathered, the clinical norms may progress towards the prevention norms, as in the case of cholesterol or hypertension, where the thresholds for intervention have been lowered dramatically in the last decade. They may, however, remain higher than the prevention norms, as clinical trials may be conducted at a stage in the natural history where the risks of prior exposure may not be completely reversible, and also because the intervention may itself be associated with some adverse effects. Thus the benefits of lowering a risk factor may appear less than those that may occur by preventing its rise in the first place.

The continuum of risk – It is clear that even though lifestyle disorders afflict some individuals, they arise from causes that are widespread in the population as a whole. Risk factors such as cholesterol and blood pressure operate in a continuum of progressively increasing risk, rather than through an all-or-none relationship suggested by cut-off values. For example, a systolic blood pressure (SBP) in the range 130–139 mmHg carries a higher risk for both heart attacks and strokes than values in the range 120–129 mmHg. Whereas an SBP of 180 mmHg carries a much higher risk for an individual than 140 mmHg, the number of persons in any population who have SBP values in the range 130–139 mmHg is higher than those with values of 180 mmHg or higher. The Multiple Risk Factor Intervention Trial's cohort study in the United States (MRFIT) revealed that of all heart attacks which are attributable to SBP, 7·2% arise from the 0·9% of the population that represents the 180+ mmHg range, whereas 20·7% of all such heart attacks occur in the 22·8% which has pressures in the range 130–139 mmHg[47] (Figure 9.2). Similarly, 57% of all excess deaths attributable to diastolic blood pressure occur in the range 80–95 mmHg, compared to only 15% which occur in the high range of 105–130 mmHg.

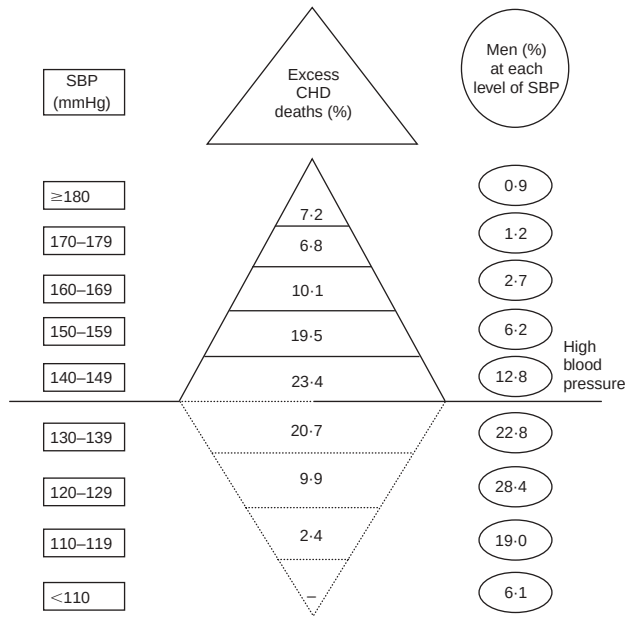

Figure 9.2 The risk pyramid for blood pressure and coronary heart disease (CHD): baseline SBP and CHD death rates for men screened in MRFIT[37] (adapted with permission from Stamler *et al*[36])

This dichotomy is also clearly seen in the Framingham Study on coronary risk factors.[49] People with a blood cholesterol level of 300 mg/dl run three to five times the risk of CHD as people at a cholesterol level of 200 mg/dl. At cholesterol levels over 300 mg/dl, 90 out of 100 persons developed the disease in the next 16–30 years of follow up in Framingham. At cholesterol levels under 200 mg/dl the rate was 20 out of 100 during the same period. However, more than twice as many people developed CHD with cholesterol levels under 200 mg% all their lives as did those with cholesterol levels over 300 mg%. This is because a 20% fraction of a 45% segment of the population is a much larger number than a 90% fraction of a 3–5% segment of the population.[49]

Thus, for most causal factors there is a "risk pyramid". Those at the top of the pyramid are at the highest individual risk of disease, but those at the lower levels account for the largest number of cases in the community because they

constitute the largest segment of the population. Any approach that targets only those at the highest risk produces limited gains for the community, despite conferring definite benefits to the individuals in that category.

The concept that "sick individuals arise from sick populations" was propounded and proved by Geoffrey Rose.[50,51] He demonstrated that risk factor "distributions" throughout the population are predictive of disease burden in that community. The mean (average) levels of a risk factor across different populations correlate with the proportions of high-risk individuals in those populations, whatever the cut-off value. Thus, as the average population blood pressure value among populations rises, the proportion of hypertensive individuals also rises. In each population there are groups who represent the extremes of the risk profile (very low risk *v* very high risk). However the proportion at "high risk" would be determined by the average value of that risk factor in the population. This in turn is dependent on the dominant behaviors that characterize the society at each stage of its development.

Multiplicative risk – The process of identifying and estimating the independent risk associated with any single risk factor led to clinical and preventive strategies to target it in isolation. However, observational studies like Framingham and MRFIT have clearly revealed that the coexistence of multiple risk factors confers a magnified risk which is multiplicative rather than merely additive. A smoker with modest elevations of cholesterol and diastolic or systolic blood pressure is at a greater risk of coronary death than a non-smoker with severe hypertension or marked hypercholesterolemia. In the MRFIT study, a non-smoker with SBP less than 118 mmHg and a total serum cholesterol level less than 182 mg% had a 20-fold lower risk of coronary death than a smoker with a SBP exceeding 142 mmHg and a serum cholesterol exceeding 245 mg% (age adjusted CHD mortality of 3·09 *v* 62·11, per 10 000 person years). A smoker who has a SBP of 132–141 mmHg and a serum cholesterol of 203–220 mg% has a CHD mortality risk of 28·87 per 10 000 person years, compared to a risk of 12·36 in a non-smoker with an SBP below 118 mmHg but with a serum cholesterol exceeding 245 mg%.[52]

The demonstration of such multiplicative risk has led to the concept of "comprehensive cardiovascular risk" or "total risk", quantifying an individual's overall risk of CVD resulting from the confluence of risk factors.[48] Both clinical and preventive strategies are veering away from unifactorial risk reduction to multifactorial risk modification, to reduce this overall risk in individuals as well as in populations.

High-risk approach for prevention

Having recognized that environmental risk factors do not affect only a few individuals in isolation but are spread across populations, with a continuous rather than a threshold relationship to disease, how should that influence disease control strategies? The health policy debate, until recently, was on whether to focus the control strategies on individuals at the highest risk of disease (in view of their markedly elevated risk factor levels) or on the population as a whole (aiming to achieve modest reductions in the risk of most members of that community). The high-risk approach aims to identify persons with markedly elevated risk factors and therefore at the highest risk of disease.[50] These individuals are then targeted by interventions which aim to reduce the risk factor levels. If successful, the benefits to individuals are large, because the individuals risks are large. However, as the number of persons in this high-risk category is proportionately much smaller than that in the moderate-risk group, the overall benefits to society are limited in terms of deaths or disability avoided. The strategy also does not minimize the risk for the individuals concerned. Although a fall of blood cholesterol from 300 mg% to 240 mg% does indeed reduce the risk, even this attained value poses greater risk than 200 mg%. Thus there is still a substantial residual risk, despite the impressive risk reduction owing to the change from the initial cholesterol levels. Further, this strategy is behaviorally inappropriate.[50] An individual with high blood cholesterol levels may be advised to eat low-fat food, but can he strictly adhere to it if his family and friends consume a very different diet? The main advantage of the high-risk approach, however, is that physicians as well as patients are highly motivated to act, because the projected risks compel attention and the benefits of reduction appear attractive.[50]

Population approach for prevention

In contrast, the population approach aims at reducing the risk factor levels in the population as a whole, through community action.[50] Because there is a continuum of risk associated with most risk factors, this mass change will result in mass benefit across a wide range of risks. Although individual benefits are relatively small, the cumulative societal benefits are large ("the prevention paradox"). The strategy is also behaviorally more appropriate.[50] If the eating habits in the community alter towards preferred consumption of foods with lower saturated fat and salt content and a greater daily intake of fresh fruit and vegetables, even the high-risk individual on a prescribed diet will find a supportive ambience which does not mark him out as a deviant from social norms. If a new generation grows up in an environment where healthy behavior is considered common practice, its average blood cholesterol level may remain below 200 mg% rather than around 240 mg%, and thus be at a lower risk than even the beneficiary of the high-risk strategy. However, the risks and benefits of such a strategy are less obvious to those in the moderate-risk range. The motivation for change is therefore not as strong as for those in the high-risk

group. The gratification of achieving readily identifiable success in high-risk individuals, through drugs or other powerful interventions, is also denied to the physicians in the population strategy, where the potential beneficiaries, though many, are faceless and nameless. Because such "anonymity of prevention" denies the pleasure of individual rescue acts, physician motivation for community counseling is neither strong nor sustained.[50] Policymakers, however, can ill afford to ignore the imperatives of investing in a population approach which will pay large long-term dividends in the control of lifestyle diseases. Health professionals too must recognize the benefits of this strategy to play a strong advocacy role for health-promoting behaviors in the community.

The success of the population strategy has been demonstrated both in developed countries (for example, Finland)[53] and in some developing countries (for example, Mauritius).[54] The North Karelia Project demonstrated large reductions in CVD mortality (50·1% in males and 63·5% in females), CHD mortality (53·4% and 59·8%) and all-cause mortality (39·5% and 40·4%) during the 20-year intervention period. These accompanied changes in CVD risk factors following community-based intervention programmes. Impressive reductions in cigarette smoking, prevalence of hypertension and mean population cholesterol levels, as well as increases in leisuretime physical activity, were noted during the period 1987–92 consequent upon lifestyle intervention programs in Mauritius.

The impact of the population strategy is likely to be large, as suggested by an estimate that if every American had a diastolic blood pressure value a mere 2 mmHg lower than his or her current value, the number of heart attacks that could be prevented would exceed those that could be avoided by effectively treating every person with a diastolic pressure of 95 mmHg or higher. The corresponding benefit for preventing paralytic strokes would be 93% of those avoided by drug therapy.[55] Such blood pressure changes can be effectively achieved and sustained through modest reductions in weight and salt intake or through exercise.

Combining the strategies

These strategies are not mutually exclusive but are synergistic, complementary and necessary. The risks and benefits demonstrated in high-risk individuals serve to educate the community about risk factors, whereas the population approach makes it easier to achieve the desired level of lifestyle change in high-risk individuals. The population-based lifestyle-linked risk reduction approach is particularly relevant in the context of the developing countries, where it is necessary to ensure that communities currently at low risk are protected from the acquisition or augmentation of risk factors ("primordial prevention"). This is true for adults in the rural regions of most developing countries, as well as for children in all populations. It is also eminently applicable to moderate-risk groups in urban areas, where lifestyle-based risk modification will help avoid drug therapy, with its attendant economic and biologic costs. There will still be some who need such pharmacologic or technologic interventions because of their high-risk status. However, their numbers too will decrease as the risk profile of the whole community gradually shifts.

Case management

Despite these preventive strategies, several individuals will manifest clinical disease because risks are not totally eliminated in the community or because genetic susceptibility is strongly expressed. The success of preventive efforts will reduce their number as well as delay the age of onset of clinical events. Those who develop disease will require optimal clinical care, which can avert early death, reduce disability and ensure an adequate quality of life. This mandates early detection of disease.

The cost effectiveness and safety of these diagnostic and therapeutic techniques would have to be established through appropriately designed clinical research. This scientific evidence has to be translated into practice guidelines, which then need to be widely disseminated. The rapid diffusion of these guidelines across various levels of healthcare and their sustained impact on clinical practice will ensure that the burden of cardiovascular disease in the community is mitigated through appropriate application of available knowledge. Postmyocardial infarction risk reduction through thrombolytic agents, aspirin, β blockers, ACE inhibitors and statins is clearly illustrative of the benefits of such evidence-based clinical care.[56–61]

The decline in CVD mortality rates in industrial countries is the collective result of population-based prevention strategies improving the risk factor profile of communities, a high-risk approach of targeted interventions to protect individuals with markedly elevated risk factor levels, and case management strategies to salvage, support and sustain those presenting with clinical problems. These strategies are not diverse and divisive but are continuous and complementary in the effort to control the incidence and impact of CVD.

The enormous need for evidence-based medicine in developed and developing countries

CVD related expenditure in developed countries

The management of CVD is often technology intensive and expensive. Procedures for diagnosis or therapy, drugs, hospitalization and frequent consultations with healthcare providers all contribute to high costs, both to those affected and to society. In developed countries they already account for

about 10% of direct healthcare costs, equal to between 0·5% and 1% of a country's gross national product.[2] As life expectancy increases and the duration of the therapy becomes prolonged, the costs may further escalate until preventive strategies succeed in greatly reducing the incidence of CVD.

CVD related expenditure in developing countries

The costs of CVD related healthcare have not been clearly estimated in the developing countries.[62] However, high expenditure on tertiary care in most of these countries probably has a large contribution from CVD. As the epidemic advances many more will be affected, escalating the costs of CVD related healthcare. This may divert scarce resources intersectorally from developmental activities, and intrasectorally from the "unfinished agenda" of infectious and nutritional disorders. As the epidemic matures, the social gradient will reverse and many of the poor who are then afflicted will be unable to afford or access the expensive healthcare that CVD demands.

Need for evidence-based medicine

The need for cost effective prevention and case management is, therefore, urgent. These practices need to be based on the best available evidence which is generalized to the context of each developing country. Where such evidence is unavailable or insufficient to guide policy and practice, health research must quickly address those information needs. International cooperation can greatly further these efforts to acquire, appraise, analyze and apply such knowledge. *Evidence* from health research must do *justice* to the needs of public health! Evidence-based cardiovascular medicine must pursue this advocacy to secure acquittal from CVD for countries under the trial of epidemiologic transition. However, the recommendations also need to be context specific and resource sensitive, in accordance with the specific needs of different regions. The challenge for cardiovascular research is to provide for such relevant knowledge generation, and the challenge for public health and clinical practice is to provide for effective knowledge translation. The course and consequences of the global cardiovascular epidemic should not merely be predicted, but ought to be favorably altered by responding to these challenges.

10 Tobacco: global burden and community solutions

Terry F Pechacek, Samira Asma, Nicole Blair, Michael P Eriksen

Introduction

While smoking is universally known to be deadly, few are aware of precisely how deadly. In the United States, smoking is the leading preventable cause of death, killing over 440 000 people each year, wasting 5 million years of potential life and costing over $75 billion in health expenditures. Since the first Surgeon General's Report on smoking in 1964, over 10 million Americans have died from smoking. If current trends continue, an additional 25 million Americans alive today, including 6·4 million children, will die a painful and premature death caused by smoking. While the United States statistics are appalling, the global projections are even more dire. Globally, if current trends continue, the number of people killed by tobacco will more than triple to 10 million a year by the year 2025. The only ray of hope is that the precursors for the projected global tobacco epidemic are not yet all in place. While high smoking rates among men are nearly universal, the same cannot be said for women and teens. Thus, despite the unprecedented toll of tobacco and the gloomy projections, there is the potential for prevention.

This chapter will explore that potential, particularly for coronary heart disease, by:

1. examining the current global burden of tobacco and future projections
2. reviewing the mixed evidence for community-based tobacco control interventions
3. proposing a new and dynamic model for community-based tobacco control, based on state innovations, proven to be effective in the United States, that may be able to be applied throughout the world.

Current global burden of tobacco and future projections

Worldwide, the only two major causes of death whose effects are now increasing rapidly are HIV and tobacco. If current smoking patterns persist, there will be about one billion deaths from tobacco during the twenty-first century, compared to "only" about 0·1 billion (100 million) during the whole of the twentieth century. About half of these deaths will be in middle age (35 to 69) rather than old age, and those killed by tobacco in middle age lose, on average, more than 20 years of non-smoker life expectancy.[1] Tobacco use is estimated to have caused about 4 million deaths a year, more or less evenly split between developed and developing countries. These numbers reflect smoking patterns several decades ago, and worldwide cigarette consumption has increased substantially over the past half century.[2] Currently, about 30% of young adults become persistent smokers, and relatively few quit. The main diseases by which smoking kills people are substantially different in America, where vascular disease and lung cancer predominate;[1] in China, where chronic obstructive pulmonary disease causes even more tobacco deaths than lung cancer;[3,4] and in India, where almost half the world's tuberculosis deaths take place and the ability of smoking to increase the risk of death from TB may well be of particular importance.[5,6]

There are already a billion smokers, and by 2030 about another billion young adults will have started to smoke. If current smoking patterns persist, worldwide mortality from tobacco is likely to rise from about four million deaths a year currently to about 10 million a year around 2030 and will rise somewhat further in later decades. This means that tobacco use will cause about 150 million deaths in the first quarter of the century and 300 million in the second quarter. Predictions beyond that are inevitably speculative, but if over the next few decades a quarter to a third of the young adults become persistent smokers and about half are eventually killed by their habit, about 15% of adult mortality in the second half of the century will be due to tobacco, implying some 600 million to 900 million tobacco deaths between 2050–2099.[7]

First, globally in 1995, 29% of the world's population aged 15 years and over smoked daily (Table 10.1). Low-income and middle-income countries whose populations account for four fifths of the global adult population, accounted for 82% of the world's smokers. East Asia and the Pacific, which includes China, accounted for 36% (43 million) of all smokers, but only 32% of the population aged 15 years and over. Overall, smoking prevalence was highest in Europe and Central Asia at 40% and lowest in Sub-Saharan Africa at 18%.

For both males and females, there was wide variation in smoking prevalence between regions. The prevalence of smoking amongst males was highest in East Asia and the Pacific, and in Europe and Central Asia, at about 60% in each case, and lowest in Sub-Saharan Africa at 29%. Among females, the prevalence of smoking was highest in Europe and Central Asia at 26% and lowest in South Asia at 5% (for cigarettes and bidis combined) and Middle East and North Africa at 6%.

Second, the prevalence of smoking amongst males was higher overall for men (47%) than for women (11%). WHO data at country level suggest that the proportion of men who smoke is well above 50% in many low-income and middle-income countries:

- 82% in Indonesia,
- 78% in the Philippines,
- 75% in Cuba,
- 72% in China.[2]

Globally, males account for four in five of all smokers.

The majority of epidemiologic studies suggest that individuals who avoid starting to smoke in adolescence or young adulthood are unlikely ever to become smokers. Nowadays, the overwhelming majority of smokers start before age 25, often in childhood or adolescence (Figure 10.1); in high-income countries, eight out of 10 begin in their teens. In middle- and low-income countries for which data are available, it appears that most smokers start in their early twenties, but the trend is towards younger ages. For example, in China between 1984 and 1996, there was a significant increase in the number of young men aged between 15 and 19 years who took up smoking. A similar decline in the age of starting has been observed in high-income countries.

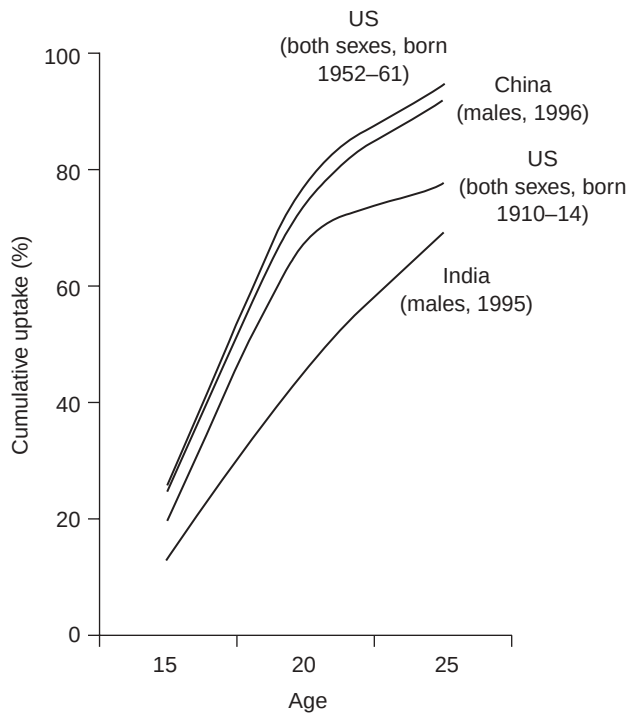

Figure 10.1 Smoking initiation age in China, India and the United States. Source: Gupta 1996; USDHHS 1989 and 1994; Chinese Academy of Preventive Medicine 1997

Tobacco: a risk factor for coronary heart disease

It is well established that prolonged smoking is an important cause of chronic disease. Prolonged smoking causes many diseases in addition to lung cancer, notably other cancers and chronic respiratory and cardiovascular diseases. However, the toll of death and disability from smoking outside the high income countries has yet to be felt. This is because the diseases caused by smoking can take several decades to develop. Even when smoking is common in a population, the damage to health may not yet be visible. The alarming size of the hazards now observable in populations that have been smoking for many decades.

Thus in the first 20 years of follow up of the British doctors, cohort (1951–71), smokers had, on average, about a 1·5 to twofold higher death rate at each age, similar to the excess reported in other studies around that time (see Table 10.1). With longer duration of smoking, death rates of smokers have increased substantially so that during the second period of follow up (1971–91), smokers in middle age had a threefold higher death rate than non-smokers. A similar excess mortality ratio was found in the CPS-II cohort based on follow up in the latter half of the 1980s. These relative risks suggest that, on average, a smoker who begins smoking in young adult life and continues to do so has at least a 50% chance of eventually being killed by tobacco, either in middle age or in old age.

The evidence from these two studies on the disease-specific risks associated with smoking are similar.[8] Current smokers have about a 20-fold higher death rate from lung cancer than never smokers, among whom lung cancer death rates have remained low and constant. There is epidemiologic evidence to suggest that this is also the case in other populations. For example, based on the two American Cancer Society studies with follow up to 1959–65 and 1982–86 respectively, lung cancer death rates among lifelong non-smokers were remarkably constant at 15·4 and 14·7 per 100 000 (age-standardized) for men, and 9·6 and 12·0 for women; the rates for current smokers were 187·1 and 341·3 for men, and 26·1 and 154·6 for women.[9] Smokers also incur a 10–20-fold excess mortality from chronic obstructive lung disease (primarily chronic bronchitis and emphysema), and a risk of death from major vascular diseases that is about twice that of non-smokers.

The excess mortality of smokers from vascular disease is particularly noteworthy. Vascular disease death rates are typically much higher than those for cancer or other causes

Table 10.1 Prevalence of smoking among adults aged 15 and over, by World Bank region, 1995

World Bank Region	Smoking prevalence (%)			Total smokers	
	Males	Females	Overall	(millions)	(% of all smokers)
East Asia and Pacific	61	4	33	413	36
Europe and Central Asia	57	26	40	145	13
Latin America and Caribbean	40	21	30	95	8
Middle East and North Africa	44	5	25	40	3
South Asia (cigarettes)	21	1	11	88	8
South Asia (*bidis*)	21	4	13	99	9
Sub-Saharan Africa	29	9	18	59	5
Low-income & Middle-income	49	9	29	939	82
High-income	38	21	29	205	18
World	47	11	29	1143	100

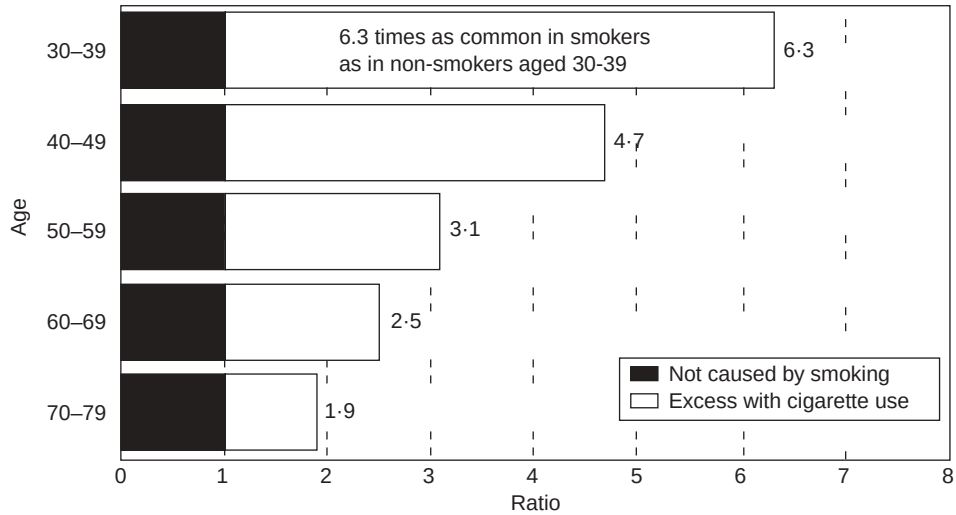

Figure 10.2 *Source*: Based on the ISIS study of over 10 000 UK heart attacks, Parish *et al*. Cigarettes smoking, Lar yields, and non-fatal myocardial infarction: 14,000 cases and 32,000 controls in the United Kingdom. *BMJ* 1994;**311**:471–7[10]

associated with smoking. Cardiovascular diseases (especially ischemic heart disease and stroke), therefore, contribute more to smoking-attributable deaths at a population level than do other causes, including lung cancer for which the relative risk is much higher, although this pattern will change as cardiovascular disease mortality declines. Finally, it is worth noting that the all-age excess mortality ratio of about 2 from cardiovascular diseases masks a very significant age gradient in relative risks. This is clearly shown in Figure 10.2 based on a large (46 000 persons) case–control study carried out in the United Kingdom.

At younger ages (<50 years), smokers have a five to six times higher death rate than non-smokers, with the relative excess declining with age. What these data suggest is that if a smoker dies from vascular disease before about the age of 50 years, there is a 70–80% chance that smoking caused it, and that this is the prinicipal mechanism through which smoking causes a threefold excess mortality rate in middle age.

Cigarette smoking is only one of several causative factors that produce disease. This is especially true for ischemic heart disease where smoking interacts synergistically with other factors such as hypercholesterolemia and hypertension to greatly increase risk of heart disease. Evidence suggests that the independent risk attributable to smoking is comparable to that of other major risk factors.[10] This interaction with dietary parameters probably explains the currently lower proportions of ischemic heart disease attributable to smoking in populations such as China where low-fat diets have predominated.[3]

The extent to which smoking is responsible for deaths from diseases other than lung cancer varies substantially from one population to another. For example, smoking is particularly cardiotoxic for people who already have other risk factors such as high blood cholesterol. The range of other diseases that are caused by smoking is so extensive that the influence of other specific risk factors may effectively average

out even in different populations. For example, although in many developing countries, cholesterol levels are low (limiting the cardiotoxic effects of tobacco), a high prevalence of respiratory diseases may greatly increase the pulmonary vulnerability to tobacco.[11]

Smokers have twice the risk of heart attack compared with non-smokers. Smoking is also a major risk factor for sudden death from heart attack, with smokers having two to four times the risk of non-smokers. The risk increases with the number of cigarettes smoked. Overall, cigarette smokers have coronary heart disease (CHD) rates 70% higher than those of non-smokers, with heavy smokers dying from CHD at a rate two to three times that of non-smokers.[1] In addition, recent epidemiologic evidence shows that never-smokers exposed to environmental tobacco smoke (ETS) have an increased risk not only for lung cancer but also for cardiovascular disease. Two recent prospective trials[12–14] and meta-analyses[15] estimate the relative risk for cardiovascular diseases at 1·2 to 1·3 individuals exposed to ETS.[12–15] Of the deaths caused by ETS, the number of deaths from heart disease is about three times the number of non-cardiac deaths[16].

Cardiovascular deaths account for a significant portion of adult deaths in all countries. Worldwide, slightly more than 50 million people are estimated to have died in 1990, 53% of whom were males. Ischemic heart disease (IHD) was the leading cause of death worldwide, accounting for just under 6·3 million deaths – 2·7 million in established market economies (EME) and formerly socialist economies of Europe (FSE); 3·6 million in the developing regions. Stroke was the next most common cause of death (4·38 million deaths – almost 3 million in developing countries), closely followed by acute respiratory infections.[17] Of the various coronary heart disease pathologies, IHD and stroke predominate in the developed regions, accounting for 75–80% of all cardiovascular deaths. Stroke is proportionately more important as a cause of cardiovascular disease death in FSE (31%) than in EME (25%). Rheumatic heart disease is estimated to cause between 1% and 6% of all CHD deaths in the developing regions (and about 2·4% globally). The category labeled as inflammatory heart disease (pericarditis, endocarditis, myocarditis, and cardiomyopathies) accounts for similar proportions of CHD deaths, being highest in Sub-Saharan Africa (SSA) (7·8%). It is also worth noting the substantial contribution of IHD in all developing regions, ranging from 52% of cardiovascular deaths in India to 26% in SSA. Stroke, on the other hand, is by far the leading cause of cardiovascular deaths in China and SSA, causing roughly half of all coronary heart disease deaths in 1990.[18]

Future projections

Policy makers must be concerned not so much by the current mortality from past smoking patterns, but by the much larger death rates that are projected in coming decades as a result of current smoking, especially for low- and middle-income countries.

Smoking-attributable deaths are projected to increase for two reasons: first, increases in the susceptible population size; and second, increase in age-specific disease rates. For example in China, male per capita consumption of cigarettes rose 10-fold between 1952 and 1992. The incidence of lung cancer in China has increased more than sixfold during the period 1970 to 1980,[19] and is likely to increase 7·5-fold in the near future. During the same period, the population that will contract lung cancer will increase fourfold. The net result is that 30 000 lung cancer deaths per year in 1975 will increase to 90 000 per year by 2025.

Tobacco will cause 0·5 billion deaths among smokers alive today. At some point in the second decade of the twenty-first century, annual deaths from tobacco will average 10 million a year. This total may appear earlier or later. Depending on smoking patterns, there will be about 450 million tobacco deaths between 2000 and 2050.[8] Projections beyond 2050 are more uncertain. If the proportion of people taking up smoking continues, as at present, to be between one quarter and one third of young adults then, given population growth, an additional 500 billion tobacco deaths are expected in the second half of the twenty-first century. Thus, in the twenty-first century overall, tobacco would be expected, on current patterns, to kill about one billion people, or ten times as many people in the twentieth century.[7]

Direct estimates for China based on retrospective and prospective studies[3,4] suggest that, on current patterns, smoking may account for one in three of all adult male deaths in China, or about 100 million of the 300 million Chinese males now aged 0–29. Annual tobacco deaths will rise to 1 million before 2010 and 2 million before 2025, when young adults of today reach old age. Similar preliminary estimates for India based on large retrospective and prospective studies suggest that about 30% of all male deaths in middle age are attributable to smoking and about 80 million Indian males currently aged 0–34 will eventually be killed by tobacco.

Projections of tobacco mortality based on econometric models by Murray and Lopez suggest that there will be 8·3 million tobacco-attributable deaths per year in 2020. These researchers have predicted elsewhere that global deaths attributed to tobacco would rise from 6% of all deaths in 1990 to about 12% in 2020.[18]

Worldwide, a very large increase in deaths from non-communicable diseases (group 2) is expected, with a rise in annual mortality from an estimated 28·1 million deaths in 1990 to 49·7 million in 2020. Conversely, annual mortality from communicable maternal, perinatal, and nutritional disorders (group 1) is predicted to decline from 17·2 million in 1990 to 10·3 million in 2020 (Figure 10.3).

It is of interest to examine how DALYs (disability adjusted life years is a measure of life lost due to disability or premature

death) from various leading causes are expected to change over the next three decades (Figure 10.4). Figure 10.5 shows the change in cause of mortality. IHD is projected to be the leading cause of disability and death by 2020. It has been plausibly predicted that the current global total of about 3 million deaths per year from tobacco (2 million developed, 1 million developing) would reach approximately 10 million deaths per year (3 million developed, 7 million developing) during the second quarter of next century (Figure 10.6). This would mean that over 200 million of today's children and teenagers will be killed by tobacco, as well as a comparable number of today's adults, predicting that a total of about half a billion of the world's population today will be killed by tobacco. About 250 million will die in middle age (35–69), with each person losing about 20 years of life.[20]

In terms of DALYs, the contribution of tobacco is projected to increase to account for nearly 9% of worldwide burden (18·2% of burden in developed countries and 7·7% in developing countries) in 2020 (Figure 10.7). Tobacco is also projected to cause about 12% of deaths worldwide (17·7% of deaths) in developed countries and 10·9% in developing countries) by 2020 (Figure 10.8). DALYs from cancers are expected to rise from 5·1% to 9·9% of the worldwide total in 2020. The proportionate share of the global burden of disease due to cardiovascular diseases is projected

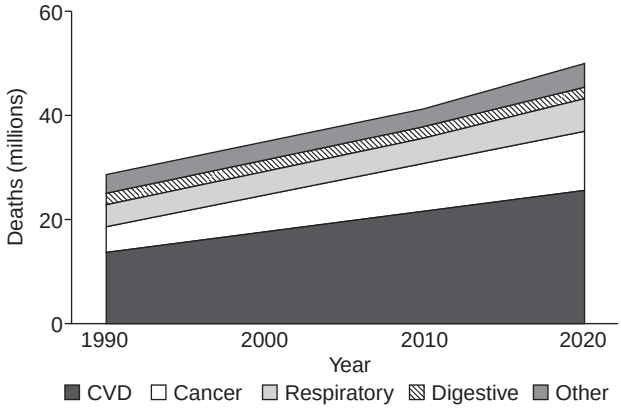

Figure 10.3 Baseline projections of deaths from group 2 causes, world, 1990–2020 (from Murray and Lopez, 1996, with permission)

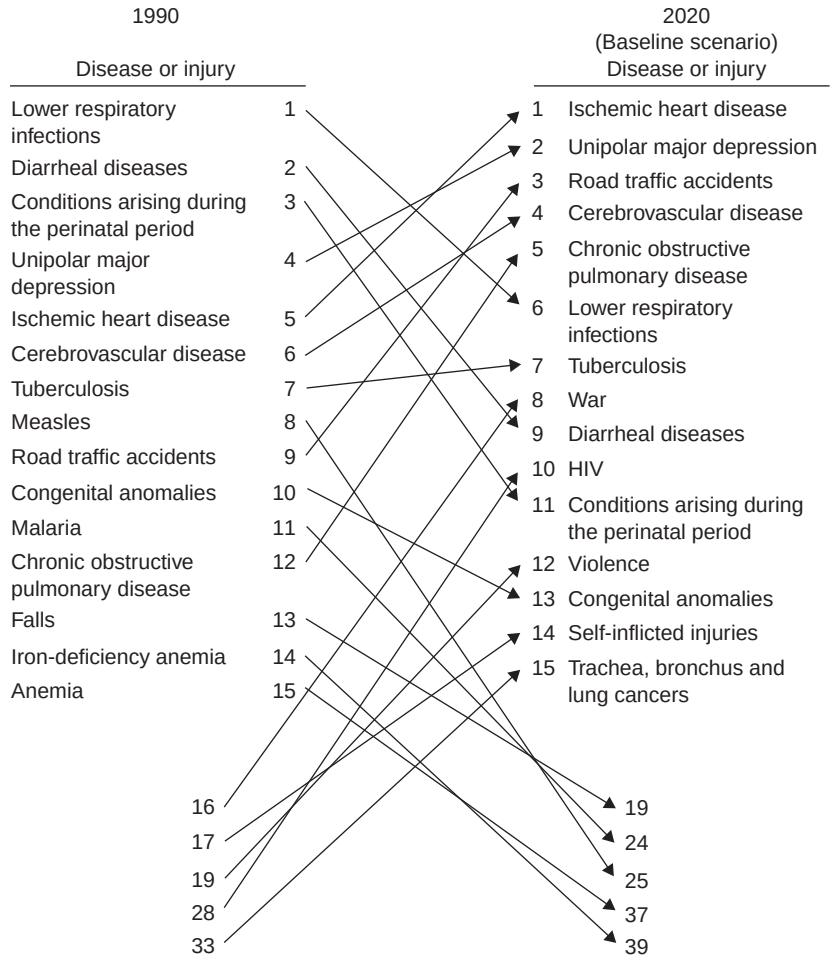

Figure 10.4 Change in rank order of DALYs for the 15 leading causes, world, 1990–2020 (from Murray and Lopez, 1996, with permission)

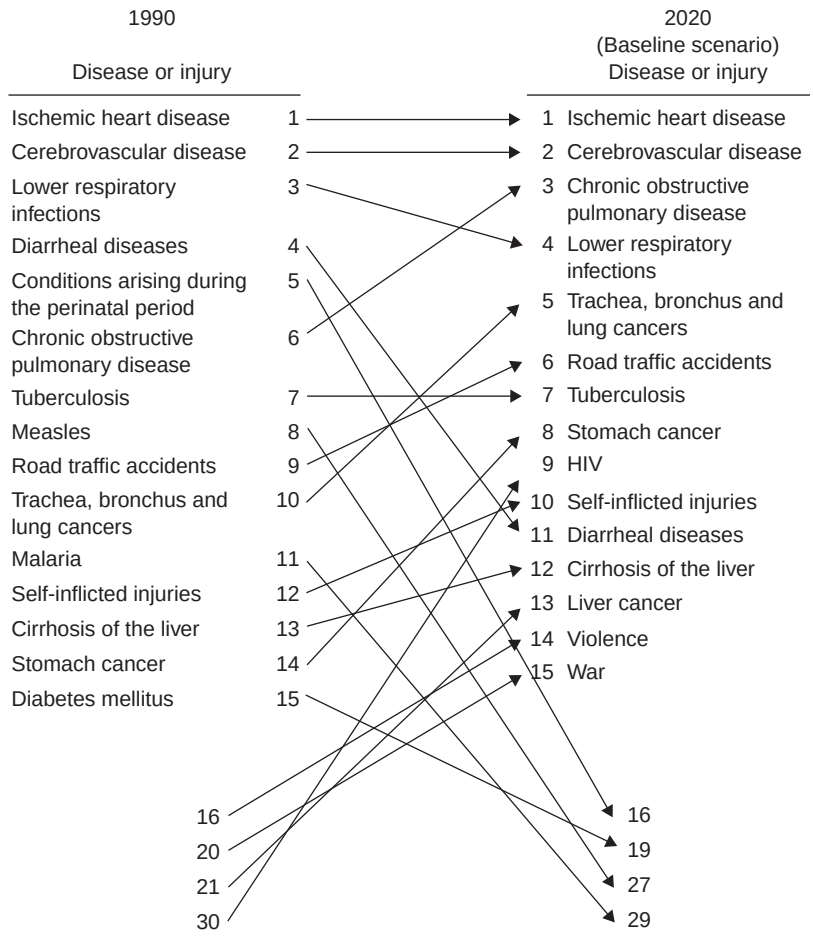

Figure 10.5 Change in rank order of deaths for the leading 15 causes, world, 1990–2020 (from Murray and Lopez, 1996, with permission)

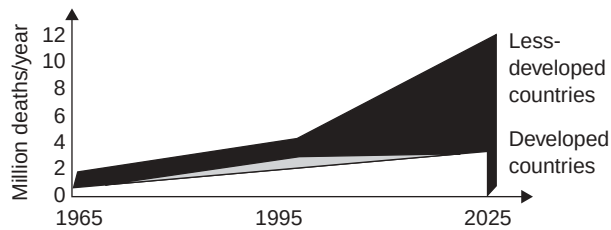

Figure 10.6 Annual deaths attributed to tobacco (WHO Program on Substance Abuse; WHO, 1995 A48/9)

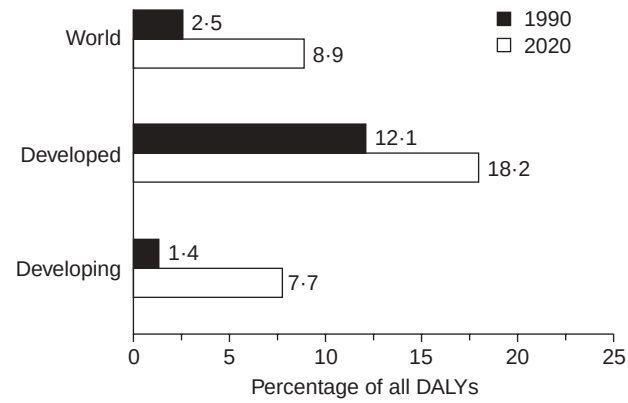

Figure 10.7 Tobacco as a cause of DALYs, 1990 and 2020 (WHO Program on Substance Abuse)

to rise from 11·1% to 14·75%.[17] In conclusion, tobacco is projected to be the leading cause of death and disability globally.

Community solutions

The relationship between smoking and cardiovascular morbidity and mortality was extensively documented throughout the last half of the twentieth century. Therefore, the reduction of tobacco use within populations has been a recommended strategy in the primary and secondary prevention of cardiovascular diseases for many years.[21] However, the development and testing of specific strategies to implement

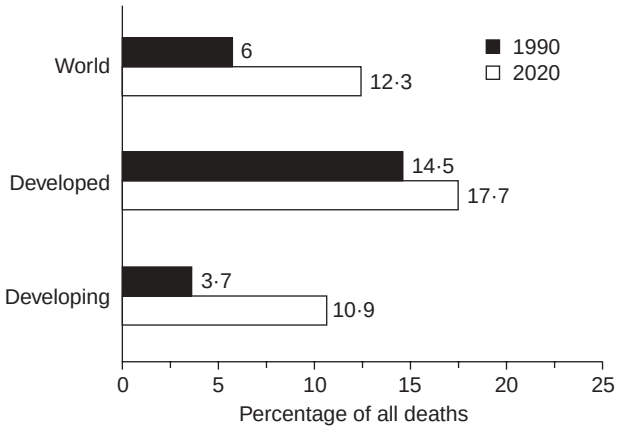

Figure 10.8 Tobacco as a cause of death, 1990 and 2020 (WHO Program on Substance Abuse)

this recommendation has proceeded more slowly. During this interval, there has been a paradigm shift from an individual or clinical approach to smoking prevention and cessation to a more public health or population-based approach.[22–24] Community-based cardiovascular prevention trials started in the early 1980s were conducted during this shift in paradigm.[25] Results from all of these trials showed significant declines in the prevalence of smoking overall; however, the declines in the intervention communities did not exceed the declines in the comparison communities by a statistically significant amount in several of the trials[26–28] nor in a joint analysis of the three US community trials.[29]

The community-based cardiovascular prevention trials initiated in the 1980s recognized that the critical behaviors related to cardiovascular risk (for example, diet, exercise, smoking) all involved individual choices but also involved societal or cultural barriers and enticements, monetary and opportunity costs, local and regional policies, and other communitywide factors.[25] The intervention methods which were developed in these trials shared many common elements, but largely were restricted from applying an ecological and policy oriented health promotion approach that combines educational, political, regulatory, and organizational supports for changes in the target health behaviors.[30] Green and Richard posit that the early community-based cardiovascular prevention trials could rely on an expansion of the traditional health education models which would initiate change in early adopters in societies.[30] However, as the rate of diffusion of the adoption of heart-healthy lifestyle changes (including smoking cessation) accelerated, these more traditional approaches lost efficacy.

The smoking cessation results from the community-based cardiovascular prevention trials initiated in the 1980s must be viewed as modest at best. While the Stanford Five-City Project observed a significantly greater decline (+13%) in smoking rates in the intervention communities among the cohort samples,[28,31] no effect on smoking rates was observed in the cross-sectional surveys by end of treatment[28,31] or at the follow up during which the comparison communities were declining somewhat, but not significantly, more rapidly than the intervention communities.[32] In the Minnesota Heart Health Project, the long-term smoking cessation results were mixed, with evidence of an intervention effect only for women in cross-sectional survey data.[26,33] Unexpectedly strong secular declines in smoking prevalence, especially among men, were observed in comparison communities. In the Pawtucket Heart Health Program, the prevalence of cigarette smoking declined slightly, but not significantly, more in the comparison community.[27]

More recently, the German Cardiovascular Prevention Study has reported more encouraging treatment effects for smoking, observing a 6·7% decline in smoking, with the strongest effect in men.[34] Among men, the prevalence of smoking among 25–69 year olds declined from 41·8% in 1985 to 39·2% in 1991 in the national reference sample, in comparison with the significantly greater decline from 44·5% to 37·4% in the intervention regions. This result is consistent with the diffusion model posited by Green[30] that the largely individually oriented health educational approaches applied in the community-based cardiovascular prevention trials initiated in the 1980s have their largest impact among populations who are at the earlier stages of adoption of the recommended preventive lifestyle.

In addition to the community-based cardiovascular prevention trials initiated in the 1980s, the Community Intervention Trial for Smoking Cessation (COMMIT) was started in the late 1980s. COMMIT focused solely on smoking cessation and built upon the initial experience in the ongoing cardiovascular prevention trials. Additionally, COMMIT was planned as a randomized community trial with 11 pairs of communities and had adequate power to detect relatively small intervention effects.[35] The modest effects observed in this trial were very sobering for the public health community. No cessation effect was observed for the "heavy" smokers (defined as smoking 25 or more cigarettes per day at baseline) for whom the trial was specifically designed. Among the evaluation cohorts of light-to-moderate smokers, a significantly greater quit rate (30·6% *v* 27·5%) was observed over the 4 year intervention period, with the effect strongest among the less educated residents of the communities.[36,37] Overall, the prevalence of smoking declined slightly, but non-significantly, more in the intervention communities (3·5 percentage points) than in the comparison communities (3·2 percentage points). While the COMMIT intervention protocol sought to apply the best smoking cessation strategies available, investigators were limited in their ability to be involved in many of the ecological and policy oriented health promotion strategies which Green and others[25,30] recommend due to the federal sources

of funds for the study. While an intervention "receipt index" of the strategies applied significantly correlated with quit rate differences across the 11 community pairs among the light-to-moderate smokers, process data showed that implemented protocol did *not* change many important intermediate variables (for example, MD/DDS counseling rates, worksite smoking bans, public attitudes toward smoking).

Several reviewers have provided some perspectives on the modest smoking cessation effects which have been observed in these community trials.[38–40] Common themes are: (1) the difficulty in observing intervention effects relative to the large secular declines in cardiovascular risk factors, including smoking, occurring during the period when the trials were implemented, and (2) the need for a more comprehensive health promotion approach to be applied. Concurrent with the implementation of these intervention trials, a broader national movement to reduce tobacco use emerged with a focus on the principles of health promotion. This concept, which included an organized approach to changing social, economic, and regulatory environments, emerged as a more effective mechanism for population behavior change than traditional health education, and included mobilization at the national, state, and local level.[41]

In 1991, the National Cancer Institute launched the American Stop Smoking Intervention Study for Cancer Prevention (ASSIST) program as a 7 year demonstration project. ASSIST included 17 states, and was the largest tobacco control project in the United States ASSIST was predicated on a coalition model, and was designed to demonstrate that a comprehensive, coordinated intervention effort could significantly reduce smoking and tobacco use. In 1993, CDC began the Initiatives to Mobilize for the Prevention and Control of Tobacco Use (IMPACT) program, which provided funding for 32 states to build capacity in state health departments to conduct effective tobacco control. Based on the lessons learned from ASSIST, IMPACT, and large state programs such as those of California and Massachusetts, the National Tobacco Control Program (NTCP) was developed to support all 50 states, seven territories, and the District of Columbia plan, establish, and evaluate comprehensive tobacco prevention and control programs.[41]

Through evidence-based analyses of California and Massachusetts, in-depth involvement with settlement States, and published evidence of effective tobacco control strategies, the federal government has set forth "best practices" recommendations for state-based programs which contain the following elements[42]:

- community programs to reduce tobacco use
- chronic disease programs to reduce the burden of tobacco-related diseases
- school programs
- enforcement
- statewide programs
- counter-marketing
- cessation programs
- surveillance and evaluation
- administration and management.

Because tobacco use is ultimately an individual behavior, educational and clinical public health approaches have historically been individually focused. In the area of tobacco use prevention among youth, this has been particularly true. In the past two decades, however, excellent social-psychological approaches have been applied to school-based prevention programs.[41] Evidence shows that school-based smoking prevention programs that identify social influences to smoke and teach skills to resist those influences have demonstrated consistent and significant reductions in adolescent smoking prevalence, and that larger-scale implementation of intensive interventions can achieve long-term reductions in cigarette smoking among young people.[41] The durability of this effect is enhanced by community wide programs that involve parents, mass media, community organizations, and other elements of an adolescent's social environment.[42] Educational strategies, conducted in conjunction with community and media-based activities, can postpone or prevent smoking onset in 20–40% of adolescents.[41] Unfortunately, the full range of recommended community wide efforts to modify the social environments of adolescents,[42] including removal of pervasive imagery-based pro-tobacco advertising, significant tobacco tax increases, enhanced enforcement of minors' access laws, and well financed and sustained youth oriented counter-advertising campaigns, need to be applied in conjunction with experimentally tested school-based tobacco use prevention curricula and tobacco-free school policies.

The efficacy of a comprehensive approach to youth tobacco use prevention was originally demonstrated in Massachusetts and California, who funded their programs with dedicated excise tax dollars. During the period of the 1990s when smoking rates among the youth in the United States were consistently increasing, rates in Massachusetts and California appear to have risen more slowly[43] and even declined among 7–8 graders in Massachusetts.[44] With the influx of revenues resulting from state settlements with the tobacco industry and increases to state tobacco excise taxes, additional states, such as Minnesota, Florida, Arizona, and Oregon have also been able to implement comprehensive tobacco control programs.[41]

In many ways, efforts to assist adult smokers to quit smoking have made the slowest progress in the paradigm shift from the clinical to the public health model. However, advancements in treating tobacco use and nicotine addiction were summarized in a recent guideline: *Treating tobacco use and dependence: a clinical practice guideline*, published by the

US Public Health Service. The guideline provides a blueprint to healthcare professionals and health insurance providers for implementing appropriate medical services that will help treat nicotine addiction. Less intensive interventions, as simple as physicians advising their patients to quit smoking, can produce cessation rates of 5–10% per year. More intensive interventions, combining behavioral counseling and pharmacologic treatment, can produce 20% to 25% quit rates in one year.[45] The most significant and sustained declines in population levels of cigarette consumption have been observed in states where changes in the social environments rather than enhanced clinical services have been the focus of the programs.[46] For example, studies have found that moderate or extensive laws for clean indoor air are associated with a lower smoking prevalence and higher quit rates.[41] There is clear and compelling scientific evidence which demonstrates that increasing the price of cigarettes is an effective way to prevent smoking initiation among youth, promote smoking cessation among adults, and reduce cigarette consumption among continuing smokers.[41] Therefore, because increased excise taxes increase the price of cigarettes, they provide a cost effective short-term strategy to reduce tobacco use. Research indicates that for every 10% increase in price, overall smoking rates would decrease by 3–5%, and as high as 7% among youth.[41] Studies of smokeless tobacco products suggest that increasing their prices would reduce the prevalence of smokeless tobacco use as well.[41] Even greater decreases can be achieved when an adequately funded comprehensive tobacco prevention and control programs are combined with a price increase.

This has been demonstrated in California, where a tobacco control program has been funded by excise tax revenues since 1989, and tobacco rates have declined at rates two or three times faster than the rest of the country. California also has the distinction of being the first state to demonstrate a reduction in tobacco-related deaths. The incidence of lung cancer in California has declined significantly faster than in other parts of the United States and this state has also seen dramatic declines in cardiovascular disease death rates.[47]

Tobacco products have been largely unregulated in comparison to other consumer products. While the importance of nicotine addiction is now well recognized as a factor maintaining tobacco use behaviors,[48] regulatory efforts to decrease the addictiveness of the product are only now emerging.[49] Smokers receive very little information regarding chemical constituents when they purchase a tobacco product. Without information about toxic constituents in tobacco smoke, the use of terms such as “light” and “ultra light” on packaging and in advertising may be misleading to smokers. Also, because cigarettes with low tar and nicotine contents are not substantially less hazardous than higher-yield brands, consumers may be misled by the implied promise of reduced toxicity underlying the marketing of such brands.[41]

Currently all 50 states and the District of Columbia have tobacco control programs in place that have the potential to achieve positive results in reducing tobacco use. CDC has synthesized an evidence-based comprehensive framework for statewide programs to reduce tobacco use. The framework integrates four program goals with four program components; optimally, each of the goals would be fully addressed in the implementation of each of the components, within each of the *Best practices* guidelines. The program goals for reducing tobacco use statewide include:

- Prevent initiation among young people.
- Promote quitting among adults and youth people.
- Eliminate exposure to environmental tobacco smoke.
- Identify and eliminate disparities among population groups.

The program components for reducing tobacco use statewide include:

- community interventions
- counter-marketing
- program policy and regulation
- surveillance and evaluation.

Aggressive and comprehensive tobacco control programs in a number of states have produced substantial declines in cigarette use. The findings from multiple states were reviewed by the US Surgeon General in the report, *Reducing tobacco use*.[41] For example:

- In California, home to one of the longest-running tobacco control programs, the overall prevalence of tobacco use has declined at nearly twice the rate of that in the United States. The declines in the rates of lung cancer and heart disease have also been significantly faster than in other parts of the country. California is also the first state to experience a decrease in tobacco-related deaths.
- In 1992, Massachusetts initiated a comprehensive statewide tobacco control program. From 1992–2000, per capita consumption declined by 36%, when the rate of decline in the remaining 48 states was only 16%. A decline in smoking prevalence among adults was also greater than in the rest of the country (excluding California). From 1995–1999, smoking declined by 70% among 6th graders, and by 38% among 7th and 8th grade students.
- Florida’s tobacco control program, which combined a counter-marketing media campaign, community-based activities, education and training, and an enforcement program, in concert with a state excise tax increase, has effectively reduced teen tobacco use. Among middle school students, tobacco use declined by 47%, from 18·5% in 1998 to 9·8% in 2001. Among high school students, current cigarette use declined by 30%, from 27·4% in 1998 to 9·0% in 2001.

- With the support of a dedicated excise tax, Arizona was able to begin funding a comprehensive tobacco control program in 1996 that includes all nine *Best practices* components. From 1996 to 1999, the proportion of healthcare providers encouraging patients to quit smoking increased significantly. Also during this time, smoking prevalence has declined significantly in women and men, whites and Hispanics, and people with low income and low education.
- With the support of a dedicated excise tax, Oregon launched a comprehensive statewide tobacco control program in 1997. From 1997–1999, Oregon experienced a 2·3% decline in consumption from 1996 to 2001, and in prevalence of smoking among adults, pregnant women, and youth. By following the lessons learned by more experienced states, Oregon was able to operate more efficiently, and has seen reductions in prevalence in spite of spending less than the *Best practices* minimum guidelines. This "Oregon Model" is now being quickly diffused out to other states to guide the development of newly funded programs.

  The Oregon program included an implementation of CDC's *Guidelines for school health programs to prevent tobacco use and addiction* in 30% of their schools. This demonstration found that a comprehensive school-based tobacco prevention program that includes tobacco-free school policies and community involvement as one component of a statewide tobacco program may contribute to reductions in current smoking among 8th graders. Also, the significantly greater declines in smoking prevalence in the schools that rated high and medium on implementation criteria emphasize the importance of monitoring activity in funded programs and the need for on-going assistance to facilitate implementation of evidence-based recommendations.

As results are obtained from these most recent states as well as continuing data from California and Massachusetts, our understanding of the potential effectiveness of the full multicomponent population-based approach to tobacco prevention and control will be expanded. However, the data already sufficient for the US Surgeon General to conclude that if the recommended intervention strategies were fully implemented, rates of tobacco use in the US could be cut in half by the year 2010.[41]

11 Tobacco and cardiovascular disease: achieving smoking cessation

Godfrey H Fowler

Worldwide, there are about one billion current smokers and about three million die annually from their smoking, half before the age of 70; this includes about 150 000 annually in the UK and half a million in the USA.[1] Even in countries where the health hazards of smoking are widely acknowledged, it remains a common behavior: in the USA and Canada, for example, about a quarter of all adults smoke, and, in the UK, the situation is worse with about one third of adults smoking.

Cardiovascular disease, in particular ischemic heart disease, is the commonest smoking-related cause of death in developed countries.[2] This is because, although the relative risk of death from cardiovascular disease in smokers, compared with non-smokers, is much lower than the relative risk from cancer (in particular lung cancer) and chronic obstructive lung disease, ischemic heart disease is much the commonest cause of death in these countries. Overall, the relative risk of death from cardiovascular disease in smokers compared with non-smokers is roughly doubled, though this varies with the different cardiovascular diseases and is greater at a younger age. Passive smoking also increases the risk of cardiovascular disease but the extent of this increase remains uncertain.[3,4]

Strategies for tobacco control

Strategies for reducing the health consequences of smoking should aim to:

- reduce the uptake of smoking by young people;
- increase the numbers of smokers stopping smoking;
- encourage a shift to less harmful tobacco use;
- decrease exposure to environmental tobacco smoke.

Reducing the uptake of smoking by young people is a priority in many countries. Laws to ban tobacco sales to those below a certain age and to prohibit tobacco advertising and promotion are common in developed countries but are frequently contravened. Other measures include restrictions on smoking in public places, fiscal policies to increase the cost of smoking, and a variety of educational programs. In spite of these, smoking prevalence in teenagers has remained remarkably resistant to change over the last decade, and in the UK about a quarter of young people are regular smokers by the age of 16 years.

Modification of cigarettes, particularly with regard to tar yield, over the last two or three decades has undoubtedly contributed to less harmful tobacco use, but it should be emphasized that this is no substitute for tobacco avoidance. However, although such changes have certainly contributed to a decline in lung cancer, possible benefits from these changes relating to cardiovascular disease have not yet been established with certainty.[5]

Decreased exposure to environmental tobacco smoke is a desirable objective in itself but, again, the contribution this might make to reducing cardiovascular disease risk is very difficult to estimate.

For established smokers, smoking cessation is the most important step for safeguarding future health, and this chapter will consider evidence-based methods of achieving this objective.

Evidence of benefits from smoking cessation

Many observational epidemiologic studies have investigated the effect of stopping smoking on smoking-related diseases, and there is a wealth of evidence that, not only is tobacco smoking a major risk factor for cardiovascular disease, but also stopping smoking reduces this risk. **Grade B** However, there is less agreement about the rate at which the risk attenuates after smoking cessation. In the 20 year follow up of the British Doctors Study, for example, excess risk was halved within 2 or 3 years of smoking cessation, and by 10 years the risk had returned to that of a non-smoker (Figure 11.1).[6]

However, follow up of the cohort men in the British Regional Heart Study indicates that attenuation of risk is much slower, and even men who had given up smoking for more than 10 years still had an increased risk, compared with non-smokers (Figure 11.2).[7]

Following myocardial infarction (MI), smoking cessation confers substantial benefits and is particularly important. In one observational study, stopping smoking halved both the number of non-fatal recurrences and the number of cardiovascular deaths (Figure 11.3).[8]

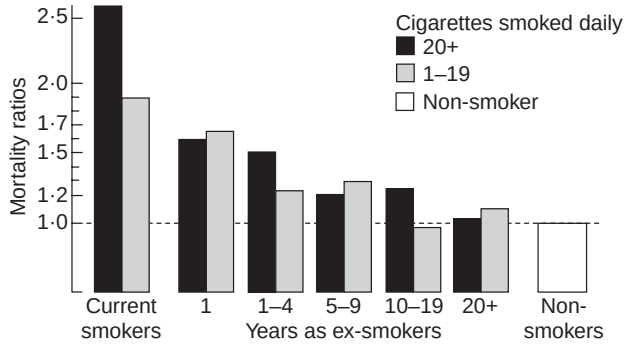

Figure 11.1 Diminished risk of death from coronary heart disease in former light and heavy smokers. Both light and heavy smokers show a steady decline in risk after stopping until, after 10–20 years, it is little different from the risk of non-smokers. (Source: Royal College of Physicians. *Smoking or health?* London: Pitman Medical, 1977.)

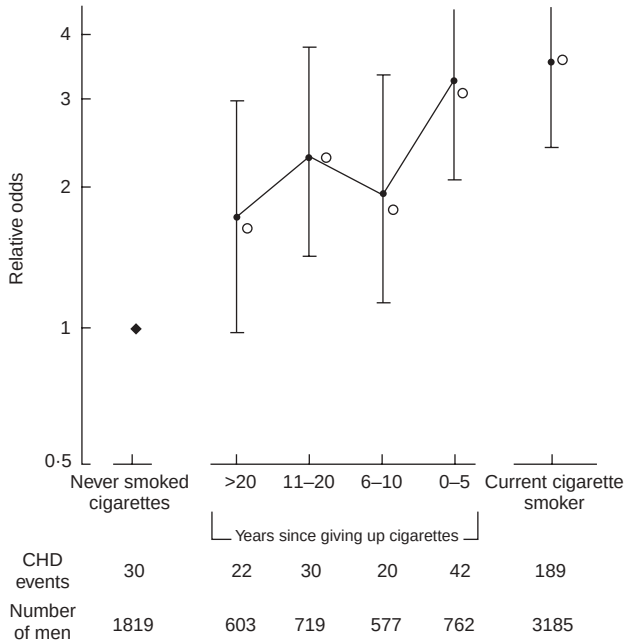

Figure 11.2 Relative odds of a major CHD event in relation to years since stopping smoking cigarettes. (Source: Cook *et al.*[7])

In another study, follow up over 13 years of post-MI patients showed a 37% mortality in those who had stopped smoking, compared with 82% mortality in those who continued smoking.[9] Furthermore, a UK trial of smoking cessation advice in smokers with evidence of ischemic heart disease showed a (non-significant) 13% difference in cumulative CHD deaths over 20 years in those given smoking cessation advice, compared with those who were not.[10]

The mechanisms through which tobacco smoking mediates its adverse cardiovascular effects are largely unknown and certainly multiple. There is evidence that smoking contributes to both the atherosclerotic and the thrombotic processes; free radical damage to vascular endothelium has been demonstrated, as have effects on platelet survival, platelet aggregation, and fibrinogen levels.[11–13]

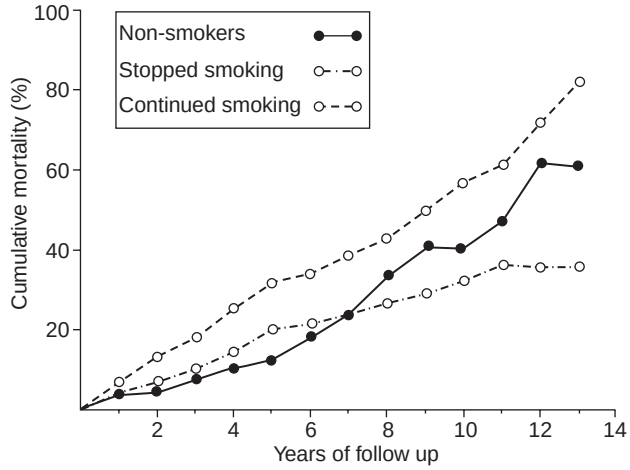

Figure 11.3 Cumulative mortality for 498 survivors of a coronary attack by smoking habit. Life-table curves start 2 years after attack. Average annual mortality was 6.5% in non-smokers, 3.7% in those who stopped smoking, and 10.2% in those who continued smoking. (Source: Daly *et al.*[8])

The nature of tobacco smoking

Before individual smoking interventions and cessation methods are considered, it is helpful to review briefly the nature of tobacco smoking and the consequent implications for interventions.

Tobacco smoking is a complex behavior to which psychologic, social, and pharmacologic factors contribute.[14] Its acquisition is almost invariably in adolescence, as the result of desire for experimental rebellious behavior, which is perceived as adult and encouraged by peer group pressure. However, pharmacologic addiction usually then becomes a factor determining persistence of the behavior, making it difficult to stop because of the addictive effects of nicotine and the discomforts associated with withdrawal. Although the balance between psychologic factors and pharmacologic addiction varies from smoker to smoker, there is now increasing awareness of the importance of nicotine addiction in maintaining smoking behavior, and the powerful nature of this addiction has been compared with addiction to heroin or cocaine.[15]

The evidence basis for smoking cessation

Emphasis on smoking cessation in individual established smokers is a vital component of any tobacco control strategy and should complement efforts to prevent the uptake of smoking by young people. Individual approaches to both cessation and avoidance can only be supplementary

to "whole population" approaches, including legislation (banning sales to "minors" and controlling advertising promotion), restrictions on smoking, public information and campaigns, tax measures, and so on. **Grade A**

For many established smokers, stopping smoking is very difficult, for both behavioral and psychopharmacologic reasons, and only a minority of established smokers ever succeed in stopping for good. Most of those who succeed in stopping find the process of stopping is a dynamic one rather than a single discrete event (Figure 11.4).

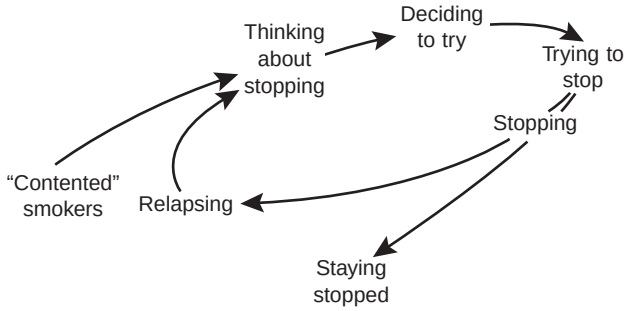

Figure 11.4 Stopping smoking is a process

Relapses are common and eventual success is usually the outcome of many attempts. Motivation to stop and confidence in the ability to succeed are important predictors of success. Relapse in the first few weeks is a common pattern, but the tendency to relapse declines as time progresses and most of those who manage to avoid relapse for a year are then able to achieve sustained abstinence.

The great majority of those smokers who do achieve long-term smoking cessation do so on their own without any special aids or assistance, but research has shown that smoking cessation advice and support from a health professional and the use of smoking cessation aids can enhance the chances of success.[17]

As already indicated, motivation to stop smoking is critical to success and this motivation may be determined by a variety of concerns – personal health, family health, financial anxieties, social pressures, and so on. The so-called Stages of Change model acknowledges different levels of motivation and activity, from precontemplation through contemplation, preparation and action, to maintenance or relapse.[18] Identification of the stage at which an individual smoker is can enable motivational or interventional methods to be targeted more appropriately (though the evidence basis for the effectiveness of such targeting is currently lacking).

A favorable factor is that the majority of smokers in many countries report that they want to quit smoking and have tried to do so, often many times. They also cite advice from a health professional as being important to them in influencing their motivation to quit. Surprisingly perhaps, only a minority of smokers say they have ever been asked by a doctor about smoking and advised to stop.[14]

Community interventions

Community- or population-based smoking cessation interventions have been implemented in a number of settings. Typically, they involve use of mass media to promote public awareness and education, to encourage health professionals to raise smoking as an issue in consultations with patients, and to offer self-help materials. Evaluation of the effectiveness of such programs is difficult and they are discussed in Chapter 10.

Individual advice

Nicotine addiction is now acknowledged as a treatable condition[16] and there is substantial scientific evidence of the effectiveness of behavioral and pharmacologic interventions. Individual smoking interventions by health professionals have been extensively studied.[17] An early and influential trial in the UK was conducted by Russell and colleagues in general practices in London in the 1970s. In this study, over 2000 smokers attending their general practitioners for routine consultations were randomly allocated to a non-intervention control group and three intervention groups:

- **Grade B** completion of a brief smoking questionnaire;
- brief (1–2 minutes) smoking cessation advice; and
- brief advice supplemented with a simple self-help smoking cessation leaflet.

Smoking cessation rates achieved at 1 month and sustained for 1 year were 1·6%, 3·3%, and 5·1% respectively in the three intervention groups compared with 0·3% in the control group (Figure 11·5).[19]

Many similar randomized controlled trials of simple, brief smoking cessation advice in medical settings have subsequently been conducted and this finding of a small percentage of biochemically validated long-term smoking cessation, resulting from such interventions, has been replicated.[20]

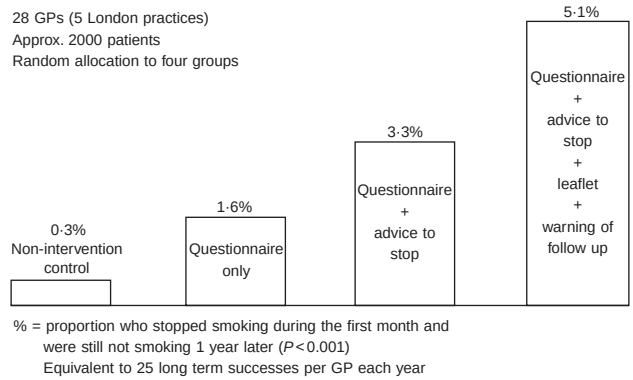

Figure 11.5 Effect of GP's advice against smoking. (Based on Russell *et al.*[19])

Nicotine replacement therapy (NRT)

The advent of nicotine chewing gum in the 1970s provided the first specific pharmacologic "treatment" for smoking cessation. **Grade B** Subsequent development of transdermal nicotine patches, nicotine nasal sprays, and nicotine oral inhalers has increased the range of products available. The objective in using these "nicotine replacement" products is to provide a temporary alternative source of nicotine to allay withdrawal symptoms and so enhance the potential for smoking cessation. Large placebo-controlled trials have clearly demonstrated that the use of such products as an adjunct to advice from a health professional can approximately double smoking cessation rates, compared with placebo.[21,22] Several systematic reviews of the many trials that have now been conducted with them have confirmed the benefits and shown that all preparations are effective, but the evidence is particularly substantial for nicotine gum and nicotine patches.[23,24] Both appear to have similar effectiveness but, because of greater social acceptability, ease of use, and simpler compliance, transdermal patches have been found by many to be preferable, though gum appears more effective for the most dependent smokers. A summary of the effectiveness of NRT and estimates of the number needed to treat (NNT) to achieve one success are provided in Table 11.1.

Table 11.1 Nicotine replacement therapy preparations and abstinence

NRT preparation (*n* of trials)	% Quitting		OR (95% CI)	NNT
	Active	Control		
Gum (39)	18·2	10·6	1·6 (1·5–1·8)	13
Patches (9)	20·5	10·8	2·1 (1·6–2·6)	10
Nasal spray (1)	25·9	9·9	2·9 (1·5–5·7)	6
Inhaler (1)	15·2	5·0	3·0 (1·4–6·6)	10

Abbreviations: NRT, nicotine replacement therapy; OR, odds ratio

Concern has been expressed about the use of NRT in patients with cardiovascular disease because of the potential adverse effects of nicotine on the cardiovascular system. In considering this issue, it is important to be aware that use of NRT is advocated only as a temporary substitute source of nicotine in those already self-administering this drug through tobacco smoking. It is also important to bear in mind that blood levels of nicotine achieved with NRT are substantially lower than those achieved by moderate or heavy smoking. Furthermore, there is no evidence that nicotine itself contributes to the atherogenic or thrombotic processes, unlike tobacco smoking.

In a placebo-controlled randomized trial specifically investigating the safety of transdermal nicotine patches in patients with cardiac disease, no increase was found in rates of arrhythmia, MI, or death in high-risk patients (with a history of MI or coronary revascularization procedure, or of angina, heart failure, arrhythmia, peripheral vascular disease, or cerebral vascular disease) in those using nicotine patches compared with those using placebo patches.[25] A review of the potential adverse effects of NRT in patients with cardiovascular disease concluded that there is no evidence to justify the withholding of these products in such patients who smoke and are motivated to stop.[27]

Bupropion (Zyban)

Originally developed as an antidepressant, bupropion (which is an inhibitor of neuronal uptake of norepinephrine, dopamine and serotonin) was found to apparently aid smoking cessation. Subsequent evidence from placebo-controlled trials[26] has confirmed this and indicate that it is at least as effective as NRT. Although side effects are rare, there is a risk of seizures in about 1 in 1000 users. It should not therefore be used by patients who have a past history of seizures and who are on drugs known to lower the threshold for seizures; this includes antipsychotics, antidepressants, antimalarials, theophylline, quinalones, and sedating antihistamines.

There is no evidence of other adverse effects in patients with cardiovascular disease and it may therefore be used by such patients. Whereas NRT should be started only when stopping smoking is actually attempted, bupropion treatment needs to be initiated 2 weeks before the attempt is made. The limited evidence currently available suggests that the combination of NRT and bupropion may be more effective than either alone, but more research is needed to elucidate this.

Review of cessation studies

Grade A In a comprehensive systematic review of 188 randomized controlled trials of the efficacy of a wide range of interventions aimed at helping people to stop smoking, it was concluded that simple advice, even on one occasion only, given by a doctor in general or family practice or in a hospital clinic to all smokers who consulted, resulted in sustained cessation of about 2% and that additional encouragement and support (additional visits, exhaled CO measurement, letters, etc.) further enhances this effect.[28] Whether similar interventions delivered by nurses are equally effective remains uncertain,[29] although there is evidence that nurse support, subsequent to doctor advice, can enhance the effect of this.[30]

This comprehensive review[25] also endorsed the use of nicotine replacement therapy but concluded that a variety of other smoking cessation interventions – hypnosis, acupuncture, aversion therapy, and pharmacologic agents other than nicotine, which are sometimes advocated – have

Table 11.2 Summary estimates of randomized controlled trials of interventions to help people to stop smoking

Intervention	% Estimate of efficacy (95% CI)	Statistical significance	Subjects (trials) (*n*)	Comment
Simple physician advice (once)	2 (1–3)	<0·001	14 438 (17)	Effective
Physician advice with additional encouragement/support	5 (1–8)	<0·01	6466 (10)	Effective
Nurse advice	1 (−1–3)	>0·10	3369 (2)	Unproven
Advice in infarct survivors	36 (23–48)	<0·001	223 (1)	Important
Advice in healthy men at high CHD risk	21 (10–31)	<0·001	13 205 (4)	Important
Hypnosis	24 (10–38)	<0·001	646 (10)	No trials with biochemical validation
Acupuncture	3 (−1–6)	>0·10	2759 (8)	No trials with biochemical validation

Adapted from Law *et al*[28]

not been shown by rigorous scientific evidence to be effective, although it must be acknowledged that the methodologic problems associated with attempts to evaluate these have yet to be overcome. A summary of estimates of effectiveness is provided in Table 11.2.

Specialist smoking cessation clinics

Specialist smoking cessation clinics have been shown to deliver effective interventions and can make a useful contribution to the provision of individual interventions, usually by providing regular group treatments. There is some evidence that they can achieve enhanced attendance and abstinence rates as high as 20% or more, but interpretation of their success should take account of the fact that they recruit widely and participants are generally highly motivated to stop, compared with the majority of those expressing an intention to do so. When available, they offer a self-referral and secondary referral service and can provide valuable opportunities for smoking cessation research.[31] However, as they are relatively few in number in relation to the huge need for such interventions, their overall contribution will inevitably be small.

Practical aspects of smoking cessation in clinical practice

The essential features of individual smoking cessation interventions in medical practice are to:

- *assess* in any medical consultation the smoking status of the patient, whether a non-smoker, smoker or ex-smoker;
- *advise* all smokers about the desirability and importance of stopping smoking because of health hazards, especially those who already have smoking-related diseases;
- *assist* smokers to stop smoking, particularly those with smoking-related diseases and especially if expressing interest to do so;
- *follow up* at subsequent consultations to assess the outcome and, if necessary, further assist those trying to stop smoking while encouraging ex-smokers to maintain their non-smoking status.[32]

Assessment

The smoking status of all patients should be recorded in medical records in such a way that the information is easily accessible in future consultations. Assessment of smoking should include a brief history of the patient's smoking, including attempts to stop and their current tobacco consumption. Assessment of nicotine addiction should also be made by inquiring how soon after waking they smoke their first cigarette and some assessment of their motivation to stop smoking.

Advice

Grade B All patients with smoking-related diseases should be advised to stop smoking and any reasons that patients put forward for wanting to stop smoking should be strongly reinforced.

Assistance

Specific help with smoking cessation should be strongly influenced by patients' preferences and patients should

themselves be active in deciding what to do. There is no set "prescription" for how to go about stopping smoking, but it is possible to provide guidance, which experience has shown to be useful. It is important to adopt an individual approach but guidance might include:

- **Grade A** setting a target date for stopping;
- some preparation for stopping, review of motivation and reasons for stopping;
- awareness of times when a particular need is felt for a cigarette, and attempts to change routines to avoid association of these times with smoking;
- eliciting support for cessation from friends and colleagues and, ideally, recruiting a fellow smoker (particularly a spouse) to join in the attempt to give up smoking.

Generally, sudden complete withdrawal is likely to be more successful than attempts to gradually reduce smoking. Strategies need to be planned for coping with withdrawal symptoms and other difficulties likely to be encountered immediately after cessation; avoidance of other smokers and smoking environments is likely to be important, particularly at "danger times", like teabreaks and after meals or when having a drink.

A number of self-help leaflets are available from a variety of sources to supplement and reinforce such simple guidance. These leaflets have particular value and effectiveness when handed out by health professionals as an adjunct to brief advice.

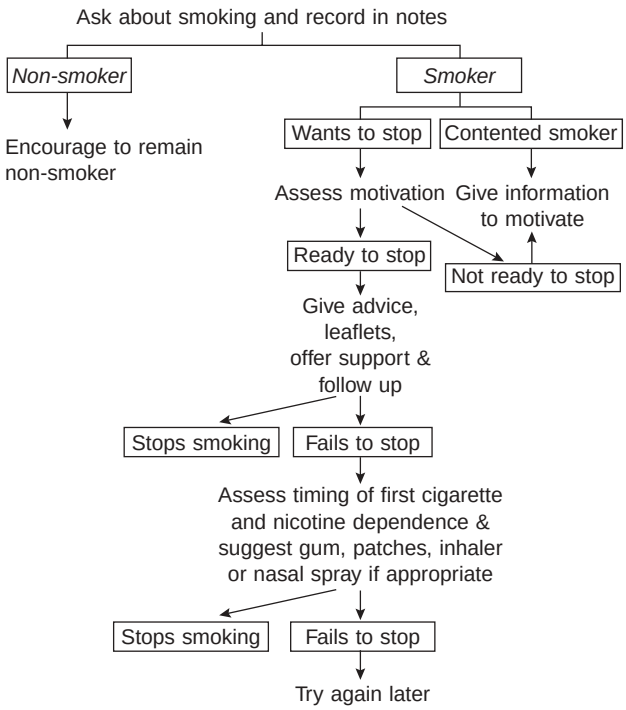

Figure 11.6 Smoking cessation protocol for doctor/nurse intervention

Use of NRT should be encouraged in all those (except perhaps the lightest smokers) for whom advice and self-help are not enough. Assessment of nicotine dependence is most simply done by asking how soon after waking the first cigarette is smoked. If this is within half an hour, this is evidence of at least moderate dependence and suggests likely benefit from using NRT.

As already indicated, although there is debate about the safety of using NRT in patients with cardiovascular disease, evidence of harm from doing this is lacking but there is some evidence that suggests that it is safe. This is likely to be so if nicotine gum or patches are used (as they should be) as a temporary substitute for smoking. A combination of smoking and nicotine replacement may well be potentially harmful and should be strongly discouraged. A simple smoking cessation protocol is illustrated in Figure 11.6.

Key points

- Tobacco smoking is a critically important, modifiable cardiovascular risk factor (especially in those with established cardiovascular disease).
- Smoking cessation attenuates cardiovascular risk and early benefits accrue (again, especially in those with established cardiovascular disease).
- There is good evidence for the effectiveness of simple, brief smoking cessation advice and the use of NRT as an adjunct to this. NRT is effective and safe.
- Smoking and smoking cessation should be routinely addressed by health professionals in any consultations with patients who smoke.
- Simple cessation advice and support should be routinely offered by healthcare professionals in any consultations with patients who smoke.
- NRT – chewing gum, transdermal patches, nasal spray, or oral inhaler – should be recommended to all smokers trying to quit. Encouragement and support should accompany this, and compliance for 2 or 3 months should be encouraged in those who achieve short-term abstinence with it.
- Bupropion (Zyban) is a proven alternative to NRT.

12 Lipids and cardiovascular disease

Malcolm Law

For many years the issue of lipids and cardiovascular disease was seen as controversial and difficult to resolve, yet the high-fat diet typical of many western countries over the greater part of the 20th century has proved to be the major underlying factor in the epidemic of ischemic heart disease, and modern cholesterol lowering drugs can reduce risk more than any other single intervention.[1]

Serum total and low density lipoprotein cholesterol

Typical values of serum total and low density lipoprotein (LDL) cholesterol in western countries are high in comparison to those in agricultural and hunter–gatherer communities, because of the high saturated fat content of the western diet. Average serum cholesterol concentration (in men aged 45–60) is about 3–3·5 mmol/l in hunter–gatherer societies and rural China (where heart disease is rare), 5·0 mmol/l in Japan, 5·5 mmol/l in Mediterranean populations and a little higher in the USA, and 6 mmol/l in Britain and several other European countries.[2] Average levels of LDL cholesterol are about 2 mmol/l lower.[2] Use of the term "normal" in reference to usual or average western cholesterol values may therefore be misleading.

Of the average total serum cholesterol in western populations, two thirds is low density lipoprotein (LDL) cholesterol and one quarter is high density lipoprotein (HDL) cholesterol. The atherogenic properties lie in the LDL fraction (sometimes measured as its carrier protein, apolipoprotein B, with which it is highly correlated). Many of the large epidemiological studies and randomized trials measured only total serum cholesterol, and results based on total serum cholesterol have been taken to estimate effects of LDL cholesterol. Fortuitously, the approximation is a good one. The absolute reduction in total serum cholesterol produced by diet and by most drugs (including statins[1]) is similar to the reduction in LDL cholesterol. Observational differences in total cholesterol between individuals are close to the corresponding differences in LDL cholesterol, because HDL cholesterol is independent of total serum cholesterol.[3,4] This arises because the tendency for HDL cholesterol to be positively associated with total cholesterol (as HDL cholesterol is part of total) is offset by the small inverse association between HDL and LDL cholesterol. Much epidemiologic and clinical trial data are therefore available to estimate quantitatively the effect of lowering serum LDL cholesterol on the risk of ischemic heart disease.

Serum cholesterol and ischemic heart disease

Evidence from genetics, animal studies, experimental pathology, epidemiologic studies and clinical trials indicates conclusively that increasing serum cholesterol is an important cause of ischemic heart disease and that lowering serum cholesterol reduces the risk,[5,6] and the results of six large randomized trials of statins have ensured that this is now widely accepted.[1,7–11] Three important practical questions arise: the nature of the dose–response relationship, the size of the effect, and the speed of the reversal of risk. To answer these questions data from both observational epidemiology (cohort studies) and randomized controlled trials are necessary. The two are complementary; examining trial data alone is misleading. Table 12.1 summarizes the advantages of each. In cohort (or prospective) studies serum cholesterol is measured in a large number of individuals and subsequent heart disease mortality (or incidence of myocardial infarction) is recorded. Cohort studies are easier to conduct than trials (as there is no intervention) and can therefore be much larger. Accordingly, their statistical power is greater and they can examine the association across a wider range of serum cholesterol values and a wider range of ages than trials have done. Most of the cohort studies and trials of cholesterol and ischemic heart disease recruited men, for reasons of economy, as ischemic heart disease is more common in men. The more limited data from women indicate a similar effect as in men.[1]

The nature of the dose–response relationship: is there a threshold?

Figure 12.1 shows mortality from ischemic heart disease plotted according to quintile groups (fifths) of the ranked serum cholesterol measurements in a large cohort study of serum cholesterol and ischemic heart disease (MRFIT Screenees).[12] With ischemic heart disease plotted on a logarithmic scale, the relationship is described almost perfectly by a straight line linking the *proportional* change in

Table 12.1 Relative advantages of cohort studies and randomized trials in assessing the relation between serum cholesterol and ischemic heart disease

Objective	Advantage (comment)
Statistical power	Cohort studies (recorded about three times more ischemic heart disease events than the trials)
Dose–response relationship	Cohort studies (observation across wide range of cholesterol values)
Wide age range	Cohort studies (ischemic heart disease events at age 35–85, but mostly 55–65 in trials)
Long-term effects of cholesterol differences	Cohort studies (on recruitment the serum cholesterol was the same in intervention and control groups)
Short-term effects of cholesterol differences	Randomized trials (on recruitment serum cholesterol was the same in intervention and control groups)
Avoid bias	Randomized trials (not a major advantage – bias in cohort studies can be allowed for)

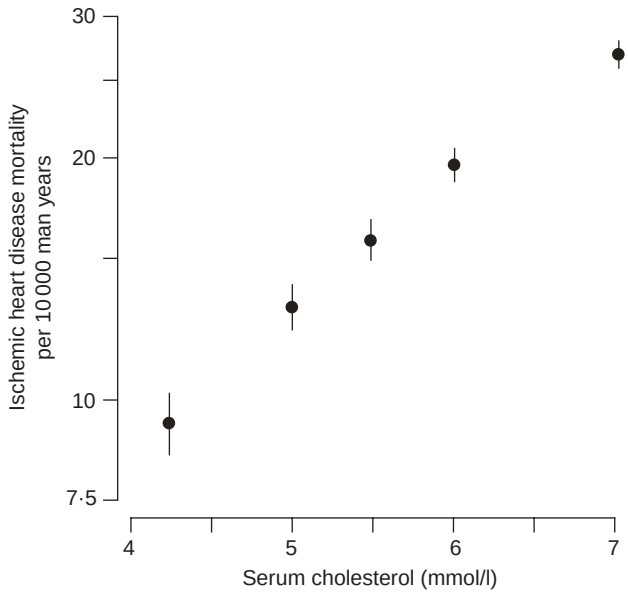

Figure 12.1 Mortality from ischemic heart disease (with 95% confidence intervals) according to serum cholesterol in a large cohort study[12]

ischemic heart disease to the *absolute* difference in serum cholesterol ($r = 0{\cdot}997$). Other cohort studies show the same relationship.[6] The 95% confidence limits of the risk estimates in each quintile group do not overlap, establishing that there is no threshold below which a further decrease in serum cholesterol is not associated with a further decrease in risk of ischemic heart disease. The exponential relationship indicated by the straight line means that a given absolute difference in serum cholesterol concentration from *any* point on the cholesterol distribution is associated with a constant proportional difference in the incidence of ischemic heart disease.

This absence of a threshold has been contentious; many published guidelines on lowering cholesterol invoke one, commonly advocating cholesterol lowering drugs only in patients whose serum cholesterol exceeds 5 mmol/l, yet the evidence is firmly against any threshold. The data in Figure 12.1 (which alone are conclusive) are supported by data from other large cohort studies,[6] including an important study from China which shows that the continuous relationship extends below serum cholesterol values of 4 mmol/l.[13] The results of a subgroup analysis in one statin trial[8] showing no reduction in coronary events in persons with the lowest serum cholesterol levels have been misinterpreted, because the confidence interval on the result was consistent both with no reduction in coronary events and with the expected reduction from the continuous association shown in cohort studies. Large randomized trials have now confirmed the result from cohort studies that the constant proportional reduction in risk extends below 5 mmol/l.[9,11,14] Experimental data on the transfer of cholesterol from the blood into atheromatous lesions exclude a threshold as low as 1 mmol/l.[15] Patients at high risk of an ischemic heart disease event (especially those with existing disease) should be offered a statin irrespective of their existing level of total or LDL cholesterol.

The size of the effect

Cohort studies provide the best estimates because they cover a wide age range and have high statistical power, and because the serum cholesterol differences between individuals recorded on entry to a cohort study will have been present on average for decades beforehand (so cohort studies show long-term associations). Trials, on the other hand, show the effect of short-term differences. Cohort studies are subject to bias, but this can be corrected. The major bias is the so-called "regression dilution bias".[3]

Table 12.2 Estimates (from 10 cohort studies) of the percentage decrease in risk of ischemic heart disease according to extent of serum cholesterol reduction and age[6]

Age (years)	Estimated percentage decrease in risk for a serum cholesterol reduction (mmol/l) of			
	0·3 (5%)	0·6 (10%)	1·2 (20%)	1·8 (30%)
40	32	54	79	90
50	22	39	63	77
60	15	27	47	61
70	11	20	36	49
80	10	19	34	47

Table 12.2 shows estimates of the long-term percentage decrease in the risk of an ischemic heart disease event according to the decrease in serum cholesterol concentration and age at event. The estimates are taken from an analysis of the 10 largest cohort studies, corrected for the regression dilution bias and for the minor distinction between differences in total and in LDL cholesterol discussed above.[6] A reduction in total or LDL cholesterol of 0·6 mmol/l (about 10%) is associated with a decrease in risk of ischemic heart disease of about 50% at age 40, 40% at 50, 30% at 60, and 20% at 70–80. The *proportional* decrease in risk decreases with age, but the *absolute* benefit increases because the disease becomes more common with age. The increasing reduction in risk with greater reduction in serum cholesterol shown in Table 12.2 follows from the exponential dose–response relationship described above. For a 0·6 mmol/l cholesterol reduction at age 60, for example, the reduction in risk is 27% and the relative risk is therefore 0·73; with a serum cholesterol reduction three times as great (1·8 mmol/l), the relative risk is $0{\cdot}73^3$ ($0{\cdot}73 \times 0{\cdot}73 \times 0{\cdot}73$) or 0·39, and the reduction in risk is 61%.

Speed of reversal and consistency of observational and trial data

Data have been analyzed from the "old generation" of 28 randomized trials in which the average serum cholesterol reduction was about 0·6 mmol/l (10%).[6] Figure 12.2 shows the reduction in incidence of ischemic heart disease in all trials combined according to time since entry. In the first 2 years there was little reduction in risk. From 2 to 5 years the average reduction in risk was 22%, and after 5 years the reduction was 25%. The ischemic heart disease events in these trials mostly occurred at an average age of about 60, and at this age the estimate of the long-term effect from the cohort studies is 27% (Table 12.2). The similarity of the estimates of effect from the cohort studies and from the trial

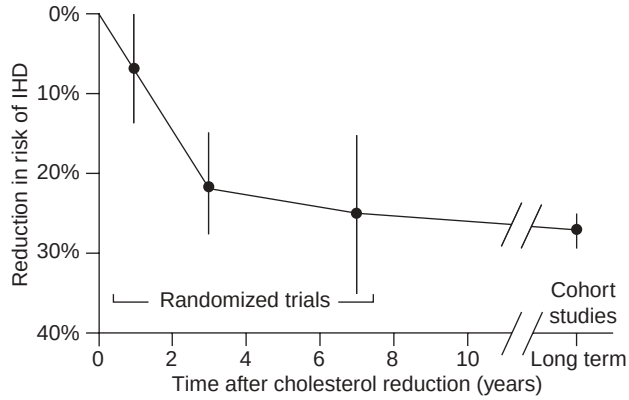

Figure 12.2 Reduction in the incidence of ischemic heart disease (IHD) per 0.6 mmol/l (about 10%) decrease in serum cholesterol, as estimated from randomized trials according to time since entry and from cohort studies (which reflect the long term association)[6]

data from the third year onwards therefore indicates that the reversal of risk is near maximal after 2 years – a surprisingly rapid effect.

The trial data show that the proportional reduction in risk from lowering serum cholesterol is similar in persons with and without previous myocardial infarction or other clinical evidence of coronary artery disease.[6]

The six large trials of statins[1,7–11] have achieved significantly larger reductions in total and LDL cholesterol. These trials too showed a relatively small reduction in ischemic heart disease events in the first 2 years, but a reduction after 2 years that is close to the maximum indicated by cohort studies. Most of these trials achieved an average reduction in total and LDL cholesterol of about 1 mmol/l in treated relative to placebo patients. The reduction in ischemic heart disease events was about 40% from the third year onwards, similar to the long-term estimate corresponding to this cholesterol reduction at age 60 (the average age at the time of the events) from the cohort studies. With relatively little reduction in risk in the first 2 years, the average reduction over the entire duration of the trials (5 years or so) was about a third. Importantly, however, the randomized trials of statins do not show their full potential for preventing ischemic heart disease events because of "contamination" – some patients allocated to the treated group leave the trial and stop taking the tablets, whereas some patients allocated to the placebo group take statins. Atorvastatin and simvastatin can reduce serum total and LDL cholesterol by about 1·8 mmol/l, but no trial has maintained this difference between all patients allocated to the treated and placebo groups over the 5 year duration of a trial. Two trials have maintained a difference of about 1·6 mmol/l – one statin trial[1] and a trial in which serum cholesterol was reduced by ileal bypass surgery.[6] A long-term reduction in ischemic heart disease events of about 55% at age 60 would be

expected from the cohort study data in Table 12.2, and this was approximately the observed reduction after 2 years in these two trials. With a serum cholesterol of 1·8 mmol/l a reduction in heart disease events of about 60% would be expected in the longer term, as Table 12.2 shows. The randomized trials therefore confirm the dose–response relationship shown in the cohort studies (the greater the cholesterol reduction the greater the reduction in heart disease events) and confirm the estimates from the cohort studies in Table 12.2 of the reduction in risk. We can therefore be confident that using atorvastatin or simvastatin in doses of around 20 mg/day to reduce cholesterol by 1·8 mmol/l will reduce risk by about 60% in the longer term.

Dietary fat and serum cholesterol

The relationship between dietary saturated fat and serum cholesterol is shown by the data from Japan and Britain in Table 12.3. This comparison is a useful one because dietary saturated fat differs greatly, yet dietary polyunsaturated fat and cholesterol are similar in the two countries. As in other situations (salt and blood pressure, for example) the size of the association varies with age, yet there has been a tendency to generalize to older age groups the results of studies conducted in younger age groups. Many dietary trials, for example, have been conducted in people under 30. The few that have been conducted in people over 50 tend to support the above Japan–Britain comparison.[6] In older people a reduction in dietary saturated fat equivalent to 10% of calories will lower serum cholesterol by about 1 mmol/l, which in turn will reduce ischemic heart disease mortality in the long term by about 40%.

The chain lengths of saturated fatty acids influence the extent to which they increase blood cholesterol. Palmitic ($C_{16:0}$) and myristic ($C_{14:0}$) acids have the major effect, lauric acid ($C_{12:0}$) some effect, and stearic acid ($C_{18:0}$) and medium chain fatty acids have little or no effect.

Table 12.3 Serum cholesterol and dietary saturated fat in Japan and Britain. Data compiled from national surveys in each country[2]

Age	Japan	Britain	Difference
Dietary saturated fat (% calories)			
All ages	6%	16%	10%
Serum cholesterol (mmol/l)			
20–9	4·5	5·0	0·5
30–9	5·0	5·6	0·6
40–9	5·1	6·0	0·9
50–9	5·2	6·2	1·0
60–9	5·0	6·2	1·2

Trans unsaturated fatty acids are also important: randomized trials show that they increase serum total and LDL cholesterol by about as much as these longer chain saturated fatty acids.[16,17] They are scanty in naturally occurring fats but are generated by the hydrogenation of vegetable oils for use as hardening agents in manufactured foods. They constitute 6–8% of dietary fat, or 2% of calories, in western diets.

Naturally occurring *cis* unsaturated fatty acids reduce serum cholesterol by approximately half as much as longer chain saturated fatty acids increase it. Reduction in dietary cholesterol has a small effect on blood cholesterol concentration.[5] Substitution of *cis* unsaturated for saturated fats in the western diet is thus the most appropriate change in lowering the high levels of blood cholesterol in western populations.

The reduction in serum total or LDL cholesterol that can easily be attained by individuals trying to alter their diet in isolation from family, friends and workmates is relatively small (about 0·3 mmol/l, or 5%). A larger serum cholesterol reduction, about 0·6 mmol/l (10%), is realistic on a community basis, as the availability of palatable low-fat food increases when other family members or the community alter their diet, and the dietary change is perceived more positively. A reduction by about 7% of calories, a realistic target for a high-fat population, would lower serum cholesterol by 0·6 mmol/l, which in turn would reduce the mortality from ischemic heart disease at age 60 by 25–30%. Reductions in serum cholesterol of about 0·6 mmol/l through dietary change have occurred in entire western communities, in the United States and Finland for example.[2] Measures that facilitate such a change include wider public education, labeling of foods sold in supermarkets, and the provision of information on the fat content of restaurant meals. Most important is the implementation of national and international policies on food subsidies that are linked to health priorities.

Serum cholesterol and circulatory diseases other than ischemic heart disease

Table 12.4 shows the death rates from all circulatory diseases according to total serum cholesterol concentration, observed in the same large cohort study (MRFIT Screenees[18]) as shown in Figure 12.1. Apart from ischemic heart disease, serum cholesterol is associated with stroke and with other circulatory diseases.

Stroke

The data from the large cohort study of the MRFIT Screenees (Table 12.4) are useful because thrombotic and hemorrhagic stroke were distinguished. For deaths from thrombotic stroke the data are consistent with a continuous dose–response relationship with serum cholesterol,

Table 12.4 Death rates per 100 000 man years (number of deaths) from circulatory diseases according to serum cholesterol in a large cohort of men[18]

Cause of death (IDC-9 code)	Serum cholesterol (mmol/l) (% of all men)				
	<4·1 (6%)	4·1–5·1 (31%)	5·2–6·1 (39%)	≥6·2 (24%)	*P* (trend)
Ischemic heart disease (410–4)	65 (160)	98 (1239)	169 (2731)	289 (2804)	<0·001
Stroke					
thrombotic (433–8)	6 (14)	6 (73)	8 (135)	13 (126)	<0·001
intracranial hemorrhage (431–2)	9 (22)	4 (55)	5 (86)	6 (57)	–
Other circulatory diseases	31 (77)	39 (483)	41 (670)	57 (556)	<0·001
All circulatory diseases (390–459)	110 (273)	147 (1850)	224 (3622)	365 (3543)	<0·001

analogous to that shown for ischemic heart disease in Figure 12.1. For hemorrhagic stroke (intracranial and subarachnoid), however, there is an *excess* risk at lower serum cholesterol levels.[18,19] Cohort studies that have distinguished thrombotic and hemorrhagic strokes are fairly consistent in showing a positive association of serum cholesterol with thrombotic stroke mortality but an inverse association with hemorrhagic stroke mortality, and cohort studies that do not distinguish the two types of stroke tend to show little or no association between cholesterol and stroke mortality, consistent with the two associations cancelling each other out.[20] Whether the inverse association is cause and effect is uncertain. It is more difficult to see how a spurious (non-causal) association with intracranial hemorrhage might arise through the disease (or predisposition to the disease) lowering serum cholesterol than is the case with depression and suicide or cancer. It is also difficult to see any mechanism by which the inverse association might be cause and effect, although experimental data lend some support to an interpretation of a causal effect of low cholesterol in that the endothelium of intracerebral arteries might be weaker at very low serum cholesterol levels.[19]

The randomized trials of serum cholesterol reduction, especially the statin trials, have shown a lower incidence of stroke (all types combined) in treated than control patients:[9–11,21] statins reduced stroke by about 26%.[21] However, these were nearly all non-fatal strokes. Thrombotic stroke has a lower case fatality than hemorrhagic stroke, so the majority of non-fatal strokes (recorded in the trials) will be thrombotic but little more than half of fatal strokes (recorded in the cohort studies) will be thrombotic. Also, the randomized trials tended to recruit patients in the upper half of the serum cholesterol distribution, where thrombotic stroke will be more common because of its positive association with serum cholesterol. These observations can probably reconcile the reduction in the incidence of stroke in trials (where most of the strokes will have been thrombotic) with the absence of an association between serum cholesterol and stroke mortality in cohort studies. **Grade A** Trials that distinguished thrombotic from hemorrhagic stroke showed that the risk of thrombotic stroke was significantly reduced by a statin,[11] but there are too few data on hemorrhagic stroke to confirm or refute the inverse association with cholesterol shown in cohort studies.

Even if the association between low cholesterol and hemorrhagic stroke is cause and effect, however, the increased mortality from hemorrhagic stroke due to very low cholesterol concentrations is small compared to the lower mortality from other vascular diseases. For example, in Table 12.4 the mortality from all circulatory diseases at the lowest serum cholesterol (<4·1 mmol/l) was 110 per 100 000 man years, lower than the rate of 147 per 100 000 man years in the next highest cholesterol group.

Patients who have had a thrombotic stroke are at high risk of a recurrent event and should receive statins, as should patients with carotid artery disease and others at high risk. Patients who have had a hemorrhagic stroke should not receive statins.

Peripheral arterial disease

Observational data show the expected association between peripheral arterial disease and serum cholesterol. In a large case–control study the association was equivalent in magnitude to an increase in risk of intermittent claudication of about 24% for a 0·6 mmol/l increase in serum cholesterol[22] (uncorrected for regression dilution bias), similar in magnitude to the association of serum cholesterol with ischemic heart disease. In the 4S trial (serum cholesterol reduction 1·8 mmol/l) the incidence of intermittent claudication was reduced by 38% (95% confidence interval 12%, 56%; 52 *v* 81 cases).[23]

Abdominal aortic aneurysm

The pathology of the condition is complex, but abdominal aortic aneurysms are associated with atheromatous disease and tend to coexist with coronary artery or peripheral arterial disease. Abdominal aortic aneurysms are associated with

a higher serum LDL cholesterol and triglyceride and a lower HDL cholesterol.

Other circulatory diseases

Table 12.4 shows a strong association between serum cholesterol and all circulatory diseases other than ischemic heart disease and stroke. Deaths from peripheral arterial disease and abdominal aortic aneurysm are too infrequent to account fully for this association. It is probably attributable also to poorly certified ischemic heart disease: deaths certified due to atrial fibrillation, heart failure, myocardial degeneration and atherosclerosis, for example, are in many cases due to ischemic heart disease.

Safety of cholesterol reduction

The uncertainty concerning the excess mortality from hemorrhagic stroke at low serum cholesterol concentrations is unresolved, as discussed above. This apart, there are no material grounds for concern about hazard. Trials of "statin" drugs, particularly informative on safety because of the large reduction in serum cholesterol that they achieve, have resolved the issue of safety because they show no excess mortality from non-circulatory causes.[1,7–11] The excess mortality from cancer and accidents and suicide at very low serum cholesterol in observational studies is attributable to cancer or depression lowering serum cholesterol, not the reverse.[19] Further reassurance on safety is provided by the condition of heterozygous familial hypobetalipoproteinemia, in which serum cholesterol levels are as low as 2–3 mmol/l. Life expectancy is prolonged because coronary artery disease is avoided, and no adverse effects from the low cholesterol are recognized[24,25] – an important natural experiment.

Statins as drugs are safe, with few adverse effects. The rare complication of rhabdomyolysis, with severe muscular pain and myoglobulinuria, has received attention with the withdrawal from the market of cerivastatin, but this is thought to affect only about one in 250 000 patients using the other statins. It is commoner with concomitant therapy with cytochrome P450 metabolized drugs, of which erythromycin and fibrates (especially gemfibrozil) are the most common.

Why was cholesterol reduction contentious?

A few years ago many clinicians regarded serum cholesterol reduction with uncertainty or suspicion. Until the early 1990s unfavorable evidence had been reported at regular intervals over the previous 30 years. The earliest trials used toxic agents to lower serum cholesterol, notably estrogen (in men) and thyroxine. Some early trials were short in duration[26] and showed no reduction in risk, because none occurs in the first year after lowering cholesterol. Cross-sectional studies of dietary saturated fat and serum cholesterol showed little or no relationship, an observation that was wrongly interpreted as indicating that lowering dietary saturated fat did not reduce cholesterol, until randomized trials established that it did. (The weak cross-sectional association arises because the inaccuracy in measuring individual dietary saturated fat is large in comparison to the small degree of variation between individuals in true saturated fat consumption.[27]) Clinicians were reluctant to accept that there was benefit in lowering average levels of serum cholesterol in high-risk patients: the notion that the average serum cholesterol in entire western populations is high appeared counterintuitive. The issue of safety caused concern, as discussed above. Lastly, it has seemed inconsistent that serum cholesterol is a poor screening test yet an important cause of heart disease, as discussed below. All these issues are now satisfactorily resolved.

Dietary fat and coagulation

Dietary fat increases blood levels of coagulation factor VII and hence increases the risk of thrombosis, myocardial infarction and cerebral thrombosis.[28,29] Saturated and unsaturated fat increase factor VII equally, and the increase appears directly related to the extent of postprandial lipemia. The importance of this effect in increasing the risk of cardiovascular death is difficult to quantify. However, analyses of differences in serum cholesterol and ischemic heart disease mortality between different populations (so-called "ecological" comparisons), such as the Seven Countries Study, yield significantly larger estimates of the relationship than obtained from the cohort studies and trials discussed above, and differences between *populations* in serum cholesterol are largely attributable to differences in dietary fat, whereas genetic differences account for over half the variation in serum cholesterol between individuals in a cohort. At age 60, for example, the ecological estimate is a 38% difference in risk for a 0·6 mmol/l cholesterol difference, compared to a 27% difference in the cohort studies (Table 12.2).[3] The difference may partly reflect the effect of dietary fat on heart disease risk.

Triglycerides

Serum triglyceride concentration was associated with the risk of ischemic heart disease in many cohort studies, but the association is subject to confounding by serum LDL and HDL cholesterol, diabetes and other factors.[4,30] The effect of dietary fat increasing factor VII will also produce an indirect association between triglycerides and heart disease mortality. Whether an independent association exists is

contentious. Very high serum levels of triglyceride caused by genetic defects (familial lipoprotein lipase deficiency, for example) are not associated with atheroma or coronary artery disease, and this observation, together with the potential for confounding in cohort studies, suggests that a material cause and effect relationship between serum triglyceride and heart disease is unlikely.

High density lipoprotein cholesterol

There is an inverse association between HDL cholesterol (or apolipoprotein A1) and ischemic heart disease. An absolute increase corresponding to 0·12 mmol/l (about 10% of the average value) is associated with about a 15% decrease in the risk of ischemic heart disease at age 60[4,30] or a 20% decrease with adjustment for the regression dilution bias.[30] The effect of alcohol in increasing HDL cholesterol is the major mechanism for the lower risk of heart disease in drinkers.[31] The effect of smoking in decreasing HDL cholesterol contributes to the excess risk of heart disease in smokers. The statin cholesterol lowering drugs increase HDL cholesterol relatively little. Certain other cholesterol lowering drugs (such as fibrates and niacin) increase HDL cholesterol more, but even in persons with relatively low HDL cholesterol the overall protective effect of these drugs is smaller because they reduce LDL cholesterol less, and so they should not be preferred to statins.

Lipids as screening tests

Serum cholesterol reduction is important in reducing the risk of ischemic heart disease, but cholesterol and other lipids are poor population screening tests for ischemic heart disease. The reason for the apparent discrepancy is that the screening potential of a factor depends not only on the strength of its relationship with disease, but also on its variation in magnitude across individuals in a community. In the case of lipids, the high average values in western societies place everyone at risk, and the variation between individuals is too small for use in population screening. By analogy, if everybody smoked between 15 and 25 cigarettes per day, cases of lung cancer would not cluster in the minority who smoked 25 cigarettes a day to the extent that those who smoked 15 or 20 could be ignored. Moreover, the Gaussian distribution of serum cholesterol means that many people have values around the average and few have relatively high values, so that most ischemic heart disease events will occur in people whose serum cholesterol is about average.

Among men aged 35–64, the 5% with the highest serum total cholesterol experience only about 12% of all deaths from ischemic heart disease – their risk is little more than double the population average.[30] The 5% of men with highest LDL cholesterol (or its carrier protein, apolipoprotein B) experience 17% of the heart disease deaths.[30] **Grade A** Including HDL cholesterol improves this poor detection by only about one percentage point. Lipids cannot identify a small minority of the population in whom the majority of future heart disease deaths will cluster.

Appropriate policy

In a small proportion of the population, notably persons with familial hypercholesterolemia, the absolute risk of death from ischemic heart disease at a young age is so great that affected persons should be identified and treated, even though the condition accounts for a fraction of all heart disease deaths in a population. **Grade A** The most appropriate screening strategy has not yet been devised; measuring lipids in relatives of known cases will not identify all cases.

Because screening cannot identify a group who would *not* benefit from a reduction in dietary fat and serum cholesterol, such measures should be directed at the entire population. Serum cholesterol reductions of 0·6 mmol/l (10%), as discussed above, have occurred in entire western communities, facilitated by health education, the wider availability of healthy food in restaurants and supermarkets, and a positive image of healthy eating. A reduction of 0·6 mmol/l is less likely when an individual attempts dietary change in isolation. The most important measures to lower cholesterol in healthy people therefore involve wider public education, encouragement of labeling of the nutrient content of foods, and the widespread availability of palatable low-fat foods.

Clinicians need to direct their activities towards high-risk patients, and the most important high-risk group (based on the proportion of all heart disease deaths that can be anticipated) are patients who have had a myocardial infarction. As a group, these patients face a risk of death from ischemic heart disease of about 5% per year (untreated), a risk that varies relatively little with age or sex. As in healthy people, serum cholesterol testing cannot identify a substantial group at either materially higher or materially lower than average risk of death. Also, the evidence strongly indicates that there is no threshold below which serum cholesterol reduction is not effective. It follows that serum cholesterol should be reduced in all survivors of myocardial infarction. Simvastatin and atorvastatin can lower serum cholesterol by 1·8 mmol/l (30%) and this, as discussed above, will reduce mortality from heart disease by about 60% after 2 years, a substantially larger reduction in risk than can be achieved by any other single intervention. Other high-risk groups include patients with angina, patients who have had a thrombotic stroke, patients with carotid artery disease, patients with peripheral arterial disease and claudication,

and diabetics. All these patients should receive statins routinely.

The "population" and "high-risk" approaches are complementary – the first primarily a public health issue aimed at altering the population diet and hence the incidence of ischemic heart disease, the second primarily a clinical activity, identifying and treating with statins patients with coronary artery disease.

Conclusions

The high levels of serum cholesterol found in western populations are a major cause of the high mortality from ischemic heart disease and, to a lesser extent, stroke and other circulatory diseases. Realistic dietary change in a community can lower serum cholesterol by 0·6 mmol/l (10%) and reduce heart disease mortality by about 25–30%. Simvastatin and atorvastatin can lower cholesterol by 1·8 mmol/l (30%) and reduce the risk of heart disease death by about 60% from the third year onwards, and should be offered to all high-risk survivors. Despite the importance of lowering cholesterol, lipids are poor screening tests of individual risk, because the average risk is high and the range across a population is relatively narrow.

Serum cholesterol and ischemic heart disease

Grade A

- The effect of serum cholesterol reduction on ischemic heart disease mortality is large and important.
- There is little reduction in risk in the first year, but the expected reduction in risk is largely attained from the third year onwards.
- There is no threshold across the range of cholesterol values in western countries below which reducing serum cholesterol reduction is not worthwhile. In particular there is no justification for withholding statins from high risk patients whose serum cholesterol is below 5 mmol/l.
- The greater the reduction in serum cholesterol, the greater the reduction in risk.
- Simvastatin and atorvastatin can lower cholesterol by 1.8 mmol/l (30%) and reduce the risk of heart disease death at age 60 by about 60% from the third year onwards; their use should be routine in high-risk patients.
- Realistic dietary change in a community can lower serum cholesterol by 0.6 mmol/l (10%) and reduce the risk of heart disease death by 25–30% at age 60. In an individual acting alone, the realistic change is half this.
- The benefits are similar in men and women.

Serum cholesterol and other circulatory diseases

- Statins reduce the risk of thrombotic stroke and peripheral arterial disease and should be used in high-risk patients.
- Cohort studies show excess mortality from hemorrhagic stroke at very low cholesterol levels. The interpretation is uncertain. The possible hazard, however, is greatly outweighed by the benefit of low mortality from heart disease at very low cholesterol levels.

Screening

- Lipids are poor screening tests for predicting heart disease death in an individual: it is not possible to identify a small minority in a community who will experience the majority of heart disease deaths.
- The 5% of men with highest total serum cholesterol experience only about 12% of heart disease deaths.
- In the extremity of the distribution, familial hypercholesterolemia is important to detect because the absolute risk of heart disease death at a young age is high, even though the condition accounts for only a small proportion of heart disease deaths.

13 Use of lipid lowering agents in the prevention of cardiovascular disease

Jeffrey L Probstfield

Introduction

According to the most recent data from the American Heart Association, 12 600 000 American adults have coronary heart disease (CHD).[1] CHD is the leading cause of death among US adults, responsible for one of every five deaths in the United States in 1999. Although the age adjusted death rate from CHD decreased by 24% from 1989 to 1999, the actual number of deaths decreased by only 6·8% over this same time.[1]

The associated morbidity, treatment of related conditions and preventive approaches for CHD are reviewed in other chapters of this book. Discussed here is the practical use of lipid lowering agents to prevent hypercholesterolemia – a well-established risk factor for the development of CHD.

Major trials have clearly demonstrated that decreases in low density lipoprotein cholesterol (LDL-C) are associated with reductions in total mortality,[2–4] CHD mortality,[2–4] fatal and non-fatal CHD as well as strokes.[2–5] Other major trials have also shown that lowering LDL-C can retard the progression of coronary artery atherosclerosis[6] and carotid atherosclerosis[7] and may even cause their regression, as well as slow the progression and occlusion of atherosclerosis in saphenous vein bypass grafts.[8] In both primary[3] and secondary[2,4] CHD prevention settings, decreases in total and cause-specific mortality have been demonstrated, and these benefits have been shown in both subjects with elevated,[2,3] average,[5] and normal LDL-C levels. Evidence of the benefits of statins in reducing the risk of stroke and observations concerning their pleiotropic effects are also reviewed.

This chapter's primary purpose is to review the evidence regarding plasma lipid-altering medications, their mechanisms of action, dosages and dosing schedules, effects on lipid and lipoprotein variables, adverse effects, and clinical uses. The evidence for cholesterol lowering in such subgroups as the elderly, women, diabetic patients, and those with small-dense LDL particles will also be summarized.

The 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor agents (statins), which are highly effective LDL-C lowering agents, are reviewed, as are niacin, bile acid sequestering agents (resins), fibrates, and ezetimibe. A brief review of the costs/1% LDL-C lowering/year and cost effectiveness concludes this chapter.

The National Cholesterol Education Program (NCEP) has been instrumental in developing and promulgating guidelines for initiating LDL-C lowering. These guidelines, developed on the basis of the patient's established baseline LDL-C and presence or absence of CHD or its risk factors, recommend treatment goals to attain desired levels of plasma LDL-C. To date, the NCEP has issued three Adult Treatment Panel (ATP) reports. ATP I emphasized primary prevention of CHD in persons with high (>160 mg/dl) or borderline-high LDL levels (130–159 mg/dl) and >2 risk factors for development of CHD. In ATP II, persons with established CHD were targeted for intensive lipid lowering therapy.

ATP III, disseminated in 2001, continues to identify elevated LDL-C as the primary target of cholesterol lowering therapy and to maintain attention on intensive treatment of patients with CHD.[9] It expands the indications for intensive therapy to lower levels of cholesterol in clinical practice. A major new feature is that intensive LDL-C lowering treatment is a primary prevention measure for persons with multiple risk factors for developing CHD, as identified by the estimated 10 year CHD risk score developed from the Framingham data. ATP III sets the optimal LDL-C level as <100 mg/dl and defines low HDL-C as <40 mg/dl (previous cutpoint was <35 mg/dl).[9]

ATP III also recommends that persons with the metabolic syndrome – a constellation of major lipid and non-lipid risk factors, life-habit risk factors, and emerging risk factors – should be targeted for intensive therapeutic lifestyle changes. Characteristics of the metabolic syndrome include abdominal obesity, elevated blood pressure, insulin resistance, and atherogenic dyslipidemia – elevated triglycerides, small LDL particles, and low HDL-C. Atherogenic dyslipidemia should be treated with lipid-altering agents.[9] Boxes 13.1–13.4 summarize the major new recommendations of ATP III and classifications of cholesterol levels.[9]

Use of individual lipid-altering agents

In this short evidence-based overview, we focus on documented activities of known lipid- and lipoprotein-altering drugs on lipid and lipoprotein variables, and their related

Box 13.1 New features of adult treatment panel III

Focus on multiple risk factors

- Raises persons with diabetes without CHD, most of whom display multiple risk factors, to the risk level of CHD risk equivalent.
- Uses Framingham projections of 10 year absolute CHD risk, (that is, the per cent probability of having a CHD event in 100 years) to identify certain patients with multiple (2+) risk factors for more intensive treatment.
- Identifies persons with multiple metabolic risk factors (metabolic syndrome) as candidates for intensified therapeutic lifestyle changes.

Modifications of lipid and lipoprotein classification

- Identifies LDL-C <100 mg/dl as optimal
- Raises categorical low HDL-C from <35 to <40 mg/dl
- Lowers the triglyceride classification cutpoints to give more attention to moderate elevations

adverse effects. We identify those issues that remain more speculative as such. The interested reader is referred to the excellent and more complete reviews by Lousberg *et al*,[10] as well as the recent ATP III guidelines.[9]

HMG-CoA reductase inhibitors (statins)

These agents have a powerful LDL-C lowering and those currently approved for use differ only in their dose-response curves and unit cost.

Mevastatin was first isolated in 1976 by Endo and colleagues as a natural product from *Penicillium* species. A related natural product, lovastatin, was approved by the FDA for cholesterol lowering in 1987. Subsequently, simvastatin, pravastatin, fluvastatin, atorvastatin, and cerivastatin were developed and approved for use in the US.[11] Cerivastatin was withdrawn later because of adverse effects.

Mechanism of action: lipid-altering effects

Brown and colleagues demonstrated that lovastatin inhibits HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis.[12] Total body cholesterol synthesis is reduced by at least 20%. Ultimately a critical reduction in cholesterol concentration occurs in the liver cell leading to enhanced production of hepatic LDL receptors,[13] and increased cellular uptake of LDL-C. Further, reduced very(V) LDL biosynthesis occurs. Although speculative, it appears that the mechanism by which an increased removal of VLDL from the plasma occurs best fits with the upregulation of LDL receptors and an enhanced removal of VLDLs from the plasma due to an alteration in VLDL structure (specifically apo B-100).[14]

Pleiotropic effects

In addition to reducing cholesterol biosynthesis, other potential antiatherogenic mechanisms of action for the statins are under current, intense investigation. Their exact role and importance remains speculative. Inhibition of 3-HMG-CoA reductase may be pleiotropic.[15] Pleiotropic effects of statins on the vascular system and the arterial walls – affecting endothelial function, inflammation, coagulation, plaque stabilization, and smooth muscle cell migration – have been identified.[15–19] Several statins have been shown to decrease smooth muscle cell migration and inhibit cholesterol accumulation in macrophages.[15] The small GTP-binding protein, Rho, has membrane localization and activity affected by post-translational isoprenylation. Its role in mediating the direct vascular effects of statins is also under intense study.[20]

The Pravastatin Inflammation/CRP Evaluation (PRINCE) provides clinical evidence of anti-inflammatory properties of a statin.[21] In this prospective, randomized, cohort study, pravastatin lowered levels of C-reactive protein (CRP), an inflammatory biomarker that is predictive of cardiovascular risk. Decreased CRP levels were seen as early as 12 weeks in pravastatin-treated participants ($P < 0{\cdot}001$). Pravastatin lowered the median CRP level by 16·9% versus placebo ($P < 0{\cdot}001$) at 24 weeks. The decreases occurred in both the primary and secondary prevention groups and occurred regardless of sex, age, smoking, body mass index, baseline lipid levels, diabetes, and use of aspirin or hormone replacement therapy.[21]

Results of the recently completed Prospective Pravastatin Pooling (PPP) Project – a meta-analysis of three large, placebo-controlled, randomized trials including almost 20 000 patients and 102 559 person-years of follow up – provide further clinical evidence that statins may be anti-inflammatory and/or antithrombotic. In particular, statins may be beneficial in reducing strokes.[22] Pooled data from two of the trials, CARE and LIPID, involving more than 13 000 patients, showed a 22% reduction in total strokes and a 25% reduction in non-fatal stroke.[22] WOSCOPS, the third trial pooled for analysis, had a similar, but smaller, trend for reduction in total stroke. Pravastatin reduced the risk of non-hemorrhagic stroke over a wide range of lipid values in patients with documented CHD.[22] These results contrast importantly with those of a 1995 meta-analysis, which found no effect of lipid lowering on stroke in earlier non-statin clinical trials.[23]

The Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) trial provides clinical evidence of an anti-ischemic effect with statins. Atorvastatin reduced early recurrent ischemic events in patients with acute coronary syndromes.[24] The statin (80 mg/day) was initiated 24 to 96 hours after an acute coronary syndrome to over 3000 adults with unstable angina or non-Q-wave myocardial infarction (MI). In the atorvastatin group, 14·8% of patients had a primary end point (death, non-fatal acute MI, cardiac arrest with resuscitation, or recurrent symptomatic myocardial ischemia requiring emergency rehospitalization) versus 17·4% in the placebo group ($P = 0{\cdot}048$).[23] The MIRACL investigators suggest that patients with acute coronary syndromes begin statin therapy before hospital discharge, regardless of baseline LDL-C levels.

Atorvastatin Versus Revascularization Treatment (AVERT) compared the efficacy of aggressive cholesterol lowering therapy versus percutaneous transluminal coronary angioplasty in low-risk, stable patients with CHD. Results favor the use of aggressive lipid lowering over angioplasty in patients with mild to moderate CHD. In addition to significantly reducing LDL-C levels, atorvastatin was associated with a 36% reduction in ischemic events and a significant delay in time to first ischemic event.[25]

Dosage

The recommended dosages of these agents have been described and are shown in Table 13.1.[11] Statins are to be

Table 13.1 Dose response lipid and lipoprotein changes (% change)

Total dose (mg/d)	5	10	20	40	80
	Total cholesterol reductions				
Lovastatin BID	19	24	29	34

From *Physicians' Desk Reference*[11]

taken with the evening meal or if they are taken twice daily with the morning and evening meals. Higher dosages of both simvastatin and pravastatin have been approved by the FDA and are now on the market.

Impact on lipid levels

All of these agents except atorvastatin will lower plasma total cholesterol between 20 and 40% and LDL-C by 25 to 45% at maximum approved doses. Fluvastatin appears to lower cholesterol by up to 20% and LDL-C by 25% at maximum doses. To achieve 35–45% LDL-C lowering, daily doses of 40 mg of simvastatin or 80 mg of lovastatin are required. Triglycerides are reduced between 10 and 30%. HDL-C plasma levels are frequently increased by 5–10%, but the increases may be more modest or absent in those with inherently low levels. Lp(a) levels are not affected.[11] Statin therapy alters small dense LDL particles to a larger more buoyant form and also normalizes the responsiveness of coronary vessels to vasoactive stimulus.[26] E-selectin, a cell adhesion molecule with increased expression in atherosclerotic states, is reduced with simvastatin or atorvastatin as monotherapy or in combination with colestipol.[27]

Atorvastatin is a more powerful member of the statin class. Reductions in total cholesterol of 45–50%, LDL-C of up to 60%, and triglycerides of 35–45% are seen at 80 mg/day doses. Reductions in apo B levels of 35–40% have been observed.[11] Changes in plasma levels of Lp(a) are small, if they occur.[28] Increases in HDL-C are inconsistent but may reach 12%.[29] Table 13.1 summarizes the effects of approved statins.

Adverse reactions

Overall adverse reactions occur in less than 2% of individuals. From 1 to 3% of persons taking a statin will have dose-related, elevated, hepatic enzyme levels.[30] Most of these abnormalities are seen within the first 3 months of beginning treatment and require monitoring.[30] In patients who abuse alcohol, there is an increased risk of hepatic toxicity. An extremely low incidence of adverse events (not significantly different from placebo) has been documented over 5·5 years in the Heart Protection Study (HPS),[4] to be discussed in more detail below.

Statins compete with other drugs for specific metabolic pathways of the cytochrome P450 system,[31] whose enzymes act as a major catalyst for drug oxidation in the liver.[32] Lovastatin and simvastatin undergo extensive first-pass metabolism by CYP3A4, and caution is urged in using them with cyclosporin (a known inhibitor of CYP3A4), particularly when other inhibitors of the cytochrome P450 system, such as azole-derived antifungal drugs, erythromycin and clarithromycin, are in use, as well as nefazodone and many HIV protease inhibitors. Atorvastatin is also at least partially metabolized by CYP3A4 but inhibitors of this enzyme only mildly increase serum concentrations.

Fluvastatin is metabolized mostly by CYP2C9 and few drug–drug interactions have been noted. Pravastatin has less potential for drug interaction with other substrates, inhibitors, or inducers of the CYP3A4 and CYP2C9 systems than the other statins because it is metabolized by sulfation, not the cytochrome system.[32]

From 5 to 10% of individuals taking statins may develop muscle enzyme elevations. However, one should consider discontinuing statin therapy if CPK increases by more than threefold. Rare (less than 0·1%) and reversible increases of greater than 10-fold in CPK levels have been described. The causes of CPK elevation remain unexplained. Statin monotherapy or combination therapy can cause myopathy, which, although rare, can progress to rhabdomyolysis.[33] This effect can be seen with any statin; however, cerivastatin was voluntarily withdrawn from the world market in 2001 because of an increased rate of rhabdomyolysis compared with other statins. Rhabdomyolysis occurred more often in patients taking full-dose cerivastatin (0·8 mg/day) and with concomitant gemfibrozil, and it led to kidney failure and death in 52 cases.[34]

Clinical use

Although the biggest proportional reduction in LDL-C levels occurs at low doses, the clinical response to statins is dose-dependent, and it appears to be independent of patient characteristics, such as age, gender, smoking status and initial lipid and lipoprotein levels.[35] ATP III calls for LDL-C lowering drug therapy in persons with CHD and CHD risk equivalents when the LDL-C is $\geqslant$130 mg/dl.[9] In persons with two or more risk factors for the development of CHD, ATP III suggests that lipid lowering drug therapy also begin at LDL-C levels $\geqslant$130 mg/dl.[9]

ATP III also recommends that LDL-C be measured, either at admission or within 24 hours, in all patients hospitalized with a major coronary event.[9] Lipid lowering drug therapy should be initiated at hospital discharge in a person with a coronary event or procedure if LDL-C is $\geqslant$130 mg/dl.[9] Treatment initiation at hospital discharge takes advantage of patients' likely higher motivation to comply with therapy at that time and may avoid the "treatment gap" that can occur if outpatient follow up is less consistent. ATP III still recommends lifestyle changes, including reduced cholesterol and saturated fat diets, weight loss if overweight, and physical activity in hyperlipidemic patients.[9]

Novel agents

The newest statin, rosuvastatin, has been submitted for approval to both the FDA and regulatory authorities in Europe. Called a superstatin because of its potency, rosuvastatin

rapidly lowers total C and LDL-C while increasing levels of HDL-C.[36] A long half life (20 hours) and lack of metabolism via the cytochrome P4503A4 isoenzyme have also been demonstrated.[37] In a phase II study, rosuvastatin across a dose range of 1–80 mg lowered LDL-C by 34–65%. Phase III trials demonstrated greater reductions in LDL-C for rosuvastatin versus atorvastatin as well as greater increases in HDL-C. A starting dose of 10 mg will reduce LDL-C by approximately 50%. The drug appears to be well tolerated at doses up to 80 mg/day.

Nicotinic acid

In the early 1950s Attschult noted profound reductions in plasma total cholesterol and triglyceride levels in association with use of nicotinic acid. Nicotinic acid has the most marked clinical effect on triglycerides and HDL,[38] and is the only lipid-altering agent to consistently lower Lp(a) plasma levels.[39] It also can alter small, dense LDL particles to larger, more buoyant forms.[39]

Mechanism of action

Nicotinic acid's predominant effect on plasma lipid levels is to reduce production of very low-density lipoprotein (VLDL) particles[40] with subsequently reduced production of intermediate density lipoprotein (IDL) and LDL particles. Nicotinic acid's major effect on VLDL metabolism results from an inhibition of hormone-sensitive, lipase-induced lipolysis in adipose tissue, and decreased triglyceride esterification in the liver. HDL-C increases, to a greater extent with niacin than with other drugs, and appears to be related to reduced apo A-I clearance and increased production of apo A-II. How Lp(a) levels are reduced is unknown, but early nicotinic acid induced hepatotoxicity may play a role.

Dosage

Crystalline nicotinic acid is available in 0·1 and 0·5 g tablets. There is a sustained-release form in dosages of 0·125, 0·25 and 0·5 g. The maximum daily dose is usually 3 g (Table 13.2).[41] A new extended-release form of niacin, available since 2000, has relatively mild hepatic effects and can be taken at bedtime to lessen cutaneous flushing.[42] Extended-release niacin is essentially equivalent to immediate-release niacin in increasing HDL-C.[43]

Results

Regardless of the patient's clinical lipoprotein abnormality, dose-dependent reductions in total and LDL-C and plasma triglycerides have been achieved with use of nicotinic acid. HDL-C levels may increase 15–40%; the average increase is 25%, with increases commonly plateauing at a dosage between 1·5 and 3·0 g/d. Reductions in Lp(a) of 25–30% are achieved.[44] As noted above, small-dense LDL particles become larger and more buoyant during nicotinic acid therapy.[45] In certain patients, optimal responses may be formulation- and dosing regimen-dependent.[46]

Adverse reactions

Even at very low doses (0·05–0·10 g), nicotinic acid often causes cutaneous flushing (>80%) and pruritus (50%). Other frequently noted adverse effects are gastrointestinal symptoms (5–20%), liver enzyme elevations (3–10%), and uric acid increases (5–10%). Liver enzyme elevations occur more commonly with slow-release preparations and rapid dose increases. The clinical picture of mild liver function abnormalities usually resolves with continued therapy or reduced doses.

Some 5 to 10% of patients who are taking nicotinic acid will have abnormal glucose tolerance tests or fasting blood sugar levels. A flu-like syndrome that can include hepatitis-like findings on liver biopsy, a secretory defect with profound decreases in LDL-C, decreases in HDL-C and a prothrombin time abnormality may occur. This clinical picture is dose-dependent and resolves when the agent is stopped.[47] Blurred vision with macular edema occurs very rarely. Prednisone is contraindicated for use with nicotinic acid; co-administration can result in patients manifesting clinical diabetes.

Clinical use

Many prescription and non-prescription forms of nicotinic acid are available in the US. Although non-prescription forms are usually less expensive, bioavailability may be a problem. Niaspan, Nicolar and Rugby brands are highly effective prescription nicotinic acids, and the latter is also available as an over-the-counter formulation. The larger crystalline-form tablets are scored, which allows easy tailoring of the therapeutic regimen starting with a single low dose of either 0·1 or 0·25 g/d. Dosing with the crystalline form requires three or four administrations a day. No preparation or dosing regimen has been shown to be superior to multiples of 0·1 g crystalline tablets administered four times a day. Many patients will have little or no effect from two administrations a day, unless using sustained-release preparations. Increases in the dosage are implemented only every few days.[46] Clinicians commonly reduce the number of administrations to three times per day and use 0·5 g tablets starting with 0·25 g qd for the first week. Sustained-release preparations should be used only in those patients with a documented response to immediate-release forms.

Nicotinic acid should always be taken with food. Hot drinks and alcoholic beverages should be avoided at time of administration and dosages should be reduced or perhaps restarted if several successive doses are missed. Cutaneous

Table 13.2 Summary of effects of non-statin lipid-altering agents

Agent	Lipid/ lipoprotein indication	Dosage and dosing	Response expected	Common adverse effects	Comments
Nicotinic acid	↑ Triglyceride (TGs) ↑ LDL-C ↓ HDL-C ↑ Lp(a)	1–3 g/d 6–8 g/d maximum dose 3–4 admin/d	↓ TGs 20–80% ↓ LDL-C 25–40% ↑ HDL-C 25% ↓ Lp(a) 10–30%	Cutaneous flushing, pruritis, GI symptoms, "Flu-like" syndrome	Start low dose Advance slowly Relative contraindications: ↑ FBS, ↑ Liver function test (LFTs)
Bile acid sequestrants	↑ LDL-C	4–24 g cholestyramine 5–30 g colestipol	↓ LDL-C 25–35% at maximum dose ↑ TGs 15–20% ↑ HDL-C 4–7%	GI symptoms	Premix, slow admin Alters absorption of other drugs, for example, glycosides, warfarin, etc.
	↓ HDL-C	2 admin/d,1 at major meal			Contraindicated in hypertriglyceridemia
Fibric acid derivatives	↑ TGs	Clofibrate 1 g bid	↓ LDL-C 10–20% ↓ TGs 40–55% ↓ HDL-C 15–20%	GI symptoms	Will ↑ LDL-C in hypertriglyceridemic patients
		Gemfibrozil 0·6 g/bid Fenofibrate 0·4 g qd			Contraindicated in those with gall stones Marked dose alteration in those with chronic renal failure
Selective cholesterol absorption inhibitor	↓ LDL-C ↑ HDL-C	Ezetimibe 5 mg/d 10 mg/d	↓ LDL-C 16–19% ↑ HDL-C 3–3·5%	No common AEs shown to date	

flushing and pruritus will occur routinely if these precautions are not followed. If symptoms occur, they are the most severe during the first administration. Pretreatment with aspirin or ibuprofen may lessen cutaneous reactions.

Although nicotinic acid may profoundly alter glucose metabolism in some, many diabetic patients have had their lipid disorders successfully managed with this agent. A fasting blood sugar >115 mg/dl predicts subjects who will lose the acute insulin response with an intravenous glucose tolerance test.[48] A fasting blood sugar level <100 mg/dl should identify those patients who can take nicotinic acid without development of clinical diabetes.

Bile acid sequestering agents (resins)

(Table 13.2)

This class of agents was first developed for the treatment of cholestasis-related pruritus by Carey and Williams in 1960. Hashim and Van Itallie subsequently demonstrated that cholestyramine lowered plasma cholesterol and it has been in clinical use for 30 years. Other agents in this class are colestipol and the recently approved colesevelam.

Mechanism of action

The enterohepatic circulation of bile acids allows for only 6 or 7% of them to be excreted each day. These polymers with a molecular weight of over 10^6 are not absorbed and function by binding bile acids in the gastrointestinal lumen. Since an increase in bile acid excretion from the body and an increased production in the liver occur, relative depletion of cholesterol from the liver cells occurs inducing an increased level of hepatic LDL-receptor activity.[49,50] The net effect is an increase in the catabolism of LDL-C and decreased plasma levels.

Dosage

Resins are dispensed in individual packets and are also available in a cost effective bulk formulation. Scoops, equivalent

in size to the number of grams in one packet, are used to dispense from the parent container. The newest resin, colesevelam, has a hydrogel tablet formulation.

Results

Resins are associated with significant reductions in plasma total and LDL-C and with small increases in plasma HDL-C levels.[51] Plasma triglycerides are inconsistently affected, but substantial increases may occur, if used in those with already elevated plasma triglyceride levels.[52] In familial dysbetalipoproteinemia (type III or remnant removal disease) plasma triglyceride levels may increase by more than threefold.

Adverse reactions

No long-term adverse effects have been demonstrated.[51] Drugs that are highly charged, including the cardiac glycosides, the anticoagulant warfarin, diuretic agents, as well as thyroid hormone, will have their absorption affected[53] if taken in close proximity to resin administration. Concomitant warfarin and resin therapy may be extremely challenging.

If a resin's effect on the absorption of a specific medication is not known, the resin should be taken at least 4 hours before or 2 hours after other medications. In clinical situations of existing gastrointestinal malabsorption, the absorption of fat-soluble vitamins may also be reduced.

Clinical use

The biggest proportional reduction in lipid levels occurs at low doses and in those who have moderately elevated levels of cholesterol.[54] Careful selection of the vehicle and logistics used in resin administration will promote long-term patient adherence. Premixing with cold water (taking advantage of the resin's hygroscopic nature) and drinking the preparation slowing is by far the most frequent and successful method of administration. Still, some patients prefer mixing with a heavily textured juice. Pre-existing gastrointestinal symptoms should be addressed before resin therapy is started. Bloating, belching and increased flatus are related to rapid ingestion. Dyspepsia and increased stool consistency or frank constipation can be managed with increases in fluids or dietary fiber intake.

The newest agent in the resin class is colesevelam, available for use in the US since 2000. It is a polymeric, high-potency, water-absorbing hydrogel with a non-systemic mechanism of action.[55] Based on data from approximately 1400 subjects, colesevelam reduced LDL-C by a median of 20%; the reduction is dose-dependent. When combined with lovastatin, simvastatin, or atorvastatin, colesevelam will reduce LDL-C levels by 8 to 16% over that seen with the statin alone.[55] Colesevelam has also been shown to increase HDL-C up to 9%; however, increases in triglycerides, as much as 25%, have also been reported.[56] Colesevelam does not cause constipation, which is likely to improve patient adherence,[55] and is formulated as a tablet, which should eliminate the palatability problems that some patients have with resin powders.[56] In drug-interaction studies, colesevelam was coadministered with digoxin, warfarin, sustained-release metoprolol and verapamil, quinidine and valproic acid, and no clinically significant effects on absorption were reported.[57]

Fibric acid derivatives (Table 13.2)

The fibrates currently marketed in the US are clofibrate, gemfibrozil, and fenofibrate. Fibrates available in other countries include bezafibrate, fenofibrate, ciprofibrate, beclafibrate, etiofibrate and clinofibrate. In a WHO study clofibrate was shown to reduce modestly ($P < 0{\cdot}05$) all cardiovascular events. However, increases in non-cardiovascular morbidity and mortality and total mortality occurred.[58] In the Helsinki Heart Study, gemfibrozil was associated with a 35% reduction in MIs, particularly in those with elevated levels of plasma LDL-C and triglycerides and low levels of plasma HDL-C. Increases in non-cardiovascular deaths and no reduction in total mortality was observed,[59] leading to concerns about the use of fibrates. No fibrate trial has yet shown a significant decrease in total mortality. These agents are approved for use primarily in those with hypertriglyceridemia. Clofibrate can be toxic; in some early studies there was a high mortality rate from malignancy and gastrointestinal disease in association with its use. Therefore, its use should be restricted to patients with severe hypertriglyceridemia unresponsive to other fibrates, niacin, or a combination of niacin and fibrate.

Gemfibrozil has been shown to lower the risk of CHD and stroke in men with previous CHD, and low HDL-C and low LDL-C levels. In the Veterans Affairs HDL Intervention Trial (VA-HIT),[60] 2531 men with CHD (mean HDL-C 31·5 mg/dl and mean LDL-C 111 mg/dl) were randomized to receive gemfibrozil 1200 mg/day or placebo. There was a 22% reduction in CHD over 5 years.[60] A more recent VA-HIT study describes the effect of therapy on stroke. There were 134 confirmed strokes (90% ischemic), 76 and 58 in the placebo and gemfibrozil groups, respectively ($P = 0{\cdot}03$). Risk reduction was evident after 6 to 12 months of gemfibrozil use. Adjusted for baseline variables, the relative risk reduction with gemfibrozil was 31%.[61] Attributing the reduction in CHD to a change in HDL-C levels has been questioned by some. Clearly the reduction in CHD may more properly be associated with changes in other lipoprotein particles[62] than with modest changes in HDL-C levels. Although the number of strokes in the study are modest,[61] this is the first suggestion that stroke can be reduced with a form of lipid-altering therapy that has little effect on LDL-C.

Mechanism of action

Decreased synthesis of VLDL with more efficient lipolysis and increased VLDL triglyceride catabolism has long been speculated as the mechanism of action of fibrates on lipid metabolism. Schoonjans *et al* in 1996 offered direct evidence that fibrates and fatty acids work as ligands for a class of compounds called peroxisome proliferator-activated receptors, of the nuclear receptor superfamily.[63] Peroxisome proliferator-activated receptor alpha partially mediates the inductive effects of fibrates on HDL-C levels by regulating the transcription of HDL apolipoproteins, apo A-1 and apo A-II. Four specific actions are noted:

1. increased hydrolysis of plasma triglycerides due to induction of LPL and reduction of apo-CIII expression
2. stimulation of cellular fatty acid uptake and conversion to acyl-CoA derivatives due to increased expression of genes for fatty acid transport protein and acyl-CoA synthetase
3. increased peroxisomal and mitochondrial beta-oxidation
4. decreased synthesis of fatty acids and triglycerides with a concomitantly decreased production of VLDLs.

Gemfibrozil was associated with a greater reduction in clinical events than the amount of cholesterol lowering or increase in HDL would predict.[64] This suggests that its effects on CHD are mediated by a different mechanism, possibly related to its effects on triglycerides or other lipoprotein particles and HDL. Fibrates also shift the size of LDL particles from smaller, denser forms to larger, more buoyant forms, which could be less atherogenic.

Dosage

Table 13.2 lists dosing information for the three fibrates marketed in the US. Bezafibrate, 0·2 g, is given tid. (0·4 g, sustained-release qd), fenofibrate, 0·3–0·4 g, is given qd, and ciprofibrate, 0·1–0·2 g, is given qd.

Results

In patients with familial combined hyperlipidemia, LDL-C levels may be reduced by fibrates, but, particularly in those with elevated baseline levels of plasma triglycerides there will almost uniformly be an increase in LDL-C levels as VLDL-C levels decrease.[65] Gemfibrozil and clofibrate had similar impact on lipids and lipoproteins in a double-blind crossover study.[66] In patients with moderate to severe forms of hypertriglyceridemia, reductions in plasma triglycerides of 40–60% may occur with concomitant increases of 12–30% in HDL-C levels, but 100% increases in LDL-C may occur.[67]

Adverse reactions

Fibrates are associated with adverse effects in 5–10% of patients. GI side effects (5%) are the most common, but only rarely are these sufficient to warrant discontinuation of the medication. The increased incidence of hepatobiliary disease (particularly gallstones) occurs with all agents in this class.[68] Minor alterations in several plasma biochemical values may occur, but these are dose-dependent and usually transient. The effective non-toxic dose-range is narrow, and at high doses fibrates cause myositis. They may potentiate the effects of oral anticoagulants and oral hypoglycemics and might also interact with statins to raise the risk of rhabdomyolysis.

Clinical use

The primary indication for the use of these agents has shifted to treatment of severe hypertriglyceridemia and more specifically for familial dysbetalipoproteinemia, or remnant removal disease. They are preferred by those who are less experienced in the use of nicotinic acid in clinical circumstances with increases in both plasma LDL-C and reductions in HDL-C levels. Because of the long-term adverse effects on hepatobiliary function and the potential for increases in LDL-C levels, liver function tests and LDL-C levels must be monitored closely. Chronic renal failure requires a 50% reduction in gemfibrozil dose.[69]

Novel agents

Cholesterol lowering agents with different mechanisms of action are in development. Ezetimibe is a novel cholesterol absorption inhibitor that selectively and potently inhibits intestinal absorption of dietary and biliary cholesterol.[70] In phase II clinical trials, ezetimibe at 10 mg/day reduced LDL-C by ≥15% in 68% of patients and by ≥25% in 22% over 12 weeks. HDL-C increased by 3·5% and the drug was well tolerated.[70] Ezetimibe may have additive effects if given in combination with a statin. When given in a fixed combination tablet with simvastatin, LDL-C was reduced by 52%.[71] Policosanol is a phytochemical that is a mixture of higher primary aliphatic alcohols isolated from sugar cane wax.[72] At dosages of 10 to 20 mg/day, it decreased total-C by 17 to 21% and LDL-C by 21 to 29%, while raising HDL-C by 8 to 15%.[72] Policosanol appears to have an acceptable safety/tolerability profile.

Combination therapy

Combination drug therapy should be used when diet and single drug therapy do not reduce LDL-C levels to the desired levels. Verification of adherence to and the efficacy of a prescribed regimen should be made on at least two occasions at monthly intervals before adding to the regimen. Table 13.3 describes a stepped approach to combination therapy depending on the lipid or lipoprotein variable(s) that are the therapeutic objective. Recall that reduction in LDL-C is the only alteration in lipid(s) or lipoprotein(s) that has been unequivocally demonstrated to reduce risks for CHD

Table 13.3 Stepped approach to lipid medication altering therapies

Elevated LDL-C	Elevated TG/LDL decreased HDL-C	Elevated Lp(a)	Markedly elevated TGs
1. Statin	Niacin	Niacin	Fibrate/ niacin
2. Statin+ resin	Niacin+resin		
3. ↑ Statin+ resin	↑ Niacin+resin		
4. ↑ Statin+ resin+ niacin or ezetimibe	↑ Niacin+statin or Statin+fibrate		

in clinical trials. Epidemiologic data demonstrate an increased risk associated with reduced levels of HDL-C,[64] increased plasma Lp(a) (usually in association with increased LDL-C levels), and, to a lesser extent, increased plasma triglyceride levels (usually in association with other risk factors). Intervention studies demonstrating reduction in CHD risk with changes in other lipid and lipoprotein particles have yet to be done.

Guidelines for selecting combination therapy

Practitioners should review four questions before adding other agents to initial diet and lipid-altering drug therapy regimens.[73]

1. Has adherence to and efficacy of the initial regimen been verified?
2. Does the patient have fasting hypertriglyceridemia? (Bile acid sequestering agents should be used as second or third agent only.)
3. What contraindications are present mitigating addition of other lipid-altering agents? (Other diseases or clinical conditions, or other lipid-altering agents.)
4. What are the total costs of additional drug therapy to the patient?

Efficacy of various combinations

Selected examples of maximum lipid and lipoprotein alterations are given in Table 13.4. Prior to the development of atorvastatin the maximum lowering of LDL-C was demonstrated with a combination of lovastatin (40 mg/day), colestipol (30 g/day) and nicotinic acid (5·5 g/day) at 70%. Triglyceride reductions of 80% can be effected with nicotinic acid alone with little to be gained in efficacy by adding another agent. Lp(a) levels are affected substantially only by nicotinic

Table 13.4 Efficacy of selected combination of hyperlipidemic drug therapy in modifying plasma concentrations of total, LDL and HDL cholesterol levels

Drug combination	% change			Reference

acid. HDL-C can be consistently raised by 25% with nicotinic acid alone with little further gain by adding other agents.

Adverse effects

The important adverse effects of the single agents are described in Table 13.2. As noted previously, the most serious interaction is seen when a statin drug is used in combination with cyclosporin and myopathy develops. While cessation of the statin allows symptomatic myopathy and elevated muscle enzymes to resolve, continued therapy at the same dose may lead to frank rhabdomyolysis necessitating hemodialysis. Statins have also been associated with myopathic syndromes in patients using erythromycin, niacin and gemfibrozil. Reduced levels of any statin should be used in transplant patients in association with niacin and gemfibrozil with careful monitoring of muscle enzyme levels. Erythromycin use should be absolutely contraindicated in transplant patients already on cyclosporin and a statin. If erythromycin is used the statin must be temporarily discontinued.

Clinical use

Although single-drug therapy offers a simple regimen, combination therapy with low-dose statin and low-dose bile acid sequestrant has been investigated.[74,75] Since the largest portion of lipid alteration is effected at low doses of both of these classes of agents and they work by very different mechanisms, an additive or synergistic response may occur. Low-dose combinations provide a good clinical alternative for patients who have symptoms at higher statin dosages and for organ transplant patients. They also appear to be more cost effective than using a statin as a single agent.

The newest resin, colesevelam, has been studied in combination with statins. Low-dose colesevelam and low-dose lovastatin were given in a double-blind, placebo-controlled study to 135 hypercholesterolemic patients.[76] The combination lowered LDL-C by 34% and 32% (the agents were either taken at the same time or colesevelam was taken at dinner, lovastatin at bedtime). Both combinations were superior to either agent alone, and both decreased total-C by 21%. Neither combination treatment significantly changed HDL-C or triglycerides. All treatments were well tolerated.[76] The resin was also studied alone or in combination with low-dose atorvastatin in hypercholesterolemic men and women. Combination therapy reduced LDL-C by 48%, statistically different from either low-dose atorvastatin or colesevelam alone, but did not affect triglycerides.[77] All treatment groups had similar frequency of adverse effects and the combination was well tolerated.[77] Colesevelam was also given in combination with simvastatin to 251 hypercholesterolemic patients in a randomized, double-blind, placebo-controlled format. All groups, including the placebo-treated patients, had decreased LDL-C levels versus baseline. Among all combination treatment groups (given different dosages of colesevelam and simvastatin), the mean decrease in LDL-C was 42%; this exceeded the decrease with either simvastatin or colesevelam alone.[78] Combination therapy was not significantly different from simvastatin monotherapy in effects on HDL-C and triglycerides. Side effects were similar among all treatment groups.[78]

Informed decisions about "gray zones"

Data have now accumulated on the use of lipid lowering drugs in previously less-well-studied subgroups such as the elderly, women, and diabetic patients. How and when should we use lipid lowering drugs in the following groups?

The elderly

If one lives until age 80 in the US, the average additional life expectancy is 8 years. Older individuals appear to be at least as responsive to cholesterol lowering agents as those in younger age groups. While some have suggested that risk attenuates for those who have hypercholesterolemia at older age, the absolute risk for developing CHD outcomes in the elderly over a short time interval is much higher than it is in younger individuals.

ATP III notes that most new CHD events and most coronary deaths occur in persons older than 65 and that a high LDL-C/low HDL-C level still has predictive power for development of CHD in an older person.[9]

WOSCOPS,[3] (primary intervention, or PI) included patients up to the age of 64 years, 4S[2] (secondary intervention, or SI) up to the age of 70 years, Post-CABG[8] (SI) up to 74 years and CARE[5] (SI) previously provided limited data for those up to 75 years. All except Post-CABG showed benefit on CHD and CVD mortality. WOSCOPS and 4S showed benefit on total mortality, although statistical significance of the data from WOSCOPS was marginal. All of these studies included limited analyses by age group. When data from WOSCOPS were pooled in the PPP, pravastatin significantly reduced relative risk of coronary events in older patients.[79]

More recently, the Heart Protection Study (HPS) enrolled over 20 000 participants – including 5082 women, 3982 type 2 diabetic patients and 1263 elderly patients between the ages of 75 and 80 years. It also enrolled 3421 subjects with low baseline LDL-C levels, and follow up lasted for 5·5 years.[4] Recently reported results show that a dose of 40 mg simvastatin once daily yielded striking results in terms of reduced events: 12% reduction in total mortality, 17% reduction in vascular mortality, 22% reduction in CHD events, 27% reduction in all strokes, and 16% reduction in non-coronary revascularizations.[4] Statin therapy appeared to be beneficial at all cholesterol levels – even in participants

whose baseline levels were well below the currently recommended target levels of 100 mg/dl.[4,80]

Other ongoing trials that will provide needed information on lipid therapy in the elderly are the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Disease Trial (ALLHAT) and the Women's Health Initiative (WHI).[81] Complete ALLHAT results, involving 10 000 participants without an upper age limit, are expected in 2002.[81] WHI will evaluate the effects of diet and lowering of fats in 48 000 female participants, aged 79 or younger, with completion expected in 2007.[81]

According to ATP III, "hard-and-fast" age restrictions do not appear to apply to the use of lipid lowering drugs in elderly persons with established CHD.[9] For primary prevention, ATP III recommends therapeutic lifestyle changes, including low-fat diet, exercise, and weight loss if overweight, and LDL lowering drugs if older persons are at increased risk because of multiple risk factors or advanced subclinical atherosclerosis.[9]

Women

Women were not included in early cholesterol lowering trials because of concerns about confounding hormonal effects on lipids, specifically in premenopausal women. Yet the relationship between increases in plasma cholesterol and CHD exists for women at all ages.

Based on recent secondary and primary prevention trials that did not convincingly show that hormone replacement therapy reduced CHD risk in postmenopausal women and did show benefits with statins, ATP III recommends a cholesterol lowering drug over hormone replacement for CHD risk reduction in women.[9] The later onset of CHD in women should be factored into clinical decision making regarding cholesterol lowering drugs.[9]

Of the "older" major clinical trials, CARE (Cholesterol and Recurrent Events) enrolled a fairly high percentage of women, 14%. It reported a 46% reduction in major coronary events among women participants versus a 20% commensurate risk reduction in men.[4] In the PPP, which included analysis of pooled data from CARE, pravastatin significantly reduced relative risk of coronary events in women.[22]

The first CHD primary prevention trial of statins to include women was the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS).[82] Among 997 postmenopausal women who received either placebo or lovastatin (20 to 40 mg/day), statin therapy showed consistent numerical decreases in first acute coronary major events and in all prespecified secondary end points (for example coronary revascularization, MI). The study was insufficiently powered, however, to detect significant differences between treatment groups.[82]

In HPS, 34% of participants enrolled were women, and benefits were consistent regardless of sex.[4] Male and female participants experienced similar reductions in risk.

Diabetic patients

Although aggressive control of blood glucose levels in type 2 diabetic patients reduces microvascular clinical outcomes, its effect on macrovascular disease outcomes remains unknown. Other traditional CHD risk factors are believed to increase dramatically the risk for clinical CHD events in these patients. Inherent in the diabetic disease process is an abnormality of lipoprotein lipase activity that is partially but not completely corrected by optimal glucose control. Any additional lipid and lipoprotein disorder(s) present in diabetic patients because of either inherited or secondary causes (obesity, alcohol consumption, etc.), accelerate atherosclerotic progression and increase the risk of clinical CHD events. Treatment of lipid disorders in diabetic patients with commensurate lowering of blood cholesterol levels suggests a similar treatment benefit in diabetic as in non-diabetic patients.[2,3,5]

The use of niacin in diabetic patients has traditionally not been recommended because of concerns about adverse effects on glycemic control. In the Arterial Disease Multiple Intervention Trial (ADMIT), however, niacin was given to diabetic patients in a prospective, randomized, placebo-controlled study enrolling 468 subjects, 125 of them with diabetes and diagnosed peripheral arterial disease.[83] Niacin was given at 3000 mg/day or to maximally tolerated dose, for up to 60 weeks. Niacin significantly increased HDL-C and decreased triglycerides and LDL-C in all participants ($P < 0{\cdot}01$: niacin *v* placebo for all). It modestly raised glucose levels in all participants while HbA_{1c} was unchanged from baseline through follow up.[83] ADMIT investigators conclude that lipid-modifying doses of niacin can be safely used in patients with diabetes and that niacin may be considered an alternative therapy in such patients who do not tolerate statins or in whom statins do not correct hypertriglyceridemia or low HDL-C levels.[83]

In CARE, 586 normocholesterolemic diabetic patients with CHD (14% of total sample) were given pravastatin or placebo for 5 years. In the diabetic patients given pravastatin, there were 8% and 25% reductions respectively in absolute and relative risks of coronary events.[84] Pravastatin also reduced the risk for revascularization procedures among diabetic patients by 32%. In subjects who were not diabetic but who had impaired glucose tolerance, pravastatin also substantially lowered the risk of recurrent coronary events.[84] According to the pooled data in PPP, pravastatin significantly reduced relative risk of coronary events in diabetic patients.[79]

The HPS trial included 3980 persons with diabetes and 2930 of these had no CVD. As noted above, the event reductions seen with simvastatin occurred in diabetic patients as well. There was a 24% decrease in CVD and a 25% decrease in total CHD.[4]

Peripheral vascular disease

In the Rancho Bernardo studies, patients with peripheral vascular disease had a several-fold increased risk of dying of

CHD. Greater than 80% of these individuals have CHD although some will manifest few symptoms. It is reasonable, but unsubstantiated, to treat these individuals as if they have CHD.

Small dense LDL-C particles (phenotype B)

The entire population may be generally divided into two categories on the basis of predominant LDL species present in plasma. People with a predominance of smaller, more dense LDL particles exhibit an increased propensity for oxidative susceptibility of these species.[85] These individuals have a higher risk for CHD, which may be associated to interrelated changes in plasma lipids, specifically an increase in triglycerides and reduced plasma levels of HDL. Alternatively, this pattern may be related to the insulin resistance syndrome, or syndrome X, which consists of impaired glucose tolerance, increased insulin levels, hypertension and abnormalities of coagulation factors. No trial of clinical outcomes and intervention of LDL subspecies has been done.

Key points

Lipid and lipoprotein alteration for prevention of coronary heart disease

1. Plasma LDL cholesterol lowering is effective in both men and women. **Grade A1a**
2. Plasma LDL cholesterol lowering is cost effective above the age of 35 years. **Grade A1a**
3. Plasma LDL cholesterol lowering is effective for ages at least to age 80 years. **Grade A1a**
4. Plasma LDL cholesterol lowering extends the patency survival of coronary artery saphenous vein grafts. **Grade A1a**
5. The variables (NIDDM, hypertension, increased plasma triglycerides, low plasma HDL-C, small-dense LDL and increased PAI-1 levels) that are components of the so-called "insulin resistance syndrome" appear to be a marker for individuals with small-dense LDLs. **Grade B2**
6. Alteration of plasma lipids (triglycerides) beyond total plasma cholesterol and LDL-C has not been demonstrated to affect CHD-cause specific morbidity or mortality. **Grade A1a**
7. Therapeutic increases in HDL-C may be associated with reductions in CHD. Associated changes in VLDL-triglyceride-rich particles appear to have an important role in CHD prevention. **Grade A1a**
8. Since it is effective even in high risk individuals with low initial LDL levels, consider initiation of appropriate therapy without initial determination of plasma lipid and lipoprotein levels. **Grade A1a** Best medical practice supports monitoring LDL-C levels during treatment. **Grade C5**

Costs and cost effectiveness of lipid alterations for CHD prevention

True benefits for individuals and the public health have only been demonstrated for alteration of plasma LDL-C. One method for comparing the costs of cholesterol lowering is shown in Table 13.5 where the cost of the various statins is given in terms of the number of dollars per per cent of LDL-C lowering per year.

Table 13.5 Comparative cost, dose and LDL-C lowering of statins

Agent	Dose (mg)	LDL-C ↓ (%)[b]	AWP ($/day)[c]	Cost/1%/ LDLR ($/yr)
Lovastatin	10[a]	−21	1·49	11·45
	20	−24	2·63	23·09
Simvastatin	10[a]	−30	2·52	27·66
	80	−47	4·40	75·27
Pravastatin	20[a]	−32	2·78	32·47
	80	−37	4·34	58·61
Fluvastatin	20[a]	−22	1·47	11·80
	40	−24	1·47	12·87
Atorvastatin	10[a]	−39	2·30	32·87
	80	−60	3·64	79·71

[a] *Common starting dose, qd.*
[b] From *Physicians' Desk Reference*[11]
[c] From *Red Book Update*. Montvale, NJ: Medical Economics Company; 2002
Cost/1%/LDLR was derived as cost/year/1% LDL reduction.

Until the release of results from the 4S study, reductions in CHD morbidity from plasma cholesterol-related CHD had been modest and reductions in CHD and total mortality had not been demonstrated. Since elevated plasma cholesterol is a major risk factor for CHD and is prevalent in Western countries, evaluation of the cost effectiveness of plasma cholesterol lowering is important because of the size of the potential population for intervention and the associated healthcare costs of what can be lifelong medical therapy. In a sensitivity analysis,[86] data from 4S demonstrate cost effectiveness of intervention for both men and women from 35–70 years and at plasma cholesterol levels above 213 mg/dl. The estimates of treatment costs for benefits observed in the 4S study, indicate that treatment is cost effective, among both men and women and at all plasma cholesterol levels between 213 and 309 mg/dl and with evidence of vascular disease.

A WOSCOPS economic analysis, comparing pravastatin with dietary changes alone, showed the economic efficiency of therapeutic intervention with a statin.[87] Caro *et al* used a generalized model of cardiovascular disease prevention and followed hypercholesterolemic men over a given time period to quantify the effect on cardiovascular diseases

avoided. Over a broad range of inputs and regardless of country, cost effectiveness ratios are below $35 000 per life-years gained. Pravastatin is cost-efficient in preventing CHD.[87] Based on US medical price levels and the clinical trial evidence up to 1998, Hay *et al* concluded that statin therapy is cost effective (that is, cost less than $50 000/year of life saved) in any patient with an annual CHD risk >1%, including those with previous CHD or diabetes.[88]

In a recent cost-effectiveness analysis of the VA-HIT trial, the cost per year of life gained with gemfibrozil was estimated. Using the prices for gemfibrozil negotiated by the VA, gemfibrozil was cost-saving.[89] Using prices for gemfibrozil paid outside the VA system, the cost of a quality-adjusted life-year saved by gemfibrozil ranged from $6300 to $17 000. The VA-HIT investigators concluded that gemfibrozil reduced cardiovascular events in men with CHD and low levels of HDL-C and LDL-C at annual drug cost-savings of $100 or less in 1998 dollars. Even at higher drug prices, the cost of a life-year saved is well below the threshold considered cost effective.[89]

Malik *et al*[90] provide a graphic demonstration of how cost effective statin therapy is versus other widely used therapies for CHD, such as ACE inhibitors, β blockers, and non-CV interventions, such as driver's side air bags (Figure 13.1). The cost effectiveness threshold here is £25 000/year of life saved (US $35 000/year of life saved).

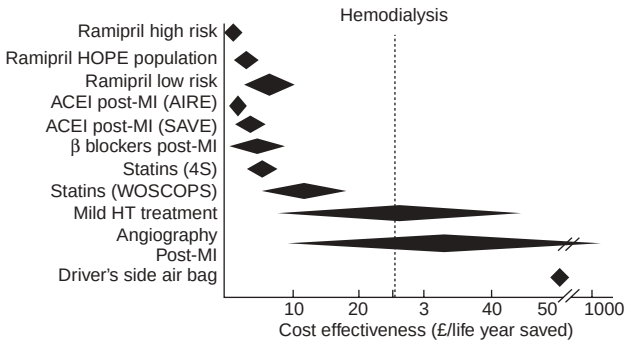

Figure 13.1 Comparison* of cost effectiveness of different strategies in prevention

*Estimates from previous studies are in 1994–1995 UK pounds. Adapted from: Malik IS, *et al Heart*, 2001;**85**:539–43

Future directions

The benefits of statins beyond the coronary vascular bed are now being intensively investigated. In addition to their lipid lowering properties, statins demonstrate pleiotropic effects on many aspects of atherosclerosis, such as plaque thrombogenicity, cellular migration, endothelial function, and thrombotic tendency.[18] Whether or not these effects can be related to a decrease in progression of atherosclerosis or to reductions in acute coronary syndromes remains to be seen. Another area for more study is the benefit of moderate versus aggressive LDL lowering. For example what are the risks and benefits of lowering LDL-C to 75 mg/dl compared to about 100 mg/dl? The exact role of manipulation of other lipoprotein particles also remains to be demonstrated.

Summary

The HMG-CoA reductase inhibitors are an important advance in the treatment of CHD and there is compelling evidence that LDL-C lowering with these agents can decrease the risk of CHD events and total mortality in both primary and secondary prevention. In addition to their effects on LDL-C, statins have pleiotropic effects, which may affect the development and the occurrence of clinical events of atherosclerosis. Lipid lowering therapy benefits the elderly, women, and diabetic patients, even if these individuals have normal LDL-C levels. Effective single- and combination-agent regimens for intervention for other plasma lipid and lipoprotein variables are also available.

Key points

Cardinal issues for using lipid altering agents

1. Is the diagnosis of hyperlipidemia certain?
2. Are there currently medications in the patient's regimen that cause dyslipidemia or offer the potential for drug interactions with hypolipidemic therapy?
3. ALWAYS start the therapeutic regimen with diet and other lifestyle modifications. **Grade A**
4. The statins act as a class of agents, but possess different dose response curves. Some may have substantial levels of adverse effects. **Grade A**
5. The currently approved statins have powerful lipid-altering effects and a very low order of adverse effects. **Grade A**
6. Nicotinic acid is a powerful agent which can be effective in many people including some diabetic patients when used carefully. **Grade A**
7. Nicotinic acid is the most effective of any agent on HDL-C levels and the only one with a possible effect on Lp(a). **Grade A**
8. Resin therapy can be effective for lowering LDL-C plasma levels with careful attention to details of dosing and administration, particularly when added to low-dose statin or low-dose niacin. **Grade A**
9. Fasting hypertriglyceridemia is a relative contraindication to primary or combination resin therapy. **Grade A**
10. Fibrates are effective agents for lowering triglyceride particularly when extremely high and moderately raising HDL-C levels, but changes in LDL-C levels need to be monitored. **Grade A**
11. Are there contraindications to the specific hypolipidemic drug combinations?
12. Consider the direct and indirect costs before initiating primary lipid-altering therapy and with the addition of each agent to the combined regimen.

14 Blood pressure and cardiovascular disease

Curt D Furberg, Bruce M Psaty

Definition

A new classification of elevated blood pressure (BP) that places greater emphasis on systolic BP was introduced in the 1993 *Fifth Report of the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure (JNC V)*[1] and slightly modified in the 1997 *JNC VI*.[2] Hypertension is defined as systolic blood pressure (SBP) 140 mmHg or greater and/or diastolic blood pressure (DBP) 90 mmHg or greater (Table 14.1). The new classification addresses the issue of severity or increased risk by defining three stages of hypertension, ranging from stage 1 (SBP 140–159 mmHg and/or DBP 90–99 mmHg) to stage 3 (SBP ≥180 mmHg and/or DBP ≥110 mmHg).

In middle-aged populations, the most common type of elevated BP is combined systolic-diastolic hypertension. A second type, isolated systolic hypertension, generally occurs in older persons, probably as a result of age-related stiffening of the arteries. A recent Clinical Advisory Statement[3] recommends that SBP should be the principal measure for the detection, evaluation, and treatment of hypertension in both middle-aged and older individuals.

Hypertension is also classified as complicated or uncomplicated according to the presence or absence of target organ manifestations. These manifestations, which can be cardiac, cerebrovascular, peripheral vascular, renal, or retinal, represent complications of hypertension, and they also increase the risk of other hypertension-related complications (Box 14.1).

Thus, hypertension is classified by its type (combined systolic-diastolic or isolated systolic hypertension), its

Table 14.1 Classification of blood pressure for adults aged 18 years and older[a]

Category	Systolic (mmHg)		Diastolic (mmHg)
Optimal[b]	<120	and	<80
Normal	<130	and	<85
High normal	130–139	or	85–89
Hypertension			
Stage 1[c]	140–159	or	90–99
Stage 2[c]	160–179	or	100–109
Stage 3[c]	≥180	or	≥110

[a] Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic blood pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For example, 160/92 mmHg should be classified as stage 2 hypertension and 174/120 mmHg should be classified as stage 3 hypertension. Isolated systolic hypertension is defined as SBP ≥140 mmHg and DBP <90 mmHg and staged appropriately (for example 170/82 mmHg is defined as stage 2 isolated systolic hypertension). In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify presence or absence of target organ disease and additional risk factors. This specificity is important for risk classification and treatment.

[b] Optimal blood pressure with respect to cardiovascular risk is <120/80 mmHg. However, unusually low readings should be evaluated for clinical significance.

[c] Based on the average of two or more readings taken at each of two or more visits after an initial screening.

Adapted from *JNC VI*[2]

Box 14.1 Components for cardiovascular risk stratification in patients with hypertension

Major risk factors

- Smoking
- Dyslipidemia
- Diabetes mellitus
- Age older than 60 years
- Gender (men and postmenopausal women)
- Family history of cardiovascular disease: women under age 65 or men under age 55

Target organ damage/clinical cardiovascular disease

- Heart diseases
  - Left ventricular hypertrophy
  - Angina/prior myocardial infarction
  - Prior coronary revascularization
  - Heart failure
- Stroke or transient ischemic attack
- Nephropathy
- Peripheral arterial disease
- Retinopathy

Adapted from *JNC VI*[2]

severity (stage 1–3), and by coexisting target organ manifestations (if present, complicated, or uncomplicated). These classifications are clinically important, since they have risk as well as treatment implications.

Prevalence

In cohort analysis,[4] mean SBP increases gradually with age, regardless of initial BP (Figure 14.1). Mean DBP also increases until the age of 55–60 years, when it levels off.[4] Later in life there is a reduction in mean DBP, especially in those with high initial levels (Figure 14.1). The age-related changes in BP explain the increase in overall prevalence of hypertension with age and the increase in the prevalence of isolated systolic hypertension with advanced age. The prevalence of target organ manifestations also increases with age, as a result of the increasing prevalence and the longer duration of hypertension.

The prevalence of hypertension is greater for African-Americans than for non-Hispanic Whites and Mexican-Americans,[5] and for less educated than more educated people.

Natural history

Hypertension is one of the major risk factors for cerebrovascular disease (stroke), coronary heart disease (acute myocardial infarction [MI]), congestive heart failure (both systolic and diastolic dysfunction), and renal dysfunction. The risk is directly associated with the BP level and with the presence of target organ manifestations and other cardiovascular risk factors. Ferrucci *et al.*[6] calculated the cardiovascular risk score for each participant of the Systolic Hypertension in the Elderly Program (SHEP) using the Multiple Risk Factor Assessment Equation.[7] The simple risk score is based on age, sex, total and HDL-cholesterol, SBP, smoking, and diabetes. In the placebo group, the 5 year rates of MI, stroke, and heart failure were progressively higher with higher quartiles of risk score in those who were free of cardiovascular disease at baseline. The *relative* event protection conferred by chlorthalidone-based treatment was similar across quartiles of risk. Thus, the *absolute* risk reduction increased by quartile of risk. This was reflected in a 2- to 10-fold lower "number needed to treat" (NNT) to prevent hypertensive complications in the highest-risk quartile (Figure 14.2). The authors concluded that hypertensive patients with additional cardiovascular risk factors should be the prime candidates for antihypertensive treatment.

Disease burden

Hypertension is one of the most common medical conditions in the developed world. It has been estimated that as many as 43 million adult non-institutionalized Americans have hypertensive BP levels or are taking antihypertensive medications. Another seven million persons may be controlling their hypertension using non-pharmacologic methods.[5]

Over the last two decades, the National High Blood Pressure Education Program has markedly raised the population's awareness concerning the high prevalence and complications of hypertension.[1] The number of patients taking

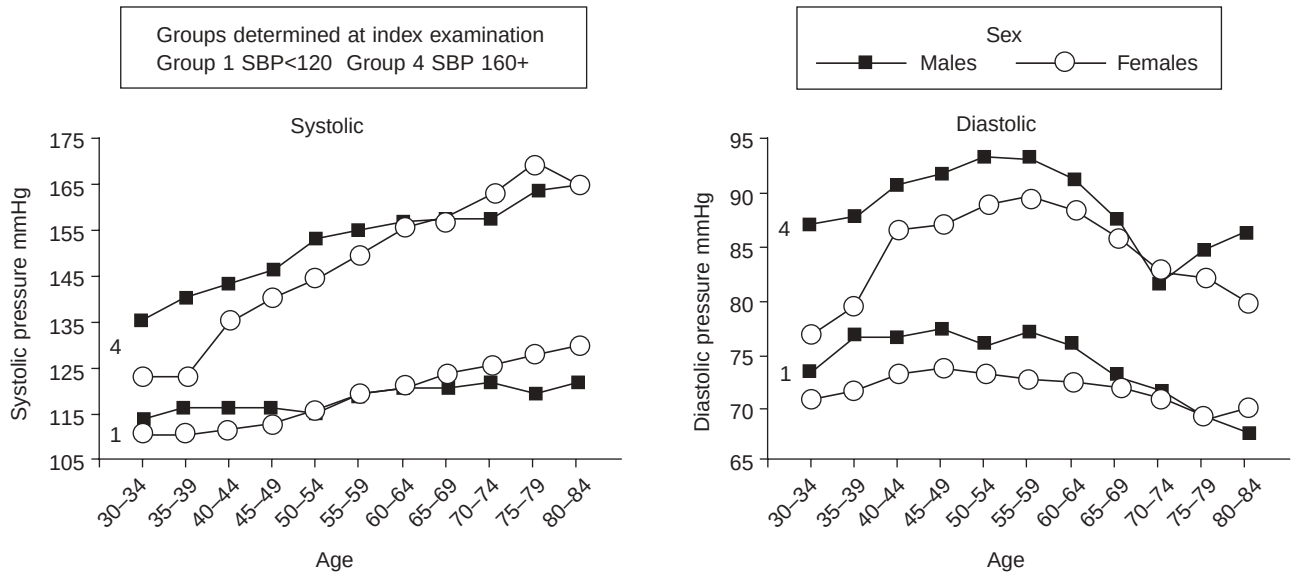

Figure 14.1 Arterial pressure components by age: group averaged data by sex. Averaged blood pressure levels from all available data for each subject with 5 year age intervals (30–34 through 80–84) by SBP groupings 1 *v* 4. (Adapted from Franklin *et al.*[4])

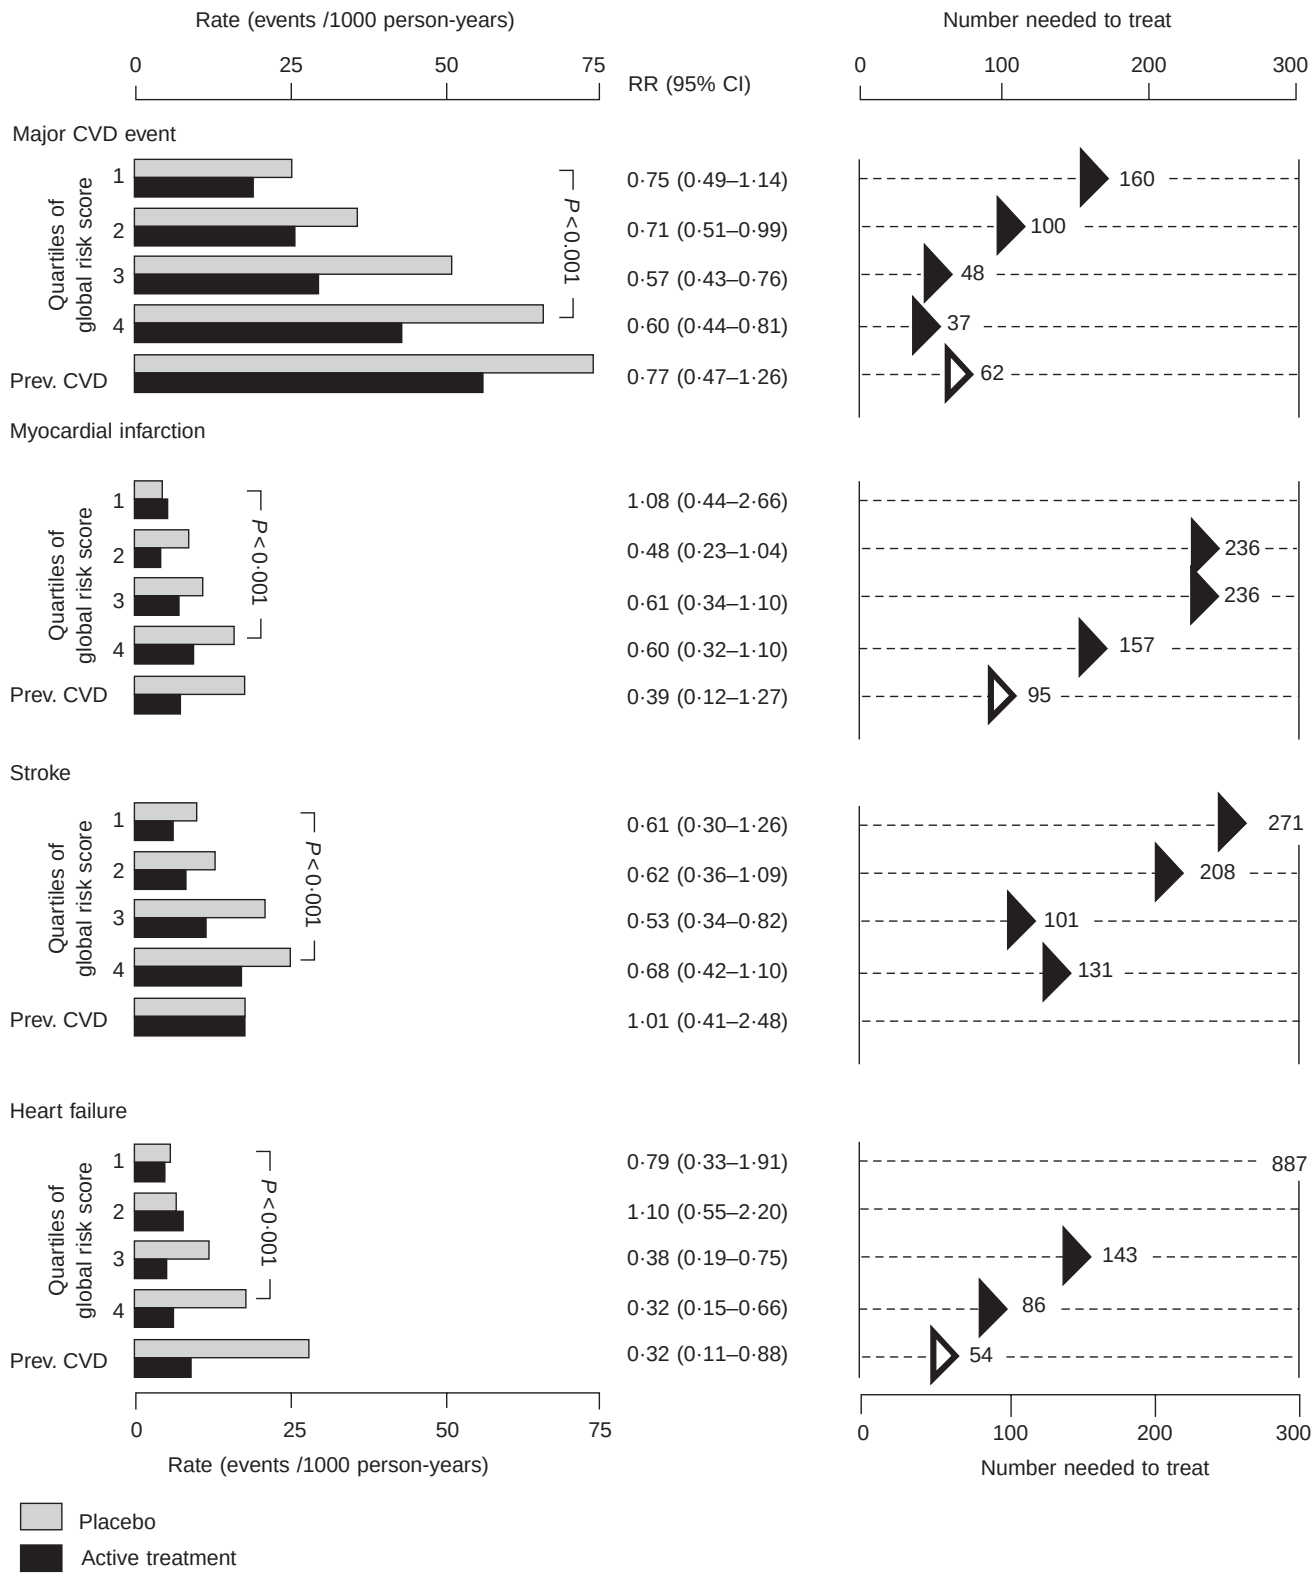

Figure 14.2 Rates of new cardiovascular events, relative risks (RR), and 95% confidence intervals and estimates of NNTs by quartile of global risk score for SHEP participants free of cardiovascular disease (CVD). The fifth group of bars in each panel shows data for subjects with prevalent (prev.) CVD at baseline. (Adapted from Ferrucci *et al.*[6])

antihypertensive medications and having their elevated BP controlled has increased dramatically. The rates of awareness, treatment, and control for hypertension for the new definition of ≥140/90 mmHg in a US population sample in 1991–1994 were 68%, 54%, and 27%, respectively.[2]

The cost of antihypertensive drugs in the USA alone in 2001 has been estimated as high as $12·3 billion.[8] Since as many as half of all hypertensives (defined as ≥140/90) remain untreated, the annual drug costs could easily double, unless we can change lifestyles more successfully or can be more efficient in allocating resources. During the late 1980s and early 1990s, the shift away from the less expensive, often generic diuretics and β blockers (with proven efficacy) to the newer, generally more expensive, ACE inhibitors, calcium antagonists, α blockers and angiotensin II blockers (with unproven efficacy) has been costly to society.[9]

Prevention of hypertension

Despite the established benefits of antihypertensive treatment, concerns are often raised about the prospect of use of antihypertensive drugs over decades by 20% or more of the adult population. All drugs have adverse effects and the cost of medical care for hypertension is considerable. Also, the 12 year follow up of approximately 350 000 middle-aged men screened for the Multiple Risk Factor Intervention Trial shows that 32% of the CHD deaths related to elevated BP occurred below the level at which drug treatment would be considered.[10] Therefore, the prevention of hypertension is a desirable goal.

The multifactorial etiology of hypertension is reflected by the large number of non-pharmaceutical approaches that have been tested.[11–13] Two types of populations have been examined. In individuals with above optimal but non-hypertensive BP levels, lifestyle interventions have been tested to determine their effect on BP. The outcome has been either BP reduction in short-term trials or prevention of BP elevation with age and reduction in the incidence of hypertension in long-term trials. Trials have also been conducted in hypertensive patients with the objective of determining the BP-lowering effects of various non-pharmacologic interventions. One rationale has been that the findings are likely to be generalizable to non-hypertensive individuals. Another rationale has been to determine the efficacy of lifestyle modifications as definitive first-line or adjuvant therapy for hypertension. All treatment guidelines recommend lifestyle modifications as the first therapeutic approach in newly diagnosed less severe hypertensive patients, with pharmacologic treatment to follow only in those who fail to respond adequately.

Cross-sectional or longitudinal observational studies have found the following factors to be associated with BP and prevalence or incidence of hypertension: adiposity, physical inactivity, alcohol consumption, high intake of sodium, low intake of potassium, magnesium, calcium, and certain types of dietary fiber, intake of certain macronutrients, and chronic stress.

Most of the 100+ published randomized clinical trials evaluating hypertension prevention and treatment were small and short term, had follow up periods of weeks or months, and focused on a single intervention. The interventions required varying amounts of involvement by the patients. Lifestyle modifications such as weight loss, exercise, or reduced alcohol or sodium intake require substantial counseling and commitment on the part of patients. Short-term changes may be accomplished, but whether these are sustained is often unknown. Other interventions have been based on supplementation (potassium, magnesium, calcium, fish oil, or fiber) by taking pills, capsules, or various forms of wheat bran, although some dietary trials have been conducted.

Trial results on the efficacy of interventions for prevention of hypertension are summarized in Table 14.2. Based on literature reviews, including meta-analysis, evidence of efficacy is conclusive for weight loss, exercise, diets high in fruits and vegetables, and reduction in alcohol and sodium intake, and potassium supplementation. **Grade A** A weight reduction of 10 lb (4·5 kg) can be expected to lower the BP by approximately 4/3 mmHg. Since exercise, as part of efforts to achieve caloric balance, influences weight, distinguishing an exercise effect on BP from the effect of weight loss can be difficult, but there is good evidence of BP reduction from fitness training.[14] Low intensity/high frequency activity appears as effective as or more effective than high intensity exercise. A sodium reduction of 80–100 mmol/day induces an average BP reduction of 5/3 mmHg in hypertensives and 2/1 mmHg in non-hypertensives.[12] Similar BP effects were observed in trials that accomplished alcohol reductions of about 85% (a mean consumption of three drinks/day reduced to three drinks/week).[15]

The BP effects of lifestyle modifications are modest, but they appear to be additive under some circumstances.[16] A short-term study recently reported substantial BP reductions in adults given a diet rich in fruits, vegetables, and low fat dairy foods, and reduced saturated and total fat.[17] A further reduction of SBP was observed when the sodium intake was reduced to below 100 mmol per day.[18] However, counseling, if required on an indefinite basis through a traditional clinical setting, may not be more cost effective than drugs. Therefore, interventions (such as reducing salt intake by modifying processed foods) that can potentially be accomplished on a population basis are attractive. The efficacy of supplementation with magnesium, fiber, fish oil, or calcium has been judged to be limited or unproven at this time.[11] The trial findings are discordant and the effect sizes small. Potassium supplementation (50–100 mmol KCl or equivalent increase from food) moderately reduces BP, especially in those who have a high sodium intake.[13]

Table 14.2 Trial results on efficacy of interventions for primary prevention of hypertension

Intervention	References	Duration (months)	Change in targeted factors	Change in BP, mmHg (systolic/diastolic)
Sodium reduction	16	6	−50 mmol/day	−2·9/−1·6
	16	18	−43 mmol/day	−2·0/−1·2
	16	36	−40 mmol/day	−1·2/−0·7
	12	0·5–36	−76 mmol/day	−1·9/−1·1
Weight loss	16	6	−4·5 kg	−3·7/−2·7
	16	18	−2·7 kg	−1·8/−1·3
	16	36	−1·9 kg	−1·3/−0·9
Exercise	14	1–16	To 65% maximum exercise capacity	−2·1/−1·6
Alcohol reduction	15	1·5	−2·6 drinks/day	−3·8/−1·4
Potassium increase	13	0·3–36	+46 mmol/day	−1·8/−1·0
Dietary pattern	17, 18	2	Increased fruit, vegetables, low fat dairy, protein, lower saturated fat, dietary cholesterol	−3·5/−2·1

Long-term trials in individuals with high-normal BP have documented that the incidence of hypertension can be reduced by as much as 50%. **Grade A** The most impressive results are from a 5 year trial of a multifactorial intervention.[19] The cumulative incidence of hypertension was 19·2% in the control group and 8·8% in the intervention group. The main factors contributing to this BP reduction were weight loss and sodium reduction.[16] Overweight adults with high-normal BP appear to be prime candidates for this intervention.

Lifestyle modification is an integral part of management of hypertension. The BP-lowering effects are on average modest. Some patients do not respond or are unable to modify their lifestyles, while others respond well. As a consequence, many patients do not have to be placed on antihypertensive drugs and, if they are, lower drug doses or fewer drugs may be required. The challenge is to sustain the lifestyle modifications.

Drug treatment

Placebo-controlled trials

Despite efforts at lifestyle modifications, many patients require pharmacologic treatment. In the USA, almost 23 million civilian non-institutionalized adults are currently taking antihypertensive medications.[5] This high level of drug use to treat an asymptomatic condition has been justified by the high population burden of major morbidity and mortality causally related to untreated hypertension, and by strong evidence of treatment efficacy and safety from large, long-term clinical trials. In SHEP,[20] which enrolled older adults with isolated systolic hypertension, the 5 year event rates for the combined end points of CHD and stroke per 100 patients were 13·6 in the placebo group and 9·4 in the active group. The risk difference of 4·2% means that about 24 older adults need to be treated for 5 years in order to prevent one coronary or cerebrovascular event. It must be recognized that calculating the number needed to treat in this manner from randomized clinical trials produces an underestimate for several reasons, chiefly the selection or self-selection of lower-risk patients into trials and the dilution of effects due to drop-in to active treatment by patients in the control group. For middle-aged populations, who are at lower risk, the number needed to treat would be much higher. Because many people must receive therapy so that a few will benefit, even uncommon adverse effects may minimize or eliminate the BP-lowering benefits of antihypertensive therapy. Only with large, long-term trials such as SHEP can we be assured that the health benefits actually outweigh the health risks of particular therapies.

In a recent meta-analysis,[21] the evidence from large, long-term, controlled clinical trials of antihypertensive therapy was reviewed. **Grade A** The 18 randomized trials included 48 220 patients followed for an average of about 5 years. Clinical trials were classified according to the primary treatment strategy. While most studies used more than one drug, the agents were generally used in a stepwise fashion, and it was usually easy to identify the first-line therapy.

Compared with controls, β blocker therapy was effective in preventing stroke and congestive heart failure (Table 14.3). Similarly, high-dose diuretic therapy, which typically started with the equivalent of 50 mg/day of hydrochlorothiazide and often went to 100 mg/day, was associated with a reduced risk of stroke and heart failure. Despite lowering BP

Table 14.3 Meta-analysis of randomized, placebo-controlled clinical trials in hypertension according to first-line treatment strategy

Outcome drug regimen	Dose	Trials (*n*)	Events, active treatment/ control	RR (95% CI)	RR (95% CI) 0·4 0·7 1·0 Treatment better / Treatment worse
Stroke

Trials indicate number of trials with at least 1 end point of interest. Abbreviations: RR, relative risk; CI, confidence interval; HDFP, Hypertension Detection and Follow-up Program Study (5484 subjects in stepped care and 5455 in referred care). For these comparisons, the numbers of participants randomized to active therapy and placebo were 7768 and 12 075 for high-dose diuretic therapy; 4305 and 5116 for low-dose diuretic therapy; and 6736 and 12 147 for β blocker therapy. Because the Medical Research Council trial included two active arms, the placebo group is included twice in these totals, once for a diuretic comparison and again for a β blocker comparison. The total number of participants randomized to active therapy and control therapy were 24 294 and 23 926, respectively.
Adapted from Psaty *et al.*[21]

by an average of about 5–6 mmHg, neither β blocker therapy nor high-dose diuretic therapy demonstrated significant reduction of coronary disease events (Table 14.3).

Compared with controls, low-dose diuretic therapy prevented not only stroke and heart failure but also CHD and cardiovascular and total mortality (Table 14.3). In contrast to high-dose diuretic therapy, the adverse metabolic effects of low-dose diuretic therapy are minimal. The safety and proven effectiveness make low-dose diuretic therapy the logical first-line pharmacologic treatment for hypertension. β blockers, which clearly prevent stroke and heart failure in hypertensive patients, are an alternative. The current US guidelines[2] appropriately identify low-dose diuretics and β blockers as preferred first-line agents in the treatment of hypertension.

It is not clear why low-dose diuretic therapy prevents CHD, but neither high-dose diuretic therapy nor β blocker therapy is associated with a reduced risk of coronary disease. The low-dose trials (see reference 21 for references) were conducted mainly in older adults while the high-dose trials were conducted largely in middle-aged adults. Evidence from observational studies suggests that, compared with low-dose diuretic therapy, high-dose diuretic therapy is associated with an increased risk of sudden

death.[22] For high-dose diuretics, the most likely explanation for this increased risk of sudden death is the dose of the diuretics rather than the age of patients. Abrupt withdrawal of β blocker therapy is associated with an increased risk of MI in patients with high BP.[23] It is possible that withdrawal reactions from non-compliance with β blockers may have minimized the drugs' ability to prevent CHD in hypertensive patients, who generally represent a low-risk population group.

The findings for β blocker and high-dose diuretic therapy provide direct evidence that BP lowering alone is not adequate to predict the effect of an antihypertensive medication on important health outcomes. "In light of all previous cardiovascular trials…" Topol and colleagues remark, "surrogate end points cannot be considered authentic measures of true clinical efficacy and safety."[24] Evidence from individual comparative trials and meta-analyses of comparative trials strongly indicates that it matters how elevated BP is lowered (see below). Although average BP reductions are similar across different classes of drugs, important differences exist between these classes in terms of their effects on major morbid events, especially heart failure and acute MI.[25] Yet drug regulatory agencies currently approve antihypertensive medications primarily on the basis of their ability to lower BP.

Results from several long-term, placebo-controlled trials of the newer classes of antihypertensive agents have been published since 1997 (Table 14.4). A placebo-controlled trial of nitrendipine, which is not available in the USA, in isolated systolic hypertension (Syst-Eur) found a statistically significant reduction in stroke risk and showed trends for reductions in risks of acute MI and congestive heart failure.[26] Two placebo-controlled trials in patients with type 2 diabetes and nephropathy, the Irbesartan Diabetic Nephropathy Trial (IDNT)[27] and the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) Study,[28] investigated two different angiotensin II receptor blockers. The primary end point in both trials was a composite renal outcome defined as a doubling of serum creatinine, development of end stage renal disease, or death from any cause. The primary results were very similar: the composite renal outcome was lowered by 20% in IDNT by irbesartan and by 16% in RENAAL by losartan ($P=0{\cdot}02$ in both trials). IDNT also evaluated the effect of amlodipine, a calcium-channel blocker, that did no better than placebo for the renal outcome (RR 1·04). In neither trial did the active treatments significantly reduce the risk of a composite cardiovascular outcome in comparison to the placebo controls.

The Perindopril Protection against Recurrent Stroke Study (PROGRESS) recently reported that ACE inhibitor-based treatment reduced the risk of stroke by 28% and the risk of total major vascular events by 26%.[29] Those receiving the combination of perindopril and the diuretic indapamide (56% of the population) benefitted the most. In this subgroup, the mean reduction in BP was 12/5 mmHg and the reduction in stroke risk was 43%. Those assigned to perindopril alone experienced a small reduction in blood pressure, 5/3 mmHg, with no significant reduction in stroke risk.

In conclusion, placebo-controlled trials conducted through the early 1990s documented conclusively that low-dose diuretics and β blockers used as first-line drugs markedly reduce the devastating cardiovascular complications experienced by hypertensive patients. **Grade A** This achievement had two important consequences. First, it established low-dose diuretics as the proper control group for comparative trials. Second, it limited the opportunity for conducting

Table 14.4 Clinical effects of newer antihypertensive agents from recent placebo-controlled trials

Trial	Study population	First-line treatment	Outcome	RR (95% CI)
Syst-Eur[26]	ISH	nitrendipine	Stroke	0·58 (0·40–0·83)

long-term, placebo-controlled trials, since withholding active treatment generally became ethically unacceptable. Only in specific subgroups of hypertensive patients – for example, those with major comorbidity such as nephropathy and cerebrovascular disease – were placebo-controlled designs considered acceptable. The focus of clinical research in hypertension has shifted from answering the question, "Is blood pressure lowering beneficial?" to asking, "Does it matter how elevated blood pressure is lowered?" The latter question requires comparative or active-controlled trials.

Active-controlled trials

ALLHAT, initiated in 1994,[30] is one of the first major active-controlled or comparative outcome trial to examine whether the type of drug used to lower high BP matters. While the study hypotheses are formally two-sided, the primary interest is a test of superiority, with the overall objective being to determine whether each of three drugs from newer drug classes (ACE inhibitors, calcium-channel blockers, and α blockers), when used as first-line therapy, are superior to low-dose diuretics in reducing the risk of cardiovascular events. The α blocker (doxazosin) arm was terminated early in 2000[31] for two reasons – a 25% excess of major cardiovascular events, primarily congestive heart failure, and a very small likelihood of observing that it is superior to low-dose diuretics in reducing major coronary events (Table 14.5). The fact that excess cardiovascular events with doxazosin occurred despite BP reduction that was similar to the diuretic group points to the importance of drug selection in the treatment of hypertension.

A meta-analysis of nine randomized comparative clinical trials of intermediate- and long-acting calcium-channel blockers (CCB) was recently published.[32] The comparators were mostly low-dose diuretics, β blockers, and ACE inhibitors. The mean BP reduction was almost identical in the CCB and non-CCB groups. In the database that included nearly 120 000 person-years of treatment, use of CCBs was associated with approximately 25% excess rates of both congestive heart failure and acute MI ($P < 0{\cdot}005$) (Table 14.5). No differences were observed between the groups for stroke or all-cause mortality. When the database from a second meta-analysis[33] was used to examine the same question – CCBs versus non-CCBs – the results were similar and statistically significant.[34]

In a similar type of meta-analysis, the benefit of ACE inhibitors was compared to that of non-ACE inhibitors, primarily CCBs in patients with diabetes.[35] The pooled analysis, supported subsequently by another trial,[36] strongly suggested that ACE inhibitors have advantages over

Table 14.5 Clinical effects of newer antihypertensive agents from recent active-controlled trials

Study	Study population	Treatment		Outcome	RR (95% CI)

[a] Updated to include reference 36.

non-ACE inhibitors in reducing the risk of acute myocardial infarction and major cardiovascular events, in spite of similar BP reduction (Table 14.5).

The fourth source of evidence concerning the relevance of how elevated BP is lowered comes from two very recent trials with similar design in patients with nephropathy (Table 14.5). The achieved BP levels were similar for the two therapies – amlodipine versus a drug blocking the renin– angiotensin system. In the AASK trial,[37] among patients with non-diabetic nephropathy, the amlodipine group was terminated early owing to a more rapid decline in renal function and a 60% higher risk of a composite renal outcome – renal disease progression, end stage renal disease, or death compared to the ramipril group. Amlodipine was also inferior to irbesartan in patients with diabetic nephropathy in IDNT.[27] The risk of the composite renal outcome was 32% higher in the amlodipine group compared to the irbesartan group. There was no group difference for a composite cardiovascular outcome.

In conclusion, these reports document that in certain circumstances it matters how elevated BP is lowered. It appears that two types or classes of drugs, α blockers and CCBs, are as effective as other antihypertensive agents in reducing SBP and DBP in the reviewed trials, but less effective in reducing the risk of heart failure (both classes) and MI (CCBs). In elderly high-risk hypertensive patients, doxazosin was less effective than chlorthalidone in reducing risk of congestive heart failure and stroke. **Grade A** There was no difference in risk of major coronary events. It is likely that these observations from ALLHAT apply to all α blockers. Two thirds of the heart failure cases were either hospitalized or fatal. Several sources of data[32–37] show that CCBs are inferior to other agents in reducing the hypertensive complications of congestive heart failure and acute MI. These findings may be especially relevant in patients with type 2 diabetes.[35,36] Since diuretics, β blockers and ACE inhibitors are effective in the treatment and prevention of heart failure and most CCBs are contraindicated in patients with this condition, these observations should not be surprising. Similarly, β blockers and ACE inhibitors are beneficial in the prevention of CHD while the CCBs are not. Additionally, recent trials have reported that amlodipine is inferior to drugs blocking the renin–angiotensin system.[27,37] In these small trials, there was no difference in cardiovascular events.

Genetics, hypertension, and some potential drug–gene interactions

The phenotype of high BP represents a complex trait influenced by both genes and environment.[38–40] While behavioral factors such as obesity and physical inactivity are clearly important in the etiology, family studies and twin studies suggest that about 30% of the variation in levels of BP can be attributed to genetic factors.[39] Several monogenic forms of high BP have been identified, and they include, for instance, glucocorticoid-remediable aldosteronism and Liddle's syndrome.[38,39] These monogenic forms of hypertension, though sometimes associated with profound elevations of BP, are rare and do not contribute measurably to the burden of hypertensive disease in humans.

Essential hypertension, generally mild to moderate elevations of BP in the population, has been associated with several genetic polymorphisms. Halushka and colleagues have identified 874 single nucleotide polymorphisms in 75 candidate genes for BP homeostasis.[41] Not surprisingly, the literature on genetics and hypertension is vast. This section will illustrate the findings for several leading candidate genes, including variations in the genes coding for angiotensinogen,[42] the β-2 adrenergic receptor,[43] and α adducin,[44] with special attention to potential drug–gene interactions that may in the future affect treatment choices. The genetic studies of hypertension are immensely important for understanding the biologic and molecular etiologies of high BP and, potentially, for the design of new drugs. The public health importance of variations in candidate genes for hypertension remains to be determined. While this work has enhanced our knowledge of molecular biology, the polymorphisms associated with essential hypertension, though some are common, tend to have small effects. As Corvol has aptly observed, "Most molecular variants lead to a low attributable risk in the population or a low individual effect at the individual level."[45]

Angiotensinogen gene (*AGT*)

Polymorphisms in the *AGT* gene, especially the *Met235Thr*, have been associated with hypertension.[46,47] The *Met235Thr* variant, which is associated with elevated plasma levels of *AGT*, is in linkage disequilibrium with the *A-6G* promoter polymorphism, and the *-6G* variant is associated with increased gene transcription[46,48] and aldosterone production.[49] In response to sodium restriction, patients with the *Thr235* variant and the *-6A* promoter variant have larger reductions in level of BP than persons with the corresponding wild type allele.[50,51] Patients with the *Thr235* variant also have more pronounced responses to ACE inhibitors than those with the *Met235* allele.[52] In one study,[46] the *AGT* polymorphism predicted the BP response to treatment with ACE inhibitors. The largest fall in BP was associated with the *T235* allele of *AGT*, which is also associated with higher levels of *AGT*.[46] Since subjects with the *Thr235* and *-6A* variant alleles appear to be more salt sensitive, and since diuretics are more effective in salt-sensitive hypertension, diuretics may be especially effective in subjects with these variant alleles.[50,51]

β-2 adrenergic receptor (*β2AR*)

Adrenergic receptors are members of a large family of receptors linked to guanine-nucleotide-binding proteins

(G proteins). Recent studies in molecular biology have contributed to our understanding of the structure, function and regulation of adrenergic receptors,[53] including their interaction with G-proteins in the heart.[54–56] In a series of studies, Liggett and colleagues identified several polymorphisms in the β-2 receptors and their functional and clinical consequences.[57] Four of the nine point mutations resulted in changes in the *β2AR* amino acid sequence, and several appear to affect agonist-promoted downregulation of the *β2AR*.

The β-2 adrenergic receptors are important in BP regulation. Genetic variation in these receptors may account in part for variation in the risk of hypertension or variation in the response to drug treatment.[58] In normotensive African-Americans compared to White Americans, dilation of forearm resistance vessels in response to the infusion of a β-2 adrenergic agonist is decreased.[59] These findings suggest that alterations in the response to β-2 adrenergic stimulation may be important in the development of hypertension in African-Americans. A polymorphism in the β-2 adrenergic receptor gene detected by a restriction fragment length polymorphism (RFLP) is associated with hypertension, both in Whites and Blacks.[60] In African-Americans, this β-2-related RFLP is associated with a salt-sensitive form of hypertension.[61] In African-Caribbeans, the *Arg16Gly* polymorphism of the β-2 adrenergic receptor is associated with hypertension[58] (OR = 2·74; 95% CI 1·72–4·36).

In one recent study, Dishy and colleagues describe the association between several *β2AR* variants and responses to isoproterenol with particular attention to the desensitization that normally occurs with prolonged exposure.[43] For the *Arg16Gly* polymorphism, subjects homozygous for the *Gly16* variant were more resistant to the agonist-mediated desensitization than subjects homozygous for the *Arg16* as measured by sustained venodilatation. For the *Gln27Glu* polymorphism, subjects homozygous for the *Glu27* variant had higher maximal venodilatation in response to isoproterenol than those who were homozygous for *Gln27*.[43]

Taken together, these findings suggest that genetic variation in the β-2 adrenergic receptor may be important in hypertension, and that the risk may vary in subgroups according to ethnicity or salt sensitivity. High-salt diets produce hypertension in part by downregulating the β-2 receptors.[62] Thus, genetic variation in these β-2 receptors may influence not only the development of hypertension but also the response to diuretics as well as β blockers.

α adducin

α adducin is the first example of molecular genetic research in the rat to provide key insights to human hypertension.[40] A series of elegant experimental comparisons between the Milan Hypertensive Strain (MHS) and the Milan Normotensive Strain identified *α adducin* as a candidate gene.[63,64] Adducin, a heterodimer of alpha and beta subunits, modifies the cell cytoskeleton and thereby modulates the cell-surface exposure of the transmembrane proteins.[65,66] This interaction between cytoskeletal proteins and transmembrane proteins helps to regulate ion transport. In the MHS, the number of Na^+/K^+ pump units and their activity are increased, and Na-K ATPase activity is upregulated.[66]

In humans, a *Gly460Trp* polymorphism of *α adducin* was recognized and investigated.[67] The variant *Trp460* allele is associated with the prevalence of hypertension in Italians and French (OR = 1·6, 95% CI 1·3–1·9).[44] The variant *Trp460* allele also modifies the response to 2 months of treatment with thiazide diuretics and to acute salt-sensitivity testing.[44] Subjects with one copy of the *Trp460* variant allele had a larger BP response to thiazide treatment than those with the wild type (decrease of mean arterial pressure of 14·7 for *Trp460* versus 6·8 mmHg for the wild type). Similarly, subjects with the *Trp460* variant also had a more pronounced response to the acute salt-sensitivity testing (change in MAP of 15·9 *v* 7.4 mmHg). These findings are consistent with role of *α adducin* in controlling renal transepithelial ion transport in humans.[68] The association with hypertension has been confirmed in some[69] but not all clinic-based studies.[70–72] In the only population-based study, the OR for the association of adducin with hypertension was 1·67 (P = 0·02).[73] The response of subjects with the variant *Trp460* allele to diuretic therapy is pronounced even in populations where the variant allele is not associated with the risk of hypertension.[74]

The *α adducin* polymorphism is strongly associated with the salt-sensitive form of hypertension, and individuals with one or two copies of the variant allele display an increased rate of renal tubular sodium reabsorption after sodium depletion or loading.[75] In one large clinical trial of antihypertensive therapy,[76] it was observed that there was a reduction in cardiovascular events, particularly stroke, in the treatment group – a reduction that could not be completely accounted for by the attained BP reduction. Among participants with the adducin variant in a recent case–control study, diuretics were compared with other antihypertensive drugs. It was found that in those participants the use of diuretics was associated with a 50% reduction in the risk for MI or stroke.[77] Treatment with thiazides in people with salt-sensitive hypertension may decrease the incidence of cardiovascular events through other mechanisms than the direct lowering of BP.

Pharmacogenetics

Over centuries and across communities, large numbers of polymorphisms have appeared in what are now called drug receptors, drug effector pathways, and drug-metabolizing enzymes. Indeed, some variant alleles have become common in the absence of any exposure to most modern medications. For instance, the allele frequencies in various

populations are 11–57% for *α adducin*, 42–72% for the *β2AR* variants at positions 16 and 27, and 36–52% for angiotensinogen. Interest in pharmacogenetics is often inspired by the point of view of drug development. Identifying the genes responsible for variation in or regulation of BP may provide opportunities to design new drugs.[78] While some studies suggest the possibility of drug–gene interactions on the outcome of level of BP, no studies have examined the potential for drug–gene interactions on the occurrence of cardiovascular events. Another perspective is the point of view of drug safety.[79] Thousands of prescription medications are already on the market. In 1994, 2·2 million hospitalized persons experienced serious adverse drug reactions, and 106 000 had fatal adverse drug reactions.[80] Work in pharmacogenetics can perhaps also improve the safety profile of medications already commonly used in the USA.

The studies in molecular biology and genetics are occurring at a breathtaking pace. The identification of polymorphisms at once answers questions about genetic variation and, at the same time, raises questions about their clinical applications in medical practice – important questions that need to be answered before these genetic studies can begin to benefit the health of the public. Many of these genetic variants are exceedingly common. If screening for genetic variants such as the *Trp460* allele of *α adducin* identifies patients for whom diuretics are particularly effective in preventing cardiovascular events, then genetic screening for selected polymorphisms might become as useful as renal function tests in the initial work up of patients with high BP. Much work needs to be done before genetic screening is indicated.

Cost effectiveness

It has been estimated that medications account for 50–90% of the direct cost of hypertensive treatment.[81] The 1996 wholesale prices for starting doses of antihypertensive drugs may vary by at least 40-fold. Thus, the choice of drug(s) has a major effect on direct treatment costs.

The direct costs of routine outpatient physician visits and laboratory tests are also substantial. If one assumes three annual office visits (at $70 each) and two serum chemistry panels (at $29), these non-drug costs of hypertension management amount to $268 per patient per year. For every one million of the 20 million untreated patients in the USA started on drug treatment, the total cost could be as low as $450 million or as high as $1 billion annually. The question from a cost-effectiveness viewpoint is not whether treatment is effective, but whether the benefits justify the costs in light of competing healthcare needs.

Formal cost-effectiveness analyses are not possible for the newer antihypertensive agents because of the lack of data on effectiveness. One has to make assumptions about the magnitude of effectiveness. **Grade A** If we assume that the newer agents are as effective as low-dose diuretics, the wholesale medication costs to prevent a fatal or non-fatal coronary event, a fatal or non-fatal stroke, a death from any cause, and any of these complications among patients with uncomplicated mild to moderate hypertension are as shown in Table 14·6. The costs are given for low-dose diuretics and a prototype of the newer unproven agents, nifedipine GITS. Recent cost data based on smallest tablet size available show that retail prices currently vary approximately 20-fold.[82]

In the context of healthcare systems in which priorities are being established (fixed budgets), the prime candidates for antihypertensive drug treatment are:

- elderly patients
- patients with moderate to severe hypertension
- patients with other cardiovascular risk factors, target organ manifestations.

These patient groups (among others) are at a higher risk of clinical hypertensive complications. Since clinical trials have demonstrated similar relative reductions in risk of stroke, acute MI, congestive heart failure, and mortality in

Table 14.6 Costs (US$) in wholesale medication prices to prevent a fatal or non-fatal CHD event, a fatal or non-fatal stroke, a death of any cause or any of these events in patients with uncomplicated mild to moderate hypertension assuming similar efficacy[a]

Event	Hydrochlorothiazide		Nifedipine GITS	
	Middle-aged	Elderly	Middle-aged	Elderly
CHD	21 374	3822	1 571 809	281 025
Stroke	7413	2453	545 141	180 372
Mortality	14 826	3931	1 090 281	289 078
Any of above	4730	1588	347 859	116 758

[a] The relative efficacy of calcium blockers compared to diuretics has not been reliably evaluated. These estimates assume similar impact of the two agents.
Adapted from Pearce *et al*[80]

low-risk compared to high-risk patients, the absolute benefit expressed as number needed to treat to prevent one event or as number of events prevented per 100 patients treated is substantially greater in the high-risk groups described above.

Unanswered questions

- In terms of clinical efficacy and safety, how do the newest agents compare with the proven treatments, low-dose diuretics, β blockers and ACE inhibitors? Are they superior, the same, or inferior? This question and the following one are the key clinical questions today. The answer to this question depends on large, long-term trials that include an actively treated control group. ALLHAT is an excellent example.[30]
- Compared to the older proven drugs, are the newer agents cost effective? Regrettably, formal analysis to date has been limited by a lack of efficacy data for the newer agents. If, in ongoing trials, they turn out to be superior, we have to decide whether the degree of superiority justifies the price differential and, if so, whether the newer drugs deserve to be considered as first-line agents. If the newer agents are the same or inferior, their use should be restricted to second- or third-line agents, and be limited to patients who do not respond to low-dose diuretics, β blockers, and ACE inhibitors, or who cannot tolerate them or to specific targeted populations.
- What is the best method for risk stratification? How can we implement feasible and acceptable risk stratification in the clinical setting, thus, allowing treatment decisions to be based on an individual's overall cardiovascular risk?
- What is the optimal level of treated BP? Should the treatment goals be even lower than 140 mmHg (systolic) or 90 mmHg (diastolic) for certain high-risk subpopulations?
- What are the optimal method(s) for long-term lifestyle modifications?
- How can we best reduce the incidence of hypertension?
- Will genetic information improve the efficacy and safety of drug treatment with specific antihypertensive agents?

Key points

- Hypertension should be classified by its type (diastolic/combined *v* isolated systolic hypertension), its severity (stage 1–3) and by coexisting target organ manifestations (complicated *v* uncomplicated). **Grade A**
- If choices must be made, high-risk hypertensive patients – that is, elderly patients, those with moderate to severe hypertension and those with target organ manifestation – ought to be the prime candidates for treatment owing to more favorable benefit–risk and cost-effectiveness ratios. **Grade A**

Key points Continued

- Lifestyle modification – primarily weight control and sodium reduction – is an integral part of management of hypertension. Good evidence on efficacy also exists for increased physical activity, moderation of alcohol intake, and ensuring adequate potassium intake. **Grade A**
- Low-dose diuretics should be the first-line drugs because of proven efficacy and safety; β blockers and ACE inhibitors are alternatives. In patients with type 2 diabetes, ACE inhibitors appear to be the drugs of choice. **Grade A** Emerging evidence suggests that angiotension II receptor blockers convey benefit similar to that of ACE inhibitors. The use of calcium antagonists, and α blockers ought to be restricted to patients who do not respond to low-dose diuretics, β blockers and ACE inhibitors or who cannot tolerate them.
- Major differences in direct drug cost between low-dose diuretics and the newer and heavily promoted agents ought to be a strong incentive to enhance use of the former. **Grade A**

15 Glucose abnormalities and cardiovascular disease: "dysglycemia" as an emerging cardiovascular risk factor

Sarah E Capes, Hertzel C Gerstein

Large epidemiologic studies have consistently shown that patients with diabetes mellitus (DM) have a two-to fourfold increased risk of cardiovascular disease relative to non-diabetic patients.[1–3] Patients with both type 1 and type 2 diabetes are at increased risk. For patients with type 1 diabetes, who present soon after the disease develops, this increased risk is not apparent until 20 to 30 years after the diagnosis is made. For patients with type 2 diabetes, who constitute over 90% of all patients with diabetes, this increased risk is apparent right at the time of diagnosis and is independent of the duration of diagnosed diabetes.[4–6] For these patients, this observation may be due to a 5–10 year antecedent history of undiagnosed diabetes, preceded by an indeterminate period of elevated glucose levels that are below the diabetic cut off.[7]

Recent studies suggest that in patients with diabetes, the degree of glucose elevation is directly related to the risk of cardiovascular disease. For non-diabetic patients, a critical overview of the available epidemiologic studies suggests that this continuous relationship extends below the diabetic threshold and includes mildly elevated glucose levels that are generally considered to be normal. There may or may not be a lower glucose threshold to this risk. Thus, like total cholesterol or diastolic hypertension, glucose appears to be a continuous cardiovascular risk factor. Whether or not modification of this risk factor by interventions that lower glucose levels will also prevent cardiovascular disease remains an important and unanswered question.

Definition and epidemiology of diabetes and impaired glucose tolerance

The diagnosis of DM applies to a heterogeneous group of disorders that are all characterized by high levels of glucose in the blood.[8] This hyperglycemia is due either to absent or minimal insulin secretion from insulin-producing β cells of the pancreas, or to insufficient insulin secretion to overcome a variable degree of "insulin resistance" that is present in a large proportion of the general population. As insulin is the primary hormone that prevents hyperglycemia, both by inhibiting hepatic glucose production and facilitating glucose clearance by muscle, insufficient insulin quickly results in an elevated glucose level. The clinical classification of diabetes and the associated characteristics and suspected causes of each type are listed in Table 15.1.

For many years it was apparent that patients with diabetes had a high risk of developing eye disease, kidney disease, peripheral nerve disease, and cardiovascular disease (that is, coronary heart disease, cerebrovascular disease, and peripheral vascular disease). In 1979 and 1980 it was also recognized that these complications were occurring in patients with both diagnosed diabetes and asymptomatic, undiagnosed diabetes.[9] On the basis of epidemiologic studies of the risk of eye and kidney disease according to the 2 hour glucose level (during a 75 g oral glucose tolerance test) in populations at high risk for diabetes, specific glucose thresholds were defined for the diagnosis of diabetes (Table 15.2). These specific levels were those above which patients were at high risk of diabetic retinopathy and nephropathy; patients with levels below this threshold had a very low risk for these diabetic complications.[7,8,10] The fact that these thresholds were not chosen to reflect the risk of cardiovascular disease is apparent from many studies demonstrating a high risk of cardiovascular disease in patients with much lower glucose levels (see below).

At the time that these thresholds were established, it was clear that a large number of people had glucose levels that fell below the diabetic threshold but that were nevertheless still elevated. This led to the classification of Impaired Glucose Tolerance (IGT), which was defined on the basis of the glucose level (Table 15.2) and not on the basis of any particular clinical characteristics.[8,9] Although people with IGT were at low risk for diabetic retinopathy and nephropathy, they had a higher risk for developing diabetes than people with normal glucose tolerance (defined by

Table 15.1 Etiologic classification of diabetes mellitus[a]

Name	Characteristics	Etiology	Epidemiology
Type 1	Primarily due to pancreatic islet β-cell destruction; prone to ketoacidosis	Autoimmune or idiopathic; genetics play a role	~10% of patients with diabetes; 0·2% of the general population
Type 2	Results from insulin resistance with an insulin secretory defect	Genetics play a key role	~90% of patients with diabetes; up to 10% of the adult population
Gestational diabetes	Diabetes with onset or first recognition during pregnancy	Usually a result of hormonal changes in pregnancy; usually resolves after delivery	Complicates ~4% of pregnancies in USA
Other specific types	Related to a genetic, congenital, pancreatic, endocrine, or infectious acquired disease, or drug-induced	Examples include hemochromatosis, pancreatitis, hypercortisolemia	Other forms of diabetes account for ~2% of all patients with diabetes

[a] Adapted from reference 8. Note that patients with any form of diabetes may require treatment with insulin at some stage of their disease. Use of insulin does not in itself classify the patient.

Table 15.2 Diagnostic thresholds for diabetes, impaired glucose tolerance, and impaired fasting glucose[a]

Classification	Random plasma glucose	Fasting plasma glucose	2 hour post-load (75 g glucose) plasma glucose
Diabetes mellitus	≥11·1 mmol/l and classical signs and symptoms of hyperglycemia[b]	≥7·0 mmol /l[b]	≥11·1 mmol/l[b]
Impaired glucose tolerance	N/A	<7·0 mmol/l	≥7·8 and <11·1 mmol/l
Impaired fasting glucose	N/A	≥6·1 and <7·0 mmol/l	N/A

[a] The diagnostic criteria for diabetes recommended by the Expert Committee of the American Diabetes Association have been modified from those previously recommended by the National Diabetes Data Group (that is, fasting plasma glucose ≥7·8 mmol/l on at least two occasions, or plasma glucose ≥11·1 mmol/l at 2 hours and at one other point in the test in an oral glucose tolerance test) and the World Health Organization (that is, fasting plasma glucose ≥7·8 mmol/l, 2 hour plasma glucose ≥11·1 mmol/l in a 75 g oral glucose tolerance test, or both).
[b] Must be confirmed on a subsequent day by any one of the three methods.

a fasting and 2 hour plasma glucose <6·1 and 7·8 mmol/l respectively[8]).

Prevalence estimates

Data from both Canada[11,12] and the USA[13] suggest that approximately 3–5% of all adults have a known diagnosis of diabetes. A large survey completed in 1994 in the USA also showed that one third of all cases of diabetes were undiagnosed.[14] Thus up to 8% of all adults in North America have diabetes. This prevalence varies with age, approaching 15–20% of all people over the age of 64 in the USA.[13] It also varies with race and ethnicity, and is higher in aboriginal populations throughout the world, in East Indians, American Blacks and Hispanics, and in Chinese and Indian migrant communities.[15] The prevalence of impaired glucose tolerance varies in a similar pattern; in most populations it is approximately equal to the prevalence of diabetes (both diagnosed and undiagnosed);[15] thus in the USA the prevalence of IGT and diabetes exceeds 20% of people aged 40–74.[14]

Relationship between the glucose level and retinopathy, nephropathy, and peripheral neuropathy

In patients with diabetes, the risk of retinopathy, nephropathy, and neuropathy is highly correlated with various measures of glycemia including fasting plasma glucose, 2 hour postprandial plasma glucose (after a 75 g oral glucose load), and glycated hemoglobin level.[10,16,17] For example, the risk of retinal and renal disease is very low below a fasting and 2 hour plasma glucose of 7·0 mmol/l or 11·1 mmol/l respectively, and increases as these measures increase within the diabetic range.

Therefore, the plasma glucose level is a continuous risk factor for these complications in patients with diabetes. It is also a modifiable risk factor. The Diabetes Control and Complications Trial[16] clearly showed that for patients with type 1 diabetes, dramatic reductions of the risk of retinopathy (63% risk reduction [RR]), laser therapy (51% RR), microalbuminuria (39% RR), clinical proteinuria (54% RR), and neuropathy (60% RR) can be achieved by "tight" glucose control. "Tight" glucose control also led to reductions in the risk of any diabetes end point and microvascular end points in patients with type 2 diabetes in the United Kingdom Prospective Diabetes Study (UKPDS) (for example, there was a 25% RR for the combined end point of renal failure or death, vitreous hemorrhage, or photocoagulation).[18] Thus achieving and maintaining normoglycemia in patients with diabetes is beneficial regardless of the etiology of the diabetes.

Relationship between the glucose level and the risk of cardiovascular disease

Risk of cardiovascular disease in patients with diabetes

As noted above, diabetes is an independent risk factor for cardiovascular disease.[2] People with diabetes have a two- to fourfold higher risk of coronary, cerebrovascular, and peripheral vascular disease than non-diabetic people.[1] The relative risk is greater for women than for men.[1,19] Diabetes is also a poor prognostic factor post myocardial infarction (MI); diabetic patients have a higher inhospital mortality, and post-discharge mortality than non-diabetic patients, and a higher risk of infarct-related complications.[20,21]

Just as the risk of eye, kidney, and nerve disease increases with the degree of glycemia, a growing number of studies of diabetic patients suggest that the risk of cardiovascular disease also rises with the degree of glycemia. For example, the Wisconsin Epidemiologic Study of Diabetic Retinopathy followed a population-based sample of 1210 patients with diabetes presenting before the age of 30 and 1780 patients with diabetes presenting at or after the age of 30.[22] In both groups of subjects 10 year mortality increased with the baseline glycated hemoglobin quartile. After controlling for other risk factors, a 1% increase in glycated hemoglobin was associated with a 10% (older onset subjects) to 18% (younger onset subjects) increase in the hazard of dying from ischemic heart disease.[22] In addition, at least two other smaller population-based epidemiologic studies noted a higher rate of CHD[23] or total mortality[24] in subjects with higher glucose levels than in those with better glucose control. In the UKPDS, every 1% increase in hemoglobin A (HbA_{1c}) in subjects with type 2 diabetes increased the risk of death by 14%, myocardial infarction by 14%, and stroke by 12%.[25]

Glucose levels and the risk for cardiovascular disease in non-diabetic patients

Many prospective studies have consistently showed that the relationship between glucose levels and the subsequent risk of cardiovascular disease extends well below the diabetic threshold. For example, after 10 years of follow up in the Whitehall study of 18 050 non-diabetic male civil servants, there was up to a twofold increase in coronary heart disease and stroke mortality in subjects whose 2 hour postload capillary glucose value was greater than 5·4 mmol/l compared to those with lower glucose levels. This increase was independent of age, smoking, blood pressure, cholesterol, and occupation.[26,27] The relationship of non-diabetic-range hyperglycemia and cardiovascular disease was also clearly noted after 14 years in the Rancho Bernardo study.[28] In this prospective study of 3458 non-diabetic men and women aged 40–70 with a fasting plasma glucose $<7{\cdot}8$ mmol/l, the age-adjusted ischemic heart disease mortality rates approximately doubled in men as the fasting glucose rose from 5 to 7 mmol/l, and tripled in women as the fasting glucose rose from 6 to 7·2 mmol/l.

Despite these, and other large cohort and cross-sectional studies[29–32] that showed a graded relationship between non-diabetic, and even non-impaired glucose tolerance levels of hyperglycemia and cardiovascular disease, some studies did not support such a relationship, especially with only moderate degrees of glucose elevation.[33–35] A systematic overview and meta-analysis of all published cohort studies of mainly non-diabetic populations was therefore done in 1998 to resolve these discrepancies, and to characterize the relationship between glucose levels and cardiovascular disease.[36] This analysis of studies describing more than one million person-years of follow up found that the risk of cardiovascular disease increased continuously with glucose levels above 4.2 mmol/l (75 mg/dl). This finding was supported by a recent prospective, population-based study of 4662 men aged 45–79, followed for up to 4 years, which found a continuous relationship between all-cause, cardiovascular, and ischemic heart disease mortality and HbA_{1c} throughout the entire population distribution, with the lowest rates in those with $HbA_{1c} < 5\%$.[37]

Hyperglycemia occurring at the time of an acute stress may also increase the risk of mortality in non-diabetic individuals. Two meta-analyses of prospective studies concluded that "stress" hyperglycemia increased the risk of mortality in non-diabetic patients with acute MI (RR 3·9)[38] and stroke (RR 3·1).[39]

Therefore, glucose appears to be a continuous cardiovascular risk factor, similar to cholesterol or blood pressure in its dose-response relationship.[40] We have suggested that the term *dysglycemia*[41] may be useful for describing this continuous relationship between glucose and cardiovascular disease. Thus people with dysglycemia alone are at risk for cardiovascular disease, people with dysglycemia and impaired glucose tolerance (IGT) are at higher risk for cardiovascular disease as well as DM, and people with DM are at even higher risk for cardiovascular disease as well as eye, kidney, and nerve disease (Figure 15.1).

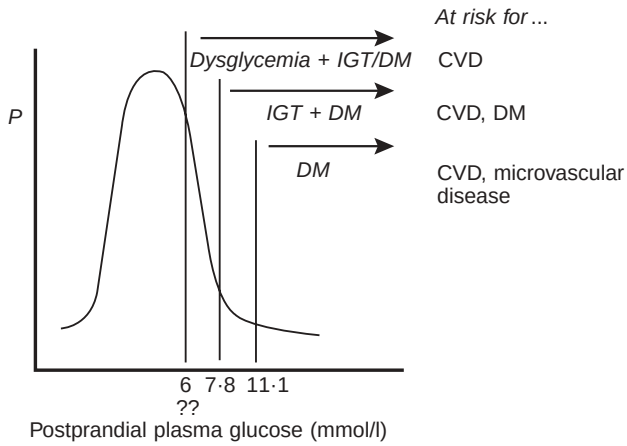

Figure 15.1 *Frequency distribution of glucose levels in the general population.* The significance of glucose as a risk factor for chronic disease depends on the level. Glucose levels above the diabetic threshold are associated with an increasing risk of cardiovascular and microvascular disease, levels above the IGT threshold are associated with an increasing risk of diabetes, and elevated levels above some as yet undefined "dysglycemic" threshold are associated with an increasing risk of cardiovascular disease. CVD, cardiovascular disease; DM, diabetes mellitus; IGT, impaired glucose tolerance.

Mechanisms relating hyperglycemia to cardiovascular disease

Possible explanations for a glucose–cardiovascular disease relationship include:

- direct toxic effects of glucose on cell function and structure
- indirect effects owing to insufficient insulin secretion to maintain normoglycemia
- a long history of insulin resistance and hyperinsulinemia prior to glucose elevations
- an association of dysglycemia with other recognized and unrecognized risk factors for cardiovascular disease, including dyslipidemia, hypertension, abdominal obesity, renal damage, and coagulation abnormalities.

Direct toxic effects of glucose

Glycation of a variety of proteins may directly promote cardiovascular disease.[42–45] Glycated albumin promotes albuminuria and endothelial cell dysfunction; glycated red cell membranes are less deformable; glycated LDL apoproteins are more susceptible than non-glycated LDL uptake by scavenger cells (which would increase foam cell formation), oxidation, and increase platelet aggregation; glycated HDL is less able to transport cholesterol, and glycated fibrin and platelet membranes adversely affect vascular homeostasis. AGE (advanced glycation end product) proteins also accumulate on vessel walls and in the vessel matrix, and may adversely affect endothelial cell function and promote atherosclerosis.[44–46]

Glucose metabolism also results in the formation of reactive oxygen species directly,[47] and indirectly through activation of the polyol pathway and AGE formation.[48] Any increased glucose metabolism owing to higher ambient glucose levels therefore presents an oxidative stress.[48] Finally, increased glucose metabolism to diacylglycerol may promote vascular cell growth, altered vascular permeability, smooth muscle contraction, and synthesis of various prostaglandins through protein kinase C activation.[49]

Insufficient insulin production

Glucose is the major stimulus for insulin secretion, which in turn prevents rises in glucose levels. Therefore an elevated glucose level implies a lack of sufficient insulin to maintain normoglycemia. Such a lack of *sufficient* insulin may occur in the presence of both low and high absolute levels of insulin, depending on the degree of insulin resistance.

A number of observations support the possibility that insufficient insulin secretion may be related to cardiovascular disease.

- Patients with both type 1 diabetes (with no endogenous insulin secretion) and type 2 diabetes (who are not able to make sufficient insulin to prevent hyperglycemia) are at high risk for cardiovascular disease. Intensified insulin therapy may decrease this risk, and certainly does not seem to worsen it (see below).
- Patients with hypertension and other cardiovascular risk factors are resistant to the antilipolytic effects of insulin;[50] any decrease in the secretory capacity of insulin would accentuate this and promote free fatty acid transport to the liver. The ensuing hypertriglyceridemia may promote atherosclerosis.[51]

- Patients with cardiovascular disease have increased levels of proinsulin and split products[52,53] – a possible biochemical marker of a failing β cell.[54]
- Many patients with atherosclerosis and/or cardiovascular disease are insulin resistant,[55] and require high insulin levels to prevent hyperglycemia. Such a prolonged demand may increase the risk of subsequent β cell failure and diabetes.[56,57]

Hyperinsulinemia

In non-diabetic people, fasting and 2 hour postload insulin levels rise with fasting and 2 hour glucose levels.[58,59] Thus even mildly hyperglycemic patients have higher levels of insulin than normoglycemic controls. Moreover, hyperinsulinemia is associated with coronary heart disease,[60,61] and many other cardiovascular risk factors including hypertension,[62] left ventricular hypertrophy,[63] elevated levels of triglyceride,[64–66] fibrinogen, von Willebrand factor-related antigen, factor VIII activity, plasminogen activator inhibitor-1 (PAI-1) antigen, and PAI-1 activity,[64] and depressed levels of HDL[65,66] and tPA.[64,67] Insulin may promote hypertension and atherosclerosis by stimulating renal sodium, water retention,[65] smooth muscle proliferation, and vascular growth factor production,[65] and sensitizing smooth muscle to the pressor effects of angiotensin II,[68] and increasing norepinephrine release through activation of the sympathetic nervous system.[69]

Despite these associations, the role of hyperinsulinemia in cardiovascular disease remains unclear.

- Hyperinsulinemia is not a consistent risk factor in large epidemiologic studies of non-diabetic patients with cardiovascular disease.[70]
- Patients with insulinomas who are insulin resistant, hyperinsulinemic, and *hypoglycemic* have normal lipid profiles and blood pressure, and no clinical evidence of cardiovascular disease.[71]
- Studies of intensified insulin therapy in patients with type 1 diabetes taking multiple daily doses of insulin suggest a reduced, and not an increased risk for the biochemical changes associated with atherosclerosis.[72]
- The fact that non-diabetic insulin levels are correlated with glucose levels suggests that the association of cardiovascular disease with insulin levels may reflect an association with glucose. The independent contribution of insulin and glucose, and any interaction of the two, to the risk of cardiovascular disease remains unclear despite multivariate analyses.

Association with other risk factors

Hyperglycemia commonly clusters with hypertension, insulin resistance, increased visceral fat, hypertriglyceridemia, and microalbuminuria.[66] It is also associated with obesity, poor socioeconomic status, and low birth weight. As such, the observed association between glucose and cardiovascular disease may be due to one of these other risk factors or to a common antecedent, and not because of any direct causal connection.[73,74]

Is glucose a modifiable cardiovascular disease risk factor?

To date, several randomized controlled trials of intensive versus conventional glucose lowering therapy have been completed in people with type 1 diabetes (in which different insulin regimens were used to lower glucose levels) and people with type 2 diabetes (in which different regimens of oral agents and/or insulin were used to lower glucose levels). None of these trials was designed or powered to determine whether or not glucose lowering reduced cardiovascular events. Nevertheless, several trials did report a non-significant trend in favor of a beneficial cardiovascular effect.

For people with type 1 diabetes, randomized trials of different levels of insulin-mediated glycemic control were designed to determine the impact of glycemic control on eye, kidney, and nerve disease (that is, microvascular disease). As such, they included mainly young people who had a low annual rate of cardiovascular events. Nevertheless, an exploratory analysis of results from the Diabetes Control and Complications trial (DCCT)[72] suggested that insulin-mediated glucose lowering may be cardioprotective. Moreover, in a recent meta-analysis that included this and other randomized trials, there was a significant 45% reduction in the total number of cardiovascular events and a non-significant 28% reduction in the risk of a first event.[75]

Clinical trials of different levels of glycemic control in people with type 2 diabetes also support the hypothesis that glucose lowering may reduce cardiovascular events (Tables 15.3 and 15.4). The strongest evidence was reported in a Swedish study of 620 diabetic MI patients randomized to conventional coronary care unit (CCU) therapy versus an insulin infusion followed by intensified insulin therapy for at least 3 months.[76] Total mortality in the treatment group was reduced by 31% (95% CI 4–51, $P = 0{\cdot}028$) at 1 year, and 28% at 3 years.[77] *This study needs to be replicated. Nevertheless, it supports the use of insulin in diabetic patients with myocardial infaction.* **Grade A1c** All of the other trials were done in ambulatory populations. The largest dataset relevant to whether or not glycemic control is cardioprotective was collected during the United Kingdom Prospective Diabetes Study (UKPDS), in which MI, stroke, and total mortality were recorded as secondary outcomes.[18] The main UKPDS study included 3867 people with newly diagnosed type 2 diabetes who were assigned to either conventional glycemic control or to intensive glycemic

Table 15.3 Glucose-lowering trials and cardiovascular events in type 2 diabetes trials

therapy starting with either insulin or a sulfonylurea. Participants assigned to the intensive policy had a median HbA_{1c} over 10 years of 7·0%, and had a non-significant 16% relative risk reduction for MI compared to participants whose median HbA_{1c} was 7·9% ($P = 0·052$). A small obese subgroup of these participants was also assigned to either conventional therapy or intensive therapy with either metformin ($n = 342$), insulin or a sulfonylurea ($n = 951$). The group assigned to metformin experienced a 39% risk reduction in MI compared to the conventional group.[78]

These studies, as well as a 6 year Japanese study of intensified versus conventional insulin therapy in patients with type 2 diabetes,[79] and one small pilot study of 153 men with type 2 diabetes[80] are summarized in Tables 15.3 and 15.4. Taken together they suggest, but do not prove, that glycemic control may lower the risk of cardiovascular disease in patients with DM. No large intervention studies of the impact of reducing glucose levels in patients with elevated glucose levels that are below the diabetic cut off have been reported to date, and no studies have studied whether or not targeting postprandial glucose is more or less important than targeting fasting glucose levels.

Conclusion

There are a number of direct and indirect biologic pathways linking dysglycemia to cardiovascular disease. Similar to dyslipidemia, in which ongoing studies are continuing to

show the therapeutic value of reducing even minimally elevated lipid levels,[81] dysglycemia may be a continuous modifiable cardiovascular disease risk factor: therapies that reduce elevated glucose levels may reduce the risk of cardiovascular disease.

A number of ongoing studies will address this issue. These include the ACCORD (Action to Control Cardiovascular Risk in Diabetes) study, which is testing whether intensive control of blood glucose and associated risk factors can reduce cardiovascular disease in people with type 2 diabetes.[82] It also includes the VA Diabetes Trial, which will study the effect of intensive glucose therapy on cardiovascular outcomes in people with poorly controlled type 2 diabetes.[83] The BARI II (Bypass and Angioplasty Revascularization Investigation) trial is testing the effect of revascularization plus aggressive medical therapy versus aggressive medical therapy alone for patients with type 2 diabetes and stable coronary artery disease. Patients in BARI II are also randomized to an insulin-providing versus and insulin-sensitizing strategy of glucose control.[82] For patients with impaired glucose tolerance, strategies to prevent diabetes may also lead to a reduction in cardiovascular disease. The Diabetes Prevention Program showed that healthy lifestyle changes (which included 5–7% weight loss through a low fat diet and at least 150 minutes of exercise per week) prevented diabetes in obese adults with impaired glucose tolerance. The drug metformin was also effective to a lesser extent.[84] Cardiovascular disease is a secondary outcome in this trial. Other strategies to prevent diabetes are being tested in ongoing clinical trials, in which cardiovascular disease is a documented secondary outcome. These strategies include ramipril and rosiglitazone (being tested in the DREAM [Diabetes Reduction Assessment with ramipril and rosiglitazone Medications] study[85]); and acarbose (being tested in the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus[86]). These studies are likely to shed new light on the relationship between glucose and cardiovascular disease and may provide ways of preventing cardiovascular disease in many individuals.

16 Physical activity and exercise in cardiovascular disease prevention and rehabilitation

Erika S Froelicher, Roberta K Oka, Gerald F Fletcher

Introduction

The goal of this chapter is to review the scientific evidence regarding the benefits and safety of physical activity and exercise with respect to a series of health outcomes. Brief coverage within this review is aimed at the adult American population in order to acquaint the physician with the latest recommendations for primary prevention. The major focus, however, is on the coronary population with a minor focus on elderly people, women, and those who are physically disabled. Existing evidence-based reviews and consensus documents are used to support the evidence. The recommendations are deliberately kept very brief, but the necessary references are cited to assist the primary care physician, internist or cardiologist in obtaining such documents.

Evidence for benefits of regular exercise in adults

An accumulation of scientific evidence provides consistent substantiation to the assertion that light to moderate physical activity in healthy adults reduces the risk for all-cause mortality and cardiovascular disease (CVD) in men and women.[1–3] However, approximately 60% of US adults are not regularly physically active and 25% are inactive.[4] Physical inactivity is a serious, nationwide problem. It poses a major public health challenge with a national burden of unnecessary illnesses and premature death. Physical activity and exercise are pivotal in health promotion and disease prevention, especially now that the evidence for the hazards of being physically inactive are clear.[5] These statistics, representing low levels of exercise in the US population, call for urgent action by health professionals. Primary care physicians, internists, and cardiologists in particular need to provide evidence-based physical activity recommendations to their patients.

Additionally, the Surgeon General's Report[5] urges healthcare providers to counsel their patients to do the following.

Box 16.1 Benefits and adverse effects in adults[5]
Grade A/B

Physical activity improves health in the following ways:

- reduces risk of dying prematurely;
- reduces risk of dying from heart disease;
- reduces risk of developing diabetes;
- reduces risk of developing high blood pressure;
- helps reduce blood pressure in people who already have high blood pressure.

Other documented health benefits include:

- reduces the risk of developing colon cancer;
- reduces feelings of depression and anxiety;
- helps control weight;
- helps build healthy bones, muscles, and joints;
- helps older adults become stronger and better able to move about without falling;
- promotes psychological wellbeing.

Adverse effects of physical activity

Types of adverse effects:

- musculoskeletal injuries
- metabolic abnormalities
- hematologic and body organ abnormalities
- hazards
- infection, allergic, and inflammatory conditions
- precipitation of cardiac events.

1. Most skeletal muscular events are preventable by gradually working up to a desirable level, avoiding excessive amounts of activity.
2. Serious cardiovascular events can occur with physical exertion. Net effect is lower risk of mortality from cardiovascular disease.

Recommendations for adults

Recent recommendations for physical activity from the Centers for Disease Control (CDC) and National Institutes of Health (NIH) suggest that American adults should engage in physical activity at a level appropriate to their capacity, needs, and interests. Regular exercise is recommended, preferably daily, of at least 30–45 minutes of brisk walking (3 mph), bicycling or working around the house or yard.

Activities may include formal exercise such as walking or jogging or intermittent types of activity that include stair climbing, gardening or housework.[5]

A well-rounded exercise program should include both muscular strength training and joint flexibility exercises in order to improve one's ability to perform tasks and to reduce the potential for injury.[3,5] Upper extremity and resistance (strength) training can improve muscle function and evidence suggests that there may be cardiovascular benefit in older patients and those with underlying CVD. This area, however, is rather new and further evidence is needed before recommendations can be made to the public. While these recommendations are especially important for elderly people, persons who have been deconditioned due to recent inactivity or illness may benefit as well. People who are already physically active will benefit even more by increasing intensity or duration of their activity. These recommendations are intended primarily for the healthy sedentary population.[5]

Box 16.2 Essentials of physical activity counseling

- All subjects should be asked about their physical activity status. Questions should address leisure and recreational activities (that is, sports and exercise), as well as intermittent activity (walking, stair climbing, household and yard work).
- Assess whether activities meet the current activity recommendation guidelines (that is, activity should be at least of moderate intensity or equivalent intensity to a brisk walk at 3 mph on most or all days).
- Patients should be assisted in planning an appropriate program of physical activity.

Evidence for benefits from regular exercise in the coronary population

A recent comprehensive evidence-based review has been completed on the benefits of exercise in the coronary population.[6] For brevity, this consensus document will be used as a source of evidence along with other consensus documents. The major focus of this review was on coronary patients (including myocardial infarction (MI), coronary artery bypass surgery (CABG), and percutaneous transluminal coronary angioplasty (PTCA)), with a lesser focus on heart failure and cardiac transplantation literature and special populations such as elderly people, women, and those with physical disabilities (see Figure 16.1 for the criteria guiding this review).

Clinical and physiologic outcomes in the coronary population

A comprehensive review by the Agency for Health Care Policy and Research[6] provides consistent scientific evidence of the benefits of exercise training on a number of outcomes that include morbidity, mortality, exercise tolerance, and symptoms (see summary below). The evidence is less consistent for the benefit of reduced blood lipids, smoking cessation, psychological wellbeing, social adjustment and functioning, reduction in excess body weight, and a series of physiologic measures.

Morbidity and safety issues

Forty-two studies – 15 randomized controlled trials (RCTs), 14 non-randomized studies, and 13 observational studies – provide evidence that exercise training does not change the rate of non-fatal re-infarction. The safety of exercise rehabilitation is well established; rates of infarction and cardiovascular complications are very low.[6] No study documented increased morbidity when comparing patients in the intervention group to the control group, with 4578 patients included in the controlled trials (randomized and non-randomized reviewed).[6]

Reduced mortality

Thirty-one studies – 17 RCTs, eight non-randomized studies, and six observational studies – provide evidence that exercise training programs significantly reduce total and cardiovascular mortality in patients following myocardial infarction (MI).[6]

Exercise tolerance

A total of 114 studies – 46 RCTs, 25 non-randomized studies, and 43 observational studies – demonstrated that exercise training consistently improved objective measures of exercise tolerance, without significant cardiovascular complications or other adverse outcomes. Therefore, appropriately prescribed exercise training is recommended as an integral component of cardiac services, particularly for patients with decreased exercise tolerance. Maintenance of continued exercise training is required to sustain improved exercise tolerance.[6] A minimum duration and frequency of exercise has not been definitively determined and more study is needed in this area.

Strength training (resistance training)

Seven studies – four RCTs and three non-randomized studies – have shown that strength training improves skeletal muscle strength and endurance in clinically stable coronary patients.[6] In the majority of these studies, weight training was added as a strength training component to the exercise regimens of coronary patients, who had already participated in aerobic exercise training for 3 months or more. Documented benefits occurred with both low and high resistance training. Weight carrying tolerance (time) or

Summary of evidence for cardiac rehabilitation outcomes:[a] effects of exercise training

Outcome	Evidence base				
	Total number of studies	Randomized studies	Non-randomized studies	Observational studies	Grading of evidence
Exercise tolerance	114	46	25	43	**Grade A**
Exercise tolerance (strength training)	7	4	3	0	**Grade B**
Exercise habits	15	10	2	3	**Grade B**
Symptoms	26	12	7	7	**Grade B**
Smoking	24	12	8	4	**Grade B**
Lipids	37	18	6	13	**Grade B**
Body weight	34	11	7	16	**Grade C**
Blood pressure	18	9	6	3	**Grade B**
Psychological wellbeing	20	9	8	3	**Grade B**
Social adjustment and functioning	6	2	2	2	**Grade B**
Return to work	28	10	9	9	**Grade A**
Morbidity	42 (+2 survey reports)	15	14	13	**Grade A**
Mortality	31 (+2 survey reports)	17	8	6	**Grade B**
Pathophysiologic measures: changes in atherosclerosis	9	5	1	3	**Grade A/B**
Changes in hemodynamic measurements	5	0	0	5	**Grade B**
Changes in myocardial perfusion/myocardial ischemia	11	6	2	3	**Grade B**
Changes in myocardial contractility, ventricular wall motion abnormalities, and/or ventricular ejection fraction	22	9	5	8	**Grade B**
Changes in cardiac arrhythmias	5	4	0	1	**Grade B**
Heart failure patients	12	5	3	4	**Grade A**
Cardiac transplantation patients	5	0	1	4	**Grade B**
Elderly patients	7	0	1	6	**Grade B**

[a] Number of studies from scientific literature by type of study design.

increases in skeletal muscle strength after completion of resistance training was reported by all studies. Five of the seven strength training studies demonstrated that submaximal and peak resistance exercise, using a variety of resistance training devices, resulted in significantly lower peak heart rate, pressure rate products, and oxygen consumption responses than did maximal treadmill exercise testing.[6] Moreover, angina, ventricular arrhythmias, and ischemic ST-segment depression occurred less frequently during resistance testing than during aerobic exercise testing to the point of fatigue.[7–9] These studies therefore provide indirect evidence of the effectiveness of resistance exercise training in selected patients with coronary disease.

A meta-analytic review by Buchner[10] concluded that high intensity exercise programs reported much more gain in strength than did low intensity training. High intensity

training was well tolerated by older adults, even those who were frail. Improvements in muscle strength can improve patients' performance of activities of daily living.[11] However, most of the studies involved small numbers of "low-risk" male patients, aged 70 years and younger, with good left ventricular function; also, training was of relatively short duration (less than or equal to 12 weeks). Hence the application of this intervention to women coronary patients is at this time based on an extrapolation.

Recommendation for strength training exercises

The strength training exercise sessions were typically started 4–6 weeks after MI or coronary artery bypass graft (CABG) and were carried out each week. The intensity ranged from 25% to 80% of the one repetition maximal; the most typical format consisted of three 30–60 minute strength training exercise sessions per week for 6–26 weeks.

Safety of strength training exercises in coronary patients

The lack of cardiovascular and orthopedic complications in the 3 year follow up of strength training was largely attributed to strict preliminary screening and careful supervision.[12] It is unclear if safety can be extrapolated to other populations of coronary or cardiac patients (for example, women, older men and women patients with low aerobic conditioning, patients at moderate to high cardiovascular risk) and this requires study. However, regimens designed to increase skeletal muscle strength can safely be included in exercise programs of clinically stable coronary patients when appropriate instruction and surveillance are provided.

Symptoms

Twenty-six studies – 12 RCTs, seven non-randomized studies, and seven observational studies – showed that exercise training decreases both angina pectoris in patients with coronary heart disease (CHD) and symptoms of heart failure in patients with left ventricular (LV) systolic dysfunction. Therefore, exercise training is recommended as an integral component of symptom management for these patients.[6]

Return to work

Twenty-eight studies – 10 RCTs, nine non-randomized studies, and nine observational studies – provide evidence that does not support an improved rate of return to work as a result of exercise training alone. A likely explanation may be that exercise training exerts less influence on return to work than many non-exercise variables including employer attitudes, prior employment status, economic incentives, and the like.[6]

Blood lipid levels

Thirty-seven studies – 18 RCTs, six non-randomized studies, and 13 observational studies – suggest that exercise training is not recommended as a sole intervention for lipid modification because of inconsistent effects on lipid and lipoprotein levels. Optimal lipid management requires specific dietary and medically indicated pharmacologic management in addition to exercise training.[6]

Smoking cessation

Twenty-four studies – 12 RCTs, eight non-randomized studies, and four observational studies – conclude that exercise training has little or no effect on smoking cessation. Smoking cessation is achieved primarily by targeted smoking cessation strategies.[6] The smoking cessation guidelines developed by an AHCPR evidence guideline panel provide detailed guidance on the optimum strategies for smoking cessation.[13]

Psychological wellbeing

Twenty studies – nine RCTs, eight non-randomized studies, and three observational studies – found that exercise training – with or without other cardiac rehabilitation services – generally results in decrease in anxiety and depression and improved physical function.[6] Exercise is therefore recommended to enhance psychological wellbeing, particularly when it is one component of a multifactorial rehabilitation program. Studies of exercise training in a supervised group setting as a sole intervention do not show consistent improvement in anxiety and depression. Studies of exercise training as a sole intervention are confounded by the consequences of group interactions, formation of social support networks, peer and professional support, and counseling and guidance, all of which may affect depression, anxiety, and self-confidence.

Blood pressure

Eighteen studies – nine RCTs, six non-randomized studies, and three observational studies – allow the conclusion that exercise training as a sole intervention had no demonstrable effect in lowering blood pressure levels. A multifactorial education, counseling, behavioral, and pharmacologic approach is the recommended strategy for the management of hypertension according to the fifth report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (1993).[14]

Social adjustment and functioning

Six studies – two RCTs, two non-randomized studies, and two observational studies – provide evidence that exercise

training improves social adjustment and functioning and is therefore recommended in the care of cardiac patients. The social benefits from participation in exercise and cardiac rehabilitation are a favorable result. More research is needed to evaluate the impact of cardiac rehabilitation on social adjustment and functioning.[6]

Body weight

Thirty-four studies – 11 RCTs, seven non-randomized studies, and 16 observational studies – provide evidence that exercise training alone has inconsistent effects on controlling excess body weight and is not recommended as a sole intervention for this risk factor. Optimal management of overweight patients requires multifactorial intervention including intensive nutritional education, counseling and behavioral modification as an adjunct to exercise training. The panel[6] concluded that after a review of behavioral therapy literature involving obese patients, state of the art weight loss programs were shown to be successful. Results of a meta-analysis of 70 studies indicated that weight reduction through dieting can also help normalize plasma lipids and lipoprotein levels in overweight individuals.[15] It is essential to note that the comprehensive use of exercise, education, counseling, and behavioral interventions as a multifactorial approach has consistently yielded much stronger evidence, in terms of health outcomes, than exercise programs alone.

Pathophysiologic measures

Atherosclerosis

Nine studies – five RCTs, one non-randomized study, and three observational studies – provide convincing evidence that exercise training as a sole intervention does not result in regression, limitation or progression of angiographically documented coronary atherosclerosis. But regression or limitation in progression of atherosclerosis may occur when exercise training is combined with intense dietary intervention, with or without lipid lowering drugs.[6]

Hemodynamic measurement

Five observational studies provide evidence that exercise training has no effect on development of coronary collateral circulation and produces no consistent changes in cardiac hemodynamic measurements during cardiac catheterization. Exercise training in patients with heart failure and depressed ventricular ejection fraction produces favorable hemodynamic changes in the skeletal musculature. Therefore, cardiac rehabilitation exercise training is recommended to improve skeletal muscle function; however, it does not enhance cardiac hemodynamic function or promote development of collateral coronary circulation.[6]

Myocardial perfusion/myocardial ischemia

Eleven studies – six RCTs, two non-randomized studies, and three observational studies – provide evidence that exercise training decreases myocardial ischemia as measured by exercise ECG testing, ambulatory ECG recording, and radionuclide perfusion imaging. Exercise training is recommended to improve the measures of myocardial ischemia.[6]

Myocardial contractility, ventricular wall motion abnormalities, and/or ventricular ejection fraction

Twenty-two studies – nine RCTs, five non-randomized studies, and eight observational studies – document that exercise training has little effect on ventricular ejection fraction and regional wall motion abnormalities. The effect of exercise training on left ventricular function in patients after anterior wall Q wave MI with LV dysfunction is inconsistent. Exercise training is not recommended to improve measures of ventricular systolic function.[6]

Other clinical populations

Heart failure and cardiac transplantation

Heart failure patients

Twelve studies – five RCTs, three non-randomized, and four observational studies – provide evidence for the benefit of exercise training in the heart failure population. Exercise training in patients with heart failure and moderate to severe LV dysfunction improves functional capacity and symptoms, without changes in LV function. Exercise training is recommended in these patients to attain functional and symptomatic improvement but there is a potentially higher likelihood of adverse events. In summary, although these studies had small numbers and populations of young patients, predominantly male, and CAD was the major etiology of heart failure, exercise training in patients with heart failure and diminished ventricular systolic dysfunction resulted in documented improvement in functional capacity. The benefits are thought to be due predominantly to adaptation in peripheral circulation and skeletal musculature.[6]

Cardiac transplantation patients

Seven studies – one non-randomized study and six observational studies – suggest that exercise training following cardiac transplantation improves exercise tolerance and is recommended for this purpose. These trials demonstrated

that participation in an exercise program produced physiological training responses that included: increased peak oxygen uptake, resting heart rate, decreased peak exercise heart rate, increased resting blood pressure, and decreased peak systolic blood pressure compared with normal controls. No change was observed in peak systolic blood pressure or pressure rate product. However, these studies were uncontrolled and therefore these changes could be either the result of spontaneous improvement or a treatment effect. While there are few studies in this area and no RCTs, initial observations demonstrate efficacy of this intervention. In addition, it is believed that strength training before the transplantation may help enhance recovery after the operation. However, more research is needed in this area to identify the extent of spontaneous recovery versus the added benefit from exercise intervention.[6]

Changes in cardiac arrhythmias

Five studies – four RCTs and one observational study – provide evidence for the role of exercise in patients with arrhythmias. Two of the four RCTs showed that exercising patients, but not the controls, had a reduction in ventricular arrhythmias.[17,18] One demonstrated no statistically significant difference between exercise patients and controls when monitoring ventricular arrhythmia frequency or severity with 24 hour ambulatory ECG.[19] One RCT reported more malignant premature ventricular contractions (PVCs) on 24 hour ambulatory ECG monitoring during exercise training days in exercise patients compared to control patients.[20] The one observational study showed no difference in PVCs at baseline versus after exercise training. Exercise training has inconsistent effects on ventricular arrhythmias.

Special populations

Elderly patients

Elderly patients constitute a high percentage of those with MI, CABG, and PTCA and are also at high risk of disability following a coronary event. Seven studies – one non-randomized study and six observational studies – provide the evidence for this review.[6] Also, the Surgeon General's report[5] concludes that physical activity, including strength training (resistance) exercise, appears to be protective against falling and fractures among elderly people, probably by increasing muscle strength and balance. Elderly coronary patients have exercise trainability comparable to younger patients participating in similar exercise rehabilitation. Elderly female and male patients show comparable improvement, but referral to and participation in exercise rehabilitation is less frequent for elderly patients,[5] especially females. Physical activity need not be strenuous to achieve health benefits.[11] No complications or adverse outcomes of exercise training in elderly subjects were described in any study. Although few studies and no randomized controlled trials specifically addressed the efficacy and safety of exercise training and multifactorial rehabilitation in elderly people, the available studies provide important new information of beneficial functional improvement from exercise training for current clinical practice. Elderly patients of both genders should be strongly encouraged to participate in exercise-based cardiac rehabilitation and special effort should be taken to overcome the obstacles to entry and participation in cardiac rehabilitation services for elderly patients.

Women

The scientific evidence was either lacking altogether or small numbers of women were included in RCTs, making separate analyses for benefit impossible. This practice resulted in lack of information at best and confusion at worst. If indeed women do experience differing responses than men in exercise training then the effects are likely to be diluted for men and non-informative for women. The consensus of the expert panel[6] was that in most instances women can benefit from exercise training. However, women have unique considerations that require special attention. In studies of CAD patients women tend to be older, live alone more often (they are widowed or divorced), and have fewer economic and social resources. These circumstances require that women be given special attention to minimize the barriers to enrollment in exercise programs and to continuation with the program.

The Center for Women's Health at the National Institutes of Health has as its primary goal compensation for this scientific deficit regarding women's health. Until these new initiatives have been completed and reported in the literature, only scant scientific evidence exists to guide the physician regarding specific recommendations for women.[21] Many studies are now in progress or have already been completed since the formulation of the Center for Women's Health in 1980.

People with physical disabilities

With the passing of the Americans with Disabilities Act (1990), physicians in the USA are now required to address the special exercise training needs of patients with a variety of physical disabilities. People with physical disabilities are advised to see a physician before starting a program of physical activity that is new to them.[11] In particular, physically disabled patients with CVD should be referred to the cardiologist for physical therapy or exercise prescription. A recent comprehensive review is available for the reader who requires greater detail than is possible here.[22,23]

General safety issues

Patients with chronic health problems, such as heart disease or diabetes, should first obtain medical clearance before beginning a new exercise program. Skeletal muscle and other injury can be avoided by beginning exercises slowly and gradually building up to the desired amount of exercise (duration, frequency, and intensity) to give skeletal muscles and the cardiovascular system time to adapt. It is recommended that men over 40 and women over 50 consult a physician prior to beginning a vigorous physical activity program. This is to ensure that the patient does not have undiagnosed heart disease or other health problems that may place them at increased risk and that may require special modification in the exercise prescription or the monitoring of their response to the exercise.[5] The ACSM,[24] AHA,[25] and AACVPR[26] have issued guidelines for assessment of an exercise facility prior to beginning an exercise program. A medical evaluation, including an exercise test, is recommended for individuals with known coronary risk factors or a strong family history of CVD. Exercise testing is recommended for persons over 40 years of age, especially if they have two or more risk factors for CVD. But it is not recommended for apparently healthy individuals less than 40 years due to the relatively low predictive value of a positive test.[25]

Other organizational and clinical issues

Adherence to exercise

The evidence for exercise interventions for cardiovascular risk reduction has been provided in the preceding pages. However, the extent to which exercise is effective may depend in large part on adherence.[27] Burke and colleagues,[27] in their comprehensive review on adherence, further concluded that non-adherence, whether it occurs early or late in the treatment course, is one mediator of clinical outcomes. Hence, specific attention is given to adherence here. Barriers to exercise are twofold: the lack of physicians' exercise prescription and patient non-adherence. Since physicians have had limited clear evidence on reduction of "hard events" until recently, coronary patients have not consistently received physician recommendations regarding exercise or have received suggestions that were too general to be beneficial. Cardiac rehabilitation programs are available for referral by the physician in virtually every major city throughout the USA.

Much of the information on adherence is derived from multifactorial cardiac rehabilitation studies that were designed *not* to evaluate or enhance adherence but to determine the effects of rehabilitation services on other outcomes. These studies demonstrate a progressive decline with longer treatment duration, with 20–25% of patients dropping out within the first 3 months, 40–50% between 6 and 12 months, and little further change occurring during the next 3–4 years.[28] Although not confirmed, this trend for high early dropout rates may relate to several factors: cost of the exercise program, insurance reimbursement, convenience associated with program scheduling and facility location, return to work or family demands or simply poor motivation. Alternatively, patients may have mastered their skills and dropped out because of adequate self-care. There are differences in adherence with different modes of delivery of exercise services; what is known about adherence to cardiac rehabilitation is based largely on studies conducted when cardiac rehabilitation content, duration, delivery, and goals were considerably different from what they are at present.

Recommendations to improve adherence

Adherence may be enhanced if the physician understands the factors that affect exercise behavior and accordingly devises an exercise program that is tailored to the needs, preferences, and health status of a given person.[29] Patients, in general, wish to be partners in healthcare decisions that affect them or their families and improving communication may be a potent adherence enhancing strategy. Attention to the interpersonal relationships between patient and provider can result in greater cooperation and greater patient and provider satisfaction, as well as improved adherence.[30] For example, increased involvement by the patient in clinical decision making has been shown to improve patient satisfaction,[27] patient adherence, and patient outcomes.[28] In addition, limited evidence supports the importance of involving family members in promoting adherence to cardiac rehabilitation services.[35] If the objective of patient counseling is to permit the patient to make informed decisions about treatments, then a patient may decide to disregard some or all professional advice. This suggests that what is inappropriate behavior from the clinician's perspective (that is, not following recommendations) may in fact be rational decision making from the patient's perspective. Many patients make the best decisions they can without considering the importance or even the implications of adherence and carry out their own risk–benefit analysis for each treatment they are offered.[36]

Other factors that may influence patient adherence include: emotional support; understanding the patient's (and family's) values, viewpoints, and preferences; integration of the intervention into the patient's lifestyle, as well as patient characteristics and demographic characteristics; aspects of treatment regimens including complexity, duration, and convenience (such as cost, facility location, time of day); and disease factors such as severity of symptoms, among others. Patient perceptions, as well as personal and

social circumstances, determine patient decisions about following recommendations.

Adherence to exercise is in general lower than that for pharmacologic interventions; Burke *et al*[27] suggest that the increased behavioral requirements for maintaining an exercise program may account for this. In general, adherence to the exercise program was better in the home exercise programs than the community-based rehabilitation programs.[27] Most likely, the convenience factor can account for these improved rates of adherence.[27]

Strategies to improve adherence

Improving patient–provider communication with more information about CVD and its treatments would likely result in more informed decision making by the patient; providing culturally sensitive care may also improve adherence and perhaps patient outcomes and is likely to improve patient and clinician satisfaction.[37,38] Successful strategies for adherence include:

- Clear communication between patient (family) and provider.
- Emotional support and alleviation of fears and anxieties.
- Understandable and practical explanations about regimens that are compatible with the patient's values, preferences, and expressed needs, acknowledging the patient's social and cultural needs.
- Integration and coordination of patient care to provide continuity of care between transitions.[6]

Alternatives to monitored exercise training

Eleven studies – seven RCTs and four non-randomized studies – informed this question. The evidence suggests that alternative approaches to the delivery of cardiac rehabilitative services, other than traditional supervised group interventions, can be implemented effectively and safely for carefully selected clinically stable patients. Transtelephonic and other means of monitoring and surveillance of patients can extend cardiac rehabilitative services beyond the setting of supervised, structured, group-based rehabilitation (see Box 16.3 for guide to ECG monitoring). These alternative approaches have the potential to provide cardiac rehabilitation services to low- and moderate-risk patients, who comprise the majority of patients with stable coronary disease, most of whom do not currently participate in supervised, structured rehabilitation. (For risk stratification guidelines, see Box 16.4.)

Box 16.3 Criteria for electrocardiographic monitoring[39]

- Two or more MIs
- New York Heart Association class 3 or greater
- Exercise capacity less than 6 METs
- Ischemic horizontal or downsloping ST depression of 4 mm or more or angina during exercise
- Fall in systolic blood pressure with exercise
- A medical problem that the physician believes may be life-threatening
- Previous episode of primary cardiac arrest
- Ventricular tachycardia at a workload of less than 6 METs

Note: MET, metabolic equivalent units

Box 16.4 Minimal guidelines for risk stratification

Risk level	*Characteristics*
Low	No significant left ventricular dysfunction (that is, ejection fraction ≥50%)
	No resting- or exercise-induced myocardial ischemia manifested as angina and/or ST-segment displacement
	No resting- or exercise-induced complex arrhythmias
	Uncomplicated myocardial infarction, coronary artery bypass surgery, angioplasty or atherectomy
	Functional capacity ≥6 METs on graded exercise test 3 or more weeks after clinical event
Intermediate	Mild to moderately depressed left ventricular function (ejection fraction 31–49%)
	Functional capacity >5–6 METs on graded exercise test 3 or more weeks after clinical event
	Patients who consistently exceed the intensity of their exercise prescription
	Exercise-induced myocardial ischemia (1–2 mm ST-segment depression) or reversible ischemic defects (echocardiographic or nuclear radiography)
High	Severely depressed left ventricular function (ejection fraction ≤30%)
	Complex ventricular arrhythmias at rest or appearing or increasing with exercise
	Decrease in systolic blood pressure of >15 mmHg during exercise or failure to rise with increasing exercise workloads
	Survivor of sudden cardiac death
	Myocardial infarction complicated by congestive heart failure, cardiogenic shock, and/or complex ventricular arrhythmias
	Severe coronary artery disease and marked exercise-induced myocardial ischemia (>2 mm ST-segment depression)

MET, metabolic equivalent units

Recent studies have explored new approaches to deliver cardiac rehabilitation services, with the goals of increasing availability and decreasing costs, while preserving efficacy and safety. Case management approaches to exercise training, smoking cessation, and diet drug management of hyperlipidemia that rely on telephone contact can be provided to appropriately selected patients with coronary disease.

Guidelines for participation in supervised and unsupervised exercise training programs are published by the American College of Sports Medicine.[24] In brief, supervision is recommended for patients with two or more major CAD risk factors and patients with known CAD with less than 8 MET functional capacity. Supervision is not suggested in apparently healthy individuals or persons who have equal or more than 8 MET functional capacity. The generalizability of these case management systems to other treatment settings – including university centers, public and community hospitals, and clinics – will depend largely on formulas for reimbursement for services and the extent of physician support for this approach, as well as the state regulations regarding medical and health practices. Within each of these settings, managed care programs seeking optimal methods for coronary risk factor reduction and exercise rehabilitation may favor case management systems that provide convenient, individualized health care at low cost.

Risk stratification

Appropriate risk stratification is recommended to minimize any adverse effects that patients might experience. This practice is also valuable in aiding the healthcare provider in deciding the type and intensity at which an exercise regimen will be started and the degree of monitoring and supervision. Furthermore, careful risk stratification also identifies the frequency of surveillance needed for a given patient, alerts the practitioner to respond promptly to changes in patient status, and promotes the safety of exercise training in any delivery system.[6]

Focus of further scientific study

Scientific studies should address the following areas:[6]

- Evaluate exercise training in special populations, including elderly people, women, members of different ethnic groups, and those of low educational and socioeconomic status.
- Evaluate exercise therapy following contemporary therapies, including thrombolysis and acute angioplasty.
- Evaluate effects of exercise training using return to work as a primary outcome.
- Identify factors that promote adherence.
- Identify the optimum degree of supervision and monitoring for high-risk groups, such as those with heart failure, elderly patients, and those with complex medical problems.
- Evaluate the safety and benefit of exercise training in patients with compensated heart failure and impaired ventricular systolic function.
- Evaluate a variety of different delivery models of exercise therapy.
- Evaluate the safety and specific added benefits of resistance training on cardiac patient outcomes.

Summary

Clear evidence exists for the recommendation of exercise for all individuals for primary preventive purposes. The evidence for patients with CAD is also well substantiated. Further research is indicated to verify how exercise recommendations are best delivered given the current rapid change in healthcare practice.

17 Psychosocial factors in the primary and secondary prevention of coronary heart disease: an updated systematic review of prospective cohort studies

Harry Hemingway, Hannah Kuper, Michael Marmot

Key points

There is widespread belief among the general public, fostered by the media, that psychologic and social factors influence the risk of disease. Over the last three decades the scientific community has picked up this interest in psychosocial factors – that is, those factors (such as work characteristics, depression, and social support) that link psychologic phenomena to the social environment. Much of this research has focused on the effect of psychosocial factors on health, in particular coronary heart disease (CHD), in part because they may mediate the association between social class and health. Our previous systematic review of prospective studies published up until 1997 investigated the association between psychosocial factors and CHD etiology and prognosis.[1] Here, in updating this review to June 2001, we have used better search methods (and identified 71 new papers), improved summaries of the results and discussed the findings in an explicit framework of causality. Our objective for this review is to assess the relative strength of the epidemiologic evidence for causal links between psychosocial factors and CHD incidence among healthy populations, and prognosis among CHD patients.

Psychosocial factors as coronary risk factors

Over time there have been improvements in the measurement of psychosocial factors, moving away from the general idea of "stress" to concepts based on theoretical models that can be tested. These psychosocial factors may relate to personality factors, such as type A behavior and psychological disorders (for instance, depression and anxiety), and to factors more explicitly involving the social environment, including work characteristics and social support. The validity and reliability of the questionnaire-based instruments used to measure the psychosocial factors has been improved through the use of psychometric techniques; increasingly studies use identical measurement scales. However, such standardization is more apparent for some factors, such as depression, than others, such as work characteristics.

Two aspects of the association between CHD and psychosocial factors have been researched intensively. The first aspect is the effect of psychosocial factors on CHD incidence, or newly diagnosed CHD. The second aspect is the impact of psychosocial factors on survival among people with CHD. Despite the large literature that has accumulated, the question of whether psychosocial factors are causally related to risk of, and survival from, CHD remains open for debate. This systematic review aims to highlight key issues in ascribing causal status to one or more psychosocial factor.

Are psychosocial CHD associations causal?

An initial question to ask of an epidemiologic association between psychosocial factors and CHD is, Can it be explained by bias? Most attention has been paid to bias intrinsic to study design as reported within a publication. One example is self-report bias that may arise if study participants tend to report adversely on both the psychosocial exposures and symptoms of heart disease. Our review addresses this issue by emphasizing death and non-fatal myocardial infarction (MI) as outcomes rather than softer end points, such as angina, which may be more prone to reporting bias. However, for a systematic review, a potentially more important set of biases lies extrinsic to individual published reports in the stages between hypothesis specification and communication to the scientific community. Of all the existing psychosocial CHD data, an unknown amount remains unreported. Positive studies may be more likely to be published than negative studies; and, once published, positive studies may have greater impact than negative studies.

However, notwithstanding these potential biases, Bradford Hill[2] outlined a set of interrelated criteria for judging an association to be causal. This is used as a framework for discussing the results of the studies.

- *Consistency*. Finding the same association in different studies, in different populations and under different circumstances – that is, consistency – strengthens the evidence for causation. As an example, depression is related to risk for CHD in Finland,[3] the USA[4] and the Netherlands,[5] as well as in both men and women.[6] However, as our review shows, studies are not unanimous for any psychosocial factor. These inconsistencies in the data may arise from, *inter alia*, differences in study designs or ways of measuring the psychosocial factors.
- *Temporal association*. In order to address the requirement that exposure should precede the disease, we limited our review to prospective cohort studies. However, the presence of effects in shorter term follow up studies, which are not found in longer term follow up, raises the possibility that early manifestations of disease might have caused the psychosocial exposure.
- *Confounders, mediators, and biologic mechanisms*. Demonstration of biologic pathways linking psychosocial factors and CHD might strengthen the evidence for a causal association. There are three plausible biologic pathways by which psychosocial factors could be linked to the incidence of CHD. These have been reviewed elsewhere.[7,8] First, psychosocial factors may influence health-related behaviors, such as smoking, diet, alcohol consumption, and exercise, which in turn have pathophysiologic consequences.[9,10] If this is true, then studies that treat health behaviors as potential confounders may be underestimating the effect of psychosocial factors. Nearly all studies do this in our review; we are therefore summarizing the direct effect of psychosocial factors on CHD events, net of lifestyle variables, and we are not assessing potential mediation of the association between psychosocial factors and CHD by health behaviors. Psychosocial factors themselves may contribute to the pathway by which social position is inversely associated with CHD. However, a minority of studies in the review considered social position. Second, psychosocial factors, including social support or depression, may produce real or apparent hurdles to help-seeking behavior and access to quality medical care, so that the progression of subclinical to clinical disease is more rapid in people with poor psychosocial characteristics. This possibility awaits adequate investigation. Third, psychosocial factors may produce direct or chronic physiologic changes that increase the risk for CHD.[11] Adverse psychosocial characteristics can induce biologic arousal through neuroendocrine mechanisms affecting blood lipids, blood fibrinogen, and blood pressure, or neuroendocrine mechanisms that increase catecholamines and cortisol.
- *Strength*. Stronger associations are more likely to be causal. This means that larger relative risks (RR) give stronger evidence for causality than smaller relative risks, so an RR of 2·86 (95% CI 1·19–6·89)[12] is more indicative of an association between type A behavior and CHD than a RR of 1·43 (95% CI 0·63–3·26).[13]
- *Dose response*. The existence of a dose-response relationship between the exposure and disease also supports causation, and an example of this is the higher relative risks for the association between major depression, than minor depression, and mortality in people with CHD.[14,15]
- *Reversibility*. Ultimately the purpose of cardiologic practice is to intervene and reduce the risk associated with psychosocial factors.

Methods of systematic review

The methods of this review, which updates our review of publications to 1997,[1] are similar to the first review in terms of qualitative data analysis, but are improved as regards searching for papers and summarizing data. A methodologic quality filter was used to determine inclusion of papers in the systematic review, so that the strength of evidence could be compared across psychosocial factors. For inclusion, papers had to meet four quality criteria relating to design, size, psychosocial variable specification, and outcomes.

Study design

Since cross-sectional and retrospective case–control studies are subject to recall bias, we limited the review to prospective cohort studies. Nested case–control studies were not included in this review, because our search methods may not distinguish nested and retrospective case–control studies.

Study size

This review was limited to studies that included at least 500 participants (etiologic studies in healthy populations) or 100 participants (prognostic studies in populations of patients with CHD). The number of participants included was taken as the total number reported after exclusion of ineligible subjects. Therefore, we do not report the restriction of the cohort for subgroup analyses, which was occasionally substantial.

Psychosocial variable specification

Psychosocial factors were included if they were used in at least two eligible study populations. Unspecified "stress" was not considered a valid psychosocial factor, since it was too vague to be informative.[16,17] Papers had to specify precisely which measurement scale was used.

Outcomes

Valid outcomes were limited to fatal CHD, sudden cardiac death, incident non-fatal MI, incident angina, incident heart failure, and, for prognostic studies only, all-cause mortality.

Searching for eligible papers

The principal method of identifying new papers for updating the review was through the Science Citation Index (accessed on the web of science at www.webofscience.com). In June 2001 the Science Citation Index was used to identify papers that cited any of the 65 papers included in our original review. This search method yielded more eligible papers, and missed none, compared to searches on PubMed. Abstracts of over 280 new papers identified with potentially relevant titles were extracted and those papers obviously not eligible were eliminated. Next, two independent researchers assessed full text versions of over 100 potentially relevant papers for inclusion criteria, as well as all the papers included in the first review. Finally, the bibliographies of all retrieved articles were manually searched to identify further studies, which lead to the inclusion of four more studies. Multiple papers from the same study were included if they met the eligibility criteria. Our search produced 71 new papers in total for this review, of which 41 were published from 1998 to June 2001.

Summary of effect (Box 17.1)

We used relative risks, where available, to summarize the association between the psychosocial factor and the outcome, and this included incidence rate ratios, cumulative incidence ratios, hazard ratios, and odds ratios (occasionally these were calculated). Unless otherwise stated, we took relative risks comparing the top (highest risk) versus bottom (lowest risk) category of exposure and statistical significance was inferred at P value of $\leq 0{\cdot}05$, and, unlike the earlier review, we report confidence intervals (CI). Where several effect estimates were reported, we took the most highly adjusted estimate, but avoided effect estimates that adjusted for other psychosocial factors, as this may reflect overadjustment. Effect estimates were reported separately for men and women and for different outcomes, data allowing.

Box 17.1

The extent to which the paper supports the hypothesis that adverse psychosocial characteristics increase risk of, or mortality from, CHD, is summarized in a single symbol (−, 0, + or ++). The description of the summary symbols is as follows:

− Relative risk <0·75
"*finding counter to hypothesis*"
Example: One SD increase on the Bortner type A behavior scale was protective for risk of mortality post MI (RR = 0·70, 95% CI 0·51–0·96)[18]

0 Relative risk 0·75–1·50
"*lack of clear association*"
Example: Low social support was unrelated to risk of fatal CHD (RR = 1·42, 95% CI 0·72–2·81) or risk of non-fatal MI (RR = 1·00, 95% CI 0·58–1·71)[19]

+ Relative risk ≥1·50 and <2·00
"*moderate association in line with hypothesis*"
Example: Depression increased risk for fatal and non-fatal MI (RR = 1·70, 95% CI 1·23–2·34)[15]

++ Relative risk ≥2·00
"*strong association in line with hypothesis*"
Example: Job strain substantially increased the risk of fatal CHD and non-fatal CHD (RR = 4·95, P value = 0·03)[20]

Number of citations per paper

In order to explore the extent to which the scientific influence of each study might relate to the degree of study positivity, we recorded the number of times that each paper was cited as of September 2001 using the Science Citation Index. From this the mean number of citations across studies by the strength of the reported association was calculated separately for different years of publication.

Results

Type A behavior pattern (TABP) and hostility (Table 17.1)

TABP is a personality trait characterized by hard driving and competitive behavior, excessive job involvement, impatience, hostility, and vigorous speech stylistics and psychomotor activity. Early positive findings for the effect of TABP on CHD risk, reported by the Western Collaborative Group's Study and the Framingham Study,[21–23] led to the National Institutes of Health declaring type A to be an independent risk factor for CHD and to the implementation of intervention trials.[24] As more data accumulated, however, the early positive findings were not confirmed and interest grew in hostility as the toxic component of TABP.

In the current review 18 etiologic studies were included. As mentioned above, the three early studies provided moderate support for the hypothesis,[21–23] although two of these studies were published from the Western Collaborative Group Study,[21,22] and this association disappeared with extended follow up.[25] Subsequently, 12 studies that did not show a clear effect were published, including two very large studies (MRFIT[26] and the Scottish Heart Health Study[27]), one of which showed evidence for a protective effect of TABP on CHD risk in women.[27] Last, the three smallest studies strongly supported the hypothesis,[12,28,29] although for one the association was found only in women[29] and for the other only with respect to angina incidence.[28]

For the prognostic studies, 10 were not supportive of the underlying hypothesis that TABP worsened prognosis in patients with CHD. Three studies actually showed a

Abbreviations: 0, lack of clear association; +, moderate association (RR ≥1·50 and <2·00); ++, strong association (RR ≥2·00); BDI, Beck Depression Inventory; BMI, body mass index; CABG, coronary artery bypass graft; CAD, coronary artery disease; CES-D, Centre for Epidemiologic Studies Depression Scale; CHD, coronary heart disease; CHF, congestive heart failure; DIS, Diagnostic Interview Schedule; GHQ, General Health Questionnaire; HDL, high density lipoprotein; IHD, ischemic heart disease; JAS, Jenkins Activity Survey; LDL, low density lipoprotein; LV, left ventricular; LVEF, left ventricular ejection fraction; me, mean or median; MI, myocardial infarction; MMPI, Minnesota Multiphasic Personality Inventory; mx, maximum; N/A, not available; NF, non-fatal; ns, non-significant; PTCA, percutaneous transluminal coronary angioplasty; PVC, premature ventricular contractions; QOL, quality of life; RR, relative risk; SCD, sudden cardiac death; SCL, symptoms checklist; sd, standard deviation; SI, structured interview; ss, statistically significant; SMR, Standardized Mortality Ratio; TAB, type A behavior

significantly protective effect of TABP on prognosis after CHD, one of which was the Western Collaborative Group Study,[30] although for the Framingham Heart Study the effect was limited to men.[31] There was only one small study that showed a strong effect of hostility on prognosis, and one study that showed a moderate increase in sudden cardiac death among patients post-MI with TABP. Therefore there was little overall support for an association between TABP and CHD risk, nor was there evidence, as had been hypothesized, that hostility alone predicted CHD.

Depression (Table 17.2)

The association between depression and CHD has attracted a great deal of research interest in recent years, with 29 studies published from 1998 to 2001 meeting our inclusion criteria. Depression, and anxiety (Table 17.3), differ from the other psychosocial factors reported here, since they are defined psychiatric disorders and are amenable to drug intervention. Furthermore, depression is a frequent result of CHD and, moreover, depression and CHD may share a common antecedent (for example, social support or environmental stressors), so that elucidation of the cause and effect association becomes particularly difficult.

Table 17.2 shows the results from the 22 prospective studies that investigated the role of depression in the etiology of CHD. Eight of these studies found a lack of clear association, five studies were moderately and four studies were strongly supportive of the hypothesis. The remaining five studies all reported strong effects of depression on CHD incidence limited to men,[32,33] angina incidence[34,35] or major depression.[36] Interestingly, the three studies that separated angina from other outcomes reported stronger effects of depression on angina,[34–36] suggesting the existence of reporting bias as angina is the CHD event least amenable to objective corroboration. Both studies that focused on the degree of depression found that risk of CHD was higher among people seriously depressed than among those who were only moderately depressed,[4,5] suggesting a dose-response association.

There were 34 studies that investigated the effect of depression on prognosis for patients with CHD. Of these studies 16 found a lack of clear association, seven were moderately supportive, and 11 were strongly supportive studies. There was, therefore, no evidence that the association between depression and events differed between prognostic and etiologic studies, although where associations were observed they were generally of greater magnitude for the prognostic studies. It is of note that for several prognostic studies depression is predictive of prognosis in the unadjusted analyses, but adjusting for traditional coronary risk factors and markers of disease severity explained much of the relationship, hence the association between depression and prognosis might be mediated by lifestyle factors, disease severity, and pharmacologic interventions. Five studies looked separately at the effect of moderate and severe depression on prognosis; one found a lack of clear association,[37] three showed a higher risk among patients with major depression,[5,14,15] and the last found a lower risk of fatal CHD in patients with major depression compared to those with depressive symptoms.[38]

Anxiety and distress (Table 17.3)

Of the eight etiologic studies identified, four studies showed a lack of clear effect. Two papers, both published from the Israeli civil servant cohort, reported strong or moderate association between anxiety and the incidence of angina.[39,40] The remaining two studies gave evidence for an association between phobic anxiety and fatal CHD, but did not show a clear effect on non-fatal CHD or of free-floating anxiety.[41,42] Furthermore, the studies with longer follow up were less likely to find a positive association than the studies with less extended follow up. This is exemplified by the Northwick Park Heart Study where the association between anxiety and fatal CHD found after 10 years of follow up,[41] disappeared when the follow up was extended by another decade.[43] Hence, anxiety may be a result of preclinical CHD rather than a cause of fatal CHD.

Of the 18 prognostic studies, half found a lack of clear association and one reported results significantly contrary to the hypothesis. Four studies showed a strong association between anxiety and prognosis and the remaining four studies showed moderate support for an association, either in the entire group or in relation to a specific subgroup, exposure or outcome.

Psychosocial work characteristics (Table 17.4)

The belief that stress at work has a deleterious effect on health is common among the general public. To combat the lack of precision in defining job stress, various constructs have been made to explain how the interaction between a worker and the job environment causes stress, and how this affects health. The Karasek and Theorell "job strain" model[44,45] proposes that high demands at work (the need to work quickly and hard), in combination with low job control, produces stress. Thus, workers cannot moderate the pressure caused by high job demands by organizing their time, making new decisions or learning new skills, and this stress has deleterious effects on health. Another model for psychosocial work characteristics is Siegrist's effort-reward imbalance model.[46] Here the mismatch between high workload and low payback (in terms of money, esteem, promotion prospects, and job security) produces a condition of emotional distress, which increases risk for CHD.

Despite these models, work characteristics have been measured with a lesser degree of standardization than, for

Prognostic studies									
Hlatky, 1995, USA, Duke Medical Center[136]	1489 (24) employed patients undergoing coronary angiography	41–59	Job strain, (decision latitude and psychological demands) (individual)	4 (me)	Fatal CHD (42) and NF MI (70)	Ejection fraction, extent of coronary atherosclerosis, myocardial ischemia	Job strain Fatal CHD: 1·01 (0·51–2·01) Total CHD: 0·96 (0·62–1·46)	40	0
Hoffmann, 1995, Switzerland Gasis, Seewis and Le Noirmont[75]	222 (0) patients 7 weeks (mean) after first MI	30–60	Job work load	1 (mx)	Poor medical outcome (death, re-infarction, New York Heart Association Class ≥ III, exercise capacity <100 W) (19)	Age, severity of MI, exercise, overprotection by friends, external locus of control	High workload was positively associated with outcome ($P = 0·01$)	9	+
Orth-Gomer, 2000, Sweden, Stockholm Female Coronary Risk Study[137]	292 (100) women post acute coronary event	30–65	Job strain (job demands, job control) (Karasek)	4·8 (me)	Fatal CHD, NF MI, revascularization procedure (81)	Age, smoking, blood pressure, HDL, triglycerides, estrogen status, diabetes, diagnosis at index event, symptoms of heart failure, education	Severe work stress: 1·67 (0·64–4·32) Age adjusted only Low control: 1·62 (0·84–3·01) High demands: 1·21 (0·63–2·32)	2	+
Welin, 2000, Sweden, Gothenburg[48]	275 (16) patients 3–6 days post first MI	<65	Extra work, mental strain at work	10 (mx)	All-cause mortality (67), fatal CHD (41), NF MI (55)	None	No association between fatal CHD and extra work ($P = 0·26$), mental stress at work ($P = 0·99$) No association with total mortality of NF MI	1	0

For abbreviations see Table 17.1.

instance, depression and anxiety. Because of the lack of consistency in measuring psychosocial work characteristics, it was difficult to compare the strength of evidence for the two theoretical models – a challenge when evaluating this literature and for future researchers. Moreover, work characteristics can be measured either through self-report or ecologic measurements (assigning a score on the basis of job title). Self-reports may be biased by early manifestations of disease, and ecologic measurements may lack precision.

There were 13 etiologic studies investigating the effect of work characteristics on CHD that were included in this review. Of these, three studies found a lack of clear association between work characteristics and CHD, and five were either moderately supportive, or supportive only for a subset of the population, a particular outcome, or a particular exposure. The final five papers showed strong evidence for an effect of work stress on CHD incidence, although in three of these studies the effect was limited either to particular psychosocial work characteristics or to women. There is some evidence that CHD incidence was more closely related to individually, rather than ecologically, measured work characteristics. This could suggest either that there is more non-differential misclassification, and therefore bias towards the null, for ecologic than individual measures, or that preclinical CHD influences subjective reporting of work characteristics. Of the four prognostic studies, two found a lack of clear association between work characteristics and prognosis, and two were moderately supportive of an association.

Social support (Table 17.5)

Social supports and networks relate to both the number and quality of a person's social contacts, and this includes emotional and confiding support. Social relationships may improve health through the emotional and instrumental support they provide; friends and family may encourage health-seeking behavior and discourage an unhealthy lifestyle. Furthermore, isolation itself may induce an unfavorable mental state, and conversely the presence of social contacts could reduce physiologic arousal and buffer the effect of environmental stressors. Reverse causation cannot be discounted: lack of social participation could be the result of subclinical coronary disease. Despite the interest in social support, there is little consensus on how it is measured, therefore variables ranging from "high love and support from wife", to "social network index" to "social isolation" were included.

Nine studies were included that used social support as the etiologic agent. Three studies showed no clear association, including the Health Professionals Follow-up Study.[19] Four studies, using a range of different measures of social support, were moderately supportive of the hypothesis that social support is etiologically linked to CHD. Finally, two studies were strongly supportive of an association between social support and risk of CHD.

Of the 21 prognostic studies, 10 were strongly supportive of the hypothesis, four were moderately supportive and seven showed no consistent effect. The strongly supportive studies included one of the largest studies[47] and two with extended follow up,[47,48] and they were generally highly adjusted for potential confounders, including lifestyle behaviors and indicators of disease severity. The stronger effect of social support on prognosis for people with CHD than on risk for CHD could potentially be explained if patients with CHD with high levels of social support are better taken care of or are more likely to seek medical care.

Modification of psychosocial factors

What are the implications of these findings for cardiologic practice? Box 17.2 summarizes the main points. When judged on the criteria used for drug interventions, the evidence for psychosocial intervention supports "options to be considered" rather than firm recommendations. There are two ways in which such criteria may not be entirely appropriate when psychosocial factors are considered. First, psychosocial interventions – unlike drug and invasive interventions – have few if any adverse effects (and may be less costly). Second, psychosocial factors may be interrelated and the quest for a single "toxic component" on which to intervene may not be as fruitful as in the case of, say, serum cholesterol. Few studies have investigated this interrelatedness; instead researchers have tended to emphasize one factor over others.

Box 17.2

Implications for cardiologic practice: options to consider

- Psychosocial components of cardiac rehabilitation (B/C)
- Detect and treat depression in CHD patients (B/C)
- Mobilize social support (B/C)
- Use socioeconomic status and psychosocial factors to risk-stratify patients (B/C)

A, strong evidence
(at least one well-designed RCT or effects strong and consistent across observational studies)

B, moderate evidence
(RCT[s] suggest effect despite methodological concerns or observational studies suggest an effect but conflicting data or observational studies alone)

C, limited evidence
(published research evidence available but not B or C)

A meta-analysis of randomized controlled trials (RCT) by Linden and colleagues[49] has suggested that psychosocial interventions are associated with a 41% reduction in mortality and a 46% reduction in non-fatal events in the first 2 years of follow up after MI. These RCTs – overwhelmingly in secondary prevention – have tended to be small, without prolonged follow up, and they have involved a diverse range

of interventions (relaxation, stress management, counseling), differing in duration and professional setting. Separate analyses including the larger but *non*-randomized Recurrent Coronary Prevention Project[50] should be viewed with caution.

An appealing target for intervention among post-MI patients is low social support and depression. Information on patients' families, friends, and colleagues is commonly available to clinicians, and this may help to risk-stratify the patient. Might improved detection and treatment of depression among CHD patients improve outcome? Frasure-Smith[51] randomized 453 male post-MI survivors to monthly monitoring of minor psychiatric morbidity (general health questionnaire) or usual care. The stress management intervention was given to participants whose psychiatric morbidity rose above a critical level; at 1 year the mortality was 4·4% in the intervention group and 8·9% in the control group ($P = 0{\cdot}05$).

However, despite this positive trial there have been three large randomized trials that have failed to show improved survival associated with psychosocial interventions among post-MI patients. In Wales, a large RCT of psychologic rehabilitation post-MI found no difference in anxiety and depression, and this may in part explain the lack of effect on mortality.[52] The Montreal Heart Attack Readjustment Trial randomized 903 men and 473 women to psychosocial support or usual care.[53] Among men there was no difference in cardiac or all-cause mortality between the intervention and control groups. By contrast, among women there was an excess of cardiac deaths among the intervention group (22/234) compared with the control group (12/239) ($P = 0{\cdot}06$). The reason for this finding – in the opposite direction to that hypothesized – awaits elucidation. A multicenter trial of 3000 patients after MI (ENRICHD – enhancing recovery in CHD) has recently been completed in the USA.[54] This trial targeted patients at high psychosocial risk (those who were depressed or socially isolated) and included large numbers of women and ethnic minorities. The results, reported at the American Heart Association in November 2001, suggest no survival benefit of the intervention of cognitive behavioral therapy.

Some trials investigated the contribution of psychosocial intervention in addition to conventional rehabilitation or other lifestyle advice post-MI. Thus, for example, Ornish[55] randomized 53 patients with coronary artery disease (CAD) to stress management, low fat diet, smoking cessation, and moderate exercise, and 43 patients to usual care. However, only 28 patients in the experimental group and 20 patients in the control group agreed to take part – a potential source of selection bias. Although quantitative coronary angiography demonstrated regression of CAD in 82% of the experimental group at 12 month follow up, it is not possible to attribute this to the stress management or any other component of the intervention.

The potential for primary prevention in relation to psychosocial factors clearly lies outside the remit of cardiologists. Psychosocial factors themselves are determined largely by social, political, and economic factors and it is therefore policymakers who influence the structure and function of communities – in the public and private domains – who may have scope for primary prevention.

Challenges in improving this systematic review

Much of the literature used for this review was based on secondary analyses of data collected for other primary purposes; only a minority of studies were set up to investigate psychosocial factors in relation to CHD. A comparison with the systematic review of randomized trials is informative. Unlike trials, few, if any, studies reported in our review had published their hypotheses detailing primary exposure, confounder, and outcome relationships prior to reporting results. This is of concern given the possibility of multiple comparisons between numerous psychosocial variables and CHD outcomes within one study. Unlike the situation with randomized trials, there is no register of studies that are testing or could test psychosocial hypotheses. Such a register provides a "denominator of hypotheses", which can then be tracked through the stages of analysis, manuscript preparation, submission, publication, and scientific impact, to determine the extent of any bias.

Study size could potentially influence the likelihood of achieving a strongly positive result. This effect was investigated by calculating the mean number of study participants in studies reporting null or negative, moderate or strong associations in line with the hypothesis, separately for each psychosocial factor. In etiologic studies on depression, the mean number of participants per study was largest for those studies that reported a moderate ($n = 8805$) compared to those reporting a strong ($n = 2993$) or null/negative ($n = 3780$) association. This pattern was the same for etiologic studies on anxiety (null/negative: 1577; moderate: 11 345; strong: 8538) and work characteristics (null/negative: 3060; moderate: 139 496; strong: 5466). However, for type A behavior (null/negative: 5521; moderate: 1919; strong: 1305) and social support (null/negative: 13 009; moderate: 6706; strong: 2730), the largest studies were more likely to show null or negative results. This supports the argument that depression, anxiety, and work characteristics are predictive of CHD occurrence, whereas for type A behavior and social support the associations are produced by the biasing effect of study size. The patterns for depression and social support, but not type A behavior, anxiety, or work characteristics, were similar among prognostic studies.

Furthermore, a number of psychosocial factors were examined in only a small number of studies, and these included anger, aggression, cynicism, dominance,

Table 17.6 Summary of prospective studies investigating psychosocial factors and CHD

	Number of reports of etiological studies ($n = 70$)				Number of reports of prognostic studies ($n = 92$)			
	−	0	+	++	−	0	+	++
Type A behavior/hostility	1	11	5	1	3	10	1	1
Depression	0	8	5	9	0	16	7	11
Anxiety	0	4	1	3	1	9	4	4
Work characteristics	0	3	5	5	0	2	2	0
Social support	0	3	4	2	0	7	4	10

−, finding counter to hypothesis; 0, lack of clear association; +, moderate association (RR ≥ 1·50 and <2·00); ++, strong association (RR ≥ 2·00)

hopelessness, neurosis, submissiveness, and vital exhaustion.[12,18,23,34,48,56–79] These less commonly used psychosocial factors tended to report strong associations with the etiology and prognosis of CHD, which is consistent with a role for publication bias.

A further bias may occur after publication. Positive studies may be more influential than studies in which there is a lack of clear association. We attempted to evaluate the effect of such an influence bias, using the number of citations on the Science Citation Index. Figure 17.1 suggests that the frequency of citation was highest for strongly positive studies, intermediate for moderately positive studies and lowest for those lacking a clear association. In the first period of assessment, studies not showing a clear association were cited most frequently, and this result is strongly influenced by the high frequency of citing the two major null studies on the TABP–CHD association.[26,80] This suggests that selective citing of positive studies, rather than using systematic reviews, may be used in specifying hypotheses. Moreover, it is clear from the tables that multiple reporting of results from the same study is an important issue and that it is not always apparent that the same study has been used for several papers. This further increases the opportunity for influence bias.

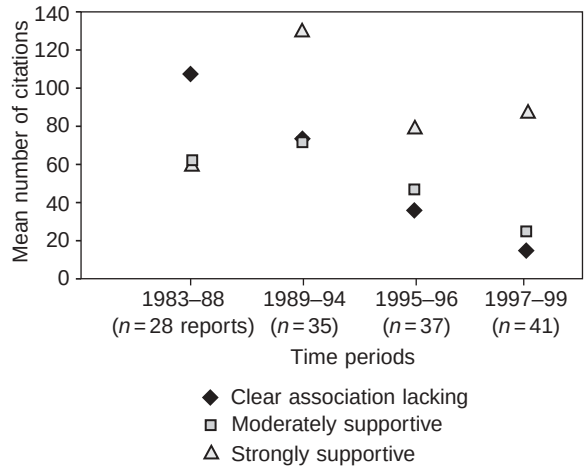

Figure 17.1 The association between the size of the effect estimate and number of citations: an indicator of influence bias

Conclusion

Our systematic review of prospective studies published up until 2001 identified 70 reports of etiologic effects and 92 reports of prognostic effects by psychosocial factors (Table 17.6). Based on prospective epidemiologic data, there was evidence for an association between depression, social support, and psychosocial work characteristics with CHD etiology and prognosis. However, the randomized trial data suggesting that psychosocial interventions reduce mortality post-MI are conflicting: three large trials to date have been negative. The field of psychosocial factors and CHD has grown over the last decade: a key challenge in terms of cardiologic practice in the next decade is to clarify the role, if any, of psychosocial factors in secondary prevention.

We should be grateful for information on any eligible studies that we may have missed.

18 Emerging approaches in cardiovascular prevention

Eva M Lonn, Marek Smieja, Salim Yusuf

Introduction

Reductions in cholesterol and blood pressure, and smoking cessation, have been shown to be effective strategies in the prevention of cardiovascular diseases (CVD).[1] However, these "classic" risk factors, along with known non-modifiable risk factors, such as age, gender, and family history, may not fully explain why certain individuals develop myocardial infarction (MI) and stroke, while others do not.[2]

These observations suggest that factors other than known risk factors for CVD play an important role in the pathogenesis of coronary heart disease (CHD) and stroke and that new preventive therapies aimed at modifying these new risk factors may be additionally useful. In this chapter, we will review a number of emerging risk factors and potential new preventive strategies. In particular, we will review the evidence for:

- The potential role for oxidation of low density lipoprotein (LDL) in atherogenesis and the use of antioxidants in CV prevention.
- The activation of neurohormonal pathways, particularly the renin–angiotensin axis and its modification by angiotensin-converting enzyme (ACE) inhibitors in high-risk groups.
- Hyperhomocysteinemia and its modification by folic acid.
- Inflammation and infection and the potential therapeutic use of anti-inflammatory and anti-infectious agents.

Other chapters in this book deal with dysglycemia, estrogens, and psychosocial factors.

Oxidative stress and use of antioxidants in cardiovascular prevention

Pathophysiology and biologic rationale

Oxidative modification of LDL cholesterol is an important step in the pathogenesis of atherosclerosis.[3,4] Oxidized LDL is potentially more atherogenic than native LDL. It is recognized and rapidly taken up by "scavenger" macrophage receptors, giving rise to foam cells; it is directly cytotoxic for endothelial cells and attracts further macrophages to the subintima; it stimulates vascular smooth muscle proliferation and autoantibody formation; and contributes to increased vascular tone and coagulability. Experimental studies *in vitro* as well as *in vivo* in different animal models of atherosclerosis suggest that antioxidants could decrease or prevent LDL oxidation and inhibit atherosclerosis.[3]

Epidemiology and randomized controlled clinical trials

Epidemiologic studies have generally reported inverse associations between intake of various antioxidants and CHD risk. Most attention thus far has been directed to the study of naturally occurring antioxidants, particularly vitamin E, vitamin C, and beta-carotene, although other carotenoids, flavonoids, selenium, magnesium, and monounsaturated fatty acids are also found in natural food products and may reduce LDL oxidation. The major lipid soluble antioxidant vitamins are vitamin E (alpha-tocopherol), the predominant antioxidant present in plasma membranes, tissues, and LDL cholesterol, and beta-carotene, a precursor of vitamin A. The major water soluble antioxidant vitamin is vitamin C (ascorbic acid), which can regenerate alpha-tocopherol from the tocopheroxyl radical form, thus preserving lipophilic antioxidant within the LDL particles. In addition to foods rich in antioxidant vitamins, antioxidants are available as vitamin supplements, generally at doses much higher than those provided by balanced diets.

A number of epidemiologic studies suggest an inverse association between dietary intake of vegetables and fruits, which are generally rich in antioxidants, and CV risk.[2,5,6] It is unclear, however, which component of these dietary products might be cardioprotective. In addition, a number of cross-sectional geographic correlation studies suggest a strong inverse association between CHD prevalence and the use of diets rich in antioxidants.[7] Large prospective cohort studies have evaluated associations between dietary and/or supplemental antioxidant vitamins and CV risk, and large randomized controlled studies have assessed the role of vitamin supplements in CV prevention.

Vitamin E

Vitamin E supplements, most of which contain 200–800 IU, lead to intake far greater than the Recommended Daily

Allowance (RDA) of 30 IU and well beyond those attainable by diets. Large prospective epidemiological studies such as the US Nurses' Health Study and the US Male Health Professionals' Study suggested that the use of vitamin E *supplements* for two or more years, most commonly at doses of 200–400 IU per day, is associated with a 20–40% lower risk of CHD.[8–10] However, other studies identified vitamin E from *food sources* (but not supplements) to be potentially cardioprotective, although in these studies supplemental vitamin E use was low.[11,12]

In contrast to the epidemiological studies, most randomized clinical trials conducted to date have failed to confirm benefit. A recent randomized trial evaluated the effects of vitamin E on the anatomic progression of carotid atherosclerotic vascular disease. The Study to Evaluate Carotid Ultrasound Changes with Ramipril and Vitamin E (SECURE), conducted in 732 middle-aged and elderly patients with vascular disease, found supplementation with natural source vitamin E (RRR-alpha-tocopherol acetate) 400 IU/day to have a neutral effect on the rate of progression of carotid intimal-medial thickness (IMT).[13] Six large randomized placebo-controlled trials of vitamin E supplementation with major CV morbidity and mortality end points have been completed (Table 18.1). These trials have evaluated different populations, comprising both low-risk individuals targeted for primary prevention,[14,15] and high-risk patients with coronary and/or other vascular disease[16–19] and have used different vitamin E preparations and doses. These trials have generally failed to demonstrate a beneficial role for the use of vitamin E supplements both in primary and secondary CV

Table 18.1 Large (>1000 subjects) randomized trials of vitamin E

Trial	Study participants	Follow up (yr)	Daily vitamin E dose	Outcomes	Relative risk reduction (%) (95% CI)
ATBC[14]	29 133 male smokers in Finland	6·1	50 mg	All-cause death	−2[b] (−9–5)
				CV death	2 (−8–11)
PPP[15]	4495 people with risk factor(s) for CHD in Italy	3·6	300 mg	CV death, non-fatal MI and non-fatal stroke	−7 (−56–26)
				All-cause death	−7 (−49–23)
ATBC[16a]	1862 men with previous MI	6·1	50 mg	CHD death and non-fatal MI	3 (−19–20)
				Non-fatal MI	11 (−20–33)
				CHD death	−5 (−37–20)
CHAOS[17]	2002 patients with CHD in the UK	1·4	800 IU/ 400 IU	Non-fatal MI	77 (53–89)
				All-cause death	−29 (−119–24)
				CV death	−10 (−96–39)
GISSI[18]	11 324 patients with recent MI in Italy	3·5	300 mg	All-cause death, non-fatal MI and non-fatal stroke	5 (−5–15)
				CV death, non-fatal MI and non-fatal stroke	2 (10–13)
HOPE[19]	9541 patients with CV disease or diabetes with additional risk factor(s)	4·5	400 IU	CV death, non-fatal MI and non-fatal stroke	−5 (−16–5)
				CV death	−5 (−22–10)
				MI	−2 (−15–10)
				Stroke	−17 (−42–5)

[a] Substudy of study.[14]
[b] Minus sign indicates an increased risk.
Abbreviations: ATBC, Alpha-tocopherol, Beta-carotene Cancer Prevention Study; CHAOS, Cambridge Heart AntiOxidant Study; GISSI, GISSI Prevenzione Trial; HOPE, Heart Outcomes Prevention Evaluation Study; PPP, Primary Prevention Project

prevention and therefore the widespread use of this intervention cannot be endorsed, especially if perceived as a "replacement" for proven, effective preventive lifestyle modifications and pharmacological therapies.

The Secondary Prevention with Antioxidants in Endstage renal disease (SPACE) trial was a randomized placebo-controlled trial of 196 hemodialysis patients with pre-existing CV disease.[20] Patients in the vitamin E arm had a 54% relative risk reduction (95% CI 22–72; $P = 0{\cdot}014$) in the primary study end point, the composite of fatal or non-fatal MI, ischemic stroke, peripheral vascular disease, and unstable angina. This relatively small trial conducted in a very high-risk population requires further confirmation.

Beta-carotene

Large prospective epidemiologic cohort studies suggest an inverse association between beta-carotene intake (derived from nutritional sources and vitamin supplements) and CV risk in men, particularly current or former smokers,[8–12,21] but not in women. Several large, long-term, well-designed randomized trials of beta-carotene in primary prevention have consistently failed to show benefit from beta-carotene, in the prevention of both CVD and cancer (Table 18.2). Furthermore, concern about an increased risk of cancer was present in some investigations. In a subset of patients with previous MI (secondary prevention) enrolled in the ATBC trial there was overall no CV benefit in subjects randomized

Table 18.2 Large randomized trials of beta-carotene

Trial	Study participants	Follow up (yr)	Beta-carotene dose	Outcome	Relative risk reduction (%) (95% CI)
ATBC[14]	29 133 male smokers in Finland	6·1	20 mg/day	All-cause death	−9[b] (−17 to −2)
				CV death	−11 (−23–1)
				Death from cancer	−9 (−23–3)
				New lung cancer	−18 (−36 to −31)
CARET[22]	18 314 male smokers, former smokers and workers exposed to asbestos in the United States	4·0	30 mg/day[a]	All-cause death	−17 (−33–3)
				CV death	−26 (−61–1)
				Death from cancer	−46 (−100 to −7)
				New lung cancer	−28 (−57 to −4)
PHS[23]	22 071 male physicians in the United States	12·0	50 mg/ alternate days	All-cause death	−2 (−11–7)
				CV death	−9 (−27–7)
				Death from cancer	−2 (−18–11)
				New lung cancer	7 (−27–32)
				MI	4 (−9–16)
				Stroke	4 (−11–17)
SCPS[21]	1188 men and 532 women in the United States	8·2	50 mg/day	All-cause death	−3 (−30–17)
				CV death	−16 (−64–18)
				Death from cancer	17 (−29–56)

[a] Patients randomized to beta-carotene also received 25 000 U/day of retinol (vitamin A).
[b] Minus sign indicates an increased risk.
Abbreviations: ATBC, Alpha-tocopherol, Beta-carotene Cancer Prevention Study; CARET, β-Carotene and Retinol Efficacy Trial; PHS, Physicians' Health Study; SCPS, Skin Cancer Prevention Study

to treatment with beta-carotene. A small increase in the risk of fatal CHD was noted in the beta-carotene group.

Vitamin C

The epidemiological studies evaluating the supplemental use of vitamin C are not very persuasive. The National Health and Nutrition Examination Survey (NHANES) prospectively evaluated 11 348 US adults and found a 34% lower standardized mortality ratio (95% CI 18·1–47·1) among subjects who received 50 mg of vitamin C per day by diet or vitamin supplements compared with those who received less vitamin C.[24] The study did, however, not correct for supplemental vitamin E use. Most other prospective data have not clearly identified vitamin C as a significant cardioprotective agent. Overall, the epidemiological data evaluating vitamin C and CVD have significant inconsistencies and a number of large prospective epidemiologic studies, after adjusting for other risk factors and for use of other antioxidant vitamins, failed to identify vitamin C use to be independently associated with lower cardiovascular risk.[10]

There have been no large randomized clinical trials of vitamin C supplementation. Three relatively small randomized trials performed in elderly patients failed to demonstrate beneficial effects of vitamin C supplementation.[25–27]

Clinical trials using combined antioxidant vitamins

It was suggested that combined antioxidant vitamin therapy might be more effective than the use of individual vitamins alone. The Antioxidant Supplementation in Atherosclerosis Prevention (ASAP) study reported that combined vitamin E and C supplementation caused a significant reduction in carotid IMT progression in men, with no benefit in women.[28] The HDL–Atherosclerosis Treatment Study (HATS), however, found that the addition of antioxidant vitamins (daily administration of 800 IU vitamin E, 1000 mg vitamin C, 25 mg beta-carotene and 100 g selenium) decreased HDL_2-cholesterol levels and tended to diminish the benefits achieved with simvastatin and niacin alone, both on the anatomic progression of coronary lesions and on clinical outcomes.[29] A large primary prevention trial conducted in China reported a marginally significant reduction in total mortality (RR, 9%; 95% CI 0–70) for a combination of daily vitamin E 30 mg, beta-carotene 15 mg, ascorbic acid 120 mg, selenium 50 g, as well as other micronutrients (retinol, zinc, molybdenum, and niacin), with a trend towards reduced CV mortality (RR, 9%; 95% CI −8–24).[30] The generalizability of this study to Western and other populations with very different diets remains uncertain. The Heart Protection Study randomized 20 536 British patients with CVD, diabetes or treated hypertension to simvastatin (40 mg/day) or matching placebo and to antioxidant vitamins – 600 mg vitamin E, 250 mg vitamin C and 20 mg beta-carotene daily – or matching placebo using a 2×2 factorial design. Treatment with antioxidant vitamins resulted in a neutral effect on all study outcomes.[31]

Clinical trials using other antioxidants

Probucol is a lipid lowering agent, which reduces low density lipoprotein (LDL) but also lowers high density lipoprotein (HDL) and has been shown to be a potent antioxidant in a number of experimental studies. The Probucol Quantitative Regression Swedish Trial (PQRST) in 274 hypercholesterolemic subjects failed, however, to reveal any benefit in the progression of femoral atherosclerosis.[32] This lack of benefit from probucol may be related to the significant reduction in HDL cholesterol (by 24%) in patients treated with probucol, compared with those in the placebo group. A small study found that probucol reduced the rate of restenosis after balloon angioplasty in small coronary arteries.[33]

Antioxidants: conclusions and recommendations

Antioxidant vitamin supplements do not reduce CVD events. **Grade A**

Renin–angiotensin axis and impact of angiotensin-converting enzyme (ACE) inhibitors

Pathophysiology and biologic rationale

Experimental and human studies suggest that ACE inhibitors may reduce CV risk through both cardioprotective and vasculoprotective effects mediated by blocking both circulating and tissue renin–angiotensin systems, as well as by bradykinin potentiation.[34] ACE inhibitors are antiproliferative, have antimigratory effects on smooth muscle cells, increase nitric oxide bioavailability, restore endothelial-mediated vascular reactivity, are potent antioxidants and have antithrombotic action by decreasing platelet aggregation and enhancing endogenous fibrinolysis.[34] A possible link between the activation of the renin–angiotensin system and CV risk is supported also by some, although not all, epidemiological and genetic studies.[35–38]

Randomized clinical trials

ACE inhibitors are effective agents in the management of hypertension and heart failure. Clinical trials in patients with low left ventricular ejection fraction with or without heart failure had unexpectedly demonstrated significant reductions in the risk of MI in patients receiving long-term ACE inhibitor therapy.[39–41]

More recently, the impact of ACE inhibitor therapy in patients *without hypertension and without heart failure or low left ventricular ejection fraction* has been evaluated. Several mechanistic studies have evaluated the effects of ACE inhibitors on surrogate outcomes. These studies demonstrate a wide range of blood pressure-independent benefits of ACE inhibitor therapy, including: (a) improved endothelial function, resulting in vasodilation in the coronary and brachial circulation,[42] and in enhanced endogenous fibrinolysis;[43] (b) retardation in the anatomic progression of atherosclerosis, shown in some but not all trials;[13] and (c) improvement in myocardial function and structure.[44]

The most persuasive evidence for the beneficial effect of long-term ACE inhibitor therapy in high-risk patients without heart failure and/or low left ventricular ejection fraction and with or without hypertension, has been provided by the Heart Outcomes Prevention Evaluation (HOPE) trial.[45] This trial enrolled 9297 patients aged 55 years or older with coronary artery disease, peripheral arterial disease or prior stroke, or diabetes with additional risk factors. Treatment with the ACE inhibitor ramipril titrated up to 10 mg daily resulted in a highly significant 22% reduction in the composite primary end point of myocardial infarction, stroke or death from cardiovascular causes (Table 18.3; Figure 18.1). In addition, the risk of stroke, myocardial infarction, need for revascularization procedures, heart failure and the development of diabetes were significantly decreased. In the 3577 patients with diabetes, ramipril significantly reduced the risk of the composite primary outcome by 25% (95% CI 12–36; $P = 0{\cdot}0004$), myocardial infarction by 22%, stroke by 33%, CV death by 37%, all-cause death by 24%, revascularizations by 17%, and overt nephropathy by 24%.[46] These effects were attained with only a modest reduction in blood pressure (3 mmHg reduction in systolic and 1·8 mmHg in diastolic blood pressure) in patients already treated with a variety of cardioprotective, blood pressure lowering and antiischemic medications, suggesting that the treatment benefit was largely independent of blood pressure lowering.

Table 18.3 Effect of ramipril on major CV outcomes in the HOPE trial

	Relative risk reduction (%) (95% CI)	*P*
Myocardial infarction, stroke or CV death	22 (14–30)	<0·0001
Myocardial infarction	20 (10–30)	<0·0001
Stroke	32 (16–44)	<0·0001
CV death	26 (13–36)	<0·0001

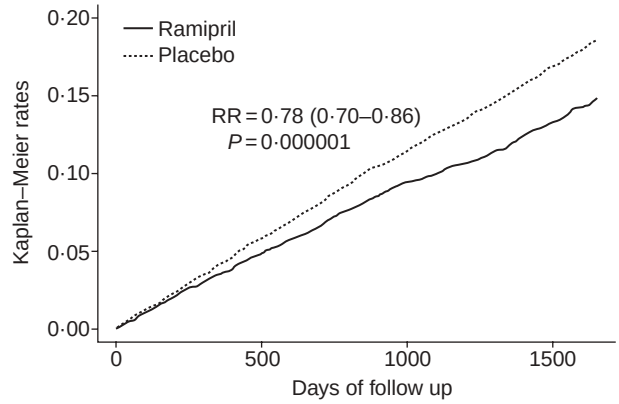

Figure 18.1 Effect of ramipril on the composite primary outcome of myocardial infarction, stroke and death from cardiovascular causes in the HOPE trial. The relative risk of the composite primary outcome in the ramipril group as compared to the placebo group was 0·78 (95% CI 0·70–0·86). (Reproduced with permission from the *New England Journal of Medicine*[45])

The efficacy of a long-term ACE inhibitor-based therapeutic strategy was shown also in the Perindopril pROtection aGainst Recurrent Stroke Study (PROGESS) conducted in 6105 patients with prior stroke or transient ischemic attack. Patients treated with perindopril with or without the addition of indapamide had a 28% reduction in the risk of recurrent stroke and a 26% reduction in the risk of major vascular events.[47]

Ongoing large randomized clinical trials are further evaluating the use of ACE inhibitors in patients with CHD with preserved left ventricular systolic function, the combined use of ACE inhibitors and angiotensin receptor blockers and the use of angiotensin receptor blockers in ACE-intolerant individuals.

ACE inhibitors: conclusions and recommendations

ACE inhibitors are effective in the prevention of major CV events and death in a wide range of patients with vascular disease or diabetes and additional risk factors. In addition, ACE inhibitors are effective in the management of hypertension, heart failure, asymptomatic left ventricular dysfunction and acute myocardial infarction and should be used consistently in these broad categories of patients with vascular disease. **Grade A**

Homocysteine and vascular disease

Pathophysiology and biologic rationale

Homocysteine is a sulfur-containing amino acid produced during catabolism of the essential amino acid methionine. It can be irreversibly degraded by cystathionine-beta-synthase, a process requiring vitamin B_6 as a cofactor. Alternatively,

homocysteine can be remethylated to conserve methionine in a process requiring methionine synthase and methylcobalamin (vitamin B_{12}) as a cofactor and methyl-tetrahydrofolate reductase (MTHFR) as a cosubstrate. This metabolic pathway requires an adequate supply of folate and the enzyme MTHFR. Genetic and acquired abnormalities in the function of these enzymes or deficiencies in folate or vitamin B_6 or B_{12} cofactors can therefore lead to elevated concentrations of intracellular homocysteine, which is then released to the plasma. Very high levels of plasma homocysteine lead to homocystinuria, which is caused by the rare homozygous deficiency of cystathionine-beta-synthase or the even more infrequent homozygous deficiency in MTHFR or defects in cobalamin metabolism. These distinct genetic abnormalities, which share very high levels of plasma homocysteine, have typical clinical manifestations, including severe premature atherosclerotic and thromboembolic disease. Histopathologically, this vascular disease is characterized by vascular endothelial injury, vascular smooth muscle cell proliferation, progressive arterial stenosis, and hemostatic changes consistent with a prothrombotic state. These findings have led McCully to formulate the homocysteine theory of atherosclerosis.[48]

More recently, the modest elevation in plasma homocysteine levels has been evaluated as a potential CV risk factor. Such "modest" elevations in plasma homocysteine can be related to genetic, physiologic, pathologic, and nutritional factors, including MTHFR mutations (for example, thermolabile MTHFR), older age, male gender, postmenopausal status in women, smoking, sedentary lifestyle, dietary factors including increased intake of animal proteins which have a higher methionine content and low intake of folate, vitamins B_6, and B_{12}, renal failure, transplantation, and medications such as corticosteroids and cyclosporin which have been associated with hyperhomocysteinemia.[49]

Potential mechanisms of atherothrombosis associated with elevated homocysteine levels include:

- Endothelial dysfunction related to direct endothelial cell damage and impaired production of nitric oxide.[50]
- Stimulation of smooth muscle cell proliferation.[51]
- Lipid abnormalities, including increased plasma triglycerides and increased susceptibility to oxidation of LDL.[52]
- Increased thrombogenicity mediated by promoting the adherence of platelets and release of platelet-derived growth factors due to homocysteine-induced endothelial damage, activation of factor V, factor Xa, inhibition of protein C activation, inhibition of cell surface expression of thrombomodulin, and decreased tissue plasminogen activator (tPA) activity.[53]

Epidemiology

Several studies have shown associations between the extent of coronary or carotid atherosclerosis and plasma homocysteine levels.[49] A large number of cross-sectional and retrospective observational studies suggest an association between elevated homocysteine levels and CV risk. Boushey *et al* reviewed the major retrospective epidemiologic investigations of homocysteine and CVD up to 1995 and found a linear, independent association between plasma homocysteine concentrations and CV risk;[54] every 5 μmol/l increment in homocysteine was associated with an increased odds ratio for CHD of 1·6 for men (95% CI 1·4–1·7) and 1·8 for women (95% CI 1·3–1·9), of 1·5 for cerebrovascular disease and of 6·8 for peripheral arterial disease.[54] Subsequent retrospective studies have generally confirmed these findings.[49]

Several, but not all, large *prospective* cohort studies (using generally a nested case–control design) also found an independent association between hyperhomocysteinemia and increased CV risk (Table 18.4).

Randomized clinical trials

Homocysteine levels can be easily reduced by supplementation with folic acid and possibly vitamins B_6 and B_{12}, or a combination of these. These simple, inexpensive and likely risk-free interventions are currently evaluated in large randomized clinical trials. To date there are no completed large

randomized clinical trials of homocysteine lowering therapies. A number of large randomized clinical trials are ongoing.[49]

Homocysteine: conclusions and recommendations

Although experimental and epidemiologic data are promising, evidence from ongoing randomized controlled trials is critical in clarifying the role of homocysteine and of homocysteine lowering therapies in CVD. In the meantime, it appears prudent to ensure adequate dietary intake of folate and vitamins B_6 and B_{12}. **Grade B**

Inflammation and cardiovascular disease

There is increasing recognition of the involvement of inflammation in human atherosclerosis, although the clinical implications are unclear. Whether inflammation is a fundamental part of the process of atherosclerosis or a secondary phenomenon has yet to be determined. The destabilization of the lipid-rich, "vulnerable" thin-capped arterial plaque may involve activation of peripherally situated macrophages, leading to platelet activation and thrombosis.[56] Chronic atherosclerotic lesions are characterized by inflammatory cells, including lipid laden macrophages and T lymphocytes, and by inflammatory proteins: endothelial expression of adhesion molecules such as Intercellular Adhesion Molecule-1 (ICAM-1) or Vascular Adhesion Molecule-1 (VCAM-1), intralesional localization of C-reactive protein (CRP) or fibrinogen, cytokines such as interleukin-1 or 6, and chemokines such as interleukin-8.[57] Circulating inflammatory molecules provide prognostic information ("risk markers"), although the reproducibility, validity, and tissue-specificity of many assays have been poorly defined. Potentially, measurement of these markers may guide the initiation or withholding of specific therapies and stimulate the development of novel therapies.[58]

C-reactive protein (CRP)

CRP is an acute phase reactant synthesized by the liver on stimulation by interleukin-6. It is a pentameric protein that binds bacterial fragments and oxidized LDL, has a long serum half life, lacks diurnal variability, and has been localized within atheroma.

Elevated serum CRP has been associated with cardiovascular events in primary and secondary prevention cohorts, and in patients presenting with acute coronary syndromes. In a meta-analysis of 14 prospective studies, with 2557 cases (mean age of 58 years and mean follow up of 8 years), CRP concentrations in the highest versus lowest third were associated with an adjusted relative risk of 2·0 (95% CI 1·6–2·5) in primary prevention cohorts, and 1·9 (95% CI 1·5–2·3) in secondary prevention cohorts.[59]

Higher serum CRP concentrations may identify patients more likely to respond to aspirin or statin therapy. Among 543 cases and matched controls in the Physicians', Health Study, aspirin reduced myocardial infarction by 56% among those with the highest quarter of baseline CRP level, versus a 14% reduction in those in the lowest quarter.[60] In the CARE[61] and AFCAPS/Texas CAPS[62] studies, patients with high CRP levels benefitted from statin therapy even in the presence of low to normal LDL cholesterol. Statins lower CRP concentrations,[63] and may have anti-inflammatory properties. The ongoing Pravastatin Inflammation CRP Evaluation (PRINCE) study is testing the effectiveness of statin therapy among patients with high CRP levels.[64] ACE inhibitors may also decrease inflammation. However, CRP levels did not predict response to ramipril in the HOPE study (Smieja *et al.*, 2002, personal communication).

Other inflammatory markers

Two other acute phase reactants, fibrinogen and serum amyloid A (SAA), have also been associated with subsequent CV events. A meta-analysis of 18 prospective studies with 4018 cases found an adjusted relative risk of 1·8 (95% CI 1·6–2·0) for the top versus the bottom third of plasma fibrinogen concentrations.[65] In four studies with 1057 cases, SAA was associated with an RR of 1·6 (95% CI 1·1–2·2) for CV events.[59]

The cytokines interleukin-1, tumor necrosis factor-alpha, and interleukin-6 have been investigated as more "proximal" components of the inflammatory cascade. These are localized within atheroma and are likely key mediators in the induction of acute phase reactants, and in adhesion molecular expression, and have systemic effects including stimulation of acute phase reactant production and altering glucose metabolism. In prospective studies, interleukin-6 was associated with cardiovascular outcomes, but was not independent of CRP.[66]

The adhesion molecules ICAM-1 and VCAM-1, and the selectins E-selectin and P-selectin, play critical roles in endothelial cell adhesion and transmigration of inflammatory cells. ICAM-1 may play an important role within atheroma, but prospective data are limited. In the one prospective study in which the three were compared, VCAM-1 was superior to either ICAM-1 or E-selectin among 1246 patients with angiographically proven CAD, and followed for a mean of 3 years for CV outcomes in the AtheroGene study.[67] The highest quarter of VCAM-1 concentration was associated with an RR of 2·1 (95% CI 1·1–4·0) for fatal CV events.

Inflammation: conclusions and recommendations

The role for measuring inflammatory markers is evolving, with a demonstrated utility of high-sensitivity CRP for risk

stratification. Whether high CRP levels require treatment, and whether other inflammatory risk markers should be measured routinely, is not clear from the available evidence. Whether these inflammatory molecules play a causal role in atheroma formation also remains unknown. The beneficial effects of aspirin and of statins in CV prevention may be mediated in part by their anti-inflammatory actions. **Grade B**

Infection and cardiovascular disease

Human atherosclerotic heart or cerebrovascular disease has been associated with previous exposure to the bacteria *Chlamydia pneumoniae*,[68,69] *Helicobacter pylori*, or *Porphyromonas gingivalis*,[70,71] and with the viruses cytomegalovirus,[72] herpes simplex virus type 1 and 2,[73] enteroviruses,[74] or hepatitis A virus,[73] but prospective studies remain limited for all but the first two infections. Overall, current data have not convincingly demonstrated an important role for infections in human CV disease.

Chlamydia pneumoniae

Chlamydia pneumoniae is a Gram-negative, obligate intracellular pathogen which has been demonstrated within human atherosclerosis.[75] The interpretation of cross-sectional seroepidemiologic data has been difficult due to inter-laboratory differences in antibody measurement and cut off values, varying control groups, emphasis on multiple subgroup analyses, and incomplete ascertainment of potential confounders. A meta-analysis of 15 prospective studies which included 3169 cases, and adjusted for potential confounders including socioeconomic status, found no association between *C. pneumoniae*, IgG antibodies, and subsequent CV events (pooled odds ratio 1·15; 95% CI 0·97–1·36).[76]

Antichlamydial antibiotics have been administered to patients after MI. In two pilot studies, the macrolide antibiotics azithromycin and roxithromycin decreased subsequent CV events.[77,78] These results were not statistically significant on longer follow up in the latter study,[79] nor in a separate larger study.[80] However, two large trials involving 9163 patients found no benefit with azithromycin (Dunne M and Cevek B, 2002. American College of Cardiology 51st Annual Scientific Session).

Helicobacter pylori

Helicobacter pylori, a major cause of peptic ulcers and gastric carcinoma, has been studied in a number of cross-sectional and prospective studies. A meta-analysis of 10 prospective studies, with 2916 cases, found no association between seropositivity and subsequent cardiovascular events, with an adjusted odds ratio of 1·15 (95% CI 0·96–1·37).[81]

Other infection and total pathogen burden

There are more limited data for other infections, such CMV, HSV, or dental infections. These require further study in prospective cohorts, with appropriate adjustment for CV risk factors. A role for influenza can be inferred from observational studies of benefit from influenza vaccination.[82] There has been recent demonstration by two separate groups of investigators of a stepwise association between total pathogen burden and subsequent CV events.[83,84] These investigators used a score including bacterial infections such as *C. pneumoniae* and *H. pylori*, and viral infections such as cytomegalovirus and other viruses in the herpes family. These findings require validation in other study populations, and do not clearly demonstrate whether markers of exposure to infections represent confounding by other CV risk factors, epiphenomena, or a causal association.

Infections: conclusions and recommendations

Meta-analyses of prospective studies of exposure to *C. pneumoniae* and *H. pylori*, as measured by serum antibodies, found no association with human CV disease. The possible association with multiple infections requires further study. Antibiotic treatment is currently not recommended. **Grade A**

Key points

- The antioxidant vitamins E, C, and beta-carotene do not reduce CV events.
- ACE inhibitors reduce the risk of myocardial infarction, stroke and CV death in high-risk patients.
- Homocysteine lowering with folic acid and vitamin B_6 is currently under investigation in large clinical trials. For now, the routine measurement of homocysteine levels in CV risk assessment and the treatment of hyperhomocysteinemia are not widely recommended.
- The role of inflammation in CVD is under investigation. For now, the routine measurement of inflammatory markers such as CRP is not recommended.
- Antibiotics are not recommended in CV prevention. Further trials are awaited.

19 Obesity

Arya M Sharma

The worldwide prevalence of obesity is increasing at an alarming rate. Recent estimates indicate that 40–60% of the population in industrialized countries and a substantial proportion of the population in developing countries must now be considered overweight or obese.[1] In the United States, the prevalence of adult obesity (defined as body mass index $>30\,kg/m^2$), based on self-reported weight and height, increased from 12·0% in 1991 to 18·9% in 1999, and it is estimated that this trend is likely to continue over the next decade.[2] In the Third National Health and Nutrition Examination Survey (NHANES III), conducted in two phases from 1988 to 1994, 63% of men and 55% of women had a body mass index of $25\,kg/m^2$ or greater.[3]

In 1998 the American Heart Association reclassified obesity as a major modifiable risk factor for coronary heart disease.[4] This is a step forward from the earlier notion that obesity contributes to heart disease primarily through covariates related to obesity, including hypertension, dyslipidemia, and impaired glucose tolerance or type 2 (non-insulin dependent) diabetes mellitus. Overweight and obesity are now also recognized as important risk factors for stroke, renal dysfunction, gallbladder disease, certain types of cancer, osteoarthritis, sleep apnea and a host of other disorders.[5] Importantly, increased body weight is also an important determinant of impaired quality of life.[6]

Obesity is a complex multifactorial chronic disease that develops from an interaction between genetic and environmental factors. Our understanding of how and why obesity develops is incomplete, but clearly involves the integration of social, behavioral, cultural, physiological, metabolic and genetic factors. Overweight and obesity are especially evident in some minority groups, as well as in those with lower incomes and less education.[1]

Definition of obesity

Definitions of overweight and obesity in adults have varied over time.[7] Ideally, a health-oriented definition of obesity would be based on the amount of excess body fat that determines the presence of weight-responsive health risk in an individual.[8] Body mass index (BMI), defined as weight in kilograms divided by height in meters squared (kg/m^2), is an easily obtained measure that is now widely used, as it has a high correlation with excess body fat or adiposity. However, BMI is not a measure of body fat and does not convey information on regional fat distribution. The latter is important, as it is now well established that central or visceral fat deposition is a major independent determinant of the metabolic and cardiovascular risk associated with an increase in fat mass.[9–11] Recent evidence-based guidelines therefore recommend the use of both BMI and waist circumference in the assessment of overweight or obese patients.[1] Table 19.1 summarizes the current classification of overweight and obesity by BMI, waist circumference and associated disease risk in Caucasians.[1] There are now also data to indicate that in south Asians[12] and other Asian populations,[13] for the same level of BMI or waist circumference health risks may be higher than in Caucasians. Lower cut offs have therefore been recommended for both BMI and waist circumference in adult Asians (Table 19.2).[14] The levels of BMI or waist circumference that can be used to define obesity related risk in other ethnic groups or populations (for example, Pacific Islanders, Native Americans, Australian Aboriginals etc.) remain to be determined.

Although there are benefits to the identification of cut-off points for monitoring overweight and obesity, it is important to realize that (as for other risk factors) health risks associated with increasing weight are part of a continuum, and individuals with BMI $<25\,kg/m^2$ can have substantial weight-associated health problems (for example, impaired glucose tolerance, hypertension), whereas others may have no identifiable health problems at BMIs significantly greater than 25. Individualized assessment of risk status and conditions associated with obesity must therefore form an integral part of patient assessment, before deciding on the potential benefits to be derived from weight management in an individual patient (Figure 19.1).[15]

Key points

- Practitioners should use the BMI to assess and classify overweight and obesity and to estimate relative risk of disease compared with normal weight. **Grade B**
- The waist circumference should be used to assess abdominal fat content. **Grade B**
- For adult patients with a BMI of $25–34·9\,kg/m^2$, sex-specific waist circumference cut offs should be used in conjunction with BMI to identify increased disease risk. **Grade C**
- Body weight alone can be used to follow weight loss and to determine the efficacy of weight loss therapy. **Grade C**

Table 19.1 Classification of overweight and obesity by body mass index (BMI), waist circumference, and associated disease risk in Caucasians[1]

		Disease risk* relative to normal weight and waist circumference	
	BMI, kg/m^2	Men, 102 cm; Women, 88 cm	Men, >102 cm; Women, >88 cm
Underweight	<18·5	–	–
Normal†	18·5–24·9	–	–
Preobese	25·0–29·9	Increased	High
Obesity, class			
I	30·0–34·9	High	Very high
II	35·0–39·9	Very high	Very high
III	40	Extremely high	Extremely high

* Disease risk for type 2 diabetes, hypertension and cardiovascular disease.
– indicates that no risk at these levels of BMI was assigned.
† Increased waist circumference can also be a marker for increased risk even in persons of normal weight.

Table 19.2 Proposed classification of weight by BMI in adult Asians[14]

Classification	BMI, kg/m^2	Risk of comorbidities
Underweight	<18·5	Low
Normal range	18·5–22·9	Average
Overweight	23·0	
At risk	23·0–24·9	Increased
Obese I	24·9–25·0	Moderate
Obese II	30·0	Severe

Hypertension

Overweight and obesity have long been recognized as important determinants of elevated blood pressure, in both black and white hypertensive and normotensive individuals.[3,16,17] The same appears true for Asian populations.[18,19] Experimental studies have shown that weight gain consistently elevates blood pressure and weight loss decreases blood pressure independent of changes in sodium intake. Nevertheless, the mechanisms underlying this relationship remain poorly understood. Several mechanisms, including increased sympathetic activity, sodium and volume retention, renal abnormalities, insulin resistance and, more recently, hyperleptinemia, have been implicated in the development of obesity related hypertension.[20,21]

Based on an assessment of 76 RCTs on the effect of weight loss on blood pressure, which included 35 lifestyle trials and 10 on pharmaceutical intervention, the authors of recent *Clinical Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults*[5] concluded that there was strong evidence that weight loss due to lifestyle modifications reduced blood pressure levels, and suggestive evidence that weight loss produced by most weight loss medications in combination with adjuvant lifestyle modifications will be accompanied by reductions in blood pressure. Importantly, substantial reductions in blood pressure, or even normalization, can be achieved with rather modest weight loss of 5–10% of initial weight.[22]

Since the appearance of this report, several newer non-pharmacologic intervention trials have been published[23–26] essentially confirming that lowering body weight lowers blood pressure. Three studies perhaps deserve special mention.

1. The Trials of Hypertension Prevention II (TOHP II),[27] a 36 month randomized trial of weight loss versus usual care in 1191 overweight adults (mean BMI around 31 kg/m^2) with non-medicated diastolic blood pressure of 83–89 mmHg and systolic blood pressure less than 140 mmHg. Although participants who lost at least 4·5 kg at 6 months and maintained this weight reduction for the next 30 months had a relative risk for hypertension of 0·35 (95% CI 0·20–0·59), this group only included 13% of the participants in the weight loss arm. Sadly, over the 36 months body weight returned to −0·2 kg below baseline in the weight loss group and increased by 1·8 kg in controls. This study thus clearly illustrates the limited success of achieving and maintaining weight loss by lifestyle measures even over a relatively short period.
2. The trial of non-pharmacologic interventions in the elderly (TONE),[28] which included 585 obese men and

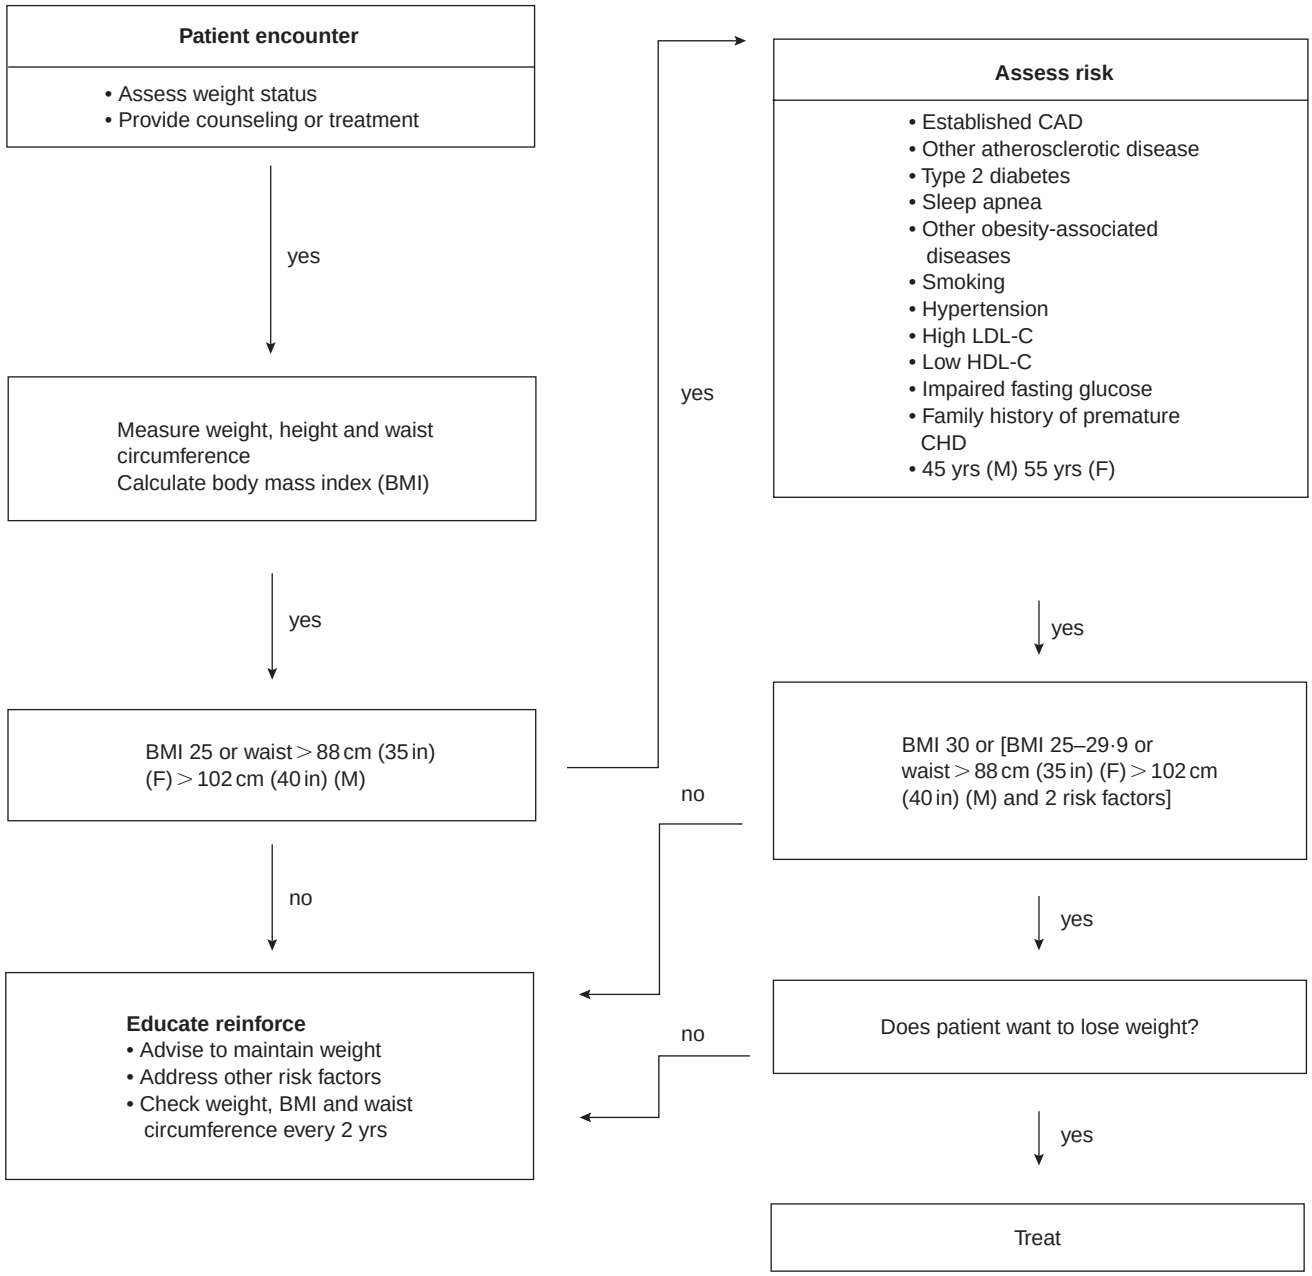

Figure 19.1 Evidence-based algorithm for the treatment of obesity (adapted from the National Institute of Health guidelines)[15]

women aged 60–80 years with systolic blood pressure lower than 145 mmHg and diastolic blood pressure lower than 85 mmHg on antihypertensive monotherapy (withdrawn after 1 month), who were randomized to reduced sodium intake, weight loss, both, or usual care for 29 months. Relative to usual care, hazard ratios for the combined outcome measure (diagnosis of high blood pressure, treatment with antihypertensive medication, or a cardiovascular event during follow up) were 0·60 (95% CI 0·45–0·80; $P < 0·001$) for reduced sodium intake alone, 0·64 (95% CI 0·49–0·85; $P = 0·002$) for weight loss alone, and 0·47 (95% CI 0·35–0·64; $P < 0·001$) for reduced sodium intake and weight loss combined.

3. A study on exercise and weight loss on blood pressure in 133 sedentary overweight men and women with unmedicated high normal BP or stage 1–2 hypertension, randomly assigned to aerobic exercise only; a behavioral weight management program, including exercise; or a waiting list control group.[29] Weight

management was associated with a 7 mmHg systolic and a 5 mmHg diastolic BP reduction, compared to a 4 mmHg systolic and diastolic BP reduction associated with aerobic exercise; the BP for controls did not change. In general, 1 kg weight loss can be expected to result in approximately 1 and 0·5 mmHg reduction in systolic and diastolic blood pressure, respectively (Table 19.3).[30]

Table 19.3 Effect of weight loss on major coronary heart disease risk factors (adapted from[30])

Measure	Units	Mean change/1 kg weight loss
Systolic blood pressure	mmHg	−0·68
Diastolic blood pressure	mmHg	−0·34
Fasting glucose	mg/dl	−3·6
Total cholesterol	mg/dl	−2·28
LDL cholesterol	mg/dl	−0·91
Triglycerides	mg/dl	−1·54
HDL cholesterol	mg/dl	+0·07

New data have also recently emerged for some of the newer pharmacologic weight reducing agents, orlistat and sibutramine. Studies with both compounds have included overweight and obese hypertensive patients. With the lipase inhibitor orlistat the reduction in blood pressure and heart rate for a given weight loss is similar to that expected with weight loss from lifestyle intervention.[31–35] With the centrally active norepinephrine and serotonin reuptake inhibitor sibutramine, weight loss in normotensive and treated hypertensive patients is associated with a modest reduction in blood pressure, that is about half of what might be expected for a given degree of weight loss.[36,37] In some instances (1–5%) patients may experience a clinically significant rise in blood pressure (>10 mmHg). Sibutramine also consistently increases heart rate by 3–5 bpm. Sibutramine therapy should be discontinued if a patient experiences an increase in resting heart rate of >10 bpm, or a rise in systolic or diastolic blood pressure of >10 mmHg at two consecutive visits. **Grade C** Similarly, treatment should be withdrawn in the event of previously well controlled hypertension shifting to a pattern of blood pressure >145/90 mmHg on two consecutive visits, or signs of progressive dyspnea, chest pain or ankle edema. **Grade C**

Which antihypertensive agent is best suited for the obese hypertensive patient? Current hypertension guidelines do not make specific recommendations for the pharmacologic management of obese patients. This may reflect the paucity of "hard data" from prospective intervention studies in obese hypertensives.[38] Indeed, there are currently no studies documenting a reduction in morbidity and mortality, or the superiority of any class of antihypertensive agents in obese hypertensive patients. Few small to moderate-sized studies have specifically addressed the efficacy of antihypertensive agents in obese patients. From these it appears that β blockers are more effective than dihydropiridine calcium-channel blockers,[39] and that hydrochlorothiazide is less effective at lower doses than the angiotensin converting enzyme inhibitor lisinopril.[40] An increased risk of type 2 diabetes[41,42] and weight gain[43] has been noted for β blockers. This may make β blockers less well suited for managing hypertension in the uncomplicated obese hypertensive. In contrast, angiotensin converting enzyme inhibitors[44,45] and AT_1 receptor blockers[46] may reduce the risk of developing type 2 diabetes and may therefore be preferable for use in obese patients.

Key points

- Weight loss by lifestyle modification is recommended to lower blood pressure in overweight and obese patients with high blood pressure. **Grade A**
- Dietary salt reduction (to <5 g/day) is recommended to lower blood pressure in overweight and obese patients with high blood pressure. **Grade A**
- Weight loss with orlistat (120 mg t.i.d) or sibutramine (10–15 mg/day), in combination with lifestyle modification, can lower blood pressure in overweight and obese patients with high blood pressure. **Grade A**
- Patients managed on sibutramine must be regularly monitored for a rise in blood pressure, deterioration in blood pressure control, or a significant increase in heart rate. **Grade C**
- Angiotensin converting enzyme inhibition or angiotensin receptor blockers may be best suited for antihypertensive monotherapy in uncomplicated obese hypertensive patients. **Grade C**
- When other indications (for example, myocardial infarction, congestive heart failure, tachyarrythmias) support the use of β blockers, these can also be used in obese hypertensive patients. **Grade C**

Diabetes

Overweight and obesity have long been recognized as important determinants of elevated blood glucose, and the vast majority of patients with type 2 diabetes are either overweight or obese. Both at a population and at an individual level, the prevalence and incidence of type 2 diabetes is dependent on the degree of obesity. Thus, in the 10 year follow up (1986–1996) of middle-aged women in the Nurses' Health Study and men in the Health Professionals Follow-up Study, the risk of developing diabetes was approximately 20 times as high in those with a BMI of 35 or more as in their same-sex peers with a BMI between 18·5 and 24·9.[47]

Importantly, the rise in risk of developing type 2 diabetes begins at BMI levels as low as 22, suggesting that adults should try to maintain a BMI between 18·5 and 21·9 to minimize their risk of type 2 diabetes and other disease. In addition to BMI, abdominal fat distribution, as indicated by an increased waist to hip ratio, is also an important independent predictor of type 2 diabetes.[48,49] An increased prevalence of obesity has also been recently implicated in the rising prevalence of glucose intolerance in childhood in North America.[50]

Despite the close relationship between obesity and type 2 diabetes, it is important to note that at least 20% of type 2 diabetic patients are not obese, and over 80% of individuals with high BMI and WHR remain non-diabetic. Thus obesity must apparently interact with other inherited or acquired factors that determine insulin resistance and β cell function in order for diabetes to develop.

A large number of studies document the benefits of even moderate (5–10%) weight loss in improving metabolic control in diabetic patients.[30] However, the impact of weight reduction on the long-term incidence of diabetic complications and survival has not been demonstrated. Improvement in metabolic control depends more on the amount of weight loss, rather than on the method by which this is achieved. A 5 kg weight loss should decrease fasting plasma glucose levels in a diabetic individual by 1 mM or 18 mg/dl (Table 19.3).[30] This is of a magnitude similar to that provided by many of the oral hypoglycemic agents. Although pharmacologic or surgical weight loss does not appear to improve glucose control beyond that achieved by lifestyle changes alone, both the degree of loss and the number of individuals achieving and maintaining weight loss are generally higher when lifestyle changes are combined with medication or surgery.[5,15]

Recent evidence from randomized prospective trials indicates that lifestyle modification including modest weight reduction will markedly reduce the incidence of type 2 diabetes in individuals at high risk. Thus in the recent Finnish Diabetes Prevention Study[51] 522 middle-aged overweight subjects (mean BMI 31) with impaired glucose tolerance were randomly assigned to either the control group or the intervention group, where participants received individualized counseling aimed at reducing weight, total fat intake and intake of saturated fat, and increasing their intake of fiber and physical activity. A mean weight loss at the end of 1 year of around 4 kg versus a 1 kg gain in the control group was associated with a 58% reduction in the incidence of diabetes after 4 years. Similarly, in the Diabetes Prevention Project[52] lifestyle intervention aimed at reducing body weight by 7% and at least 150 minutes of physical activity per week over 2·8 years in non-diabetic persons (mean BMI 34), with elevated fasting and postload plasma glucose concentrations, reduced the incidence by 58% compared with placebo; the lifestyle intervention was also significantly more effective than metformin in preventing the development of type 2 diabetes.

In contrast to metformin and acarbose, other antidiabetic medications, including sulphonylureas, thiazolidinediones and insulin, promote weight gain. Weight gain in patients with both type 1 and type 2 diabetes is associated with an increase in blood pressure and deterioration of metabolic control.[53,54] In the UK Prospective Diabetes Study, metformin was more effective than sulphonylureas or insulin in reducing diabetes related end points.[55] Furthermore, metformin is both cost saving and extends life expectancy when used as first-line pharmacologic therapy in overweight type 2 diabetics.[56] Weight gain can be promoted by the use of β blockers,[43] and their use may increase the risk of developing type 2 diabetes.[41,42] In contrast, ACE inhibitors[44,45] and angiotensin receptor blockers[46] have been found to reduce the incidence of diabetes in high-risk individuals.

Pharmacologically induced weight loss with orlistat[57,58] or sibutramine,[59,60] in conjunction with a lifestyle modification program, significantly improves metabolic control and lower HbA1c levels in patients with type 2 diabetes.

Key points

- Adults should maintain a BMI between 18.5 and 21.9 to minimize their risk of developing type 2 diabetes. **Grade C**
- Weight loss is recommended to lower elevated blood glucose levels in overweight and obese individuals with type 2 diabetes. **Grade A**
- Weight loss is recommended to prevent diabetes in overweight and obese individuals at risk for developing type 2 diabetes. **Grade A**
- Metformin is both cost effective and extends life expectancy when used as first-line pharmacologic therapy in overweight patients with type 2 diabetes. **Grade A**
- Use of β blockers is associated with greater weight gain than are ACE inhibitors in patients with type 2 diabetes. **Grade B**
- Use of ACE inhibitors or angiotensin receptor blockers may reduce the risk of developing diabetes in overweight or obese individuals at risk for developing type 2 diabetes. **Grade B**

Dyslipidemia

Lipid abnormalities in overweight and obese individuals are typically characterized by high triglycerides, increased small LDL particles and low HDL cholesterol levels.[61] In the presence of abdominal obesity, high serum triglycerides are commonly associated with a clustering of metabolic risk factors known as the metabolic syndrome (atherogenic lipoprotein phenotype, hypertension, insulin resistance, glucose

intolerance, prothrombotic and proinflammatory states). Thus, in obese patients elevated serum triglycerides are a marker for increased cardiovascular risk. The US National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP III) therefore recognizes the metabolic syndrome as a secondary target of risk reduction therapy, after the primary target – LDL cholesterol.[61]

Numerous studies document the short- and medium-term benefits on blood lipids associated with lifestyle modification, including weight reduction.[62] Current evidence-based guidelines thus recommend weight reduction and increased physical activity as first-line therapies for all lipid and non-lipid risk factors associated with the metabolic syndrome.[61] Weight reduction will enhance LDL lowering and reduce all of the risk factors of the syndrome. Significant reductions in blood triglycerides and increases in HDL cholesterol have been observed in randomized controlled trials of pharmacologically induced weight loss with orlistat[63,64] and sibutramine.[65,66] Possibly because of its mode of action on intestinal lipid absorption,[67] the use of orlistat has been associated with a greater reduction in LDL cholesterol than can be expected by weight reduction alone.[63] Observational studies have shown profound metabolic benefits associated with surgical weight reduction in the morbidly obese.[68,69] However, as for other high-risk groups, the long-term effect of weight reduction on morbidity or mortality in overweight or obese dyslipidemic patients has yet to be demonstrated.

Key point

- Weight loss is recommended to lower elevated levels of total cholesterol, LDL cholesterol and triglycerides and to raise low levels of HDL cholesterol in overweight and obese individuals with dyslipidemia. **Grade A**

Coronary artery disease

Overweight and obesity are now considered major independent risk factors for coronary artery disease;[4] nevertheless, the impact of excess body fat and fat distribution in different populations (men and women, young and elderly, ethnic groups) remains to be fully determined. In a recent review of 11 independent studies, Anderson and Konz[30] estimated an overall RR of 2·71 for women and 2·80 for men for a BMI of 33 *v* 23 kg/m^2, respectively. This increased risk was partly (but not fully) accounted for by other major risk factors for coronary artery disease, including hypertension, lipids and diabetes. This may in part be accounted for by an association between obesity and other non-conventional risk factors for coronary artery disease, including alterations in coagulation and risk for thrombosis or increased inflammatory cytokines.[70–72] A recent study also found a substantially increased risk for angiographically assessed coronary artery disease associated with an increase in waist circumference, that reached an odds ratio of over 12 in patients with familial hypercholesterolemia.[73] Weight gain has also been associated with a significant increase in coronary risk.[30] Thus, a weight gain of 15 kg after age 21 was associated with an increased coronary risk of 83% in women and 46% in men.

Weight reduction has been consistently shown to lower blood pressure, lower plasma glucose and insulin levels, prevent the development of type 2 diabetes, lower plasma triglycerides and raise low levels of HDL cholesterol, and improve other risk factors for coronary artery disease.[5,15] It is therefore very likely that weight reduction will substantially lower coronary risk in obese patients. However, there are currently no hard end-point data from randomized controlled trials of weight loss on morbidity and mortality in patients with coronary artery disease.

In a large prospective study of patients surviving a first myocardial infarction, overweight, grade I and grades II–III obesity were associated with a 1·16, 1·49 and 1·80 relative risk for a recurrent coronary event, respectively.[74] Readily measured markers of diabetes, hypertension and dyslipidemia explained some of the risk conferred by obesity. Other investigators have identified obesity as an independent predictor of hospital mortality in older (but not younger) patients with myocardial infarction.[75] No effect of body weight was found in 1 year mortality in overweight or obese patients. Thus, although obese patients should certainly be targeted for proven preventive therapies following acute myocardial infarction, whether or not weight loss should be included in these treatments remains an important but unresolved question.

Key points

- Weight reduction is recommended to reduce risk factors for coronary artery disease, including hypertension, dyslipidemia and impaired glucose tolerance/type 2 diabetes. **Grade A**
- Weight reduction is recommended in patients with coronary artery disease to reduce morbidity and mortality. **Grade C**

Congestive heart failure

In a recent report from the Framingham cohort, after adjustment for established risk factors, there was an increase in the risk of heart failure of 5% for men and 7% for women for each unit increment in body mass index.[76] Surprisingly, however, a large retrospective observational study suggests that increased BMI may confer a more favorable prognosis in patients with overt heart failure.[77] However, interpretation of these findings is complicated by the fact that lower

BMI may reflect the presence of circulatory compromise, ultimately leading to cardiac cachexia in patients with advanced cardiac function. Nevertheless, based on available data, it currently remains unclear whether weight loss promotion in medically optimized patients with heart failure is a worthwhile therapeutic goal.

Key points

- Increased body weight increases the risk for the development of heart failure. **Grade A**
- Increased body weight may confer a more favorable prognosis in patients with heart failure. **Grade B**
- Weight reduction is currently not recommended for patients with congestive heart failure. **Grade C**

Sleep apnea and obesity hypoventilation syndrome

Obesity is the most common precipitating factor for obstructive sleep apnea and is a requirement for the obesity hypoventilation syndrome, both of which are associated with substantial morbidity and increased mortality.[78] Numerous case reports and non-controlled trials document substantial improvement in sleep apnea and the obesity hypoventilation syndrome, particularly with surgically induced weight loss. In a recent Cochrane review of lifestyle modification for obstructive sleep apnea, the reviewers concluded that there were currently no randomized trial data available for analysis.[79] Thus, there are currently no data regarding the magnitude of weight loss necessary to produce a clinically significant improvement in obesity related obstructive sleep apnea, nor regarding which group of patients is most likely to benefit from this intervention.

Key point

- Surgically induced weight loss can improve the clinical picture of sleep apnea and the obesity hypoventilation syndrome. **Grade B**

Goals for weight loss

The general goals of weight loss and management are to reduce body weight, to maintain lower body weight over the long term, and to prevent further weight gain.[5,15] Weight loss should be recommended for all patients with a BMI ≥30 and for those with a BMI ≥27 with two or more risk factors.[5,15] There is consistent evidence from randomized controlled trials to indicate that overweight and obese patients in well designed programs can achieve and maintain moderate (5–10%) weight loss over time if some form of therapy continues. The initial goal of weight loss therapy should therefore be to reduce body weight by approximately 10% from baseline.

Randomized trials suggest that weight loss at a rate of 0·45–0·90 kg/week commonly occurs for up to 6 months.[5,15] The rate of weight loss in patients with type 2 diabetes may be slower than in non-diabetics.

Key points

- Weight loss should be recommended for all patients with a BMI ≥30 and for those with a BMI ≥27 with two or more risk factors. **Grade B**
- The initial goal of weight loss therapy should be to reduce body weight by approximately 10% from baseline. **Grade A**
- Weight loss should be about 0·45–0·90 kg/week for a period of 6 months. **Grade B**

How to achieve weight loss

Successful weight loss requires the combination of multiple interventions and strategies, including diet, physical activity, behavior modification, pharmacotherapy and surgery. Because obesity is a chronic condition, all treatment, including pharmacotherapy, should be initiated with the expectation that it will be long term.[15] An evidence-based algorithm is provided in Figure 19.2.

Lifestyle intervention

With regard to dietary therapy, a review of 48 randomized controlled trials[5] concluded that an average weight loss of 8% can be obtained over 3–12 months with a controlled energy low-calorie diet (LCD) aimed to reduce caloric intake by 500–1000 kcal/day (2092–4184 kJ/day), and that this weight loss effects a decrease in abdominal fat. It also appears that lower-fat diets with energy reduction promote greater weight loss than energy reduction alone. Very low-calorie diets (VLCDs), generally involving the use of protein and dietary supplements, can produce greater initial weight losses that LCDs, but long-term (>1 year) weight loss appears to be only marginally greater.[80] Importantly, unless accompanied by physical activity, weight loss with dietary measures is not associated with an improvement in cardiorespiratory fitness as measured by maximum oxygen consumption.[5,15]

A review of 13 randomized controlled trials provides strong evidence that physical activity alone results in rather modest weight loss but improves cardiorespiratory fitness, may reduce abdominal fat and may help long-term weight maintenance.[5] A review of 15 randomized controlled trials combining dietary measures and physical activity provides strong evidence that

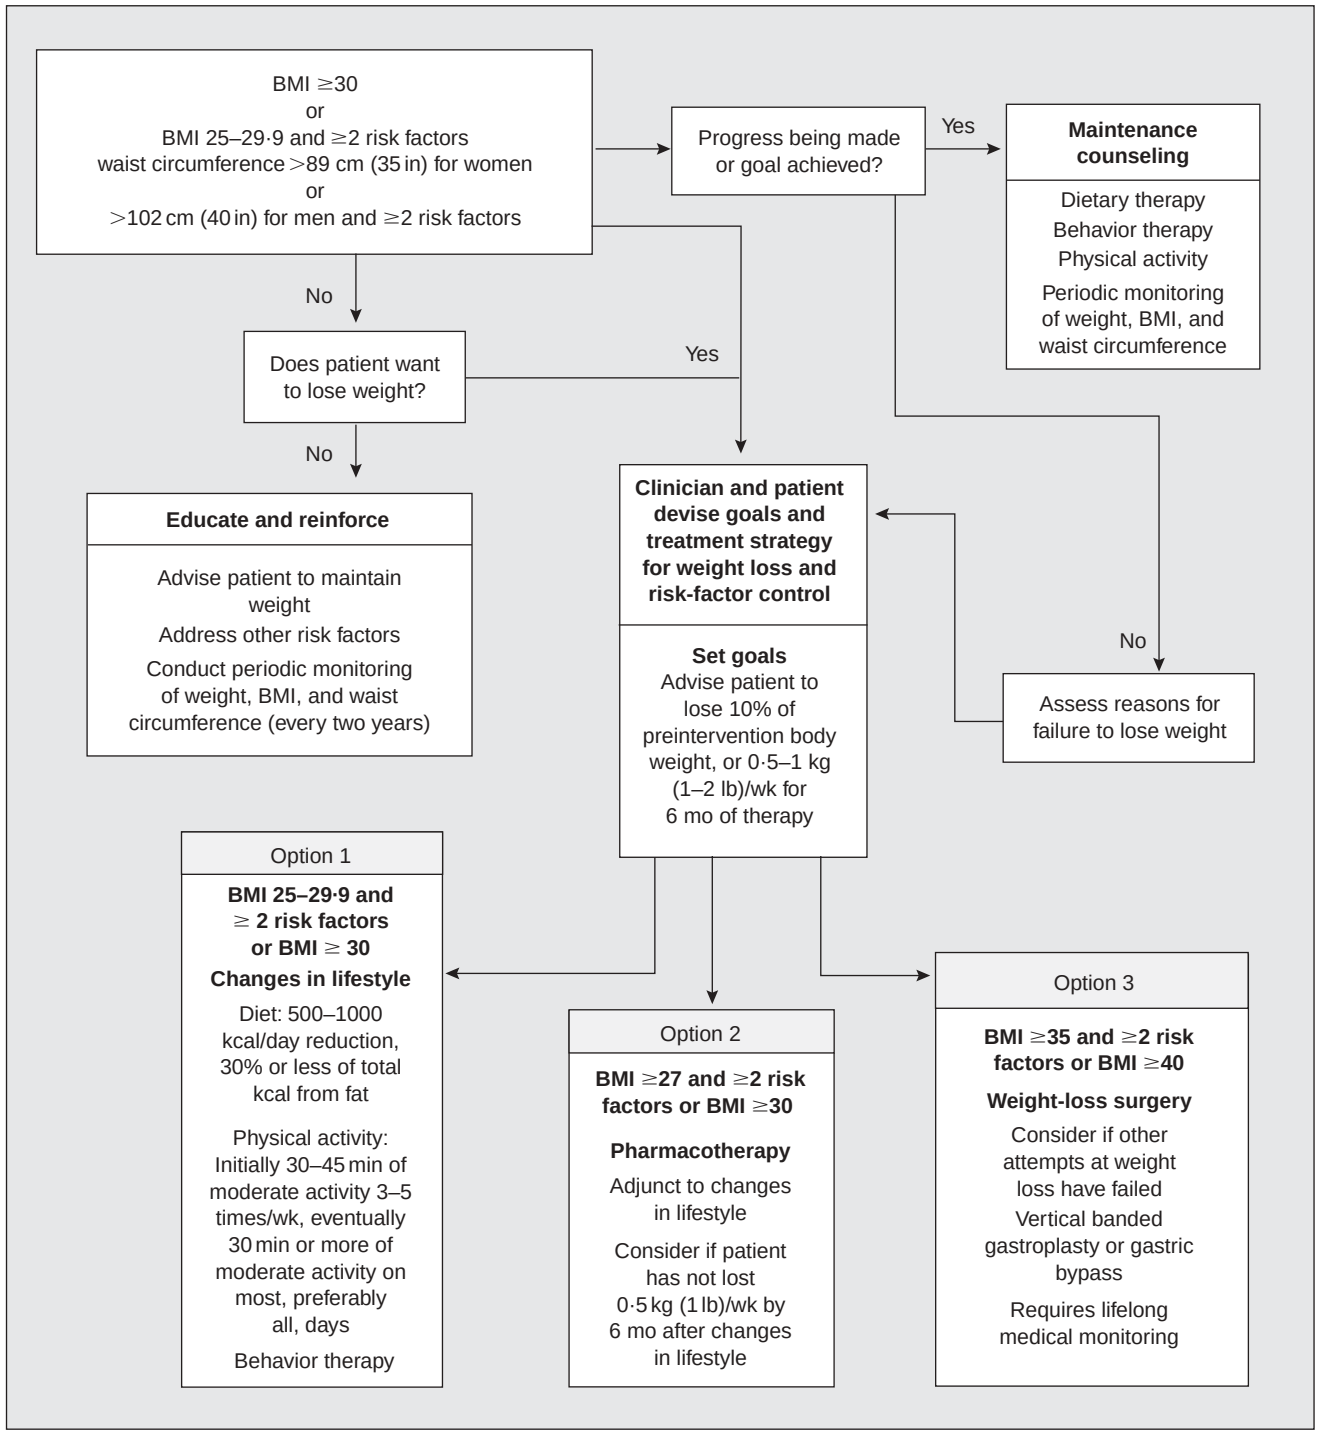

Figure 19.2 Evidence-based algorithm for the treatment of obesity. Adapted from the National Institute of Health guidelines[15]

the combination of these measures results in substantially greater weight loss than either measure alone.[5] There also appears to be additional value in behavioral therapy, although no one behavioral therapy appears to be superior to any other in its effect on weight loss. In general, the greater the intensity of the intervention, the greater the weight loss. No additional long-term benefits of behavioral therapy are found at 3–5 years. Nevertheless, there is evidence to suggest that patient motivation is an important determinant of success in weight loss programs.

Key points

- Weight loss and weight maintenance therapy should use a combination of low-calorie diets (LCDs), increased physical activity and behavioral therapy. **Grade A**
- Low-calorie diets (LCDs) providing a deficit of 500–1000 kcal/day (2092–4184 kJ/day) are a practical way to reduce calories and should be an integral part of any program aimed at achieving a weight loss of 0·45–0·90 kg/wk over 6 months. **Grade A**
- Physical activity should be an integral part of weight loss therapy and weight maintenance, as it contributes modestly to weight loss, **Grade A** increases cardiovascular fitness, **Grade A** modestly decreases abdominal fat, **Grade B** and may help with maintenance of weight loss. **Grade C**
- Initially, moderate levels of physical activity for 30–45 minutes, 3–5 days a week, should be encouraged, with the long-term goal of accumulating at least 30 minutes or more of physical activity on most or all days of the week. **Grade B**
- Behavioral therapy is a useful adjunct when incorporated into treatment for weight loss and weight maintenance. **Grade B**
- Practitioners need to assess the patient's motivation to begin weight loss therapy, assess their readiness to implement the plan, and take appropriate steps to motivate them for treatment. **Grade C**
- A weight maintenance program should be a priority after the initial 6 months of weight loss therapy. **Grade B**

Pharmacotherapy of obesity

Strong evidence indicates that the use of appropriate weight loss drugs can augment diet, physical activity and behavior therapy in weight loss.[5,15] Orlistat is gastrointestinal lipase inhibitor that reduces enteral fat absorption by around 30%.[81] Sibutramine is a centrally active serotonin and norepinephrine uptake inhibitor that reduces hunger, increases satiety, and which may have a small thermogenic effect.[82] Both compounds have been approved by licensing authorities in most countries for the pharmacologic treatment of obesity and the management of overweight patients with related comorbidities. They can be used as an adjunct to diet and physical activity for patients with a BMI of 30 or greater with no concomitant obesity risk factors or diseases, as well as patients with a BMI of 27 or greater with concomitant obesity related risk factors (hypertension, dyslipidemia, type 2 diabetes), when these patients have failed to reduce and maintain weight loss by lifestyle interventions alone.[5,15] Both have been shown to decrease the rate of weight regain following weight loss induced by combining lifestyle intervention with weight loss medication[66,83,84] or very low-calorie diets.[85] Starting with the lowest dose and discontinuation in non-responders can decrease the likelihood of adverse effects.

Mode of action, efficacy, side effects and contraindications for the use of orlistat and sibutramine are summarized in Table 19.4.

Unlike fenfluramine and dexfenfluramine, sibutramine does not induce serotonin release and has not been implicated in the development of valvular heart disease.[86] Small, dose dependent increases in heart rate and blood pressure have been consistently noted with the use of sibutramine.[87] Furthermore, reductions in blood pressure seen with sibutramine-induced weight loss tend to be less than the reductions seen with weight loss obtained by other treatments. Nevertheless, weight reduction in hypertensive patients is accompanied by a fall in both systolic and diastolic pressure, and several randomized controlled studies have shown that sibutramine can be used in overweight and obese patients with well controlled hypertension.[88] As with other weight loss interventions, sibutramine-induced weight loss is associated with a significant improvement in metabolic parameters.

Because of its lack of systemic effects on the heart and circulation, orlistat has obvious advantages over sibutramine for use in high-risk patients with established coronary artery disease, arrhythmias, stroke or heart failure. Thus, weight loss with orlistat results in a reduction in heart rate and blood pressure corresponding to that expected for a similar degree of weight loss achieved with non-pharmacologic intervention. Furthermore, owing to its mode of action the use of orlistat has been associated with a greater reduction in LDL cholesterol than can be expected by weight reduction alone.[63]

Key points

- Orlistat and sibutramine may be used as part of a weight loss program in patients with a BMI greater than 30, or in patients with a BMI greater than 27 when associated with obesity related comorbid conditions. **Grade B**
- Weight loss drugs should not be used without concomitant lifestyle modification. **Grade B**
- Continual assessment of drug therapy for efficacy and safety is necessary. **Grade C**
- If the drug is efficacious in helping the patient to lose and/or maintain weight loss and there are no serious adverse effects, it can be continued; if not, it should be discontinued. **Grade C**
- Starting with the lowest dose and discontinuation of antiobesity medication in non-responders can decrease the likelihood of adverse effects. **Grade C**

Surgery

There is currently good evidence to support the use of surgical interventions in adults with clinically severe obesity (BMI > 40 or above, or BMI > 35 with obesity related

Table 19.4 Medications approved for the long-term treatment of obesity* (adapted from[15] and [89])

	Orlistat	Sibutramine
Trade names	Xenical	Reductil/Meridia
Mechanism of action	Lipase inhibitor	Mixed norepinephrine and serotonin reuptake inhibitor
Dosage	120 mg 3 times/day with or within 1 h after fat-containing meals, plus a daily multivitamin	5–15 mg/day
Cost (US wholesale price)	$3·56/day	$2·98–3·68/day
Average weight loss when used together with lifestyle modification	4–7%	5–8%
Most frequent side effects	Flatulence with discharge, fecal urgency, fecal incontinence, steatorrhea, oily spotting, increased frequency of defecation, decreased absorption of fat-soluble vitamins	Dry mouth, headache, insomnia, constipation, anorexia, increase in heart rate, increase in blood pressure†
Potential drug interaction	Cyclosporine	SSRIs, MAOIs, centrally active anorexants, sumatriptan, dihydroergotamine, dextromethorphan, meperidine, pentazocine, fentanyl, lithium, tryptophan
Contraindications	Chronic malabsorption syndromes, cholestasis	Uncontrolled hypertension, severe renal impairment, severe hepatic dysfunction, narrow-angle glycoma, history of substance abuse, coronary artery disease, congestive heart failure, arrhythmias, stroke

*Ephedrine plus caffeine and fluoxetine have also been tested for weight loss but are not approved for use in the treatment of obesity. Mazindol, diethylpropion, phentermine, benphetamine and phendimetrazine are approved only for the short-term use for the treatment of obesity. Herbal preparations are not recommended as part of a weight loss program. These preparations have unpredictable amounts of active ingredients and unpredictable, potentially harmful effects.
† If there is a sustained increase in blood pressure or heart rate, either a reduction in the dose or discontinuation should be considered.

comorbid conditions).[5,15] In these patients, surgery can result in substantial weight loss and a marked improvement in comorbid conditions. Two types of operations have proved effective: those that restict gastric volume (banded gastroplasty) and those that, in addition to limiting food intake, also alter digestion (Roux-en-Y gastric bypass).[15] Patients who have undergone surgery require lifelong medical surveillance.

Key point

- Weight loss surgery is appropriate for carefully selected patients with clinically severe obesity (BMI > 40, or BMI > 35 with comorbid conditions) when less invasive methods have failed and the patient is at high risk for obesity associated morbidity or mortality. **Grade B**

Summary

Obesity is now recognized as an important risk factor for cardiovascular morbidity and mortality. Weight reduction induced by lifestyle, pharmacologic or surgical measures has been shown to substantially improve obesity related comorbidities, perhaps with the exception of congestive heart failure. Weight loss programs should focus on weight maintenance rather than weight loss alone. Randomized controlled outcome studies with hard end points, required to establish weight loss as an effective measure that reduces cardiovascular mortality, are still lacking.

20 Postmenopausal hormone therapy and cardiovascular disease

Jacques E Rossouw

Gender and cardiovascular disease

In the United States the number of women who die annually from cardiovascular disease is higher than men. The cardiovascular disease burden is particularly high in older women. In women aged 55 and older, major cardiovascular diseases (ICD 390–448·9) accounted for 473 569 deaths in 1997 compared to 402 310 deaths in older men.[1] Major cardiovascular diseases accounted for 44% of all deaths in older women and 40% of all deaths in older men. The number of deaths from coronary heart disease (CHD) was only slightly higher in older women (229 628) than in men (223 246), but the number of deaths from stroke was considerably higher in women (88 768 compared to 55 149 respectively). There were 4607 deaths from pulmonary embolism in older women compared to 3465 in men. As exemplified by these absolute numbers of deaths, cardiovascular disease now represents a larger health problem in older women than in older men.

CHD in particular occurs at a later age in women than in men, and this is one reason why early trials (including estrogen trials) attempting to prevent "premature" CHD focused on middle-aged men. On average, death from CHD occurs about 10 years later in women (Figure 20.1) than in men. The incidence rate of CHD mortality rises after the age of 65, and rises particularly steeply after 75 years when the great majority of CHD events occur. Though their incidence rates remain lower at any age than in men, the fact that older women with CHD outnumber men explains why the absolute number of CHD deaths is higher in women. Deaths from strokes and pulmonary embolism also rise markedly with age. Since CHD and strokes are the major contributors to overall cardiovascular disease rates, the effects of estrogen on these conditions will dominate the overall cardiovascular outcome.

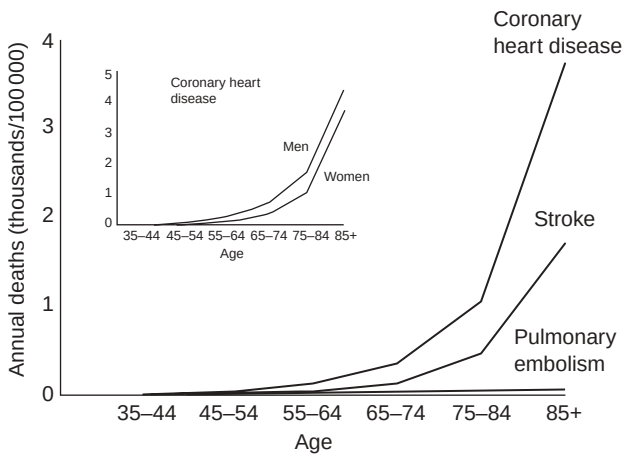

Figure 20.1 Annual mortality rates by 10 year age groups for CHD, stroke, and pulmonary embolism in US women, 1997.[1] Inset: Comparison of coronary heart disease mortality rates by age for men and women.

The sex differential in the age of onset of CHD is also one of the reasons why estrogen is of interest as a potential preventive treatment for CHD. Lipid levels in children of both sexes are similar until puberty, when high density lipoprotein (HDL) cholesterol levels fall by about 10 mg/dl in boys only, while low density lipoprotein (LDL) cholesterol levels decrease by about 5 mg/dl in girls.[2] These changes may be attributable to rising androgen and estrogen levels in boys and girls respectively. The sex differential for HDL cholesterol persists through adult life, but is less marked in older persons. LDL cholesterol levels rise during adulthood, and in older women LDL cholesterol levels eventually catch up with those in men. Estrogen levels in women gradually decline, starting some years before the menopause, during which time LDL cholesterol levels rise and HDL cholesterol levels decrease.[3] These lipid changes may underlie the lower CHD risk in premenopausal women, and the gradual increase in postmenopausal women. However, the menopause does not represent a sharp demarcation in risk; some longitudinal studies have not shown changes in risk factors over the menopause, and the rise in coronary rates may simply reflect the effects of aging itself, as suggested when the data for coronary deaths are plotted on a semi-logarithmic scale (Figure 20.2).[1,4] Nonetheless, premature menopause due to oophorectomy is associated with a higher CHD risk, and oophorectomy followed by estrogen therapy is not associated with increased risk for CHD.[5] When exogenous estrogen is administered via the oral route to postmenopausal women, LDL cholesterol levels decrease, HDL cholesterol levels increase, triglyceride levels increase, and lipoprotein (a) levels decrease.[6–10] However, exogenous oral estrogen has multiple non-lipid effects. Some changes in coagulation factors are potentially favorable (for example,

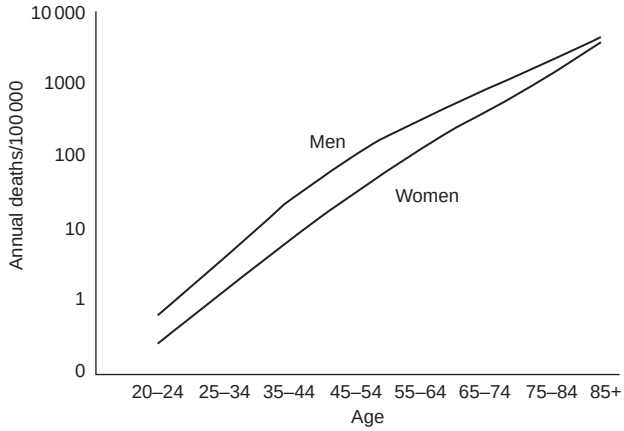

Figure 20.2 Annual mortality rates for CHD by age for US men and women on a semi-logarithmic scale

a decrease in fibrinogen level[7–9]) while others are potentially unfavorable (for example, an increase in factor VII[8,9]), and the net effect of estrogen on coagulation is uncertain. Similarly, some effects on markers of inflammation are potentially unfavorable (for example, increases in C-reactive protein) and others favorable (for example, decreases in vascular endothelial adhesion molecules).[11,12] Other potential influences of estrogen on vascular biology include direct effects on the vessel wall, which improve blood flow,[13,14] and antioxidant properties that may slow the early stages of atherosclerosis.[15] It should be noted that many, but not all, of the biologic effects of estrogen are counteracted by the progestins, which are now routinely prescribed in combination with estrogen in women with intact uterus.[7–9]

Thus, there is a plethora of potential mechanisms by which estrogen may reduce the risk of CHD.[16] Unfortunately, the existence of mechanisms does not necessarily translate into clinical benefit. A treatment that has a favorable effect on an intermediate mechanism may decrease the incidence of target clinical events, or may turn out to have no effect, or may actually increase the event rates. The treatment may also have unanticipated adverse effects on other clinical events.[17] For example, a number of early lipid lowering drugs, such as thyroxin and estrogen, were abandoned after it was found that, although these drugs decrease cholesterol levels, they also increase the cardiovascular morbidity and mortality in men.[18]

Box 20.1

- Cardiovascular disease is a major health problem in older women.
- Coronary heart disease occurs at a later age in women than in men.
- The later onset of coronary disease may be due to gender-specific hormone-induced changes in blood lipid levels.
- Increased rates of coronary heart disease after the menopause may be due to declining estrogens or may be due to aging.

Coronary heart disease

Throughout this chapter, the term postmenopausal hormone therapy (sometimes shortened to hormone therapy) is used to describe the use of estrogen or estrogen plus a progestin in postmenopausal women. The term hormone replacement therapy is not used, because this term implies a judgment that postmenopausal women suffer from a hormone "deficiency" that needs treatment.

More than 30 observational studies have suggested that women who are taking estrogen appear to have a lower risk of heart disease, and several have shown similar apparent risk reductions for estrogen when it is used in combination with progestin.[19–23] Only a few key studies will be reviewed in detail, since they illustrate sufficiently the findings from observational studies, and their limitations. "Primary prevention" studies are those in which women with prevalent coronary artery disease (CAD) were removed from the cohort, while "secondary prevention" studies followed only those women with a history or other evidence of CAD at baseline. The growing body of evidence from clinical trials with surrogate outcomes and clinical trials, with "hard" clinical outcomes for secondary prevention, will be reviewed in detail. Thus far, these secondary prevention trials have failed to confirm the cardiovascular benefit predicted from observational studies, and in fact the trials suggest that there is likely to be harm in the first few months to years after initiation of hormone therapy. Substantive data from primary prevention trials have yet to be published.

Primary prevention

Observational studies

With the exception of the initial report from Framingham on this issue, all the observational studies of healthy postmenopausal women comparing hormone users with non-users described an association of hormone use (particularly current hormone use) with lower risk for CHD.[19–24] However, as reviewed elsewhere, the consistency of these results may be due to powerful systematic biases in observational studies, which may lead to an overestimation of benefit and an underestimation of harm associated with hormone use.[25,26]

The Nurses' Health Study is representative of the observational studies, and the women in this study comprise one of the largest and best studied cohorts in the USA.[21] The 1976 baseline examination included 121 700 nurses aged 30–55 years of whom 21 726 were postmenopausal. With the passage of time a progressively larger proportion entered the menopause and these women contributed data to a series of papers on the associations between menopause, hormone therapy, and cardiovascular disease. Data on

hormone use and health status were updated biennially by questionnaire. The most recent analysis included 70 533 women with up to 20 years average follow up for a total experience of 808 825 person-years during which time the study accrued 1258 major coronary events (non-fatal myocardial infarction or coronary death).[21] There were 662 major coronary events during the 358 125 person-years of never users, 337 events during the 185 497 person-years of past users, and 259 events during the 265 203 person-years of current users of postmenopausal hormone therapy. Conjugated equine estrogen (CEE) accounted for about two thirds of the estrogen used. Proportional hazards models were used to calculate relative risks for incidence of clinical outcomes, using women who had never used hormones as the reference group. Multivariate adjustments were made for age, body mass index, history of diabetes, hypertension, high cholesterol level, cigarette smoking, and parental history of premature heart disease.

The adjusted relative risk of major coronary disease in current users compared to never users was 0·61 (95% CI 0·52–0·71), and in past users it was 0·82 (95% CI 0·72–0·94). Current users of CEE alone had a relative risk of 0·55 (95% CI 0·45–0·68), and current users of CEE with medroxyprogesterone acetate (MPA) had a relative risk of 0·55 (95% CI 0·49–0·85). Duration of hormone use appeared to have little influence; however the relative risk appeared to be lowest in current users for less than 1 year (0·41, 95% CI 0·21–0·77) (Figure 20.3). The reduced risk for CHD was observed at all estrogen doses, but appeared to be more marked at the doses of 0·3 mg conjugated equine estrogen (0·58, 95% CI 0·37–0·92) and 0·625 mg (0·54, 95% CI 0·44–0·67) than at the dose of 1·25 mg or higher (0·70, 95% CI 0·51–0·97) (Figure 20.3).

An earlier publication from the Nurses' Health Study noted that the rates of coronary revascularization did not differ between current users and non-users.[27] Since it differs from the findings for fatal and non-fatal myocardial infarction, this observation argues against an immediate beneficial effect of estrogen on the vessel wall. Most patients undergo revascularization for symptoms and, if estrogens had a direct effect, symptoms would have been less likely in users. The data as regards to revascularization have implications for the interpretation of the data for CHD events: if estrogen confers no immediate benefit, the finding of lower CHD rates in current users may be due to the compliance bias known to operate in subjects who are regularly taking medications, or to selection bias as to who goes onto estrogen and who is removed from therapy.

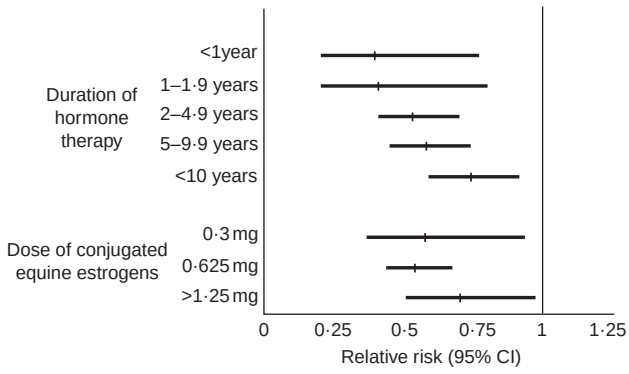

Figure 20.3 Relative risks and 95% confidence intervals for CHD by duration and dose of current hormone use in the Nurses' Health Study[21]

Data on risk for CHD in healthy women soon after initiation of estrogen therapy are sparse and inconsistent, although most studies suggest reduced initial risk in estrogen users. As noted above, the Nurses' Health Study observed the lowest relative risk during the first year of use.[21] Several other studies found little or no association of hormone use with risk in the first year or two after initiating therapy,[28–30] while two suggested some early increase in risk.[31,32] By contrast (see below) the data for secondary prevention are much more consistent in suggesting cardiovascular harm after initiation of therapy.

Clinical trials

A pooled analysis of 23 randomized controlled trials, which were done for the study of non-cardiovascular short-term effects of hormone therapy but which recorded numbers of clinical events, found twelve cardiovascular (arterial) events in the hormone groups and five in the control groups.[33] Though not statistically significant, the results were in the opposite direction to that predicted by the observational studies.

Large clinical trials of estrogen in healthy women with sufficient statistical power to provide a definitive answer to the question of benefit for cardiovascular disease are underway (Table 20.1). The first of these forms part of the Women's Health Initiative (WHI) in the USA. The WHI enrolled 27 347 women aged 50–79 in the trials of menopausal hormone therapy during 1993–1998 and will be completed in 2005 after 8·4 years average follow up.[34] The study comprises two randomized controlled clinical trials: the 16 608 women with an intact uterus randomized to CEE 0·625 mg/day plus MPA 2·5 mg/day or placebo, and the 10 739 women with a hysterectomy randomized to CEE 0·625 mg/day or placebo. No results have yet been published, but in 2000 the trial participants were advised that during the first 2 years after randomization small excesses in numbers of heart attacks, strokes, and blood clots in the lungs were observed in the active treatment groups.[35] In 2001 a follow up communication to participants stated that small absolute excesses of these conditions persisted beyond the first 2 years, but that the trials will continue because the overall risk and benefit remained uncertain.[35]

Table 20.1 Randomized controlled clinical trials for primary or secondary prevention of coronary heart disease or stroke in postmenopausal women

Trial	Population	Number	Age range	Active treatment	Primary end points	Findings
WHI (Women's Health Initiative)[34,35]	Primary prevention	27 347	50–79	CEE 0·625 mg plus MPA 2·5 mg/day, or CEE 0·625 mg/day	Non-fatal MI or CHD death	Small excess of heart attacks and strokes in first few years after randomization, planned stop in 2005
WISDOM (Women's International Study of long Duration Oestrogen after the Menopause)[36]	Primary prevention	Target 22 000 in UK, 34 000 with international collaboration	50–69	CEE 0·625 mg plus MPA 2·5 mg/day, or CEE 0·625 mg/day	Non-fatal MI, CHD death, non-fatal or fatal stroke	Results expected approx. 2010
RUTH (Raloxifene Use for The Heart)[55]	High risk primary and secondary prevention	10 101	>55	Raloxifene 60 mg/day	(1) Non-fatal MI, CHD death, or hospitalized ACS (2) Breast cancer	Results expected approx. 2005
HERS (Heart and Estrogen/progestin Replacement Study)[45]	Secondary prevention	2763	55–80	CEE 0·625 mg plus MPA 2·5 mg/day	Non-fatal MI or CHD death	No overall effect on risk for CHD; excess CHD in first year
WEST (Women's Estrogen for Stroke Trial)[53]	Secondary prevention of stroke	664	46–91	Estradiol 1 mg/day	Stroke	No overall effect on risk for stroke; excess stroke in first 6 months
PHASE (Papworth HRT and Survival Enquiry)[52]	Secondary prevention	255	?	Transdermal estradiol with or without cyclic norethisterone	Non-fatal MI, death, or hospitalized ACS	Non-significant excess of events in active treatment group, trial stopped after average 2·5 years follow up because of futility and possibility of harm
ESPRIT (oEStrogen in the Prevention of Re-infarction study)[54]	Secondary prevention	1017	50–69	Estradiol valerate 2 mg/day	Non-fatal MI or CHD death	Results expected in 2002

Abbreviations: ACS, acute coronary syndromes; CEE, conjugated equine estrogens; CHD, coronary heart disease; MI, myocardial infarction; MPA, medroxyprogesterone acetate

A second large trial being conducted in the United Kingdom and New Zealand, known as the Women's Intervention Study of long-Duration Oestrogen after the Menopause (WISDOM), is enrolling women aged 50–64 and randomizing women with a uterus to CEE 0·625 mg/day plus MPA 2·5 mg/day or placebo, and women who have had a hysterectomy to CEE 0·625 mg/day, CEE 0·635 mg/day plus MPA 2·5 mg/day, or placebo.[36] Up to 34 000 women will be enrolled. The primary analysis will compare CEE plus MPA to placebo, and the secondary analysis will compare CEE plus MPA to CEE alone. The primary outcome of interest is combined CHD and stroke.

Box 20.2

- The effect of postmenopausal hormone therapy on risk for CHD in healthy women remains unknown.
- Observational studies suggest potential benefit for CHD in long-term hormone users, but these studies can be biased towards benefit.
- Pooled data from short-term clinical trials suggest possible cardiovascular harm.
- One major clinical trial in healthy women has informed participants of a small excess of CHD in the hormone groups during the first few years of the study, but has not published the results.

Secondary prevention

Observational studies

Observational studies in women undergoing angioplasty or coronary artery bypass grafting (CABG) have found that use of postmenopausal hormone therapy was associated with lower rates of cardiovascular events and improved survival.[37–40] A retrospective analysis of postmenopausal women undergoing angioplasty found that 12% of patients taking hormones had cardiovascular events over 7 years of follow up, compared to 35% of non-users.[37] A second similar study found that inhospital and 2 year mortality after angioplasty was lower in hormone users.[38] In women undergoing CABG, one study found that hormone use was associated with a 62% survival benefit; however, this was not confirmed in a subsequent study.[39,40] Several observational studies have compared the experience of women currently on hormone therapy and who suffer a myocardial infarction with those who were not on hormone therapy at the time of the myocardial infarction.[41–44] These studies have consistently found better outcomes for women who were currently on hormone therapy at the time of the event.

The largest study of inhospital mortality was performed prospectively in 114 724 women aged over 55 who were entered into the National Registry of Myocardial Infarction-3.[41] At the time of hospitalization, 6·4% of women reported current use of hormone therapy. There were significant differences between hormone users and non-users. Hormone users were younger, more likely to be white, less likely to have a history of diabetes, heart failure, prior myocardial infarction, and prior stroke compared to non-users, but were more likely to have high blood cholesterol and family history of CAD, or to smoke. Hormone users were also more likely to receive aggressive inhospital care including angiography, angioplasty, bypass grafting, reperfusion therapy, aspirin, heparin, β blockers, and nitrates (Table 20.2). Complication rates were similar in users and non-users; however, after adjustment for the potential confounders, hormone use was associated with a reduced odds of inhospital mortality (0·65, 95% CI 0·59–0·72). The association was strongest in the youngest group of women (age 55–64 years). The authors acknowledge that some or all of this apparent survival benefit could be due to one or more sources of bias – for example, residual differences between users and non-users or the healthier profile that decreased mortality may also have increased the likelihood of taking hormone therapy; or the hormone users may have received care at hospitals with greater experience of myocardial infarction care; or hormone users may have been better at compliance with treatment and may thus have an improved survival. The many differences in patient characteristics and inhospital treatment observed between hormone users and non-users illustrate the difficulties of interpretation of observational studies.

Three observational studies have suggested that recent initiation of hormones after the index myocardial infarction

Table 20.2 Observational study of inhospital treatment of postmenopausal women with myocardial infarction and adverse events by prior usage of hormone therapy[41]

	Hormone replacement therapy

Heart failure	19	28
Recurrent ischemia	14	10
Recurrent myocardial infarction	2	2
Stroke	2	2
Death	7	16

is associated with an increased risk for recurrent events in the short term; two of these studies provided data suggesting a possible decreased risk in later years among the survivors (Table 20.3).[42–44] This pattern of increased risk in the first year with apparently reduced risk in later years is similar to that observed in several randomized controlled clinical trials, notably the Heart and Estrogen/progestin Replacement Study (HERS).[45] It should be noted that these analyses of risk by recency of hormone use were performed after publication of the HERS results; therefore the possibility of publication bias cannot be excluded.

Clinical trials with surrogate outcomes

The primary outcome of the Estrogen Replacement and Atherosclerosis (ERA) trial was change in the angiographic minimal diameter of coronary artery lesions.[46] Women ($n = 309$) with angiographically defined CAD were randomized to one of three groups: CEE 0·625 mg, CEE 0·625 mg plus MPA 2.5 mg, or placebo. At the end of the trial, compliance ranged from 74% in the estrogen-only group to 84–86% in the other groups. Over the mean treatment duration of 3·2 years, all three groups showed a decrease in minimal coronary artery diameter and there were no differences between the groups. In other words, treatment with estrogen with or without MPA failed to arrest the progression of existing coronary artery lesions, even though the estrogen and estrogen plus MPA treatments lowered LDL cholesterol by 9·4 and 16·5%, and raised HDL cholesterol levels by 18·8 and 14·2%, respectively. Several additional clinical trials with angiographic outcomes are underway.

Clinical trials

A randomized controlled clinical trial in 293 postmenopausal women with unstable angina, aged 43–93, failed to demonstrate benefit with estrogen or estrogen plus progestin for reduction in number of ischemic episodes.[47] The premise of the trial was that endothelial dysfunction with subsequent impairment of coronary blood flow has an important pathophysiologic role in acute coronary syndromes, and that reversal of the endothelial dysfunction by estrogen would improve the clinical outcome. Participants received one of three study treatments within 24 hours of the onset of symptoms: an infusion of 1·25 mg of CEE followed by oral CEE 1·25 mg/day for 21 days, or an infusion of CEE followed by oral CEE plus MPA 2·5 mg/day, or an infusion of placebo followed by oral placebo. The trial was

Table 20.3 Risk of recurrent coronary events in relation to recent initiation of hormone therapy in observational studies of women with prior coronary heart disease

Author	Type of study	Risk for recurrent coronary events by interval since starting hormone therapy[a]		Comment
		Short-term	Long-term	
Grodstein[42]	Cohort of 2489 female nurses with prior myocardial infarction or documented atherosclerosis	1·25 (0·78–2·00%) for use <1 year[b]	0·38 (0·22–0·66%) for use >2 years	$P = 0·002$ for trend, main analysis; replicates HERS and includes women who commenced hormones before initial event
		2·10 (0·88–5·10%) for use <1 year[b]	0·50 (0·32–0·77%) for use >2 years	$P = 0·02$ for trend, alternative analysis; short-term use largely reflects women who commenced hormones after initial event
Heckbert[43]	Cohort of 981 women hospitalized for acute myocardial infarction	2·16 (0·94–4·95%) for use 0–60 days[b]	0·76 (0·42–1·36%) for use >1 year	$P = 0·05$ for trend
Alexander[44]	Cohort of 1857 postmenopausal women enrolled in trial of coumadin and aspirin within 3–21 days of acute myocardial infarction	1·44 (1·05–1·99%) over median of 15 months[c]	No data	Increased risk for composite primary outcome exclusively due to unstable angina; no increase in risk among prior/current users

[a] Current hormone users compared to never users.
[b] Acute myocardial infarction or coronary death.
[c] Death/acute myocardial infarction/unstable angina.

stopped short of its planned enrollment of 351 when the Data and Safety Board determined that there was no difference between treatment groups. During the first 48 hours the mean number of ischemic episodes per patient recorded by ambulatory ECG monitoring was 0·74, 0·86, and 0·74 in the estrogen, estrogen plus progestin, and placebo groups respectively, and symptomatic ischemia occurred in 39%, 52%, and 42%. Inhospital incidence of refractory ischemia, death, myocardial infarction, and revascularization procedures were similar in the three groups (Table 20.4). The groups did not differ at 21 days for ischemia, or at 6 months for clinical events. The authors cite several possible reasons for the failure of the estrogen therapy to improve ischemia: lack of functional estrogen receptors in advanced lesions or with age, countervailing adverse effects of estrogen on thrombosis or inflammation, and the fact that participants almost uniformly received standard anti-ischemia therapy (including heparin, aspirin, β blockers, and nitroglycerin). The numbers of ischemic episodes were also lower than anticipated in the power calculations. From this study it would appear that acute estrogen therapy is not a useful addition to the standard therapy for acute coronary syndromes.

HERS is a landmark study, as it represents the first substantive test of the hypothesis that hormone therapy prevents coronary events in women with existing disease (Table 20.1).[45] The 2763 postmenopausal women aged 44–79 who enrolled all had established CAD and had not had a hysterectomy. They were randomized to CEE 0·625 mg/day plus MPA 2·5 mg/day or to placebo. The hormones induced the expected lipid changes, reducing LDL cholesterol by 11%, raising HDL cholesterol by 10%, and raising triglycerides by 8% compared to placebo. Over the average study duration of 4·1 years there was no net benefit for the principal outcome of CHD (non-fatal myocardial infarction plus coronary death) with 172 cases in the placebo group and 176 cases in the active treatment group.

However, in the first year of HERS there was a nominally significant ($P < 0{\cdot}05$) 52% excess of coronary events in the treatment group compared to the placebo group (Figure 20.4). In the second year there was no difference in event rates and thereafter there was a trend towards a reduction in the active treatment group, mainly due to a reduction in non-fatal myocardial infarction. The trend for coronary heart disease risk over time was significant ($P = 0{\cdot}009$). However, it should be noted that the significance of the trend depended on the adverse direction of events in the first year, and that events after the first year were recorded in survivors of the first year (that is, after the first year the arms were no longer balanced). There was no benefit for any other cardiovascular outcome, including angina or revascularization procedures. Other important findings were a significant increase in venous thromboembolism and a marginally significant increase in gallbladder disease (84 in hormone

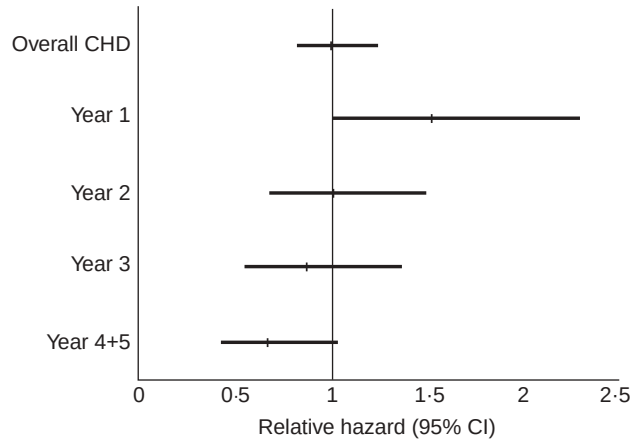

Figure 20.4 Relative hazard and 95% confidence intervals for CHD in HERS over the entire trial duration and by year since randomization[45]

Death	5	5	3

Abbreviation: MPA, medroxyprogesterone acetate

group and 62 in the placebo group, $P = 0{\cdot}05$). There was no reduction in fractures (130 compared to 138).

Thus, HERS provided some results for hormone therapy that were expected (increased risk for venous thromboembolism and gallbladder disease) and some that were unexpected (no overall reduction in CHD, and no reduction in fractures). The trend over time for coronary disease was also unexpected, and in fact the investigators anticipated that the immediate effects of estrogen – for example, on fibrinolysis and vascular reactivity – might have led to early benefit, sustained in later years by beneficial changes in plasma lipid concentrations. The observed early adverse effect needs to be explained: possibilities include that hormone therapy induces inflammatory changes in unstable plaques, or that a procoagulant effect predominates early on. There is no doubt that menopausal hormone therapy is procoagulant, as shown by the excess of venous thromboembolism. The findings may be explained by the existence of a subset of women who are particularly susceptible to one or more of the adverse metabolic or local tissue changes induced by hormone therapy, and that the remaining women who did not have an early event reap the later benefit of lipid lowering. Alternatively, there may be no real benefit, and the apparent later benefit may simply reflect a survivor effect in that women most susceptible to an adverse effect of the treatment have been removed from the cohort. A post-hoc analysis of HERS data indicated that women with higher lipoprotein (a) levels were less likely to have an initial adverse outcome, and were more likely to benefit in later years, presumably because some of the adverse effects of the hormones were counteracted by a reduction in high lipoprotein (a) levels.[10]

One possible explanation for the HERS findings is that MPA negated any possible benefit from estrogen, for example by blocking the direct vascular effects of estrogen and blunting the rise in HDL cholesterol induced by estrogen. (However, it is noted that HDL cholesterol levels in fact increased by 10%.) Another explanation might be that many participants were receiving medications that would lower risk for recurrent coronary events (for example, aspirin, β blockers, lipid lowering medications, and to a lesser extent angiotensin-converting enzyme [ACE] inhibitors), thus masking any potential for benefit from estrogen. This seems unlikely, but even if true the trial still demonstrates that hormone therapy is not a useful adjunct to established secondary prevention treatments. Other possible explanations offered are that the women in HERS were too old and their arteries too diseased to benefit from hormone therapy, or that the type and dose of hormones was not optimal.[48–50] These explanations ignore the fact that the observational studies suggesting benefit and which prompted the need for HERS were conducted in populations similar to that studied in HERS, and the hormones were the same as those tested in HERS.

Though unexpected and controversial, the pattern of early harm observed in HERS has found support in two other secondary prevention trials for coronary disease and one for stroke (and as noted above, in the WHI primary prevention trial, a pooled analysis of short-term studies, and in several observational studies).[35,42–44,51–53] Stimulated by the HERS findings, a re-analysis of data from an earlier trial of CEE 2·5 mg/day in men with existing heart disease revealed a pattern of no overall benefit but with increased risk for CHD in the first 4 months after randomization (relative hazard 1·58, 95% CI 1·04–2·40) similar to that found in HERS for the same period (2·29, 95% CI 0·94–5·56).[51] A trial of transdermal estradiol (with cyclic norethisterone for women with a uterus) was stopped after an average of 2·5 years follow up for reasons of futility and possible harm (Table 20.1).[52] At the time of stopping this trial, 255 women with angiographically defined CAD had been enrolled and only 61% of women were still on estrogen. Though clearly underpowered, with short follow up, and reported only in abstract form, the results were nonetheless consistent with HERS in that there was a 23% ($P = 0{\cdot}3$) excess of unstable angina, myocardial infarction, and death. Finally, the Women's Estrogen for Stroke Trial (WEST) in women with a recent stroke found that oral estradiol did not prevent recurrent strokes overall, and compared to placebo there was a higher risk for fatal strokes, and a higher risk for all strokes in the first 6 months.[53] The combined data from these clinical trials leave little room for doubt that, at least in women with existing arterial disease (coronary or cerebrovascular), estrogen use for up to 4 years is unlikely to result in benefit, and in the first few months to a year is associated with an increased risk for arterial complications.

One other trial testing estradiol valerate versus placebo in 1017 women with CHD is due to report results soon.[54] A secondary analysis of safety data from a trial of raloxifene (a selective estrogen receptor modulator) in 7705 women with osteoporosis showed no benefit for cardiovascular outcomes over 4 years of treatment, but suggested a risk reduction of 40% (95% CI 5–62) in a subset of 1035 women with increased cardiovascular risk at baseline.[55] A randomized controlled clinical trial of raloxifene (a selective estrogen receptor modulator) versus placebo is underway in several countries in order to test whether raloxifene reduces the risk for CHD and breast cancer in women with existing heart disease or who are at high risk for heart disease.[56] This trial has enrolled 10 101 women and the study is planned to end after 1670 participants have experienced a coronary event (expected in 2005).

Box 20.3

- Postmenopausal hormone therapy does not benefit women with existing heart disease, and initiation of hormone therapy after a coronary event may increase risk in the short term.
- Observational studies of women with heart disease suggest reduced risk for coronary disease in long-term hormone users.

Box 20.3 continued

- Several observational studies suggest increased risk for recurrent coronary disease during the first year in women who initiate hormone therapy after a coronary event.
- In a randomized controlled trial, conjugated equine estrogens and conjugated equine estrogens with MPA failed to slow progression of coronary disease on angiography.
- Acute postmenopausal hormone therapy did not reduce the rate of recurrent ischemia in women with unstable angina.
- Two randomized controlled trials with clinical outcomes failed to show benefit for postmenopausal hormones, and provide evidence for an increased initial risk.
- The apparent reduction in risk after the first 2 years observed in one of these trials is subject to a variety of interpretations, including real long-term benefit or a survivor effect only.

Abbreviation: MPA, medroxyprogesterone acetate

Cerebrovascular disease

Primary prevention

Because stroke may be fatal, and often leaves the survivors cognitively and functionally impaired, primary prevention is of the greatest importance.

Observational studies

As reviewed elsewhere, the data for stroke are less consistent than those for CHD.[57] Five case–control studies of risk for incidence of all stroke or ischemic stroke reported essentially null results, and six of 16 internally controlled cohort studies reported a significant reduction in risk while two reported significantly increased risk among hormone users. Data on stroke subtypes are scanty and variable. Among current users in five cohort studies, three studies found essentially no effect on ischemic stroke while one each found an increased risk and the other a decreased risk. Similarly, the data on duration and type of hormone therapy (estrogen alone or combined with progestin) are variable. Data for thromboembolic, intracerebral hemorrhage, and subarachnoid hemorrhage stroke subtypes are very scanty.

A meta-analysis of stroke studies suggested that, in aggregate, estrogen users had the same risk for all incident strokes as non-users; however, this meta-analysis antedated the most recent data from the large Nurses' Health Study.[19] Examination of the 20 year follow up data from the Nurses' Health Study is not entirely reassuring.[27] The relative risk for all strokes (767 strokes during 808 825 person-years) in current hormone users compared to never users was 1·13 (95% CI 0·94–1·35), but for ischemic strokes (432 cases) the relative risk was somewhat higher (1·26, 95% CI 1·00–1·61). Furthermore, for all strokes and for ischemic strokes there was a significant increase in relative risk at the usual dose of 0·625 mg, with a further increase at the higher dose of 1·25 mg or greater (Figure 20.5). For example, at the most commonly used dose of 0·625 mg/day the relative risk for all stroke was 1·35 (95% CI 1·08–1·68) and for ischemic stroke it was 1·44 (95% CI 1·07–1·93). The association of stroke with hormone use was stronger in women who used estrogen combined with progestin (1·45, 95% CI 1·10–1·92) than in women who used estrogen alone (1·18, 95% CI 0·95–1·46). There was no excess of strokes in past users. Unlike in CHD, duration of hormone therapy did not appear to influence the risk for stroke (Figure 20.5).

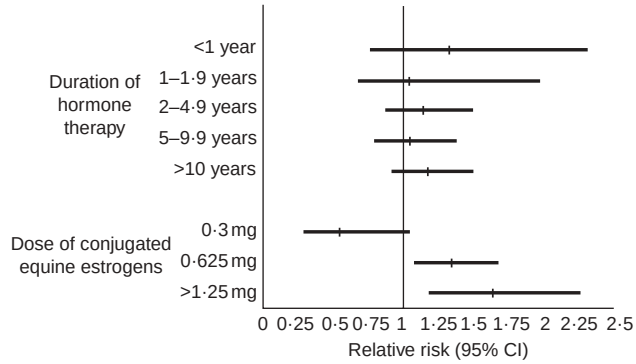

Figure 20.5 Relative risks and 95% confidence intervals for stroke by duration and dose of current hormone use in the Nurses' Health Study[21]

Data for fatal stroke are somewhat more consistent across studies in suggesting an association with reduced risk in current users. Of nine internally controlled cohort studies, there was a significantly reduced risk in three, and with one exception the point estimates for the remaining six studies were below unity.[56]

Clinical trials with surrogate outcomes

A randomized placebo-controlled trial of oral estradiol in 202 (199 with evaluable outcomes) healthy postmenopausal women aged 46–80 years found that the rate of progression of carotid intima media thickness (IMT) over 2 years was lower in those taking unopposed estradiol than in those on placebo ($P = 0·046$).[58] Adherence to study medications was very good (95% in estradiol group and 92% in placebo group). Per protocol, 122 participants received lipid lowering medications (primarily statins) because their LDL cholesterol values exceeded 160 mg/dl. The numbers were similar in the estradiol and placebo groups. The participants in the estradiol group who received lipid lowering medications lowered their LDL cholesterol levels by 20%, compared to 15·1% change in the placebo group ($P = 0·02$), and both estradiol and placebo groups experienced some regression of intima media thickness. In the 77 participants who did not receive lipid-lowering therapy, estradiol lowered LDL cholesterol by 10·5% compared to 1·1% in the placebo

group ($P = 0{\cdot}001$), and in this subgroup the estradiol group but not the placebo group showed regression ($P = 0{\cdot}002$ for difference). The authors conclude that reduction in the progression of subclinical carotid atherosclerosis was seen in women who did not take lipid lowering medication but not in those who took these medications. From these results, it would appear that estrogens would not augment the known benefits of statins for inhibiting atherosclerosis.

Clinical trials

WHI is the only clinical trial of healthy women that has provided any indication of the effect of hormone therapy on strokes. As noted above, study participants have been informed of a small absolute increase in the number of strokes in the hormone groups compared to the placebo groups during the first few years of the trial.[35] Stroke is also a predefined outcome of interest in the WISDOM trial.[36]

Box 20.4

- The effect of postmenopausal hormone therapy on stroke in healthy women remains unknown.
- Observational studies provide mixed results for strokes, but several suggest no effect on stroke incidence but some reduction in stroke mortality.
- The Nurses' Health Study suggested an increased risk for ischemic stroke, and an increased risk for all strokes at higher doses of estrogen or if estrogen was combined with progestin.
- One randomized trial of estradiol showed less increase in carotid intima media thickness in the subset of women who did not receive statin therapy.
- One major clinical trial in healthy women has informed participants of a small excess of strokes in the hormone groups during the first few years of the study, but has not published the results.

Secondary prevention

Clinical trials with surrogate outcomes

A randomized trial of oral estradiol 1 mg with standard dose progestin (gestodene 0·025 mg 12 days every month), or estradiol with low-dose progestin (gestodene 0·025 mg 12 days every third month), or placebo for 4 years in 321 women aged 40–70 at high risk for cardiovascular disease (that is, carotid IMT >1 mm) failed to show any benefit for reducing the rate of progression of subclinical atherosclerosis in the carotid arteries.[59] Exclusion of the small number of subjects (14%) who received lipid lowering therapy did not alter these results. LDL cholesterol decreased by 13% in the active treatment groups and fibrinogen by 20%. Adherence was good with only 12–20% of participants discontinuing study medications; compliance was 98% in the remaining participants. Reasons for the difference in outcome of this study with the study of Hodis *et al*[58] are not known. It is possible that the addition of a progestin to the estradiol may have negated the effects of estradiol, but the fact that the results in the standard and low-dose gestodene groups did not differ argues against that possibility. Though this study is regarded as secondary prevention, the distinction is somewhat artificial and is based on the entry level of carotid IMT.

Clinical trials

Where HERS examined the effect of hormone therapy on recurrent coronary disease, WEST is its counterpart for recurrent stroke.[53] There are important parallels between the two trials, and also a few differences. WEST randomized 664 women aged 46–91 who had suffered a transient ischemic attack or stroke in the previous 90 days to receive oral estradiol 1 mg or placebo and followed them for an average of 2·8 years. By the end of the trial 34% had stopped estradiol and 24% had stopped placebo. Compared to placebo, estradiol had no effect on the primary outcome of combined non-fatal stroke and all-cause mortality, or on non-fatal stroke or death individually (Table 20.5). However, estradiol increased the risk for fatal stroke (relative risk 2·9, 95% CI 0·9–9·0) and the non-fatal strokes in the estradiol group were associated with more functional and neurologic deficits. A post-hoc analysis of strokes by time since randomization indicated that during the first 6 months, there were three fatal strokes and eighteen non-fatal strokes in the estradiol group, compared to one fatal and eight non-fatal strokes in the placebo group (relative risk for any stroke 2·3, 95% CI 1·1–5·0). There were no differences in the rates of transient ischemic attacks or myocardial infarction.

Table 20.5 Selected outcomes according to treatment assignment in the WEST[53]

Outcome	Estradiol group ($n = 337$)	Placebo group ($n = 327$)	Relative hazard (95% CI)
Death or non-fatal stroke	99	98	1·1 (0·8–1·4)
Death	48	41	1·2 (0·8–1·8)
fatal stroke	12	4	2·9 (0·9–9·0)
CHD	11	13	0·8 (0·4–1·9)
Non-fatal stroke	51	52	1·0 (0·7–1·4)
Non-fatal myocardial infarction	14	12	1·2 (0·5–2·5)

HERS has published a more complete analysis of the stroke data, which indicated that there was no significant effect of hormone therapy on any category of stroke (fatal, non-fatal, ischemic, hemorrhagic, any stroke, transient ischemic attack).[60] However, the point estimate was above

unity for each category except transient ischemic attack (0·90, 95% CI 0·57–1·42), and the highest relative risk was for fatal stroke (1·61, 95% CI 0·73–3·55). The trend towards an excess of more severe strokes in the hormone group is similar to that observed in WEST.

Box 20.5

- Postmenopausal hormone therapy has no effect on the overall risk for strokes in women with existing cerebrovascular disease or with existing CHD.
- Observational studies suggest no effect of postmenopausal hormone therapy on stroke incidence but a possibly reduced risk for fatal strokes.
- Estradiol failed to reduce progression of carotid intima media thickness in a randomized controlled trial.
- A randomized controlled trial of estradiol in women who had recently suffered a stroke failed to show benefit for recurrent strokes, but strokes in the active treatment group tended to be more severe and there was increased risk for strokes in the first 4 months after randomization.
- A secondary prevention trial of women with CAD did not show benefit for strokes, and fatal strokes were non-significantly higher in the active treatment group.

Venous thromboembolism

Observational studies

Early observational studies did not suggest an increased risk for venous thromboembolism (deep vein thrombosis or pulmonary embolism) in postmenopausal hormone users; however, as reviewed elsewhere, several more recent studies have found a two- to fourfold increased risk in hormone users.[61] The studies are consistent in showing an increased relative risk for current but not past use of hormones. Recent onset of current use conferred higher risk than long duration of use, consistent with an immediate effect on coagulation factors. Some but not all studies reported a dose-response relationship. Estrogen alone, as well as estrogen with progestin, appeared to be associated with higher risk. Though transdermal estradiol causes less perturbation of coagulation proteins than oral estrogen, one study suggested that the risk for venous thromboembolism was present for this formulation also.

Clinical trials

Venous thromboembolism is usually recorded as an adverse effect in clinical trials of hormone therapy. A pooled analysis of short-term trials found five thromboembolic events in the hormone groups and one in the control groups.[33] HERS found a significant, almost threefold increase in the risk for venous thromboembolism (34 in the hormone group and 13 in the placebo group, relative hazard 2·7, 95% CI 1·4–5·0, $P = 0·003$).[62] The trend towards higher excess risk in the first few years was not significant, and some excess persisted over the duration of the study. These findings on an adverse event from a clinical trial are very similar to those from the observational studies. In exploratory analyses, other risk factors for venous thromboembolism included older age at menopause, lower extremity fractures, cancer, being within 90 days of inpatient surgery, or non-surgical hospitalization. After non-fatal MI the risk was increased for 90 days. Use of statins or aspirin appeared to decrease risk; it should be noted, however, that these were non-randomized comparisons and that the large number of comparisons performed may have led to chance findings. The WEST study investigators stated that there were no differences in venous thromboembolism between treatment groups.[53] As noted above, healthy women in the WHI have been informed of an excess risk during the first few years of the study.[35] Some trials with intermediate or surrogate outcomes (for example, the Postmenopausal Estrogen-Progestin Interventions and ERA) have also noted small numbers of venous events, with more events in the active treatment groups than the placebo groups, although numbers were too small for statistical testing.[7,46]

One randomized controlled trial, initiated before it was known that estrogen increases risk for venous thromboembolism, strongly suggested that hormone therapy increases the risk for recurrent events.[63] Women with prior venous thromboembolism ($n = 140$) received either oral estradiol 2 mg and norethisterone acetate 1 mg or placebo for 2 years. Though predefined stopping boundaries had not been crossed, the trial was stopped prematurely because of the emergence of data from observational studies and clinical trials, and the clustering of end points (recurrent venous thromboembolism) in one treatment group. There were eight events in the active treatment group (10·7%) and one in the placebo group (2·3%) indicating a 4·6-fold increase in the hormone group. All of the recurrent events in the active treatment group occurred during the 9 months, while the single event in the placebo group occurred at 14 months. Five of the eight cases with recurrent events in the hormone group also had familial thrombophilia (three with factor V Leiden, two with anticardiolipin antibodies).

Box 20.6

- Postmenopausal hormone therapy increases the risk for venous thromboembolism two- to fourfold.
- The risk is increased more markedly in the first few months to years after initiation, but persists for up to 4 years.
- Several observational studies have shown an association of hormone therapy with risk for venous thromboembolism.
- A pooled analysis of short-term clinical trials suggested an increased risk for venous thromboembolism, but numbers were small.
- One major clinical trial in healthy women has informed participants of a small excess of venous thromboembolism in the hormone groups during the first few years of the study, but has not published the results.

contd

- A large trial for the secondary prevention of coronary heart disease showed an increased risk for venous thromboembolism.
- A randomized trial in women with prior venous thromboembolism strongly suggested that hormone therapy increases the risk for recurrent events, particularly in women with familial thrombophilia.

Treatment recommendations

Based on current evidence, postmenopausal hormone therapy is not recommended for prevention or treatment of CHD or stroke.[64] For primary prevention, the American Heart Association (AHA) states that firm recommendations should await the results of ongoing randomized clinical trials, and that there are currently insufficient data to suggest that hormone therapy should be initiated for the sole purpose of primary prevention of cardiovascular disease.[64] The AHA makes a stronger statement that hormone therapy should not be initiated for the secondary prevention of cardiovascular disease; however women on hormone therapy for several years do not necessarily have to stop since they have presumably passed through the period of initial increased risk. Women with a prior history of venous thromboembolism should be counseled against using hormone therapy.[62]

Because the trials have failed to show benefit for secondary prevention, and there are no published trial data for primary prevention, in both instances decisions about hormone therapy should be based on established non-cardiovascular risks and benefits.[64] The major proven benefits of estrogen are relief of the symptoms accompanying the menopause, urogenital atrophy, and prevention of osteoporosis. Known risks include endometrial cancer, venous thromboembolism, pancreatitis (in women with high blood triglycerides), and gallbladder disease. At the average age of menopause, the risk for cardiovascular and non-cardiovascular disease conditions is low, and therefore, the short-term use of estrogens to manage the menopause is not at issue.[65]

However, long-term use (5 years or more) of hormone therapy is more problematic, given the possible increase in breast cancer associated with prolonged use.[65] Calculations show that in older women and with prolonged use, the potential risks for breast cancer, stroke, and venous thromboembolism, may outweigh the potential benefit for reduction in fractures if the treatment does not reduce risk for CHD.[66] Since CHD and stroke are by far the most common causes of disease and death in older women, the clinical trial data on the long-term effects of hormone therapy on cardiovascular disease will provide the key information on whether long-term estrogen should be prescribed for any indication in older women. If these trials show that long-term use confers cardiovascular benefit (and if methods are found to screen out women at high initial risk for cardiovascular complications), then hormone therapy may in future play a more prominent role as a viable prevention strategy.

However, until these clinical trial data are known, it may be wise to consider alternatives to hormone therapy even for proven indications such as prevention of osteoporosis.[65] For osteoporosis prevention, exercise, diet, calcium, and vitamin D may be recommended, and for treatment the bisphosphonates and raloxifene have been shown to prevent fractures. Lifestyle measures and medical management of risk factors such as high blood cholesterol and high blood pressure will prevent many cases of CHD and stroke, and for secondary prevention of CHD aspirin, statins, β blockers, and ACE inhibitors have all been found to be effective.[64] The AHA statement acknowledges that the current recommendations are based mainly on data from trials using standard doses of conjugated equine estrogens and medroxyprogesterone, and that evidence is insufficient for different preparations, routes of delivery, and doses that may have a more favorable or more adverse effect on cardiovascular outcomes.

Box 20·7

- Postmenopausal hormone therapy is not recommended for primary prevention of CHD, because the observational studies may have overestimated benefit, and there are no substantial clinical trial data. **Grade B**
- If there is no benefit from reductions in CHD, the potential harm from breast cancer, endometrial cancer, venous thromboembolism, gallbladder disease, and pancreatitis may exceed the benefit from reduced fracture risk. **Grade B**
- Postmenopausal hormone therapy is not recommended for secondary prevention because trials have not shown benefit for CHD or stroke, and observational studies and trials suggest cardiovascular harm in the first few months to 1 year after initiation. **Grade A**
- Until and unless the currently ongoing clinical trials provide evidence to the contrary, the focus of CHD prevention efforts should be on proven effective and safe measures. **Grade A**
- Reasons for early coronary harm need to be identified with a view towards screening out a subset of women at high risk.
- Clinical trials of different hormone regimens (dose, formulation, route of administration) are needed.
- Women with prior venous thromboembolism should be counseled against using hormones. **Grade A**

Addendum

On July 9, 2002, the National Heart, Lung, and Blood Institute announced that the WHI trial[67] of estrogen plus progestin versus placebo in 16 608 healthy women with an intact uterus had been stopped early, after an average of

5·2 years of follow up rather than the planned 8·5 years. The reasons for stopping were that an increased risk for breast cancer started emerging at 4 years, which by 5 years had crossed the prespecified monitoring boundary. In addition, there was evidence of overall harm. At the time of stopping, the hazard ratios (HR) for the major adverse effects were: breast cancer 1·26 (95% CI 1·00–1·59), CHD 1·29 (95% CI 1·02–1·63), stroke 1·41 (95% CI 1·07–1·85), and pulmonary embolism 2·13 (95% CI 1·39–3·25). There were benefits for colorectal cancer, HR 0·63 (95% CI 0·43–0·93), and for hip fracture, HR 0·66 (95% CI 0·45–0·98), while endometrial cancer and all-cause mortality were not affected. The investigators conclude that the risk-benefit profile found in this trial is not consistent with the requirements for a viable prevention treatment, and in particular that this regimen should not be initiated or continued for the primary prevention of CHD. In addition, the substantial risks for cardiovascular disease and breast cancer must be weighed against the benefit for fracture in selecting from the available agents for osteoporosis. WHI has answered the question of whether combined estrogen plus progestin, given by mouth for several years, prevents cardiovascular disease: it does not, and it does in fact increase the risk. However, as stated by the investigators, the use for a few years (less than 4 years) to treat the symptoms of menopause may be reasonable, since the benefits may outweigh the small absolute risk of cardiovascular disease in younger women. Of importance, the WHI trial of estrogen only in women who have had a hysterectomy is continuing, because the overall balance of benefits and risks remains uncertain.

21 Ethnicity and cardiovascular disease

Sonia S Anand, Stephanie Ounpuu, Salim Yusuf

Introduction

The major risk factors for cardiovascular disease (CVD), which include elevated blood pressure, elevated cholesterol, cigarette smoking, and diabetes, have been derived from epidemiologic studies conducted primarily in white populations.[1] Globally, non-white populations constitute the majority of the world's population, although the most influential risk factors for CVD in these populations remain unconfirmed. Ethnicity-related research provides important epidemiologic information that documents the rates of known risk factors for a disease, identifies new risk factors, provides us with clues regarding similarities and differences in disease causation, and allows us to define high-risk populations for specific diseases.[2] Further, knowledge of variations in response to preventive strategies, medical therapies, and healthcare utilization patterns can lead to specific prevention strategies that are appropriately tailored to culturally diverse groups. Therefore, studies that explore reasons for the differences in CVD rates among ethnic populations are of major public health importance.

General issues

Defining ethnic groups

The concept of race was based on the belief that members of a race were homogeneous with respect to biological inheritance.[3] However, over the past 20 years, as our ability to unravel the genetic code has increased, there is little evidence to support the contention that the historical "racial" divisions represent differences in genetic make-up.[3,4]

Ethnicity on the other hand is used to describe a group of people whose lifestyles are characterized by distinctive social and cultural traditions which are maintained within the group and passed on from generation to generation. Therefore ethnicity has both sociocultural and biological components.[5] Given that variations in disease rates between populations may be explained by socioeconomic, sociocultural, biologic, and genetic factors, classification by ethnic origin rather than race is desirable.[6]

Interpretation of studies in ethnic populations

The methodologic limitations of studies of ethnic populations must be recognized.[7] Mortality statistics often provide the first clues of differences in CVD rates between ethnic groups. Most developed countries have methods to collect reliable mortality statistics, although this system is not as well developed among poor nations.[8] In developing countries, where mortality statistics are not available, conclusions about disease rates are usually based upon data from sample registration systems, community surveys, and hospital admissions.

Worldwide patterns of disease

Globally, 58·8% of the total global morality is attributable to non-communicable diseases such as cardiovascular disease (CVD), cancer, and diabetes.[9] CVD accounted for approximately 30·9% of all deaths in 1998, as well as 10·3% of the total disease-related burden.[10] Approximately 78% of global CVD mortality, and 86% of the global CVD morbidity is experienced in the low and middle income countries.[9–11]

In most developed countries CVD rates are declining due to primary prevention of CVD risk factors, and improved secondary prevention strategies.[12] However, in developing countries an epidemiologic transition from acute infectious diseases to a rise in the major non-communicable diseases is occurring. Reasons for this include increasing life expectancy associated with a decline in childhood and adult deaths from infections, and an increase in the prevalence of CVD risk factors associated with industrialization and urbanization.[13]

Population differences in the CVD mortality rates are influenced by geographical and environmental differences. Ethnic variations in disease rates are closely tied to geographical patterns of disease.[14] Often the first clue that ethnic variations in disease burden exist comes from observations made between countries. These geographical differences have provided many of the initial hypotheses of the association between lifestyle factors and CVD. One of the first epidemiologic studies to highlight the variation in coronary heart disease (CHD) rates between countries was the Seven Countries Study.[15] In this major longitudinal cohort study, 16 cohorts of men aged 49–59 years were examined and followed for CHD mortality and total mortality. Large differences in CHD mortality between countries were observed, with low CHD rates in Japan and the Mediterranean countries, and high CHD rates in Finland and the USA. These differences were in large part explained

Table 21.1 Inter-country CVD mortality rates, 1996–99

Country	CHD mortality rates (men)	CBVD mortality rates (men)	CHD mortality rates (women)	CBVD mortality rates (women)
Russian Federation (1998)	639	361	230	229
Finland (1998)	288	72	81	40
USA (1999)	230	41	95	33
Argentina (1996)	140	116	39	63
China, rural (1999)	64	243	41	152
China, urban (1999)	106	217	71	147
France (1998)	85	41	21	22
Japan (1997)	57	79	20	41

*Rates for ages 35–74 per 100 000, adjusted to the European Standard population.
Source: Bothing (MONICA Project)[16]

by differences in diet, serum cholesterol, and blood pressure. More recent data from WHO MONICA (MONItoring of trends and determinants in CArdiovascular disease), a CVD surveillance project which includes 117 reporting units in 40 centers from 26 countries,[16] indicate a greater than 14-fold difference in CHD mortality among men, and more than 11-fold differences in CHD mortality for women exists between countries (Table 21.1). These inter-country observations have raised questions as to whether these differences are due to differences in ethnic group susceptibility to CVD, differences in environmental factors, or both.

Migrant groups

Observational studies reveal that when members of a given ethnic group change to a new environment (migration) their physical response to a given set of environmental factors differs from those who remain in their native lands. This suggests that environmental influences are very powerful factors in CVD causation. Conversely, despite different environments, similarities in disease rates within an ethnic group suggest a predominant genetic propensity towards or protection from CVD. Comparing the mortality rates of long-settled migrants to the disease rates in their country of origin helps to establish the relative contribution of genetic and environmental influences to differences in mortality rates. The Ni-Ho-San Study of Japanese migrants to Hawaii and San Francisco revealed that changes in disease rates in this population likely reflected changing environmental influences.[17] The age adjusted CHD mortality rate rose as the Japanese moved from Japan, to Hawaii, and to California. More than half of the increase in CHD was attributable to different levels of conventional risk factors, as the US cohort had a higher fat diet and higher mean serum cholesterol compared to the Hawaii or Japan cohorts.[17] This suggests that the low rates of CHD mortality in Japan may be attained in Japanese migrants by maintaining their risk factors at levels similar to those in Japan. This, however, can only be achieved if the Japanese maintain their traditional lifestyle, most notably their dietary and physical activity patterns.

Specific ethnic groups

The following sections review the CVD profile of seven major ethnic groups. Based on the best available data, we will document their disease burden and changes in disease rates over time, and review common/influential CVD risk factors. We then suggest special ethnic group specific preventive strategies which need to be developed or reinforced.

European origin (including North Americans)

People of European origin include those who originate from Northern Europe such as the Nordic countries and Germany, Western Europe including the United Kingdom and France, Southern Europe including Spain and Italy, and Eastern Europe which includes the Slavic countries.

Disease burden

Differences in the Age Standardized Mortality Rates (ASMR) vary widely between European populations. Data from the WHO indicate that wide variations in disease rates exist between the Eastern European countries and Southern European countries such as Italy and France.[18] In 1998, the ASMR for CHD among males in the Russian Federation was 639 per 100 000 compared to 85 per 100 000 among males in France.[18] The cerebrovascular disease (CBVD) ASMR was 361 per 100 000 among males in the Russian Federation compared to 41[18] per 100 000 in France.[18] Although in all countries the CVD mortality rates are much lower among

Table 21.2 CVD mortality rates in selected Eastern European countries

Country	CHD mortality rates (men) 1996/98	CBVD mortality rates (men) 1996/98	CHD mortality rates (women) 1996/98	CBVD mortality rates (women) 1996/98
Bulgaria	216/222	183/189	126/131	140/144
Czech Republic	240/207	122/112	129/106	92/91
Estonia	392/385	166/150	208/203	120/117
Kyrgyzstan	328/326	225/207	196/190	172/164
Latvia	394/382	204/190	178/195	152/151
Romania	247/232	212/202	155/149	172/161
Ukraine	454/453	187/172	279/277	141/133

Source: WHO[18] and Thorvaldsen *et al* (MONICA Project)[19]

women, these impressive between-country differences persist. Over the past 30 years most European countries have experienced declines in the CVD mortality rates. The Eastern European countries (for example, Ukraine, the Russian Federation, Hungary, and the Czech Republic) continue to have among the highest rates of CHD and CBVD in the world, with a few showing a decline (Poland) and several showing an increase (Ukraine) (Table 21.2).[18,19]

Common risk factors

Throughout European populations the high rates of CVD are mainly attributable to the classical CVD risk factors, namely diets high in saturated fats, elevated serum cholesterol, elevated blood pressure, diabetes, and smoking. The epidemic of CVD in the Eastern European countries is in part related to high levels of smoking in the face of diets high in saturated fat, along with excessive alcohol consumption and social disparity.[14,20] Research to explain why the Italian and French populations remain relatively "protected" from CHD has yielded numerous hypotheses. It is likely that dietary differences primarily account for the differences in disease rates. It is believed that the high consumption of monounsaturated fats such as olive oil and antioxidants are responsible for the low rates of CHD in Italy. In France, despite having similar saturated fat consumption, serum cholesterol, blood pressure, and smoking, the CHD mortality rate remains very low.[21] This immunity to CHD has been attributed to high consumption of ethanol (wine), which is usually ingested with meals and may offer cardioprotection by increasing HDL cholesterol levels, or inhibiting postprandial hyperlipidemia and platelet aggregation.[22] Others believe the lower rate of CHD mortality may simply be due to a time lag between increases in consumption of animal fat and elevations in serum cholesterol concentrations (which have occurred only recently) and the expected increase in CHD mortality.[23] The total mortality rate in France is no different from other Western countries, which suggests an increase in alcohol-related non-CHD deaths such as cirrhosis occurs.[22]

Influential risk factors

CHD, like other epidemics, relates closely to social conditions and its prevalence appears to be strongly related to the social and cultural conditions of society more so than its genetic make-up. This is evidenced by the rapid decline in the rates of CHD in parallel to economic changes in the United States and Japan, and the increase in CHD rates in the Eastern European countries. These changes have occurred too quickly for changes in gene frequencies to have occurred.[14] Therefore, rather than explaining differences in CHD rates between populations largely on genetic differences, rapid changes in CHD rates can occur and are usually explained by changes in diet (including alcohol consumption), smoking or economic factors.

Special approaches to prevention

It is clear that major lifestyle changes, and vigilant treatment of risk factors, result in declines in CVD rates. In Finland, an impressive 60% reduction in CHD mortality and stroke was observed between 1972 to 1994, and it is estimated that approximately 75% of this decline in CHD mortality can be explained by a substantial lowering of serum cholesterol by 13% (0·88 mmol/l) in men and by 18% (1·19 mmol/l) in women, diastolic blood pressure by 9% (6·6 mmHg) in men and 13% (12·2 mmHg) in women, and a significant reduction in smoking rates (30% in men).[24]

Furthermore in the USA a 34% decline in CHD mortality occurred between 1980 and 1990. One quarter of this decline is attributable to primary prevention efforts, and 29% is explained by secondary prevention efforts such as reduction in serum cholesterol, diastolic blood pressure,

and smoking. Furthermore, 43% of this decline is attributed to improved medical and surgical management in patients with established coronary disease.[25] More recently in Poland, during the 1990s, a rapid decrease (about 25%) in CHD deaths in early middle age was observed. This decline in CHD rates is attributed in large part to marked dietary changes such as the reduction in consumption of animal fats.[26] Therefore efforts at reducing the consumption of animal fat, diastolic blood pressure, and decreasing tobacco consumption can lead to large reductions in CHD deaths. By contrast, a marked increase in death rates from CVD, accidents, violence, and infectious diseases has been observed in Russia over a relatively short time period, and is thought to be due to socioeconomic upheaval.[27] The rapidity with which CV diseases rise (as in Russia) or fall (as in Poland) indicates that societal factors can have a substantial and rapid impact on disease rates.

Japanese

Disease burden

Mortality rates from CVD are much lower in Japan than Western countries[18] (see Figure 21.1) Initial data from the Seven Countries study confirmed that the Japanese experience relatively lower rates of CVD compared to Western populations.[15] In Japan, the pattern of CVD differs from Western populations as they tend to experience relatively higher proportions of CBVD (ASMR: M 79, F 41/100 000) and less CHD (ASMR: M 57, F 21/100 000).

Temporal trends

In parallel with a rise in economic prosperity, the CHD rates in Japan have declined more markedly than those of Western countries. For CHD the ASMR has decreased from 47/100 000 in 1995 to 42/100 000 in 1997 among males, and from to 25 to 21/100 000 during the same time period among females.[18] Given the low rate of CHD in Japan, the life expectancy in Japan is among the highest in the world.[28] The mortality from CBVD has also declined substantially in men and women in Japan since 1950.[14] Between 1995 and 1997, ASMR decreased for both men from 82/100 000 in 1995 to 79/100 000, and in women from 54 to 41 during the same time period. Dietary changes such as reduction in salt consumption and increased pharmacologic treatment of hypertension in a socially stable environment are probably responsible for the declines in CHD and CBVD.[14,28]

Common risk factors

A review of CVD risk factors in the Japanese population reveals that hypertension is the most significant determinant of CVD, more so than cholesterol and cigarette smoking.[28] Low serum cholesterol related to a diet low in saturated fat and cholesterol is probably responsible in part for the low rates of CHD mortality observed in the Japanese. Despite the fact that two thirds of Japanese men smoke, CHD rates remain unexpectedly low. However, the prevalence of type 2 (non-insulin dependent) diabetes in Japanese males and females is higher than the rates in most Western countries. In the Hisayama cohort study the prevalence of type 2 diabetes was 13% in males, and 9% in females and the relative risk of type 2 diabetes for CVD was 3·0 (95% CI 1·8–5·2).[29] Furthermore, the prevalence of type 2 diabetes appears to be increasing among young children, with a 1·5-fold increase observed over the past two decades among children younger than 18 year of age.[30] This increase has been associated with the increasing prevalence of obesity. Therefore, type 2 diabetes appears to be an emerging and important risk factor for both stroke and CHD in the general Japanese population.[29,31]

Influential risk factors

Over the past 30 years blood pressure levels have declined in Japan due to increased diagnosis and treatment of hypertension.[32] However, during this period a two- to threefold increase in glucose intolerance and type 2 diabetes, as well as obesity, and more recently hypercholesterolemia (the mean cholesterol is only 10% lower than in the USA in 1989) has occurred.[28,31] The increase in diabetes, obesity, and serum cholesterol is most likely due to "Westernization" of Japanese lifestyle. It is possible that as cholesterol levels and glucose levels rise the impact of high cigarette smoking may result in increased CVD rates in the future.

Special approaches to prevention/treatment

With increasing adoption of urban lifestyles in Japan,[32] the rates of CHD risk factors are approaching those of Americans. Ecological studies between Japan and the USA demonstrate this difference in CHD rates may be explained by differences in diet and serum cholesterol. However, recent studies have documented that the average serum cholesterol concentration among Japanese has increased from 1980 to 1989. The age adjusted total serum cholesterol levels increased from 4·84 to 5·22 mmol/l in men and from 4·91 to 5·24 mmol/l among women, and this combined with the substantial use of tobacco among Japanese males (59%) suggests that Japan may soon experience a significant increase in CHD rates.[28] Therefore, maintenance of a low fat diet, prevention of obesity (through decreased energy intake and regular physical activity), and avoidance of cigarette smoking should prevent the development of elevated cholesterol, type 2 diabetes, and ultimately CVD.

Chinese

Disease burden

Although the overall mortality from CVD is less in China than in Western countries, CVD is the most common cause of death in mainland China and Taiwan. When compared to Western populations, Chinese experience higher stroke rates, and relatively lower rates of CHD, a pattern similar to that observed in Japan. In 1999 in urban China, the ASMR for CHD in men aged 35–74 was 106/100 000 and women 71/100 000.[18] These rates are fivefold lower than the highest rates observed in the MONICA project from Western and Eastern Block countries.[18] In 1999, the ASMR for CBVD in men aged 35–74 was 217 and 147 per 100 000 in Chinese women.[18] Recent data from the Sino-MONICA study in China reveal that by international standards, the incidence of CHD in Chinese is low. The highest incidence was 108·7/100 000 (1987 to 1989) for men 35–64 years of age whereas by international standards the incidence of cerebrovascular disease is high. The highest incidence of stroke was 553·3/100 000 (1987 to 1989) for men 35–64 years. There were significant geographic variations in both CVD incidence and mortality rate, with higher rates in the north and lower rates in the south. Comparison with five stroke registries from the West suggests that intracerebral hemorrhage occurs between two and three times more frequently in the Chinese than in Caucasians.[33] Only 6–12% of strokes in whites are reported as intracerebral hemorrhages compared to 25–30% of hemorrhagic strokes in Chinese.[19]

Temporal trends

Death rates from the major adult CVD (particularly CHD) have been increasing in China in recent decades.[34] Mortality attributable to CVD increased from 86/100 000 (12% of total death) in 1957 to 214/100 000 (36%) in a recent analysis of urban Chinese.[34] Although most Western countries report a decline in CVD mortality, the decline in stroke deaths in China has not been as striking. A recent study in Shanghai from 1984 to 1991 reported no changes in the stroke incidence, yet a decline in the case fatality rate from stroke in both rural and urban China.[33] In China, CVD mortality increased as a proportion of total deaths from 12·8% in 1957 to 35·8% in 1990.[35] This rise is attributable to the rapid pace of urbanization, with the associated lifestyle changes. Data from the Sino-MONICA project, which is a 7 year study monitoring trends and determinants of cardiovascular disease (CVD) in geographically defined populations in different parts of China, indicate that between 1987 to 1993 increasing trends were found in CVD rates in some populations, whereas decreasing trends were found in others.[36]

Common risk factors

A case–control study from Hong Kong of acute myocardial infarction (AMI) sufferers provides evidence that conventional CVD risk factors are important among people of Chinese origin.[37] The odds ratio for AMI associated with cigarette smoking was 4·3, 3·3 for hypertension, and 2·4 for diabetes. Although the mean serum cholesterol among Chinese would be considered low by Western standards, a prospective observational study of approximately 9000 Chinese in urban Shanghai demonstrated that serum cholesterol was directly related (continuous relationship) to CHD mortality even at these low levels.[38] Cigarette smoking is highly prevalent among Chinese males, as over 60% of men smoke and there is evidence that these rates are increasing.[39,40] Positive associations between body mass index (BMI) and CV risk factors have also been reported for a very lean rural Chinese population (mean BMI approximately 20).[41] While the problem of underweight and undernutrition still exists in rural China, the prevalence of overweight is increasing in both urban and rural areas, with larger increases observed among urban residents.[42] Further, in a recent prospective cohort study conducted among 37 655 urban Chinese, systolic blood pressure was a significant determinant of stroke, as the risk of stroke increased by 25% for every 10 mmHg rise in systolic blood pressure.[43]

Influential risk factors

Although the rates of cigarette smoking are high, elevated blood pressure appears to be the most influential risk factor for CVD in this group. However, with increasing urbanization (increasing BMI), and the subsequent increase in serum cholesterol, these factors may lead to increased rates of CHD.

Geographic variations

Trends in morbidity and mortality from CVD within China indicate that the mortality rate attributable to CVD is higher in North China (Beijing) than in South China (Guangzhou)[44] (Table 21.3). Comparison of urban and rural areas in China indicate that CHD rates increase by twofold in urban areas compared to rural areas, although the stroke rates are higher among rural Chinese compared to urban dwellers, especially among men[44] (see Table 21.1). The prevalence of hypertension, mean serum cholesterol, and mean BMI were all lower in the South compared to the North and in rural compared to urban areas (see Table 21.3). However, the greatest differences in the prevalence of cigarette smoking exist between men and women (74% *v* 20%), and it does not share the same geographic distribution as do the other major CVD risk factors.

Table 21.3 North (Beijing)–South (Guangzhou) and urban–rural comparisons of CVD risk factors in China

Factor	Urban Beijing	Rural Beijing	Urban Guangzhou	Rural Guangzhou
Hypertension (men) (%)	29·6	25·5	9·4	7·6
Hypertension (women) (%)	25·1	17·9	12·4	4·0
Cholesterol (men) (mmol/l)	4·78	4·42	4·71	4·11
Cholesterol (women) (mmol/l)	4·83	4·34	4·83	4·0
HDL (men) (mmol/l)	1·37	1·39	1·29	1·26
HDL (women) (mmol/l)	1·52	1·47	1·37	1·24
Smoking – current (men) (%)	71·0	78·0	73·0	77·0
Smoking – current (women) (%)	23·0	31·0	3·0	7·0
BMI (men)	23·0	22·0	21·0	20·0
BMI (women)	24·0	23·0	22·0	20·0

Migrant patterns

Data from Chinese migrants to Singapore and Mauritius provide evidence that the effects of exposure to urban environments lead to adverse risk factor profiles for CVD.[45,46] Another survey of three populations undergoing three different grades of transition in mainland China and Taiwan confirmed that adverse risk factor profile (based on blood pressure, BMI, lipid levels, HbA1c and dietary patterns) was associated with increased level of urbanization.[47] In a comparative study of Chinese migrants to Mauritius the prevalence of CHD revealed by ECG was six times greater (24% *v* 4%) than in Beijing, China. Also, the prevalence of diabetes and the mean serum cholesterol was higher in Mauritius Chinese (5·5 mmol), than in Beijing Chinese (4·4 mmol/l), whereas the prevalence of hypertension and smoking was greater in Beijing.[45] Therefore, although the prevalence of hypertension and smoking may decline with migration, the rates of obesity, late onset diabetes, elevated serum cholesterol, and CHD appear to increase. A comparison of rural Chinese in China to urban Chinese subjects living in Hong Kong and Australia, found that despite a slightly better risk factor profile among the urban Chinese (based on HDL cholesterol and lower blood pressure), carotid atherosclerosis was lower among the rural subjects (0·50 + 0·10 mmHg) than among urban subjects (0·56 + 0·12 mmHg).[48] Among Chinese migrants to Canada, Chinese exhibit markedly lower rates of CHD compared with other groups, and have low and similar rates of CBVD compared with Canadians of South Asians and European origin.[49] Given that Canada has the second lowest rate of strokes in the world, these data indicate that marked declines in stroke rates can occur among Chinese without a concomitant increase in CHD. The low rates of risk factors among Chinese in Canada are accompanied by relatively lower prevalence of the conventional CV risk factors, atherosclerosis, and CHD.[50] These data also suggest that if risk factors levels rise among Chinese to levels that are similar to Europeans, the rates of CHD may become similar.

Special approaches to prevention

Economic modernization in China is resulting in an increased prevalence of conventional CVD risk factors over time in urban populations.[30,42,51] This offers a major challenge for prevention efforts among urban Chinese both in China and abroad, as the Chinese who have traditionally had a very low prevalence of CHD will likely not remain protected from developing CHD with their changes in lifestyle. Important prevention strategies in this group include smoking cessation/prevention, maintenance of a traditional Chinese diet (high consumption of vegetables, high fish intake, and low saturated fat intake) to prevent increases in BMI, diabetes, serum cholesterol, and blood pressure.

South Asians

South Asians include people who originate from India, Sri Lanka, Bangladesh, and Pakistan.

Disease burden

Studies of South Asian migrants demonstrate that this group suffers a higher mortality from CHD when compared to other ethnic groups (Table 21.4).

Within India

There are relatively few mortality studies from India as there is no uniform completion of death certificates, and no centralized death registry for CVD.[52] However, the WHO and the World Bank data indicate that mortality attributable to

Table 21.4 Standardized mortality ratios (SMR) (per 100 000) for CHD in South Asians worldwide

[a] Standardized mortality to reference indigenous population of 100.

CVD has increased in parallel with the expanding population in India, and now accounts for a large proportion of disability adjusted life years (DALY). Of all deaths in 1990, approximately 25% were attributable to CVD, which is greater than the 10% due to diarrheal diseases, the 13% due to respiratory infections, and the 8% due to tuberculosis.[11]

South Asian migrants

Studies of South Asian migrants to countries such as the United Kingdom, South Africa, Singapore, and North America provide evidence that South Asians suffer between 1·5 and 4·0 times higher CHD mortality compared to other ethnic groups (see Table 21.4).[53]

Temporal trends

In India the CHD rate is expected to rise in parallel with the increase in life expectancy due to an increase in per capita income, and a decline in infant mortality. The average life expectancy has increased from 47 years in 1960 to 58 in 1990. This trend is expected to continue, with life expectancy at birth reaching 72 years by 2030 leading to large increases in CVD prevalence.[54] Although the CHD mortality rate of South Asians compared to other populations remains high, a decline in CHD rates has been observed in most South Asian migrants over the past ten years, although this decline has been less than that observed in the general population in most countries except Canada.[55,56]

Common risk factors

South Asians, despite having increased rates of CHD, do not typically display an excess of conventional cardiovascular risk factors such as smoking, hypertension, or elevated cholesterol.[50,57,58] However, over the past several decades, the prevalence of these conventional risk factors – for example, hypertension – has been increasing, especially in urban areas.[59] These factors remain strong determinants of CHD in South Asians. Data from a case–control study in Bangalore, India[60] in which 200 cases of AMI were compared to 200 age and sex matched controls, revealed[60] an increasing relative risk of MI as the number of conventional risk factors increased. The odds ratio for smoking was 3·6, 2·6 for diabetes, and 2·7 for hypertension. In this study serum cholesterol did not seem to differ between cases and controls and the levels were similar to Western values. Cross-sectional studies of CHD risk factors in South Asians living in North America have identified that this group suffers a high prevalence of diabetes, impaired glucose tolerance, central obesity, elevated LDL cholesterol,[53] elevated triglycerides, and low HDL cholesterol.[58,61] The prevalence of impaired glucose tolerance and type 2 diabetes is four to five times higher in South Asian migrants than in Europeans by the age of 55 (20% *v* 4%).[57,58] The prevalence of diabetes in South Asians in the UK was 10–19%, 21% in Trinidad, 25% in Fiji, 22% in South Africa, 25% in Singapore, 20% in Mauritius, and 10% in Canada.[50,58] In rural India it is 3%, and between 11% and 30% in urban India, which is similar to the rates reported among Indians living abroad.[62] There is preliminary evidence that South Asians have elevated levels of Lp(a) – a lipoprotein which is genetically mediated and associated with increased atherosclerosis and thrombogeneis.[63,64] Recent studies have confirmed that South Asians also have higher levels of homocysteine, fibrinogen, and plasminogen activator inhibitor (PAI-1),[50] all of which could increase the risk for thrombosis. Although the

degree of subclinical atherosclerosis is related to clinical events, it appears that South Asians have a higher propensity for clinical events compared with Europeans or Chinese, even after adjusting for all known risk factors and the degree of atherosclerosis (Figure 21.1). This suggests that South Asians may have an increased rate of plaque rupture due to differences in plaque composition, and or an increased propensity to develop thrombosis in response to plaque rupture which leads to an increased number of clinical events.

Influential risk factors

Glucose intolerance, abdominal obesity, and its associated dyslipidemia appear to be dominant factors associated with the development of CHD in South Asians. This cluster of factors is also associated with impaired fibrinolysis, increased C-reactive protein, and enhanced thrombogenesis. Increasingly, data support the idea that elevations of glucose in the non-diabetic range which is prevalent among South Asians is associated with the development of atherosclerosis among South Asians.[65,66]

Geographic variations

During the last half of the twentieth century, the urban population of India doubled from 17% to 34% of the total population.[67] Epidemiologic data support a striking urban–rural difference in the prevalence of CHD and CHD risk factors in South Asians living in India and abroad.[68] Data from India demonstrate at least a twofold excess of CHD in urban compared to rural environments. A recent overview of prevalence surveys in India reported a ninefold increase of CHD in urban centers, compared with a twofold increase in rural population over two decades of study.[69] Although these studies used somewhat different methods of sampling and varying definitions for CHD, collectively, they suggest that this is likely a real increase in CHD; however, the magnitude of the increase remains uncertain. Data from a study by Reddy *et al.* conducted in 1989–94 in which a population-based sample from urban Delhi was compared to a similar sample from rural Haryana revealed the CHD prevalence was 10/1000 in Delhi compared to 2/1000 in rural Haryana.[70] Associated with this increase in CHD rates in urban areas is an increase in the prevalence of lipid and glucose abnormalities. An increased prevalence of IGT, and type 2 diabetes, lower HDL cholesterol and higher triglycerides, increased abdominal obesity BMI, and hypertension is observed in the urban areas compared to the rural[71] (Table 21.5). By contrast, the rates of tobacco smoking are higher within rural environments among both men and women.

Migration patterns

An urban–rural difference in CHD prevalence and risk factors is observed within India and abroad. A recent study which compared the risk profiles of urban South Asians living in the UK with their siblings living in India revealed that the UK cohort had a higher BMI (27 *v* 23), systolic BP (144 mmHg *v* 137 mmHg), total cholesterol (6·35 *v* 5·0 mmol/l), a lower HDL cholesterol (1·14 *v* 1·27 mmol/l), and higher fasting glucose (5·4 *v* 4·6 mmol/l) compared to

Table 21.6 Comparison of South Asians from India and migrants in the United Kingdom

	Indian subcontinent	Sibling migrants UK	Significance
Mean age (yr)	45·0	46·0	NS
Serum glucose (men) (mmol/l)	4·5	5·7	0·001

their siblings. Lp(a), which is genetically determined, was similarly high in both groups (Table 21.6).[72] Therefore, adverse changes in CVD risk factors and disease rates are observed when South Asians adopt an urban lifestyle, whether they live in India or abroad (see Table 21.5).

Prevention strategies

Changes in the risk factor profiles of South Asians are attributable to lifestyle changes associated with urbanization such as decreased physical activity and increased energy consumption which leads to obesity, abdominal obesity, and its harmful sequelae. Clearly strategies to prevent the development of obesity are required to decrease the number of South Asians who suffer from glucose intolerance, its associated dyslipidemia, and ultimately CHD.

Arabs

The term Arab refers to Semitic people who originate from the Middle East. Included in this region are the countries of Egypt, Saudi Arabia, Jordan, Iran, Iraq, and the United Arab Emirates.

Disease burden

CVD is the leading cause of death among Arabs living in the Middle East.[11] This is primarily caused by the rapid socioeconomic development, urbanization, and improved survival over the past several decades. The Global Burden of Disease report estimates that the acute myocardial infarction (AMI) rate among men and women was 139/100 000 and 124/100 000 respectively in 2000, which is an increase of 12% among men and 5% among women since 1990.[11]

Temporal trends

While national incidence and mortality data are not readily available for many Arab counties, one indication of the increase in CVD is the rise in hospital admission for CVD over time. In Egypt the proportion of hospital admissions due to CVD has increased in Egypt from 12% of deaths in 1970 to close to 40% in 1990.[73] In Saudi Arabia, CHD represented the leading cause of admissions in 1995.[74,75] In Oman during 1985–87 CHD and CBVD accounted for 30% of hospital deaths in the age group 15 years and above.[76]

Common risk factors

Overweight (defined as BMI in the range of 25–30) and obesity (BMI $>$ 30) are highly prevalent in the Arabian Peninsula, and over half of all adults aged 40–69 years are either overweight or obese.[77] Obesity rates vary from 16% to 25% among men and from 17% to 43% among women. Adverse lifestyles associated with socioeconomic development and urbanization, such as diminished physical activity (with the availability of domestic help, private cars, popularity of television etc.) and altered dietary patterns (increased fat and energy intakes) influence the prevalence of obesity.[77] The prevalence of leisure time physical activity from a nationally representative sample in Bahrain was low among all age and sex groups, though higher among men (30–49 years: 19·9%) than among women (30–49 years: 9·9%).[78] The high rates of overweight and obesity in this region are associated with the increasing prevalence of type 2 diabetes observed in this region. In 1995, prevalence of diabetes in Middle Eastern was approximately 6·3% (18·3 million people), and the prevalence of diabetes is expected to increase to 8·2% (53·5 million people) by the year 2025.[79] Rapid

urbanization, increasing obesity, abdominal obesity, and sedentary lifestyles are key factors underlying this increase of type 2 diabetes. In 1995, there were approximately twice the number of diabetics in urban compared to rural areas of the Middle East. By 2025, this ratio will increase dramatically, and there will be approximately 3·5 times the number of diabetics in urban compared to rural areas.[79] The high prevalence of obesity and sedentary lifestyles may also be associated with high levels of hypertension in this region. National surveys have demonstrated high prevalence of hypertension in Oman (27%),[80] Egypt (26%),[81] and the United Arab Emirates (37%).[82] In the United Arab Emirates, 26% of hypertensive subjects were aware that they had high blood pressure, 41% were being treated for the disease, and only 19% were under control.[82] This high prevalence, coupled with low awareness and poor control, suggest the need for additional focus on prevention. The prevalence of hypercholesterolemia in Saudi Arabia is also associated with age level of obesity and glucose tolerance.[83] Results of a National Survey conducted in Saudi Arabia, indicated that the prevalence of total cholesterol levels >5·2–6·2 mmol/l was 9% for males and 11% among females respectively, while prevalence of total cholesterol >6·2 mmol/l was 7% for males and 8% among females.[84] These levels are lower than observed elsewhere, however they reflect a young population (60% of the Saudi population is <30 years old), therefore the prevalence of hyperlipidemia is likely to increase as the population ages. Smoking is typically more common among men than women for cultural reasons, and the prevalence varies markedly between countries within the region. In Saudi Arabia, the prevalence of smoking is 12% among men, compared to only 1% among women.[83] However, the increasing use of the "water pipe" has resulted in increased smoking among women. In Bahrain, approximately 46% of men and 30% of women reported smoking. Furthermore, women more often reported exposure to passive smoke (44%) compared to men (29%).[78]

Influential risk factors

In comparison with European populations with similar degrees of obesity and glucose tolerance, Arabs experience more hyperglycemia associated with insulin resistance. This suggests that Arab people may have an increased genetic susceptibility to abdominal obesity (for example, the "thrifty gene"), which is expressed as glucose intolerance and excess abdominal fat in the face of an environment of abundant energy intake and relatively little physical activity.[85] Profound changes associated with urbanization which have occurred in Arab countries during the past 30 years are associated with the emergence of both obesity and diabetes, and this trend is expected to continue.

Special approaches to prevention

Increased susceptibility to insulin resistance among Arabs suggests that control of obesity and primary prevention and control of type 2 diabetes are critical. Attention to lifestyle practices that promote obesity, such as sedentary lifestyles and increased energy intake, should be a focus. Cultural beliefs about overweight and obesity for both men and women must be understood in order to develop effective prevention strategies. These directions have already been established in many countries of the Arabian Peninsula, and more recently in collaboration with the World Health Organization.

Hispanics

The term Hispanic includes Cuban Americans, Mexican Americans, and Puerto Rican Americans. There are approximately 35·3 million Mexican Americans living in the USA, and they comprise approximately 12·5% of the US population.[86,87] The majority of information on CVD in Hispanics has been derived from studies in Mexican Americans.

Disease burden

CVD is the leading cause of death among Hispanic males (28%) and females (34%).[87] Although death certificate registries report that the age adjusted mortality rates for major CVD among Mexican Americans (28·8 and 26·6 per 100 000 men and women respectively) are lower than those of African Americans (40·5 and 39·6 respectively) and whites (30·0 and 23·8 respectively) in the USA,[88] the Corpus Christi Heart Project (CCHP), Texas reported a greater incidence of MI in Mexican Americans compared to non-Hispanic whites over a 4 year period.[89] This population-based surveillance project conducted between 1988 and 1992 reported that age adjusted incidence ratios comparing Mexican Americans to non-Hispanic whites were 1·52 (95% CI 1·28–1·80) and 1·25 (95% CI 1·10–1·42) among women and men respectively.[89] Although cross-sectional studies reveal a similar or lower prevalence of MI among Mexican Americans than non-Hispanic whites, the CCHP has reported a greater case-fatality rate following MI among Mexican Americans than non-Hispanic whites. Therefore a lower CHD prevalence in Mexican Americans does not necessarily reflect a lower incidence of CHD.

Under the age of 60 years Hispanics have a significantly elevated CBVD death rate compared to non-Hispanics whites (M 32 *v* 19, F 23 *v* 18 per 100 000 respectively). However in older age categories the CBVD rate in Hispanics is substantially lower than whites (M 589 *v* 765, F 535 *v* 847 per 100 000).[18] Therefore, overall the CBVD death rate over 45 years of age in Hispanics is lower when compared to whites (M 115 *v* 147 per 100 000 and F 110 *v* 209 per 100 000).[18]

Temporal trends

Although declines in CHD and CBVD mortality have occurred in Mexican Americans over the past 20 years, this decline has been less than that which has occurred among non-Hispanic whites.[18,90,91]

Common risk factors

Mexican Americans suffer a high prevalence of conventional CVD risk factors such as smoking (42·5% in men and 23·8% in women), hypertension (17% men and 14% women), low HDL cholesterol (<0·90 mmol/l: 15·2% men and 5% women), elevated cholesterol (total cholesterol >6·2 mmol/l: 16·5% men and 16·5% women), diabetes (24%), physical inactivity (39%), and obesity (BMI >85th percentile, 30% men and 39% women).[92] The San Antonio Heart Study reported that Mexican Americans had 2·5 times the prevalence of NIDDM compared to the non-Hispanic whites as diagnosed by the oral glucose tolerance test.[92] They also observed that a socioeconomic gradient within the Hispanic population existed, with diabetes being more prevalent in the lower socioeconomic groups.[93] Furthermore, Mexican Americans have higher blood concentrations of triglycerides and lower HDL cholesterol levels compared to non-Hispanic whites.[91]

Influential risk factors

Glucose intolerance appears to be the most influential risk factor for CHD among Mexican Americans.[87] The greater mortality observed among Mexican Americans following MI in comparison to non-Hispanic whites is attributed in large part to the increased prevalence of diabetes.[94] Furthermore, glucose intolerance also defines which Mexican Americans are more likely to suffer CHD events within their own population, as diabetic Mexican Americans are four times more likely to suffer an MI compared to their non-diabetic counterparts.[95]

Geographic variations

This population suffers a high prevalence of glucose metabolic derangements upon the adoption of an urban lifestyle.

Special approaches to prevention/treatment

Due to the discrepant data concerning the CHD mortality rates of Mexican Americans, despite their adverse risk factor profile, many researchers believe they remain "protected" from CHD.[95] Clearly, the burden of CHD among Mexican Americans is considerable, and risk factor modification of conventional CHD risk factors must be initiated. Furthermore, primary prevention strategies such as prevention of obesity through environmental changes, and increased physical activity will reduce the rate of glucose intolerance in this group. Promotion of these strategies is important given that Mexican Americans are less likely to receive treatment for diabetes, hypercholesterolemia, and hypertension compared to non-Hispanic whites.[88,89] Therefore, it is critical that culturally sensitive strategies to bring about both primary and secondary prevention in this growing group of Americans be developed.

Aboriginal populations

Disease burden

Although mortality rates for CVD among aboriginal populations appear to be lower than whites, CHD is the leading cause of death in North American Indian and Alaskan Native males and females.[18] Although research in this ethnic group is limited, the Strong Heart Study,[96] which was initiated in 1988, studied 4549 American Natives aged 45–74 years from 13 tribes in the Southern US. The prevalence estimates of definite MI in those aged 45–74 years was 2·8% in men without diabetes, and 5·3% in men with diabetes, 0·4% in women without diabetes, and 1·4% in women with diabetes. Data from US cohort studies indicate that Native Americans may have a lower prevalence of MI than whites (7·9%), African Americans (6·1%), and Hispanics (5·6%).[96] However, data from Canada indicate that Aboriginal people suffer higher rates of CHD compared to the general population.[97,98]

There is little published information concerning the epidemiology of CBVD in native populations. In the USA the CBVD mortality rate under the age of 65 years is similar in Native Americans and white Americans, and substantially lower than rates in African Americans.[99] Over the age of 65, the CBVD rate in Native Americans is substantially lower than whites. The age adjusted mortality rate for CBVD in Native American men in 1988–98 was approximately 80 per 100 000 compared to 120 per 100 000 in white American men, and 60 per 100 000 compared to 100 per 100 000 in Native women compared to white American women.[18] In Canada, CVD is the leading cause of death among Aboriginal peoples.[100,101] Although the CHD mortality rates among Aboriginal and Canadian males are similar, the CHD mortality among Aboriginal women is 61% higher compared with Canadian women. In addition, the stroke mortality rate is 44% and 93% higher among Aboriginal men and women respectively, compared with the general Canadian population.[101] However, all of the above data are based on studies conducted more than 10 years ago. More recent data from a prevalence study in Canada indicates a 2·5-fold higher rate of CVD among Aboriginal peoples compared with Canadians of European origin.[98]

Temporal trends

As more Aboriginal people give up their traditional lifestyles and adopt "urban" lifestyles, the prevalence of CVD and its risk factors will likely increase.

Common risk factors

The common CHD risk factors among Aboriginal people include obesity, abdominal obesity, diabetes, elevated blood pressure, low HDL cholesterol, and tobacco use. The prevalence of cigarette smoking is generally high and increasing among Aboriginal people; the prevalence varies greatly between reserves.[98,102] The prevalence of diabetes in the Strong Heart Study was an astounding 48% in the 45–64 year age group compared to approximately 5·5% in the US general population, and the prevalence of obesity was between 26% and 41%, with an average BMI of 31 and waist–hip ratio of 0·96 in men.[103] Interestingly, the prevalence of hypertension and elevated serum cholesterol among Aboriginal people appears to be lower when compared to the general US population. In Canada, however, the prevalence of hypertension requiring drug treatment, and elevated cholesterol requiring medication, was significantly increased among Aboriginal people compared to a similar sample of non-Aboriginal people.[98] In addition, the prevalence of low HDL cholesterol is greater in this group, as approximately 25% of Aboriginal people have HDL cholesterol values less than 0·90 mmol/l.[98] In a recently completed Canadian study, Aboriginal people had a higher prevalence of CVD, atherosclerosis, glucose abnormalities, obesity, abdominal obesity, and tobacco use compared to European-origin Canadians.[98] Furthermore, a high proportion of Aboriginal people in North America live in poverty.[98] This is important to note as a strong inverse relationship exists between low income and an increased prevalence of CVD risk factors and CVD (Figure 21.2).[104]

Influential risk factors

Clearly obesity, diabetes, and tobacco use among Aboriginal people are the most influential risk factors for future CHD. Aboriginal people who are diabetic are two to four times more likely to suffer CVD than non-diabetic people.[102,103] In the Strong Heart Study other important risk factors for CHD included hypertension, obesity, and low HDL cholesterol.[103]

Geographic variations

Studies in aboriginal populations in North America have revealed important regional and inter-tribal differences in the prevalence of CVD risk factors (diabetes and cigarette smoking) and disease rates.[96–98] Most of the current data on Aboriginal CVD rates and risk factors have come from studies of Native people living on reserves. There is relatively little information regarding these profiles among city-dwelling Aboriginal people.

Special approaches to prevention/treatment

Control of obesity using environmental strategies to promote increased physical activity and lower energy consumption is

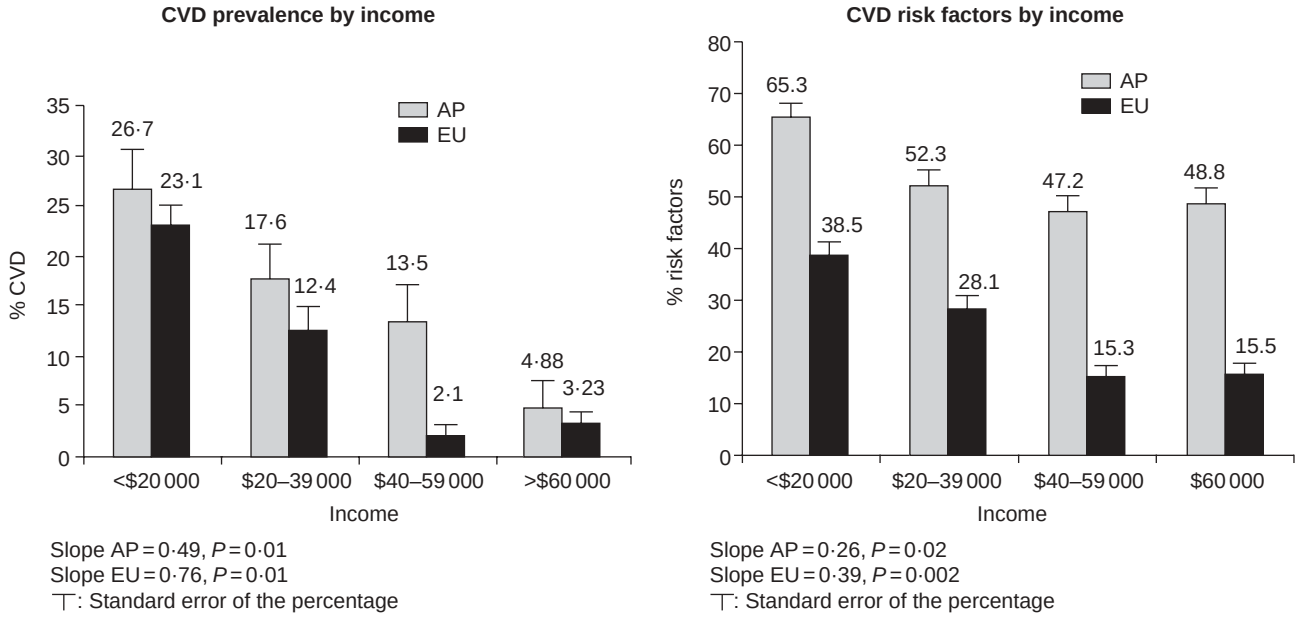

Figure 21.2 Relationship between low income and prevalence of CVD and number of CVD risk factors

required by Aboriginal people who have adopted a predominantly Western lifestyle. While tobacco has a cultural role in the lives of some Aboriginal people, increased tobacco taxes and other disincentives are required to prevent smoking initiation and promote smoking cessation on reserves. Despite community prevention strategies, the imbalance in socioeconomic circumstances between Aboriginal people and non-Aboriginal peoples must be addressed, as socioeconomic disparity is clearly associated with adverse lifestyle practices, psychosocial stress, and CVD prevalence.

Blacks of African origin

Disease burden

CVD mortality data from countries in Sub-Saharan Africa (SSA) are limited, as only 1·1% of all deaths are registered with a central agency.[10] Data from other sources such as sample registries and small scale population studies in 1990 indicate that the prevalence of acute MI in males and females of all ages was 4·5 million DALY, and that the CHD mortality was 41/100 000.[105] These rates are considerably lower than those of whites and South Asians who live in Africa, as well as rates of most Western countries, which are on average five times higher. Even so, in SSA, the proportional mortality rate from CHD accounts for 26% of all deaths, and in the 60–70 year age group it is responsible for over 80% of all deaths.[10,105] Furthermore, the case-fatality rate of CHD is higher in SSA compared to Western countries, meaning that once an individual develops CHD in SSA, the probability of death in SSA is higher than in Western countries. This probably reflects the limited access to acute and chronic treatment strategies.

Risk factors

The prevalence of most conventional risk factors for CHD is lower among blacks compared to other groups within Africa, and the world, with the exception of hypertension and smoking among urban blacks.[106–110] Data from the WHO Inter-Health Program, a substudy of the MONICA project, assessed the risk factor profile of men and women aged 35–64 years from Tanzania.[107] The prevalence of smoking was 37% among men, and 4% among women, the mean BMI was 21 in men, and 22 in women, the mean BP was 126/79 mmHg among men compared to 125/79 mmHg in women, the mean serum cholesterol was 4·1 mmol/l in men, and 4·3 mmol/l in women. When compared to the risk factor profile of other developing and developed countries, Tanzania's was more favorable, with the exception of smoking among men. Furthermore, the prevalence of multiple risk factors for CHD was low, as 65% of the population had no identifiable risk factors, 30% had a single risk factor, and only 5% had at least two risk factors, compared to 50%, 40%, and 10% in the USA.[107]

Geographic variations

In most urban and virtually all rural regions of SSA the prevalence of traditional CVD risk factors among blacks is low. However, with urbanization, an increase in conventional cardiovascular risk factors and CVD rates is expected.[111] An example of this is found in South Africa, as the rapid migration of blacks to urban centers has led to increased poverty, obesity, hypertension, LDL cholesterol, and a decrease in HDL cholesterol.[112–115]

Special approaches to disease prevention

Although CHD rates among people of African origin remains relatively low, the data are limited, and given the increased migration of blacks to urban centers, and a subsequent rise in the number of conventional CHD risk factors, the rates of CHD and CBVD are expected to rise. Primordial prevention strategies such as reducing the availability of saturated fats, and increasing the availability of monounsaturated fats, control of cigarette smoking by increasing the price of cigarettes, controlling the amount of salt consumption, and promoting regular physical activity are required on a community level, especially among urban populations. Key primary and secondary prevention strategies among blacks include control of hypertension, and tough antismoking campaigns.

West Indies

Disease burden

In Trinidad, data from 1989 reveal that the age adjusted incidence of CHD in people of African origin was 6·8/1000 person years at risk among men, and 5·4/1000 person years at risk among women. The rate in men approximated that of males of European decent (6·8 *v* 6·5/1000), whereas the rates among women were higher in blacks (5·4 *v* 2·9/1000). The rates in both sexes and groups were substantially lower than males (16 per 1000) and females (13/1000) of South Asian origin.[116]

Risk factors

The most prevalent and influential risk factor among West Indian blacks is hypertension. In Trinidad the prevalence of hypertension among African blacks was 33%, diabetes 8·1%, and smoking 39%.[116] Furthermore, the mean HDL and LDL cholesterol in men was 1·03 and 4·04 mmol/l, and in women 1·30 and 4·11 mmol/l. The most important predictors of CHD in this cohort were hypertension, high LDL cholesterol, low HDL cholesterol, and diabetes mellitus.

African Americans

African Americans comprise the largest non-white population in the USA and represent approximately 13% of the population.

Disease burden

CVD is the leading cause of death among African Americans, and the incidence of both CHD and CBVD is higher in African Americans compared to white Americans. The CHD mortality rate in African American males is 2·4% higher than in white males (138·1 *v* 134·8 per 100 000), and 33% higher in African American women compared to white American women (85 *v* 64 per 100 000).[18] Moreover, sudden cardiac death (defined by ICD codes 410-414) are more common among African American men (137/100 000) compared to white American men (122/100 000) aged 35–74 years, and women (67 *v* 41/100 000) respectively.[117] The CBVD mortality rate is 98% higher in African American males compared to white males (52 per 100 000 *v* 26 per 100 000) and 77% higher in African American females compared to white females (40 per 100 000 *v* 22 per 100 000).[18]

Temporal trends

Although there has been a decline in mortality rates from CVD in both African Americans and white Americans over the past 30 years, these declines have been less marked in African Americans.[18]

Common risk factors

Compared to whites, African Americans develop high blood pressure at an earlier age, and it is more severe.[18] The reason for black–white differences in hypertension prevalence likely involves a complex interaction between environmental response to diet, and stress, and a potential genetic/physiologic difference such as differences in sodium/potassium excretion, perhaps linked to their origins in Africa. Serum cholesterol levels are not higher among African Americans than white Americans, as 47% of African American men have cholesterol values over 5·2 mmol/l, compared to 54% of white males, and 51% of women have levels greater than 5·2 mmol/l, compared to 53% of white females.[18] On average, African Americans have higher HDL cholesterol levels compared to whites, a difference which is more marked among women. The prevalence of cigarette smoking is greater among African American males (33% *v* 27%) than in white men, whereas fewer African American females smoke compared to white American women.[18] Obesity is an emerging problem among African Americans especially in women, as approximately 50% of African American women are reported to be overweight, compared to 33% of white American women.[18] Closely linked to the prevalence of obesity is a low prevalence of self-reported regular physical activity. Approximately 65% of African Americans lead a sedentary lifestyle compared to about 56% of whites.[18] Furthermore, the prevalence of diabetes in African Americans is higher than in whites, as demonstrated by NHANES II conducted from 1976 to 1980 in which African Americans aged 20–74 years showed a prevalence of type 2 diabetes of 9·9% compared to 6% in white Americans.[18] Furthermore, the rate of type 2 diabetes is increasing faster among African Americans than among whites, especially in women, as it is closely tied to the development of obesity.[18] Although elevated levels of Lp(a) are found more often in African Americans than whites, whether or not elevated Lp(a) levels are related to an increased CHD risk among African Americans is unclear.[118] However, even after consideration of "biomedical" differences in conventional risk factor prevalence such as hypertension, smoking, and obesity, other factors are likely to play a role in slower decline in CVD rates which has been observed among blacks. Differences in socioeconomic status between African American and whites translate into decreased access to medical therapies and hospital services and results in the performance of fewer diagnostic tests and lower rates of coronary revascularization procedures.[119,120]

Influential risk factors

Black and white differences in CVD mortality appear to be largely due to differences in hypertension prevalence. However, late onset diabetes is an increasing problem among African Americans due to the increase in obesity. Even so, at least 30% of the excess CHD mortality between blacks and whites can be accounted for by differences in socioeconomic status, and these socioeconomic differentials lead to less access to healthcare services and acceptance of preventive strategies.[120]

Geographical variations

Early investigators noted high stroke mortality rates among black Americans in the Southeastern coastal states. By late 1980s, this "stroke belt" had dissipated in the Southeastern coastal areas and shifted to the Midwest regions of the Mississippi and Ohio river valleys.[121] CHD mortality has shown a similar westward shift to the so called coronary valley. The increased CVD mortality among blacks has been mainly confined to the Southern states (Mississippi river valley). Although changes in regional profile of risk factors, local environment, and migration pattern may have played a role, recent economic shifts in these areas may be the principal reason for changes in disease rates.[122] Whereas Southeastern coastal areas have undergone considerable economic development, the more westwardly regions have

not kept pace.[124] In Mississippi, one of the most economically and educationally disadvantaged US states, CVD mortality has risen among African Americans over the past two decades while among whites there has been a decline.[123] Similar patterns are also observed in the Northeastern states and the Midwest.[124,125]

Special approaches to prevention/treatment

The rates of CHD among blacks in Africa are relatively low compared to the rates in most Western countries. With urbanization, however, both within Africa and among migrant Africans to the West Indies and the USA, the rates of CVD are comparable to or higher than the rates of most Western countries. As in other populations, conventional CVD risk factors remain important, but the dominant CVD risk factor among people of African origin is hypertension. Special efforts at detection, prevention, and treatment of hypertension, both through lifestyle changes and appropriate pharmacologic therapy, are necessary. In the USA, the socioeconomic disparity of this population results in enhanced disease burden. This black–white differential in disease rates, risk factors, and access to medical treatments necessitates that specific prevention strategies be initiated in this group. Such strategies include primary prevention programs to prevent unhealthy lifestyle behaviors such as poor dietary practices and cigarette smoking. As these risk factors are closely tied to low SES, other factors besides "biomedical" ones must be targeted. Health care providers must ensure equal access to healthcare services especially among the lower socioeconomic status black population. However, in order to overcome the larger differential in socioeconomic status between African Americans and whites, overall changes in social policy are required at the national level.

Studies of multiple ethnic groups

Studies of diverse ethnic populations who reside in a single country and hence are exposed to a similar environment indicate that the pattern of CHD mortality between these groups initially resembles that of their home country. However, through the process of acculturation, prolonged exposure to new environmental factors results in similarities in CVD risk factors and trends within multiethnic populations. A study of multiple ethnic groups in the US revealed that CVD mortality rates were highest among African Americans, followed by whites, and Hispanics.[126] By contrast Japanese, Chinese, Koreans and Filipinos had much lower CHD mortality rates. Another study conducted in

Table 21.7 Summary of disease rates by ethnic group in North America[a]

USA[b]	White Caucasian	Japanese	Black African	Hispanic	Aboriginal
CHD mortality per 100 000 in North America	M 230 F 95	M 81 F 38	M 222 F 120	M 112 F 52	124
CBVD mortality per 100 000 in North America	M 41 F 33	M 25 F 33	M 102 F 83	M 31 F 25	40
CVD prevalence (aged 35–75 yr)	7·5%	3%	8%	4%	4%
CHD incidence per 1000 (65–74 yr)	M 26 F 8	M 11	M 16 F 13	M 14 F 14	M 7 F 12
CBVD incidence per 1000 (65–74 yr)	M 14 F 6	M 8	M 12 F 16	M 8 F 3	M 15 F 8

Canada	White Caucasian	Chinese	South Asians	Aboriginal
CHD mortality per 100 000[c]	M 320 F 110	M 107 F 40	M 320 F 144	M 320 F 176[d]
CBVD mortality per 100 000[c]	M 49 F 35	M 46 F 42	M 47 F 39	M 71 F 67
CVD prevalence (aged 35–75 yr)[e]	5·4%	2·4%	10·7%	17%

[a] Note that disease rates will vary by study. This table provides a useful but approximate comparison between ethnic groups.

[c] Age (35–74 yr) standardized death rates per 100 000.
[d] Estimated from Mao *et al*, 1992.
[e] From the Study of Health Assessment and Risk in Ethnic Groups.

California between 1985 and 1990 compared CHD and CBVD death rates in six ethnic groups. Once again, African American men and women in all age groups were found to have the highest CVD death rates. Hispanics, Chinese, and Japanese had much lower CVD rates, although the CBVD deaths were proportionally a more important cause of death among the Chinese and Japanese. Furthermore, a study that compared the rates of hospitalization for CHD among Asian Americans compared to Americans in Northern California revealed that the risk of hospitalization for CHD was the lowest among the Chinese Americans (0·6), and the highest among the South Asians (3·7, $P < 0{\cdot}001$).[126] Recent data from the United Kingdom (UK) reveals that although the CHD mortality rates were approximately 43% higher among South Asian men and women compared to the general UK population (ASMR men 282/100 000, women 89/100 000), among South Asians a decline of 26% in men and 18% in women in the CHD rates occurred.[127] This is in keeping with a decline in CHD mortality in the UK as a whole over the past decade. In Canada, an analysis of the Canadian national mortality database of South Asians, Chinese and Canadians of European origin (EU), demonstrated that the ASMR per 100 000 for CHD in South Asians (M 320, F 144) was similar compared to those of EU origin (M 320, F 110), yet was much higher than Chinese (M 107, F 40). Furthermore, a significant decline in CHD death rates between 1979–83 and 1989–93 was observed in all groups, with the greatest declines being apparent among South Asian men and women compared to EU and Chinese respectively (M 22%, 13%, and 5·4%, F 6%, 4%, and 2%)[49] (Table 21.7). Furthermore, in Canada the inverse relationship between mortality and socioeconomic status is observed in European Canadians, but not in South Asians and Chinese. This raises the issue of whether this relationship is acquired within societies and therefore is potentially preventable/modifiable.

Conclusions

CVD accounts for the largest percentage of deaths worldwide. To date, recognition and modification of the major CVD risk factors have led to declines in CVD rates in most Western countries, although these declines have lagged behind in most non-white populations. Socioeconomic development, urbanization, and increasing life expectancy have led to a progressive rise in the CVD rates in developing countries such as India and China.

It is clear that elevated serum cholesterol, elevated blood pressure, cigarette smoking, and glucose intolerance are the major risk factors for CHD and CBVD in most populations. However, the prevalence of these factors and the strength of association of these factors to CVD vary between ethnic groups. Furthermore, other risk or protective factors (levels of endogenous fibrinolysis, dietary factors such as flavonoids and antioxidants) probably exist. Identification of these factors is important so that new approaches to prevention of CVD in these populations may be developed. Research into ethnic populations who suffer adverse glucose and lipid changes upon urbanization (that is, Hispanics, Aboriginal, and South Asians) should be a priority, as a greater proportion of these groups are adopting urban lifestyles which are associated with observed increases in CVD rates. Furthermore, in developed countries, research into reasons for social disparity and its impact on the distribution of CVD risk factors among ethnic groups must be continued so that specific interventions may be developed to reduce the adoption of unhealthy lifestyle behaviors, and barriers to healthcare services may be reduced. Ultimately all of this information will lead to special strategies for prevention which may be tailored to ethnic populations, and generate important areas for future study.

22 The fetal origins of coronary heart disease

David JP Barker

Hitherto the search for the causes of coronary heart disease (CHD), and the way to prevent it, has been guided by a "destructive" model. The principal causes to be identified are thought to act in adult life and to accelerate destructive processes, for example the formation of atheroma, rise in blood pressure, and loss of glucose tolerance. This model, however, has had limited success. Obesity, cigarette smoking, and psychosocial stress have been implicated, and evidence on dietary fat has accumulated to the point where a public health policy of reduced intake is prudent, if not proven. The effects of modifying adult lifestyle, when formally tested in randomized trials have, however, been disappointingly small.[1] The model has proved incapable of answering important questions. For example, in Western countries the steep increase in the disease has been associated with rising prosperity, so why do the poorest people, and those living in the poorest parts of these countries, have the highest rates?[2]

One explanation for our failure to understand and prevent rising epidemics of CHD is that people are heterogeneous in their responses to environmental influences. Smoking, for example, is harmful to some people but not others. Some statisticians argue that we therefore need much larger studies to overcome this, while geneticists argue that the heterogeneity results from genes as yet unknown. There is, however, another way forward which is to examine the biologic basis of the differences between individuals. The recent discovery that people who develop CHD grew differently to other people during fetal life, infancy, and childhood encourages this view,[3] and has led to a new "developmental" model for the disease.[4,5]

Growth and CHD

Figure 22.1 shows the growth of 357 boys who in later life were either admitted to hospital with CHD or died from it.[3] They belong to a cohort of 4630 men who were born in Helsinki, and their growth is expressed as Z-scores. The Z-score for the cohort is set at zero, and a boy maintaining a steady position as large or small in relation to other boys would follow a horizontal path on the figure. Boys who later developed CHD, however, were small at birth, remained small in infancy but had accelerated gain in weight and body mass index (BMI) thereafter. In contrast, their heights remained below average. Table 22.1 shows hazard ratios for CHD according to size at birth. The hazard ratios fall with increasing birthweight and, more strongly, with increasing ponderal index (birthweight/length^3), a measure of thinness at birth. These trends were found in babies born at term or prematurely and therefore reflect slow intrauterine growth. Table 22.2 shows that the hazard ratios also fell with increasing weight, height, and BMI at age 1 year. Small size at this age predicts CHD independently of size at birth. In a simultaneous analysis with birthweight the hazard ratio associated with each unit decrease in Z-score for weight between birth and 1 year is 1·21 (95% CI 1·08–1·36, $P = 0·001$).

Figure 22.1 Growth of 357 boys who later developed CHD in a cohort of 4630 boys born in Helsinki.[3] BMI, body mass index; CHD, coronary heart disease.

The association between CHD and small size at birth has been shown in studies in Europe, North America, and India.[6–10] The association with poor weight gain in infancy was first shown in Hertfordshire,[6] and confirmed in Helsinki:[3] the strength of the association being similar in the two studies. The association with rapid childhood weight gain was first shown in a study of an older cohort of men

Abbreviation: CHD, coronary heart disease

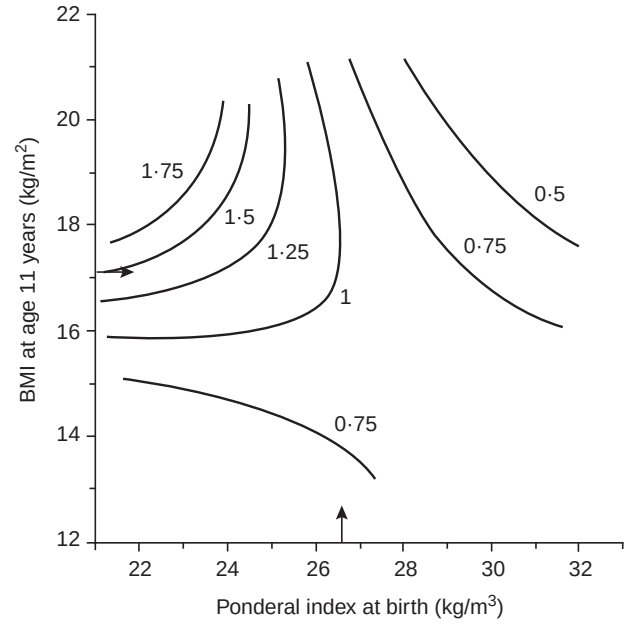

Figure 22.2 Hazard ratios for CHD (coronary heart disease) according to ponderal index at birth and BMI (body mass index) at 11 years. Arrows indicate average values: lines join points with the same hazard ratios.[3]

born in Helsinki,[11] while the association with low rates of height growth is consistent with the known association between the disease and short adult stature in men.[12]

Figure 22.2, based on the same data used in Figure 22.1, shows the combined effects of ponderal index at birth and BMI in childhood in the Helsinki cohort.[3] The figure uses BMI at age 11 years, but BMI at ages around this gives similar results. The lines on the figure join points with the same hazard ratios. For example, the line for the highest ratio, 1·75, is associated with low ponderal index at birth but above average BMI in childhood. Boys who had a low ponderal index at birth increased their risk of CHD if they attained even average BMI in childhood. In contrast, among boys with a high ponderal index, no increased risk was associated with a high childhood BMI. The interaction between ponderal index at birth and BMI in childhood is strongly statistically significant ($P < 0{\cdot}001$). Findings among girls are similar, and again the risk of CHD is determined more by the tempo of weight gain than the body size attained.[13]

Table 22.3 is taken from the total Helsinki cohort which comprises 15 846 men and women of whom 13 517 had their BMI recorded at 11 years of age.[3,11,13] It is based on 1235 patients who were admitted to hospital or died from CHD, and 480 patients who died from the disease. It shows hazard ratios according to birthweight and quarters of BMI at age 11 years. The risk of disease falls with increasing birthweight and rises with increasing BMI. The pattern is similar in the two sexes. The hazard ratios for admissions and deaths are 0·80 (95% CI 0·72–0·90) for each kilogram

Table 22.3 Hazard ratios (95% CI) for CHD according to birthweight and BMI at 11 years: 13 517 men and women born 1924 to 1944

Birthweight (kg)	BMI at 11 years (kg/m^2)

increase in birthweight and 1·06 (95% CI 1·03–1·10) for each kg/m^2 increase in BMI at age 11 years. The hazard ratios for deaths alone are 0·83 (95% CI 0·69–0·99) and 1·10 (95% CI 1·04–1·16).

Growth and hypertension and type 2 diabetes

There is now a substantial body of evidence showing that people who were small at birth remain biologically different to people who were larger. The differences include an increased susceptibility to hypertension and type 2 diabetes, two disorders closely linked to CHD.[14–17] Table 22.4 is based on 698 patients being treated for type 2 diabetes and 2997 patients being treated for hypertension. It again shows odds ratios according to birthweight and quarters of BMI at age 11 years. The two disorders are associated with the same general pattern of growth as CHD. The risks for each disease fall with increasing birthweight and rise with increasing BMI. The odds ratio for type 2 diabetes is 0·67 (95% CI 0·58–0·79) for each kilogram increase in birthweight and

Table 22.4 Odds ratios (95% CI) for hypertension and type 2 diabetes according to birthweight and BMI at 11 years: 13 517 men and women born 1924 to 1944[3,11,13]

>4·0	1·0	1·9 (1·1–3·1)	1·0 (0·6–1·7)	1.7 (1.1–2.8)

Abbreviation: BMI, body mass index

1·18 (95% CI 1·13–1·23) for each kg/m^2 increase in BMI at age 11 years. The corresponding figures for hypertension are 0·77 (95% CI 0·71–0·84) and 1·07 (95% CI 1·04–1·09). Similarly to CHD the risk of disease is determined not only by the absolute value of BMI in childhood but also by the combination of body size at birth and during childhood.[15,17] It is the tempo of growth as well as the attained body size that determine risk.

Associations between low birthweight and hypertension and type 2 diabetes have been found in other studies.[14–17] There is also a substantial literature showing that birthweight is associated with differences in blood pressure and insulin secretion within the normal range.[14,18,19] These differences are found in children and adults but they tend to be small. For example, a 1 kg difference in birthweight is associated with around 1–2 mmHg difference in systolic pressure.[19] This contrasts with the large effects on hypertension. A possible explanation for this is that, following an intrauterine lesion, regulatory mechanisms may maintain homeostasis for many years until further damage, owing to age, obesity, or other influences, initiates a self-perpetuating cycle of progressive functional loss.[20] Brenner has proposed such a model for the development of hypertension following reduced nephron numbers at birth, a known correlate of low birth weight.[20]

Biologic mechanisms

The association between altered growth and CHD has led to the suggestion that the disease may originate in two phenomena associated with development – "developmental, or phenotypic plasticity" and "compensatory growth". Phenotypic plasticity is the phenomenon whereby one genotype gives rise to a range of different physiologic or morphologic states in response to different environmental conditions during development.[21,22] Such gene–environment interactions are ubiquitous in development. Their existence is demonstrated by the numerous experiments showing that minor alterations to the diets of pregnant animals, which may not even change their offspring's body size at birth, can produce lasting changes in their physiology and metabolism – including altered blood pressure and glucose/insulin and lipid metabolism.[23,24] The evolutionary benefit of phenotypic plasticity is that, in a changing environment, it enables the production of phenotypes that are better matched to their environment than would be possible if one genotype produced the same phenotype in all environments.[22] When undernutrition during development is followed by improved nutrition many animals stage accelerated or "compensatory" growth in weight or length. This restores the animal's body size but may have long-term costs which include reduced life span.[25]

There are several possible mechanisms by which reduced fetal and infant growth followed by accelerated weight gain in childhood may lead to CHD. Babies who are thin at birth lack muscle, a deficiency that will persist as the critical period for muscle growth is around 30 weeks *in utero*, and there is little cell replication after birth.[26] If they develop a high BMI in childhood, they may have a disproportionately high fat mass. This may be associated with the development of insulin resistance, as children and adults who had low birthweight but are currently heavy are insulin resistant.[18,27,28]

Small babies have reduced numbers of nephrons.[20,29] It has been suggested that this leads to hyperperfusion of each nephron and resulting glomerular sclerosis, further nephron death, and a cycle of increasing blood pressure and nephron death. This may be exacerbated if accelerated growth increases the degree of hyperperfusion. This framework fits with the hypothesis that essential hypertension is a disorder of growth with two separate mechanisms, a growth-promoting process in childhood and a self-perpetuating mechanism in adult life.[30]

People who were small at birth also have different vascular structure. One aspect of this is that they have reduced elastin in their larger arteries as a consequence, it is thought, of the hemodynamic changes that accompany growth retardation *in utero*.[31] Elastin is laid down *in utero* and during infancy and thereafter turns over slowly. Reduced elastin leads to less compliant, "stiffer" arteries and to a raised pulse pressure. The gradual loss of elastin, and its replacement with collagen that accompanies aging, tends to amplify the increase in pulse pressure.[31]

The existence of such self-perpetuating cycles, initiated *in utero*, but triggered by aging, obesity, or other influences in later life, would explain the small effects of birth size on blood pressure in the normal population, but its large effects on blood pressure in people with hypertension. Studies in South Carolina showed that hypertensive patients with low birthweight more often require second-line therapy, with calcium-channel blocking agents or ACE inhibitors, as opposed to first-line therapy with diuretics or β blocking agents.[32] The suggestion that among hypertensive patients those with the lowest birthweights have the highest blood pressures has been confirmed in the Helsinki cohort (unpublished).

Findings in Hertfordshire suggest that one of the mechanisms linking poor weight gain in infancy with CHD is altered liver function, reflected in raised serum concentrations of total and low density lipoprotein cholesterol, and raised plasma fibrinogen concentrations.[33,34] Unlike organs such as the kidney, the liver remains "plastic" during its development until the age of around 5 years. Its function may be permanently changed by influences that affect its early growth.[35–37] Support for an important role for liver development in the early pathogenesis of CHD comes from findings in Sheffield.[38] Among men and women, reduced abdominal circumference at birth a measure that reflects reduced liver size, gave stronger predictions of later serum

cholesterol and plasma fibrinogen than any other measure of body size at birth.

Responses to adult living standards

Observations on animals show that the environment during development permanently changes not only the body's structure and function but also its responses to environmental influences encountered in later life.[21] Men who had low birthweight are more vulnerable to developing CHD and type 2 diabetes if they become overweight.[8,17] Table 22.5 shows the effect of low income in adult life on CHD occurrence among men in Helsinki.[39] As expected, men who had a low taxable income had higher rates of the disease.[2,40,41] There is no known explanation for this and it is a major component of the social inequalities in health in Western countries. The effect of low income, however, is confined to men who had slow fetal growth and were thin at birth, defined by a ponderal index less than 26 kg/m^3. Men who were not thin at birth were resilient to the effects of low income on CHD, so that there was a statistically significant interaction between the effects of fetal growth and adult income.

Table 22.5 Hazard ratios (95% CI) for CHD according to ponderal index (kg/m^3) at birth and taxable income in adult life

Household income 1000 marks (pounds sterling) per year	Ponderal index ≤26.0 (n = 1475)	Ponderal index >26.0 (n = 2154)
>140 (15 700)	1·00	1·19 (0·65–2·19)
111–140 (15 700)	1·54 (0·83–2·87)	1·42 (0·78–2·57)
96–110 (12 400)	1·07 (0·51–2·22)	1·66 (0·90–3·07)
76–95 (10 700)	2·07 (1·13–3·79)	1·44 (0·79–2·62)
≤75 (8400)	2·58 (1·45–4·60)	1·37 (0·75–2·51)
P for trend	<0·001	0·75

P for interaction between the effects of ponderal index at birth and income = 0·005.
Abbreviation: CHD, coronary heart disease

One explanation of these findings emphasizes the psychosocial consequences of a low position in the social hierarchy, as indicated by low income and social class, and suggests that perceptions of low social status and lack of success lead to changes in neuroendocrine pathways and hence to disease.[42] The findings in Helsinki seem consistent with this. People who are small at birth are known to have persisting alterations in responses to stress, including raised serum cortisol concentrations.[43] Rapid childhood weight gain could exacerbate these effects.

Strength of effects

The associations between slow fetal, infant, and childhood growth and later CHD are strong and graded. Men and women in the Helsinki cohort who had birthweights above 4 kg and whose body mass index at 11 years was in the lowest quarter, had around half the risk of CHD, type 2 diabetes, and hypertension when compared with people who had birthweights below 3 kg but whose BMI was in the highest quarter (Tables 22.3 and 22.4). Boys who at birth had a ponderal index above 26 kg/m^3 and who at 1 year of age were above the cohort average for BMI (17·7 kg/m^2) and height (76·2 cm) were at half the risk of developing CHD before the age of 65 years.[3] Such findings confirm the strong effects of early growth on later disease.

Statements such as, "Low birthweight explains only a small proportion of diabetes",[44] are not merely statistically incorrect but misrepresent biology in two ways. First, birthweight is an inadequate description of those phenotypic characteristics of a baby that determine its long-term health.[5] One commentator has pointed out that, "Birthweight and ponderal index (as well as body mass index) are crude measures of how fetal nutrition has affected body composition, so the true size of the effect of fetal growth on later disease is hard to measure."[45] Furthermore, the wartime famine in the Netherlands produced lifelong insulin resistance in babies who were *in utero* at the time with little alteration in birthweight.[46]

The second point has been described already. The effect of a high body mass in childhood is conditioned by size at birth (Figure 22.2). The effect of poor living standards in adult life is conditioned by size at birth (Table 22.5). The effects of any single influence cannot therefore be quantified as "small proportion" or "large proportion" of disease. It depends on the path of development that preceded it. The pathogenesis of CHD or type 2 diabetes cannot be understood within a model in which risks associated with adverse influences at different stages of life add to each other.[47] Rather the consequences of adverse influences depend on events at earlier critical stages of development.[3] This embodies the concept of developmental "switches" triggered by the environment.[21] The effects of any particular birthweight on disease will depend not only on the subsequent path of development but also on the path of growth that led to that birthweight. The same weight can be attained by many different paths of fetal growth and each is likely to be accompanied by different gene–environment interactions, though this remains to be demonstrated.[48]

Mothers and babies today

Given the body of evidence showing that CHD, and the related disorders stroke, hypertension, and type 2 diabetes, originate through undernutrition and other adverse

influences *in utero*, followed by accelerated weight gain thereafter, protecting the nutrition and health of young women and their babies must be part of any effective strategy for preventing these diseases. The so-called "fetal origins" hypothesis resulted from studies of the geographical association between CHD and poor living standards in England and Wales, and the realization that a poor intrauterine environment played a major role in this association.[49] Areas of the country with high coronary mortality are characterized historically by poor maternal nutrition and health, reflected in high maternal and neonatal mortality.[50]

As yet we do not know the impact of maternal nutrition on fetal development.[51] The relatively disappointing effects of dietary interventions in pregnancy on birthweight in humans have led to the erroneous view that fetal nutrition is little affected by maternal nutrition.[48] It is becoming clear, however, that the concept of maternal nutrition must be extended beyond the mother's diet in pregnancy to include her body composition and metabolism both during pregnancy and at the time of conception.[51–55] Moreover, birthweight is an inadequate summary measure of fetal experience, and we need a more sophisticated view of optimal fetal development, which takes account of the long-term sequelae of fetal responses to undernutrition. If we are to protect babies, we must also protect girls in childhood and adolescence. Body composition is established by childhood growth, and obesity and eating habits are entrained during childhood and adolescence.

CHD epidemics

As Westernization improves the nutrition of undernourished populations, fetal nutrition improves more slowly than nutrition during childhood or adult life, because the fetus is linked to its mother by a long and precarious supply line that is partly established during the mother's fetal life. It may require more than one generation of improved nutrition before fetal growth responds, whereas child growth responds in one generation. During this phase of economic development, children who were small at birth undergo accelerated, compensatory growth. This is the path of growth that leads to CHD and, it seems, may generate the epidemics of the disease (Figure 22.1). As a consequence of phenotypic plasticity and the costs of compensatory growth, people who follow this path are permanently biologically different and at increased risk of CHD. They are also more vulnerable to the effects of poor living standards (Table 22.5), obesity, and other adverse influences in adult life.

Conclusion

This chapter outlines a new "developmental" model for the origins of CHD and the related disorders type 2 diabetes, hypertension, and stroke. The finding that people who develop these disorders have altered growth *in utero*, during infancy, and childhood provides a new starting point for research. This research, now being carried out in many countries, has two goals: preventing disease in the next generation and treating disease in the present one. The immediate prospect for prevention is through protecting infant growth and preventing accelerated weight gain in children made vulnerable to later disease by small size at birth and during infancy. Ultimately we need to optimize maternal diet and body composition before and during pregnancy. Despite current levels of nutrition in Western countries the nutrition of many fetuses and infants remains suboptimal, because the nutrients available are unbalanced or because their delivery is constrained by the long and vulnerable fetal supply line.[5,48] We need to know more about fetal responses to undernutrition; what they are; what genes underlie them; what induces them; how they leave a lasting mark upon the body; and how this gives rise to CHD.

23 Molecular genetics of cardiovascular disorders

AJ Marian, Robert Roberts

The sequencing of the human genome is likely to be a landmark study of millennium proportions. The implications for cardiology of knowing the sequence of the human genome are many, among which the most obvious is identifying the gene responsible for familial disorders. Abnormalities of the heart and blood vessels are the most common of human birth defects, occurring in about 1% of live births.[1,2] Genetic diagnosis and management are expected to be routinely incorporated into the practice of cardiology by the end of this decade.[3] Knowing the etiology and understanding the pathogenesis of genetic disorders is most likely to improve the diagnosis, prevention and treatment of those disorders, and in addition often provides fundamental insights into acquired disorders that simulate the phenotype. A good example is that of familial hypercholesterolemia, in which there is a defective receptor for cellular uptake of cholesterol.[4] This confirmed that cholesterol was a major factor in coronary artery disease and subsequently led to unraveling of the synthesis, transport and degradation of cholesterol. The standard treatment today for coronary artery disease, both familial and acquired, is the use of statins to lower the cholesterol. The identification of a gene responsible for disease and its associated network should provide new targets for which specific therapy can be developed to treat the acquired form of the disease. It must be emphasized that practically all genetic disorders have an environmental component, and the resulting phenotype is usually due to an interaction between the gene (genotype) and the environment (phenotype).[5] An obvious example of the importance of environmental factors is that of familial hypertrophic cardiomyopathy. This is a single gene disorder that is transmitted in an autosomal dominant fashion, giving rise to a phenotype of left ventricular hypertrophy.[6] The same genetic defect is present in the same abundance in the right ventricle, yet the disease is seldom manifested in the right ventricle. This would imply that the high pressure of the left ventricle is an important stimulus in the pathogenesis of the phenotype of hypertrophy. Genetic disorders are considered in three categories, namely, chromosomal abnormalities, single gene disorders and polygenic disorders. Chromosomal abnormalities are usually detected by the pediatric cardiologist while the infant is still very young. Examples of adult forms of chromosomal abnormality would be Turner's syndrome. In this discussion, emphasis will be on single gene disorders because we do not yet have much information on polygenic disorders; however, the future promise will be with polygenic disorders.

Mutations responsible for single gene disorders

Inherited diseases caused by an abnormality in a single gene are inherited in a predictable pattern termed mendelian transmission. Each individual has two copies of the gene, one from each parent, referred to as alleles. The odds of inheriting the mother's allele rather than the father's are by chance alone, that is, 50%. Genes are units of heredity that are passed on and transmitted independently to the next generation. The two genes, separated on different chromosomes, assort themselves independently through the process of crossover between chromosomes. The greater the distance between two loci, the more likely they are to be separated during genetic transmission. The same disease may be due to multiple mutations in the same gene (allele heterogeneity), or to a single or multiple mutation(s) in two or more genes (locus heterogeneity). It is important to bear in mind, however, that within any one family the gene and the mutations responsible for the disease are the same, and that only rarely would two genes be transmitted for the same disease. Mutations involving only a single nucleotide are known as point mutations and are responsible for 70% or more of all adult single gene disorders (Table 23.1). A point mutation may be due to substitution of one nucleotide for another (missense mutation); or it may change the amino acid to a stop signal which will truncate the protein (truncated mutant); or it may eliminate a stop signal so that the protein is elongated (elongated mutant). Nucleotides may be deleted or added, which will result in a different reading from left to right, and the gene may be read entirely differently, resulting in a non-functioning product (nonsense).

Patterns of inheritance of single gene disorders

Autosomal dominant disorders are so named because the disease occurs despite a mutation in only one of the alleles.

Table 23.1 Cardiac diseases with an identified genetic locus or gene Grade A1a

Cardiomyopathies	Chromosomal locus
Hypertrophic cardiomyopathy	1q3, 3p, 7q3, 11q11, 12q, 14q, 15q2, 19p3
Dilated cardiomyopathy without conduction defects	1q32, 6q1, 9q12, 10q24, 15q1, 2q31
Dilated cardiomyopathy with conduction defects	1q1, 3p22, 6q23
Arrhythmogenic right ventricular dysplasia	1q12, 2q32, 14q12, 14q23, 3p23
Mitochondrial cardiomyopathies	
	Mitochondrial DNA
Cardiac septal defects	
Holt–Oram syndrome	12q2
Di George syndrome	22q
Noonan syndrome	12q
Aortic diseases	
Aneurysms	11q23–24
Supravalvular aortic disease	9q
Marfan's syndrome	15q
Conduction disorder	
Familial heart block	19q13, 1q32
Ventricular arrhythmias	
Long QT Syndrome	3p21, 4q24, 7q35, 11p15, 21q22
Brugada syndrome	3p21
Idiopathic VT	3p21
Atrial arrhythmias	
WPW	7q3
Atrial fibrillation	9q

Males and females are equally affected, with about 50% of the offspring being expected to have the defective gene (Figure 23.1). The following features are characteristic of autosomal dominant inheritance: each affected individual has at least one affected parent; 50% of the offspring will have the defective gene; normal children of an affected individual bear only normal offspring; males and females are equally affected; both sexes are equally likely to transmit the abnormal allele to male and female offspring, and male to male transmission occurs; vertical transmission through successive generations occurs; and it is typical for autosomal dominant disorders to have a delayed age of onset and variable clinical expression. Autosomal dominant is the main form of inheritance in adult cardiovascular disorders, and examples would be familial hypertrophic cardiomyopathy (HCM) and long QT syndrome. Autosomal recessive inheritance, in contrast, requires both alleles to be defective and so both parents must have the defective gene. The following are characteristics: parents are clinically normal heterozygotes; alternate generations are affected, with no vertical transmission; both sexes are affected with equal frequency; and each offspring of heterozygous carriers has a 25% chance of being affected, a 50% chance of being an unaffected carrier and a 25% chance of inheriting only normal alleles. Examples of autosomal recessive disorders affecting the heart include Jervell and Lang-Nielson long QT syndrome and Pompe's disease.

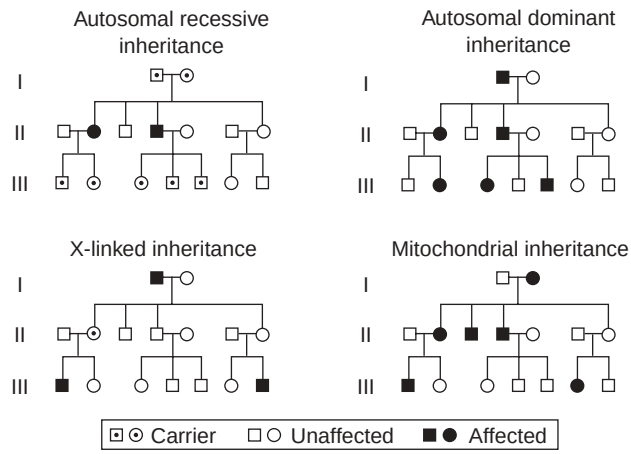

Figure 23.1 Mendelian patterns of inheritance

X-linked inherited disorders are caused by genes located on the X chromosome. Because a female has two X chromosomes, she may carry either one mutant allele or two mutant alleles; the trait may therefore display dominant or recessive expression. Because males have only a single X chromosome they are likely to display the full syndrome

whenever they inherit the abnormal gene from their mother. Hence, the terms X-linked dominant and X-linked recessive apply only to the expression of the gene in females. As males must pass on their Y chromosome to all male offspring, they cannot pass on mutant X alleles to their sons; therefore, no male to male transmission of X-linked disorders can occur. All females receiving a mutant X chromosome are thus carriers, and those who become affected clinically are usually homozygous for the defective gene. The characteristic features of X-linked inheritance are as follows: (1) no male to male transmission; (2) all daughters of affected males are carriers; (3) sons of carrier females have a 50% risk of being affected and daughters have a 50% chance of being carriers; (4) affected homozygous females occur only when an affected male and a carrier female have children; and (5) the pedigree pattern in X-linked recessive traits tends to be oblique because of the occurrence of the trait in the sons of normal carrier sisters of affected males. Examples of X-linked disorders of the heart include X-linked cardiomyopathy, Barth's syndrome and muscular dystrophy.

Another uncommon inheritance pattern is that of mitochondrial abnormalities. Mitochondria have their own genome of about 37 genes contained in 16K of DNA in a single circular chromosome. Most of the disorders involve oxidative phosphorylation and are usually evident very early in life. Phenotypes due to mitochondrial DNA mutations are transmitted by maternal inheritance only, as the ovum has mitochondria but the sperm does not. The characteristic features of mitochondrial disease inheritance include: equal frequency and severity of disease for each sex; transmission through females only, with offspring of affected males being unaffected; all offspring of affected females may be affected; extreme variability of expression of disease within a family; phenotypes may be age dependent; and organ mosaicism is common. An example of mitochondrial inherited cardiac disease is the cardiomyopathy of Kearns–Sayre syndrome.

Polygenic inheritance of cardiac disease

Many important cardiac disorders are due not to a single gene but rather to several genes, which increases susceptibility to the disease; examples are hypertension and coronary artery disease. There is ample evidence from dizygotic and monozygotic twins, as well as endemic populations, to indicate that such diseases have a significant genetic predisposition,[7] owing to the inheritance of multiple genes. However, each gene may contribute less than 5% susceptibility to the phenotype, and thus most computer models for mapping and detecting genes require a much more dominant effect, such as in single gene disorders. There is a lack of mathematical models for detecting a 5% influence on a disease. It is highly likely that 20 or 30 genes contribute to the susceptibility of diseases such as atherosclerosis or hypertension. The small effect of any one gene requires a sample size of several thousand. The sequencing of the human genome in itself will accelerate finding the susceptible genes, but the recent hope for polygenic diseases is with the new chromosomal markers referred to as single nucleotide polymorphisms (SNP). The new markers (SNP) distributed throughout the human genome are present about every 1000 base pairs (bp), as opposed to conventional markers at every 10 million bp.[8] Thus, as the markers are so close they can detect even a 5% effect. This is still a formidable task, in that one must genotype for several hundred thousand markers, but the sample size can be less. Automation is now available for high throughput of SNP. It is hoped that some of the SNP represent mutations that alter susceptibility to polygenic diseases. The SNP will at the very least serve as signposts to map genes responsible for susceptibility to disease. The combination of technology for high-throughput genotyping of thousands of markers, together with high-throughput sequencing, may enable one to map and identify genes responsible for polygenic disorders. Several genes have been identified to add susceptibility to disorders such as hypertrophy and coronary artery disease, but primarily from association through case studies, which remain suspect until there is a proven causative relationship. Examples would be the DD allele of angiotensin-converting enzyme, which predisposes to hypertrophy and sudden death,[9] and alleles of fibrinogen that predispose to thrombosis.[10]

Family history and inherited cardiovascular disorders

Diseases that segregate in a particular family are identified from the family history. Obtaining a careful family history has not been a priority for the cardiologist and so represents an area not hitherto emphasized. Recognizing the importance of family history in single gene disorders, and also in family cluster disorders such as atherosclerosis and hypertension, must be at the fore-front of the history and physical examination. Certain ethnic groups may direct specific testing, such as for hemoglobinopathies in populations from the Mediterranean, or sickle cell disease in African Americans. The first individual to be recognized as having the disease is usually referred to as the proband. Once a proband is recognized, information should be collected on all first, second and third degree relatives. The information should include also medical problems, pregnancies, and information on deceased relatives. Frequently, it is important to pursue miscarriages, birth defects and other problems that might appear to be unrelated. A pedigree should be constructed to determine the pattern of inheritance, analogous to those shown in Figure 23.1.

Genetic counseling

Once it has been established that there is a familial disease it is important to provide information appropriate to the level of education of the individual or parents. Every attempt must be made to explain the disease, so that important issues are understood by the individual. An attempt must be made to outline the diagnosis, prognosis if known, and mode of transmission, together with a discussion of the psychological and social issues. It is also important in young couples to emphasize the mode of transmission and their chances of passing on the disease, as well as the availability of prenatal diagnosis if appropriate. The information must be provided in a non-judgmental and unbiased manner. The family must be able to make a decision with respect to their religious, social and cultural background. It is sometimes frustrating for the counselor but personal bias must be avoided. Sometimes the issues are extremely sensitive and the options must be presented with concern and compassion while still remaining non-directional.

Single gene cardiovascular disorders

Several cardiovascular disorders have been shown to have a familial basis. These diseases cover a wide spectrum, from structural defects such as familial atrial septal defects to functional defects such as long QT syndrome (Table 23.1). For most of these diseases the chromosomal location (locus) has been mapped but the gene has not yet been identified. However, diseases such as the cardiomyopathies, particularly hypertrophic cardiomyopathy, have undergone major investigations, with elucidation of the pathogenesis. Animal models of human familial HCM have been developed and therapies have been evaluated. There is considerable progress in the identification of genes responsible for ventricular arrhythmias, particularly the long QT and Brugada syndromes. It is still premature to manage these disorders based on their genetic etiology. This is partly because genetic screening is not available and the populations studied have not yet been adequately characterized to provide generalized approaches to treatment. A few of these disorders will be discussed to indicate progress in improving diagnosis, prevention and treatment. It also indicates the trends for the future, when most of these genes will be identified and data be available on the pathogenesis and prognosis as they relate to the specific molecular defects.

Long QT syndrome

Several mutations have been identified in the sodium or potassium channel genes responsible for long QT syndrome, which predisposes to ventricular arrhythmias and sudden death. The inherited form of long QT syndrome is caused by discrete mutations in genes that encode ion channels. Several mutations have been identified in the sodium channel gene *SCN5A*.[11–13] The long QT associated mutations in *SCN5A* are associated with increased sodium flux and prolong depolarization. The mechanism believed to be responsible for the arrhythmias is an imbalance between the inward and outward currents during the plateau of the action potential. Most of the mutations in the sodium channel appear to be gain of function. The pattern of inheritance is most frequently autosomal dominant, although a rare recessive form has also been identified.

Several mutations have also been noted in potassium channels, which reduce potassium flux through a loss of function.[12,14] These mutations appear to have a dominant negative effect. Rarely, the QT syndrome is inherited in an autosomal recessive manner and may be associated with deafness, such as in the Jervell and Lang-Nielsen syndrome. This led to the recognition that the inward potassium current is necessary for endolymph production in the inner ear.[15] There is extensive phenotypic variability among these various genes and mutations, and within the same family, in keeping with other genes, there are many modifiers yet to be recognized to properly interpret genotype/phenotype correlations.

Another form of cardiac channelopathy is idiopathic ventricular fibrillation. The electrocardiogram may be normal, although some individuals have an associated electrocardiographic abnormality that includes ST segment elevation V1–3 together with right bundle branch block, referred to as Brugada syndrome.[16–18] Mutations responsible for this disease have been linked to *SCN5A* with dominant inheritance. There is at present no proven mechanism for the ventricular arrhythmias; however, it is believed to be due to inhomogeneity between the epicardium and the endocardium during repolarization, which leads to reentry.

Genetic studies have led to improved treatment for some of these disorders. Patients with long QT syndrome due to mutations in *SCN5A* can be treated by sodium channel blockers such as mexelitine. These drugs block the mutant sodium channel's current and have been shown to be selective and effective. No specific treatment for long QT syndrome due to potassium channels has yet been identified, except for oral potassium supplementation and automatic indwelling defibrillators. It is expected that many more of these channelopathies will be identified, and it is reasonable to assume that most of the channels responsible for atrial and ventricular currents will be discovered through mutations. A locus for familial atrial fibrillation has been mapped to 10q32 but the gene has yet to be identified.[19] A gene responsible for an uncommon form of Wolff–Parkinson–White (WPW) syndrome was identified and shown to be *AMPK*.[20,21] Several mutations in *AMPK* have since been identified[22–24] as inducing WPW, which is associated with hypertrophic cardiomyopathy, conduction disorders and a high incidence of atrial fibrillation. It appears that *AMPK* induces abnormalities in glycogen which leads to all three phenotypes.

Familial hypertrophic cardiomyopathy

Clinical and pathological features of HCM

HCM is an autosomal dominant disease defined by cardiac hypertrophy in the absence of an increased external load (unexplained hypertrophy). Patients exhibit protean clinical manifestations, ranging from minimal or no symptoms to severe heart failure and sudden cardiac death (SCD). The clinical manifestations often do not develop until the third or fourth decades of life and the majority of patients are asymptomatic or mildly symptomatic. HCM is a relatively benign disease with an estimated annual mortality rate of <0·7% in the adult population.[25] However, SCD is often the first and tragic manifestation of HCM in the young.[26] HCM is the most common cause of SCD in young competitive athletes, accounting for approximately one third of all SCD cases.[26] The main pathological features of HCM include myocyte hypertrophy and disarray, interstitial fibrosis and, to a lesser extent, thickening of the media of intramural coronary arteries. Whereas hypertrophy and fibrosis are the common responses of the heart to all forms of injury, myocyte disarray is considered the pathological hallmark of HCM.[27] Cardiac hypertrophy and interstitial fibrosis are the major determinants of mortality and morbidity in HCM.[28–32] In those with mild or no cardiac hypertrophy, myocyte disarray is a major predictor of SCD.[33]

Molecular genetics

HCM is a genetic disease with an autosomal dominant mode of inheritance. A family history is present in approximately two thirds of all index cases (familial HCM) and the remainder are sporadic. Sporadic cases are also caused by genetic mutations, albeit *de novo*, and affected individuals transmit the mutation and disease to their offspring in the same patterns as familial cases. HCM usually is due to mutations in at least 10 contractile sarcomeric proteins (Table 23.2). Over 100 mutations in 10 genes have been identified.

Genotype/phenotype correlations

Genotype/phenotype correlation studies suggest that causal mutations affect the magnitude of cardiac hypertrophy and the risk of SCD (Figure 23.2). Mutations in β-MyHC are generally associated with an early onset and more extensive hypertrophy and a higher incidence of SCD.[34–36] In contrast, mutations in MyBP-C are associated with a low penetrance, relatively mild hypertrophy, late onset of clinical manifestations and a low incidence of SCD.[34–38] Mutations in cTnT are usually associated with a mild degree of hypertrophy but a high incidence of SCD and more extensive disarray.[33,39,40] Mutations in α tropomyosin are generally associated with a benign phenotype and mild left ventricular hypertrophy. However, a phenotype of mild hypertrophy and a high incidence of SCD also has been described.[41] Mutations in essential and regulatory myosin light chains have been associated with midcavity obstruction in HCM and skeletal myopathy in some,[42] but not in others.[43] Mutations in titin[44] and α actin[45–47] have been observed in a small number of families.

The results of genotype/phenotype correlation studies are subject to a large number of confounding factors, such as the small size of the families; the small number of families with identical mutations owing to the low frequency of each mutation; variability in the phenotypic expression in affected individuals within the same family or among families with identical mutations; the influence of modifier genes;[48] the influence of non-genetic factors; and, rarely, homozygosity for causal mutations and compound

Table 23.2 Causal genes for HCM: genes coding for sarcomeric proteins Grade A1a

Gene	Symbol	Locus	Frequency %	Mutations
β-Myosin heavy chain	*MYH7*	14q12	~35	>70, predominantly missense mutations
Myosin binding protein-C	*MYBPC3*	11p11·2	~20	>40, predominantly splice junction and insertion/deletion mutations
Cardiac troponin T	*TNNT2*	1q32	~20	>15, mostly missense
α-Tropomyosin	*TPM1*	15q22·1	~5	>5 missense mutations
Cardiac troponin I	*TNNI3*	19p13·2	~5	3 missense and 1 deletion mutations
Essential myosin light chain	*MYL3*	3p21·3	<5	2 missense mutations
Regulatory myosin light chain	*MYL2*	12q23-24·3	<5	7 missense and 1 truncation mutations
Cardiac α-actin	*ACTC*	15q11	<5	2 missense mutations
Titin	*TTN*	2q24·1	<5	1 missense mutation
α-Myosin heavy chain	*MYH6*	14q1	Rare	1 missense and 1 rearrangement mutation
Cardiac troponin C	*TNNC1*	3p21·3-3p14·3	Rare	1 missense mutation in a patient with HCM

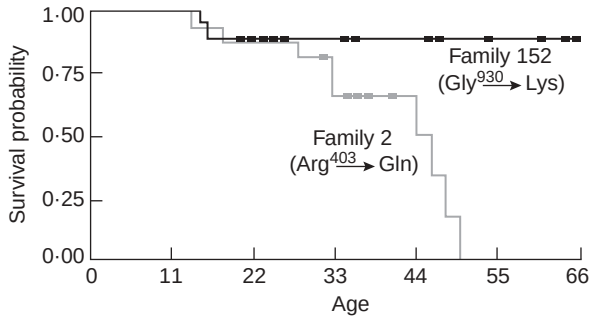

Figure 23.2 Stratification of risk according to mutation. Shown here are two different mutations in the β-MHC gene. The mutation in Family 152 is associated with essentially normal life span, whereas Family 2 has a mean life span of about 28 years. This emphasizes the potential prognostic significance of individual mutations.

mutations.[49–51] Correlations between the small number of patients studied suggest prognostic stratification by the mutations, but caution must be exercised until larger studies are performed[52] (Figure 23.2).

Pathogenesis of HCM

The initial defects induced by the mutant sarcomeric proteins are diverse. They comprise impaired actomyosin interaction and cardiac myocyte contractile performance, altered Ca^{2+} sensitivity, reduced ATPase activity, sarcomere dysgenesis, altered subcellular localization and altered stoichiometry of the sarcomeric protein.[53] However, despite the diversity of the initial defects, the final phenotype is hypertrophy, fibrosis and disarray. We have proposed that a common link between the initial defect and the final phenotype is impaired cardiac myocyte contractile function,[54] which increases myocyte stress and leads to the activation of stress-responsive intracellular signaling kinases and trophic factors. Release of trophic factors activates the transcription machinery, leading to cardiac hypertrophy, interstitial fibrosis and other histological and clinical phenotypes of HCM.[54] Accordingly, myocyte hypertrophy and disarray, interstitial fibrosis and thickening of the media of intramural coronary arteries are considered "secondary" phenotypes and thus potentially reversible. In addition, the severity of the phenotype is affected by factors other than the causal genes, that is, the environmental factors and the modifier genes. In support of this hypothesis, we have shown that stress-responsive signaling kinases ERK1 and 2 are activated in the heart of transgenic animal models of HCM, and that cardiac hypertrophy and interstitial fibrosis could be reversed or attenuated by pharmacologic interventions discussed later.

Dilated cardiomyopathy (DCM)

Genetics of dilated cardiomyopathy

Dilated cardiomyopathy (DCM) is a primary disease of the myocardium, diagnosed by a decreased left ventricular ejection fraction (<0·45) and an increased left ventricular cavity size (end diastolic diameter $>2{\cdot}7\,cm/m^2$). Clinical features of DCM are those of heart failure, including syncope, cardiac arrhythmias and SCD. The etiology of DCM is diverse and a family history is present in approximately half of all index cases.[55–57] In such cases DCM is therefore considered a familial disease. The remainder have no family history and thus DCM is considered sporadic. A significant number of patients with DCM and their affected relatives are asymptomatic and are mistakenly considered normal, unless subjected to clinical and genetic investigation.[55] Familial DCM is commonly inherited as an autosomal dominant disease[55] which clinically manifests during the third and fourth decades of life. An X-linked and an autosomal recessive pattern of inheritance also occur, which often manifest early and often during the second decade of life. The mode of transmission is matrilineal when DCM occurs because of mutations in the mitochondrial DNA. DCM also occurs in conjunction with the triplet repeat syndromes and follows their pattern of inheritance.

DCM is an extremely heterogeneous disease (Table 23.3). Despite the diversity of the causal genes and mutations, the vast majority of them encode for proteins that are either components of the myocardial cytoskeleton or support it. Therefore, DCM is considered a disease of cytoskeletal proteins. Given the diversity of causal genes and mutations, it is not surprising that each causal gene accounts for a very small fraction of familial DCM and that none predominates. Collectively, the mapped genes account for approximately half of all familial DCM cases, and in a significant number of families although the chromosomal loci have been mapped, the causal genes remain unidentified. The gene encoding cardiac α actin (*ACTC*) was the first causal gene identified for familial DCM, with an autosomal dominant mode of inheritance.[58] The authors proposed that defects in the cytoskeletal proteins could, by impairing the transmission of contractile force, cause DCM.[58] Recently, mutations in two additional components of the sarcomere, namely the β myosin heavy chain and cardiac troponin T, were found in patients with DCM.[59] As discussed earlier, mutations in *ACTC*, *MYH7* and *TNNT2* are also known to cause HCM. Thus, these findings suggest that the topography of the mutations within the sarcomeric proteins plays a significant role in determining the ensuing clinical phenotype. Mutations in cytoskeletal proteins δ sarcoglycan,[60] metavinculin and dystrophin[61] are also known to cause DCM. Mutations in α sarcoglycan (adhalin) cause an autosomal recessive form of DCM that occurs in conjunction with limb–girdle muscular dystrophy. An intriguing causal gene for familial DCM is the

Table 23.3 Genetic causes of dilated cardiomyopathy Grade A1a

Gene	Symbol	Locus	Frequency	Phenotypes
Cardiac α-actin	*ACTC*	15q11-14	Low	DCM or HCM, based on topography of the mutation and probably genetic background
β-Myosin heavy chain	*MYH7*	14q11-13	Low	DCM or HCM, based on topography of the mutation and probably genetic background
Cardiac troponin T	*TNNT2*	1q32	Low	DCM or HCM, based on topography of the mutation and probably genetic background
δ-Sarcoglycan	*SGCD*	5q33-34	Low	DCM
Dystrophin	*DMD*	Xp21	Low	X-linked DCM
Lamin A/C	*LMNA*	1p21.2	Low	DCM and conduction defect Emery–Driefus muscular dystrophy, lipodystrophy (Dunnigan variety)
Taffazin (G4.5)	*TAZ*	Xq28	Low	DCM, ventricular non-compaction, skeletal myopathy, mitochondrial abnormalities
Desmin	*DES*	2q35	Low	Desmin-related myopathies
αB-Crystallin	*CRYAB*	11q35	Low	Desmin-related myopathy
Desmoplakin	*DSP*	6p23-25	Low	Recessive DCM

?	?	10q21-23	?	DCM + MVP

lamin A/C gene,[62–64] which encodes a nuclear envelope protein. The observed phenotype resulting from mutations in the rod domain of lamin A/C is progressive conduction disease, atrial arrhythmias, heart failure and SCD. Finally, mutations in the intermediary filament desmin and its associated protein α/B crystallin have been identified in patients with DCM.[65–67] Often such mutations lead to a phenotype of cardiac and skeletal myopathy referred to as desmin-related myopathy.[66] Collectively, these findings suggest that mutations affecting the integrity of the cytoskeleton can cause DCM. Systematic genotype/phenotype studies are not yet available.

Pathogenesis of DCM

Mutations in cardiac α actin, β myosin heavy chain, cardiac troponin T and other cytoskeletal proteins impart a dominant-negative effect on transmission of the contractile force to the extracellular matrix proteins.[58] Mutations in the dystrophin gene lead to a decreased expression level of dystrophin, a major cytoskeletal protein in skeletal and cardiac muscles. Decreased expression of dystrophin impairs efficient mechanical coupling and myocyte shortening. In X-linked DCM, the severity of the clinical phenotype correlates inversely with the expression level of dystrophin. The pathogenesis of DCM resulting from mutations in desmin and α/B crystallin involves the deposition of desmin, and α/B crystallin aggregates in the myocardium. The molecular pathogenesis of DCM caused by mutations in lamin A/C or emerin remains largely unknown. It is likely that lamin A/C is also involved in maintaining the integrity of the cytoskeleton. The pathogenesis of cardiomyopathies in patients with the triplet repeats syndrome is also unclear. Expansion of the CTG (CUG in mRNA) repeats in the 3′ untranslated region of the myotonin protein kinase gene could lead to unstable mRNA and decreased expression of the protein. It is also possible that proteins that bind to CUG repeats may be necessary for proper transcription, splicing, translation and nuclear transport of mRNAs of cardiac genes.

Arrhythmogenic right ventricular dysplasia (ARVD)

ARVD is the primary abnormality of the myocardium, characterized by a progressive loss of myocytes, fatty infiltration and replacement fibrosis, which occur predominantly in the right ventricle.[68] ARVD, also named arrhythmogenic right ventricular cardiomyopathy, often manifests as ventricular arrhythmias originating from the right ventricle. A characteristic electrocardiographic pattern is the presence of ε wave,

and less characteristic findings are depolarization/repolarization abnormalities in the right precordial leads. The age of onset of the disease is variable but commonly ARVD manifests with minor arrhythmias during adolescence, progressing to serious ventricular arrhythmias during the third and fourth decade of life leading to SCD. In Italy, ARVD is a relatively common cause of SCD in the young.[69] Gradual fibrofatty infiltration of the myocardium leads to regional and global right ventricular dysfunction and, less frequently, left ventricle failure. In advanced stages both ventricles are involved and heart failure is the predominant manifestation.

Several loci for ARVD have been mapped, including loci on 14q23-q24 (ARVD1),[70] 1q42-q43 (ARVD2),[71] 14q12-q22 (ARVD3),[72] 2q32-q32·3 (ARVD4),[73] 3p23 (ARVD5)[74] and 10p14-p12 (ARVD6).[75] The causal gene for the ARVD2 locus on chromosome 1q42-q43 has been identified as the cardiac ryanodine receptor gene (*RYR2*).[76] Mutations in *RYR2* have been identified in four independent families with ARVD.[76] It is also likely that catecholaminergic (stress-induced) ventricular tachycardia, although it classically occurs in a structurally normal heart, is a phenotypic variant of ARVD, as mutations in *RYR2* have been identified in such patients.[77] Naxos disease, so named because it was first reported from the island of Naxos in Greece, is an autosomal recessive disorder characterized by ARVD, palmoplantar keratoderma and other ectodermal features, such as woolly hair.[78] Recently, a 2 bp deletion mutation in the plakoglobin gene, located on 17q21, was identified in patients with Naxos disease.[78]

Genetics of hypertension

Hypertension is among the top three or four most common diseases worldwide. It is an independent risk factor for cardiac morbidity and mortality and a major stimulus for cardiac hypertrophy, which itself significantly increases susceptibility for sudden cardiac death. Hypertension, as indicated previously, is primarily a polygenic disease. It is expected that there are several genes that increase susceptibility to developing hypertension. These genes interact with the environment, and the onset of hypertension is usually age dependent, with 20–30% of the population being hypertensive in their elderly years. Identification of the susceptibility genes remains an elusive goal and is likely to occupy most of the present decade. A recent study emphasizes the importance of identifying the genes responsible for hypertension. Geller and his associates[79] recently identified a family with early onset of hypertension. The disease segregates as a dominant mendelian disorder. A mutation was identified in the mineralocorticoid receptor. The patient had severe hypertension, decreased plasma renin activity, decreased serum aldosterone, and no other underlying cause for hypertension. The mutation was a missense in which leucine was substituted for serine at codon 810, and is in the domain of the receptor that binds to the hormone. Normally, 21-hydroxyl group steroids are necessary to activate this receptor. In contrast, the receptor with the mutation seems to activate itself and does not require 21-hydroxyl stimulation. The potent antagonist spironolactone, which normally would block mineralocorticoid activity in normal individuals, acts as an agonist in individuals with this mutation, causing hypertension and further activating mineralcorticoid activity. This is quite a drastic and unexpected change for the mutation not only to have a positive effect, but to change the receptor to respond to hormones and drugs in a manner opposite to normal. Another important observation was in pregnancy, in which about 6% of individuals develop hypertension and may proceed to pre-eclampsia. It was noted that progesterone, which normally does not activate the mineralcorticoid receptor, does so in individuals with the mutation. This has significant implications in pregnancy, as progesterone levels are normally increased 100-fold and thus women with this mutation would be expected to develop hypertension. Furthermore, treatment with spironolactone would increase the hypertension and may precipitate pre-eclampsia. Two of the carriers in this family had undergone pregnancies all complicated by hypertension. It is also of note that while pregnant, these women had a decreased serum potassium and aldosterone levels, in keeping with the expected abnormal response induced by the mutation. Although this is not one of the polygenic causes of hypertension, it emphasizes the pathogenetic mechanism involved and has clearly improved the treatment of this condition, which is particularly important in pregnancy. It is hoped that other mendelian disorders causing hypertension will be identified, as although they form a very small percentage of the etiology of hypertension compared to polygenic forms, they could have significant implications for prevention and treatment.[79]

Coronary artery disease

Although atherosclerosis is a polygenic disease, certain susceptible genes have been ascertained through association studies in populations enriched for coronary artery disease. The results of these studies are still regarded as preliminary until causation is proved. Nevertheless, these susceptibility genes have shed light on the pathogenesis and are likely to be incorporated into future genetic profiles for risk stratification and treatment. There are obviously several components to coronary artery disease, namely, lipids and coagulation factors. The list of potential candidate genes for coronary atherosclerosis is extensive (Table 23.4). Two examples, *ABCA1* and *CYBA*, are discussed briefly. Plasma levels of high density lipoprotein C (HDL-C) and its apolipoprotein A1 are under tight control of genetic factors, which are largely

Table 23.4 Selected candidate genes for coronary atherosclerosis and myocardial infarction Grade B3

Gene	Locus	Polymorphism	Allele	Function

Abbreviations: ACE, angiotensin-1 converting enzyme; AGT, angiotensinogen; AT1, angiotensin II receptor 1; CBS, cystathionine β synthase; CETP, cholesteryl ester transfer protein; eNOS, endothelial nitric oxide synthase; GpIIb-IIIa, glycoprotein IIb-IIIa; HDL, high density cholesterol; LCAT, lecithin cholesteryl acyltransferase; LDLr, low density lipoprotein receptor; LPL, lipoprotein lipase; MTHFR, methylenetetrahydrofolate reductase; PAI-1, plasminogen activator inhibitor-1; VLDL, very low density cholesterol

unknown. Mutations in the adenosine triphosphate (ATP) binding cassette transporter (*ABCA1*) gene in patients with Tangier disease[80] have very low plasma levels of HDL-C and apoA1 and an increased risk of coronary atherosclerosis. This suggests a major role for the ABCA1 protein in regulating plasma HDL-C and apoA1 levels and thus the risk of atherosclerosis. This notion is further supported by a recent observation of increased frequency of coronary artery disease in members of families with Tangier or familial hypoalphalipoproteinemia who are heterozygous for mutations in the *ABCA1* gene.[81]

Recent studies have implicated variants of *ABCA1* in susceptibility to coronary atherosclerosis in the general population.[81,82] We recently reported that a single nucleotide polymorphism (SNP) located in the promoter region of *ABCA1* was associated with increasing severity and progression of coronary atherosclerosis.[82] Subjects with the TT variant, which is associated with reduced promoter activity, had more severe coronary atherosclerosis than those with the CC genotype, and those with the CT genotype had an in-between risk.

A second example is the *CYBA* gene, which is involved in maintaining the delicate balance between oxidation and reduction (redox) in the vessel wall. *CYBA* codes for $p22^{phox}$ protein, which is a component of the plasma membrane-associated enzyme NADPH oxidase. NADPH oxidase is the most important source of superoxide anion, the precursor to a variety of potent oxidants, in intact vessel walls. $p22^{phox}$ in conjunction with gp91 forms a membrane-bound

heterodimeric protein referred to as flavocytochrome b_{558}. The latter is considered the redox center of the NADPH oxidase. The $p22^{phox}$ protein is essential for the assembly and activation of the NADPH oxidase and plays a major role in NADPH-dependent O_2^- production in the vessel wall.

CYBA is located on chromosome 16q24 and has several allelic variants, including a 242C/T transition that results in replacement of histidine by tyrosine at amino acid position 72 (H72Y), a potential heme binding site. We determined the association for the 242C/T variant with severity and progression of coronary atherosclerosis and response to treatment with a statin in a well characterized cohort of Lipoprotein Coronary Atherosclerosis Study (LCAS) patients.[83] We showed that in the placebo group, subjects with the mutation had three to fivefold greater loss in mean minimum lumen diameter (MLD) and lesion-specific MLD than those without. Progression was also more and regression less common in those with the mutation. These results suggest that variants of $p22^{phox}$ are involved in the progression of coronary atherosclerosis.

Genetics and future therapy

Once the gene responsible for a disease is identified, it is usually possible through genetic animal models to determine the function as well as the pathogenesis of the disease. Genetic animal models of human FHCM have been developed in both mice and rabbits.[84–86] In mice, expression of Arg 403, known to cause human FHCM, exhibited myocyte and myofibrillar disarray, impaired cardiac function and extensive fibrosis. However, there is very little hypertrophy. Expression of this same mutation Arg 403 in rabbits was associated with a phenotype that is virtually identical to that observed in human FHCM.[86] This may be because the rabbit has βMHC as the predominant myosin in the heart, just as is found in human myocardium, whereas the mouse heart has αMHC. In the transgenic rabbit there is myocyte disarray, impaired systolic and diastolic function, extensive interstitial fibrosis, and extensive septal and posterior wall hypertrophy. There is also a significant incidence of sudden death. Utilizing these two models, the pathogenesis of FHCM has been considerably elucidated. It does appear that impaired contractility due to the inherited defect in βMHC leads to impaired contractility,[54] which in turn is associated with disarray and upregulation of several growth factors that stimulate fibroblast proliferation, with increased matrix formation, myocyte hypertrophy and further disarray.[54] It has been shown that in human FHCM several growth factors are upregulated,[54] and the pathology is that of fibrosis and hypertrophy. As the fibrosis and hypertrophy are secondary phenotypes, it would imply that, with appropriate therapy, there could be attenuation, prevention or even regression of these phenotypes.

A single blinded placebo controlled study[87] was performed in the animal mouse model with 12 transgenic mice receiving placebo, 12 receiving losartan, and 12 controls. This study showed that, despite a fully developed phenotype of disarray and fibrosis, there was essentially a reversal of the phenotype to normal after about 6 weeks of therapy. The fibrosis in the treated group was similar to that in controls, along with improved cardiac function. Transforming growth factor β (TGFβ), which is known to be a stimulus of fibroblastic activity and collagen deposition, also returned to control levels. It is thus likely that TGFβ is a major mediator of fibrosis in the mouse. In the rabbit model, a similar single blinded placebo controlled study[88] was performed with simvastatin. After 12 weeks of therapy this model showed a 37% reduction in hypertrophy and fibrosis and a significant improvement in ventricular function. The mechanism whereby simvastatin induces regression of hypertrophy and fibrosis is most likely via the inhibition of isoprenylation of signaling proteins. This process is necessary to induce growth of the cardiac myocytes and/or fibroblasts. These studies are very exciting and provide compelling evidence for an appropriate clinical study in patients. We are even more excited about these results because both drugs are known to be safe, as they have been taken by millions of patients for other reasons. These animal models provide the potential to identify other targets for the development of new therapies, but clearly losartan and simvastatin can be evaluated in the near future. Studies are now under way in animals to determine whether it is possible to prevent the development of hypertrophy and fibrosis in the transgenic rabbit expressing βMYC. It is of note that one seldom sees FHCM in humans prior to puberty, and thus there is at least a 10–12 year window in those positive for the mutation in which one could, with appropriate therapy, prevent or modulate the rate of development of the phenotype of fibrosis and hypertrophy. There is also of course the possibility that one could inhibit the fibrosis separately, which would lead to more specific therapy for the treatment of the disease in humans. It is an example of how one can work from the bedside to the bench in identifying the gene, and then back to the bedside having developed therapies in animal models that can be evaluated in clinical trials.

A diagnostic test for preclinical FHCM derived from genetic animal models

We are very excited about a novel diagnostic means for the preclinical diagnosis of FHCM. In the transgenic rabbit model of human FHCM induced by expression of the Arg 403 mutation, tissue Doppler velocities of the myocardium were assessed. It was observed that rabbits positive for the mutation, and despite having no hypertrophy, exhibited impaired tissue Doppler velocities. These animals developed hypertrophy and the full phenotype, but not until several months

later.[89] Tissue Doppler velocities were evaluated in patients with FHCM, those positive for a mutation but without any clinical features, and controls:[90] 11 patients positive for mutations without hypertrophy or any other clinical phenotype exhibited decreased myocardial tissue velocity. We compared their findings with controls and patients with a clinical phenotype of FHCM. Tissue Doppler imaging had a sensitivity of 85% and specificity of 90% in individuals without other clinical findings. These findings have been confirmed by other investigators (personal communication) and hopefully will be used to initiate therapy for prevention, and possibly for screening of athletes. The combination of effective therapy in animal models and a non-invasive test for preclinical diagnosis in patients offers great promise for the future.

Key points

- In single gene disorders the phenotype is predominately due to the effect of a single gene. Other genes (modifier genes), together with environmental factors, interact to give the observed differences in the phenotype.
- Polygenetic disorders often have no predominant gene, but rather multiple genes interacting with the environment to give the phenotype.
- Single gene disorders exhibit mendelian patterns of inheritance and the genes can be mapped and identified utilizing two and three generation families.
- Familial hypertrophic cardiomyopathy is caused by more than 10 genes involving more than 150 mutations.
- Familial dilated cardiomyopathy: although several have been mapped only a few have been identified.
- Long QT syndrome and Brugada syndrome are present in either the sodium or the potassium channels.
- Wolff–Parkinson–White syndrome has so far been shown to be due to mutations in *AMPK* gene.
- A gene responsible for atrial fibrillation has been mapped to chromosome 10q32 but the gene has not yet been identified.
- Genetic animal models of human familial FHCM treated with losartan or simvastatin have had a reversal of the phenotype, including fibrosis and hypertrophy.
- Tissue Doppler echocardiography has been shown to diagnose FHCM in humans and in animal models prior to the development of cardiac hypertrophy and other features on the phenotype.

24 Cost effectiveness of prevention of cardiovascular disease

Daniel B Mark

Introduction

Medical care for cardiovascular disease is expensive. In the US, the total annual direct cost of caring for coronary heart disease, stroke, hypertension and heart failure patients is estimated to be $130 billion, with another $18·6 billion lost owing to the effects of these diseases on employment and productivity.[1] Although Canada, western Europe and many other industrialized countries spend less on medical care than the US, their incidence and prevalence of cardiovascular diseases are similar and their spending on this segment of the medical population as a proportion of all medical spending is comparable to that of the US. Because cardiovascular diseases are chronic, therapies are largely palliative rather than curative. Patients may live 20 or 30 years with these disorders, during which time they can experience numerous cardiovascular complications, often necessitating expensive hospitalizations and interventions.

In this context, it is easy to see why preventive medical care is appealing. By pre-empting the first manifestation of disease, the entire set of downstream consequences (with their attendant morbidity and cost) is also prevented. Because it is rarely (if ever) possible to know precisely which at-risk subject will develop clinically manifest disease, however, preventive therapies must be given to many in order to protect a few. Consequently, the number needed to treat to prevent one new case of cardiovascular disease is often quite large. Also, as preventive therapies must generally be used indefinitely, the associated lifetime treatment costs are often substantial. For this reason, the economic attractiveness (assessed as the cost per additional unit of medical benefit produced) of preventive therapies has been controversial.[2]

In an earlier chapter, Hlatky reviewed the basic principles of cost-effectiveness analysis (see Chapter 6). As he pointed out, cost effectiveness is a type of economic analysis that relates the extra benefits of a new strategy or therapy to the extra costs required to produce those benefits. Most commonly, such cost-effectiveness ratios are expressed as dollars (or other currency) required to add an extra life year (or a quality-adjusted life year) with the new therapy. In this context, an economically attractive ("cost effective") therapy is one that yields an extra life year for ≤$50 000, whereas an economically unattractive ("not cost effective") therapy is one that requires ≥$100 000 for every extra life year produced. (These benchmarks should not be interpreted dogmatically.[3]) For reasons reviewed in detail by Hlatky, the incremental effectiveness of a new therapy often has a much greater impact on its cost-effectiveness ratio than its incremental cost. Consequently, therapies where the number needed to treat to produce one extra unit of benefit (for example, one extra survivor, one extra coronary artery disease (CAD) free subject) is large may not be economically attractive at even a modest price per subject treated, whereas therapies that are very effective or which are applied to high-risk populations may be economically attractive at a substantially greater cost per subject.

Preventive therapies are now typically divided into those used in disease-free subjects to prevent the initial manifestation of disease (that is primary prevention) and those used to prevent complications or disease progression in patients with established disease (that is secondary prevention). In this chapter we will review what is known about the economics of both types of prevention for atherosclerotic coronary artery disease.

Cholesterol lowering

Primary prevention Grade A

Many observational studies (reviewed in Chapter 12) have established a strong dose–response relationship between cholesterol level and risk of coronary artery disease (CAD). These data suggest that therapies that reduce cholesterol the most should prevent the greatest number of coronary events. Trials evaluating the first generation of lipid-lowering agents (for example, Helsinki [gemfibrozil], LRC-CPPT [cholestyramine], and WHO [clofibrate]) yielded modest reductions in cholesterol (~10%) and produced equivocal clinical results. Given the limited clinical effectiveness of these agents, cost-effectiveness analyses indicated that cholesterol reduction using them in primary prevention was economically unattractive, although therapy targeted at high-risk subjects with multiple risk factors had a more favorable economic profile.[4] With HMG-CoA reductase inhibitors (statins), total and LDL

cholesterol reductions of 20–30% or more can be achieved, with a resulting decrease in all-cause mortality of 21%.[5] As a consequence, the cost effectiveness of preventive therapy with these agents appears more favorable.

There are two major primary prevention trials with statin therapy that have published economic data: the West of Scotland Coronary Prevention Study (WOSCOPS) and the Air Force/Texas Coronary Atherosclerosis Prevention Study (AFCAPS/TexCAPS). WOSCOPS randomized 4159 men between the ages of 45 and 65 without overt coronary disease who had LDL cholesterol levels ≥155 mg/dl to either pravastatin (40 mg/day) or placebo.[6] During the mean follow up of 4·9 years, pravastatin reduced the total cholesterol by 20% and decreased all-cause mortality by 22% ($P = 0{\cdot}051$) (Table 24.1).

To evaluate the economic profile of statin therapy in primary prevention, Caro and colleagues[7] used the WOSCOPS database along with long-term survival of Scottish subjects (matched to the WOSCOPS subjects on age, gender and cardiac event profile) obtained from the Scottish Record Linkage system. This allowed the creation of a full survival curve for each treatment arm (empirical data for 5 years, Scottish survival data after 5 years based on subject event profile). Cost data were derived from Scottish 1996 medical prices and are cited below in their US dollar equivalents. Caro and colleagues estimated that to prevent one extra subject progressing from an asymptomatic state to clinical disease (indicated in the WOSCOPS database by death, MI, stroke, revascularization or angina) 31·4 men would need to be started on statin therapy.[8] Pravastatin therapy (the average daily dose in the trial was 40 mg) was assigned a cost of $934 per year. The investigators estimated a drug treatment cost (over 5 years) of $3735 per subject, with a cost offset of $85 per subject owing to adverse events prevented by treatment, leaving a net undiscounted 5 year incremental cost per subject of $3650 ($3196 discounted at 6%). On the medical benefit side, the investigators projected an average (undiscounted) increase in life expectancy per subject of 0·25 years (approximately 0·10 years discounted). The resulting base case cost-effectiveness ratio indicated that statin therapy as primary prevention in the WOSCOPS population added an additional life year at a cost of approximately $29 132. Using the benchmarks cited earlier, this would be an economically attractive therapy (that is <$50 000 per life year added).

The AFCAPS/TexCAPS trial randomized 6605 subjects free of clinically evident CAD who had average total cholesterol and LDL cholesterol levels to lovastatin or placebo.[9] Over a mean follow up of 5·2 years, lovastatin reduced the incidence of a first major acute coronary event by 37% ($P < 0{\cdot}001$) (Table 24.1). In an analysis of the cost consequences in this trial, lovastatin cost $4654 per patient over the duration of the trial and saved $524 owing to reduced cardiac events and procedures.[10] These savings came from a 19% reduction in coronary bypass graft surgery (CABG), a 37% reduction in percutaneous transluminal coronary angioplasty (PTCA), and a 26% reduction in cardiovascular hospital days. A cost-effectiveness analysis of AFCAPS/TexCAPS is not planned. The availability of generic lovastatin in the near future will probably substantially reduce the net cost of this therapy.

A third important analysis in this area was performed using the Coronary Heart Disease (CHD) Policy Model, a computer simulation model that estimates the annual incidence of coronary disease in subjects aged 35–84 based on their risk factor profile.[11] The effectiveness of diet and statin therapy was estimated from analysis of pooled clinical trials. The model estimated that for men with an LDL cholesterol ≥160 mg/dl primary prevention with statin therapy relative to a Step I diet had a cost-effectiveness ratio between $130 000 and $260 000 per QALY added.[12] Further classifying risk by considering HDL cholesterol, smoking status and blood pressure led to the identification of subgroups with cost-effectiveness ratios as low as $54 000 per QALY (male aged 35–49 years with all three additional risk factors) or as high as $420 000. Most of the subgroups had

ratios above $100 000. For women, cost effectiveness (CE) ratios for primary prevention with statin therapy were even higher, with the most favorable being $61 000 per QALY and the least favorable subgroup having a ratio of $1·4 million per QALY.

There are several possible reasons why the WOSCOPS analysis and the CHD Policy Model analysis reached different conclusions about the economic attractiveness of statin therapy as primary prevention. The most important is probably the different amount of incremental life expectancy attributed to statin therapy by the two models. In particular, the 0·25 year incremental life expectancy per patient estimated in the WOSCOPS analysis may overstate the benefit of a therapy that saves one life per 1000 per year of therapy.

Primary prevention with statins is most economically attractive in high-risk subjects. Thus, a recent model-based analysis estimated that primary prevention with statin therapy was economically attractive in both diabetic men (CE ratio <$10 000 per year of life saved) and women (CE ratio <$40 000 per year of life saved).[13]

Secondary prevention Grade A

The National Cholesterol Education Program May 2001 update identifies an LDL level of <100 mg/dl as optimal in patients with established CAD.[14] Several major clinical trials have demonstrated significant clinical benefit for statin therapy as secondary prevention. The Scandinavian Simvastatin Survival Study (4S) was a double-blind placebo-controlled trial of adjusted-dose simvastatin in 4444 men and women between the ages of 35 and 60 with a history of angina or prior MI and total cholesterol levels between 210 and 310 mg/dl despite dietary interventions.[15] Median follow up was 5·4 years. The majority of patients received 20 mg/day of simvastatin, but more than one third required 40 mg/day. Simvastatin reduced total cholesterol by 25% and LDL-C by 35%, and it decreased all-cause mortality by 30% ($P = 0·003$) (Table 24.1).

Pedersen and colleagues[16] evaluated the incremental cost of simvastatin therapy in the 4S trial. During the 5·4 years of trial follow up, simvastatin therapy reduced hospitalizations for acute cardiovascular disease by 26% ($P < 0·0001$) and total hospital days by 5138 ($P < 0·0001$). The beneficial effect of simvastatin on hospitalization first became evident after 10 months of therapy, became statistically significant after 22 months, and appeared to increase over time. The use of antianginal and other cardiovascular drugs was not altered by statin therapy. Using US DRG-based reimbursement rates as cost weights, Pedersen and coworkers estimated that simvastatin therapy would save an average of $3872 per patient, owing to reduced need for hospitalization. The cost of the drug itself over the 5 year trial period averaged $4400 (discounted) per patient. Added to this were the cost of laboratory monitoring of the statin therapy (three to four lipid and transaminase measurements in the first year, and annually thereafter), which amounted to $250 (discounted) per patient. Thus, the net cost of the statin arm in the 4S trial over a mean of 1915 days of follow up was $778 per patient, which equates to approximately $148 per patient per year.[16]

Johanesson and colleagues[17] constructed a modified Markov model to estimate the cost effectiveness of using statin therapy for 5 years as secondary prevention for subgroups defined by age, sex and cholesterol level. The increased life expectancy produced by statin therapy was estimated from the 4S trial data. For a 59 year old male with a pretreatment cholesterol level of 261 mg/dl, life expectancy was prolonged by 0·28 years; for a 59 year old woman the corresponding figure was 0·16 years. Cost figures were derived from four Swedish hospitals and converted to US dollars. For the prototypical 59 year old man cited above, treatment costs averaged $2242 with a cost offset of $718 owing to reduced morbidity, leaving a net incremental cost of $1524 per patient. The cost per year of life added with statin therapy for this patient was $5400.[17] For the corresponding 59 year old woman, the net incremental cost was $1685 and the cost per life year added with statin therapy was $10 500. The cost effectiveness of 5 years of simvastatin ranged from $3800 per life year added for a 70 year old man with a cholesterol of 309 mg/dl, to $27 400 for a 35 year old woman with a cholesterol of 213 mg/dl. Extensive sensitivity analyses showed that statin therapy as secondary prevention was economically attractive under a wide range of assumptions. A recent model-based analysis estimated that statin therapy for secondary prevention was economically attractive in the diabetic subpopulation in the US, with CE ratios from $7000 to $15 000 for diabetic men and $24 000 to $40 000 for diabetic women.[13]

Differences between cardiovascular care in Sweden and North America raise the question of how generalizable an economic analysis of the 4S trial is. For example, Swedish use of coronary revascularization procedures was far lower than in the US and many European countries. In the 4S trial, the 5 year rate of revascularization was 17·2% in the placebo arm, and 81% of those procedures were coronary bypass surgeries. With the higher procedure rates in the US, even a modest relative reduction in the need for revascularization could generate greater cost savings than were seen in 4S. In addition, important benefits of therapy may be seen in patients who have undergone revascularization. For example, in the Post Coronary Artery Bypass Graft Trial, aggressive lipid lowering with lovastatin to an LDL-cholesterol <100 mg/dl reduced the need for repeat revascularization over a 4 year follow up by 29% relative to moderate lipid lowering therapy.[18]

The CARE (Cholesterol and Recurrent Events) trial randomized 4159 postmyocardial infarction (MI) patients with an average total cholesterol of 209 mg/dl to either pravastatin

40 mg/day or placebo.[19] After 5 years of follow up, death and non-fatal MI were reduced by 24% ($P = 0{\cdot}003$) (Table 24.1).

A cost-effectiveness analysis based on the CARE trial results has recently been published.[20] Based on the mean pravastatin dose in the active therapy arm, the cost of pravastatin therapy in the trial was $925 per year ($5 550 for the 6 years of the trial). Use of other cardiac medications was similar in the two arms (about $1250 per year). Over the 6 year follow up, the pravastatin arm saved about $1700 in hospital costs relative to placebo. Extrapolated to a lifetime perspective, the average cost of the pravastatin strategy discounted at 3% per year was $53 177, whereas that for the placebo arm was $42 223 for an incremental cost of $10 954. Extrapolating the observed (non-significant) mortality difference in CARE yielded a discounted quality-adjusted life expectancy of 13·62 QALYs for the pravastatin arm and 13·27 QALYs for placebo, for an incremental benefit of 0·35 QALYs. The resulting cost-effectiveness ratio was $31 000 per QALY saved with pravastatin therapy. Results were similar in men and women. For patients 60 and older the CE ratio was $9100 per QALY, and a similar result was obtained in patients with pretreatment LDL-cholesterol >150 mg/dl. On the other hand, for patients with an LDL-cholesterol <125 mg/dl, this analysis estimated that pravastatin therapy would be both more costly and less effective than placebo. These results show that statin therapy is economically attractive when applied to the majority of CARE participants, namely post-MI patients with an "average" cholesterol level.

What remains unsettled is the value of treating previously untreated patients with LDL-cholesterol values <125 mg/dl. Also unsettled is the value of very aggressive lipid lowering in secondary prevention populations to LDL-cholesterol levels substantially below 100 mg/dl. Ongoing clinical trials should provide additional guidance in these areas over the next 5 years.

Cessation of smoking Grade A

Cigarette smoking has many adverse health effects, including a significant risk of coronary disease. Given the addictive nature of smoking, most smoking cessation programs have limited success (~6% more patients stop smoking in 12 months than do controls).[21] As reviewed in previous chapters, observational data suggest that those who succeed in quitting experience a sharp decline in the high cardiovascular risk associated with smoking in the first 6 months, and their risk reaches the level of non-smokers after 1–2 years. This decrease in cardiovascular risk from smoking cessation has been estimated to increase life expectancy for each quitter by between 2 and 5 years.[22] Furthermore, each smoker who quits is associated with an average reduction in CAD-related medical costs of about $900 over the ensuing 8 years.[23]

In a primary prevention study, Cummings and colleagues[24] created a model to examine the cost effectiveness of physician counseling (versus no counseling) on smoking cessation. In their model, the authors assumed that physician counseling led to a 2·7% decrease in smoking at 1 year, with a subsequent 10% relapse rate. They assumed that the cost of this brief advice would be $12. These data yielded CE ratios from about $1000 to $1400 per year of life saved for men, and from about $1700 to $3000 per year of life saved for women. Sensitivity analysis of a worst case scenario (cost increased to $45, cessation rate decreased to 1%, 50% relapse after the first year) still indicated that brief physician advice to quit smoking was economically attractive. Although physician counseling is only very modestly effective, it remains an important prevention strategy because it is so inexpensive.

A similar analysis was performed by Oster and coworkers comparing nicotine gum as an adjunct to physician advice versus physician advice alone.[25] Based on randomized clinical trials, the authors assumed that nicotine gum for 4 months resulted in a cessation rate of 6·1% versus 4·5% for physician counseling. The cost of 4 months of nicotine gum was $161 (1984 figures). The CE ratios for this form of smoking cessation intervention ranged from about $6000 to $9000 per life year added for men, and about $9500 to $13 000 for women.

In the arena of secondary prevention, Krumholz and colleagues evaluated the effect of a nurse counseling smoking cessation program for post-MI patients.[26] Data from a previously published randomized trial was used in a decision model to define the 1 year quit rate and postcessation mortality.[27] The model assumed an incremental life expectancy of 1·7 years per quitter. The estimated cost of the program was $100 per patient. With an incremental smoking cessation rate of 26%, the program's cost-effectiveness ratio was highly favorable at $265 per life year added. Sensitivity analyses showed that the cost-effectiveness ratio remained attractive at below $10 000 per life year added if only 1% of smokers quit (instead of 26%), or if quitters gained only 0·1 year of life expectancy (instead of 1·7 years).

For those who are able to stop smoking, observational data suggest significant gains in life expectancy. When these favorable estimates are combined with the relatively modest cost of smoking cessation interventions, these programs appear very economically attractive.

Treatment of hypertension Grade A

Hypertension is an ideal disease for preventive therapy. It is a highly prevalent disorder, with more than 60 million Americans (one in four adults) estimated to have the disease.[1] If untreated, hypertension leads to significant morbidity and mortality, with coronary disease, heart failure and

strokes being the main cardiovascular complications. Finally, numerous interventions capable of lowering the blood pressure are available, including a wide spectrum of antihypertensive pharmacologic agents.

Using data from the Framingham study, Stason and Weinstein evaluated the cost effectiveness of treatment of hypertension as primary prevention by modeling stepped care, from screening for hypertension to drug compliance.[28] When stratified by initial blood pressure, age, gender and race, most subgroups had cost-effectiveness ratios of less than $50 000 per quality-adjusted life year. Not surprisingly, the cost effectiveness was more favorable for those with higher initial blood pressures. Other determinants of cost effectiveness were gender, age and compliance.

Because hypertension usually requires lifetime therapy, and as most antihypertensive agents are equally efficacious at reducing blood pressure, an important determinant of the economic profile of this form of prevention is the cost of the antihypertensive regimen. Edelson[29] evaluated the cost effectiveness of five specific monotherapies in persons without coronary disease aged 35 to 64. The study involved simulation of 20 years of therapy (1990–2010) based on the Coronary Heart Disease Policy Model. Effectiveness data was based on a meta-analysis of 153 studies in the literature. A key assumption was that if different agents produce the same reduction in diastolic blood pressure, then the clinical benefit would be the same. Of the five agents studied, propranolol and hydrochlorothiazide had the most favorable cost-effectiveness ratios, at $10 900 per year of life saved and $16 400 per year of life saved, respectively (expressed in 1987 dollars). Captopril had a higher cost and a lower estimated reduction in diastolic blood pressure, yielding a cost-effectiveness ratio of $72 100 per life year saved. A limitation of the study was that estimates of 20 year outcomes were based on trials often lasting only several months. More recently, Littenberg and colleagues[30] modeled the cost effectiveness of treating mild hypertension (diastolic pressure from 90 to 105) and also found that the cost-effectiveness ratio was more attractive when the least costly antihypertensive agent was used.

Even though the various antihypertensive agents are all capable of lowering blood pressure, evidence for a mortality benefit is strongest for diuretics and β blockers.[31] In an overview of four trials, ACE inhibitors were found to reduce stroke (by 30%) and coronary heart disease (by 20%).[32] In placebo-controlled trials, calcium channel blockers reduced stroke (by 39%) and major cardiovascular events (by 28%). Some continue to argue that long-acting calcium-channel blockers are inferior to other antihypertensives based on the available trial data, but this point remains contentious.[33]

Although no recent economic models have evaluated treatment of hypertension in the elderly, an overview of the available randomized trial data showed that two to four times as many younger subjects needed to be treated for 5 years to equal the benefits of therapy in preventing morbid and fatal events in the older population.[34] Thus, the economic profile of treatment in the elderly would be expected to be correspondingly favorable.

No large randomized clinical trials have evaluated hypertension control as secondary prevention, and no cost-effectiveness models addressing this issue have been published.

Exercise as therapy

Many epidemiologic data support the idea that regular exercise is associated with less coronary heart disease and improved longevity (see Chapter 16). The improved outcomes are attributed, at least in part, to improvements in blood pressure, weight and cholesterol levels. Analysis of the economic benefits of regular exercise in the primary prevention of cardiovascular disease has been limited to model simulations of clinical outcomes based on epidemiologic data. In 1000 hypothetical 35 year old males, a 2000 kcal/week jogging program (~20 miles) was assumed to reduce CHD risk by 50% compared with no exercise.[35] Direct costs attributed to the program included exercise equipment and a portion of an annual physician visit ($100 per year). The model also used a sliding scale of indirect costs due to lost productivity for time spent in jogging, based on how much the individual disliked exercise ($9·00 per hour for subjects who disliked exercise, $4·50 per hour for neutral subjects, and $0 for subjects who enjoyed exercise). The cost-effectiveness ratio using direct costs was $1395 per quality-adjusted life year added; with the indirect costs, the ratio increased to $11 313 for regular exercise versus no exercise. The model assumed that compliance was 100% even for those who disliked exercise.

A second analysis of this issue used the Cardiovascular Disease Life Expectancy Model to forecast the long-term benefits of exercise training.[36] This model is based on the risk factor and outcome data from the Lipid Research Clinics Program Prevalence and Follow-Up Studies. This model was applied to the average risk profiles of a population-based cohort of Canadian men and women with and without cardiovascular disease to estimate life expectancy. The effectiveness of exercise was projected based on its reported effects on blood lipids (a 4% decrease in LDL, a 5% increase in HDL) and blood pressure (6 mmHg decrease in systolic pressure). Costs were based on Canadian sources and converted to 1996 US dollars. Two exercise programs were considered: a supervised exercise class at $605 for the first year and $367/year after year 1, and an unsupervised walking program at $311 for the first year and $73/year after that. Adherence was estimated at 50% for the first year, dropping to 30% for all subsequent years. The unsupervised exercise program had an estimated cost per year of life saved of $12 000, for both primary and secondary prevention.

The supervised exercise program was also economically attractive, with cost-effectiveness ratios of $20 000 per year of life saved for secondary prevention in men, and between $20 000 and $40 000 per year of life saved for secondary prevention in women and for primary prevention in men. With greater adherence than was assumed, the economic attractiveness of both exercise programs improves.

Most studies of exercise as secondary prevention in coronary disease involve structured programs of cardiac rehabilitation in post-MI patients. Because of limited sample size, no single randomized trial has definitely shown that cardiac rehabilitation reduces cardiac events. Two meta-analyses pooled data from the available trials and estimated a 20–25% reduction in death and non-fatal MI with cardiac rehabilitation in post-MI patients.[37,38] In 1993, Oldridge[39] published an economic evaluation of an 8 week cardiac rehabilitation program in post-MI patients with mild to moderate depression and/or anxiety. There were no differences in mortality or non-fatal MI, but quality of life, as measured by the time trade-off method, did improve, leading to 0·052 quality-adjusted life years gained during the 1 year of follow up. The corresponding cost-effectiveness ratio in this analysis was around $10 000 per quality-adjusted life year added. A second, more recent analysis of formal cardiac rehabilitation after acute MI estimated a cost-effectiveness ratio of $4950 per year of life saved (1995 dollars).[40]

The value of these analyses on the cost effectiveness of exercise is heavily dependent on the credibility of the assumptions about the amount of benefit to be derived. In this respect, the absence of large-scale mortality trials represents a weakness in the evidence that economic models cannot rectify.

Pharmacologic secondary prevention Grade A

For those with coronary disease, aspirin therapy leads to a substantial reduction in death and non-fatal MI, and its costs and long-term side effects are minimal.[41] Even though there are no formal cost-effectiveness analyses of aspirin therapy, its efficacy and low price make aspirin a "best buy" of secondary prevention therapy.

For post-MI patients, several trials have shown that β blockers prevent death and cardiac events. Goldman and coworkers performed a cost-effectiveness analysis of β blocker therapy after an acute MI in men.[42] The model assumed a mortality reduction of 25% per year for the first 3 years of therapy, and 7% per year for years 4–6, with gradual attenuation over the subsequent 9 year period, based on an overview of the available literature. After 6 years of therapy, the model assumed that β blockers were discontinued. The average cost of propranolol therapy used in this study was $208 per patient per year (1987 rates). The cost-effectiveness ratios ranged from $2300 per life year added in high-risk patients, to $13 600 per life year saved for low-risk patients. The β-blocker trials upon which this model was based were all completed in the prethrombolytic era and the cost effectiveness of this form of secondary prevention has not been re-examined in patients undergoing reperfusion therapy. Furthermore, recent analyses of the Beta Blocker in Heart Attack Trial (BHAT) showed that MI patients who survived the first year with low- to moderate-risk courses (the typical profile of a postreperfusion therapy patient) did not evidence any long-term benefit from β blockers.[43]

A more recent analysis using the CHD Policy Model examined the epidemiologic impact and cost effectiveness of increasing β blocker use in acute MI survivors from current levels (estimated to be 44% in 2000) to target levels (estimated to be 92%).[44] Treatment was projected to continue over 20 years. The additional costs of this full-use β-blocker strategy were estimated at $570 million for the USA. However, with a cost offset from decreased CAD-related events, the net cost was estimated at $158 million. The incremental cost per QALY added with full use β blocker therapy was $4500. A strategy of phasing in higher β blocker use by concentrating on achieving target use levels in all first-MI survivors over the next 20 years was estimated to save 72 000 lives and be cost saving (a dominant strategy). Thus, improving evidence-based use of β blockers in CAD offers major health gains at a very attractive cost, and may even be cost saving.

Angiotensin-converting enzyme (ACE) inhibitor efficacy in secondary prevention was demonstrated in the SAVE (Survival and Ventricular Enlargement) trial, a double-blinded placebo-controlled trial of captopril in 2231 acute MI survivors with an ejection fraction (EF) ≤40%. SAVE showed a 19% reduction in mortality during the average follow up of 3·5 years. Based on the SAVE results, Tsevat and colleagues[45] created a decision model to determine the cost effectiveness of ACE inhibitors in 50–80 year old acute MI survivors with an ejection fraction (EF) of ≤40%. Assuming that the survival benefits of captopril extended beyond 4 years, the cost-effectiveness ratios averaged $10 400 per QALY or less (1991 dollars), depending on age. The use of 6 weeks of lisinopril therapy in acute MI patients was recently reported to be economically attractive ($2080 [1993 US dollars] per extra 6-week death avoided), based on the GISSI-3 trial data.[46]

Between 1993 and 1995, the Heart Outcomes Prevention Evaluation (HOPE) Study randomized 9297 patients aged 55 or greater who had either manifest vascular disease (CAD, stroke, peripheral vascular disease) or diabetes plus one other risk factor to ramipril or placebo.[47] Over a mean follow up of 4·5 years, the ramipril group experienced a 22% reduction in the composite of cardiovascular death, MI or stroke ($P = 0{\cdot}005$). All-cause mortality was reduced 16% ($P = 0{\cdot}005$) and non-fatal MI was reduced 20% ($P < 0{\cdot}001$). In addition, ramipril decreased the need for revascularization by 15% ($P = 0{\cdot}002$). Lamy and colleagues recently

examined the economic implications of ramipril therapy in HOPE.[48] Medicare reimbursements were used to estimate hospital costs and the Medicare Fee Schedule provided physician costs. The retail cost of 10 mg per day of ramipril therapy in the US is approximately $440 per year. Over the follow up of the HOPE Study the cost of the ramipril was $1480 per patient. Use of ramipril had no significant effect on use of other cardiac medicines. However, hospitalization costs were reduced by $614, and revascularization costs (coronary, carotid, peripheral) were reduced by $750. Although this economic analysis was retrospective and therefore could not include all costs of interest, use of the Medicare cost weights was conservative. Similar results were obtained when the analysis was done using Canadian cost weights. Thus, over the duration of the study follow up, ramipril appeared to pay for itself by reducing complications and related need for hospital-based care. This study did not attempt to project results out to a lifetime perspective. Based on the HOPE economic analysis, therefore, ramipril used in HOPE-eligible patients is a dominant therapy (better clinical outcomes, equivalent costs).

Preventive strategies ripe for cost-effectiveness analysis

Multiple risk factor interventions Grade B

The studies reviewed thus far have focused on the cost effectiveness of single risk factor interventions independent of other risk factors. In clinical practice patients have multiple risk factors that require multiple concurrent interventions. The Stanford Coronary Risk Intervention Program (SCRIP) evaluated the effect of multifactor risk modification on the progression of angiographic CAD in 300 patients.[49] The intervention program consisted of exercise, dietary modifications, weight loss, lipid lowering pharmacotherapy and smoking cessation. After 4 years, patients in the intervention arm had on average a 20% increase in exercise capacity, a 4% decrease in weight, and a 22% reduction in LDL cholesterol compared with those receiving usual care. Angiographically, those in the risk intervention arm had significant attenuation of coronary disease progression. In addition, there was a decrease in the composite end point of death, non-fatal MI, PTCA and CABG ($P = 0{\cdot}05$). Based on these results and the reduction in cardiac hospitalizations, Superko and coworkers estimated the net cost of the program at $630 per patient per year.[50]

Diabetes Grade A

Diabetes leads to many long-term complications, including retinopathy, neuropathy, nephropathy and atherosclerosis. However, only recently has control of glucose level been demonstrated to reduce these complications. The DCCT (Diabetes Control and Complications Trial) randomized 1441 insulin-dependent diabetic patients to intensive insulin therapy versus conventional therapy, with a mean follow up of 6·5 years.[51] The intensive therapy arm showed significant reductions in retinopathy, neuropathy and nephropathy. However, as there were few cardiovascular events in this primary prevention study the lower rate of cardiovascular events in the intensive therapy arm was not significant ($P = 0{\cdot}08$). A Monte Carlo simulation model based on the reduction of renal, neurological and retinal complications estimated that the cost effectiveness of lifetime intensive insulin therapy compared with conventional therapy was $28 661 per life year added.[52]

Conclusions

Based on the available cost-effectiveness data, the following preventive strategies are considered economically attractive: secondary prevention with statins in hyperlipidemia; smoking cessation programs for both primary and secondary prevention; treatment of hypertension for primary prevention, especially with β blockers and thiazide diuretics; secondary prevention with ACE inhibitors in high-risk vascular disease patients (meeting eligibility for the HOPE Trial); primary prevention with a regular exercise program; secondary prevention with cardiac rehabilitation; and for post-MI patients, the use of β blockers and ACE inhibitors. Even though no formal cost-effectiveness analysis has been carried out for aspirin (in secondary prevention), given its low cost and substantial clinical benefits it should be considered in the "best buy" category. The cost effectiveness of clopidogrel added to aspirin for secondary prevention is currently under study. The cost effectiveness of primary prevention with statins in hyperlipidemia remains unsettled. We await more clinical effectiveness data prior to consideration of cost-effectiveness analysis for achieving euglycemia in diabetics for both primary and secondary prevention. Finally, it is important to bear in mind that as therapeutic options and their associated cost change, cost effectiveness will need to be reassessed.

25 Diet and cardiovascular disease

K Srinath Reddy

Introduction

The rapid escalation of the global epidemic of cardiovascular diseases (CVD), projected for the first quarter of the twenty-first century, requires a comprehensive public health response that can reduce risk at both population and individual levels.[1] Diet, as regularly consumed, and the nutrients supplied by it are major determinants which initiate and influence the course of atherothrombotic vascular disease. Identification of increased or decreased risk associated with dietary patterns or specific nutrients, in a methodologically rigorous manner, should lay the scientific foundation for general dietary recommendations to populations as well as specific nutritional interventions in individuals at a high risk of CVD.

Methodological issues in the study of causal associations

Issues related to study design

Studies investigating the influence of diet on CVD or cardiovascular risk factors have employed a wide variety of study designs: ecological studies within and across populations, cross-sectional surveys, case–control studies (*de novo* or nested), cohort studies, community-based demonstration projects, randomized clinical trials, and before-after type of metabolic studies. These differ widely in terms of their ability to (a) identify, avoid, and adjust for confounding; (b) establish a temporal relationship of cause preceding the effect; (c) minimize bias; (d) provide a wide range of exposure; (e) ascertain composite end points, including fatal outcomes; (f) evaluate population attributable risk; and (g) yield generalizable results.

These issues related to study design become relevant when interpreting the results of reported studies on diet and CVD and assessing their public health implications. Frequently, conclusions from studies employing weak designs are negated by the results emerging from methodologically stronger studies. Public policy and clinical practice must both be judiciously guided by credible evidence provided by scientifically stronger studies and not be misled by controversial results emerging from feeble study designs.

Clinical trials, if well designed, provide the best framework for studying associations, as free from the effects of bias and confounding as possible. However, they often evaluate interventions that are relatively short term and introduced late in the natural history of disease and may not replicate the effects of long-term dietary exposures. Genetics now offer a possible alternative to clinical trials through "mendelian randomization". This approach takes into account that genotypic differences in the metabolism of food ingredients may cause lifelong differences in exposure to food components and their metabolites or to purported risk factors. It may be a powerful way to establish causality without the need for prolonged follow up.[2,3]

A related issue is the use of experimental animals. Although these are often referred to as "animal models" their validity in predicting outcomes in humans is unclear. Lipid metabolism especially is species-specific, as exemplified by the lack of efficacy of cholesterol lowering statin drugs in many animal species, including monkeys.[4] Experiments in animals are therefore best reserved for elucidating mechanisms, and cannot be used to argue that a particular food will have a particular effect on cardiovascular disease in humans.

Issues involving outcome variables

These principally relate to a choice between disease end points and intermediate variables and the types of variables, which are selected for study within each category. Ideally, disease-related end points are preferable since they clearly demonstrate the benefits or risks of dietary exposures. In an exposure such as diet, effects may extend beyond cardiovascular outcomes. The need to evaluate impact of diet on total mortality and major co-morbidities, therefore, becomes an imperative. It must also be recognized that dietary exposures which influence thrombotic pathways may have different effects on the risk of hemorrhagic stroke and thrombotic stroke, often in opposite directions. The need to differentiate the types of stroke in outcome evaluation is, therefore, clear and has important implications for populations that differ in their stroke profiles. Similarly, selective benefits limited only to non-fatal outcomes, as in the case of CHAOS study which reported a possible benefit of vitamin E administration on non-fatal myocardial infarction,[5] are seldom replicated and cannot influence either public health policy or clinical practice.

The ascertainment of disease-related end points, as the primary outcome, has most often been attempted in large and

long-term cohort studies, or in clinical trials conducted in population groups in whom high event rates were anticipated in a short or medium time frame. Thus, observational cohort studies investigating the long-term impact of diet on primary prevention of cardiovascular disease frequently compete with secondary prevention trials. If the results are discordant, it is difficult to interpret whether the differences are due to methodologic reasons of confounding or due to the fact that exposures occurred at different times and for variable periods in the natural history of the disease. It must, however, be recognized that pathologic processes such as endothelial dysfunction, plaque instability, thrombosis and cardiac arryhythmias can be influenced even by short-term exposures.

Intermediate variables have been frequently utilized in studies evaluating the association of dietary constituents or dietary patterns to cardiovascular diseases (CVD). Most often, these are risk factors like blood pressure or plasma lipids. However, it must be recognized that similar changes in total plasma cholesterol may be associated with variable effects on levels of LDL cholesterol and HDL cholesterol and on the ratio of total to HDL cholesterol. The impact on risk of atherosclerotic CVD may thus vary. The 25 year follow up experience of the Seven Countries Study revealed that while the increase in relative risk of CHD for comparable levels of plasma cholesterol elevation was similar across diverse populations, the absolute risk of CHD varied widely at the same level of plasma cholesterol, possibly due to other dietary and non-dietary influences.[6] Dietary changes may also influence LDL particle size differentially, as also the level of plasma triglycerides, with variable net effects on the atherogenicity of the plasma lipid pool. Such limitations were clearly illustrated in a study by Rudel *et al*[7] where monkeys fed monounsaturated fat had similar lowering of LDL cholesterol as monkeys fed polyunsaturated fat but developed atherosclerosis equivalent to those fed saturated fat. In monkeys fed monounsaturated fatty acids, there was an enrichment of cholesteryl oleate in plasma cholesteryl esters, which correlated with coronary artery cholesteryl ester concentration.[8] Plasma lipids, as intermediate variables, could not also explain the degree of cardiovascular protection conferred by the Mediterranean diet in the Lyon Diet Heart Study.[9] While studies of intermediate variables are useful in identifying mechanistic pathways of dietary harm or benefit and plasma cholesterol has served well so far to explain much of the coronary risk associated with certain diets, there is a need for methodologically strong studies which relate dietary patterns or dietary interventions to hard end points such as total mortality, cardiovascular mortality, and combined fatal and non-fatal cardiovascular events.

Issues involving the exposure variables

These involve the type of exposure selected for study, the methods of measurement employed as well as the duration and dose of exposure. First, the types of dietary exposure assessed for associations with CVD, have varied from specific nutrients (such as saturated fat) to dietary items (such as fish) to food groups (such as fruit and vegetables) to dietary patterns (such "Mediterranean" diet or "Adventist" diet) and composite dietary interventions (such as the DASH diet). A reductionist approach has inherent limitations in the area of diet, because multiple interactions among many nutrients are likely to determine the physiologic effects and pathologic outcomes much more than the individual effects of an isolated nutrient. Multi-component dietary exposures, however, render identification of mechanistic causal pathways difficult to elucidate. While this frustrates efforts to develop and market specific food supplements or nutriceuticals, interests of public health are likely to be better served by a combined food- and food-component-based approach to a causal inquiry exploring the connections between diet and cardiovascular health.

Second, the strengths and limitations of various methods of collecting accurate food consumption data are well recognized.[10] Questionnaire methods of ascertaining information related to habitual food intake pose problems of validity and reproducibility even within well defined populations, but these problems are likely to be magnified when such instruments are applied across different cultures. Even if the nutrient composition of self reported diets is accurately estimated, different cooking methods may alter the final bioavailability of those nutrients as actually consumed. The need for valid and reproducible biomarkers is, therefore, important when studies of specific nutrients are proposed. For example, adipose tissue fatty acid composition is a suitable biomarker for habitual type of dietary fat intake.[11] There may, however, be technical and financial constraints which limit the use of such biomarkers in large epidemiologic studies.

Third, a causal inquiry needs to recognize the lag time effect, wherein a long period of exposure to dietary variables is required before effect is evident on outcome variables (especially disease-related end points of atherosclerotic vascular disorders). Short-term studies may be incapable of identifying true effects even when they exist. This is clearly illustrated by trials evaluating the effect of sodium restriction on blood pressure, where benefit was demonstrated only in trials in which the duration of exposure was at least 5 weeks.[12] The dose of exposure is another critical variable in an area like diet, where many of the nutrients are physiologic requirements at a certain level but may pose risk of cardiovascular dysfunction and disease at other levels. The relationships may vary from linear to J-shaped or threshold, for different variables. Ascertainment of dose-related effects is essential, whether the exposure is salt, alcohol or fish.

Issues related to diet as an independent variable

These relate to the association of dietary behaviors with other behaviors which influence cardiovascular risk and the

impact of diet on several cardiovascular risk factors which may partly or wholly be in the causal pathway to CVD as intermediate variables. Unhealthy dietary behaviors often occur in association with other unhealthy behaviors such as physical inactivity and smoking. Furthermore, unhealthy dietary practices such as high consumption of saturated fats, salt and refined carbohydrates as well as low consumption of fruit and vegetables tend to cluster together. In contrast, persons who habitually adopt one healthy dietary practice are more likely to adopt other healthy dietary habits as well as practice regular physical activity and abstinence from smoking. Dietary behaviors may also reflect patterns influenced by social class and may be influenced by stress levels. Dissociating the specific effects of individual dietary components from other dietary components, physical activity levels, and other behaviors becomes difficult outside the setting of a carefully controlled clinical trial. In observational studies, the question arises whether some dietary practices are merely a surrogate for other dietary practices or for a composite of multiple health behaviors. Whether diet should be considered in dissociation from physical activity or should preferably be studied in combination is also an issue for observational research.

The effects of diet on multiple cardiovascular risk factors, ranging from body weight to blood lipids and blood pressure to thrombotic mechanisms, also poses the question of when and how far to adjust for these variables in evaluating the relationship of diet to CVD. Since many of these are intermediate variables linking diet to CVD, adjustment to exclude their effect would underestimate the effect of diet. However, such variables are also influenced by factors other than diet. In such cases, the decisions related to adjustment should be carefully considered.

Nutrients and CVD

Dietary fats

The relationship between dietary fats and cardiovascular disease (CVD), especially coronary heart disease (CHD), has been extensively investigated, with strong and consistent associations emerging from a wide body of evidence accrued from animal experiments, as well as observational studies, clinical trials, and metabolic studies conducted in diverse human populations. The relationship of dietary fat to CVD was initially considered to be mediated mainly through the atherogenic effects of plasma lipids (total cholesterol, lipoprotein fractions, and triglycerides). The effects of dietary fats on thrombosis and endothelial function as well as the relationship of plasma and tissue lipids to the pathways of inflammation have been more recently understood.[11,13] Similarly, the effects of dietary fats on blood pressure have also become more evident through observational and experimental research.

Cholesterol in the blood and tissues is derived from two sources: diet and endogenous synthesis. Dairy fat and meat are major sources. Egg yolk is particularly rich in cholesterol but, unlike dairy and meat, does not provide saturated fatty acids. Dietary cholesterol raises plasma cholesterol levels.[14] Although both HDL and LDL increase, the effect on the total/HDL ratio is still unfavorable, but small.[15] Observational evidence on an association of dietary cholesterol intake with cardiovascular disease is contradictory.[16,17] The upper limit for dietary cholesterol intake has been prescribed, in most guidelines, to be 300 mg/day. However, since there is no requirement for dietary cholesterol, it is advisable to keep the intake as low as possible.[13] If intake of dairy fat and meat are controlled, there would be no need for a severe restriction of egg yolk intake, although some limitation remains prudent.

Fatty acids are grouped into three classes – saturated fatty acids (SFA), monounsaturated fatty acids (MUFA), and polyunsaturated fatty acids (PUFA). While such a classification is useful in providing a structural grouping, it tends to oversimplify the effects of dietary fats. Individual fatty acids, within each group, are now known to have differing effects on lipids, lipoproteins and platelet-vascular homeostasis. SFA and MUFA can be synthesized in the body and hence are not dietary essentials. PUFA are essential fatty acids, since they cannot be synthesized in the body.

Saturated fatty acids (*SFAs*) as a group raise total and LDL cholesterol, but individual SFAs have different effects.[11,18] Myristic and lauric acids have greater effect than palmitic acid, but the latter is more abundant in food supply. The plasma cholesterol raising effects of these three SFAs is higher when combined with high cholesterol diets. Stearic acid has not been shown to elevate blood cholesterol and is rapidly converted to oleic acid (OA) *in vivo*. Metabolic (feeding) studies demonstrate a marked elevation of both HDL and LDL cholesterol induced by SFA diets.[19,20] Replacement of saturated fatty acids by polyunsaturated fat reduces the total to HDL cholesterol ratio but replacement by carbohydrates does not. Also, tropical fats rich in lauric acid (C12) raise total cholesterol strongly, but because of their specific effect on HDL, the ratio of total to HDL cholesterol falls. Thus effects on blood lipids can be variable, depending on which blood lipids are studied, and we need data on actual outcomes to determine the true effects of fats on coronary heart disease.[21] The relationship of dietary saturated fat to plasma cholesterol levels and to CHD was graphically demonstrated by the Seven Countries Study involving 16 cohorts, in which saturated fat intake explained 73% of the total variance in CHD across these cohorts.[22] In the Nurses Health Study[20] the effect of saturated fatty acids was much more modest, especially if saturates were replaced by carbohydrates. The most effective replacement for saturated fatty acids in terms of coronary heart disease outcome is by polyunsaturated fatty acids – that is, linoleic acid. This

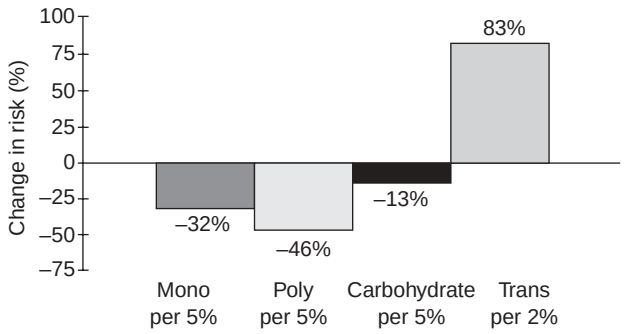

Figure 25.1 Change in CHD risk associated with replacement of saturates by other fats: Nurses Health Study (based on Hu *et al*[22]).

agrees with the outcome of large randomized clinical trials, in which replacement of saturated and *trans* fats by polyunsaturated vegetable oils effectively lowered coronary heart disease risk (see Figure 25.1).[23]

Trans fatty acids (*t-FAs*) are geometrical isomers of unsaturated fatty acids that assume a saturated fatty acid-like configuration. Partial hydrogenation, the process used to create t-FA, also removes essential fatty acids such as linoleic acid and α-linolenic acid. Metabolic studies have demonstrated that t-FAs render the plasma lipid profile even more atherogenic than SFA, by not only elevating LDL cholesterol to similar levels but also decreasing HDL cholesterol.[24] As a result, the ratio of LDL cholesterol to HDL cholesterol is significantly higher with a t-FA diet (2·58) than with a SFA diet (2·34) or an oleic acid diet (2·02). Evidence that intake of t-FA increases the risk of CHD initially became available from large population-based cohort studies in the USA[25,26] and has recently been corroborated in an elderly Dutch population.[27] Levels of t-FA in a biochemical analysis of replicated baseline food composites correlated with the risk of coronary death in the cohorts of the Seven Countries Study. Most t-FAs are contributed by industrially hardened oils, but the dairy and meat fats of ruminants are also a source. Whether these two sources have the same effect on coronary heart disease risk is unclear, but reductions in ruminant fats are already advisable for other reasons. Eliminating t-FAs from the diet would be an important public health strategy to prevent cardiovascular disease. Since these are commercially introduced agents into the diet, policy measures related to the food industry would be required along with public education. *Trans* fatty acids have been eliminated from retail fats and spreads in a large part of the world, but deep-fat fried fast foods and baked goods are a major and increasing source.[28]

The only nutritionally important *monounsaturated fatty acid* (*MUFA*) is oleic acid, which is abundant in olive and canola oils and also in nuts. The epidemiologic evidence related to MUFA and CHD is derived from studies on the Mediterranean diet, as well as from the Nurses Health Study and other similar studies, which investigated the association and controlled for confounding factors.[29] MUFAs have been shown to lower blood glucose and triglycerides in type II diabetic patients and may decrease susceptibility of LDL to oxidative modification.

Polyunsaturated fatty acids (*PUFAs*) are derived from dietary LA (n-6 PUFAs) and dietary ALNA (n-3 PUFAs). The important n-6 PUFAs are arachidonic acid (AA) and dihomogammalinolenic acid (DHGLA), while the important n-3 PUFAs are eicosapentaenoic acid (EPA) and docasahexaenoic acid (DHA). Eicasanoids derived from AA have opposing metabolic properties to those derived from DHA. A balanced intake of n-6 and n-3 PUFAs is, therefore, essential for health.

The biologic effects of n-3 PUFAs are wide ranging, involving lipids and lipoproteins, blood pressure, cardiac function, arterial compliance, endothelial function, vascular reactivity, and cardiac electrophysiology as well as potent antiplatelet and anti-inflammatory effects including reduced neutrophil and monocyte cytokine production.[11,30] Recent data have also shown that EPA and DHA have differential effects on many of these. DHA appears to be more responsible for the beneficial effects of fish and fish oils on lipids and lipoproteins, blood pressure, heart rate variability, glycemic control, in comparison to EPA, while a mixture of DHA and EPA significantly reduced platelet aggregation in comparison to ALNA *in vitro*.[11,31] The very long chain n-3 polyunsaturated fatty acids powerfully lower serum triglycerides, but they raise LDL cholesterol.[32] Therefore, their effect on coronary heart disease is probably mediated through pathways other than cholesterol.

Much of the epidemiologic evidence related to n-3 PUFAs is derived from the study of fish consumption in populations or interventions involving fish diets in clinical trials. Fish oils were, however, used in the GISSI study of 11 300 survivors of myocardial infarction.[33] In this factorial design, fish oil (1 g/day) and vitamin E (300 mg/day) were compared, alone and in combination, to placebo. After 3·5 years of follow up, the fish oil group had a statistically significant 20% reduction in total mortality, 30% reduction in cardiovascular death, and 45% decrease in sudden death. While most published studies do not indicate that dietary n-3 PUFA prevent restenosis after percutaneous coronary angioplasty or induce regression of coronary atherosclerosis, one study reported that occlusion of aortocoronary venous bypass grafts was reduced after 1 year by daily ingestion of 4 g fish oil concentrate.[34]

The Lyon Heart Study incorporated an n-3 fatty acid (alpha linolenic acid) into a diet altered to develop a "Mediterranean diet" intervention.[9] In the experimental group plasma ALNA and EPA increased significantly and the trial reported a 70% reduction in cardiovascular mortality at 5 years in its initial report. Total cholesterol and LDL cholesterol were identical

in the experimental and control groups, suggesting that thrombotic and perhaps arrhythmic events may have been favorably influenced by n-3 PUFA. Since the diet altered many other variables, such as fiber and antioxidants (by increasing fruit and vegetable consumption), direct attribution of benefits to n-3 PUFA becomes difficult to establish.

The effect of different fatty acids on cardiac arrhythmias has been an area of great interest. Diets rich in saturated fatty acids increase the risk of ventricular fibrillation and sudden cardiac death in primates. A recent population-based case–control study, using biomarkers, revealed a modest association of *trans* fatty acids in general and a strong association of *trans* isomers of linoleic acid in particular, with primary cardiac arrest in humans.[35] Several studies in different animal models, primate and rodent, have shown that n-3 PUFA are protective against cardiac arrhythmias, especially ventricular fibrillation.[36] It has been suggested that the fall in coronary heart disease mortality in USA and Australia, since 1967, is probably attributable to an increase in polyunsaturated fat consumption in both countries since 1960.[37] The decline in CHD mortality in the Zutphen cohort has similarly been attributed to a decreased consumption, over time, of *trans* fatty acids.[27]

The proportions of SFA, MUFA, and PFA as constituents of total fat intake and total energy consumption have engaged active attention, in view of the strong relationship of these fatty acids to the risk of CVD, especially CHD. The reduction of SFA in the diet has been widely recommended, but its replacement remains an area of debate as to whether the place of reduced SFAs should be taken by MUFA, PUFA or carbohydrate. Both MUFA and PUFA improve the lipoproteins profile, although polyunsaturated fatty acids are somewhat more effective. In view of this, recent US dietary recommendations suggested that SFA should be reduced to 7–8%, MUFA should be increased to 13–15%, and PUFA raised to 7–10% of daily energy, with the total fat contributing to no more than 30% of all calories consumed.[29,38] These may need to be adjusted for populations who consume less quantities of total fat, so as to ensure an adequate intake of MUFA and PUFA even under those circumstances.

The total quantity of fat consumed, as a proportion of daily energy intake, has not shown a relation to CVD that is independent of the SFA content. It has been argued that the type of fat consumed in diet is far more important than the total amount of fat consumed.[39] The compatibility of high fat Mediterranean diets (with total fat contributing >30% of calories) with coronary protection has also been cited as supportive evidence. While the emphasis on the type of fat is well placed, it must be recognized that high fat diets are also high in energy. Whether this contributes substantially to overweight is a subject of much debate.[40]

Enhancing the nutritional quality of dietary fat consumption, to provide greater cardiovascular protection, may be attempted by decreasing the sources of saturated fats and eliminating *trans* fatty acids in the diet, increasing the consumption of foods containing unsaturated fatty acids (both MUFA and PUFA) and decreasing dietary cholesterol consumption. Modification of cooking oils, either through appropriate admixture of different oils[41] or through genetic modification of oilseed crops,[42] may provide methods for improving the quality of dietary fat consumed through edible oils.

Carbohydrates

The relationship of dietary carbohydrates to CVD appears to be mediated through indirect mechanisms: contribution to total energy and its effect on overweight and obesity; influence on central obesity; effects on plasma lipids, especially triglycerides; and effects on glycemic control. The balance between carbohydrates and fat as sources of energy as well as the fiber component of the diet are also areas of interest while considering this relationship. In feeding experiments, an increase in dietary energy from carbohydrates is usually associated with a moderate increase in fasting plasma triglyceride levels in the first few weeks but these return to near original levels in the first few weeks. Epidemiologically, high carbohydrate intakes are associated with low plasma cholesterol and variable plasma triglyceride concentrations.[43]

The effect of a high carbohydrate diet on HDL cholesterol and thereby on the total LDL to HDL cholesterol ratio as well as on the particle size of LDL are matters of interest while considering the influence on vascular function and risk of CVD. High carbohydrate diets appear to reduce HDL cholesterol levels and increase the fraction of small dense LDL, both of which may impact adversely on vascular disease. This dyslipidemic pattern is consistent with the elevation of plasma triglycerides. There is as yet no clear evidence that the risk of CVD is altered independently by the carbohydrate levels in the diet. The glycemic index of foods might also be a determinant of the extent to which carbohydrates can influence the glycemic status. Carbohydrate diets with high glycemic index might adversely impact on glucose control, with associated changes in plasma lipids.[44,45]

Dietary fiber

Dietary fiber is a heterogeneous mixture of polysaccharides and lignin that cannot be degraded by the endogenous enzymes of vertebrate animals.[46] Water soluble fibers include pectins, gums, mucilages, and some hemicelluloses. Insoluble fibers include cellulose and other hemicelluloses. Most soluble fibers reduce plasma total and LDL cholesterol concentrations, as reported by several trials.[47] Pectins, psyllium, gums, mucilages, algal polysaccharides, and some hemicelluloses lower total and LDL cholesterol levels

without affecting HDL cholesterol, the reductions in total cholesterol being usually in the range of 5–10%. Human experiments have clearly shown that oat fiber tends to lower plasma total and LDL cholesterol but wheat fiber does not. Rice, bran, and barley may also lower cholesterol.[48] Fiber consumption predicted insulin levels, weight gain, and cardiovascular risk factors like blood pressure, plasma triglycerides, LDL and HDL cholesterol, and fibrinogen more strongly than other dietary components in the CARDIA cohort study of young adults.[49] However, fiber intake may be confounded with many other determinants of cardiovascular health.

Between 1996 and 2001, five very large cohort studies in the USA, Finland, and Norway have all reported that subjects consuming relatively large amounts of whole grain cereals have significantly lower rates of CHD.[48,50] High intake of fiber from cereal sources was associated with a reduced risk of CHD in the Nurses Health Study[50] and was inversely associated with the risk of hypertension in the Health Professionals Follow-up Study.[51] Available evidence supports a recommendation for consumption of about 15 g/1000 kcal of fiber.[47] Since some of the reported benefits may have arisen from other dietary components occurring in association with fiber in natural foods, dietary consumption of high fiber foods should be recommended rather than isolated fiber. Addition of wheat or cereal bran may be considered, where necessary, to supplement natural foods in order to attain the recommended dietary intake.

Antioxidants

The oxidation of LDL by oxygen free radicals results in the unregulated uptake of modified LDL by macrophages in arterial walls, accelerating the atherosclerotic process. Antioxidant nutrients, which can directly scavenge free radicals, include alpha-tocopherol (vitamin E isomer) and ascorbic acid (vitamin C), which have shown antioxidant activity both *in vitro* and *in vivo*, as well as beta-carotene (a provitamin A carotenoid) which has displayed anti-oxidant activity *in vitro*.[52] These mechanisms suggested that increased dietary intake or supplementation of these nutrients would be protective against atherosclerotic vascular disorders. This was supported by evidence from observational studies for vitamin E and beta-carotene, but results of clinical trials employing supplements have been disappointing.

Observational cohort data suggest a protective role for carotenoids. In a meta-analysis, the pooled relative risk reduction for cardiovascular death in those who ate diets rich in beta-carotene was 31% (95% CI 41–20), when dietary and blood carotene levels were measured to compare high and low consumers. The randomized trials, in contrast, reported a moderate adverse effect of beta-carotene supplementation, with a relative increase in the risk of cardiovascular death of 12% in a meta-analysis of four trials.[53] Cancer risk was also increased.

Several large cohort studies showed significant reductions in the incidence of cardiac events in men and women taking high-dose vitamin E supplements.[52] However, the HOPE trial, a definitive clinical trial relating vitamin E supplementation to cardiovascular outcomes, revealed no effect of vitamin E supplementation (at 400 IU/day, for a mean follow up of 4·5 years) on MI, stroke or death from cardiovascular causes in men or women.[54] Other trials also failed to demonstrate a cardioprotective effect of vitamin E supplements.[55]

The conflict between diet-based observational studies and clinical trials employing supplements may arise because of one or more explanatory factors: confounding, interactions/synergistic activity (among antioxidants – with other nutrients), isomers with differing activity in food compared to supplements, other associated protective elements in natural foods (for example, flavonoids, phytoestrogens) and/or temporal dissociation of antioxidant blood levels from fat intake in meals when administered as once a day pills. While the failure of pill supplementation does not necessarily exclude protective effects of dietary antioxidants, current evidence does not support supplementation of any of these antioxidant vitamins for prevention of CHD. However, intake of their primary food resources, especially fruit and vegetables, may be encouraged.

Folate

The relationship of folate to CVD has been mostly explored through its effect on homocysteine, which has been incriminated as an independent risk factor for CHD and probably stroke.[56–59] Folic acid is required for the methylation of homocysteine to methionine. Reduced plasma folate has been strongly associated with elevated plasma homocysteine levels and folate supplementation has been demonstrated to decrease those levels.[60] However, the role of homocysteine as an independent risk factor for CVD has been subject to debate, in view of the data from several prospective studies which did not find this association to be independent of other risk factors.[61] It has also been suggested that elevation of plasma homocysteine is a consequence and not a cause of atherosclerosis, wherein impaired renal function due to atherosclerosis raises plasma homocysteine levels.[62]

Whether homocysteinemia is the cause or consequence of atherosclerosis, its role in promoting thrombosis makes an intervention with folate appear attractive. There is also recent evidence that suggests that homocysteinemia results in endothelial dysfunction, an effect that is reversed by oral folate supplementation.[63,64] An independent antioxidant role for folate has also been postulated. Data from the Nurses Health Study showed that folate and vitamin B_6, from diet and supplements, conferred protection against CHD (fatal and non-fatal events combined) and suggested

a role for their increased intake as an intervention for primary prevention of CHD.[65] Food grain fortification with folate and cyancobalamin has also been recommended as a cost effective measure for CHD prevention.[66]

Recommendations related to folate supplementation must, however, await the results of ongoing clinical trials. Dietary intake of folate through natural food sources may be encouraged in the meanwhile, especially in individuals at a high risk of arterial or venous thrombosis and elevated plasma homocysteine levels.[67]

Flavonoids and other phytochemicals

Flavonoids are polyphenolic antioxidants which occur in a variety of foods of vegetable origin, such as tea, onions and apples. Data from several prospective studies indicate an inverse association of dietary flavonoids with coronary heart disease.[68] A benefit on stroke risk has also been reported.[69] However, confounding may be a major problem and may explain conflicting results of observational studies on flavonoids and coronary heart disease. Fruit and vegetables also contain other phytochemicals that may have protective properties, including isothiocyanates and indoles (found in cruciferous vegetables), sulfides (found in onions and garlic), terpenes (found in citrus oils), and phytoestrogens.[47] While their role in relation to CVD risk is not clearly established and trial evidence related to garlic supplements is generally not supportive, their consumption in the natural food form may have benefits, which need to be evaluated.

Minerals: blood pressure and cardiovascular disease

Sodium

High blood pressure (HBP) is a major risk factor for coronary heart disease (CHD) and both forms of stroke (ischemic and hemorrhagic). The relative risk of CVD for both systolic and diastolic blood pressures operates in a continuum of increasing risk for rising pressure but the absolute risk of CVD is considerably modified by coexisting risk factors.[70]

Of the many risk factors associated with high blood pressure, the dietary exposure most investigated has been daily sodium consumption. It has been studied extensively in animal experimental models, in epidemiological studies, controlled clinical trials, and in population studies on restricted sodium intake.[70] Salt or sodium intake has been directly correlated with mean blood pressure levels and prevalence of hypertension in many populations. Comprehensive epidemiological evidence was provided by the INTERSALT Study[71,72] which investigated the relationship of 24 hour urinary electrolyte excretion to blood pressure in 52 population groups across 32 countries, using standardized methodology to provide comparable data. In adults aged 20–59 years, there was a significant positive relationship between urinary sodium excretion and blood pressure across the 52 population samples. Further, it was also observed that in four of these populations in whom the mean 24 hour urinary sodium excretion was lower than 100 mmol/day, systolic blood pressure did not rise with age.[73]

The consequences of increased sodium consumption accompanying urbanization, on blood pressure levels, was demonstrated in the Kenyan Luo Migration Study wherein rural farmers who traditionally consumed a low salt diet were observed to have an elevation of blood pressure when they migrated to an urban environment. These migrants exhibited blood pressure levels higher than rural controls and comparable to levels observed in Western populations.[74] This rise in blood pressure was related to an increase in salt consumption and a reduced dietary intake of potassium. An overview of observational data in populations suggested that a difference in sodium intake of 100 mmol/day could be associated with average differences in systolic blood pressure of 5 mmHg at age 15–19 years and 10 mmHg at age 60–69 years.[75] Diastolic blood pressures are reduced by about half as much, but the association increases with age and the magnitude of the initial blood pressure. It was estimated that a universal reduction in dietary intake of salt by 50 mmol/day would lead to a 50% reduction in the number of people requiring antihypertensive therapy, a 22% reduction in number of deaths due to strokes, and a 16% reduction in number of deaths from coronary heart disease.[75]

A recently reported cohort study in Finland prospectively followed up 1173 men and 1263 women aged 25–64 years, with complete data on 24 hour urinary sodium excretion and cardiovascular risk factors.[76] The hazard ratios for CHD, CVD, and all-cause mortality, associated with a 100 mmol increase in 24 urinary sodium excretion, were 1·51 (95% CI 1·14–2·00), 1·45 (95% CI 1·14–1·84) and 1·26 (95% CI 1·06–1·50) respectively, in both men and women. The frequency of acute coronary events, but not acute stroke events, rose significantly with increasing sodium excretion. Disaggregated analyses revealed significant risk ratios in men only and revealed that sodium predicted mortality in men who were overweight. Despite the limitations of such subgroup analyses, the overall association of increasing sodium excretion with CVD and all-cause mortality further support the evidence linking increased sodium intake to adverse cardiovascular health outcomes.

Several clinical intervention trials, conducted to evaluate the effects of dietary salt reduction on blood pressure levels in hypertensive and normotensive individuals, have been systematically reviewed.[12,77] Many of the earlier trials were of limited size, short duration, and deficient in statistical power. Based on an overview of 32 methodologically adequate trials (22 in hypertensive subjects and 12 in

normotensive persons), Cutler *et al*[12] concluded that a daily reduction in intake of sodium by 70–80 mmol was associated with a lowering of blood pressure both in hypertensive and normotensive individuals, with systolic and diastolic blood pressure reductions of 4·8/1·9 mmHg in the former and 2·5/1·1 mmHg in the latter. Clinical trials have also demonstrated the sustained blood pressure lowering effects of sodium restriction in infancy,[78] as well as in the elderly population, in whom it provides a useful non-pharmacologic therapy.[79]

The results of the low sodium – DASH – diet trial[80] further strengthen the conclusion that reduction of daily sodium intake, through salt restricted diets, lowers blood pressure effectively and is additive to the benefits conferred by the DASH diet. This trial revealed that low sodium diets, with 24 hour sodium excretion levels around 70 mmol/day, are effective and safe. Sodium consumption has also been linked to the presence of left ventricular hypertrophy[81,82] and restricted sodium intake has been demonstrated to result in regression of this important indicator of cardiovascular risk.[81,82]

Of three population studies on restriction of salt, two (the Portuguese Salt Trial and the Tianjin trial in China) revealed significant reductions in blood pressure in the intervention group, while the third (the Belgian Salt Intervention Trial) did not reveal success because of difficulties in reducing salt consumption.[83–85] Animal models as well as ecological associations derived from the INTERSALT suggest a direct relationship between sodium consumption and the risk of stroke, though the methodology employed in these studies is not strong.[86,87]

Based on the observational and trial data so far available, it would be justified to recommend a daily salt intake of less than 5 g/day.[80] Such advice would be appropriate even in tropical climates, as sodium homeostasis regulates sodium excretion in sweat and urine without adverse effects under such conditions.

Potassium

Cardioprotective effects of dietary potassium have been hypothesized as the basis for low CVD rates in populations consuming "primitive" diets and in vegetarians in industrialized cultures.[88] The INTERSALT study provided evidence of an inverse association between urinary potassium excretion and blood pressure levels, across diverse populations.[71] Migrant studies also revealed a rise in blood pressure when diets changed to a lower potassium and higher sodium intake.[74]

A protective effect of potassium on blood pressure was suggested by clinical studies reporting that severe short-term potassium restriction induces salt sensitivity in normotensive humans,[89] as well as the blood pressure lowering effect of potassium supplements to the diet (ranging from 24–104 mmol/day) in hypertensive subjects.[88]

Whelton *et al* concluded from a meta-analysis of randomized controlled trials that potassium supplements reduced mean blood pressures (systolic/diastolic) by 1·8/1·0 mmHg in normotensive subjects and 4·4/2·5 mmHg in hypertensive subjects.[90] An increase in dietary intake of potassium, from approximately 60 to 80 mmol/day, was shown to be inversely and significantly related to the incidence of stroke mortality in women.[91]

While dietary potassium has been shown to have protective effects on blood pressure and CVD, there is no evidence to suggest that long-term potassium supplements should be administered for cardiovascular protection. The beneficial effects of fruit and vegetables recommend their regular use in daily diets at a level that should assure an adequate intake of dietary potassium.

Calcium and magnesium

A meta-analysis of studies involving calcium supplements reveal modest effects on blood pressure. The estimated blood pressure reduction was 2·1 mmHg for systolic blood pressure and 1·1 mmHg for diastolic blood pressure.[92] A review of 29 studies of magnesium was inconclusive due to methodological problems but suggested that there was no negative association of blood pressure with magnesium.[93] There is presently no evidence to recommend public health or clinical interventions involving the use of these minerals for cardiovascular protection in populations or individuals, other than in the form of a balanced diet providing an adequate daily intake.

Food items and food groups

Fruit and vegetables

While the consumption of fruit and vegetables has been widely believed to promote good health, evidence related to their protective effect has only been presented in recent years.[94–96] A systematic review reported that nine of ten ecological studies, two of three case–control studies and six of sixteen cohort studies found a significant protective association for coronary heart disease with consumption of fruit and vegetables or surrogate nutrients.[96] For stroke, three of five ecological studies and six of eight cohort studies found a significant protective association.[96]

A 5 year follow up study of 39 876 female health professionals,[97] observed a significant inverse association between fruit and vegetable intake and CVD risk. For increasing quintiles of total fruit and vegetable intake, the relative risks were 1·0, 0·78, 0·72, 0·68, and 0·68. After excluding participants with a self reported history of diabetes, hypertension or high cholesterol at baseline, the multivariate adjusted relative risk was 0·45 when extreme quintiles were compared (95% CI 0·22–0·91). In a 12 year follow up of

15 220 male physicians in the USA,[98] men who consumed at least 2·5 servings of vegetables per day were observed to have an adjusted relative risk of 0·77 for coronary heart disease, compared with men in the lowest category (<1 serving per day). Combining analyses of data from two large prospective cohort studies of women and men respectively, Joshipura *et al* reported that overall fruit and vegetable consumption were inversely related to the risk of ischemic stroke after adjusting for confounders.[99] Assessed as a continuous trend, an increment of 1 serving/day was associated with 6% lower risk of ischemic stroke among men and women combined. When analyzed separately for the type of fruit and vegetables, the lowest risks were observed for high consumption of cruciferous vegetables, green leafy vegetables, citrus fruits, vitamin C-rich fruits and vegetables.

The effects of increased fruit and vegetable consumption on blood pressure alone or in combination with a low fat diet, were assessed in the DASH trial.[100] While the combination diet was more effective in lowering blood pressure, the fruit and vegetable diet too lowered the blood pressure in comparison to the control diet (2·8 mmHg systolic and 1·1 mmHg diastolic). Such reductions, while seeming modest at the individual level, would result in a substantial reduction in population-wide risk of CVD by shifting the blood pressure distribution.

Fish

Most, but not all, population studies have shown that fish consumption in populations is associated with a reduced risk of CHD.[101–103] A systematic review concluded that the discrepancy in the studies may be due to differences in the populations studied, with only high-risk individuals benefitting from increasing their fish consumption.[103] It was estimated that, in high-risk populations, an optimum fish intake estimated at 40–60 g/day would lead to approximately a 50% reduction in death from coronary heart disease. In the Diet and Reinfarction Trial, 2 year mortality was reduced by 29% in survivors of a first myocardial infarction in persons receiving advice to consume fatty fish at least twice a week.[104] While the protective effects of fish on CHD are principally mediated by n-3 PUFA, the contribution of other constituents of fish cannot be ruled out. The effect of dietary fish on the risk of stroke has been investigated in cohort studies, with conflicting results on the risk of ischemic stroke.[105,106] A recent study reported that fish consumption is associated with a reduced risk of death from all causes as well as CHD and stroke mortality, using data from 36 countries.[107]

Nuts

Five large epidemiological studies have, thus far, demonstrated that frequent consumption of nuts was associated with decreased risk of CHD, the best known among them being the Adventist Health Study.[108–111] The relative risk ranged from 0·43 to 0·82 for subjects who consumed nuts more than five times per week compared to those who never consumed nuts. An inverse dose–response relationship was demonstrated between the frequency of nut consumption and the risk of CHD, in men as well as in women. Most of these studies considered nuts as a group, combining many types of nuts.

The effect of specific nuts on lipid and lipoprotein end points were evaluated in several clinical studies. The nuts studied to date include walnuts, almonds, legume peanuts, macadamia nuts, pecans, and pistachio nuts.[108] Collectively, these clinical studies indicate that inclusion of nuts in a lipid lowering diet has favorable effects, but does not provide unequivocal evidence of an additive effect of nuts to the effects of a low saturated fat diet *per se*. The fatty acid profile of nuts (high in unsaturated fatty acids and low in saturated fatty acids) contributes to cholesterol lowering by altering the fatty acid composition of the diet as a whole. Nuts are also a rich source of dietary fiber. It must, however, be recognized that the high fat content of nuts makes them high in calorie content and advice to include nuts in the diet must be tempered in accordance with the desired energy balance. While further research is needed to characterize the independent protective effects of nuts against CVD and identify the mechanisms of such protection, available evidence suggests that nuts should be recommended as part of an energy-appropriate healthy diet which is intended to reduce the risk of CHD.

Soy

Several trials indicate that intake of soy has a beneficial effect on plasma lipids.[112,113] A composite analysis of 38 clinical trials found that an average consumption of 47 g of soy protein a day led to a 9% decline in total cholesterol and a 13% decline in LDL cholesterol in subjects free of CHD.[112] The benefit of soy consumption was associated with baseline cholesterol levels, such that those with the highest cholesterol levels derived the maximum benefit (subjects with total cholesterol >335 mg/dl showed a 19% reduction in total and 24% reduction in LDL cholesterol). Cholesterol lowering of this magnitude could potentially reduce the risk for CAD by 20–40%.

Soy is rich in isoflavones, compounds that are structurally and functionally similar to estrogen. Several animal experiments suggest that intake of these isoflavones may provide protection against CHD,[114] but human data on efficacy and safety are still awaited. Naturally occurring isoflavones, isolated with soy protein, reduced the plasma concentrations of total and LDL cholesterol without affecting the concentrations of triglycerides or HDL cholesterol in mildly hypercholesterolemic individuals, in a casein-controlled clinical trial.[115]

Dairy products

Milk and milk products are important contributors to dietary fat and can be high in saturated fat and cholesterol. They are also sources of minerals like potassium, magnesium, and calcium. Milk protein has been implicated in a study reporting elevated levels of antibodies to milk protein in myocardial infarction patients in comparison with healthy controls.[116] Dairy consumption has been correlated positively, in an ecological study, with blood cholesterol as well as coronary mortality. Milk consumption correlates positively with coronary mortality rates in 43 countries and with myocardial mortality in 19 regions of Europe.[117,118] In contrast, a population-based study in men of Japanese ancestry in Honolulu reported a reduced risk of ischemic stroke in older middle aged men, which could not be explained by the intake of dietary calcium.[119]

On the basis of presently available evidence, reduced intake of high-fat dairy foods should be recommended for cardiovascular protection. Whether milk or milk products modified to substantially lower the content of saturated fat are associated with an increase or decrease in cardiovascular risk cannot be commented upon at present. They formed a component of the DASH diet which significantly lowered blood pressure and may be considered as part of a composite dietary advice.

Alcohol

The relationship of alcohol to overall mortality and cardiovascular mortality has generally been J-shaped, when studied in Western populations in whom the rates of atherothrombotic vascular disorders are high.[120–124] The protective effect of moderate ethanol consumption is primarily mediated through its effect on the risk of coronary heart disease (CHD), as supported by more than 60 prospective studies.[121] A consistent coronary protective effect has been observed for consumption of one to two drinks per day of an alcohol-containing beverage, but heavy drinkers have higher total mortality than moderate drinkers or abstainers, as do binge drinkers. Moderate alcohol consumption (up to two drinks per day) has also been associated with a reduced risk of ischemic stroke in men and women.[125] Long-term heavy alcohol consumption ($>$60 g/day) increases an individual's risk for all stroke subtypes.

Several mechanisms for the cardioprotective effects of alcohol have been proposed: increase in plasma HDL cholesterol; reduced platelet aggregation or clotting; enhanced fibrinolysis; phenolic constituents of some alcoholic beverages acting as antioxidants or platelet inhibitors.[126] Genetic variations which slow alcohol metabolism have been shown to increase HDL cholesterol and reduce the risk of myocardial infarction.[3] Based on current evidence, the benefit of moderate alcohol consumption seems to be a generic effect regardless of the type of beverage.[127] While the specific advantages of red wine over other alcoholic beverages is unproven, the claimed beneficial effects of flavonoids on lipoprotein oxidation are available from grape juice as from wine.[128]

The possible beneficial effects of moderate ethanol consumption must be weighed against the deleterious effects of high intake, including increased risk of hypertension, cardiomyopathy, and hemorrhagic stroke. Alcohol consumption, in excess of three drinks per day, is associated with a rise in blood pressure and plasma triglyceride levels. Reduction or cessation of alcohol consumption is a widely recommended measure for non-pharmacologic therapy of hypertension, in many international guidelines. The recommendations related to alcohol should be made in accordance with the cultural practices of the populations and the clinical profile of individuals, with advice to avoid excess in all cases.

The optimal intake, for cardiovascular protection depends on age, gender, presence of other risk factors or associated diseases, and on the intake of folic acid. However, it is generally recommended to be about two drinks a day for men and one a day for women.

Eggs

Eggs are unique because of their high cholesterol content. Major effects on atherosclerosis are observed in experimental animals but extrapolation to humans is doubtful. A large observational study suggested that there was no increase in the risk of CHD up to one egg per day (except in a diabetic subgroup), in the US population.[129] In terms of global recommendations, it may still be prudent to limit the intake to three to four eggs per week.

Dietary patterns and composite dietary interventions

The Mediterranean diet

The traditional Mediterranean diet has been described to have eight components: (i) high monounsaturated-to-saturated fat ratio; (ii) moderate ethanol consumption; (iii) high consumption of legumes; (iv) high consumption of cereals (including bread); (v) high consumption of fruit; (vi) high consumption of vegetables; (vii) low consumption of meat and meat products; and (viii) moderate consumption of milk and dairy products.[130] Most of these are found in many diets. The characteristic component is olive oil, and many equate a Mediterranean diet with consumption of olive oil.

Based on ecological comparisons, Keys *et al*[131] hypothesized that traditional Mediterranean diet conferred protection against CVD and several other disorders, principally because of a low saturated fat content. Three prospective population studies in Greece, Denmark, and Australia provided supportive evidence of protective effects on overall mortality.[132]

However, this traditional form of "Mediterranean diet" has not been tested in controlled clinical trials.

A secondary prevention trial of dietary intervention in survivors of a first recent myocardial infarction, which aimed to study the cardioprotective effects of a "Mediterranean type" of diet, actually left out its most characteristic component, olive oil.[133] This diet was designed to supply <35% of energy as fat, <10% of energy as saturated fat, <4% of the energy as linoleic acid (n-6) and >0·6% of energy as alpha– linolenic acid (n-3). The main fat source was rapeseed oil. Vegetables and fruit were also increased in the diet. Two major biologic factors were modified by the intervention: plasma levels of alpha-tocopherol and ascorbic acid were elevated and plasma n-3 fatty acids increased along with a decrease in n-6 fatty acids. Other biologic mediators of altered risk, like flavonoids, folate and minerals like potassium were probably altered but not measured. While the initial publication reported a 70% reduction in recurrence of myocardial infarction and cardiac death, the 4 year follow up study reported a 72% reduction in cardiac death and non-fatal myocardial infarction. The risk of overall mortality was lowered by 56%.[9]

Vegetarian diets

A reduced risk of CVD has been reported in populations of vegetarians living in affluent countries[134–136] and in case–control comparisons in developing countries.[137] Reduced consumption of animal fat and increased consumption of fruit, vegetables, nuts and cereals may underlie such a protective effect. However vegetarian diets *per se* need not be healthful.[136] If not well planned, they can contain a large amount of refined carbohydrates and *trans* fatty acids while being deficient in the levels of vegetable and fruit consumption. The composition of the vegetarian diet should, therefore, be defined in terms of its cardioprotective constituents rather than use or endorse the "vegetarian" label as an omnibus category.

"Prudent" *v* "Western" patterns

Using factor analysis on a 131-item food frequency questionnaire, Hu *et al.* identified two major dietary patterns at baseline in 44 875 men followed up for 8 years in the Health Professionals Follow-up Study.[138] The "prudent" pattern was characterized by higher intake of vegetables, fruit, legumes, whole grains, fish, and poultry whereas the "Western" pattern was characterized by higher intake of red meat, processed meat, refined grains, sweets and desserts, French fries, and high fat dairy products. After adjustment for age and other coronary risk factors, relative risks, from the lowest to the highest quintiles of the prudent pattern score, were 1·0, 0·87, 0·79, 0·75, and 0·70. In contrast, the relative risks, across increasing quintiles of the Western pattern, were 1·0, 1·21, 1·36, 1·40, and 1·64. These associations persisted in subgroup analyses according to cigarette smoking, body mass index, and parental history of myocardial infarction.

Japanese diet

The traditional Japanese diet has attracted much attention because of the highest life expectancy and low CHD mortality rates among the Japanese.[139] This diet is low in fat and sugar and includes soy, seaweeds, raw fish, and a predominant use of rice. It has been high in salt, but salt consumption has recently been declining in response to Japanese Health Ministry guidelines. There is also recent trend towards increased fat consumption and plasma cholesterol levels have risen, and their effects on CHD and CVD mortality rates need to be watched.

DASH diets

The effects of composite dietary interventions on blood pressure levels, in "normotensive" and "hypertensive" individuals were studied in well designed clinical trials.[80,100] The initial dietary intervention, used in the Dietary Approaches to Stop Hypertension (DASH) trial, involved a diet that emphasized fruit, vegetables, and low fat dairy products, and included whole grains, poultry, fish, and nuts while reducing the amounts of red meat, sweets, and sugar-containing beverages. Two variants of the intervention diet were used: a fruit and vegetables (F-V) diet and a low fat F-V (DASH) diet. The latter was designed to lower the intake of total and saturated fat as well as dietary cholesterol. In comparison with a "typical" diet in the USA, both intervention diets lowered blood pressure but the DASH diet was more effective in substantially reducing systolic and diastolic blood pressures, both in people with hypertension and in those without hypertension.[80] The DASH diet was also demonstrated to be effective as first line therapy in individuals with stage I isolated systolic hypertension (that is, with a systolic blood pressure of 140–159 mmHg and a diastolic blood pressure below 90 mmHg), with 78% of the persons on the DASH diet reducing their systolic blood pressure to <140 mmHg, in comparison to 24% in the control group.[140] The DASH diet resulted in lowering plasma levels of total cholesterol and LDL cholesterol but these changes were also accompanied by a reduction in HDL cholesterol levels.[141] While the Framingham risk score improved as a result of the impact on total and LDL cholesterol as well as blood pressure, the impact of the associated reduction in HDL cholesterol needs to be assessed.

The DASH trial was followed by a well designed factorial trial combining the DASH diet with high, intermediate, and low levels of sodium consumption and measuring the effects on blood pressure, in comparison to a control diet typical of the USA, administered with similar graded variations in the sodium content.[100] Within each assigned group

(DASH *v* typical), participants ate foods with high intermediate and low levels of sodium for 30 consecutive days each, in random order. Reduction in sodium intake, at each level, resulted in significant lowering of systolic and diastolic blood pressures in both DASH and control groups. The fall was, however, maximal when the DASH diet was modified to reduce the sodium content. As compared with the control diet with a high sodium level, the DASH diet with a low sodium level led to a mean systolic blood pressure that was 7·1 mmHg lower in participants without hypertension and 11·5 mmHg lower in participants with hypertension (Figure 25.2). There was also a −4·5 mmHg difference in the mean diastolic pressure level, between the low sodium–DASH diet phase and the high sodium–control diet phase of the trial.

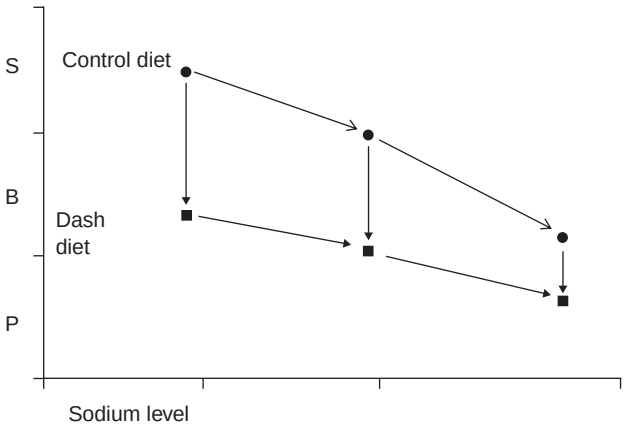

Figure 25.2 Effect of the low sodium–DASH diet on systolic blood pressure (adapted from Sacks *et al*[80])

The effects of the low sodium–DASH diet have a great potential for application in both population-based and individual focused strategies for prevention and control of high blood pressure and associated CVD. Adoption of the low sodium–DASH diet, by populations at large, is likely to be safe and beneficial in shifting the population distributions of blood pressure (and plasma cholesterol) towards lower levels of cumulative risk of CVD in those populations. Similarly, this diet will also provide an effective non-pharmacologic therapeutic intervention in the clinical management of individuals identified to be at an increased risk of CVD because of high blood pressure and associated risk factors.

Dietary recommendations for cardiovascular health

- A low intake of saturated fatty acids (SFA): less than 7% of daily energy intake (within these limits, intake of foods rich in myristic and palmitic acids should be especially reduced). **Grade A**
- A very low intake of *trans* fatty acids (hydrogenated oils and fats): less than 1% of daily energy intake. **Grade B**
- Adequate intake of polyunsaturated fatty acids (PUFA): 6–10% of daily energy intake, with an optimal balance of n-6 PUFA and n-3 PUFA at 5–8% and 1–2% levels of daily energy intake, respectively. **Grade B**
- Intake of monounsaturated fatty acids (MUFA) to make up the rest of daily energy intake from fats, with daily total fat intake ranging between 15% and 30% of daily energy intake (this may be based on current levels of population consumption in different regions and modified in accordance with age, activity and goals of body weight). **Grade A**
- While there is no evidence that links the quantity of dietary fat to CVD, independent of the effects of fat composition and unhealthy weight gain, there are concerns over potential excess energy consumption associated with an unrestricted fat intake. These support a recommendation that fat intake should not exceed 30% of daily energy intake. However, in very active groups with healthy dietary practices and stable healthy weight, fat intake may go up to 35% of energy. **Grade B**
- Restriction of dietary cholesterol consumption: less than 300 mg per day, mainly through the restriction of dairy fats. **Grade B**
- Daily intake of fresh fruit and vegetables (including berries, green leafy and cruciferous vegetables and legumes) in an adequate quantity: 400–500 g per day is recommended to reduce the risk of CHD, stroke and high blood pressure. **Grade A**
- Restriction of daily salt (sodium chloride) intake: less than 5 g per day. This should take into account total sodium intake from all dietary sources. **Grade A**
- Minimization of other forms of sodium consumption such as through food additives or preservatives, such as monosodium glutamate (MSG). **Grade B**
- Potassium intake at a level which will keep the sodium:potassium ratio close to 1: a daily potassium intake level of 70–80 mmol per day. This may be achieved through adequate daily consumption of fruit and vegetables. Such a balance may also be obtained through use of potassium enriched low sodium salt substitutes. **Grade A**
- Consumption of fish and other marine foods to provide over 200 mg per day of docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA). **Grade A**
- Regular low to moderate consumption of alcohol (that is, 1–2 drinks per day) is protective against CHD, concerns about other cardiovascular and health risks associated with alcohol consumption (including stroke, hypertension, and some cancers) do not favor a general recommendation for its use. **Grade B**

Implications for policy

The rising global burden of CVD requires a rapid response that integrates policies and programs which enable effective prevention and control in diverse geographical and resource settings. Diet and nutrition play a critical role in the causation of major CVDs and, along with physical activity, influence many of the biologic variables that mediate the risk of those diseases. There is, therefore, an opportunity to alter the direction and dimensions of the global CVD epidemic through policy interventions (at the local, national, and global levels), which promote the availability, affordability, and acceptability of health promoting diets and restrain the marketing and consumption of unhealthy foods.

Currently available evidence strongly indicates that cardiovascular health is strongly influenced by the quality of dietary fat and the quantity of fruit and vegetables as well as salt consumed daily. While several other food items also contribute to enhanced or decreased risk of CVD, these remain the principal determinants of diet-related CVD risk. Whether the evidence is derived from controlled clinical trials or an ecologic study of reasons for a sharp decline in coronary mortality in Poland since 1991, the evidence suggests that dietary changes can substantially alter the risk of CVD.[142,143] Policies must, therefore, address these directly and decisively.

These measures must encompass a wide range of educational as well as regulatory measures, acting through price and non-price mechanisms. That success in reducing CVD risk factor levels as well as CVD mortality is achievable through such measures that influence usual diet patterns is clear from the experience of developed countries.[144] Developing countries like Mauritius have shown that population levels of CVD risk factors can be altered by a combination of community education and regulatory interventions related to the price of edible oils.[145]

Measures to influence the quality of dietary fat (as well as the total quantity) consumed must address the elimination of *trans* fats and reduction of saturated fats from the daily diet. Governments must work with the food industry to influence production, processing, pricing, and labeling of food products so that these goals can be met. Consumer education must be enhanced so that informed choices can be made, even as the availability of healthier foods is promoted through such measures. As market economy becomes a globally pervasive economic model, it must be recognized that markets are not autonomous entities and should be molded, for public good, by consumer consciousness as well as enlightened regulatory measures.

Part IIIa

Specific cardiovascular disorders: Stable coronary artery disease

Bernard J Gersh and John A Cairns, *Editors*

Grading of recommendations and levels of evidence used in *Evidence-based Cardiology*

GRADE A

Level 1a Evidence from large randomized clinical trials (RCTs) or systematic reviews (including meta-analyses) of multiple randomized trials which collectively has at least as much data as one single well-defined trial.

Level 1b Evidence from at least one "All or None" high quality cohort study; in which ALL patients died/failed with conventional therapy and some survived/succeeded with the new therapy (for example, chemotherapy for tuberculosis, meningitis, or defibrillation for ventricular fibrillation); or in which many died/failed with conventional therapy and NONE died/failed with the new therapy (for example, penicillin for pneumococcal infections).

Level 1c Evidence from at least one moderate-sized RCT or a meta-analysis of small trials which collectively only has a moderate number of patients.

Level 1d Evidence from at least one RCT.

GRADE B

Level 2 Evidence from at least one high quality study of non-randomized cohorts who did and did not receive the new therapy.

Level 3 Evidence from at least one high quality case–control study.

Level 4 Evidence from at least one high quality case series.

GRADE C

Level 5 Opinions from experts without reference or access to any of the foregoing (for example, argument from physiology, bench research or first principles).

A comprehensive approach would incorporate many different types of evidence (for example, RCTs, non-RCTs, epidemiologic studies, and experimental data), and examine the architecture of the information for consistency, coherence and clarity. Occasionally the evidence does not completely fit into neat compartments. For example, there may not be an RCT that demonstrates a reduction in mortality in individuals with stable angina with the use of β blockers, but there is overwhelming evidence that mortality is reduced following MI. In such cases, some may recommend use of β blockers in angina patients with the expectation that some extrapolation from post-MI trials is warranted. This could be expressed as Grade A/C. In other instances (for example, smoking cessation or a pacemaker for complete heart block), the non-randomized data are so overwhelmingly clear and biologically plausible that it would be reasonable to consider these interventions as Grade A.

Recommendation grades appear either within the text, for example, **Grade A** and **Grade A1a** or within a table in the chapter.

The grading system clearly is only applicable to preventive or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or pathophysiologic.

26 Anti-ischemic drugs

Lionel H Opie

> A major problem … is the lack of sufficient data comparing antianginal and placebo treatment.[1]

The major anti-ischemic drugs are, in historical order of appearance, the nitrates, the β adrenergic blockers, the calcium-channel antagonists, the metabolic modifiers, and the potassium-channel openers. In addition, there is increasing evidence that the angiotensin converting enzyme (ACE) inhibitors and the statin lipid lowering drugs have indirect anti-ischemic properties. Preservation of endothelial function may also be an indirect anti-ischemic procedure. The antiplatelet agents, including aspirin, clopidogrel, and the GPIIb/IIIb receptor blockers, as well as the antithrombotics and thrombolytics, will not be considered here but in the following section of Part III on acute ischemic syndromes. Special attention will be paid to the potential effect of the standard anti-ischemic drugs not just in giving symptomatic relief of angina, but, in keeping with the aim of this book, on hard outcome end points such as re-infarction and mortality.

What is ischemia?

Ischemia of the myocardium is probably the most important cause of cardiovascular and total mortality and morbidity in Western societies. Although there are many definitions, in the end they come down to an inadequate blood supply to the myocardium.[2] The Greek *ischo* means "to hold back" and *haima* means "blood". The word "ischemia" was, it seems, first used by Rudolf Virchow in 1858, to describe a situation in which limitation of blood flow resulted from an increased resistance to blood flow. The "modern" concept of supply-demand imbalance as a cause of ischemia dates back to observations made nearly two hundred years ago on the exercising limb[3]:

> If we call into vigorous action a limb around which we … applied a ligature, we find then that the member can only support its action for a very short time; for now its supply of energy and its expenditure do not balance each other.

Myocardial ischemia therefore exists when the reduction of coronary flow is so severe that the supply of oxygen is inadequate for the demands of the tissue, which is the generally accepted situation in acute effort angina. Ischemia is often distinguished from infarction, the latter reflecting prolonged irreversible ischemia with myocardial cell death. Therefore the ischemia is also the underlying situation in unstable angina and the very early phase of the clinical syndrome of acute myocardial infarction (AMI), when reperfusion can still reverse the ischemic myocardial damage. Myocardial ischemia is also thought to contribute, together with the underlying anatomical substrate, to the potentially lethal ventricular arrhythmias found in patients with ischemic heart disease.

Myocardial ischemia may also occur chronically, as proposed for hibernation. In the latter case, the proposal is that the myocardium has undergone a chronic adaption to ischemia by downregulation of contraction. The simplified concept is "little blood, little work".[4]

Therefore, there is a wide spectrum of conditions in which myocardial ischemia is clinically relevant (Table 26.1) and for which anti-ischemic drugs can be used. As will be argued, the hard evidence for their long-term benefit is, in general, strikingly absent.

Safety and efficacy

General aspects

Safety and efficacy are ultimately linked: the more pronounced the beneficial effects of a therapeutic regimen, the greater the degree of side effects that may be tolerated. A drug that significantly prolongs life, such as alteplase or streptokinase in AMI, is recommended for use despite an increased incidence of hemorrhagic stroke, because the balance of mortality plus stroke favors the use of the drug. There exists a hierarchy for the significance of end points, the most important primary end point being prolongation of life, with a secondary end point being an improved quality of life, either by reduction of morbidity or by relief of symptoms such as anginal pain. Tertiary end points are those that neither improve the quantity nor the quality of life, but which are expected to prevent disease by reducing risk factors, examples being the treatment of mild asymptomatic arterial hypertension.

Evidence for the first of these end points is, in general, scant in relation to the anti-ischemic drugs. Information gathered in one situation is not necessarily directly relevant to another. Thus, for example, the benefits of β blockade in post-MI prevention[5] do not necessarily show that these

Table 26.1 The clinical spectrum of acute ischemia and the various drugs used

Clinical syndrome	Pathophysiology	Drug therapy	Outcome in RCTs
Effort angina	Imbalance of oxygen supply–demand, transient	Nitrates, β blockers, calcium antagonists, metabolic modifiers, K-channel openers	None for nitrates or metabolic modifiers, limited for β blockers and calcium antagonists, positive for K-opener
Unstable angina, acute NSTE coronary syndrome	As above, prolonged	As above, antithrombins, antiplatelet agents	None for anti-ischemic drugs
Threatened MI	As above prior to start of cell necrosis	β blockade	Possible benefit for β blockade, harm for nifedipine
Ischemic arrhythmias	Ischemia-induced rise in cyclic AMP and cell calcium; increased I_f in Purkinje fibers; lipid changes	β blockade	Indirect evidence strongly favors β blockade, but no RCTs have been directed towards ischemic arrhythmias

Abbreviations: I_f, "funny current"; MI, myocardial infarction; NSTE, non-ST elevation; RCTs, randomized controlled trials

drugs also prolong life in stable effort angina. The present author agrees with Hjemdahl *et al*[1] that the pathophysiologic situation in patients with symptomatic angina is often very different from that in the post-MI setting. In MI, there is a zone of dead tissue, and depending on its size there will be reactive remodeling in the rest of the ventricle, introducing a different pathophysiologic situation and predisposing to left ventricular (LV) failure. Also, the presence of viable and non-viable myocardium creates electrical inhomogeneity that predisposes to re-entry with risks of lethal ventricular arrhythmias. Furthermore, the possibility of the coexistence of stunning, hibernation, and preconditioning, collectively called *the new ischemic syndromes*, all predispose to a highly complex and multifarious spectrum that constitutes ischemic LV dysfunction.[6] Although some of these abnormalities may be found in chronic stable angina because there may be coexisting previous MI, nonetheless the predominant and basic pathology is in the one case transient myocardial ischemia causing effort angina, and in the other case dead tissue with reactive ventricular remodeling. Of note, a sizable portion of patients in studies on chronic stable angina – up to one third – have had previous infarcts.[1] Post-MI angina therefore merits specific consideration, but again outcome studies are missing.

How is safety assessed? The hierarchy of evidence

Safety is not well defined but could be regarded as the absence of significant adverse effects when the drug is used with due regard for its known contraindications.[7] Safety implies the added assurance that there are no hidden dangers in the legitimate use of the drug. Evidence for safety, like evidence for efficacy, can come from a variety of sources. There is a hierarchy of evidence regarding safety, starting from anecdotal case reports as the least reliable, followed by case series, case–control studies, cohort studies, going through to more coherent information with emphasis on large controlled randomized trials (RCTs) and carefully conducted meta-analyses of these trials. These lead to acceptance of the overall evidence as favoring a position where the benefit and the safety of a drug group is well established (which is the most reliable evidence).[7] For example, in the case of calcium antagonists, most of the earlier evidence on adverse effects comes from case–control or cohort studies or small RCTs. Such data are subject to serious intrinsic problems of the methodology, which can generate hypotheses without providing proof or otherwise. On the other hand, in the case of β blockers, there is concordant evidence for benefit in the data on post-MI patients from many large trials,[5] and a very large observational study on over 200 000 patients.[8]

Are there safety concerns regarding calcium antagonists and β blockers?

A number of safety concerns have been raised in relation to calcium antagonists, and to some extent also to β blockers. Many of these are based on case–control or cohort studies,

which are not a reliable source of information.[7,9] There are major contradictions between the various studies. The question of cancer and gastrointestinal hemorrhage as possible side effects is reviewed by the WHO-ISH committee, and by Opie *et al*[7] without a causative association being found.[10] In the case of cancer, one small cohort study is outweighed by two bigger negative studies.[11,12] In the case of hemorrhage, the evidence is incomplete and not supported by prospective studies. In general, it is the short-acting calcium antagonists,[13] and in particular short-acting nifedipine, that have been associated with adverse effects.[7,14]

There is long-standing good evidence that short-acting instant release (IR) nifedipine in capsule form can increase mortality in acute ischemic syndromes[7,15,16] so that it is contraindicated in unstable angina or early phase MI unless accompanied by β blockade. It follows that:

- the mechanism of the adverse effects of IR nifedipine is very probably by reflex adrenergic activation;
- even in stable effort angina, neither short-acting nifedipine nor any other short-acting dihydropyridine should be used in the absence of an accompanying β blocker.

Indirect data from a meta-analysis of effort angina[17] could also suggest that any short-acting dihydropyridine should be avoided in effort angina. Experience in unstable angina would, however, suggest that combination with β blockade would be safe. **Grade B**

Safety concerns have also been raised in relation to β blockers. Case–control studies suggest an increased incidence of sudden cardiac arrest or death in hypertensive patients treated by β blockade.[18,19] In a prospective observational study on 12 550 hypertensive patients over 6 years,[20] those taking calcium antagonists or ACE inhibitors were at no increased risk of diabetes versus hypertensive patients not receiving therapy, whereas with β blockers there was a 28% increase (RR 1·28, 95% CI 1·04–1·57). Although the potential weakness of observational studies must again be emphasized, other short-term studies have shown that β blockade added to thiazide therapy for hypertension has a hyperglycemic effect.[21]

Safety *v* safe use

Whenever a serious side effect of any given drug becomes known, and acted on, then that safety issue should be obviated so that the drug becomes safer. For example, β blockers are no longer given to patients with pre-existing excess bradycardia, sick sinus syndrome, or asthma. In that sense, the increased mortality long known in relation to the use of IR nifedipine in acute ischemic syndromes is a safety issue that should already have been overcome by the appropriate warnings.

RCTs

Calcium antagonists and β blockers in effort angina

Regarding trials with outcome end points, the major studies are two relatively small RCTs comparing calcium antagonists with β blockers in effort angina, neither trial having a placebo arm. In the APSIS[22] study, slow release verapamil was compared with metoprolol, the main prognostic end points being a combination of morbidity and mortality (total and cardiovascular), and non-fatal cardiovascular complications including MI, revascularization, stroke, and peripheral vascular events, as well as treatment failure. These end points did not differ significantly between the treatments, nor were side effects or quality of life indices different between the two drugs. Because of the very low death rate, which was about 2% per year of follow up, it is impossible to exclude that either drug might be better than the other, or that one or the other drugs might be better or worse than placebo (not tested). Studies to settle the mortality issue are unlikely to be undertaken, so we must evaluate the combined end points actually tested. On present evidence there are not enough data to conclude that either the calcium antagonists or the β blockers differ one from the other, or from placebo.

TIBET[23] compared slow release nifedipine (twice daily formulation) with atenolol. As there were three treatment arms including the combination of these drugs, and only 682 patients in total to start with, there were only 450 patient-years in each group. Outcome was assessed by a combination of end points considered either "hard" (cardiac mortality, MI, or unstable angina) or "soft" (revascularization or treatment failure). Thus the major conclusion of this study is that it is underpowered for hard end points and even for combined hard and soft end points. The firm conclusion is the poor tolerance of nifedipine tablets.

The more recent Stanford meta-analysis[24] added 59 short-term studies in which cardiac death or MI were reported during the use of β blockers or calcium antagonists for effort angina, giving 116 extra events, still with no differences between the outcomes and an odds ratio very close to unity.

In addition there are two placebo-controlled trials, ASIST and PREVENT. The ASIST[25] study is the only one in mild effort angina or silent ischemia that compares a β blocker, atenolol, with placebo. Patients with moderate to severe angina were excluded. Over 1 year, atenolol gave better event-free survival, using a mixed bag of end points, including death, resuscitation, non-fatal MI, hospitalization for unstable angina, aggravation of angina, and revascularization. There were only a few serious events and the most evident difference was that there was less aggravation of angina with atenolol (9 of 152 *v* 26 of 154 with placebo, $P = 0{\cdot}003$). This trial, therefore, tells us that atenolol is antianginal, which is not surprising. PREVENT makes

roughly a similar message for the long-acting dihydropyridine (DHP), amlodipine, which reduced unstable angina and revascularizations when added to existing treatment, which often included a β blocker.[26]

The combined message emerging from APSIS, TIBET, ASIST, and PREVENT is this: the real problem is that the incidence of hard end points, such as mortality, infarction, or unstable angina, is so low in chronic stable effort angina that vast trials would be needed to show beyond doubt that calcium antagonists or β blockers do more than relieve symptoms. For example, it can be estimated that a study of 600 total deaths in effort angina, even with a risk reduction of one quarter, would need about 30 000 patients in a long-term trial (60 000 if the end point is cardiac mortality) to show any differences between calcium antagonists and β blockers. Trials of this size are, in the view of the present author, unlikely ever to be undertaken. Rather, it makes much more sense to select high-risk patients (see section on nicorandil) with clusters of risk factors, such as age, male gender, hypertension, smoking, and hypercholesterolemia. Alternatively, trials carefully designed to establish whether or not two treatments have an equivalent effect may be considered because fewer numbers are required than in mega-trials.[27] From the point of view of evidence-based medicine, and except for nicorandil the data currently available are insufficient.

Therefore the author has argued that the choice of drug between β blocker and calcium-channel blocker should be geared to the needs and the pathophysiology of the individual patient.[28] For example in a middle-aged man athletically active and anxious to avoid impotence, a calcium-channel blocker would be first choice. **Grade B** In a person with a compromised myocardium or with a previous MI, a β blocker appropriately titrated would be first choice. **Grade A** In someone at high risk of MI, antihypertensive therapy started with a β blocker is somewhat safer than starting with a calcium-channel blocker, while, if the major aim is prevention of stroke and hence intellectual integrity, a calcium-channel blocker may be preferable (Figure 26.1).[29]

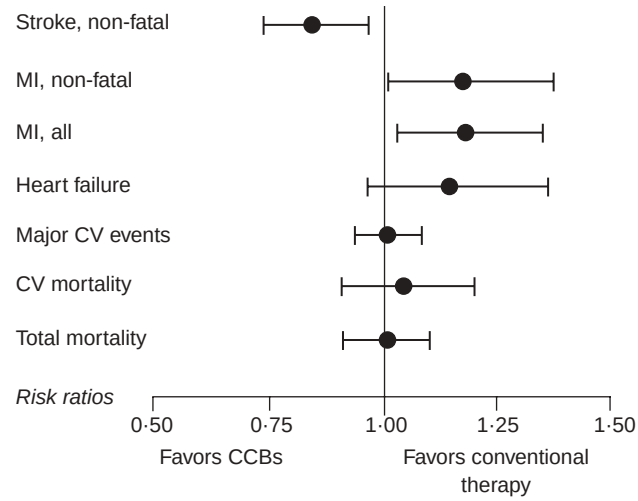

Figure 26.1 Outcomes in a meta-analysis of hypertension trials, comparing calcium-channel blocker (CCB)-based therapy *v* therapy conventional therapy (starting with either diuretic or β blocker). Note decrease ($P = 0{\cdot}013$) in non-fatal stroke, the increase in non-fatal myocardial infarction (MI) ($P = 0{\cdot}036$), and unchanged cardiovascular (CV) and total mortality. Figure corrected from error in original publication of Opie and Schall.[29]

Combination therapy: calcium antagonist added to β blocker in higher risk effort angina

ACTION is a large trial testing the outcome efficacy of long-acting nifedipine (GITS, gastro-intestinal tract system) in higher risk patients with chronic effort angina.[30] It is powered both for efficacy (death, AMI, heart failure, stroke) and for safety (death, AMI, stroke). Of the 7720 entrants, 78% were already taking β blockade. Therefore this trial is chiefly going to tell us about changes in hard end points when nifedipine GITS is added to a β blocker. Extrapolating from what little is already known from unstable angina, but with only 48 hour re-infarction as the outcome, the combination of nifedipine with a β blocker is likely to improve outcome. The trail will terminate in late 2003. There may be enough of a difference in the subgroup of those not receiving a β blocker to help judge on the efficacy of long acting nifedipine alone.

Nitrates in effort angina

There are no such trials reported and none is being planned. Nitrates therefore remain strictly in the realm of agents that provide symptomatic relief, without evidence for outcome benefit. **Grade C** Theoretically, the reflex tachycardia that they invoke might adversely affect the long-term outcome in ischemic states. Equally theoretically, their capacity to act as nitric oxide donors might protect the vascular endothelium and provide protective preconditioning.[31]

Unstable angina as an example of prolonged ischemia

This condition has two major components: acute myocardial ischemia and a disturbance of the thrombotic mechanism. Antianginal drugs therefore constitute only part of the therapy. In contrast to the good data on the benefit of heparin and aspirin, and now on clopidogrel, there is again no good evidence for the benefit of nitrates in unstable angina. Compared with intravenous diltiazem, intravenous nitroglycerin was less effective on short-term end points such as refractory angina and MI.[32] Furthermore, there was still a benefit in favor of diltiazem-treated patients at 1 year

of follow up.[33] Regarding long-term outcome with nitrates in unstable angina, there has been only one trial, which compared transdermal nitroglycerin with placebo therapy over 4 months, each arm receiving in addition conventional medical treatment. Outcome events such as death, MI or refractory angina were similar in the nitrate and placebo arms.[34]

There is a difference in the safety profile of the dihydropyridines (DHPs) and the non-DHPs (such as verapamil and diltiazem). Of the DHPs, only IR nifedipine has been well tested, with an adverse outcome in two trials. In the HINT study,[27] IR nifedipine was inferior to placebo with MI within 48 hours as an end point (OR 2·0, 95% CI 1·1–3·6) so that the trial was stopped,[35] while in the other study[36] there was an increase in early mortality. The heart rate-increasing effect of IR nifedipine[36] was probably the result of adrenergic activation because a benefit for the addition of IR nifedipine to prior β blockade was shown in both these trials and also by Gerstenblith *et al.*[37] By contrast, the non-DHP diltiazem was successfully used in comparison with a nitrate, both agents being given intravenously with a relative risk of 0·49 in favor of diltiazem for short-term events, chiefly recurrent pain.[32] Diltiazem decreased the heart rate whereas the nitrate increased it. Although there has been no similar trial with verapamil, several smaller trials suggest efficacy.[38–40] While it is possible that long-acting DHPs such as amlodipine that do not increase the heart rate might be safe in unstable angina, no such trials are likely to be done. The conclusion from the safety point of view is that the non-DHP diltiazem is best tested without the trial being large enough to yield outcome data, that verapamil may be similar in its effects though even less well tested, and that the DHPs as a group are relatively contraindicated in the absence of β blockade, with short-acting nifedipine (and nicardipine) totally contraindicated.

In the case of β blockade, there are no good studies in unstable angina, the only one available showing an insignificant trend to short-term benefit as measured by the decrease in recurrent ischemia or MI within 48 hours.[35] Neither of two older studies had hard end points.[41,42]

Prinzmetal's variant angina

This type of angina at rest is caused by coronary spasm and is specifically relieved by calcium antagonists. There are no outcome studies with hard end points, perhaps because the condition is potentially fatal and therefore placebo-controlled trials would be impossible. Some of the studies with remission of attacks as end point are reviewed by Opie and Maseri.[43] **Grade B** Short-acting agents are standard. Of these, nifedipine should not be used unless the diagnosis is firm and it is sure that the patient does not have unstable angina or threatened MI.

Threatened infarction

In this situation where ischemia is threatening to develop into infarction, IR nifedipine had adverse short-term (2 week) effects in a relatively small randomized trial, in which mortality was increased from 0 of 82 placebo patients to 7 of 89 nifedipine patients ($P = 0{\cdot}018$).[15] By contrast, in another relatively small trial with propranolol started intravenously within 4 hours of the onset of symptoms of AMI and then continued orally, there were fewer completed infarcts as shown by a limitation of blood enzyme rise,[42] and the incidence of ventricular fibrillation was less.[44] **Grade B** When given in a pilot study to patients with clinically threatened MI, atenolol reduced eventual infarction but, as the authors point out, the small numbers mean that the statistics are far from robust.[45] These small trials do not provide definitive information but are in agreement with the general concept that adrenergic activation is harmful in threatened infarction[42] so that β blockade is the preferred mode of therapy. This recommendation is, however, not based on good trial data.

Postinfarct effort angina

Two large RCTs suggest that long-term post-AMI therapy by instant release capsular nifedipine in standard doses is not beneficial or possibly harmful.[16,46] **Grade A** The presumed mechanism is reflex sympathetic stimulation. Angina was not a specific end point. Even though evidence from cohort studies is contradictory,[47,48] this agent is far from ideal for post-MI patients with angina.

Only one of the post-MI trials with calcium antagonists specifically reported on the incidence of angina pectoris in a subgroup of the postinfarct DAVIT II study,[49] in which verapamil 360 mg/day was started 7–15 days following infarct and continued for up to 18 months. Verapamil was significantly antianginal.[50] Regarding the outcome of the DAVIT II study as a whole, in the verapamil group there was a reduction (RR 0·80, 95% CI 0·64–0·99) in the combined end point predetermined as death and/or re-infarction. Although total mortality did not fall, the RR was also 0·80 (95% CI 0·61–1·05), and the lack of significance could possibly be ascribed to the relatively small numbers involved. Regarding heart failure, analysis of predetermined subgroups, undertaken before the code was broken, showed that in patients without prior heart failure during their stay in the coronary care unit, there was a mortality reduction ($P = 0{\cdot}024$). There was no effect of verapamil, either beneficial or harmful, in those with prior (not concurrent) heart failure. However, subgroup analysis even with predetermined end points is open to criticism. **Grade B**

Regarding diltiazem, the MDPIT post-MI study, in which diltiazem was given as 240 mg/day for a mean of 25 months,

did not report on effort angina.[51] An earlier study in which diltiazem was given for 14 days after non-Q wave infarction found no difference in the incidence of chest pain "recognized as angina pectoris".[52] Outcome evidence that this drug increases cardiac events (cardiac deaths and/or nonfatal infarction) in post-MI patients with congestive heart failure cannot be disputed.[51] **Grade A**

Regarding β blockers, there is impressive evidence that these drugs prolong life in post-MI patients.[5] Furthermore, in a very large observational study on over 200 000 post-MI patients, mortality was reduced by about 40% in all subgroups of those receiving β blockers, including those with prior revascularization.[8] **Grade A** Therefore, although there appear to be no formal trials on antianginal properties in post-MI patients, the large number of post-MI trials and the many patients studied, mean that these drugs have more overall compelling evidence in their favor in the postinfarct situation than does verapamil and much more compelling evidence than for the DHP calcium antagonists. First principles suggest it is likely that they are exerting their benefit at least in part by an anti-ischemic effect, although benefits on remodeling and postinfarct heart failure are a reasonable alternative.[53,54]

Ischemic arrhythmias

The Cape Town hypothesis is that β blockers have a ventricular antiarrhythmic effect in AMI by limiting metabolic changes, such as increased levels of cyclic AMP in the ischemic tissue.[55] Nonetheless, other modes of action are possible, for example by inhibition of the current I_f that initiates pacemaker activity in injured Purkinje cells. A meta-analysis has shown that β blockade is effective when given as prophylactic antiarrhythmic therapy in the context of AMI, and that it reduces mortality with an odds ratio of 0·81 in 55 trials.[56] Further evidence for outcome benefit for β blockers, as in postinfarct patients, comes from the Cardiac Arrhythmia Suppression Trial (CAST) in which prior β blockade therapy was associated with a one third reduction in arrhythmic death or cardiac arrest.[54] By contrast, calcium antagonists had a slightly increased relative risk, albeit not of statistical significance. Yet these findings do not prove that the β blockers were acting as anti-ischemic agents, and only provide indirect evidence that β blockers are safe when deliberately chosen as anti-ischemic drugs in other clinical situations.

Calcium antagonists in stable angina after angioplasty

There still is no convincing evidence that pharmacologic therapy by any of the anti-ischemic drugs alters the incidence of restenosis. There is some evidence from a meta-analysis that calcium antagonists as a group may help to prevent restenosis,[57] which should mean lessened effort angina – a possibility that was not reported. In one specific study over 6 months, twice daily verapamil reduced restenosis following percutaneous transluminal coronary angioplasty (PTCA), but only in patients with stable angina.[58] **Grade B** β blockers appear to be untested in this situation.

Congestive heart failure and effort angina

There are no studies with this combination as a predetermined end point. In view of the consistent benefit that accrues to patients with heart failure, already receiving a diuretic and an ACE inhibitor when a β blocker is carefully phased in, such added therapy can be expected to improve angina. However, direct evidence is missing. **Grade C**

ACE inhibitors as potential anti-ischemic drugs

There are at least four potentially anti-ischemic mechanisms whereby ACE inhibitors may operate. First, angiotensin II is known to facilitate sympathetic adrenergic transmission, also in humans.[59] Second, ACE inhibitors, by formation of bradykinin, indirectly promote the formation of nitric oxide, which in turn inhibits myocardial oxygen consumption.[60] Third, ACE inhibitors are potentially antihypertensive and thereby reduce the afterload. Fourth, in 15 hypertensive patients of whom 11 had effort angina, ACE inhibitors improved coronary flow reserve after long-term therapy.[61] The mechanism may be by reversal of endothelial dysfunction. Not surprisingly, these agents have a documented antianginal effect in hypertensive patients with angina[62,63] without, however, any outcome data. In patients with low ejection fractions, below 35%, chronic therapy by enalapril in the Studies of Left Ventricular Dysfunction (SOLVD) trials led to less hospital admissions for unstable angina, and therefore might well have reduced stable effort angina, but the data are not clear on this point.[64] In the SAVE study there was an unexpected reduction in recurrent MI in the group given captopril.[65]

The hypothesis that ACE inhibitors can protect against manifestations of ischemic heart disease in those at high risk was tested in HOPE,[66] in which one of the predetermined secondary or other outcomes was reduction of revascularization (RR 0·85, 95% CI 0·77–0·94) and of worsening angina (RR 0·89, 95% CI 0·82–0·96). However, what is controversial is the mechanism: is it just blood pressure reduction,[67] or an additional explanation specific to ACE inhibition such as an increased formation of bradykinin? Objective anti-ischemic effects can be found in hypertensive but not normotensive people.[68] **Grade A** In "standard"

angina of effort, without hypertension or heart failure, ACE inhibitors have an inconstant effect, as reviewed elsewhere.[69] Logically, the expected benefit would be more in patients with more severe ischemia and a greater activation of the adrenergic and renin–angiotensin systems.[70]

Metabolic modifiers

Trimetazidine and ranolazine are antianginals that act metabolically, probably through multiple mechanisms including partial fatty acid oxidation. While there is no doubt about their antianginal efficacy, supported by the recent oral presentation of data on 800 patients in the case of ranolazine, there are no outcome trials.

Nicorandil

This antianginal drug acts through several mechanisms including nitric oxide formation and potassium channel opening, the latter leading to preconditioning and to an antiadrenergic effect during experimental ischemia.[71] In a large prospective trial on higher risk patients with stable effort angina,[72] the primary composite end point was achieved, namely a reduction of coronary heart disease death, non-fatal MI, or unplanned hospitalization for cardiac chest pain. The secondary end point, coronary heart disease death or non-fatal MI, showed a strong trend to reduction without significance being reached. This trial is remarkable because it shows that a trial testing hard end point reduction in effort angina can be undertaken. Nicorandil is thus, in the view of the present author, the only antianginal that has strong evidence-based data in its favor. It is licensed in the UK, Japan, and several other countries, but not in the USA. **Grade A**

Statins as potential anti-ischemic drugs

Statins have made a considerable difference to the mortality of patients with ischemic heart disease in several studies. In the West of Scotland Coronary Prevention Study (WESCOPS), pravastatin was able to reduce hard end points in middle-aged hypercholesterolemic men without prior MI. In this group, the occurrence of angina pectoris was highly correlated ($P < 0{\cdot}0001$) with the primary end point, which was definite coronary heart disease death or non-fatal MI.[73] Therefore, in hypercholesterolemic males with angina, statins are able to reduce hard end points. That they have a direct anti-ischemic effect is shown by reduction of ST segment deviations on 48 hour Holter traces in patients with stable angina pectoris, documented coronary artery disease and pre-existing antianginal therapy, the latter not being specified.[74] **Grade A** Statin therapy can improve endothelial function, measured in the brachial artery, within 3 days in high-risk patients (elderly patients).[75] Formal prospective proof that cholesterol lowering by a statin has clinical antianginal efficacy is provided by the MIRACL study (Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering) in which a high daily dose of atorvastatin (80 mg/day) reduced symptomatic ischemia and hospitalization in patients within 16 weeks of an acute coronary syndrome.[76]

Diuretics as potential anti-ischemic drugs

Short-term diuretic therapy has an antianginal effect, possibly by reduction of the left ventricular preload.[77] No outcome data are available. Some case–control studies on hypertensive patients have suggested increased mortality on diuretics when given in high doses and without potassium supplementation.[18,19]

Conclusions

There are few if any satisfactory outcome studies available with the conventional antianginal drugs in effort angina. There are no trials at all on nitrates, and only rather small trials comparing β blockers and calcium antagonists. Some indirect evidence suggests that the ACE inhibitors may have antianginal properties. Statins are indirectly antianginal. Adequately powered outcome trials in patients with cardiac death and non-fatal MI as end points in effort angina would require mega-trials in view of the low incidence of these events. It would be more practicable to select high-risk categories or to aim trials at showing drug equivalence. Thus in higher risk patients with effort angina, the relative new antianginal nicorandil gave a positive outcome with a reduction in the primary end point of coronary heart disease death, non-fatal MI and hospitalization, or unplanned cardiac chest pain. In unstable angina, where ischemia is prolonged, there are no good trials showing that nitrates, β blockers or calcium antagonists – all commonly used drugs – have outcome benefit. Although β blockers have good evidence favoring their use as prophylactic antiarrhythmic drugs in AMI, with a reduction in mortality shown by meta-analysis, it is not certain that they are acting as anti-ischemic drugs in this situation.

Key points

- Standard anti-ischemic drugs (nitrates, β blockers, calcium antagonists) relieve anginal pain but their effect on outcome in effort angina is not known. Two relatively small trials and a meta-analysis suggest equivalence between calcium antagonists and β blockers. It is desirable but

unlikely that mega-trials will be conducted to settle this issue.

- Nicorandil is a relatively new anti-anginal with hard outcome data in its favor when tested in higher risk patients with effort angina.
- Likewise in unstable angina, outcome data for the anti-ischemic agents are lacking.
- An exception is short-acting nifedipine, which in two trials in acute ischemic syndromes has increased mortality, probably by reflex adrenergic activation.
- The closer the patient is to AMI, the stronger are the data for the safety of β blockers.
- In the postinfarct phase the data for safety and efficacy of β blockers are especially strong. The only calcium antagonist with good evidence for safety is verapamil, but without mortality benefit in the relatively small trials conducted.
- In acute ischemic ventricular arrhythmias, there is indirect evidence for the prophylactic effect of β blockers on mortality, even though there is no formal trial.
- Indirect evidence suggests that angiotensin converting enzyme inhibitors have some anti-ischemic properties without clear evidence for antianginal efficacy except in hypertensive patients. A large prospective study shows that ramipril protects from worsening angina in high-risk patients.
- In one trial, early use of high-dose statin following an acute coronary syndrome reduced symptomatic ischemia within 16 weeks.

27 Impact of revascularization procedures in chronic coronary artery disease on clinical outcomes: a critical review of the evidence

Charanjit S Rihal, Dominic Raco, Bernard J Gersh, Salim Yusuf

Coronary artery disease (CAD) is the leading cause of death worldwide and a major determinant of morbidity, use of healthcare resources, and lost productivity from illness. Since the original descriptions of surgical[1] and percutaneous[2] revascularization, the number of revascularization procedures has increased yearly (Figure 27.1). By 1998, 1 202 000 cardiac catheterizations, 926 000 percutaneous transluminal coronary angioplasty (PTCA) procedures, and 553 000 coronary artery bypass graft (CABG) operations were being performed annually in the USA alone.[3] An equivalent number are likely being performed in the rest of the world. Because the immediate risks of invasive procedures must be balanced against future potential benefits, it is important to critically evaluate the evidence supporting the use of these procedures, and to define the types of patients most likely to benefit and those unlikely to have any substantial benefit.

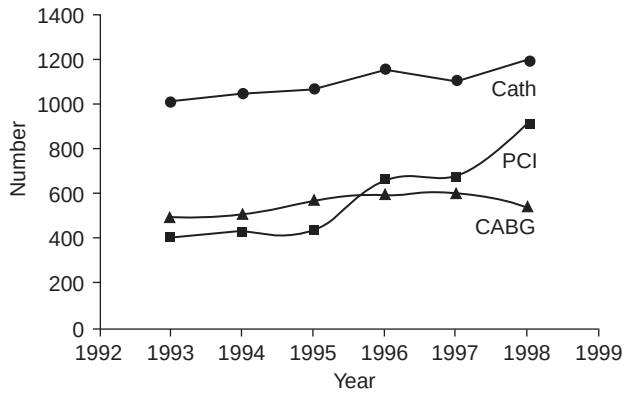

Figure 27.1 Annual growth in number of invasive cardiac procedures performed in the USA 1993–1998. Data are from the annual National Hospital Discharge Surveys 1993–1998. National Center for Health Statistics, Hyattsville, Maryland (www.cdc.gov/nchs). Values represent total number of discharges, not patients, with the indicated procedure listed as the primary procedure. Because federal, military, and Veterans Affairs hospitals are not included, the numbers may be underestimated. CABG, coronary artery bypass graft surgery (ICD-9 Code 36.1); Cath, catheterization; PCI, percutaneous coronary intervention.

Considered empirically, there are three broad potential reasons to recommend myocardial revascularization:

- to alleviate symptoms caused by myocardial ischemia;
- to improve the likelihood of long-term survival; and
- to reduce the risk of future non-fatal cardiac events such as myocardial infarction, serious arrhythmias, or congestive heart failure.

Within these categories, the potential and magnitude of benefit must be balanced against the intrinsic risk of invasive procedures. These considerations require thorough knowledge of both the technical aspects and the pertinent evidence, in particular relative efficacies with respect to outcomes of interest, estimation of individual risk-to-benefit ratios, and an understanding of the limitations and potential harm of each procedure. This chapter reviews the evidence comparing CABG surgery, PTCA, stents, and medical therapy for chronic CAD with respect to both fatal and non-fatal clinical outcomes. By building a conceptual framework, this chapter attempts to place the evidence from more recent trials of percutaneous revascularization into the context of previous trial data that compared CABG with medical therapy. Limitations of the available data and application to clinical practice are also discussed.

CABG surgery versus medical therapy

The first generation of randomized clinical trials of chronic CAD tested CABG surgery against medical therapy. Three moderate sized, prospective randomized studies conducted two decades ago provide the bulk of the data: the European Coronary Surgery Study (ECSS), the Veterans Administration (VA) Coronary Artery Bypass Surgery Cooperative Study Group, and the Coronary Artery Surgery Study (CASS).[4–6] These trials and numerous retrospective studies from associated registries demonstrated that the benefits of CABG were proportional to the long-term risk among patients who

received medical therapy.[5–7] Although both the VA study and CASS failed to demonstrate a difference in overall mortality between the medical and surgical groups that was statistically significant, subgroups in which CABG appeared to be superior to medical therapy were identified early. These subgroups included patients with left main CAD,[8,9] so-called left main equivalent disease,[10] and three vessel disease with left ventricular dysfunction.[11] Because each trial was relatively small (350–400 patients per treatment arm), only the ECSS trial demonstrated a decrease in mortality overall that was statistically significant.[4,9]

The three major trials (CASS, VA, and ECSS) plus four smaller trials (50 patients per treatment arm), in which patients were followed for 10 years, have been subjected to meta-analysis.[7] In all, 2649 patients randomly allocated to CABG or medical therapy were included. Original clinical and angiographic data were collected and analyzed according to uniform definitions. Enrolled patients had stable angina pectoris, whereas those with medically refractory or unstable angina generally were not included. The baseline angiographic and clinical characteristics are listed in Table 27.1. Of note, the majority had three vessel (50·6%) or left main CAD (6·6%), most of the patients were between 40 and 60 years old, almost all were male, and only 20% had an ejection fraction less than 50%. About half of the patients were taking β adrenergic blockers, but only 3·2% were receiving antiplatelet drugs at enrollment.

Table 27.1 Clinical and angiographic characteristics of patients enrolled in randomized trials of CABG versus medical therapy

Characteristic[a]	% of patients
Age distribution (years)	
≤40	8·5
41–50	38·2
51–60	46·0
>60	7·3
Ejection fraction (n = 2474)	
<40	7·2
40–49	12·5
50–59	28·0
≥60	52·3
Male	96·8
Severity of angina	
none	11·2
class I or II	53·8
class III or IV	35·0
History	
myocardial infarction	59·6
hypertension	26·0
heart failure	4·0
diabetes mellitus	9·6
smoking (*n* = 1949)	83·5
current smokers (*n* = 2298)	45·5
ST-segment depression > 1 mm	
resting (*n* = 2423)	9·9
exercise (*n* = 1985)	70·5
Drugs at baseline	
β blockers (*n* = 2308)	47·4
antiplatelet agents (*n* = 1195)	3·2
digitalis (*n* = 2319)	12·9
diuretics (*n* = 1940)	12·6
Number of vessels diseased	
left main coronary artery	6·6
one vessel[b]	10·2
two vessels[b]	32·4
three vessels[b]	50·6
Location of disease	
proximal left anterior descending	59·4
left anterior descending diagonal	60·4
circumflex	73·8
right coronary	81·6

Abbreviation: CABG, coronary artery bypass graft
[a] Data on some characteristics are not available for all patients.
[b] Without left main artery. (From Yusuf *et al*[7] by permission of *The Lancet* Ltd.)

Mortality

Cumulative mortality after initial medical therapy or initial CABG over 12 years of follow up is shown in Figure 27.2. Because of the perioperative mortality associated with CABG, 1 year mortality was not different between the groups and a net benefit in favor of CABG was not observed for 2 to 3 years (Figure 27.2). The advantage in favor of an initial strategy of CABG substantially widened at 5 to 7 years, before narrowing again by 10 to 12 years. At 5, 7, and 10 years, 10·2%, 15·8%, and 26·4% of patients, respectively, assigned to CABG had died, compared with 15·8%, 21·7%, and 30·5% of their medically assigned counterparts. Risk reductions were significant at all three time points (relative risk [RR], 0·61, 0·68, 0·83), even though 40% of patients initially assigned to medical treatment had delayed CABG surgery by 10 years. Because such crossovers tend to occur in the highest risk medical patients (left main coronary artery or three vessel disease, unstable angina), these trials may underestimate the real benefits of CABG surgery compared with medical therapy alone, and this underestimation would be greatest among high-risk subsets. This tendency for the relative – but not the absolute – benefit to converge is likely due to high rates of crossover to surgery among the highest risk medical patients, the development of graft atherosclerosis, and progression of underlying native vessel disease.

Significant heterogeneity of treatment effect was observed between various angiographic and clinical subgroups (Table 27.2). In general, the survival advantage of CABG over medical therapy was proportional to the

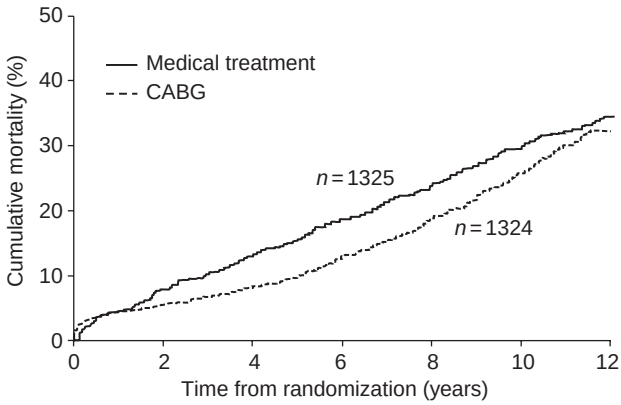

Figure 27.2 Overall survival after random allocation to medical treatment or coronary artery bypass graft (CABG). (From Yusuf *et al*[7] by permission of *The Lancet* Ltd.)

number of diseased coronary arteries (three vessel RR, 0·58; $P < 0 \cdot 001$, or left main RR, 0·32; $P = 0 \cdot 004$), particularly if the left anterior descending artery was involved (RR, 0·58). Although the relative benefits were similar regardless of left ventricular function (RR, 0·61 if normal and 0·59 if abnormal), the *absolute* benefit was greater among patients with an abnormal ejection fraction, because the risk of death was twice as high in this group (5 year medical mortality rate of 25·2% with an ejection fraction <50% *v* 13·3% if it was >50%). Similarly, absolute (and to some extent relative) mortality benefits were greater among patients with evidence of myocardial ischemia (abnormal exercise test results or severe angina).

To put the relative and absolute benefits of CABG further into the perspective of baseline risk, a score stratified by clinical and angiographic markers was developed. This indicated that patients at high risk (5 year medical mortality, 23%) experienced a clinically and statistically highly significant

Table 27.2 Outcomes of various subgroups in medical therapy versus CABG trials at 5 years

improvement in survival (RR, 0·50; $P = 0·001$). Those at moderate risk (5 year medical mortality, 11·5%) also benefitted (RR, 0·63; $P = 0·05$), but the absolute benefits were smaller. No evidence of a survival benefit was observed among those at low risk (5 year medical mortality, 5·5%; RR, 1·18; $P = 0·70$).

Myocardial infarction and other non-fatal end points

Registry studies have suggested a favorable effect on late myocardial infarction only among the highest risk subsets, such as patients with three vessel disease and severe angina pectoris.[12] In the meta-analysis, no overall effect of CABG on subsequent infarction could be demonstrated, primarily because of an excess of infarction in the perioperative period (10·3% incidence of death or myocardial infarction at 30 days) among those assigned to surgery.[7] Although the risk of subsequent myocardial infarction was lower during extended follow up, this was not statistically significant (24·4% incidence of death or myocardial infarction at 5 years for the CABG group *v* 30·7% for the medical group).[7] Most trials did not prospectively collect data on rehospitalization for unstable angina, stroke, quality of life, or cost.

Recent trials

Few randomized data from the modern era compare CABG surgery with medical therapy. The Asymptomatic Cardiac Ischemia Pilot (ACIP) prospectively assigned 558 patients with asymptomatic ischemia to one of two medication strategies or to routine revascularization with CABG or PTCA.[13,14] Despite the relatively small sample size, mortality (1·1% *v* 6·6% and 4·4% for the two medical groups, $P < 0·02$), and death or myocardial infarction (4·7% revascularization *v* 12·1% and 8·8%, $P < 0·04$) was significantly lower after 2 years of follow up among the patients assigned to routine revascularization.[15] Rates of non-protocol revascularization procedures and hospital admission were also lower among the routine revascularization group (29% of medically assigned patients "crossed over" to invasive procedures).

The Medicine, Angioplasty, or Surgery Study (MASS) prospectively enrolled 214 patients with proximal left anterior descending artery stenoses to CABG surgery with an internal thoracic arterial conduit ($n = 70$), to PTCA ($n = 72$), or to medical therapy alone ($n = 72$). Rates of death (one in each group) or non-fatal myocardial infarction (one CABG, two PTCA) were very low over a mean 3 year follow up. After 3 years, 98% of patients assigned to CABG and 82% assigned to PTCA were free of angina, compared with only 32% of those in the medical group; however, 21 patients (29%) in the PTCA group required repeat procedures. No patient in any treatment group had severe angina (class III or IV).

Because previous trials have systematically tended to exclude elderly patients, precise estimates of relative risks and benefits are not available and must be extrapolated from other data. A recently published Swiss study focused on elderly patients. Patients older than 75 years (mean age, 80 years; 44% women) who had chronic, severe angina pectoris were randomly assigned to either an invasive approach or continued medical therapy.[16] Of 155 patients assigned to the invasive approach, 80 received PTCA, 33 CABG surgery, and 34 continued medical treatment. A third of the medical group required non-protocol revascularization for symptom control. By 6 months, angina severity and quality of life measures had improved in both groups but to a significantly greater extent in the invasive group. In the invasive group, 16·3% of patients had either died or had a non-fatal infarction, compared with 15·5% in the medical group. A greater proportion of the medical group (49% *v* 9·8%) required hospital admission during the ensuing 6 months. Although this was a relatively small trial, the findings affirmed the role of revascularization in improving symptoms and quality of life among elderly patients, the most important goal of treatment in this group.

Although the findings described above were derived from relatively small trials, they suggest that among patients with evidence of myocardial ischemia, modern revascularization techniques may be more effective than previously thought. These data point to a need for larger, more definitive randomized trials that test current revascularization techniques against modern medical therapy so that reliable estimates of effect of size on clinical outcomes with narrower confidence intervals can be made.

Conclusions

The available data suggest that a strategy of early CABG surgery improves long-term survival in a broad spectrum of patients at moderate to high risk with medical therapy. Relative reductions in mortality risk of about 40% over 5 years can be expected in comparison with the alternative of medical therapy. Absolute benefits are proportional to the risk expected with medical therapy. Clinical and angiographic markers of risk, including severity of CAD, left ventricular dysfunction, and myocardial ischemia, can identify patients in various risk strata. The benefits of CABG are greatest among those who are at highest risk with medical therapy (5 year mortality greater than 20%).

Limitations of first generation randomized clinical trials

During the last two decades, advances have occurred in both surgical and medical treatments that potentially could alter the results if trials were repeated today. These advances include the use of left internal thoracic artery

conduits that have long-term patency rates markedly superior to venous bypass grafts, and aggressive lipid lowering and chronic antiplatelet therapies.[17,18] The CABG surgery versus medical therapy trials were confined to patients 65 years or younger, but more than 50% of CABG procedures are now performed on patients 65 years or older.[3] Similarly, only CASS enrolled women, whereas women now commonly undergo CABG surgery. The use of internal thoracic conduits was limited to only 14% of the patients in CASS, and this conduit was not used in the other trials. Lipid lowering agents were not widely used, HMG-CoA reductase inhibitors were not available, and aspirin was not widely used in either the medical or surgical groups. High-risk patients, such as those with severe angina and left main coronary artery stenosis, were underrepresented in these trials. These considerations and the results of the small recent trials suggest that the benefits of CABG surgery on clinical outcomes are likely to be larger than in the old randomized trials, especially among subsets of high risk patients.

PTCA versus medical therapy

PTCA was first introduced in the late 1970s as a treatment for single vessel CAD,[2] and it has become one of the most commonly performed major procedures. Most PTCA procedures are still performed for single vessel disease,[19,20] but its role in multivessel disease is expanding, and rates of procedural success and complications[19,20] have been described in large observational databases. Six prospective trials have enrolled patients to strategies of initial medical therapy versus balloon angioplasty.[21–26]

The first of such trials, A Comparison of Angioplasty With Medical Therapy in the Treatment of Single-Vessel Coronary Artery Disease (ACME), was published in 1992,[21] 13 years after the first report of PTCA.[2] In this trial, 212 patients with stable, single vessel CAD and exercise induced myocardial ischemia were randomly assigned to PTCA or medical therapy. The proportion of patients free of angina at 6 months was greater in the PTCA arm (64% *v* 46%, $P < 0{\cdot}01$), and the number of monthly anginal episodes was fewer among those with angina despite a low (by current standards) technical success rate of only 80% with PTCA. These patients required fewer medications and had better improvement in treadmill exercise duration (increase, 2·1 *v* 0·5 minutes; $P < 0{\cdot}0001$) and psychologic wellbeing scores. However, these symptomatic improvements came at a considerable price, which included two emergency CABG operations and five myocardial infarctions. An accompanying trial from the ACME group enrolled 328 patients with double vessel disease and was reported in 1997. In this trial, functional improvement occurred in both the medical and angioplasty treated groups, and without statistically significant differences between the groups.[25]

The largest prospective trial of PTCA versus medical therapy was the multicenter Randomized Intervention Treatment of Angina (RITA) 2 trial.[23] Most of the patients had mild symptoms (80% Canadian Cardiovascular Society class 0 to II), 60% had single vessel CAD, and 33% had two vessel disease; only 6% had marked left ventricular dysfunction. The primary end point of death or myocardial infarction occurred in 6·3% of the PTCA group and 3·3% of the medical therapy group (absolute difference, 3·0%, 95% CI 0·4–5·7; $P = 0{\cdot}02$). The combined rates of death, myocardial infarction, and non-protocol revascularization were about 25% in both groups by 3 years of follow up, and were primarily due to repeat procedures in the PTCA group and progression of symptoms in the medical group (Figure 27.3). Angina pectoris and treadmill exercise time improved significantly in both groups. Patients with grade 2 or worse angina appeared to benefit more from PTCA; they had a lower incidence of angina and longer treadmill

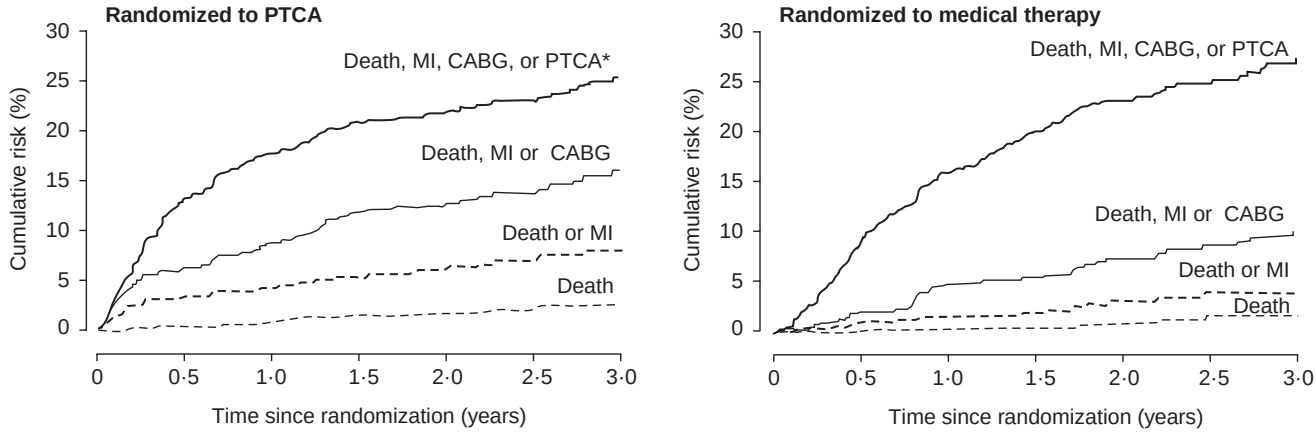

Figure 27.3 Cumulative risk of percutaneous transluminal coronary angioplasty (PTCA) and coronary artery bypass graft (CABG) for myocardial infarction (MI), or death. * denotes PTCA in addition to randomized PTCA. (From RITA-2 Trial participants[23] by permission of *The Lancet* Ltd.)

exercise times than that of the medical therapy group. Patients with mild symptoms at enrollment had no measurable improvement from PTCA. Quality of life measures were assessed at 6 months and at 1 and 3 years with the SF-36 instrument.[1] Both groups experienced improvement, with PTCA producing greater improvement in physical functioning, vitality, and general health at 3 months and 1 year; 33% of the PTCA group and 22% of the medical therapy group rated their health much improved ($P = 0 \cdot 008$). These improvements were related to breathlessness, angina, and treadmill exercise time. By 3 years, no intergroup differences were observed, which may be explained partly by the 27% crossover to PTCA among the medical therapy group.[27]

The Atorvastatin Versus Revascularization Treatment (AVERT) trial[26] randomly assigned 341 patients with low risk CAD (99% of patients had stable Canadian Cardiovascular Society class 0 to II angina) to percutaneous revascularization plus usual medical care, or to medical care including aggressive therapy with atorvastatin. Over a mean follow up of 18 months, the PTCA group experienced more cardiac events (cardiac death or arrest, revascularization, stroke, or worsening angina) overall than the atorvastatin group (21% *v* 13% for PTCA and atorvastatin groups, respectively, $P = 0{\cdot}048$). However, a greater proportion of the PTCA group had improvement in anginal symptoms (54% *v* 41%, $P = 0{\cdot}009$).

The findings of the individual trials are reinforced by a systematic review of PTCA versus medical treatment for stable CAD.[28] The review included data from six randomized clinical trials that enrolled 953 patients given balloon angioplasty and 951 given medication. Treatment with PTCA resulted in significant improvement in angina (RR, 0·70, 95% CI 0·50–0·98); however, patients who had PTCA required CABG more frequently (RR, 1·59, 95% CI 1·09–2·32). No differences in death (RR, 1·32, 95% CI 0·65–2·70) or myocardial infarction (RR, 1·42, 95% CI 0·90–2·25) were observed (Figure 27.4). Because a substantial proportion of patients enrolled in medical arms required PTCA for symptom control, the overall odds of non-protocol PTCA did not differ despite the occurrence of restenosis after initial PTCA (RR, 1·29, 95% CI 0·72–3·36).

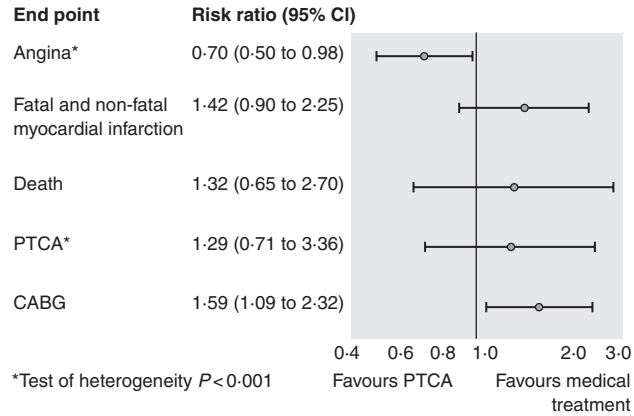

Figure 27.4 Pooled risk ratios for various end points from six randomized controlled trials comparing percutaneous transluminal coronary angioplasty (PTCA) with medical treatment in patients with non-acute coronary heart disease. CABG, coronary artery bypass grafting; n=953 for PTCA and 951 for medical treatment. (From Bucher *et al*[28] by permission of BMJ Publishing Group.)

Conclusions: PTCA versus medical therapy

On the basis of the results of the above trials, it is evident that among patients with low risk symptomatic CAD (Canadian Cardiovascular Society class II or greater and average mortality of <1% per year), PTCA can improve symptoms and measures of quality of life compared with medication alone. No apparent reduction can be expected in overall mortality, need for subsequent PTCA, myocardial infarction, or CABG (which may be higher than with medical therapy). These data suggest that PTCA is indicated if the desired level of anginal relief and physical activity cannot be achieved with medical therapy. Aggressive lipid lowering therapy is indicated for all patients with stable CAD. With the excess risk of cardiac events seen in several trials, PTCA purely for the treatment of an anatomical coronary artery stenosis or for ischemia without symptoms cannot be recommended. Similarly, PTCA for prevention of myocardial infarction is not indicated.

Theoretic considerations for comparison of CABG, PTCA, and medical therapy

Although PTCA was conceived originally as an alternative to CABG, rates of both PTCA and CABG have increased consistently and in parallel.[3] This and the fact that most PTCA procedures have been performed for single vessel disease suggest that PTCA has been used primarily as an alternative to medical therapy rather than to CABG. More recently, with increased experience and technical advances, the pattern of use of PTCA has increasingly included subsets of patients previously referred for CABG. Several prospective randomized clinical trials have compared multivessel PTCA, CABG, and stents. Before the results of these trials are reviewed (which compare two active invasive therapies without medical or placebo controls), several methodologic issues need to be considered.

Moderate- to high-risk patients

As mentioned above, several outcomes can be assessed in comparing PTCA with CABG: mortality, non-fatal events (such as non-fatal myocardial infarction), symptoms, cost, and

surrogate laboratory end points (such as left ventricular function). Because neither PTCA nor CABG has been shown to decrease the incidence of non-fatal myocardial infarction compared with medical therapy, this end point is unlikely to be sensitive to a possible differential effect of the two procedures. Indeed, considering non-fatal infarction in a composite end point may dilute event rates sufficiently to preclude detection (by lowering statistical power). Similarly, inclusion of low-risk subgroups in which CABG has *not* been shown to improve survival compared with medical therapy, such as single vessel disease, would decrease the ability to demonstrate mortality differences. An exception would occur if PTCA were significantly worse than medical therapy or substantially superior to CABG (both of which can be considered unlikely).

It has been demonstrated that CABG is associated with a 30–50% mortality risk reduction in moderate- and high-risk subgroups at 5 years compared with medical therapy. The detection of a difference in relative risk difference of half this magnitude (15–25%) between CABG and PTCA would be clinically relevant. If such a comparison indicated superiority of PTCA over CABG, it could reasonably be concluded that PTCA was superior to both medical therapy (indirect extrapolation) and CABG (direct inference). However, if a 20% difference in the relative risk of mortality in favor of CABG existed, surgical revascularization generally would be preferred over PTCA for such patients if the goal were improvement in prognosis. If the available data from such a comparison were large, the confidence interval of any observed difference would be narrow enough (for example, 20% ± 10%) to suggest that PTCA was superior to medical therapy to a clinically worthwhile extent, an indirect extrapolation that would be necessary in the absence of a medical control arm.

If no difference were observed between CABG and PTCA, it could be concluded that PTCA is equivalent to CABG only if trials were large enough to reliably detect or exclude relative differences in mortality of about 20% (with narrow confidence intervals) and included a large number of patients for whom CABG has been shown to improve prognosis. Because approximately 600 deaths would be needed in the "control" group to exclude a relative risk difference of 20% with 90% power, trials with about 8000 moderate- to high-risk patients would be needed. If a 30% risk difference were considered the smallest clinically important difference, then trials of about 4000 patients would be required. Moreover, in such a comparison, if the confidence limits of any difference included the possibility that PTCA was worse than CABG by 50% (relative risk), it could not be inferred that PTCA had any favorable effect on survival compared with medical therapy.

Low-risk patients

Among low-risk patients (annual mortality <2%), it may be moot to assess mortality differences between PTCA and CABG, because CABG has not been shown to decrease mortality. Conducting a trial to detect clinically important differences in such patients would be extremely difficult because of the large number of patients that would be required. For example, if a control group annual mortality rate of 1% is assumed, 8000 patients would need to be followed for 5 years to detect reliably a 30% risk reduction (or 16 000 patients to detect a 20% risk reduction). In such low-risk patients, any absolute benefit is likely to be too small to justify the costs and risks associated with revascularization. A large difference (for example, a 50% risk reduction that could be demonstrated with about 4000 randomized patients) would be extremely unlikely.

Therefore, among low-risk patients, the most relevant comparison is between PTCA and medical therapy. Such trials are unlikely to demonstrate a difference in mortality between PTCA and medical therapy (unless PTCA were harmful), and symptom improvement is the most relevant outcome of interest. Effects on a combined clinical variable could be compared, potentially including other non-fatal events such as myocardial infarction, severe angina, cost, and need for further revascularization procedures. Non-fatal events in a composite end point would need to be chosen carefully. As mentioned above, neither CABG nor PTCA has been shown to decrease the risk of subsequent non-fatal myocardial infarction, and inclusion of such an end point would dilute relative differences and decrease the likelihood of detecting differences. Both PTCA and CABG are effective in relieving angina and myocardial ischemia, and a relevant composite end point could include death plus severe angina. Such trials are feasible and could provide clinically relevant answers. It must be borne in mind that invasive procedures may increase rates of myocardial infarction, because of periprocedural risks, while decreasing subsequent angina pectoris.

Conclusions

These considerations indicate that to reliably compare the relative effect of PTCA versus CABG and to avoid missing clinically important differences, the following conditions need to be met:

- inclusion of subgroups in which surgery has been shown to be superior to medical therapy;
- inclusion of a sufficient number of patients (that is, adequate statistical power);
- follow up of at least 4–5 years to accrue a sufficient number of end points and to obtain data well beyond the early period when periprocedural events predominate; and
- a high rate of compliance to the original treatment allocation.

If a substantial proportion of patients crossover (30–40% by 5 years), the ability to detect differences in survival decreases markedly.

Trials of PTCA versus CABG

Technologic advances in the last 5–7 years have increasingly allowed wider application of PTCA, and a number of prospective, randomized trials have directly compared PTCA with CABG. A systematic review of eight of these trials[29] has been published.

Single vessel disease

In patients with single vessel CAD, medical therapy generally is indicated first, but revascularization may be indicated for symptom relief. Both PTCA and CABG offer a high rate of procedural success in such patients. Three randomized trials have provided data comparing PTCA and CABG for single vessel disease. The largest of these was the British RITA trial, which included 456 patients with single vessel disease.[30,31] After a median 6·5 years of follow up, no significant difference in death plus myocardial infarction was found (16·7% CABG *v* 19·3% PTCA, $P = 0{\cdot}56$) among patients with single vessel disease. Patients randomly assigned to PTCA required a significantly greater number of repeat interventional procedures (38% *v* 12%, $P = 0{\cdot}01$).

The results of MASS, the only three-way randomization among PTCA, CABG, and medical therapy to date, have been reviewed above. A second, single-center Swiss study was published in 1994.[32] In this trial, 134 patients with isolated proximal left anterior descending coronary artery stenosis were randomly assigned to angioplasty or CABG with a left internal thoracic artery conduit. Over 2·5 years of follow up, only one cardiac death occurred in the CABG group and none in the PTCA group, confirming the generally low-risk status of these patients. No significant difference was found in cardiac death or myocardial infarction (4·5% CABG *v* 11·7% PTCA, $P = 0{\cdot}21$), and the only significant difference between the two groups was a higher rate of repeat revascularization in the PTCA group (34%) because of restenosis. Relief of angina was achieved in a high proportion of each group (more than 95% of patients were in Canadian Cardiovascular Society class I at 1 year), and no difference in the duration of the exercise test was found.

The meta-analysis of Pocock *et al*[29] included 732 patients with single vessel disease. Results of an updated meta-analysis, including the RITA long-term follow up data, are presented in Table 27.3. No significant differences were found in overall mortality. Rates of death or myocardial infarction favored CABG but did not reach statistical significance. Rates of additional revascularization procedures were significantly higher after PTCA.

In summary, the data available suggest that both PTCA and CABG are effective in providing symptom relief for patients with severe single vessel CAD. Rates of myocardial infarction may be higher after PTCA, likely because of periprocedural events; however, because no such difference was found for multivessel disease (see below), caution is needed to avoid overinterpretation of these data. Patients undergoing PTCA unequivocally have a greater likelihood of repeat procedures because of restenosis. If this is acceptable to patients and their physicians, then PTCA offers a simpler and less invasive method of revascularization. Of note, the meta-analysis of CABG versus medical therapy trials suggested a mortality benefit for CABG in one or two vessel disease with involvement of the proximal left anterior descending coronary artery (odds ratio, 0·58, 95% CI 0·34–1·01).[7] These patients have a large area of myocardium at jeopardy and are at higher risk for death than those with other forms of single vessel disease and may represent a group that merits special consideration. For single vessel disease, the current conclusions and recommendations are based on a relatively small number of patients and events ($n = 731$, with 44 deaths), and the possibility that potentially important differences between therapies were missed cannot be excluded.

Multivessel disease

For multivessel disease, CABG has remained the mainstay of therapy, especially for moderate- and high-risk patients such as those with severe two or three vessel disease with concomitant left ventricular dysfunction. The group of patients with multivessel disease is a heterogeneous group, with marked heterogeneity in the location and extent of anatomical stenosis, clinical symptoms, ventricular function, and coexistent disease. Thus, characteristics of patients enrolled need to be evaluated carefully when comparing trial results.

Nine prospective randomized clinical trials have compared PTCA (that is, balloon angioplasty) with CABG surgery in the treatment of multivessel disease.[24,30,32–38] These trials have enrolled 5200 patients and, although they vary in design, methods, and stage of follow up, they are broadly comparable and it is instructive to consider them together. The main characteristics of these trials are compared in Tables 27.3 and 27.4. All trials shared important features: treatment allocation to PTCA or CABG was randomly assigned, a high degree of compliance with the assigned therapy was achieved (more than 95%), and follow up data describing vital status, incidence of myocardial infarction, and prevalence of angina pectoris (or measures of myocardial ischemia) were collected. No trial individually was powered to detect or to exclude differences in mortality, and various composite clinical end points were used. Length of follow up varied, and in some instances, additional follow up is planned.

The largest of the PTCA versus CABG trials, the Bypass Angioplasty Revascularization Investigation (BARI), was published in 1996.[39] Designed as an "equivalence" trial,

sample size calculations were predicated on an estimated cumulative 5 year mortality of about 5%, with the goal that the upper 95% confidence limit for any observed difference would not exceed 2·5%.[37] Approximately 30% of screened angiograms of patients with multivessel disease were considered eligible and 1829 patients were enrolled. About 40% of these patients had three vessel disease, and 22% had an ejection fraction less than 50%. Assignment to PTCA or CABG was randomly allocated, and follow up was continued for 5 years before the first results were presented. Five year mortality among patients assigned to CABG was 10·7%, and 13·7% among those assigned to PTCA (absolute difference 3·0%, 95% CI −0·2–6·0; $P = 0·19$). The study was interpreted as negative because the 22% relative risk reduction in favor of CABG did not reach statistical significance, but the study had less than 40% power to detect the observed difference. Extension of follow up to 7 years demonstrated a mortality advantage to CABG that was nominally significant (15·6% *v* 19·1% for PTCA, $P = 0·043$).[40] The entire difference appears to be confined to the subgroup of 353 (19% of total enrollees) patients with diabetes mellitus (7 year mortality 23·6% CABG *v* 44·3% PTCA, $P = 0·0011$). No difference in survival was noted among the remaining 1476 (81%) patients (7 year mortality, 13·6% CABG *v* 13·2% PTCA, $P = 0·72$). Implications of the findings in the diabetic subgroup are discussed in more detail below; however, considerable caution should be applied to interpretation of these findings unless they are confirmed by other randomized clinical trials.

A systematic review of eight of these trials has been published;[29] however, BARI was published after the initial meta-analysis. Results of updated systematic reviews of all-cause mortality (death or myocardial infarction) and non-protocol revascularization after the initial randomly assigned treatment are presented in Table 27.3. Inclusion of late follow up data, particularly from BARI, yielded a nominally significant difference in total mortality in favor of CABG (11·1% PTCA *v* 9·5% CABG; odds ratio 1·20, 95% CI 1·00–1·45; $P = 0·05$). The combined end point of death or myocardial infarction, however, did not differ (17·2% PTCA, 16·8% CABG; odds ratio 1·04, 95% CI 0·89–1·20). Rates of repeat procedures were much higher after PTCA (52% *v* 11%; odds ratio 9·15, 95% CI 7·9–10·6).

Substudies have demonstrated that PTCA and CABG produce similar benefits on quality of life measures and return to employment, and are roughly equivalent in cost over 3–5 years of follow up.[41–44] CABG is associated with more complete revascularization, but differences in degree of revascularization of major lesions are less pronounced.[43]

Conclusions: PTCA (balloon angioplasty) versus CABG

In summary, 5200 patients with multivessel CAD have been enrolled in nine trials of PTCA versus CABG. When long-term follow up data are considered, cumulative mortality rates are lower with CABG than with PTCA, and fewer patients require repeat procedures. However, the initial morbidity is less with PTCA, rates of myocardial infarction are similar, and overall anginal relief is nearly equivalent by 3 years. Restenosis continues to be a major limitation of PTCA. These data suggest that for patients at high risk for death, CABG is preferred. For other patients, PTCA is a reasonable alternative if a higher rate of repeat procedures is acceptable.

Can it be concluded, then, that PTCA and CABG are roughly equivalent modes of revascularization for multivessel disease among angiographically eligible patients, except for the unsolved problem of restenosis? To answer this question, it is necessary to consider the marked heterogeneity of what is termed "multivessel disease". Although discrete lesions of the right coronary and circumflex arteries in a patient who has a normal left ventricle or diffuse three vessel disease in a patient with an ejection fraction of 30% can rightly be classified under the term "multivessel disease", the prognoses, risks, and potential benefits of revascularization vary considerably.

In the recent PTCA versus CABG trials, enrolled patients were relatively low risk: fewer than 20% had left ventricular dysfunction and almost 70% had one or two vessel disease. In the meta-analysis of Pocock *et al*,[29] for example, the observed first year mortality of 2·6% and 1·1% per year thereafter confirms the relatively low-risk status of these patients. (However, no medical control arms were present.) Patients enrolled in BARI had higher observed mortality rates and more closely approximated moderate-risk patients, in part because of the higher proportion of patients with diabetes mellitus. Even in BARI, however, nearly 60% of patients had two vessel coronary artery disease. In contrast, patients enrolled in the earlier CABG versus medical therapy trials had a 20% prevalence of left ventricular dysfunction and 60% had three vessel or left main CAD.[7] Thus, the current PTCA versus CABG trials include a high proportion of patients in whom CABG has *not* been shown to be superior to medical therapy. Moreover, the total enrollment of 5200 patients falls short of the roughly 8000 needed to demonstrate clinically important differences in mortality of 20–30% among low- and moderate-risk patients. It is reasonable to surmise that, if CABG were superior to PTCA in moderate- and high-risk patients, the current PTCA versus CABG trials would have low power to reliably detect significant differences, and that such a difference cannot be ruled out. Large mortality differences on the order of 40–50%, however, are unlikely, given the current data. Also, these trials were performed before the wide use of intracoronary stents, and whether stents may change the observed outcomes is discussed below.

Relative effect of PTCA and CABG in patients with diabetes

BARI findings

On 21 September 1995, the National Heart, Lung, and Blood Institute took the unusual measure of issuing a Clinical Alert to physicians in the United States about the observed superiority of CABG over PTCA among the 353 treated diabetic patients enrolled in the BARI randomized trial.[45] After 5 years of follow up, the cumulative mortality after CABG was 19% among patients with diabetes compared with 35% for those treated with PTCA ($P < 0{\cdot}0024$). The findings, however, were unexpected. At the initiation of the trial, patients were categorized into four subgroups for purposes of analysis: by anginal status, left ventricular function, extent of ischemia, and angiographic risk. Patients with diabetes were not among the original four pre-assigned subgroups, but within 1 year after the trial began, the Data and Safety Monitoring Board requested that these patients be monitored separately.[46] The magnitude of the difference favoring CABG met the pre-specified significance criteria ($P < 0{\cdot}005$) for subgroup analyses and led to the Clinical Alert.

The recently published 7 year outcome data have extended these observations.[40] Among the patients with diabetes in the BARI randomized trial, estimated 7 year survival was 76·4% after CABG and 55·7% after PTCA ($P = 0{\cdot}0011$). The difference in outcome was confined to diabetic patients who received at least one internal mammary arterial graft (7 year survival 83·2%, $n = 140$), whereas diabetic patients who received only saphenous vein grafts had a 7 year survival (54·5%, $n = 33$), similar to those who had PTCA (55·5%, $n = 170$).[40] Long-term follow up from the much smaller Emory Angioplasty versus Surgery Trial (EAST) that included 59 patients with diabetes was consistent with these results, although it did not attain statistical significance (8 year survival, 75·5% after CABG and 60·1% after PTCA; $P = 0{\cdot}23$).[47] Of course, the key question is whether the BARI outcomes among diabetic patients were real or only a play of chance. Several lines of evidence suggest it is real, and they have been reviewed in detail.[46]

In a combined analysis from the BARI trial and registry of 641 diabetic patients and 2962 non-diabetic patients, 5 year death (20% *v* 8%) and Q wave myocardial infarction (8% *v* 4%) rates were significantly higher among those with diabetes.[48] Multivariate analysis identified insulin treated diabetes, heart or renal failure, black race, and older age as most strongly associated with high overall mortality.[49] The only significant interaction term was between treatment and insulin treated diabetes ($P = 0{\cdot}042$).[49] Overall, CABG did not have a protective effect against the incidence of Q wave myocardial infarction; however, CABG greatly decreased the risk of death among diabetic patients when infarction occurred (RR 0·09, 95% CI 0·03–0·29; $P < 0{\cdot}001$). This effect may account for up to 50% of the overall reduction in mortality after CABG observed in the diabetic subgroup of BARI.

An independent, angiographic case–control study has suggested a significantly higher propensity for the development of new coronary vascular lesions among patients with diabetes, both when previously instrumented (16·9% *v* 12·7% of non-diabetic arteries) and *de novo* (13·2% *v* 7·3%).[50] Unpublished 5 year angiographic follow up data from BARI 1 (Frye RL, read at the American College of Cardiology 50th Annual Scientific Sessions, Orlando, Florida, 20 March 2001) have suggested similar findings. These data suggest that

CABG, particularly with internal mammary artery conduits, confers a protective shield against the complications of progression of the underlying vascular disease in patients with diabetes. Whether intensive medical therapy for diabetes can influence progression of macrovascular complications in this group is not known.

The results of the BARI subgroup have not been reproduced in other large trials, and observational data sets and caution must be exercised in the interpretation of the BARI diabetic data.[51–55] Retrospective analysis of small subgroups may overestimate or even misdirect the treatment effect. A Duke University study of 3230 patients (24% with diabetes), selected for similarity to BARI enrollees, found that diabetes was a marker of a worse prognosis after both CABG and PTCA, but with no clear superiority of one procedure over the other.[52]

The largest database study of patients with diabetes undergoing revascularization is from Emory University, where 2639 such patients with multivessel coronary artery disease who underwent PTCA or CABG between 1981 and 1994 were examined. CABG was superior only among the 889 patients treated with insulin, but confidence intervals were wide (hazard ratio for mortality after PTCA 1·35, 95% CI 1·01–1·79 compared with CABG). This finding is consistent with the BARI trial, in which CABG superiority was more pronounced among patients with diabetes who were taking insulin.[54] In the BARI observational registry, which accompanied the randomized trial, a clear difference in outcomes after CABG or PTCA was not observed.[53] Five year mortality among diabetic patients after PTCA ($n=182$) was 14·4% and 14·9% after CABG ($n=117$; RR 1·10, $P=0·86$).[54] Significant differences in adverse socioeconomic and angiographic characteristics (such as number of significant lesions and presence of diffuse disease) between patients treated with PTCA or CABG were present. Generally, patients who had PTCA had fewer adverse risk factors than those assigned to CABG. After adjustment for these differences, the hazard ratio for mortality after PTCA rose to 1·41 but did not attain significance (95% CI 0·60–3·29).

Conclusions: revascularization in patients with diabetes

In both trials and observational data sets, diabetes mellitus is clearly a marker for high risk and, in comparison with non-diabetic patients, the prognosis is worse after either PTCA or CABG. In the largest randomized trial of PTCA versus CABG, patients with diabetes who received internal mammary artery grafts had better outcomes than those treated with PTCA. However, large non-randomized registry data suggest equivalent outcomes after either procedure as long as the sicker patients are triaged to surgery. One conclusion that may resolve the apparent dilemma is that selected patients with diabetes, such as those with favorable angiographic characteristics, may do as well with PTCA and CABG, whereas those with more diffuse or advanced coronary artery disease do better with CABG as initial therapy. Because 5200 patients have been enrolled in trials of PTCA versus CABG surgery, collaborative meta-analysis based on individual patient data may allow more definitive characterization of outcomes after revascularization among diabetic patients. It remains to be determined whether the use of stents, particularly in combination with parenteral antiplatelet drugs and aggressive metabolic management, will change these conclusions.

Although no prospective randomized trial of myocardial revascularization in patients with diabetes exists, the BARI 2 trial will test the hypothesis that revascularization for diabetic patients early in the stages of CAD may significantly decrease 5 year mortality. This study will incorporate strict metabolic and risk factor control and test both insulin-providing and insulin-sensitizing agents.

Effect of stents on outcome after revascularization

Since first approved by the US Food and Drug Administration in 1993, coronary stents have been adopted rapidly and widely as the main method of percutaneous revascularization, although the pace of adoption has outstripped the pace of the accompanying clinical investigation and regulatory approval.[56,57] Likely, more than 1 000 000 patients now receive intracoronary stents in the USA annually, with an equivalent number in the rest of the world, primarily Europe.

The first indication for stents was for the treatment of severe coronary artery dissection with acute or threatened vessel closure. The National Heart, Lung and Blood Institute 1985–86 PTCA registry documented the risks of balloon angioplasty before the development of stents. Abrupt vessel closure occurred in 6·8% of all procedures, with 32% of these patients requiring emergency CABG and 42% having a myocardial infarction; the case fatality rate was 5%.[58] A prospective multicenter registry of 518 patients with acute or threatened vessel closure after PTCA treated with stents was reported in 1993.[59] Successful stent deployment occurred in 95·4% of cases. The rates of inhospital emergency CABG and myocardial infarction among these patients with severe coronary artery dissections were 4·3% and 5·5%, respectively, markedly lower than the historical control rates mentioned above. Although not randomized, this study and others[60] established the role of stents in the treatment of arterial dissections after PTCA.

Numerous prospective, randomized trials published over the past 10 years have compared elective stenting to balloon angioplasty under various circumstances. These studies have enrolled patients with various lesion types, including elective procedures for single discrete lesions in vessels

of 3·0 mm or larger,[61–71] restenosis lesions after previous balloon angioplasty,[72] lesions of saphenous vein grafts,[73] small caliber vessels,[74–77] and chronic total occlusions.[78–84] The effect of stents versus balloon angioplasty on the clinical outcomes of death, death or myocardial infarction, and repeat procedures, and the angiographic outcome of restenosis are shown in Table 27·5. In total, almost 7000 patients have been randomly allocated in published trials of stent versus balloon angioplasty, including 4694 who had systematic angiographic follow up. As shown in Table 27·5, overall mortality was low (1·5% *v* 1·9% for stent versus balloon angioplasty patients, respectively; odds ratio 0·83, 95% CI 0·57–1·21), as were death or myocardial infarction rates (6·1% *v* 6·5%; odds ratio 0·93, 95% CI 0·77–1·14). The impact of stenting on clinical end points was related to the need for repeat revascularization (14·7% after stenting *v* 23·9% after balloon angioplasty; 9·2% absolute risk reduction; odds ratio 0·53, 95% CI 0·46–0·60). A significant decrease in the incidence of angiographic restenosis was found (27·5% *v* 42·2%; odds ratio 0·50, 95% CI 0·44–0·57) among patients who had systematic follow up angiography (26·6% stent *v* 41·6% PTCA; odds ratio 0·48, 95% CI 0·42–0·56).

As with any rapidly evolving therapy, advances have occurred in techniques of stenting – for example, high pressure inflations[85] and improved antiplatelet therapy with oral[86,87] and parenteral antiplatelet[69] agents – that have allowed wider application.

A novel approach to the further optimization of results – the use of local drug delivery to inhibit the restenotic process after intracoronary stenting – is being evaluated in multiple trials. The first published trial tested a metal stent coated with the macrolide antibiotic sirolimus, an immunosuppressive agent that is a potent inhibitor of lymphocyte and smooth muscle cell proliferation.[88] In animal studies, sirolimus has been shown to be a potent inhibitor of restenosis.[89] The trial enrolled 238 patients with standard clinical indications for stenting and randomly assigned them to receive stents

Table 27.5 Summary of meta-analyses of revascularization for chronic coronary artery disease

PTCA[a] *v* CABG

[a] Meta-analyses were performed using RevMan 5·0 software (Cochrane Collaboration). To accrue the largest number of events possible, data used represent the longest term follow up available for each trial included, whether published or presented orally; 1 was added to all zero cells. Data are presented in summary form only. Details of each meta-analysis are beyond the scope of the current review.

coated with a sirolimus-polymer matrix or uncoated stents. Results were assessed by routine angiography at 6 months. None of the patients who received a sirolimus-coated stent had restenosis, as defined by at least 50% stenosis within the stent, compared with 26·6% of those who had a bare metal stent ($P < 0{\cdot}001$). After 1 year of clinical follow up, there were no episodes of stent thrombosis, and 5·8% of the sirolimus group experienced an adverse cardiac event (death, MI, CABG, or revascularization of the original target vessel) compared with 28·8% of control stent group ($P < 0{\cdot}001$). Although the decrease in restenosis rate and the corresponding reduction in need for further procedures are striking, the trial was only a relatively small single study with follow up limited to 1 year. Whether potent intra-arterial immunosuppression will have unanticipated long-term problems related to impaired arterial healing is unknown.

Several prospective randomized trials have compared multivessel stenting with multivessel CABG, although follow up periods remain short. The Arterial Revascularization Therapy Study (ARTS)[90] enrolled 1205 patients with multivessel disease (average, 2·7 treated lesions) to either stenting or CABG. At 12 months of follow up, 2·5% of the 600 stent patients and 2·8% of the 605 CABG patients had died. Kaplan–Meier estimated rates of the irreversible end points of death, stroke, or myocardial infarction at 1 year were 9·5% for the stent group and 11·2% for the CABG group (RR 0·92, 95% CI 0·62–1·35; $P = 0{\cdot}65$). Stent patients required more follow up procedures than those assigned to CABG, with cumulative event rates at 1 year of 26·2% for the stent group and 12·2% for the CABG group (absolute difference, 14%). Within the stent group, the incremental 16·7% event rate at 1 year attributable to repeat revascularization was about half of the corresponding 33·7% 1 year repeat revascularization rate after balloon angioplasty in a meta-analysis of the balloon versus CABG trials,[29] and was consistent with the findings of the stent versus balloon trials described above. For comparison, 1 year rates of repeat revascularization after CABG have remained constant: 3·3% in the meta-analysis and 3·5% in ARTS.

Data from four other trials of stents versus CABG have been published or presented, including Stents or Surgery (Sigwart U, read at the American College of Cardiology 50th Annual Scientific Sessions, Orlando, Florida, 20 March 2001), a multicenter European study of nearly 1000 patients; Argentine Randomized Trial of PTCA Versus Coronary Artery Bypass Surgery in Multivessel Disease (ERACI) II,[91] a multicenter Argentinian study of 450 patients; and Stenting versus Internal Mammary Artery (SIMA),[92] a Swiss–Italian study of 123 patients. Findings are summarized in the accompanying meta-analyses in Table 27.3 and are consistent with those of ARTS. Data from Angina With Extremely Serious Operative Mortality Evaluation (AWESOME),[93] a prospective randomized clinical trial conducted at 16 Veterans Affairs Medical Centers that assigned 454 patients with refractory angina and markers of high risk to either percutaneous coronary intervention or CABG, are included because a high proportion of the patients in the percutaneous coronary intervention group received stents. Together, these randomized clinical trials have enrolled 3218 patients. No significant differences in mortality (5·45% after percutaneous coronary intervention *v* 5·61% after CABG; odds ratio 0·98, 95% CI 0·98–1·34), or death or myocardial infarction (7·9% after percutaneous coronary intervention *v* 8·9% after CABG; odds ratio 0·87, 95% CI 0·67–1·14) were found. The need for repeat procedures remains higher after stenting (19% *v* 4·5% after CABG; odds ratio 5·54, 95% CI 3·83–6·51), although lower than the rates reported earlier after multivessel balloon angioplasty.

Longer follow up and accrual of events is necessary before final conclusions can be drawn. Similarly, the number of patients with diabetes enrolled was small and no specific conclusions can be drawn yet.

Miscellaneous interventional device trials

Numerous devices have been developed to allow or facilitate percutaneous revascularization. After balloon angioplasty, the directional atherectomy catheter was the first such device, gaining FDA approval in 1990. This device allows cutting and removal of coronary plaque in a controlled ("directional") manner. The hypothesis was that plaque removal would cause less trauma to the artery, incite a less vigorous neointimal response, and, ultimately, significantly decrease rates of restenosis and repeat procedures. Although marginal benefits regarding angiographic restenosis were observed in some trials (CAVEAT, BOAT),[94,95] this was not so in others (CCAT).[96] Worrisome increases in rates of myocardial infarction, death, and other major complications were noted in several trials (BOAT, CAVEAT, CAVEAT-II).[97,98] The rapid ease of use and rapid adoption of intracoronary stents have made directional atherectomy a so-called niche device, used only for particular anatomic circumstances.

Rotational atherectomy is another procedure that can be used for performing lesion debulking. It is performed with a high-speed rotating, diamond-tipped abrasive burr. The device allows recanalization of heavily calcified lesions or fibrotic lesions as well as debulking. No tissue is removed, and the device pulverises atherosclerotic plaque into tiny particles that pass through the microcirculation and are removed by the reticuloendothelial system. The device is associated with a relatively high incidence of poor flow after use and non-Q wave myocardial infarction and has had no particular benefit on restenosis (ERBAC).[99–101] Currently it is used primarily to facilitate stent deployment when this would otherwise be impossible because of severe calcification or fibrosis of the target lesion.

Intracoronary brachytherapy, or the local delivery of radiation to inhibit the restenotic process, was approved for the treatment of in-stent restenosis, a vexing problem that is difficult to treat initially and has high recurrence rates. Two

competing systems, one capable of delivering beta radiation, and the other, gamma radiation, have been widely used. These devices have been demonstrated to significantly lower the rates of subsequent recurrent restenosis (14·6% *v* 60·8% in pooled data from three studies totalling 442 patients) and adverse cardiac events (24·5% *v* 70% $P < 0{\cdot}001$).[102–6] A triple-blind design with dummy radiation sources was used in some studies.[104] A delayed risk of stent thrombosis, particularly when a new stent was placed at the time of the procedure, was observed in follow up (6·2% of brachytherapy patients with a new stent *v* 0·7% of control patients with a new stent).[102] Avoidance of placement of new stents and continuation of dual antiplatelet therapy with aspirin and clopidogrel for 6–12 months has largely obviated this problem. If local drug-elution essentially eliminates or greatly reduces the incidence of in-stent restenosis, utilization of coronary brachytherapy is expected to decrease.

Database studies

Prospective randomized trials provide the highest level of evidence for clinical decision making; nonetheless, information from trials frequently must be supplemented and enhanced by observational studies. Long-term survival for 9263 patients with angiographically documented CAD has been reported recently from Duke University Medical Center.[107,108] Although treatment assignment was non-random, the 97% complete follow up of this consecutive series has provided insight into the outcomes after various treatments (2449 patients, medical only; 2924, PTCA; and 3890, CABG), with concurrent controls. Nine risk strata based on the number and extent of diseased coronary arteries were identified (left main CAD and stenoses less than 75% were excluded). Long-term survival comparisons between treatments were assessed with Cox proportional hazards models and Kaplan–Meier survival analysis. CABG was significantly associated with improved long-term outcomes in comparison with medical therapy for patients in moderate-and high-risk strata (for three vessel disease [$n = 2771$]: odds ratio, 0·44, 95% CI 0·42–0·80) (Figure 27.5). PTCA, however, was superior to medical therapy only among low-risk strata.[108] In comparison with PTCA, CABG was associated with improved outcomes among high-risk strata, namely, all patients with three vessel disease and two vessel disease with

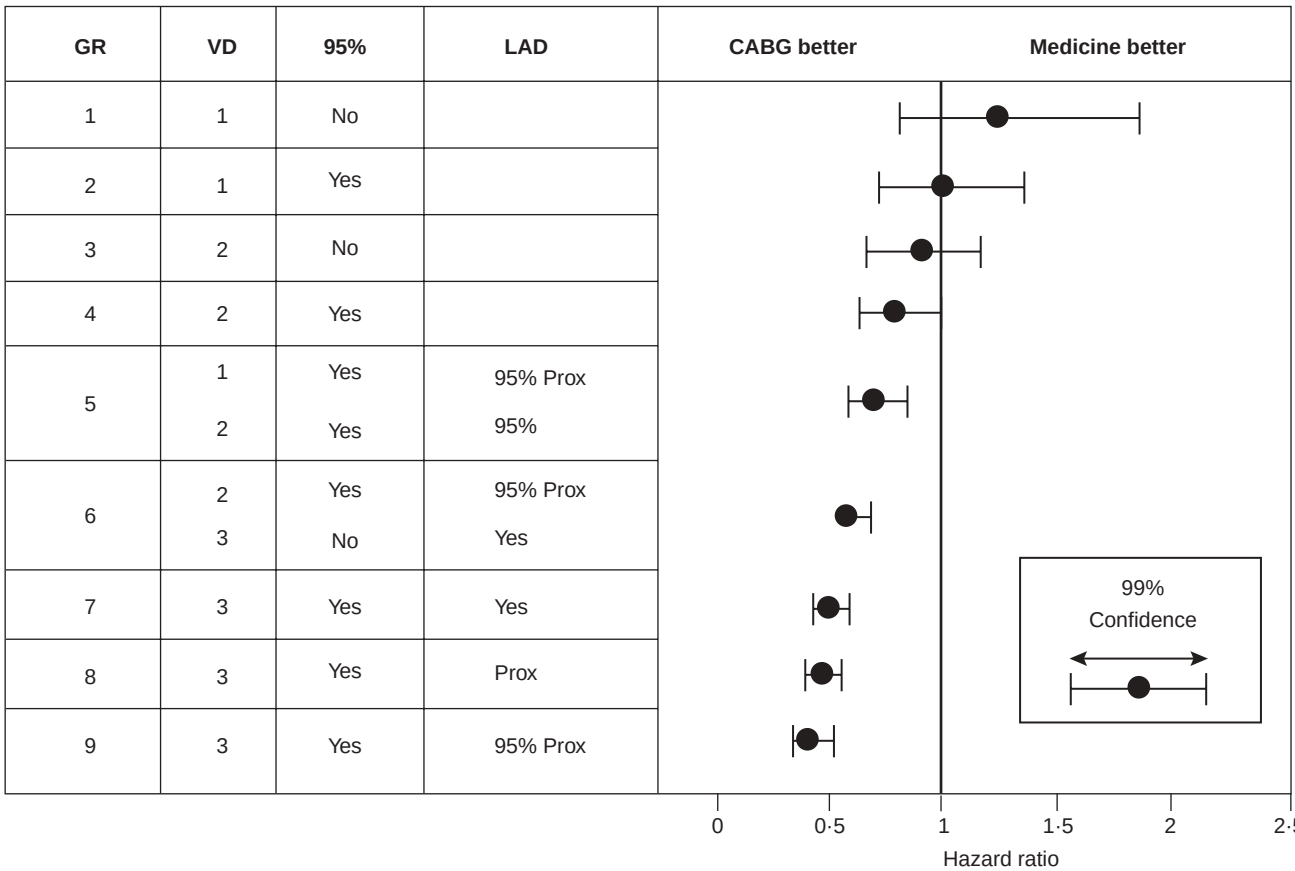

Figure 27.5 Adjusted hazard ratios comparing coronary artery bypass graft (CABG) and medicine for the nine coronary anatomy groups. (From Jones *et al*[108] by permission of Mosby-Year Book, Inc.)

95% involvement of the proximal left anterior descending coronary artery. Conversely, adjusted hazard ratios demonstrated superiority of PTCA over CABG among low-risk patients (Figure 27.6) and a trend toward superiority among moderate-risk patients.

These prospective observational data are broadly consistent with the previously presented framework placing PTCA versus CABG trials in the context of CABG versus medical therapy trials. Although a definitive benefit of CABG over medical therapy for one and two vessel disease could not be demonstrated in the randomized trials (with the possible exception of proximal left anterior descending CAD), non-significant trends favoring CABG were found. The relatively low number of observed events (113 deaths over 5 years) in these trials may have precluded detection of even a large benefit (type II error). The Duke observational data extended the randomized trials and, by virtue of the much larger number of events (related to the larger number of patients and longer duration of follow up), allow further characterization of possible treatment differences. As with any non-randomized study, important limitations related to intrinsic biases in patient selection remain, and definitive conclusions require performance of larger randomized trials. For example, determination of time zero is a problem and deaths occurring while awaiting revascularization were assigned to medical therapy, which would tend to inflate event rates among medical patients.

Limitations of current data

In an evolving field, all trials designed to address specific clinical questions at a specific time should be interpreted in the context of relevant changes in the procedures and complementary treatments. This is especially notable for the CABG versus medical therapy trials performed 20 to 25 years ago. The wide application of antiplatelet, antihyperlipidemic, and ACE inhibitor therapy in current practice may substantially mitigate the published results. Temporal changes in angioplasty and surgical techniques are continuing and, in some cases, accelerating. The development of new interventional devices designed to deal with procedural complications, specific high-risk lesions, or previously unapproachable lesions

has broadened the feasibility of percutaneous procedures. Coronary stents have decreased the incidence of both emergency and late CABG and lower restenosis. New adjunctive medical therapies such as platelet IIb/IIIa receptor antagonists reduce the risk of non-fatal myocardial infarction and emergency CABG with interventional procedures. CABG, too, has undergone considerable technologic advances. Internal thoracic arterial conduits with excellent long-term patency are now widely used. Improved myocardial preservation techniques, adjunctive medical therapies, and less invasive surgical approaches have been developed.

Specific methodologic concerns also exist about the available data. All the trials discussed above compared two active treatments and were not placebo controlled, decreasing the chances of detecting differences among arms. Invasive or surgical trials are logistically very complex, tend to be small compared with drug therapy trials, and are inherently open label. The possibility of missing potentially important differences, even when one exists, is always higher for small trials. Although systematic reviews, preferably based on individual patient data, can provide some redress, larger definitive trials (along with meta-analysis of their results) are preferable. In trials of invasive treatments, crossover to the other therapy occurs with increasing frequency during the course of follow up, necessitating consideration of therapeutic strategies rather than specific treatments. As with many large surgical trials, applicability of results to medical centers with lower volume and different levels of experience remains unproven.[109–111]

The greatest limitation of the currently available data is the low statistical power to detect potential differences in clinical outcomes, in particular the PTCA trials, whereas PTCA rates have grown dramatically. This situation could be rectified partly by long-term follow up of the trials that have been completed, accompanied by a collaborative meta-analysis based on individual patient data. Even if this were done, however, the lack of large trials incorporating all three major approaches to patients with coronary artery disease – medical, interventional, and surgical – would limit comprehensive comparisons to observational databases.[107]

Summary: overview of the evidence for myocardial revascularization in patients with chronic stable angina

CABG surgery versus medical therapy

- Among patients with medically refractory angina pectoris, CABG is indicated for symptom improvement. **Grade A1a**
- Among patients with medically stable angina pectoris, CABG is indicated for left main coronary artery or three vessel disease, regardless of left ventricular function, for prolongation of life. **Grade A1a**
- CABG may be indicated for prolongation of life if the proximal left anterior descending coronary artery is involved, regardless of the number of diseased vessels. **Grade A1c**

Percutaneous coronary intervention versus medical therapy

- Among patients with medically refractory angina pectoris, PTCA is indicated for symptom improvement. **Grade A**
- In the absence of symptoms or myocardial ischemia, PTCA is not indicated merely for the presence of an anatomical stenosis. **Grade A**
- Stents are indicated for the treatment of arterial dissections with abrupt or threatened vessel closure after balloon angioplasty. **Grade B**
- Electively placed stents are superior to balloon angioplasty for reducing the need for repeat procedures and, likely, the risks of periprocedural myocardial infarction and emergency CABG surgery. **Grade A1a**

Percutaneous coronary intervention versus CABG

- For single vessel disease, both PTCA and CABG provide excellent symptom relief, but repeat revascularization procedures are required more frequently after PTCA. **Grade A**
- For multivessel disease, the higher the baseline risk of the patient, the more CABG is to be preferred. **Grade A1c** This includes both diabetic and non-diabetic patients with three vessel or diffuse disease or with left ventricular dysfunction. The following caveats should be considered:
  - Large differences in mortality (40–50%) between PTCA and CABG are unlikely, but smaller differences in mortality (on the order of 20–30%) cannot be excluded given the available data.
  - CABG is associated with more complete revascularization and superior early relief of angina, but these differences are lessened after 3–5 years.
  - No significant differences in rates of myocardial infarction have been demonstrated.
  - Repeat revascularization procedures are required significantly more often after PTCA, an effect partly mitigated by the use of stents.
  - The cost, quality of life, and return to work are initially more favorable with PTCA than CABG, but these variables roughly equalize over 3–5 years.

28 Adjunctive medical therapy in percutaneous coronary intervention

James L Velianou, Ronald R van der Wieken, Maarten M Simoons

Introduction

The introduction of percutaneous transluminal coronary angioplasty (PTCA) has proven to be a major step forward in the treatment of coronary heart disease. Unfortunately, the gain has not come without a price: frequent and serious complications can occur, acute as well as chronic. In 1977, when Gruentzig introduced PTCA, it was clear that the technique required pharmacologic support. Since then, the development of adjunctive therapy has come a long way. Great progress has been made, but some major problems still wait to be resolved.

The goal of this chapter is to provide the reader with a general overview of adjunctive therapy directed primarily against acute complications, and the pathophysiologic principles involved in percutaneous coronary interventions (PCI).

Key points

Acute complications of PCI

- Intimal dissection with or without thrombus
- Plaque rupture with thrombus
- Spasm
- Perforation
- Distal embolization

Acute complications

The complications in the key points box can each lead to abrupt vessel closure. This occurs in 6·8–8·3% of PTCA procedures and is responsible for a sizeable mortality (up to 1·7%), acute myocardial infarction (1·3–8·6%), emergency bypass surgery (1·3–3·6%), and emergency re-PTCA (4·5%).[1–5] Abrupt vessel closure usually happens in the catheterization laboratory, with the great majority taking place within 6 hours post-PTCA. If it is not possible to open the vessel rapidly, major problems can be expected: persisting anginal pain and myocardial infarction, hemodynamic instability and arrhythmias. Rather unexpectedly, these difficulties can also arise with the abrupt re-closure after opening a chronically occluded vessel. The incidence of abrupt vessel closure is more frequent in unstable coronary syndromes and in angiographically complicated lesions.

Intimal dissection is caused by intravascular maneuvering of guidewires, balloons or other devices. It occurs in a wide variety, from minor and acceptable to major and occlusive. It is usually but not always accompanied by thrombus formation. At present, the only feasible therapy for a significant dissection is mechanical. The most widely used therapy used to be prolonged balloon inflation at the site of the dissection, preferably with a perfusion catheter, but this has to a large extent been replaced by the application of stents.[6,7]

Plaque rupture results from pressure applied to an atherosclerotic lesion. The fibrous cap of the plaque ruptures, uncovering highly thrombogenic plaque contents, in many ways resembling the events in the acute coronary syndromes. This probably happens in a large number of angioplastic maneuvers, often without deleterious consequences. It is only harmful if excessive flow limitation and thrombus formation takes place, leading to coronary occlusion or near occlusion. Antiplatelet strategies usually prevent thrombus formation to a large extent. However, it may still occur and treatment often proves to be difficult. Though often used, thrombolysis in the form of intracoronary urokinase,[8] streptokinase or intravenous or intracoronary rTPA has not been proven to be effective in a randomized fashion. Furthermore, it may complicate an ensuing emergency bypass operation. It is likely that abciximab can be helpful in these often-awkward situations and it is indeed frequently used for this indication, but its beneficial effect has not yet been demonstrated in a randomized trial.[9]

Spasm can be caused by the mere touch of the intracoronary guidewire. Isolated spasm, without dissection or plaque rupture, can rarely lead to abrupt vessel closure. More often, spasm is associated with dissection and/or plaque rupture. Antispasmodic therapy usually consists of intracoronary nitroglycerin.[10,11] In refractory cases a calcium antagonist can be given.[12,13]

Chronic sequelae

Restenosis is an indirect sequela of angioplastic trauma to the endovascular structures. Six months after successful conventional angioplasty, it is angiographically present in approximately 40% of cases. Causal factors of chronic restenosis are shown in the key points box.

Key points

Events leading to chronic restenosis
- Elastic recoil
- Formation of mural thrombus
- Intimal proliferation and synthesis of intracellular matrix
- Pathological arterial remodeling

Many drugs have been named as potentially valuable in the prevention of chronic restenosis. A host of trials have been conducted but only a few have reported a positive outcome. It was shown in a double-blind, placebo-controlled, randomized trial that probucol, an antioxidant, was effective in reducing the restenosis rate.[14] One month before PTCA, 317 patients were randomly assigned to receive one of four treatments: placebo, probucol (500 mg bid), multivitamins (30 000 IU of betacarotene, 500 mg of vitamin C, and 700 IU of vitamin E, bid), or both probucol and multivitamins (bid). Patients were treated for 4 weeks before and 6 months after angioplasty. Follow up angiography 6 months after PTCA showed restenosis in 20·7% in the probucol group, 28·9% in the combined treatment group, 40·3% in the multivitamin group, and 38·9% in the placebo group. The difference between the probucol and non-probucol groups is statistically highly significant ($P = 0{\cdot}003$). More recently, a double-blind, placebo-controlled, randomized trial of folate treatment revealed a reduction in restenosis. A total of 205 patients were randomized after successful PCI to folate treatment (folic acid 1 mg, vitamin B_{12} 400 micrograms and pyridoxine 10 mg) or placebo for a total of 6 months. Follow up angiography was carried out at 6 months (or earlier if clinically indicated). The rate of restenosis was significantly reduced in the folate group (19·6% *v* 37·6%, $P = 0{\cdot}01$), as was the need for revascularization (10·8% *v* 22·3%, $P = 0{\cdot}047$).[15] These results need confirmation in other trials before probucol or folate treatment can be advocated as an indispensable adjunct to PTCA.

Pharmacologic suppression of restenosis is, however, still under intense research. Trials are presently being conducted with new pharmacologic agents, systemically or locally delivered. Promising new strategies include drug-eluting stents. Stents alone have been successful, at least in large vessels.[16,17] Effects in smaller coronary arteries are awaited, but seem to be less promising. Stenting prevents recoil and pathological remodeling to a large extent, but leaves formation of mural thrombus and intimal proliferation unhampered. Stenting is therefore at best a partial remedy to the problem of chronic restenosis, reducing the incidence of restenosis but not abolishing it. However, drug-eluting stents may provide the ability to localize therapy without systemic effects. Rapamycin, an anti-rejection drug, has shown the most promise to date. The recent RAVEL study, a double-blind, placebo-controlled, randomized trial of rapamycin drug-eluting stent versus bare stents revealed a significant decrease in both restenosis (0% *v* 26·6%, $P < 0{\cdot}001$) and major adverse events (5·8% *v* 28·8%, $P < 0{\cdot}001$) at 6 months. A total of 238 patients were randomized of which 88·7% underwent 6 month angiograms.[18] However promising these agents appear, more studies are required to fully evaluate the efficacy, safety and cost effectiveness of drug-eluting stents.

Thrombus, platelets, and thrombin

Thrombus formation

This plays a leading role in abrupt vessel closure and may be of importance in chronic restenosis. The composition of arterial thrombi ("white thrombi"), with their predominance of platelets, shows that thrombocytes are central in angioplasty-related thrombus formation and acute vessel occlusion. A second agent of great importance is thrombin.

Platelets, physiology, and pathophysiology

The properties of platelets relevant to the formation of thrombus are shown in the key points box and are discussed in some detail below. Platelets are produced by the megakaryocyte. Through processes yet unexplained, this cell fragments into many platelets, which are disk-shaped cells with a diameter of 2–3 μm derived from the cytoplasm of the megakaryocyte without a nucleus. They do contain platelet-specific granules and a dense tubular system as well as a skeleton consisting of actin. The surface has a host of receptors for a wide variety of agents all playing a role in the very complex processes of adhesion, aggregation, and release of granules.

Normally, platelets are in contact solely with the other blood components and the endothelial lining of the blood vessels. Any other contact is inducive to platelet adhesion, with the potential to escalate to aggregation. As long as the endothelial lining of the blood vessels is intact, platelets are not activated. This does not mean that they are inert. Platelets produce substances responsible for the maintenance of the integrity of the vessel walls.

Platelets are normally heterogeneous, both physically and functionally. Younger platelets seem to be larger and more responsive to thrombin than older ones.[19] The lifespan of the platelet is 7–10 days. They are not distributed evenly throughout the lumen; the arterial flow pattern is such that platelets tend to concentrate near the wall, while red blood cells are present predominantly in the central part of the vessel.

Key points

Platelet properties relevant to thrombus formation
- Adhesion
- Aggregation
- Synthesis and release of prostaglandins, thromboxane, and intracellular granules

Adhesion

Platelets contacting surfaces other than erythrocytes, leukocytes or intact endothelium can adhere to them. They adhere to subendothelial structures, macrophages, activated leukocytes, and endothelial cells activated by inflammatory cytokines, and through the expression of membrane integrins, a subset of the glycoprotein receptors situated on the platelet membrane. The main endothelial adhesive protein is the von Willebrand factor, but many others can play a role. Adhesion denotes the deposition of thrombocytes on a surface perceived as foreign, involving a monolayer of platelets and, at least theoretically, having the effect of providing a more natural environment for the other blood corpuscles. Often, however, aggregation ensues.

The most frequently encountered foreign structure is subendothelial tissue that is exposed when endothelium is damaged, for example, during angioplasty. The level of platelet adherence is dependent on the nature of the foreign structure; deeper seated structures are a stronger stimulus than those just under the endothelial lining,[20] and on the presence of the von Willebrand factor. The von Willebrand factor can bind to certain types of collagen and form complexes that bind to the platelet membrane glycoprotein GP IIb and thus cause adhesion.[21] Adhesion involves one single layer of thrombocytes only.

On adhesion, contact with subendothelial collagen can initiate the following physiologic events:

- intracellular platelet granules are released into the extracellular space;
- P-selectin, a platelet membrane glycoprotein, expresses itself on the platelet surface, mediating adhesion to white blood corpuscles;
- activation of the intraplatelet eicosanoid pathway, starting with the emanation of arachidonic acid;
- a profound change in the shape of the platelets, from a smooth disc to a spiculated structure.

These reactions together constitute the activation of the platelets which leads to platelet aggregation, a process that accelerates itself considerably in a short passage of time.

Aggregation

More extensive vessel damage induces platelets to aggregate. Activation and ensuing aggregation can be caused by many factors including adenosine diphosphate (ADP) and serotonin, which are produced (among many others) by the release of platelet granules, thromboxane A_2 (TXA_2), which is generated in the interior of the platelet as an end product of the eicosanoid pathway, and platelet activating factor, which is produced by injured endothelial cells. Adrenaline, noradrenaline, and thrombin (most powerful) also activate platelets, and vice versa; platelet activation catalyzes the conversion of prothrombin to thrombin, thereby accelerating the process of activation and aggregation. Fibrillar collagen, which is exposed when the vessel is damaged, not only promotes adhesion, but also induces aggregation.

After the specific agents have made contact with the platelet membrane, the platelet changes in shape from disc to spiculated sphere. This change in shape is regulated by a skeleton of actin situated interior to the plasmalemma. The filopodial projections that constitute the spiculae probably facilitate contact between GP IIb/IIIa, the receptor on the platelet surface which is the final common pathway responsible for aggregation, and crucial proteins: fibrinogen and von Willebrand factor. In the next stage the GP IIb/IIIa receptor changes in conformation, allowing fibrinogen and von Willebrand factor to bind simultaneously to the GP IIb/IIIa receptors on the surface of two platelets, thus creating a link between them. This usually irreversible linkage is called aggregation. A plug of linked platelets constitutes a thrombus and may obstruct a vessel lumen.

Synthesis and release of prostacyclin, thromboxanes, and intracellular granules

The eicosanoid pathway exists in endothelial cells as well as in the interior of the platelet. Arachidonic acid is converted by cyclo-oxygenase to endoperoxides that form prostacyclin in the endothelial cells but generate TXA_2 in the platelet. TXA_2 enhances aggregation, and is a vasoconstrictor; prostacyclin, on the other hand, has strong vasodilatory and antiaggregant properties. Platelets contain at least three different types of intracellular storage granules. These granules contain a host of substances that can be liberated from the activated platelets by an exocytotic mechanism.[22] The various materials are able to potentiate platelet aggregation and blood coagulation and increase vascular permeability.

Thrombin

Thrombin is the second major player in the pathogenesis of acute coronary thrombosis. It is at the center of reactions essential to thrombus formation. It can activate platelets strongly and independently.[23] Thrombin can cause the release of the von Willebrand factor from endothelium, and facilitates the activation of factor V and VIII and the transition of fibrinogen to fibrin. It promotes the formation of a fibrin mesh around thrombi. Thrombin is abundantly generated during angioplasty.[24]

Antiaggregatory strategies

Four major classes of antiaggregatory agents can be discerned:

- cyclo-oxygenase inhibitors, for example, aspirin;
- thienopyridines, for example, ticlopidine, clopidogrel;

- glycoprotein IIb/IIIa inhibitors, for example, abciximab (Reopro), eptifibatide (Integrilin) and tirofiban (Aggrastat);
- thrombin inhibitors, for example, heparin, LMWH and hirudin.

Aspirin

Platelet aggregability can be inhibited to some extent by aspirin. In thrombocytes, aspirin irreversibly inhibits cyclooxygenase and thereby the generation of TXA_2 which is an aggregation promotor. Aspirin thus inhibits platelet aggregation and thrombus formation. However the production of antiaggregatory prostacyclin is also reduced in the endothelium. Possibly this unfavorable side effect becomes more pronounced with higher doses of aspirin, rendering the lower doses relatively more effective.[25] Aspirin leaves other platelet activation pathways untouched. It is therefore a relatively weak antiaggregatory agent.

Aspirin has been used as premedication to angioplasty since its debut in 1977 and is a universally used adjunctive,[26] but with few prospective trials ever having proven the efficacy. In one trial, a daily dose of 990 mg aspirin combined with dipyridamole (225 mg daily) showed no effect on restenosis compared to placebo, but periprocedural infarctions were significantly less in the treatment group.[27] Among the 376 randomized patients, there were periprocedural Q wave infarctions in 6·9% in the placebo group and 1·6% in the active drug group, the difference reaching statistical significance ($P = 0{\cdot}0113$). A retrospective angiographic study also showed a clear periprocedural advantage of aspirin and dipyridamole.[28] After doubts had been raised concerning the contribution of dipyridamole to the antithrombotic action of aspirin,[29] this drug disappeared from the adjunctive armamentarium.

The optimal daily dosage of aspirin with a reliable effect in angioplasty is not known. In the USA, 325 mg is usual, while in Europe 100 mg or 80 mg is accepted. The higher dosages (over 100 mg) are associated with more, predominantly gastrointestinal, side effects but not convincingly with greater efficacy. Aspirin is rapidly absorbed from the stomach and upper small intestine. Following ingestion, peak plasma levels are reached 20 minutes after ingestion.[30] Clinically relevant inhibition of platelet aggregation requires 80–90% blockade of TXA_2 synthesis.[31] With daily oral dosages of 80 mg it takes 48 hours to develop this effect on TXA_2 production and aggregation.[32] In higher dosages effective inhibition is reached earlier. It is therefore advisable to start oral aspirin at a low dose at least 48 hours before the angioplasty. Often time is lacking to prepare the patient along these lines. If an immediate procedure has to be performed and the patient is not on aspirin, chewing of enteric coated aspirin results in a sufficient antiplatelet effect after 30 min.[33] Intravenous injection of 250 or 500 mg aspirin results in an even more immediate platelet inhibition, however this is not readily available in many countries.[34]

Ticlopidine and clopidogrel

Ticlopidine is metabolized to an as yet unknown substance, which inhibits ADP-induced platelet aggregation but has no effect on TXA_2-induced aggregation. It leads to a remarkable prolonging of the bleeding time. An effect on platelet aggregation is demonstrable only after 3–5 days of medication.

Ticlopidine has proven its usefullness in conjunction with aspirin in the prevention of acute and subacute stent thrombosis. This complication occurs after insertion of an intracoronary stent in 2–8% of cases, usually between days 2 and 14 with a peak between days 5 and 7 after stent placement. Very extensive regimens, consisting of vitamin K antagonists, dipyridamole, and dextran as well as aspirin and heparin, did not positively influence this complication and led to unacceptable bleeding complications.[16] However, the combination of aspirin and ticlopidine achieved a significant decrease of stent thrombosis as well as bleeding complications.[35] Simultaneously, significant improvement of stent delivery technique such as high pressure implantation also affected results. Until recently, the standard of practice was to administer ticlopidine daily, beginning 7 days before scheduled stent placement. If a stent is inserted as a bailout procedure or because of a suboptimal result, it is customary to start the drug immediately after the procedure. It is continued for 30 days in a regimen of 250 mg bid. The main untoward but reversible effect is bone marrow depression, especially of the neutrophil granulocytes, occurring in less than 2% of patients.[36] In less than 1%, thrombocytopenia is encountered. Two weeks after starting ticlopidine, a white blood cell and thrombocyte count should be performed.

However, clopidogrel is now utilized for most patients treated by PCI in North America and Europe. While in many respects similar to ticlopidine (though it differs in its chemical structure and shares no common metabolites), it displays a lesser tendency to bone marrow depression and other adverse side effects, prompting its use in lieu of ticlopidine.[37] Multiple studies of clopidogrel versus ticlopidine have been carried out.[38–47] Initially, evidence for clopidogrel use in PCI came from non-randomized, single center registries.[38–44] These centers initially had altered their practices from ticlopidine to clopidogrel due to the belief that the benefits of the two drugs would be similar, but the side effects of ticlopidine were significantly worse. Moderate-sized randomized trials were subsequently carried out comparing ticlopidine (plus aspirin) and clopidogrel (plus aspirin) in PCI. These included the Clopidogrel Aspirin Stent International Cooperative Study (CLASSICS), the Ticlid Or Plavix Post-Stent (TOPPS) trial and another by Muller *et al.*[45–47] CLASSICS was the largest study and the only one that was double-blinded. None of these individual studies revealed any significant differences in terms of 30 day major adverse cardiac events. A meta-analysis of these registries and trials reveals that clopidogrel is associated with a lower adverse cardiac event

rate (2·1% *v* 4·0%, OR 0·51; $P = 0·001$) and mortality (0·48% *v* 1·09%, OR 0·44; $P = 0·001$) at 30 days.[48] Overall, given the totality of evidence, clopidogrel appears as effective if not more effective at reducing adverse events in standard PCI.

Patients with unstable angina or non-ST elevation myocardial infarction undergoing PCI are a known higher-risk subset with regard to adverse cardiac events. Pretreatment with 300 mg and continued treatment after one month with 75 mg per day of clopidogrel (in addition to aspirin) prior to PCI in the CURE-PCI study decreased adverse cardiac events at both 30 days (adjusted relative risk 0·65, $P = 0·01$) and long-term follow up at 12 months (adjusted relative risk 0·72, $P = 0·03$).[49]

IIb/IIIa receptor blockers

Although there are many ways to activate the platelet, all converge into the same final common pathway, the IIb/IIIa receptor. Blockade of this receptor impedes aggregation to a very large extent, if not completely, with all modes of platelet activation using the final common pathway.

Presently, IIb/IIIa blockers are known in four forms:

- a chimeric monoclonal antibody (derived from murine antibodies), abciximab, which is commercially available;
- naturally occurring snake venom polypeptides. These non-enzymatic peptides have a low potency and short half life, diminishing their therapeutic value;[50]
- synthetic peptides, for example, integrilin and tirofiban;
- non-peptide IIb/IIIa inhibitors, which have not been efficacious until now.

Relevant large scale clinical investigations have been conducted with abciximab, integrilin, and tirofiban.

Abciximab was tested in the CAPTURE, EPILOG, EPIC and EPISTENT trials. All were prospective, multicenter, randomized, double-blind, placebo-controlled, Phase III studies, with over 8500 patients. Table 28.1 shows the main results of these studies.

EPIC studied 2099 patients at increased risk for ischemic complications during or after PTCA[51]: unstable angina and/or recent non-Q wave infarction, acute Q wave infarction within 12 hours of symptom onset, and clinical and angiographic characteristics predictive of increased risk of ischemic complications according to AHA Medical/Scientific Statement Guidelines.[52] Patients were randomized to one of the following regimens:

- placebo bolus+infusion;
- abciximab bolus 0·25 mg/kg IV+12 hour infusion of placebo;
- abciximab bolus 0·25 mg/kg IV+12 hour infusion of abciximab 10 migrograms/min.

Treatment started at least 10 min before PTCA, all patients received 325 mg aspirin orally and 10 000–12 000 IU heparin intravenously. Abciximab dosages were devised to reach a receptor blockade of at least 80%. Patients were followed for 30 days, 6 months and 3 years post-procedure. The 30 day composite end point, as in the other two studies, comprised death from any cause, acute infarction or the need for urgent coronary intervention and was statistically significantly reduced by 34·8% in the group treated with bolus and infusion of abciximab as compared to placebo bolus and infusion ($P = 0·008$). Thirty days emergency repeat PTCA was necessary in 6% of the placebo group and in 1% of the bolus plus infusion group ($P = 0·002$). At 6 months and after 3 years, the 30 day benefits were sustained.

Thrombocytopenia (<100 000/ml) was seen more often in the bolus plus infusion than in the placebo group (respectively 5·2% and 3·4%; $P = 0·01$). Of the patients who received abciximab, 6·5% developed human antichimeric antibody, mostly in low titers; none showed allergic reactions. Major hemorrhagic complications immediately after angioplasty, predominantly involving the access site, were higher in the abciximab treated patients. Hemorrhage was especially prominent in patients with a body weight under 75 kg receiving abciximab bolus plus infusion, suggesting that the fixed dose heparin was to blame.

This concept was tested in EPILOG.[53] A total of 2792 patients undergoing elective angioplasty were allocated among three regimens. In the EPIC trial an abciximab regimen was used almost similar to the bolus plus infusion in two of the three groups: one with standard dose heparin (100 IU/kg with a maximum of 10 000 IU) and one with low dose heparin (70 IU/kg, with a maximum of 7000 IU). A third cohort received placebo with standard dose heparin. In all groups additional heparin was administered to keep ACT above 300 seconds.

It was demonstrated that the efficacy of abciximab was preserved under the low dose regimen of heparin. It was also shown that the rate of major bleeding could be reduced to acceptable values: 2·0% in the low dose heparin group versus 3·1% and 3·5% in the heparin-only and the standard heparin with abciximab groups respectively (P = NS). Minor bleeding was 3·7% in the heparin-only group, 4·0% in the low dose heparin with abciximab and 7·4% in the standard heparin and abciximab group ($P = 0·01$). In this study, too, the benefit of abciximab was preserved after 6 months: primary end points after 30 days were reached in 11·7% in the heparin-only group, 5·2% in the standard dose heparin with abciximab group, and 5·4% in the low dose heparin with abciximab group ($P < 0·0001$).

In the CAPTURE trial, 1265 patients with refractory unstable angina were randomized to abciximab (bolus and infusion 18 hours preceding angioplasty) or placebo. Abciximab was given as a bolus and an infusion during 18–24 hours preceding the PTCA procedure. This infusion was stopped 1 hour after PTCA. Heparin was administered prior to randomization, until at least 1 hour after PTCA and

Table 28.1 Main results of CAPTURE, EPILOG, EPIC and EPISTENT trials

Abbreviations: CAPTURE, C7E3 Anti Platelet Therapy in Unstable Refractory Angina; EPIC, Evaluation of C7E3 to Prevent Ischemic Complications; EPILOG, Evaluation in PTCA to Improve Long-term Outcome with abciximab GP IIb/IIIa blockade; EPISTENT, Evaluation of Platelet IIb/IIIa Inhibitor for Stenting; MAE, major adverse events, comprising death, myocardial infarction, urgent revascularization of any sort, in percentages

adjusted to keep APTT between 2·0 and 2·5 times normal or an ACT of 300 s.[54]

It should be noted that EPILOG and CAPTURE were terminated early, interim analyses demonstrating a significant reduction in end points in the abciximab treated groups.

The relative reduction of primary end points was of the same magnitude as in EPIC. The difference in primary end points between CAPTURE (placebo *v* active drug: 15·9% *v* 11·3%; $P = 0{\cdot}012$) and EPIC (12·8% *v* 8·3%; $P = 0{\cdot}008$) can be explained by inclusion of more severely unstable patients in CAPTURE ("refractory" *v* "high risk"). The significance of the difference in regimens – abciximab being administered before and during angioplasty in CAPTURE, and during and after in EPIC – is not clear.

Stent use was low in these early studies. However, practice patterns changed with increased stent use and less PTCA alone or "plain old balloon angioplasty" (POBA). The Evaluation of Platelets IIb/IIIa Inhibitor for Stenting (EPISTENT) was initiated to evaluate the use of abciximab in PCI with stent implantation.[55] A total of 2399 patients were randomized to one of three treatment arms; stent plus abciximab, PTCA plus abciximab or stent plus placebo. Patients were otherwise treated with standard medications including aspirin, ticlopidine, and heparin. The primary end point was a composite of death, myocardial infarction and the need for urgent target revascularization in the first 30 days. Patients randomized to the stent/abciximab therapy had a lower event rate compared to stent/placebo (5·3% *v* 10·8%, $P < 0{\cdot}001$, hazard ratio 0·48) and PTCA/abciximab (5·3% *v* 6·9%, $P = 0{\cdot}007$, hazard ratio 0·63). Major bleeding complications were not significantly different, but this study was not powered to detect this. The benefits of abciximab appear to be maintained over time.[56] Debate over the implications of the results continues to occur. Many of the events prevented were troponin and CK rises which may or may not be an accurate surrogate of mortality. As with any therapeutic intervention, higher-risk patients probably benefit most from abciximab. In the case of PCI, diabetic patients appear to benefit both in the short-term and longer follow up. However, evidence from EPISTENT is a substudy analysis with different baseline characteristics. Other non-randomized studies have confirmed the 30 day but not the long-term results.[57]

Eptifibatide was tested in the IMPACT II study,[58] which involved 4010 patients undergoing angioplasty or atherectomy. The incidence of major ischemic complications or emergency revascularization at 24 hours was lower in two groups treated with integrilin (135 micrograms/kg bolus plus 0·5 micrograms/ kg/min or 0·75 micrograms/kg/min, both for 20–24 hours) than in the placebo treated patients, but this was not statistically significant after 30 days (11·4% *v* 9·2% *v* 9·9% respectively for placebo, low-dose, and high-dose eptifibatide; $P = 0{\cdot}063$ placebo *v* low-dose eptifibatide). There was no difference in the occurrence of major bleeding. The IMPACT II study displayed statistically non-significant results. However, it was felt that platelet inhibition was not optimal. The Enhanced Suppression of the Platelet IIb/IIIa Receptor with Integrilin Therapy (ESPRIT) trial compared eptifibatide to placebo in stable patients undergoing PCI with stent.[59] Patients in this study were deemed appropriate not to necessarily need GP IIb/IIIa inhibitor, therefore considered lower risk than patients in the abciximab trials. Furthermore, patients were excluded if they were pretreated with clopidogrel greater than 24 hours. The ESPRIT study utilized a significantly higher dose of eptifibatide (2 boluses 180 micrograms/kg 10 min apart plus 2·0 micrograms/kg/min for 18–24 hours). The primary end point was the composite of death, myocardial infarction, urgent target vessel revascularization and bailout glycoprotein IIb/IIIa inhibitor use at 48 hours. ESPRIT was terminated early due to efficacy. The primary end point was reduced in the eptifibatide group (6·6% *v* 10·5%, $P = 0{\cdot}0015$). There appeared to be continued benefit out to 6 months.[60] However, many of the events in the ESPRIT trial were arguably of borderline significance such as enzymatic rise and bailout use of glycoprotein IIb/IIIa inhibitor.

Tirofiban was tested in the RESTORE (Randomized Efficacy of Tirofiban for Outcomes and Restenosis) study in 2139 patients with unstable angina or acute myocardial infarction, undergoing PTCA or atherectomy. Tirofiban (bolus of 10 micrograms/kg + 0·15 micrograms/kg/min for 36 hours) was compared with placebo, both groups receiving aspirin and heparin. At 30 days, the incidence of a composite end point of death, acute infarction, urgent or emergent PTCA or CABG was 10·5% in the placebo group and 8·0% in the tirofiban group ($P = 0{\cdot}052$). Here also, the incidence of major bleeding did not differ significantly.[61] The RESTORE study did not conclusively prove that tirofiban provided protection from adverse events peri-PCI. However, since there were differences between the small-molecule inhibitors (eptifibatide and tirofiban) and monoclonal antibodies (abciximab) in both structure and cost, a direct comparison was carried out. The TARGET (do Tirofiban And ReoPro Give similar Efficacy Trial) was designed as a non-inferiority trial of tirofiban and abciximab. This was a double-blind, double-dummy randomized trial of 4809 patients undergoing PCI with stent. Primary end point was a composite of death, non-fatal myocardial infarction, and urgent target vessel revascularization at 30 days. A significantly higher number of patients treated with tirofiban reached the primary end point (7·6% *v* 6·0%, $P = 0{\cdot}038$). Importantly, pretreatment with clopidogrel was associated with fewer adverse events in both treatment arms.[62]

Comparison of abciximab, eptifibatide, and tirofiban shows that abciximab is probably the most effective in reducing ischemic complications. This can be possibly explained by the tightness of the abciximab-IIb/IIIa binding, while eptifibatide and tirofiban are loosely bound. Also, actual dosages of the small molecule GP IIb/IIIa inhibitors

may be inadequate. Furthermore, it is probable that only abciximab also binds to the vitronectin receptor (which shares an epitope with IIb/IIIa), extending its blocking capacities. Unfortunately, a direct comparison of abciximab and eptifibatide is not currently available.

Antithrombins

The most widely used thrombin antagonist is heparin. In its unfractionated form, it has been used in PTCA since its introduction. Its effect on peri-procedural complications has never been demonstrated unequivocally.

Heparin is not a simple substance but consists of a combination of agents that all bind to antithrombin III (ATIII). Its molecular weight is 15 000. Through a reversible binding with ATIII, a naturally occurring inhibitor of activated blood coagulation factors,[63,64] heparin converts ATIII from a slow inhibitor to a rapid inhibitor of factors XIIa, XIa, IXa, Xa, and thrombin. Thrombin is more sensitive to the effects of heparin than is Xa and in keeping with this, unfractionated heparin exerts its action mainly through inhibition of thrombin-induced activation of factors V and VIII.[65] For thrombin inhibition it is necessary that both thrombin and ATIII bind to heparin. This requires a minimum chain length of 18 monosaccharides.

Heparin also comes in fractionated forms. These low molecular weight heparins (LMWH) have a molecular weight of 4000–5000 and a chain length >18 monosaccharides. These LMWH, when compared to the heavier components of unfractionated heparin, are more prone to bind to ATIII. They cannot bind to thrombin but they retain anti-Xa activity. The heavier components, on the other hand, are probably responsible for heparin-associated thrombocytopenia and possibly for some platelet activation. LMWH can be administered subcutaneously once daily.

In accordance with the better binding to ATIII, LMWH are more effective than unfractionated heparin in the prevention of deep venous thrombosis.[66] Hopes for a better safety profile did not materialize: in a meta-analysis of 62 studies with a total of over 20 000 patients, it was shown that LMWH are associated with a higher bleeding risk than heparin.[67]

In the treatment of unstable angina, LMWH were proven valuable in various trials as compared to unfractionated heparin, without excessive bleeding.[68–70] LMWH inhibits *in vitro* smooth muscle cell migration and proliferation without affecting endothelial cell growth.[71] However, *in vivo*, one LMWH, enoxaparin, did not show any effect on the incidence of restenosis nor did another,[72] reviparin, compared to unfractionated heparin in patients undergoing PTCA.[73] Reviparin was not associated with a decrease in the incidence of bleeding complications nor did it show any advantage in the occurrence of acute complications during and after PTCA. Further studies have been carried out by the National Investigators Collaborating on Enoxaparin (NICE) utilizing enoxaparin with (NICE-4) and without (NICE-1) abciximab. These were registries, but the results appear promising. Presently, there are no compelling evidence-based arguments to replace unfractionated heparin with LMWH as an adjunctive to PTCA.

Heparin is a relatively weak antiplatelet agent, in part because it does not inhibit the other platelet activators that operate independently from thrombin. Also, it tends to bind to the platelet surface, thus increasing platelet activity.[74,75] Furthermore, thrombin is incorporated into a developing thrombus and binds to fibrin. This fibrin bound thrombin can generate activated factors V and VIII, producing additional thrombin and promoting thrombus growth.

The heparin-ATIII complex is a potent inhibitor of free thrombin but only weakly inhibits fibrin bound thrombin. Heparin therefore can only inhibit but not completely prevent the growth of thrombi.[76,77] Moreover, heparin can only exert its influence in the presence of adequate levels of antithrombin III.

Direct thrombin inhibitors have been developed to circumvent the need for antithrombin III. Hirudin is a natural antithrombin, produced by the salivary glands of the European leech. A recombinant form is equipotential. Both inhibit all known functions of thrombin,[50] at least theoretically overcoming many of the disadvantages of heparin. However, in contrast to heparin, thrombin generation is left intact. In the HELVETICA (Hirudin in a European Trial versus Heparin in the Prevention of Restenosis after PTCA) trial hirudin was compared with heparin in patients with unstable angina undergoing PTCA.[78] This study in 1141 patients was designed to evaluate the effect of hirudin on chronic restenosis. In the occurrence of early cardiac events, a clear advantage could be attributed to hirudin: after 96 hours a combination of death, myocardial infarction, bypass surgery and second angioplasty occurred in 11% of the group treated with heparin, 7·9% in the intravenous hirudin group and 5·6% in the intravenous and subcutaneous hirudin group ($P = 0{\cdot}023$). There was a particular benefit in patients in Braunwald class III angina;[79] in patients who had angina at rest during the 48 hours before randomization, the event rate was 21·6% in the heparin group as compared with 5·3% in the patients receiving intravenous hirudin and 12·3% among the patients receiving intravenous and subcutaneous hirudin ($P = 0{\cdot}006$). After 7 months, however, there was no difference in major end points between the three cohorts, nor was there any difference in the angiographic degree of restenosis. Bleeding complications did not differ significantly. It was argued that the hirudin dosage was sufficient to limit acute thrombin mediated platelet aggregation and thus could affect acute complications, but insufficient to produce an adequate level of anticoagulation to influence restenosis.

In the GUSTO IIb study, in acute myocardial infarction, immediate angioplasty was performed in a subgroup. Patients were randomized to heparin and hirudin and to

immediate angioplasty and thrombolysis. No beneficial effect of hirudin over heparin was found.[80]

Hirulog is a synthetic peptide designed on the structure of hirudin. Its effectiveness in angioplasty was studied in a prospective double-blind randomized trial of 4098 patients with unstable angina who were treated with either heparin or bivalirudin (hirulog).[81] No difference was demonstrated in short- and long-term complications. Bivalirudin was associated with a lower incidence of major hemorrhage.

At present, neither a direct thrombin inhibitor nor LMWH can be advocated to take the place of heparin in PTCA.

Recommendations

Preventive

Aspirin is indispensable as an adjunct to PTCA. It is safe, cheap, and effective as well as easy to administer. It should be given in a single daily dose of at least 80 or 100 mg for at least 3 days before PTCA. It should be continued afterwards indefinitely. **Grade A1a**

If a stent is inserted, ticlopidine (250 mg bid) or clopidogrel (75 mg od) preferably starting 7 days before and continuing at least 2–4 weeks after the procedure should be added to the regimen. **Grade A1a**

Heparin is the thrombin inhibitor of choice in all PTCA procedures; dosage is a bolus of 70–100 IU/kg bodyweight or 5000 IU IV at the start of the procedure, with repeated bolus injections during procedure to maintain therapeutic APTT (around 70 sec) or ACT (above 200 sec). It is still not clear as to the ideal ACT, but clear heparin required for PCI. Other anticoagulants such as LMWH or direct thrombin inhibitors can also be utilized during PCI, but there is still no significant evidence they are more efficacious than standard heparin. **Grade A1a**

In high-risk procedures, as in unstable angina or angiographically complicated lesions (type B2, C), abciximab should be considered, before PCI, followed by a 12 hour infusion. Heparin should be rigorously weight adjusted. Abciximab, eptifibatide or tirofiban can be considered for lower risk PCI, but overall absolute benefit may not be significant. **Grade A1a**

Therapeutic

Spasm can be countered with nitroglycerin or nifedipine. **Grade B2**

Acute or threatened closure due to dissection/thrombus can be treated with thrombolytics or glycoprotein IIb/IIIa inhibitors, but there is weak evidence that this is useful. **Grade B2**

29 Restenosis: etiologies and prevention

Giuseppe Sangiorgi, David R Holmes, Robert S Schwartz

Introduction

Percutaneous coronary interventions have revolutionized the treatment of coronary atherosclerosis, creating an alternative strategy to medical and surgical therapy for myocardial ischemia and acute coronary events. The concept was that atherosclerotic plaque can be fractured, removed or ablated within the vessel by different device technologies. However, it was quickly understood that following the intervention, a healing response, known as restenosis, significantly reduced the long-term success of the procedure.

Restenosis is a substantial medical problem, both because it occurs in 40–50% of patients undergoing coronary revascularization procedures, with increased patient morbidity, but also for the significant burden of medical costs,[1,2] which is estimated to be of nearly $2·0 billion per year.[3] Restenosis may be effectively treated by repeat angioplasty. However, further interventional procedures entail additional cost, and the redilated lesions are more prone to the development of restenosis than native lesions.

Because of this unacceptably high restenosis rate and the huge health cost implications, it is not surprising that in the past ten years or so there have been intense efforts to elucidate the pathophysiologic mechanisms of this process and, most importantly, extensive clinical trials aimed at a wide array of strategies to prevent restenosis. Today, while the cellular mechanisms and interactions involved in the pathobiology of restenosis have been better understood, and powerful effects have been obtained in some animal models with the use of different drugs and devices, the search for successful therapeutic effects continues, because when transferred into clinical practice, restenosis is still a shadow over the broad use of the interventional techniques. The introduction of the drug-eluting stent has recently offered a light at the end of the tunnel. As we stand on the verge of a "cure" for restenosis, it is interesting to ask, "Why has it taken so long?"

Since the late 1970s, enormous efforts and resources have been directed to the problem of restenosis. Our understanding of restenosis evolved slowly, but major components in the evolution of the restenosis process have been identified, and in the early 1990s several pivotal studies distinguished basic restenosis mechanisms such as early recoil, negative remodeling, and proliferative response to injury.[4,5] Other landmark studies established the concept that the extent of luminal "late loss" at follow up is proportional to the amount of "acute gain" achieved during the initial procedure.[6] Although this strategy provided incremental reduction in restenosis under the philosophy of "bigger is better", the scientific community soon realized that restenosis could not be eliminated using only mechanical devices like bare stents. Thus, the fertile soil for the development of drug-eluting stents was created. This also required the development of predictable animal models to allow precise, quantitative documentation of the *in vivo* response to injury.[7] The initial stent coatings, however, were dismal failures.[8] Only recently, biocompatible materials have been developed that maintain adequate patency in the animal model. Another problem was applying coating to stent struts and then sterilizing the combination without altering the properties of the coating or the drug.

With these aspects kept in mind, this chapter will review four aspects of the restenosis problem. First, it will highlight the mechanisms of restenosis, including neointimal hyperplasia, acute recoil, and vascular remodeling. These, in turn, influence the response of the vessel wall to mechanical injury. Second, the issue of mural thrombus in restenosis will be addressed for both stenting and balloon angioplasty, since blood elements and factors produced by circulating cells play a key role in the initiation and propagation of neointima formation. The importance of antithrombotic agents such as GPIIb/IIIa receptor antagonists in reducing morbidity and mortality after percutaneous transluminal angioplasty (PTCA) and their potential in reducing the restenosis process will be reviewed. Third, emerging concepts in gene therapy and moreover in drug-eluting stents and their clinical trials will be reviewed.

The problem of restenosis

Defining restenosis

Restenosis studies have suffered to various degrees from methodological problems. Since native coronary atherosclerotic and restenotic lesions are both identified and treated with the use of angiography, one would hope that a uniform angiographic definition of restenosis exists. Unfortunately, such definitions are currently lacking, representing a major limitation in comparing different studies.

The numerous angiographic definitions used in clinical studies,[9] and more recently, definitions based on absolute changes in minimal lumen diameter at follow up,[10] have led to confusion and hampered investigations in this field[11] (Box 29.1).

Box 29.1 Angiographic definitions of restenosis

- An increase of ≥30% from immediate postangioplasty diameter stenosis to follow up stenosis
- An initial diameter stenosis <50% after angioplasty, increasing to ≥70% at follow up angiography
- An increase in diameter stenosis at follow up angiography to within 10% of the preangioplasty value
- A loss of >50% of the initial diameter stenosis gain achieved by angioplasty, from immediate postangioplasty to follow up angiography
- A postangioplasty diameter stenosis <50% increasing to >50% at follow up angiography
- A decrease in the minimal lumen diameter at the lesion of >0·72 mm from immediate postangioplasty to follow up angiography
- Cumulative distribution of MLD

Using clinical criteria, restenosis may be defined by evidence of recurrent myocardial ischemia after the revascularization procedure discovered during clinical tests by the presence of symptoms (that is, recurrence of angina, need for target vascular revascularization). Difficulties occur with a discordance between angiography and clinical status. A patient with a lesion fitting the angiographic criteria for restenosis but who is asymptomatic and/or has negative tests for ischemia will likely not be recatheterized on the basis of clinical criteria alone.

Moreover, restenosis has been previously characterized as an "all or none" phenomenon and, by subsequent studies, as a continuous variable that takes place to a different extent in all treated lesions.[12] Many studies have been small, and the timing and methods of follow up have been variable,[1,13] introducing the selection biases and misleading interpretations of the data.

It is clear that a more uniform definition, that includes a combination of angiographic and clinical criteria, and studies with more uniform groups of patients, may provide a more accurate picture of the restenosis phenomenon.[14]

Predicting restenosis

While many clinical studies have been performed to identify correlates of restenosis,[1,13,15–19] the ability to predict an excessive healing response after percutaneous interventions has remained particularly difficult.[20]

Three different categories of variables are related to an increased risk of restenosis. These include clinical patient-related factors, anatomic-related factors, and interventional procedure-related factors. Patient-related variables include older age, male gender, diabetes, hypertension, hyperlipidemia, unstable angina prior to angioplasty, vasospastic angina, and continued smoking after angioplasty. Anatomical and procedural factors include ostial lesions, longer lesions, total occlusions, multilesion and multivessel angioplasty procedures, saphenous vein graft location, left anterior descending location, presence of calcium, balloon-to-artery ratio, suboptimal results with significant residual stenosis, and extent of dissection.

However, no variables have yet been found that predict restenosis with absolute certainty. Of all the factors, the most consistent in predicting a better long-term outcome appears to be a large postprocedural lumen diameter.[21] This finding has led to the current aphorism "bigger is better",[6] which has been widely applied as a therapeutic strategy of angioplasty and which may explain the improved long-term outcome observed with coronary stents or directional atherectomy.[22,23]

Other factors that are not yet fully evaluated may also predict restenosis. Angioscopic observations suggest that coronary thrombus is an important determinant of the late outcome.[24] Recent clinical studies using the glycoprotein IIb/IIIa receptor antagonist 7E3 have shown in support of the role of thrombus a significative reduction in the incidence of restenosis.[25] Experimental evidences suggest that oxidative stress may be important in the restenotic process, and the results of the MVP study[26] indicate that probucol is effective in reducing restenosis by means of low density lipoprotein oxidation prevention, decreasing platelet aggregation and modulation of prostaglandin and leukotriene synthesis.[27–29]

Studying restenosis

Traditionally, animal models are the cornerstone to test strategies aimed at developing treatments for pathologic conditions and for understanding pathophysiologic mechanisms that may cause that particular condition. In this respect, restenosis is no exception and several animal models have been developed during the past decade in an attempt to reproduce restenotic lesions and find a therapeutical strategy to reduce neointimal formation. Unfortunately, although several models of restenosis have been evaluated in the past 15 years, there is no perfect animal model for human restenosis. Common models include the rat carotid air desiccation or balloon endothelial denudation model,[30,31] the rabbit femoral or iliac artery balloon injury model with or without cholesterol supplementation,[32] and the porcine carotid and coronary artery model.[33]

The rat model, based on elastic arteries, does not develop severe stenotic neointimal lesions, and is therefore very permissive in terms of efficacy of pharmacological interventions. The cholesterol-fed rabbit model has been criticized for the high level of hyperlipidemia required for the

development of lesions. The latter results in a large macrophage foam cell component, resembling fatty streaks rather than human restenotic lesions. Conversely, the histopathologic features of neointima obtained in porcine models closely resemble the human neointima, and the amount of neointimal thickening is proportional to injury severity. This has allowed the creation of an injury–neointima relationship that can be used to evaluate the response to different therapies. However, the repair process in the pig coronary artery injury model using normal coronary arteries is certainly more rapid and may be different from the response to balloon angioplasty that characterizes human coronary atherosclerotic plaques.

The major limitation in the use of animal models of restenosis is that agents effective in reducing neointima in those models are ineffective when transferred into the clinical arena. Many explanations might support those differences. Different animal species, types of artery, degree of arterial injury, volume of neointima, drug dosages and timing regimens, and atherosclerotic substrate might be considered.

To address this concern, we believe that before transferring the results obtained in animal models into clinical trials, standardization of injury type, the method of measurement, and the dose and timing of drug administration among different animal models is necessary.

Other issues in the study of restenosis are the limitations in the design of restenosis clinical trials. Incomplete angiographic follow up leading to the occurrence of selection and withdrawal biases, followed by inadequate power due to small patient sample leading to the potential of β (type II) errors, are the most common problems. Non-uniform definitions of angiographic restenosis and poor correlation between angiographic and clinical outcome are other problems that need to be resolved when comparing different trial results. Future restenosis studies should utilize composite clinical outcomes as primary end points, with multiple, simultaneous treatment approaches and careful choice of the appropriate regimen. These studies should also include an angiographic or IVUS subset to allow assessment of mechanisms of action, and using these data can help limit sample size necessary to detect efficacy at reducing neointima.

Understanding restenosis

To better understand the mechanisms of restenosis, it is useful briefly to review the potential mechanisms by which coronary interventional procedures increase lumen patency. Since the explanation given by Dotter and Judkins,[34] who ascribed the enlargement of vessel lumen by balloon angioplasty to compression of atheromatous plaque against the arterial wall, several morphologic and histologic observations have been made both in human necropsy studies[35–37] and experimental models.[38] Different mechanisms of action have been identified. The original concept of plaque compression is unlikely to occur because the majority of atherosclerotic plaques are composed of dense fibrocollagenous tissue with hard calcium deposits, and thus, are difficult to compress. However, this mechanism can play a major role in the dilation of newly formed atherosclerotic plaque – that is, soft plaques – or recently formed thrombus.

Subsequent data suggest that the major mechanisms of action of coronary angioplasty are breaking, cracking, and splitting of the intimal plaque with partial disruption of the media and stretching of the plaque-free vessel wall.[39–41] In particular, intravascular ultrasound studies have shown that those mechanisms may vary depending on the histologic plaque composition, with more plaque dissection in calcified lesions and more vessel expansion in non-calcified plaques.[42]

Conversely, directional and rotational coronary atherectomy improve lumen caliber by tissue removal, with little disruption and expansion of the vessel wall. Finally, the mechanism of laser angioplasty is related to atherosclerotic tissue photoablation and dissection associated with vessel expansion.

Based on these clinical and experimental observations, the presumed healing and repair processes leading to arterial restenosis may be categorized as follow: (a) exaggerated cell proliferation at the site of injury; (b) incomplete plaque dissection by balloon angioplasty or incomplete tissue removal by directional coronary atherectomy (DCA), rotational atherectomy, and laser angioplasty; (c) thrombus formation and organization at the site of injury; (d) favorable or unfavorable artery wall remodeling.

Pathobiologic events in restenosis: from growth regulatory factors to cell cycle genes

It has been more than a decade since Essed *et al* first documented intimal proliferation after PTCA as a cause of restenosis.[43] During this interval, enormous progress has been made in defining the pathogenetic mechanisms of human restenotic lesions. At the same time, molecular techniques coupled with increasing understanding of the regulatory events at the level of nucleic acids have been applied to investigation of the restenotic process. Today, there is a general consensus that restenosis involves the interactions of cytokines, growth factors, vascular elements, blood cells, and the extent of injury.

Based on the experiences derived from experimental models, cell culture, human pathologic evidence as well as angiographic, angioscopic, and intravascular ultrasound observations, the sequence of events that take place in the artery and that characterize the restenotic process can be divided into three phases (Figures 29.1 and 29.2). **Grade A**

1. A first phase of elastic recoil, usually occurring within 24 hours of the procedure.

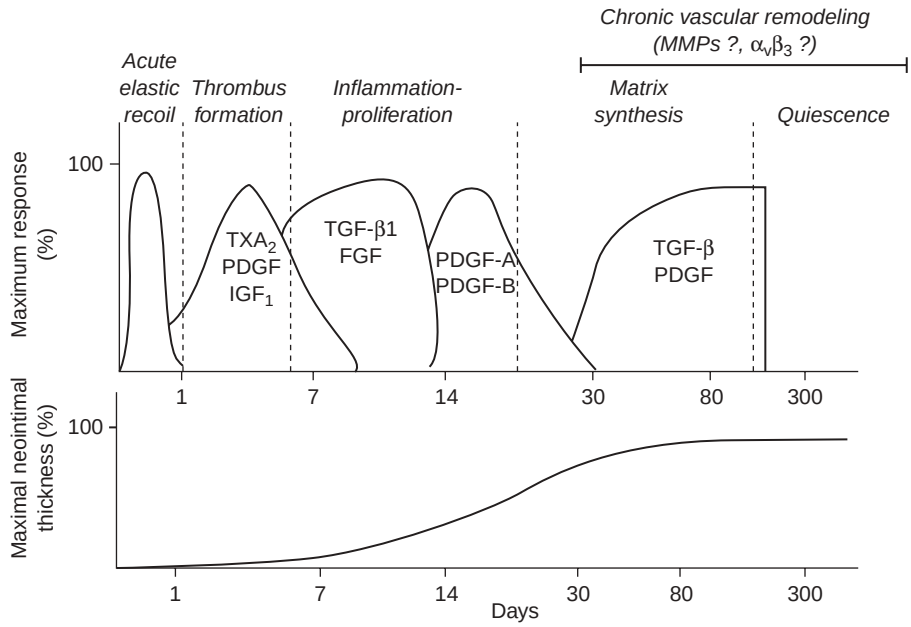

Figure 29.1 Different phases of the restenotic process. The lower panel indicates the increase in neointimal thickening and the upper panel the associated expression of growth factors (for abbreviations see text).

2. A second phase of mural thrombus formation and organization associated with inflammatory infiltrate at the site of vascular injury in the subsequent 2 weeks. In this phase, immediately after stent implantation, activation, adhesion, aggregation, and deposition of platelets and neutrophils occurs. The platelet thrombus formed can even become large enough to occlude the vessel. Within hours the thrombus at the injured site becomes fibrin-rich and also fibrin/red cell thrombus adheres to the platelet mass. From day 3 the thrombus is covered by a layer of endothelial-like cells and intense cellular infiltration begins at the injury site with monocytes (which become macrophages after migration into the mural thrombus) and lymphocytes. In the process these cells progressively migrate deeper into the mural thrombus and vessel wall.
3. A third phase of cell activation, proliferation, and extracellular matrix formation, which usually lasts from 2 to 3 months. In this phase, smooth muscle cells from different vessel wall layers proliferate and migrate and thereafter resorb the residual thrombus until all of it is gone and replaced by neointimal cells. For several weeks proliferative activity can be detected in the endothelial layer, the intimal layer, the medial layer, and in the adventitia. Thereafter a more or less quiescent fourth state will ensue, characterized by further buildup of extracellular matrix.[33,44]

Therefore, several factors may influence the production of excessive neointimal volume, including the amount of platelet–fibrin thrombus at the injury site, the total number of smooth muscle cells (SMC) within the neointima, and the amount of extracellular matrix elaborated by neointimal cells. Limiting one of those steps, either individually or in combination, might perhaps reduce the neointimal response following mechanical injury (Table 29.1).

Phase I: elastic recoil

The vessel wall itself can participate in acute lumen loss observed in some patients just after coronary interventions by a mechanism termed "recoil". Elastic recoil occurs within minutes to hours following balloon angioplasty and seems to be the consequence of the "spring-like" properties of the non-diseased vascular wall responding to its overstretching.[45–47] Other possible explanations are vasoconstriction due to vessel endothelial disruption[48] or platelet activation and thrombus formation with consequent release of vasoconstrictive substances.[49,50] Whenever the normal wall is significantly stretched, recoil may be the predominant mechanism of restenosis. Different studies, indeed, have shown that this very early vessel wall recoil increases the likelihood of subsequent restenosis with a rate of 73·6% for the lesions that had lumen loss >10% and only 9·8% for lesions that diminished by <10%.[51,52] Early recoil may possibly have a significant importance in restenosis when the vessel has not been severely injured and the lesion consists of SMC. When the vessel wall injury is more severe, thrombus formation with consequent activation of growth factors

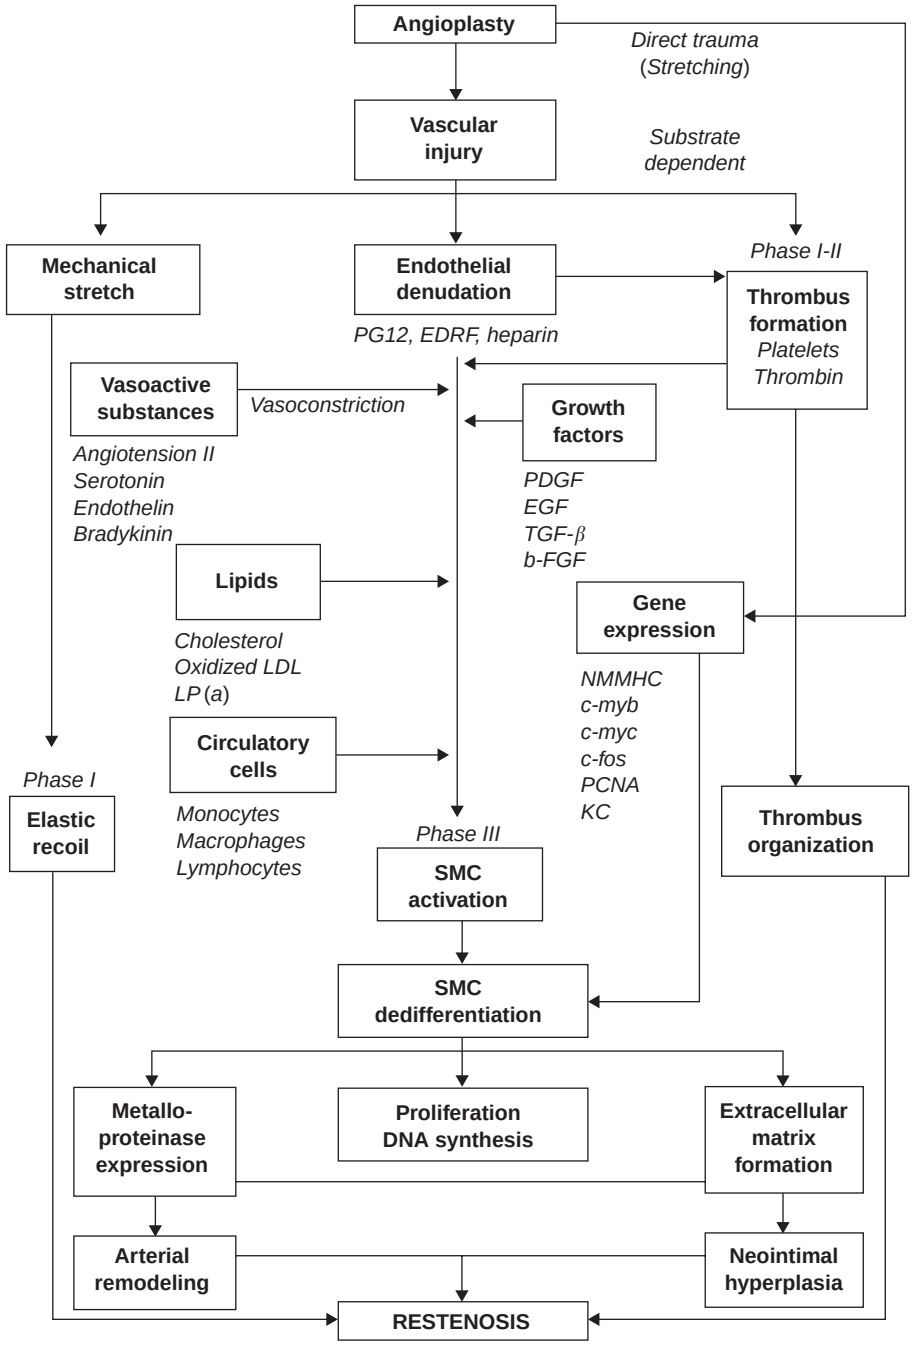

Figure 29.2 Sequence of events resulting in restenosis after vessel injury (for abbreviations see text)

and release of cytokines may be, instead, the predominant mechanism of restenosis.

Prevention of phase I: mechanical *v* pharmacologic approaches

It is clear that the utilization of methods to minimize the angioplasty injury, reduce the elastic recoil and enlarge the lumen size should result in a lower incidence of restenosis.

Balloon angioplasty allows manipulation of only few parameters that cause injury or recoil. Several studies have evaluated the number of balloon inflations,[53,54] duration of inflation,[53,55–57] inflation pressure,[58–60] and balloon–artery ratio.[54,59,61,62] Although higher inflation pressures and larger balloon size have been related to a small decrease in restenosis rate, they also cause a substantial increase in acute complications such as rate of emergency surgery and myocardial infarction.[59,63]

Table 29.1 Potential therapeutic approaches for the treatment of the different phases of the restenotic process

Response to vessel injury	Potential therapy
Early elastic recoil	Achievement of greater MLD by stents
Thrombus formation	Antithrombotic agents Antiplatelet agents Rapid re-endothelization Molecular therapies
Inflammation	Coated/drug-eluting stents
Neointimal proliferation	
SMC activation	Molecular therapies, coated/drug-eluting stents
SMC migration	Rapid re-endothelization, MMP inhibitors, coated/drug-eluting stents
SMC proliferation	Antiproliferative agents, brachytherapy, rapid re-endothelization, molecular therapies, coated/drug-eluting stents
ECM formation	Antiproliferative agents, rapid re-endothelization, molecular therapies, coated/drug-eluting stents
Chronic vascular remodeling	Stents

Abbreviations: ECM, extracellular matrix; MLD, minimal lumen diameter; MMP, metalloproteinase; SMC, smooth muscle cells

Coronary stents, by means of their rigid structure, significantly decrease acute recoil. One of the most important advantages of intracoronary stents is that those devices represent the "bigger is better" approach. Stents address restenosis from the direction of greater luminal gain and a decrease in the elastic recoil. By this radial support, the technique results in increased residual lumen and expansion of the artery at the long-term follow up.[6,64] Furthermore, coronary stents limit the exposure of deep vessel wall tissue to blood elements, diminishing the activation of unfavorable rheological factors and allowing a higher anterograde flow through a smooth contoured lumen.

Randomized studies such as the Stent in Restenosis Study (STRESS)[65] and the European Belgian–Netherlands Stent trial (BENESTENT)[22] have both shown a significant decrease in restenosis in the groups with stent placement compared with conventional balloon angioplasty.[22,66] **Grade A** The STRESS investigators reported a 10% decrease in restenosis rate with Palmaz–Schatz stent compared with balloon angioplasty (32% *v* 42% respectively), and the BENESTENT trial also demonstrated a 10% decrease in restenosis (22% in the stent group *v* 32% in the PTCA group), with better event-free survival and fewer revascularization procedures at 8 month follow up. Stenting technique has continued to evolve and other trials have compared conventional balloon angioplasty with contemporary stenting techniques – high pressure deployment,[67] IVUS,[68] reduced anticoagulation,[68] ostial placement,[69] – always demonstrating a reduction of restenosis rate in patients receiving coronary stents. **Grade B** The pilot phase of a new study, the BENESTENT-II trial, has shown that the rate of restenosis was impressively reduced to less than 13% when heparin coated stents were placed with high pressure delivery.[70] These results were confirmed by the BENESTENT-II trial,[71] which demonstrated that use of a heparin coated stents plus antiplatelet therapy resulted in better event-free survival at 6 months compared to standard balloon angioplasty. However, with respect to an antiproliferative effect of heparin, data of preclinical studies as well as from the BENESTENT-II trial suggest no reduction of neointimal hyperplasia within the stent in comparison to uncoated stents.[71–74] **Grade A**

Other devices, such as directional atherectomy, rotational atherectomy, and TEC atherectomy, improve lumen patency by tissue removal and are associated with less vessel wall recoil and dissection.[75,76] The CAVEAT-I and the C-CAT trials did not show a significative advantage of atherectomy over conventional balloon angioplasty.[77–79] This was a surprising finding since experimental and clinical studies have shown that a larger final lumen correlates with lower restenosis rates. However, it is important to note that in those trials the final lumen achieved with atherectomy did not differ compared with that obtained by balloon angioplasty. Indeed, a prospective multicenter registry of 199 patients treated by optimal DCA (<15% residual stenosis), the OARS study,[80] demonstrated a 6 month restenosis rate of 28·9% with a target lesion revascularization rate of 17·8% at 1 year follow up. These results have been recently confirmed by the Balloon versus Optimal Atherectomy Trial (BOAT),[81] which randomized 1000 patients with single *de novo*, native vessel lesions to DCA (<20% short-term post-treatment residual stenosis) or PTCA and demonstrated that optimal DCA provided lower angiographic restenosis than conventional PTCA (31·4% *v* 39·8%, respectively) at 6 month follow up. **Grade B** Other debulking modalities, such as aggressive rotational atherectomy utilized in the STRATAS study, demonstrated a trend toward increasing late loss index, restenosis, and target revascularization.[82]

Phase II: platelet aggregation/thrombus formation and inflammation

As an integral part of the dilation mechanism, coronary angioplasty results in injury to the arterial wall, including

endothelial damage with loss of antithrombotic properties (EDRF, PGI2, t-PA), induction of procoagulant factors (thrombin, tissue factor) and inflammatory infiltrate at the site of vascular injury. In addition, rupture of the internal elastic lamina and medial disruption, with exposure of the blood elements to wall constituents like collagen, von Willebrand factor, and extracellular matrix components, stimulates the interaction with platelet surface receptors (primarily glycoprotein Ib and IIb/IIIa integrins), resulting within minutes to hours after the intervention in platelet activation and deep mural thrombus formation[83–86] inaccessible to the action of heparin.[87,88] Experimental and clinical studies have also shown that platelets are activated by contrast medium.[89,90] Activated platelets secrete several substances from their α granules that stimulate vasoconstriction, chemotaxis, and activation of neighboring platelets.[91,92] In addition, platelet aggregation releases or stimulates the production of several factors and cytokines including thrombin, tromboxane A2, serotonin, plasminogen activator inhibitor (PAI-1), platelet derived growth factor (PDGF), transforming growth factor-β (TGF-β), basic fibroblast growth factor (b-FGF), epidermal growth factor (EGF), insulin-like growth factor (IGF-1), interleukin-1, and monocyte chemoattractant protein-1 (MCP-1) (Box 29.2).[93–95] These factors are believed to be responsible for neointimal growth by attracting and stimulating SMC migration and proliferation at the site of injury. (Figure 29.3).[96–99] The severity of the thrombogenic response depends on the degree of vascular injury, the surface area of exposure, the type of substrate exposed in the underlying vessel wall, and the rheological conditions such as shear stress and time of exposure.

Platelet activation leads to the recruitment of glycoprotein IIb/IIIa integrin surface receptors, which mediate platelet aggregation and thrombus formation by binding fibrinogen molecules between adjacent receptors.[93,100,101] Aggregated platelets accelerate the conversion of prothrombin to thrombin, which in turn stimulates further platelet activation.[102] Thrombin is involved in both thrombus formation, upregulation of E-selectin and P-selectin expression on endothelial cells, monocyte and neutrophil migration in the injured wall,[103] and stimulation of endothelin and tissue factor release from endothelial cells with a mitotic effect on SMC.[104] Of interest, there is also evidence that monocyte-macrophage recruitment may contribute to thrombus myofibrotic organization.[105] Genes for the PDGF ligands and receptor components are expressed in normal and injured rat carotid arteries.[106] Basic FGF and FGF receptor Type 1 are both expressed by endothelial cells and SMC after mechanical injury and inhibition of this growth factor reduces neointimal formation.[94,107,108] TGF-β seems to be the principal growth factor involved in the regulation and synthesis of proteoglycans, the major components of the extracellular matrix.[109–111] TGF-β induces both migration and proliferation of vascular cells and recent evidences suggest that this is an important factor in the vascular remodeling process associated with restenosis.[112,113]

Box 29.2 Extracellular factors involved in restenosis

- Angiotensin-II
- Collagen
- Collagenase
- Colony stimulating factors (CSFs)
- Elastic fibers
- Endothelins (ETs)
- Epidermal growth factor/transforming growth factor α (EGF/TGF-α)
- Fibroblast growth factors, acidic and basic (a-FGF, b-FGF)
- Heparin
- Heparin-binding epidermal growth factor (HB-EGF)
- Insulin-like growth factor 1 (IGF-1)
- Interferon γ (IFN-γ)
- Interleukin-1 (IL-1)
- Low density lipoprotein, oxidized (oxLDL)
- Monocyte-macrophage colony stimulating factor (M-CSF)
- Monocyte chemotactic protein 1 (MCP-1/MCAF-1)
- Nitric oxide/endothelium-derived relaxing factor (NO/EDRF)
- Plasmin
- Plasminogen activator inhibitor (PAI-1)
- Platelet derived growth factor A (endothelium, PDGF-AA)
- Platelet derived growth factor B (smooth muscle cells, PDGF-BB)
- Prostacyclin (PGI_2)
- Prostaglandin E

- Thrombin
- Thromboxane A_2 (TXA_2)
- Tissue plasminogen activator (tPA)
- Transforming growth factor β (TGF-β)
- Tumor necrosis factor α (TNF-α)

Following platelet activation, circulating inflammatory cells adhere to the site of injury and migrate into the thrombus. Neutrophils, lymphocytes, and monocytes have been observed within the mural thrombus 1–5 days following angioplasty in an atherosclerotic rabbit model,[114] and presence of leukocytes and macrophages has been demonstrated by scanning electron microscopy adherent to the luminal surface of stented arteries in different animal models.[115,116] Stent deployment can also cause a foreign body reaction due to deeper arterial injury compared to balloon angioplasty.[117] Karas *et al* found reactive inflammatory infiltrates and multinucleated giant cells surrounding the stent wires at 4 week follow up in a porcine model of coronary injury.[118] Recently, the present authors demonstrated in a large

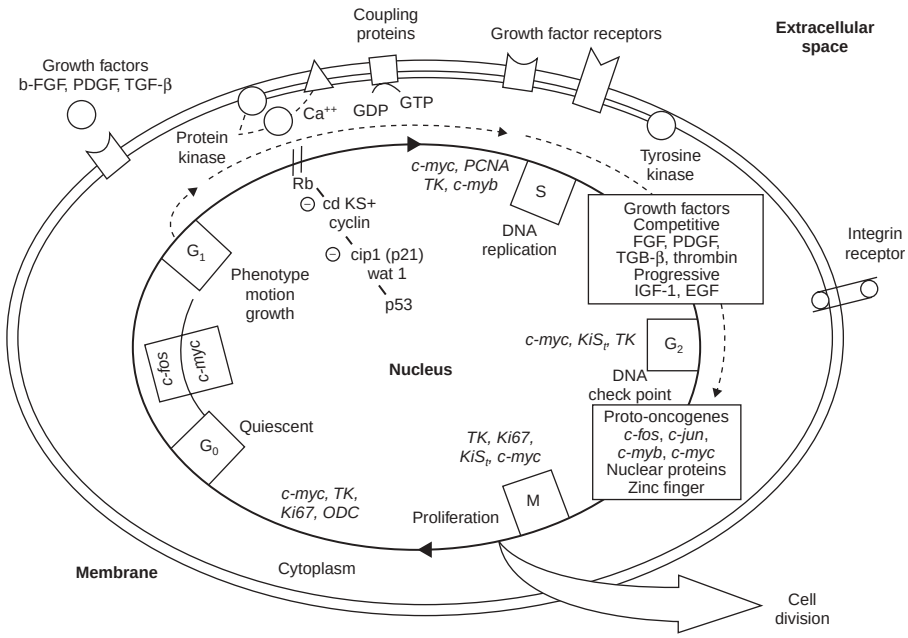

Figure 29.3 Cytoplasmatic and nuclear control points for SMC division and proliferation: CDKS, cyclin-dependent kinases; ODC, ornithine decarboxylase gene; Rb, retinoblastoma protein; TK, tyrosine kinase (for other abbreviations see text)

autopsy series that acute inflammation (mainly composed by neutrophils) linked to the extent and location of vessel injury and that chronic inflammation (lymphocytes and macrophages) was frequently observed around metallic struts at different time points following stent placement in humans.[119] Furthermore, it has been demonstrated that the extent of inflammatory reaction is significantly correlated, both independently and in combination with the degree of arterial injury, with the amount of neointimal formation.[120] The inflammatory response after stent deployment is also related to the material, design, and surface of the stent.[8,121–124]

In summary, the extent of vessel wall injury, amount of thrombus formation, and likelihood of neointimal proliferation are interrelated. Although the relationship of thrombus formation to restenosis remains to be elucidated, evidence suggests that thrombus contributes directly to restenosis by vessel occlusion[125] and indirectly by mediating the release of several factors, which in turn are also involved in the third phase of the restenotic process.[126]

Prevention of phase II: the role of new antithrombotic drugs

Since platelet function and consequent thrombus formation are important in the vascular response to injury, they have been logical targets of several therapeutic strategies. In addition to existing antithrombotic and anticoagulant drugs (that is, heparin and aspirin), antiplatelet therapies to prevent restenosis have been recently boosted by the development of newer agents that specifically inhibit critical steps in the coagulation cascade and proteins on the surface of platelets. These new drugs include inhibitors of thrombin generators (factor Xa inhibitors),[127,128] thrombin action (direct thrombin inhibitors),[129] or platelet aggregation (Gp IIb/IIIa receptor antagonists).[130]

Although aspirin,[131] dypiridamole,[132] ticlopidine,[133] warfarin,[134–136] thromboxane antagonists,[137–139] and prostacyclin analogs,[140,141] have been shown to be effective in animal models of restenosis, these drugs have failed to show any benefit in clinical practice. **Grade B** However, several factors may confound the interpretation of those studies. For example, differences in the lesion substrate, inappropriate drug doses, or incomplete block of the target, may explain the discrepancy between animal models and human studies. Moreover, while the magnitude of injury and thrombus formation correlate with the degree of neointimal formation in animals, the relationship in humans is by no means established. In addition, specific anticoagulant agents such as heparin,[142–145] low molecular weight heparin,[146,147] hirudin and hirulog,[148–151] did not show any favorable effect either on angiographic or clinical outcome related to restenosis. Recently, dietary fish oils have been demonstrated to inhibit platelet aggregation and thromboxane synthesis.[152] It has also been shown that fish oil intake reduces blood and red cell viscosity and reduces the inflammatory response to injury.[153,154] However, the two largest trials designed to test the hypothesis that restenosis could be reduced by fish oil intake have definitively demonstrated the lack of efficiency of these agents in the clinical arena.[155,156] **Grade A**

Both animal models of restenosis and clinical trials demonstrated a reduction of neointimal proliferation by blocking the platelet Gp IIb/IIIa ($\alpha_{IIb}\beta_3$) or the vitronectin receptors ($\alpha_v\beta_3$).[25,157–160] By using a chimeric 7E3 antibody directed against the platelet membrane IIb/IIIa receptor complex, the EPIC trial demonstrated a reduction in the onset of acute complications and clinical restenosis in high-risk angioplasty.[25] Since this trial was published, other studies have evaluated the effect at 6 month follow up of IIb/IIIa antagonists versus placebo. Unfortunately, IMPACT[161], IMPACT-II[160], RESTORE[162], EPILOG, and CAPTURE trials,[163,164] that studied the efficacy of integrilin, tirofiban, and abciximab, respectively, did not demonstrate a reduction in target vessel revascularization compared to placebo treatment. The EPISTENT trial demonstrated lower need for repeat target vessel revascularization among diabetic patients receiving abciximab compared to placebo,[165,166] as previously noted at 6 months.[167] **Grade A**

Aggarwal *et al* reported results of platelet Gp IIb/IIIa antibody eluting from cellulose polymer coated stents, implanted in iliac arteries of rabbits after balloon injury. There was a significant improvement in patency rates after both 2 hours and 28 days, but no difference in mean neointimal thickness at 28 days.[168] **Grade C** A clinical trial has been planned (UK RESOLVE trial), but thus far clinical results have not been reported. Alt *et al* coated a Palmaz-Schatz stent with a 10 μm layer of biocompatible and biodegradable high molecular weight poly-l-lactic acid and incorporated in this coating recombinant polyethylene glycol (r-PEG)-hirudin and the prostacyclin analog iloprost. Both drugs have antithrombotic and potentially antiproliferative effects. Stents were implanted in the non-overstretch model in sheep and in the overstretch pig model and compared to non-coated controls. At 28 days a greater luminal diameter was seen with a significant reduction of mean restenosis area of 22·9% in the sheep and 24·8% in the pig model, independently of the extent of vascular injury.[169] **Grade C**

Prevention of phase II: the role of anti-inflammatory approaches

The inflammatory reaction in restenosis relates to neointimal formation and arterial remodeling. Therefore, inhibition of the inflammatory response after vascular injury may have some beneficial effects on restenosis.

P-selectin, a protein stored in the α granules of platelets and Weibel–Palades bodies of endothelial cells, and binding to circulating monocytes and leukocytes, plays a crucial role in the early inflammatory response. Manka *et al* reported that apolipoprotein E-deficient mice with targeted disruption of the P-selectin gene exhibited dramatically decreased monocyte infiltration into the arterial wall and significantly decreased neointimal formation in a carotid artery injury model.[170] Mac-1 (CD11b/CD18, $\alpha_M\beta_2$), a leukocyte integrin, promotes adhesion and transmigration of leukocytes and monocytes at the site of vascular injury. Upregulation of Mac-1 in patients is associated with increased restenosis.[171,172] M1/70, a CD11b blocking Mab, was shown to inhibit neutrophil infiltration and medial SMC proliferation in a balloon denudation model.[173] Administration of recombinant human interleukin-10 (rhuIL-10), an anti-inflammatory cytokine, inhibited monocytes and macrophage infiltration in hypercholesterolemic rabbits, which was associated in turn with dramatic reduction in neointimal hyperplasia.[174] In addition, due to a broad range of anti-inflammatory and immunosuppressive activities, dexamethasone stent coating has been shown to reduce neointima hyperplasia compared to uncoated stents in canine femoral arteries.[175] Tranilast, a novel anti-inflammatory agent, has been shown to interfere with the PDGF-induced proliferation and migration of SMCs. This drug has been evaluated in the largest interventional anti-restenosis trial conducted to date, the Prevention of Restenosis with Tranilast and Its Outcome (PRESTO) trial,[176] which enrolled more than 11 500 patients after successful percutaneous coronary intervention. Unfortunately, this trial provided unequivocal evidence that this compound has no effect on both restenosis and clinical events. **Grade A/C**

Phase III: smooth muscle cell activation and synthesis of extracellular matrix

This final phase of vascular healing is predominantly characterized by neointimal formation due to SMC proliferation and extracellular matrix accumulation produced by the neointimal cells at the injury site.[45,177–180] The healing response is a normal process which is essential in maintaining vascular integrity after an injury to the vessel wall, but varies in the degree to which it occurs. One pathogenetic explanation of restenosis is, indeed, an exaggeration of this healing response.

Phase III could be further divided into three different waves.[44] In the *first wave* (days 1–4 after vessel injury), medial SMC from the site of injury and possibly from adjacent areas are activated and stimulated by the triggering factors mentioned earlier. In addition to mitogenic factors released by endothelial cells, stretching of the arterial wall is a potent stimulus for SMC activation and growth.[181] Once activated, SMC undergo characteristic phenotypic transformation, from a "contractile" to a "synthetic" form,[178] which is responsible for the production of extracellular matrix rich in chondroitin sulfate and dermatan sulfate seen in the first 6 months after injury. The *second wave* (3–14 days after vessel injury) and the *third wave* (14 days to months after vessel injury) are respectively characterized by the migration of SMC through breaks in the internal elastic lamina into the intima, the local thrombus,[182] and

SMC proliferation followed by extracellular matrix formation.[126,183–186] Those events are characterized by complex interactions between growth factors, second messengers, and gene regulatory proteins resulting in phenotypic change from a quiescent state to a proliferative one.[96] The peak of proliferation is observed 4–5 days after balloon injury but the duration of migration is not known, nor is it known whether a phase of cellular replication is required before SMC migration. Few studies have been done to identify the matrix molecules involved in the migration into the intima. Osteopontin is expressed in sites of marked remodeling,[187] and antibodies to osteopontin inhibit SMC migration into the intima after balloon angioplasty.[188] Proteoglycans may also be important for the formation of neointima. CD44, a receptor for hyaluronic acid, seems to play a role in the migration of cells into fibrin or osteopontin.[189,190] SMC migration presumably requires degradation of the basement membrane surrounding the cells. Several metalloproteinases, including tissue type plasminogen activator, plasmin, MMP-2, and MMP-9, may be responsible for this process,[191,192] and the administration of a protease inhibitor reduces SMC migration into the intima.[193] Cell migration is probably initiated by recognition of extracellular matrix proteins by a family of cell surface adhesion receptors known as integrins.[194,195] *In vitro* and *in vivo* studies have demonstrated that the selective blockage of the $\alpha_v\beta_3$ integrin inhibits SMC migration and reduces neointimal formation.[158,196]

Experimental studies have suggested that endothelin-1 (ET-1) and endothelin receptors may also be indirectly implicated in the SMC migration and matrix synthesis.[197–199] Immunohistochemical studies demonstrate a time-dependent increase in endothelin immunoreactivity after balloon angioplasty in the rat model.[200] The administration of endothelin receptor antagonists in different animal models of balloon injury has been shown to be effective in reducing neointimal formation.[197,201,202]

Several *in vitro* studies have suggested that different growth factors, such as PDGF-AA, PDGF-BB, β-FGF, IGF, EGF, FGF, TGF-β, and angiotensin II, may also play a major role in this process.[96,185,203–207] Control of SMC proliferation is regulated by the actions of mitogens (that is, PDGF) and the opposing effect of inhibitors (that is, TGF-β). The growth factors bind to cell surface receptors and initiate a cascade of events which leads to cell migration and division. Components of the cascade include different tyrosine kinases, coupling proteins, and membrane-associated and cytoplasmic protein kinases (see Figure 29.3). On stimulation by growth factors, proto-oncogenes are transiently activated and together with other cell cycle-dependent proteins such as zinc finger proteins, mediate the effects within the nucleus. Several studies have demonstrated that stimulation of SMC *in vitro* is associated with an increase of the proto-oncogenes *c-myc*, *c-myb*, and *c-fos*.[208–210] The ornithine decarboxylase (ODC) gene and the thymidine kinase (TK) messenger RNA are both expressed in stimulating cells and in continuously cycling cells.[210] SMC proliferation may also result from a reduction in an inhibitory factor which normally prevents cell division. Proteins such as p21 are inhibitors of the cyclin-dependent kinases (cdks) which regulate the entry of the cell in the cycle (see Figure 29.3). Stimulation of these proteins, indeed, inhibits SMC proliferation and neointima formation after balloon injury.[211]

As smooth muscle cells decrease their proliferation rate, they begin to synthesize large quantities of proteoglycan matrix. The extracellular matrix production continues for up to 20–25 weeks and over time it is gradually replaced by collagen and elastin, while the SMC turn into quiescent mesenchymal cells. The resulting neointima is composed of a fibrotic extracellular matrix with few cellular constituents. The endothelial cells proliferate and cover the denuded area resulting in a re-endothelization process, and the new endothelium begins to produce large quantities of heparan sulfate and nitric oxide, both of which inhibit SMC proliferation.[86] However, whether SMC proliferation and extracellular matrix production cease after re-endothelization is still unknown at this time.

Prevention of phase III: the past and the future

Multiple experimental and clinical trials[212,213] have been carried out specifically to target what seemed the key in the restenosis process: smooth muscle cell proliferation. To date, with only few exceptions, no pharmacologic or mechanical agent has been conclusively shown to reduce restenosis.

Antiproliferative approaches

The aim of an antiproliferative approach to restenosis is to control and modulate the action of possible mediators of proliferation at any point in the biologic pathway in which they are involved or to enable the cell to respond appropriately to the proliferative stimulus. Two different strategies to inhibit neointima hyperplasia are available:

1. the cytostatic approach, by which regulation and expression of cell cycle modulating proteins at any level along the pathway is performed;
2. the cytotoxic approach, by which proliferating cells are killed and eliminated.

The latter approach has the disadvantage of necrosis induction, associated with inflammation, which may contribute to vessel wall weakening. Hence, the cytostatic approach is conceptually more attractive.

Several antiproliferative agents targeting SMC migration and proliferation have been evaluated, including glucocorticoids, colchicine, somatostatin, hypolipidemic drugs, antineoplastic agents, and angiotensin-converting enzyme (ACE) inhibitors. Both natural and synthetic corticosteroids are potent inhibitors of SMC proliferation, leukocyte migration, and degranulation, PDGF and macrophage derived growth factor release, and matrix production.[214] While experimental and preclinical studies[215–217] have reduced SMC proliferation with the use of local glucocorticoids delivery, three different human trials using oral steroid dosage have failed to shown any reduction in restenosis rate.[131,218,219] **Grade A**

Contradictory results have been obtained as well with antineoplastic agents such as methotrexate, cytarabine, azathioprine, etoposide, vincristine, taxol, and doxorubicin. While some *in vitro* and *in vivo* studies show an attenuation of vascular SMC proliferation,[220,221] other studies show no efficacy in reducing the incidence of restenosis after PTCA.[222–224] Colchicine, which has an antimitotic and anti-inflammatory action in addition to an inhibitory effect on platelet aggregation and release of secretory products, has been shown to reduce restenosis in animals.[225] However, no clinical benefit has been seen with colchicine in two randomized placebo-controlled clinical trials.[226,227] **Grade A** As with other chemotherapeutic agents, the narrow therapeutic index of these drugs may be of concern. However, the recent availability of new local delivery systems (Box 29.3), such as drug eluting stents, has increased interest in the antiproliferative approach and has led to the evaluation of a multitude of compounds with antiproliferative properties. Furthermore, local therapy offers the combined advantages of high local concentrations at the injury site and diminished systemic levels, with decreased risk of adverse effects. The problem of systemic toxicity may be overcome.[228–233]

Box 29.3 Local drug delivery systems

- Double balloon system
- Iontophoretic porous balloon
- Balloon with hydrophilic polyacrylic polymer (hydrogel)
- Channel catheter
- Transport porous catheter
- Dispatch catheter
- Rheolytic system
- Ultrasonic energy and radiofrequency
- Balloon over a stent
- Biodegradable drug eluting polymer stent
- Dacron stent
- Silicone stent
- High molecular weight poly-l-lactic acid stent
- Nitinol stent with polyurethane coating
- Fibrin coated stent
- Stent with cell layer
- Stent with radioactive substance

After verification of an inhibitory effect on neointimal hyperplasia in animal models,[234–236] ACE inhibitors have been extensively studied to assess the clinical effect on restenosis. Unfortunately, two large clinical studies (MERCATOR and MARCATOR), with over 2129 patients enrolled, failed to show any impact on clinical or angiographic restenosis.[237,238] **Grade A** Intensive treatment with cholesterol lowering agents such as the HMG-CoA (3-hydroxy-3methylglutaryl coenzyme A) reductase inhibitors lovastatin, pravastatin, simvastatin, and fluvastatin, reduces intimal hyperplasia in the rat and rabbit models,[224,239,240] probably for serum lipid reduction and decreased platelet aggregation. Despite this promising preliminary data, chronic high-dose lovastatin treatment does not attenuate the incidence of clinical restenosis.[241] Antioxidant agents such as probucol, ascorbic acid and α-tocopherol may be useful in limiting restenosis by reducing platelet aggregation, and modulating prostaglandin and leukotriene synthesis. Both animal[242,243] and clinical[26,244] studies have recently shown a reduction in restenosis with the use of such agents. **Grade B**

Paclitaxel is a cytostatic drug which is extensively used in cancer therapy. It is a micro-tubule stabilizing agent with antiproliferative activity as well as inhibition of migration of smooth muscle cells. *In vitro* studies with cultured human vascular smooth muscle cells (VSMC) and endothelial cells show strong antiproliferative effects on the VSMC.[245] In rabbits an antiproliferative effect was seen at 1 month, which was dose-related. However, in this *in vivo* model more inflammation was seen in the paclitaxel group as well as a poor endothelization.[246] Herdeg *et al* have reported a significant reduction in neointimal stenosis after balloon dilation and subsequent local paclitaxel delivery with a double balloon catheter, compared to balloon dilation alone in rabbit carotid arteries. **Grade C** They observed marked enlargement of vessel size with positive remodeling after paclitaxel treatment (at 7, 28, and 56 days).[247] Phosphorylcholine (PC) coated stent with incorporated angiopeptin has also been tested (Table 29.2). This is a somatostatin analog which is hypothesized to prevent myointimal thickening after vessel injury mainly by inhibiting secretion of growth factors. After balloon injury effective inhibition of intimal hyperplasia has been shown in porcine coronary arteries.[248] In a randomized clinical trial including 553 patients with 742 lesions the incidence of events was significantly reduced in the angiopeptin treatment group, despite no difference in angiographic variables at follow up.[249] **Grade B** De Scheerder *et al* demonstrated the feasibility of loading a polymer coated stent with angiopeptin and significant reduction of neointimal proliferation was found 6 weeks after stenting in porcine coronary arteries.[250] Armstrong *et al* demonstrated in pig coronary arteries using 125-I angiopeptin loaded PC stents that the drug was still detectable in the vessel wall after 28 days.[251] Impressive

Table 29.2 Stent coating and covering categories

Material type	Examples
(In)-organic/ceramic materials	Gold, iridium oxide, silicium carbide, diamond-like carbon, biogold
Synthetic and biologic polymers	PC, PU, PLA, PE, cellulose
Human polymers	Chondroitin sulfate, hyaluronic acid, fibrin, elastin, endothelial cells
Immobilized drugs	Heparin, paclitaxel, abciximab
Eluting, degradable matrices	PLA-hirudin-iloprost, PLA-paclitaxel, PC-angiopeptin, cellulose-abciximab, PU-forskolin, PLA-PC-viral vector, PE-DNA
Covering substances	PTFE, autologous vein

Different materials can be used to cover a stent surface using an array of techniques such as dipping, (plasma) spraying, plating, sputtering, and surface induced mineralization. Some materials have been used as coatings *per se*, while others have been tested as a platform for local drug delivery.
Abbreviations: PC, metacrylyl phosphorylcholine lauryl-methacrylate; PE, polyester; PLA, poly-l-lactic acid; PTFE, polytetrafluoroethylene; PU, polyurethane.

results have been demonstrated in the RAVEL trial[252,253] using rapamycin coated stent (Sirolimus). **Grade A** Rapamycin is a potent immunosuppressive agent that inhibits vascular SMC proliferation by blocking cell cycle progression. Significant reduction of arterial proliferative response after systemic administration of rapamycin was already shown in the porcine coronary model by Gallo *et al.*[254] Finally, other drugs, such as tranilast, a novel inflammatory agent, batimastat, a matrix metalloproteinases inhibitor, and nitric oxide-eluting polymer coated stents are currently under investigation and the clinical results are eagerly awaited. In the case of the Batimast-coated stent, preliminary results are negative.

The concept and technique of applying ionizing radiation to the arterial wall (brachytherapy) during percutaneous coronary intervention procedures has emerged and gained considerable momentum,[255–261] including entry in clinical trials.[262,263] Ionizing radiation affects dividing cells by chromosomal damage in the vascular smooth muscle cells, fibroblasts, and, when present, endothelial cells, resulting in the loss of cells' ability to reproduce, with mitotic cell death.[264] Radiation may also reduce neointima proliferation by increasing the rate of apoptosis within the intima.[265] External beam radiotherapy involves the generation of a beam of radiation from a source external to the patients, for example linear accelerator or ^{60}Co unit. Brachytherapy is a method of delivering radiation to a target organ by placing radioactive sources, for example ^{90}Yt or ^{192}Ir sources, close to or within an organ. This method is well suited (as opposed to external beam radiation) to deliver high doses of radiation to a small defined region. Both γ and β emitters have been utilized in clinical trials of intracoronary radiation therapy.[266–269] However, γ emitters deliver a more uniform dose to the arterial wall than β emitters, but at the cost of increased radiation risk. In addition, radioactive stents, made either by bombardment with subatomic particles, ion implantation of the stents with radioisotopes, or by chemical methods that incorporate the radioactive material into the metallic stents, have been evaluated.[270] Encouraging results from small human clinical studies utilizing both γ and β emitters have set the stage for human clinical trials. The SCRIPPS trial[263] was the first randomized, placebo-controlled clinical trial to evaluate the safety and efficacy of coronary brachytherapy with a γ radiation source (^{192}Ir) in reducing restenosis. At 6 months, the angiographic restenosis rate was 53·6% in the control versus 16·7% in the irradiated group. The clinical benefit was maintained at 2 year follow up with target vessel revascularization of 15·4% as against 44·8% of the placebo group.[271] The GAMMA-1 trial randomized 252 patients with in-stent restenosis to placebo or gamma irradiation. The restenosis rate was 22% in the irradiated arm compared to 51% for the placebo arm.[272]

Several clinical trials (ARREST, Angiorad Radiation for REStenosis trial; ARTISTIC, Angiorad Radiation Therapy for In-Stent Restenosis Intra-Coronary trial; SMART, Smart Artery Radiation Therapy trial; WRIST-SVG, Washington Radiation for In-Stent Restenosis-Saphenous Vein Graft trial) are still ongoing and the results as awaited. BETA CATH, which is the largest multicenter placebo-controlled trial assessing intracoronary β radiation therapy (^{90}Sr/Y source) for restenosis prevention, recently started the enrollment phase. In this trial, clinical end points will be MACE at 8 months, 1 and 2 years follow up. BRIE (Beta Radiation in Europe) is a European trial in 180 patients with encouraging interim results.[270] Finally, European trials on radioactive stents, such as the ^{32}P-Isostent BX^{TM} stent, resulted in an increased restenosis rate (43–50% of the lesions treated) due to neointimal hyperplasia development at the stent edge, the so called "candy wrapper effect".[273]

Growth factor approaches

For the reason that several growth factors have been implicated in the pathogenesis of restenosis, interference with the cellular processes that control cellular migration, replication, and matrix deposition has attracted much interest in the continuous search for pharmacologic agents to reduce the incidence of restenosis.

Angiopeptin, an analog of somatostatin, prevents the mitotic effect of several growth factors, including somatomedin-C, epidermal growth factor, insulin-like growth factor, and PDGF. It inhibits SMC proliferation and reduces neointimal hyperplasia in different experimental models.[274–276] A multicenter trial in which 1246 patients were randomized to receive placebo or three different doses of angiopeptin showed no reduction in clinical events and restenosis rates between the different groups.[277] **Grade A** On the other hand, in a smaller randomized study, angiopeptin treatment reduced restenosis after PTCA (7·5% *v* 37·8% of the placebo group).[278] However, using the same drug regimen, this promising finding was not confirmed by another multicenter European study.[279] Questions remain whether a more prolonged dosing of this agent is needed to affect neointimal growth.

Trapidil is a potent thromboxane-A2 and PDGF antagonist which significantly reduces neointimal formation in animal models of restenosis.[280] The STARC trial randomized 305 patients to receive trapidil versus aspirin and showed a reduction in restenosis rate by 40%, and reduction in clinical symptoms at 6 month follow up in the trapidil treatment group.[281] **Grade B** The efficacy of trapidil in the prevention of restenosis after balloon angioplasty has also been reported in a meta-analysis by Serruys and coauthors.[282] However, results from a randomized trial of trapidil versus aspirin (performed in the stent era) showed no benefit in terms of late restenosis in patients treated systemically with trapidil compared to the aspirin control group.[283]

Molecular approaches

With the growing understanding that the failure of several antiproliferative agents to reduce neointima hyperplasia may be related to the amplification and redundancy present in the membrane and nuclear protein signaling, several attempts have been made to control and transform the gene expression at the molecular level.[284] The mechanisms by which genetic material is transferred into the target tissue include:

1. *in vivo* gene transfer by infusion of naked DNA or antisense oligonucleotides;[285]
2. transport by hybrid liposomes containing viral coat particles;[286]
3. transport by cationic liposomes containing the DNA;[287]
4. via viral vectors using retro- or adenoviruses.[288,289]

Besides the potential safety concern of gene therapy, there are also problems of transfection efficiency and which gene should be delivered. In previous years, in agreement with the restenosis hypothesis, SMC have been the preferential target. In more recent years, however, with the improved knowledge of the pathogenetic mechanisms involved in the restenosis phenomenon, other targets have been selected, including endothelial cells, thrombus formation, growth factors, matrix production, and vascular remodeling.[290–294] In addition, increased extracellular growth inhibitors of SMC proliferation might be another potential approach.[211,295,296] Other future approaches may include enhancement of re-endothelization and repair by cell seeding,[297–300] and photodynamic therapy with light which shows cytotoxic properties on SMC and cell membranes through the production of activated singlet oxygen species.[301–304]

New etiologies in restenosis: the role of chronic vascular remodeling and adventitia

Vascular remodeling, first described in relation to atherosclerosis,[305,306] has assumed great importance as a cause of coronary restenosis in the past few years in non-stented patients.[307] In atherosclerotic vessels a chronic focal enlargement of the artery occurs in response to plaque increase, in order to preserve blood flow.[308–312] Artery size changes also occur following coronary angioplasty[313] and the artery may exhibit three different remodeling responses:

1. compensatory enlargement;[314]
2. absence of compensation;[315] or
3. vascular constriction.[316,317]

Intravascular ultrasound (IVUS) has become an important means to understand the concept of remodeling. IVUS imaging has shown that after PTCA there is an axial plaque redistribution, and that failure to cause dissection is one of the causes of early lumen loss by elastic recoil.[39,42] More recently, serial IVUS studies indicated that the restenotic lesion led to contraction of the artery and late lumen narrowing.[5,318–320] While the mechanisms of chronic remodeling are poorly understood, several explanations have been postulated to explain the late lumen narrowing after PTCA: fibrosis of the vessel wall underlying the lesion, rearrangement of extracellular matrix composition and structure, and response to increased shear stress.[4,321–323] A recent paper suggests that $\alpha_v\beta_3$ may regulate contraction of the vessel wall.[324] The integrins may therefore play a role in active contraction as well as migration of SMC. Animal studies indicate that after PTCA, stretching of the adventitia may result in the proliferation and synthesis of extracellular matrix by myofibroblasts within the adventitia, itself with consequent scar-like contraction and compression of the underlying vascular wall.[325–327] This mechanism, however, does not seem relevant for late lumen narrowing in human coronary arteries subjected to balloon angioplasty.[328]

The potential impact of neointimal hyperplasia and geometric remodeling on restenosis requires further studies. Methods to prevent constrictive remodeling or to promote compensatory enlargement should be investigated. The metallic stent or drugs like cytokalasin B, which seems to function as a biologic stent, may serve this function.[329]

Conclusions: is the end of restenosis possible?

The failure effectively to circumvent the problem of restenosis, after 15 years of research, underscores the complexity of this biological process, which, to date, has not yet been fully understood. The elimination of the intimal healing response to injury is probably not achievable, nor is it desirable, considering that this physiologic response to preserve vascular integrity has been maintained across millions of years in different species. The more we delve into it, the more complex and redundant this process appears.

From the above description of the postulated model of restenosis, although SMC proliferation and neointima formation undoubtedly play a central role in restenosis, it is more likely that multifactorial mechanisms, involving different stimuli, interacting in a synergistic manner, are responsible for the restenosis phenomenon. Given the multimechanistic nature of restenosis, it is too simplistic to expect that a single drug or mechanical device will solve this problem completely. The solution, as the problem, will most likely be multifactorial, possibly involving the use of drug therapy in conjunction with adjunctive second-generation mechanical devices. Of these devices, coronary stents are the most promising, especially for their ability to achieve the best post-treatment luminal size in comparison with other devices.

In the history of medicine, human attempts to interfere with the natural course of a disease by active interventions have often led to undesired consequences. Restenosis is a new disease, one of the many that medicine has encountered trying to solve an old disease. Enormous progress has been made in the past years in understanding the pathogenetic mechanisms of restenosis and in the search for a cure. If the efficacy of drug eluting stents was to be confirmed, this would lead to a repositioning of the indications for percutaneous coronary interventions. Most of the events observed after balloon angioplasty, with or without stent implantation, in recent multicenter trials were linked to the problem of restenosis in the first months of evolution. It may well be that in the future new clinical trials could demonstrate that percutaneous coronary intervention is proven to be superior to surgical revascularization techniques. To some it may seem a nightmare, to us, as interventional cardiologists, and to our patients, it may indeed seem like a dream.

Part IIIb

Specific cardiovascular disorders: Acute ischemic syndromes and acute myocardial infarction

John A Cairns and Bernard J Gersh, Editors

Grading of recommendations and levels of evidence used in *Evidence-based Cardiology*

GRADE A

Level 1a Evidence from large randomized clinical trials (RCTs) or systematic reviews (including meta-analyses) of multiple randomized trials which collectively has at least as much data as one single well-defined trial.

Level 1b Evidence from at least one "All or None" high quality cohort study; in which ALL patients died/failed with conventional therapy and some survived/succeeded with the new therapy (for example, chemotherapy for tuberculosis, meningitis, or defibrillation for ventricular fibrillation); or in which many died/failed with conventional therapy and NONE died/failed with the new therapy (for example, penicillin for pneumococcal infections).

Level 1c Evidence from at least one moderate-sized RCT or a meta-analysis of small trials which collectively only has a moderate number of patients.

Level 1d Evidence from at least one RCT.

GRADE B

Level 2 Evidence from at least one high quality study of non-randomized cohorts who did and did not receive the new therapy.

Level 3 Evidence from at least one high quality case–control study.

Level 4 Evidence from at least one high quality case series.

GRADE C

Level 5 Opinions from experts without reference or access to any of the foregoing (for example, argument from physiology, bench research or first principles).

A comprehensive approach would incorporate many different types of evidence (for example, RCTs, non-RCTs, epidemiologic studies, and experimental data), and examine the architecture of the information for consistency, coherence and clarity. Occasionally the evidence does not completely fit into neat compartments. For example, there may not be an RCT that demonstrates a reduction in mortality in individuals with stable angina with the use of β blockers, but there is overwhelming evidence that mortality is reduced following MI. In such cases, some may recommend use of β blockers in angina patients with the expectation that some extrapolation from post-MI trials is warranted. This could be expressed as Grade A/C. In other instances (for example, smoking cessation or a pacemaker for complete heart block), the non-randomized data are so overwhelmingly clear and biologically plausible that it would be reasonable to consider these interventions as Grade A.

Recommendation grades appear either within the text, for example, **Grade A** and **Grade A1a** or within a table in the chapter.

The grading system clearly is only applicable to preventive or therapeutic interventions. It is not applicable to many other types of data such as descriptive, genetic or pathophysiologic.

30 Acute non-ST-segment elevation coronary syndromes: unstable angina and non-ST-segment elevation myocardial infarction

Pierre Theroux, John A Cairns

Introduction and historical perspective

The definition of acute myocardial ischemic syndromes as well as their management has dramatically changed over the past two decades. Not long ago, clinical acute myocardial ischemia was classified as stable angina, Q and non-Q wave myocardial infarction, and unstable angina. The latter encompassed all the highly heterogeneous manifestations of ischemia intermediate between stable angina and myocardial infarction. Fowler proposed the terminology of unstable angina in 1971,[1] following half a century of retrospective observations on the premonitory symptoms of myocardial infarction and of prospective studies of the clinical outcomes. The importance of risk stratification became recognized, at that time focusing on ischemic chest pain patterns and on ST-T abnormalities. A variety of interventions were also attempted to interrupt the disease process and prevent death or myocardial infarction. One of these studies by Wood was prematurely interrupted because of the observation of a greater efficacy of oral anticoagulants versus no anticoagulants observed in a few patients.[2] The term "acute coronary syndromes" was introduced in 1985 by Fuster to highlight the specific pathophysiologic mechanisms that distinguish unstable angina and myocardial infarction from stable coronary artery disease.[3] Pathologic studies by Michael J Davies[4,5] and by Erling Falk[6,7] had then documented the presence of intracoronary thrombus on a ruptured plaque in 95% of patients with unstable angina suffering sudden cardiac death. Thrombi of various ages were described.[6] They could be at multiple sites, typically occurring on lesions of only moderate severity, and were often associated with platelet aggregates in small intramyocardial arteries and microscopic foci of necrosis.[4,5] DeWood documented that an occlusive thrombus was consistently present in angiograms obtained very early after the onset of myocardial infarction.[8] The analyses of angiograms in unstable angina then shifted from descriptions of the severity and extent of atherosclerosis, which could not distinguish unstable angina from stable angina, to morphologic descriptions of the culprit lesion. Complex plaques with fissures and ruptures and partially occlusive thrombi were identified and confirmed by angioscopic studies. The concept of the active vulnerable plaque was established, opening a new era of advances in cell biology and clinical investigation. The science was advanced and oriented by clinical trials that reached a level of unprecedented sophistication, providing the setting for the current evidence-based approach to clinical medicine.

New dimensions and definitions

Unstable angina has achieved the maturity of a syndrome with a well-defined spectrum of clinical manifestations, epidemiology and prognosis, pathophysiology, and options for effective treatment. Delineation of the syndrome has led to unique research opportunities for better understanding of atherosclerosis and mechanisms of plaque activation, and potential patient management. The definition has evolved to become practical by incorporating algorithms for rapid diagnosis, risk stratification, patient orientation, and therapy.

The diagnosis of an acute coronary syndrome implies recognition of a change in the pattern of ischemic chest pain – or equivalent symptoms – to more severe, in the absence of evidence of an extracoronary cause for the increased severity. Thus, the diagnosis of an acute coronary syndrome is first clinical. Current nomenclature has been developed to provide clinicians with a logical framework within which to categorize patients who present with a constellation of clinical symptoms that are compatible with acute myocardial ischemia, and to guide early diagnosis and management. The nomenclature is also helpful for ensuring consistency in clinical trials and in epidemiologic studies. Hence, the acute coronary syndromes are considered to encompass unstable angina, non-ST-segment elevation (non-Q wave) myocardial infarction (NSTEMI), and ST-segment elevation (Q wave)

myocardial infarction (STEMI). The designation of possible acute coronary syndrome (ACS) is useful when patients first present, at a point where there is uncertainty about the likelihood of the presence of myocardial ischemia. As ECGs are done and biochemical cardiac markers are assessed over the next few hours, the patient may eventually be characterized as having unstable angina, non-Q wave MI or Q wave MI. Unstable angina has been traditionally classified as new onset angina, increasing angina, rest angina, and recurrent ischemia after myocardial infarction (Table 30.1).[9] Braunwald classified unstable angina by severity of symptoms and clinical circumstances (Table 30.2).[10] Details of timing and duration of pain have been included in these classifications to optimize their specificity. Thus, classification as new onset angina and increasing angina requires a component of severity, and rest pain a component of duration.

Table 30.1 Clinical presentation of ACS

Rest angina	Angina occurring at rest and prolonged, usually >20 minutes
New onset angina	New onset angina of at least CCS class III severity
Increasing angina	Angina that has become distinctly more frequent, longer in duration, or lower in threshold (that is, increased by greater than or equal to 1 CCS class to at least CCS class III severity)
Early post-MI ischemia	Ischemic chest pain recurrent within 30 days after MI

Source: adapted from Braunwald *et al*[24]

The clinical management first requires a search for ST-segment elevation, the presence of which or a new left bundle branch block, mandates consideration for immediate reperfusion therapy.[10] In the absence of ST-segment elevation, the working diagnosis is non-ST-segment elevation acute coronary syndrome.[11] Table 30.1 summarizes the clinical manifestations, Table 30.2 the Braunwald classification, and Figure 30.1 an early and highly practical diagnostic scheme. Most ST-segment elevation will evolve to a Q wave myocardial infarction. Most non-ST-segment elevation ACS will eventually be diagnosed as unstable angina or non-ST-segment elevation MI according to the absence or presence of an elevation of the various markers of cell necrosis. Accordingly, all patients with suspect symptoms should be evaluated clinically and should have a 12-lead ECG as soon as possible – immediately if ischemic pain is present. The availability of troponin T and troponin I has increased the sensitivity of the diagnosis of myocardial infarction and has sharpened the distinction between unstable angina and myocardial infarction.[12] The troponins are highly sensitive and specific markers of cell damage and permit the diagnosis of cell necrosis and myocardial infarction in up to 30% of patients who would otherwise be diagnosed as having unstable angina based on normal CK-MB blood values.[13]

The new insights into disease have modified previous statistics on the incidence and prognosis of unstable angina versus myocardial infarction. Thus myocardial infarction is more frequently diagnosed with the use of the troponins. However, the non-ST-segment elevation MI is often small, does not affect ejection fraction, and is considered and managed more like unstable angina. Epidemiological data may include ST- and non-ST-segment elevation MI in a single category, whereas clinical data reflect on one hand STEMI and, on the other, unstable angina and NSTEMI.

Table 30.2 Braunwald classification of unstable angina

	Clinical circumstances		
Severity	A: Develops in presence of extracardiac condition that intensifies myocardial ischemia (secondary unstable angina)	B: Develops in absence of extracardiac condition (primary unstable angina)	C: Develops within 2 weeks after acute myocardial infarction (postinfarction unstable angina)
New onset of severe angina or accelerated angina: no rest pain	IA	IB	IC
Angina at rest within past month but not within preceding 48 h (angina at rest, subacute)	IIA	IIB	IIC
Angina at rest within 48 h (angina at rest, acute)	IIIA	IIIB	IIIC

Source: reproduced with permission from Braunwald[10]

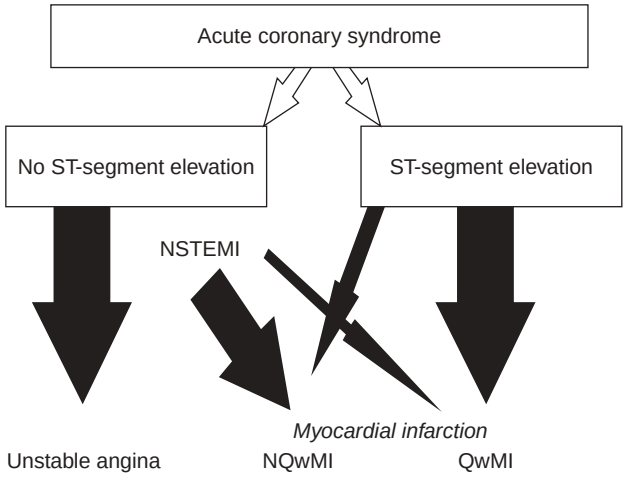

Figure 30.1 Nomenclature of acute coronary syndromes (ACS). The spectrum of clinical conditions that range from unstable angina to non-Q wave AMI and Q wave AMI is referred to as acute coronary syndrome. Patients with ischemic discomfort may present with or without ST-segment elevation on the ECG. Most patients who present with non-ST-segment elevation ACS will eventually be classified as having unstable angina or non-Q wave MI. The distinction between these two diagnoses is ultimately made based on the presence or absence of a cardiac marker detected in the blood. Only a minority of patients with non-ST-elevation MI will develop Q wave MI. Most patients with ST-segment elevation will evolve to develop Q wave MI. Adapted with permission from Antman and Braunwald.[11]

Incidence and prognosis

It is estimated that the number of consultations for chest pain in emergency departments in the USA approximates 5 500 000 yearly.[14] In the 1990s, hospital discharges for unstable angina exceeded 700 000 annually, about equal to those for MI, one third of which were of the non-Q wave type.[15,16] In 1996, a total of nearly 1 500 000 patients were hospitalized for unstable angina or NSTEMI, exceeding the number of hospitalizations for STEMI.

There is evidence that the incidence of acute coronary syndromes defined as unstable angina and non-ST-segment elevation has been increasing, whereas that of ST-segment elevation MI has been decreasing. Epidemiologic data using the WHO MONICA criteria for the diagnosis of Q wave myocardial infarction from Halifax county (Canada),[17] Turku (Finland), Oxfordshire (England),[18] Denmark,[19] the Netherlands,[20] France, and northern Italy showed that the mortality rates from Q wave MI have decreased by more than 30% between 1975 and 1995, two thirds of the decline being attributable to reduced incidence and one third to decreased hospital mortality. These decreases were observed in women as well as men.

On the other hand, the number of patients hospitalized for a non-ST-segment ACS exceeds that of ST-segment elevation MI and statistics suggest that the magnitude of the excess is increasing. In the ENACT registry of 3092 patients from 29 European countries performed in the mid-1990s, the admission diagnosis was unstable angina/NSTEMI in 46%, myocardial infarction in 39%, and a suspected ACS in 14% (ratio 1·2 : 1) and is similar across Europe.[21] The Global Registry of Acute Coronary Events (GRACE) extended the data collection to 10 693 patients recruited between 1999 and 2001 from North and South America, Australia, New Zealand, and Europe. Two thirds of admitted patients had unstable angina/non-ST-segment elevation ACS, and one third STEMI.[22]

A large epidemiologic study of 5 832 residents from metropolitan Worcester, Massachusetts has shown that the incidence of Q wave MI progressively decreased between 1975/78 (incidence rate = 171/100 000 population) and 1997 (101/100 000 population).[23] By contrast, the incidence of non-Q wave MI has progressively increased during the same period (62/100 000 population in 1975/78 and 131/100 000 population in 1997). While the hospital mortality of Q wave MI has progressively declined from 24% in 1975/78 to 14% in 1997, that of non-Q MI has remained constant at 12%. These trends persisted after adjusting for potentially confounding prognostic factors. Therefore, despite impressive declines in the incidence of Q wave MI and the inhospital and long-term mortality, the incidence of non-Q wave MI has been increasing with unchanged mortality rates compared to about 22 years ago.

The shifts in the clinical manifestations of acute coronary syndromes correspond to changes in patterns of practice and referral in accordance with the emphasis on primary and secondary prevention and earlier intervention. Public education programs may also favor early diagnosis, referral, and treatment. Figure 30.2 describes the distribution of admission diagnoses in the Coronary Care Unit of the Montreal Heart Institute, a referral center, over the past decade. There is a major shift in the distribution of admissions from STEMI to non-ST-segment elevation ACS, as well as an increase in the total number of admissions.

Natural history

Patients admitted for an ACS experience 10 times more events in the short term than patients with stable angina and several-fold more than individuals with high cholesterol values and no known coronary disease. The natural history of unstable angina/NSTEMI is determined by the severity and extent of coronary artery disease, the presence of comorbid conditions, age, and the ischemic pain pattern which may range from the simple onset of new angina, to profound and prolonged episodes of angina at rest,

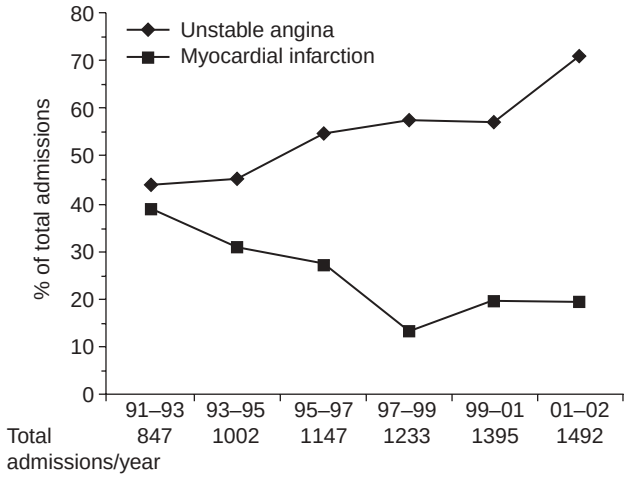

Figure 30.2 This figure describes the distribution of admission diagnosis in the Coronary Care Unit of the Montreal Heart Institute, a referral center, over the past decade. The total number of patients admitted through the past decade has nearly doubled. A major shift has occurred, however, in the distribution of ST-segment elevation versus non-ST-segment elevation ACS. Patients with a non-ST-segment elevation ACS now represent more than two thirds of patients admitted in the CCU, while the incidence of ST-segment elevation MI has decreased from 40% to 20% of admissions. This phenomenon is observed in most hospitals in industrialized countries.

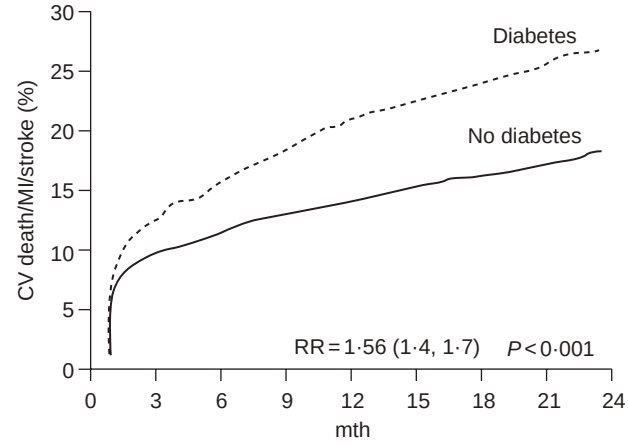

Figure 30.3 Kaplan-Meier event curves for diabetic and non-diabetic patients for total cardiovascular death, MI, stroke, and new onset of congestive heart failure for a 24 month follow up period after an episode of non-ST-segment elevation ACS. Data from the OASIS Registry study reproduced with permission from Malmberg *et al*.[25]

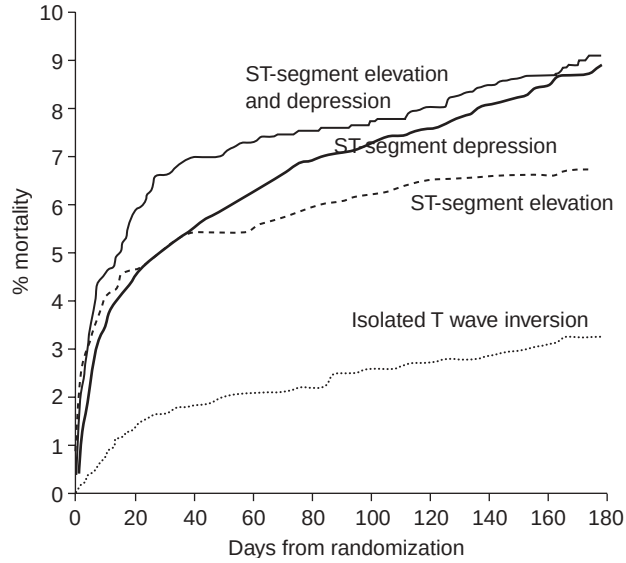

Figure 30.4 Kaplan-Meier estimates of probability of death at 6 months by ECG changes at admission. The event rate was highest inhospital in patients with ST-segment elevation MI. However, by 6 months, mortality in patients with ST depression exceeded that of patients with ST elevation. Data from the GUSTO-II study, reproduced with permission from Savonitto *et al*.[26]

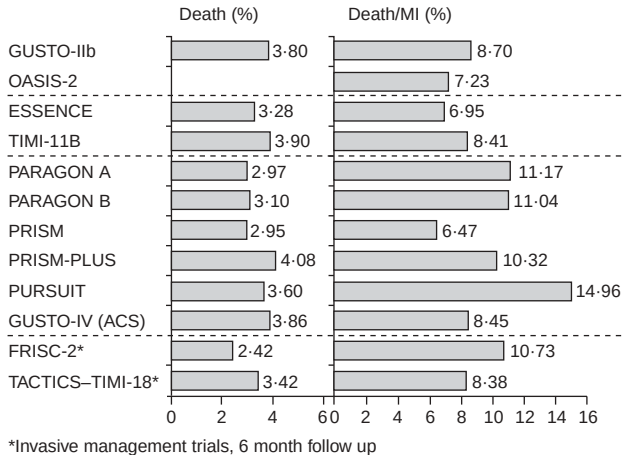
accompanied by LV dysfunction and resistance to medical therapy.[24] The risk of the disease is highest in the first few days, decreases over the following weeks and months, and eventually becomes similar to the prognosis of patients with stable angina. The long-term prognosis is influenced by the severity of the underlying disease. In the OASIS registry, the incidence of events was 10% at one month and increased steadily in the following 2 years to reach more than 20% after 24 months (Figure 30.3), higher in diabetic patients and in patients with previously known coronary artery disease.[25] In the GUSTO-II study, the inhospital mortality rate was highest, as expected, in patients with STEMI; however, increasing mortality during follow up in patients with ST-segment depression eventually exceeded that of patients with ST elevation after 6 months, reaching 8·7% as against 6·8% (Figure 30.4).[26] The empirical concept that NSTEMI represents an unresolved acute coronary syndrome at risk of being completed by a recurrent MI may therefore be partially true in many patients, and is likely explained by an underlying disease process that remains active. This is supported by data showing that markers of inflammation and of activation of coagulation may remain elevated months past the acute phase of an episode of acute coronary syndrome.[27,28] It is difficult to evaluate the effect of advances in treatment on the natural history of unstable angina/NSTEMI, since the diagnostic criteria have evolved concurrently. Recent randomized trials have shown an impressive decrease in MI and death. Prior to the routine prescription of bed rest, nitrates and β blockers for unstable angina, the rate of MI after one month was in the range of 40% and of death, 25%.[29] By the 1970s these rates had fallen to about 10%

and 2%. In 1979–80, a study of all patients hospitalized with unstable angina in Hamilton, Canada over a period of one year noted inhospital and 1 year mortalities of 1·5% and 9·2% respectively.[30] By the time of the re-evaluation of heparin in the late 1980s, study inclusion criteria had shifted toward patients at somewhat higher risk, and some trials included patients with NSTEMI. In these trials, the rates of the composite outcome of death or non-fatal myocardial infarction by 5 days were about 10%.[31,32] These rates fell to the range of 4% with the addition of heparin to aspirin, and fell further with enoxaparin and the glycoprotein IIb/IIIa antagonists. The event rates at 30 days in recent trials with new antithrombotic therapies and an invasive management strategy are shown in Figure 30.5.[33–44]



*Invasive management trials, 6 month follow up

Figure 30.5 Rates of death and of death or myocardial infarction in contemporary trials that evaluated new antithrombotic drugs and routine invasive treatment strategy in patients with non-ST-segment ACS. Data are the average of events in the intervention and control groups. The interventions resulted in a reduction in rates of death ranging from −5% to 36% and in rates of death or myocardial infarction ranging from −8% to 27%.[33–44]

Risk stratification

A gradient in risk exists in ACS from relatively benign to severe; accordingly, patient management should be guided by clinical risk stratification. The high-risk features for death and ischemic events present at admission, or developing rapidly, have been identified in many registries and clinical trials. Registry studies look at a broad spectrum of patients with acute chest pain, while clinical trials enroll more selected populations predefined by entry criteria in a specific study. Recent registries have focused mainly on regional differences in application of drug therapy and interventional procedures,[21,22,25] whereas trials have evaluated specific predictors, biased by entry criteria of the trials. Nevertheless, important common determinants of risk have been identified by the two approaches. These include older age, presence of ST-segment shifts, elevation of the cardiac markers, and recurrent ischemia (Table 30.3). Ejection fraction is not available in the majority of patients but is known to be a potent predictor of prognosis in all manifestations of coronary artery disease. Cardiac risk factors are in general poor predictors of acute risk in patients with an ACS but are useful for the evaluation of the likelihood of coronary artery disease and its prognosis.[45] The rate of the progression of the severity of chest pain is clinically recognized as suggesting a more rapidly evolving coronary stenosis. There is a gradient in risk from new onset, to crescendo, to prolonged rest angina.[9] Women and the elderly are more likely to have atypical presentations. The prognosis for patients who have atypical symptoms at the time of their infarction can be worse than that of patients with more typical symptoms.[46] Women enrolled in clinical trials are in general older than men and have more risk factors such as diabetes and hypertension. The proportion of women with ST-segment elevation is less than in men but their prognosis is then worse. Women who present with a non-ST-segment elevation acute syndrome less often have an elevation of the cardiac markers and have a better prognosis. The odds for infarction and death in the GUSTO-IIb study in women compared to men was 0·65 (95% CI 0·49–0·87; $P = 0·003$),[47] and in the non-invasive strategy arm of the FRISC-II study 0·64 (95% CI 0·43–0·97; $P = 0·03$).[48] Coronary angiography in general revealed less severe coronary artery disease for women than for men.[48] Diabetes is present in 20–25% of patients

Table 30.3 Determinants of prognosis

Determinants of short-term prognosis	
Confirming the diagnosis of ACS	Clinical pattern of pain
	ST-T ischemic changes
	Troponin T or I elevation
	Hemodynamic or electrical instability
Other major determinants	Older age
	Left ventricular dysfunction
	Recent myocardial infarction
	Recurrent ischemia
	Diabetes
	Previous myocardial infarction
	Previous CABG
	Previous aspirin use
	Depression
Determinants of long-term prognosis	
	Left ventricular dysfunction
	Diabetes
	Extensive coronary artery disease
	Strongly positive provocative testing
	Elevated CRP levels
	Depression

enrolled in trials in ACS. Diabetes carries a major negative impact on morbidity and mortality in the setting of ACS and after percutaneous interventions and coronary artery bypass grafting. In the OASIS registry, diabetes was an important and independent predictor of 2 year mortality (RR 1·57; 95% CI 1·38–1·81; $P < 0·001$), as well as of cardiovascular death, new myocardial infarction, stroke, and new congestive heart failure.[25] The risk of death in diabetic women was significantly higher than the risk in diabetic men (RR 1·98 and 1·28 respectively). Diabetic patients without prior cardiovascular disease had the same event rates for all outcomes as non-diabetic patients with previous vascular disease (see Figure 30.3). The impact of depression on prognosis is more and more recognized. In a study of 430 patients with a non-ST-segment elevation ACS, depression predicted the end point of cardiac death or non-fatal MI, with an adjusted odds ratio of 6·73 (95% CI 2·43–18·64; $P < 0·001$) after controlling for other significant prognostic factors that included baseline ECG, left ventricular ejection fraction, and number of diseased coronary vessels.[49]

The 12-lead ECG and the troponin T or I blood levels have become powerful instruments for risk evaluation. They are now part of the entry criteria in clinical trials and of recommended treatment algorithms. Troponin elevation in the blood follows the ischemic insult by 6 hours, as does CK-MB. Myoglobin serum concentration rises earlier, within 2 hours after the onset of pain, and peaks within 4–6 hours. Myoglobin can be useful as an early and sensitive marker of necrosis, but it is non-specific, mandating confirmation of the cardiac origin with the CK-MB or troponin levels. Although failure to detect a rise of myoglobin after 2–4 hours rules out an infarction, the prognostic value with regard to recurrent coronary events in patients with non-ST-segment elevation ACS has been less well characterized.

The presence of ST-segment shifts and/or the elevation in troponin T or I levels confirm the working diagnosis of a non-ST-segment elevation ACS, identify the patient at high risk for an ischemic event, and are useful for immediate patient orientation and management by identifying those who will benefit most from the new treatment strategies that include enoxaparin, the Gp IIb/IIIa antagonists and revascularization procedures. The absence of such changes does not rule out the diagnosis, but places the patient in a more favorable risk category. Patients with an indefinite but possible diagnosis of an ACS need to be observed for the clinical evolution, changes on serial ECGs, and elevation of troponin levels after 8–12 hours.

Prognostic value of troponin levels

In contrast to CK-MB and myoglobin, cardiac troponins T and I are usually not detectable in the peripheral blood and, thus, provide a more distinct and sensitive marker of minute cardiomyocyte damage. The damage detected is usually of ischemic origin but may be due to non-ischemic myocardial injury, such as myocarditis, severe heart failure, pulmonary embolism, trauma or cardiotoxic agents. Multiple studies since the original publication by Hamm *et al* have validated the prognostic value of an elevation in the blood troponin levels.[50]

Figure 30.6 depicts the results of one trial of patients enrolled in a clinical trial[18] and of one study of patients consulting in the emergency department for acute chest pain;[18] the 30 day rate of death or myocardial infarction was highest in patients with elevated troponin T or troponin I levels, intermediate in patients with ST-segment depression, and lowest in patients with normal troponin levels. The higher the elevation in troponin levels,[51] the worse the prognosis, but even small elevations are associated with a significantly impaired prognosis.[52] In the FRISC study, among patients with a non-ST-segment elevation ACS, the risk of myocardial infarction or cardiac death at 6 months was respectively 4·3%, 10·5%, and 16·1% in patients within the first, second, and third tertile of maximal elevation of troponin during the first 24 hours.[53]

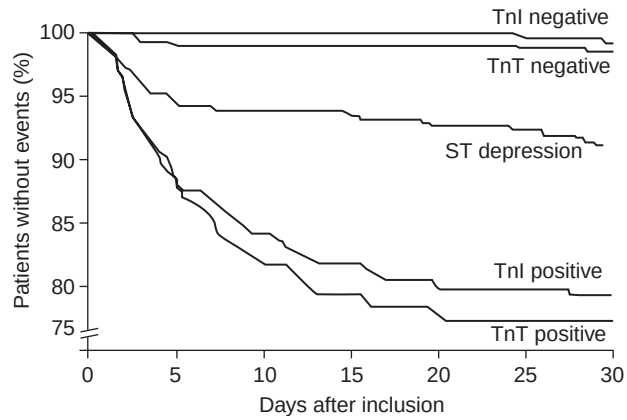


Figure 30.6 Risk of death or non-fatal myocardial infarction during 30 days of follow up by troponin T (TnT) and I (TnI) levels, elevation (positive) or no elevation (negative), and ST-segment depression on the ECG. The risk for myocardial infarction and death increases with increasing serum troponin concentrations and may be 20% in 30 days and 25% within 6 months in patients with the highest troponin levels. Reproduced with permission from Hamm *et al.*[13]

Three meta-analyses were performed and provided results in the same direction. The first, including 12 reports with troponin T and nine with troponin I of patients with unstable angina, demonstrated risk ratios for occurrence of myocardial infarction at 30 days of 4·2 (95% CI 2·7–6·4; $P < 0·001$) for troponin I and of 2·7 (95% CI 2·1–3·4; $P < 0·001$) for troponin T.[54] The second included 18 982 patients with unstable angina from 21 studies and showed odds of death or myocardial infarction at 30 days of 3·44

(95% CI 2·94–4·03; $P < 0·00001$) for the total population of troponin positive patients, 2·86 (95% CI 2·35–3·47; $P < 0·0001$) for patients with ST-segment elevation, 4·93 (95% CI 3·77–6·45; $P < 0·0001$) for patients with non-ST-segment elevation, and 9·39 (95% CI 6·46–13·67; $P < 0·0001$) for patients with unstable angina.[55] The third meta-analysis included seven clinical trials and 19 cohort studies. The odds of mortality among 11 963 patients with positive troponin T or I was 3·1 (5·2% *v* 1·6%). The discriminative value of elevated troponin levels was greater in cohort studies than in clinical trials, 8·4% *v* 0·7% (OR 8·5) for troponin I, and 11·6% *v* 1·7% (OR 5.1) for troponin T.[56]

Determination of troponin levels has many utilities. Beyond providing a highly sensitive and specific test for the diagnosis of myocardial infarction, any elevation provides important prognostic information in acute coronary syndromes. Patients with troponin elevation are also more likely to profit from therapy with a Gp IIb/IIIa antagonist,[57] from a low molecular weight heparin,[58] and from interventional procedures.[59] All evidence converges to relate the elevation of troponin to an ongoing intracoronary thrombotic process, associated with small foci of myocardial necrosis, likely related to distal embolization of thrombotic material originating from the culprit lesion.

Prognostic value of the 12-lead ECG

Current information on the prevalence of ECG abnormalities is difficult to obtain, in part because ECG criteria are often used to define eligibility for clinical studies and the use of heterogeneous inclusion criteria among trials. In a report by Langer *et al* on 135 patients hospitalized with unstable angina without evidence of acute myocardial infarction, ST-segment depression was found in 25% of patients, ST-segment elevation in 16%, both in 4%, and none in 55%.[60] In this study, ST-segment depression and the magnitude of depression were both associated with a higher prevalence of multivessel and left main disease.[60] In the TIMI-3 Registry of 1416 patients enrolled because of unstable angina or non-Q wave MI, ST-segment deviation ≥ 1 mm was present in 14·3% of patients, isolated T wave inversion in 21·9%, and left bundle branch block (LBBB) in 9·0%. By 1 year follow up, death or MI occurred in 11% of patients with ST-segment depression, 6·8% of patients with isolated T wave inversion, and in 8·2% of those with no ECG changes. ST-segment depression 0·5 mm or more and LBBB were significant predictors of death and MI, with rates of 16·3% and 22·9%, respectively.[61] The ECG is not infrequently confounded by LBBB, left ventricular hypertrophy, paced rhythm or other derangements. In the PARAGON-A study, these confounders were associated with near doubling in the 1 year mortality rates (12·6% *v* 6·5%).[62] Among the 12 142 patients enrolled in the GUSTO-II trial with symptoms at rest within 12 hours of admission and ischemic ECG changes, 22% had T wave inversion, 28% ST-segment elevation, 35% ST-segment depression, and 15% ST-segment elevation and depression.[26] The 30 day rates of death or myocardial re-infarction were 5·5%, 9·4%, 10·5%, and 12·4% respectively ($P < 0·001$). The cumulative rates of death in this study are shown in Figure 30.4.

There exists therefore a gradient of increasing risk of death or myocardial infarction in hospital and up to 1 year, from non-specific ECGs to T wave inversion to ST-segment depression including confounding ST-T changes. Such a gradient exists from ST-segment depression $>0·05$ mm, to >1 mm, to >2 mm, to ≥ 2 mm, and to depression in more than two contiguous leads.[62] The prognostic value of ST-segment depression extends to 4 years following hospital discharge.[63] Special attention is required for patients showing deep T wave inversions in leads V1 through V6 and in leads 1 and AVL on the admission or subsequent ECGs; the changes are quite specific for the presence of significant disease in the proximal left anterior coronary artery disease and are predictive of a high risk of progression to an infarction that can be massive.[64]

The importance of recording the 12-lead ECG during chest pain must be emphasized. The detection of ST-segment depression during pain has diagnostic and prognostic value.[65] Occasionally, transient ST-segment elevation will be detected associated with a critical dynamic coronary artery stenosis caused by spasm or thrombus formation. ST-segment shifts during pain occurring on medical management indicate refractory ischemia, an end point commonly used in clinical trials. Refractory ischemia predicts near tripling of adjusted 1 year mortality.[66]

Risk scores

Prognosis can be predicted by various clinical, ECG, and laboratory parameters. Accordingly, predictive models have been derived from various databases by applying multiple regression analyses to identify the independent predictors of prognosis. The results of such analyses are influenced by the characteristics of the test populations and by the baseline data collected. From the population of 9461 patients enrolled in the PURSUIT trial, more than 20 parameters were predictive of mortality and the composite end point of death or MI, the most important being age, heart rate, systolic blood pressure, ST-segment depression, signs of heart failure, and cardiac enzyme elevation.[67]

The TIMI risk score has gained popularity, since it can be readily and simply assessed at admission or shortly thereafter. It was derived from the control cohort of patients in the TIMI-11B study.[68] The seven independent predictors of death, myocardial infarction or recurrent ischemia that were identified are shown in Table 30.4. Their mathematical

Table 30.4 Components of the TIMI risk score

Age 65 yr
At least three risk factors for CAD
Significant coronary stenosis (for example, prior coronary stenosis 50%)
ST-segment deviation
Severe anginal symptoms (for example, two anginal events in last 24 h)
Use of aspirin in last 7 days
Elevated serum cardiac markers

Source: Antman *et al*[68]

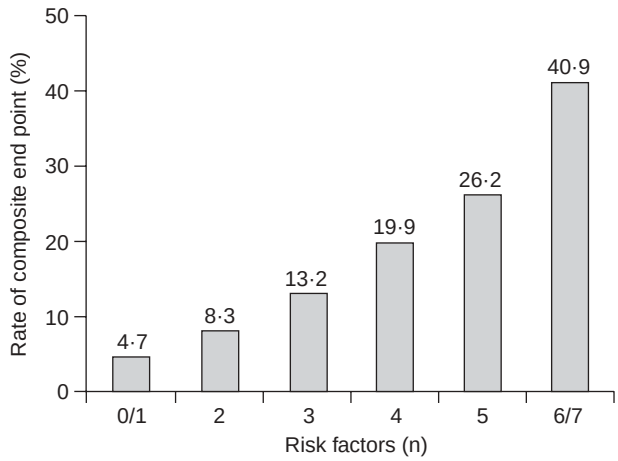

Figure 30.7 Original validation of the TIMI risk score. Rates of all-cause mortality, myocardial infarction, and severe recurrent ischemia prompting urgent revascularization through 14 days by TIMI risk score at admission. The score discriminates a gradient in risk from 5% to 40%. Reproduced with permission from Antman *et al*.[68]

addition provided a seven-point score that could discriminate a 10-fold difference in risk through 14 days (Figure 30.7). The score was subsequently validated in other populations including PRISM-PLUS[69] and TACTICS.[44] Greater treatment benefit was observed with enoxaparin treatment,[68] Gp IIb/IIIa antagonists[69] and reperfusion procedures[44] in patients with higher scores, ST-segment shifts, and elevated troponin levels.

Inflammation markers

Blood levels of numerous markers of inflammation are elevated in patients with an ACS, including acute phase proteins (C-reactive protein, serum amyloid A protein, fibrinogen), pro-inflammatory cytokines (interleukin-6, TNF-α, interleukin-18), soluble adhesion molecules (sVCAM-1, sICAM-1, E-selectin, P-selectin), and matrix metalloproteinases. C-reactive protein (CRP) is a non-specific but highly sensitive marker of an inflammatory state. Interleukin-6, which is induced by TNF-α, IL-1, IL-18, platelet derived growth factor, antigens, and endotoxins, is the main stimulus for the production of CRP by the liver. CRP has a half life of 19 hours and can be assessed in the blood by tests with high sensitivity. Many epidemiologic studies in individuals with or without known cardiovascular disease have consistently shown a 3- to 3·5-fold increase in the risk of cardiac events in the highest distribution quartile. The predictive value is additive to that of cholesterol levels.[70] CRP levels are elevated in myocardial infarction. The elevation preceded that of markers of myocardial necrosis in patients who had previous unstable angina, but not in patients who had no preceding angina.[71] Levels are elevated in 40–50% of patients with a non-ST-segment elevation acute coronary syndrome and remain high for months after the acute phase. These elevated levels are associated with high rates of late cardiac events, including death/MI/recurrent ischemia at 12 months,[72] death/MI at 6 months[73,74] and up to 2 years,[75] and death at 36 months.[76] The predictive value for occurrence of early events has been less consistent. In the TIMI-11A study of 630 patients with a non-ST-segment elevation ACS, the risk of death at 14 days was highest with elevated troponin T and CRP, intermediate when either marker was elevated, and lowest when both were normal (CRP $< 1{\cdot}55$ mg/l).[77] In the CAPTURE trial of 447 patients, CRP levels >10 mg/l did not predict mortality or myocardial infarction at 72 hours in contrast to elevated troponin T levels, but did predict death or MI at 6 months (18·9% compared to 9·5%), independently of the troponin status (Figure 30.8).[74]

The assessment of CRP levels is not currently part of the recommendations of various guidelines. The cut points that best predict early and late prognosis as well as the ideal timing for blood sampling at admission or hospital discharge remain to be better defined. Moreover, the impact on risk evaluation of treatment with statins, which reduce the CRP levels and the prognostic significance of elevated levels,[78] and of aspirin, which reduces the prognostic value,[79] need additional characterization. Of interest, PCI or CABG appear to have little effect on the 1 year excess of recurrent ischemic events in patients with a non-ST-segment elevation ACS and high CRP levels. Elevated CRP levels are associated with increased risk of restenosis and of acute complications after PCI,[80,81] and with an increased risk of new ischemic events up to 8 years after CABG.[82]

Pathophysiology

This section will focus on the mechanisms of acute coronary syndromes that are the most relevant with respect to management. Interested readers are referred to more exhaustive

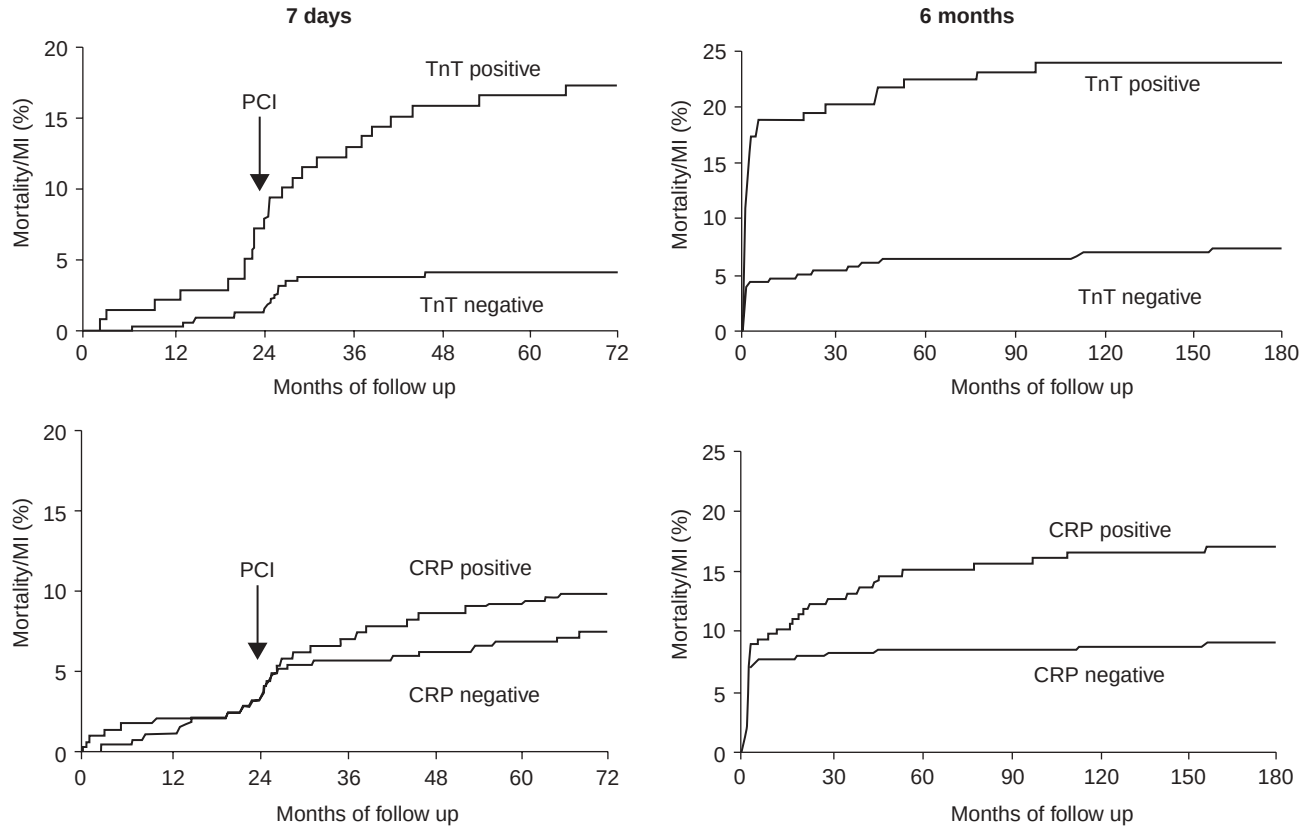

Figure 30.8 Rates of death or MI at 7 days (top left panel) and at 6 months (top right panel) by troponin T (TnT) status (top panels), and C-reactive protein (CRP) status (lower panels) at admission. PCI was performed in all patients 20–24 hours after admission. The risk of death or MI was especially high in TnT positive patients within the first 7 days and increased only slightly thereafter. The event rates were not statistically different for CRP negative patients and CRP positive patients after 7 days (including the coronary intervention) (10·3% *v* 8%; $P = 0{\cdot}41$). During the 6 month follow up period, however, the event rate curves for CRP positive and CRP negative patients continually diverged. There were significant differences both after 30 days (14·1% *v* 7·6%; $P = 0{\cdot}03$) and especially at 6 months (18·9% *v* 9·5%; $P = 0{\cdot}003$). The excess events in CRP-positive patients were related to higher incidence of MI (13·5% *v* 8·4%; $P = 0{\cdot}16$) and of mortality rate (5·4% *v* 1·1%; $P = 0{\cdot}005$). Reproduced with permission from Heeschen *et al.*[74]

reviews.[83–85] Figure 30.9 outlines the cascade of patho physiologic events that build up on an atherosclerotic plaque and eventually result in myocardial infarction and death. The culprit lesion becomes clinically manifest only with the development of an obstruction severe enough to impede coronary blood flow at rest, or when it is the site of a thrombotic occlusion shedding thromboembolic material into the distal circulation. Therefore, the active plaque is clinically detected only at an advanced stage of the underlying disease. Further, the concept of a single active plaque has been challenged. Pathologic studies have shown multiple rupture sites and thrombi at multiple sites often associated with platelet aggregates in small intramyocardial arteries and microscopic foci of necrosis.[7,86–88] An angiographic study in 253 patients with an acute myocardial infarction documented that complex and ruptured plaques could be found in 40% of patients and that these were associated with a 10-fold increase in the risk of a recurrent ACS.[89]

Atherosclerosis is the substrate for ACS. The severity of atherosclerosis in acute coronary syndromes is highly variable, ranging from absence of significant stenoses to the presence of left main disease in 5–10% of patients, and single, double or three vessel disease in respectively 20%, 30%, and 40%.[90] A severely obstructive lesion is most often identified, providing a rationale for coronary revascularization. On inspection and histologic analyses, the culprit lesion is clearly distinct from the stable plaque; it is most often of only moderate severity, with an inner core rich in cholesterol and cholesterol esters and a thin fibrous cap, poor in connective tissue and smooth muscle cells.[83] At microscopy, the culprit lesion is rich in monocyte-macrophages, mast cells, lymphocytes, and neutrophils. Biologically, it is extremely active, with an intense inflammatory reaction marked by heterotypic cell-to-cell interactions and activity of proinflammatory cytokines, matrix-degrading metalloproteinases, and growth factors.[84,85] This culprit lesion is the site of a rupture or

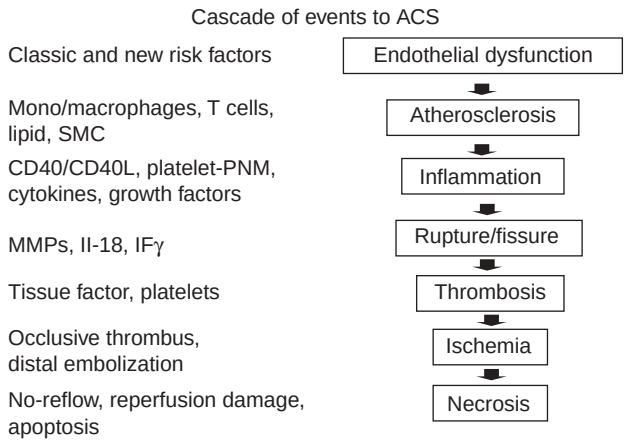

Figure 30.9 Cascade of events leading to ACS. There is a progression of events at the level of an atherosclerotic plaque to excessive inflammation, plaque degeneration, plaque rupture, and intravascular thrombus formation. These events become clinically manifest only when the thrombus becomes obstructive or sheds distal emboli to cause myocardial ischemia and eventually myocardial infarction and death. The cascade of events offers multiple possibilities for intervening at various levels to control and prevent ACS. Il-18, interleukin 18; IFγ, interferon γ.

fissure, occurring most often at the shoulder region of the plaque. The endothelial disruption is occupied by a thrombus extending variably within the lumen of the artery and the vessel wall.[83] The mainstay of immediate therapy in ACS is the control of the thrombotic activity to prevent its rapid progression to occlusion or distal microembolization of thrombotic material. The best results have been achieved with combinations of antiplatelet and anticoagulant therapy consistent with the contributions of both intravascular coagulation and platelet activation and aggregation to arterial thrombosis. Circulating platelets adhere within seconds to the damaged endothelium through receptor–ligand interactions. Gp Ib/IX recognizes von Willebrand factor present in large quantities in the subendothelium, and Gp Ia/IIa recognizes collagen. Platelet adhesion and other local agonists produce intracellular signaling that increases cytosolic Ca^{2+} content and induces shape change, release of potent vasoactive, proaggregant and procoagulant substances, and activation of the Gp IIb/IIIa receptor.[83] The activated Gp IIb/IIIa receptor recognizes and binds the RGD sequence of various moieties, particularly fibrinogen, resulting in platelet cross-bridging and platelet aggregation. The outside translocation of the inner anionic phospholipid layer of platelets early during activation provides a membrane surface well suited for the assembly of coagulation factors and thrombus formation and growth. Tissue factor, expressed by lipid laden macrophages in the core of the atherosclerotic plaque and the diseased endothelium, forms a complex with circulating factor VIIa to activate factors IX and X of the coagulation cascade. Factor IXa is part of the intrinsic tenase complex that activates factor X. Factor Xa converts prothrombin to thrombin within the prothrombinase complex. Thrombin has multiple pathophysiologic effects. It converts fibrinogen to fibrin, activates factor XIII which cross-links fibrin, amplifies its own generation by activation of factors V, VIII, and XI on the platelet surface, and is a potent platelet agonist. P-selectin expressed on the platelet membrane and on the endothelial cell attracts leukocytes, linking thrombosis and inflammation.

In addition to antithrombotic therapies, other strategies may be employed to control the acute coronary syndromes, as shown in Figure 30.9. The prevention of atherosclerosis is the ultimate goal. Realistic targets in the shorter term are plaque passivation to control the pathophysiologic triggers to plaque rupture and thrombus formation, and cell protection to prevent progression of ischemia to irreversible cell necrosis.[91]

Management

The goals of treatment in ACS are to decrease the substantial risk of myocardial infarction and death, relieve pain, and prevent recurrent ischemia. These objectives can be collectively regrouped under the term plaque passivation, implying the conversion of an unstable plaque into a plaque that will be stable and not prone to complications. During the acute phase, this is best achieved with prompt use of antithrombotic agents, and in selected patients reperfusion procedures. Anti-ischemic therapy is also used to control symptoms. Therapies to control the inflammatory processes within the plaque are effective in secondary prevention and their potential is now being investigated during the more acute phase.

Acute therapy

The therapeutic approaches include general measures, anti-ischemic therapies, antithrombotic therapies, and revascularization procedures. The intensity of treatment is guided by risk as estimated from the clinical presentation, the 12-lead ECG and the troponin levels, as discussed above. Additional patient characteristics associated with an enhanced risk must also be considered. These are listed in Table 30.3 above, along with other predictors of an impaired long-term prognosis. Risk stratification is an ongoing process that must be repeatedly updated during the clinical course and integrated with the results of the various tests performed.

General measures

The patient may present in a non-medical setting or by telephone, in the office, or in the hospital emergency room or ward. Those with the simple new onset of angina or mild exacerbation of previously stable angina, with no angina at rest, ECG changes, or hemodynamic abnormalities should be carefully assessed, initial treatment and educational materials provided, and medical follow up planned, but they

may generally be managed as outpatients with initial limitation of activities, providing that necessary investigations can be performed promptly. High-risk patients require admission to the CCU, generally to remain for about 24 hours following the last episode of rest pain. Patients at intermediate risk might go to the CCU, an intermediate care unit, or even to a regular ward depending on the availability of facilities and the specific level of risk.

Whatever the pathophysiology of the acute ischemia in a given patient, there is an imbalance of myocardial oxygen supply and demand, and restricted activities and rest in bed or a recliner chair will be helpful in reducing myocardial oxygen demand. Stool softeners are likely to be helpful. Emotional distress with its attendant increase in myocardial oxygen demand should be minimized by judicious control of environmental noise and light, supportive medical and nursing care, limitation and education of visitors, provision for restful sleep, and control of ischemic pain with intravenous narcotics and nitrates, and other specific anti-ischemic agents as appropriate. Special attention is indicated to detect depressive symptoms that carry an impaired prognosis independently of other predictors.[49] Routine oxygen administration is not recommended unless chest pain is ongoing or respiratory or left heart failure are present. **Grade C** Finger pulse oximetry is then recommended to monitor arterial oxygen saturation. **Grade B**

Anti-ischemic therapies

Nitroglycerin has been a mainstay in the therapy of unstable angina since the prognostic importance was first recognized, and as longer-acting nitrate preparations became available, these were incorporated into treatment regimens without rigorous comparisons to placebo. Studies of the use of IV nitroglycerin among patients with unstable angina have been relatively small, of sequential or case–control design, and the dose regimens have varied considerably.[92] At least partial relief of anginal episodes is usually achieved, occasionally relief is complete, and absence of benefit is an infrequent observation. However, the trials have been of brief duration, generally a few days only, and problems of nitrate tolerance and recurrence of ischemic events emphasize that nitrates are not definitive therapy for unstable angina beyond the acute phase. A trial comparing nitrate therapy and diltiazem[93] indicates that diltiazem is more effective in controlling angina and preventing ischemic events but these studies do not reflect clinical approaches that have employed long acting or intravenous nitroglycerin in combination with a β blocker or a rate limiting calcium antagonist. The widespread use of oral, topical, and IV nitrates in unstable angina is based upon reasonable extrapolation from pathophysiologic observations, case series, evidence of modest reduction of mortality in acute MI,[94–96] and extensive clinical experience using regimens developed in careful clinical studies.[96] **Grade B** Patients must be monitored for the potential adverse effect of marked arterial hypotension, which must be managed quickly to avoid exacerbating ischemia. The use of sildenafil (Viagra) within the preceding 24 hours is a contraindication to nitrate therapy.[97] **Grade B** Efforts should be made to minimize the development of nitrate tolerance by reducing IV dosage and intermittent dosing by non-IV routes when ischemic pain allows.

The β blockers were introduced in the 1960s and their effectiveness in the treatment of stable angina resulted in rapid acceptance for the management of unstable angina. There was remarkably little objective evidence for the efficacy of β blockers prior to their widespread use.[29] Subsequently, β blockers were evaluated in well-designed studies. In one study, a group of 126 patients hospitalized with unstable angina (characterized by progressive or rest ischemic pain plus ECG changes with pain and documented coronary artery disease) were randomly allocated to the addition to their regular therapy of either nifedipine or the combination of propranolol/isosorbide dinitrate, with appropriate placebos.[98] The principal outcome was absence of recurrent chest pain for at least 48 hours, and the period of evaluation was 14 days. There was no overall difference between the two treatment regimens. However, in a post-hoc analysis of the data amongst the 59 patients not receiving β blocker on admission, the propranolol/isosorbide was more effective than the nifedipine in producing pain relief ($P < 0{\cdot}001$). Conversely, among the 67% of patients already receiving a β blocker on admission, nifedipine was more effective than augmentation of β blocker accompanied by isosorbide ($P = 0{\cdot}026$).

The HINT study[99] examined metoprolol and nifedipine in patients hospitalized with prolonged rest pain. The 338 patients who were not receiving β blocker on admission were randomly allocated to nifedipine, metoprolol, both, or neither in a double-blind placebo-controlled fashion. The outcome of AMI or recurrent angina with ST change within 48 hours occurred with the following frequencies: placebo (37%), nifedipine (47%), metoprolol (28%), nifedipine plus metoprolol (30%). Metoprolol was significantly more effective than nifedipine ($P < 0{\cdot}05$). The 177 patients already on a β blocker on admission were randomly allocated in double-blind fashion to nifedipine or placebo and treatment failure occurred in 51% of placebo and 30% of nifedipine ($P < 0{\cdot}05$).

Gottlieb *et al.*[100] studied 81 patients hospitalized with at least 10 minutes of ischemic chest pain at rest. All patients were receiving "optimal" doses of nitrates and nifedipine and were therefore treatment failures on this regimen. They were randomly allocated to the addition of either propranolol or placebo. In the first 4 days, propranolol resulted in a statistically significant reduction of recurrent rest angina episodes, duration of angina, nitroglycerin requirement, and ECG abnormalities. Although recurrences of rest angina

remained less among the propranolol treated group over the next 4 weeks, the incidence of aortocoronary bypass, AMI, and sudden death was no different between the two groups.

In another study, patients hospitalized with prolonged pain accompanied by ECG abnormalities, and who had failed maximum treatment with propranolol and long-acting nitrates, were randomized to the addition of nifedipine or placebo;[101] the failure of medical treatment (sudden death, AMI, or bypass surgery) was less frequent with nifedipine than with placebo ($P = 0{\cdot}03$). The benefit was most marked among patients with ST-segment elevation.

These trials suggest that among patients not receiving a β blocker on hospitalization, the institution of β blockade and the institution or maintenance of nitrates is more effective treatment than the institution of nifedipine. **Grade A** Amongst patients whose pain persists with optimal doses of nitrates and nifedipine, the addition of a β blocker is efficacious in the initial few days, although the incidence of ischemic outcomes (bypass surgery, AMI, sudden death) is not reduced. **Grade A** On the other hand, in patients hospitalized and already receiving a β blocker, then the addition of nifedipine is more effective than simply augmenting the β blocker dose. **Grade B** Recent data suggesting potentially harmful effects of short-acting dihydropyridines[102] indicate that a more prudent choice for the addition to a β blocker would be a long-acting dose preparation or an agent with an intrinsically long half-life such as amlodipine, although rigorous studies have not been conducted. **Grade C**

Diltiazem was compared to propranolol in a randomized single-blind study of patients hospitalized for crescendo rest, or following MI angina accompanied by ECG abnormalities.[103] Chest pain frequency was significantly reduced by both regimens, and there was no difference in efficacy. The 5 month follow up was rather discouraging in both groups, with a high incidence of AMI, death, and bypass surgery, and few patients without bypass surgery were symptom free. In another study, patients with rest angina were randomized to diltiazem or propranolol in maximum tolerated doses.[104] The agents were equally effective in reducing the frequency of daily anginal episodes, but in the subgroup with angina only at rest, diltiazem was efficacious whereas propranolol was not.

There is little rigorous evidence for the value of verapamil in unstable angina. Small placebo-controlled trials[105,106] demonstrated statistically significant reductions in the frequency of ischemia. Long-term follow up in these small trials[107] showed that in general ischemic pain continued to be well controlled but there was a high incidence of AMI and death.

In addition to reducing ischemic episodes, a reduction in MI would be desirable. Yusuf *et al*[108] examined five trials involving about 4700 patients with threatened MI who were placed on intravenous β blocker followed by oral therapy for about a week. There was a modest 13% reduction in the risk of development of MI in this group. Meta-analysis of studies of calcium antagonists among patients with unstable angina shows no reduction of death or non-fatal MI.[108] Diltiazem and verapamil appear to be effective as initial single agents in the management of unstable angina, and diltiazem appears to be no different in efficacy from propranolol in one direct comparison. However, the meta-analytic data for benefit of β blocker but not calcium antagonists and the evidence for improved long-term outcomes with β blocker therapy among survivors of myocardial infarction,[108] and those with chronic ischemia, support β blockers over rate-limiting calcium antagonists as the first choice therapy in patients with unstable angina. **Grade A** Patients at high risk may have benefit from initial intravenous β blocker, followed by an oral regimen. **Grade C** Diltiazem or verapamil are suitable alternatives for patients with a contraindication to β blocker therapy. **Grade B** Nifedipine should not be the initial single agent for patients with unstable angina.[98] **Grade A** The new dihydropyridines have not been evaluated in patients with an acute coronary syndrome. Nicorandil, an ATP sensitive potassium (K^+) channel opener with arterial and venous vasodilator properties and cardioprotective potential by pharmacologic preconditioning, was shown in one small trial of 188 patients to reduce the number of transient ischemic episodes on continuous Holter monitoring.[109] Nicorandil is not approved for use in North America.

Among patients with variant angina, characterized by recurrent ischemic episodes occurring mainly at rest and in the early morning hours accompanied by transient ST-segment elevation, randomized placebo-controlled, double-blind trials of verapamil,[110–112] diltiazem,[113–116] and nifedipine[117–119] have demonstrated the efficacy of each of these agents in reduction of angina frequency. Several comparisons of calcium antagonists to β blockers have demonstrated greater efficacy with the calcium antagonists.[111,112,116] These agents are regarded along with nitrates as the therapy of choice for variant angina, although there is little direct comparative data with long-acting nitrates. **Grade A**

Antithrombotic therapy

Antithrombotic therapy is cornerstone therapy in ACS. It prevents death or myocardial infarction in patients managed medically and in patients undergoing a reperfusion procedure. Optimal benefit is obtained with combined inhibition of platelets and of the coagulation process. Thrombolytic therapy is beneficial in ST-segment elevation MI but contraindicated in non-ST-segment elevation MI.[120]

Antiplatelet therapy – Whereas aspirin has long been, and is still, the gold standard of antiplatelet therapy, a new armamentarium of agents acting on different platelet functions has

been developed. Physicians now have options in drug selection used in mono- or poly-therapy. Antiplatelet agents evaluated in ACS have been aspirin, dipyridamole, prostacyclin, sulfinpyrazone, inhibitors of thromboxane synthase and/or its receptor, ticlopidine, clopidogrel, and the intravenous and oral Gp IIb/IIIa antagonists. The various drugs can be classified first by their site of action on the main steps of platelet function from adhesion to activation and aggregation, and secondarily by their specific effects at each step (Figure 30.10). Adhesion can be inhibited by agents under development acting mainly on von Willebrand factor and its ligand, Gp 1b/IX. Activation can be inhibited by agents acting on intracellular calcium mobilization such as dypiridamole, which prevents catabolism of cAMP and nitric oxide, which promotes production of cGMP, and by agents inhibiting specific activation pathways. Aspirin blocks the thromboxane pathway and ADP-receptor antagonists block purinergic receptors on platelets. Gp IIb/IIIa antagonists occupy the receptor to prevent fibrinogen binding and platelet aggregation.

Aspirin – Four conclusive trials have shown consistent benefit with aspirin in patients with non-ST-segment elevation ACS, despite different study designs and different doses. The Veterans Administration Study, performed between 1974 and 1981, included 1338 men with unstable angina randomly allocated within 72 hours of admission to ASA 324 mg or placebo.[121] The rate of death or myocardial infarction was reduced from 10·1% to 5·0% (RR 49%, $P = 0{\cdot}0005$) over a 12 week treatment period.

In the Canadian Multicenter Trial conducted between 1979 and 1984, 555 patients (73% men) with unstable angina were randomized before hospital discharge to aspirin (325 mg four times daily), sulfinpyrazone (200 mg four times daily), placebo, or both drugs.[122] The outcome of death or myocardial infarction at 2 years was reduced from 17% to 8·6% (RR 49·2%; $P = 0{\cdot}008$) by efficacy analysis and by 30% ($P = 0{\cdot}072$) by intention-to-treat analysis, and the outcome of death was reduced by 71% ($P = 0{\cdot}004$) and 43·4% ($P = 0{\cdot}035$) respectively. Sulfinpyrazone had no

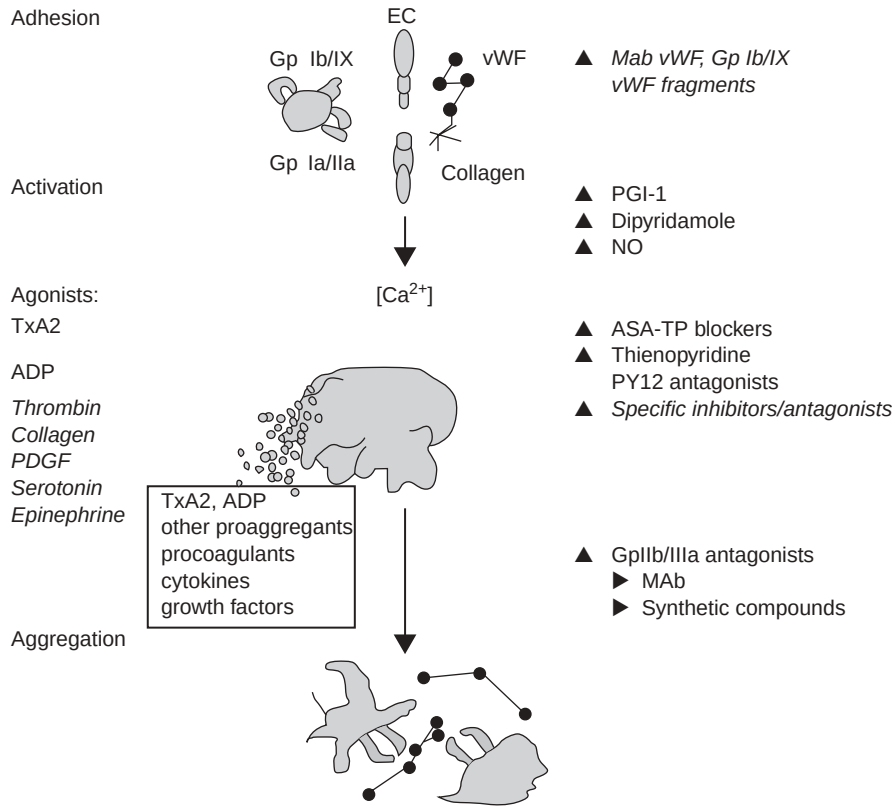

Figure 30.10 Mechanisms of platelet adhesion, secretion and aggregation, and sites of action of various antiplatelet drugs. The drugs approved for clinical use are in bold and the drugs under development in italics. Adhesion to the damaged endothelium and other agonists triggers intracellular signaling with an increase in cytosolic free calcium content (Ca^{2+}), shape change, and release of numerous proaggregants, procoagulants, growth factors, and inflammatory mediators. The GP IIb/IIIa receptors undergo conformational changes making them competent to cross-link fibrinogen to form platelet aggregates and the platelet thrombus. ADP, adenosine diphosphate; ASA, aspirin; Mab, monoclonal antibody; PDGF, platelet derived growth factor; PGI_1, prostacyclin; TP, thromboxane receptor; TxA2, thromboxane A2; vWF, von Willebrand factor. significant effect or interaction with aspirin. In the Montreal study, 479 patients were randomized during the acute phase of disease to aspirin (325 mg bid), heparin, both or neither in a 2×2 factorial design.[32] Aspirin reduced the risk of death or myocardial infarction at 6 days from 6·3% to 2·6%, a 63% risk reduction ($P = 0{\cdot}04$). The RISC study randomized 945 patients to aspirin (80 mg daily), intravenous heparin, both or placebos.[31] End points were assessed in 796 patients meeting the entry criteria. Aspirin, compared to no aspirin, reduced the rate of death or MI at 5 days from 5·8% to 2·6% ($P = 0{\cdot}033$), at 7 days from 13·4% to 4·3% ($P = 0{\cdot}0001$), and at 30 days from 17·1% to 6·5% ($P = 0{\cdot}0001$).

The Antiplatelet Trialists' Collaboration updated their initial meta-analysis by including 287 studies involving 135 000 patients administered antiplatelet therapy versus control and 77 000 patients randomized to different antiplatelet regimens.[123] Overall, among high-risk patients, allocation to antiplatelet therapy reduced the outcome of any serious vascular event by 25%, non-fatal MI by 33%, non-fatal stroke by 25%, and vascular mortality by 16%. Aspirin was the most widely studied antiplatelet drug. The absolute benefit of aspirin increases with the inherent risk of the condition for which it is prescribed, and is substantial in patients with a non-ST-segment elevation ACS, as illustrated in Figure 30.11.[124] Aspirin has numerous physiologic effects on platelets and the inflammatory process, many of which are only partly characterized. The mechanism accounting for the benefit in ACS is believed to be the irreversible inhibition of cyclo-oxygenase-1 (COX-1) in platelets, blocking formation of thromboxane A2; the doses of 75–160 mg daily that have been shown to be at least as clinically effective as higher doses are quite specific for this effect.[123] This inhibition is dose-related, cumulative and irreversible. A loading dose of 160–365 mg is recommended followed by doses of 80–160 mg daily. **Grade A** Higher doses have anti-inflammatory effects and inhibit cyclo-oxygenase-2 (COX-2). COX-2 is not constitutive and is expressed in endothelial cells and white cells in response to an inflammatory stimulus. It is inhibited selectively by the coxibs and less selectively by the non-steroidal anti-inflammatory drugs (NSAIDs). The term aspirin resistance is increasingly used to describe failure of aspirin to prevent events in some patients. Laboratory data suggest that there is a non-optimal biologic response in about 30% of patients.[125,126] Practical reasons for the failure of aspirin are non-compliance to therapy and intake of NSAIDs prior to aspirin. NSAIDS, and typically ibuprofen, flurbiprofen, indomethacin, and suprofen, bind COX-1 on the same serine residue as aspirin to mask the active site; the biologic actions of aspirin are therefore prevented when these NSAIDS are present in blood, an effect that is favored by the short plasma half life of aspirin.[127] Other reasons for aspirin failure could be individual variations in metabolism

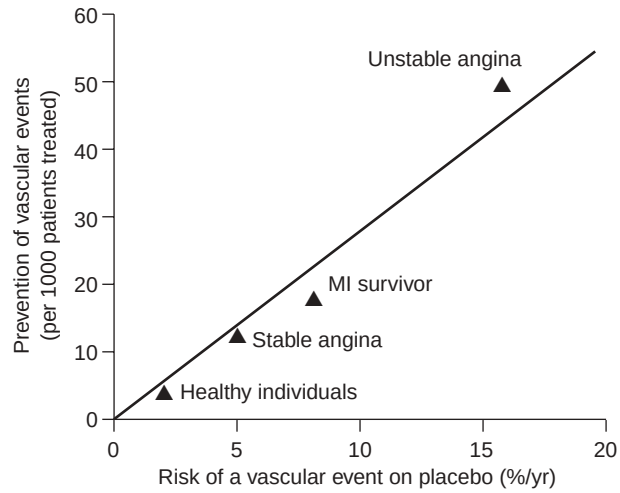

Figure 30.11 Benefits of aspirin by risk groups. The absolute risk of vascular complications is the major determinant of the absolute benefit of antiplatelet prophylaxis. Data are plotted from placebo-controlled aspirin trials in different clinical settings. For each category of patients, the abscissa denotes the absolute risk of experiencing a major vascular event as recorded in the placebo arms of the trials. The absolute benefit of antiplatelet treatment is reported on the ordinate axis as the number of subjects in whom an important vascular event (that is, non-fatal MI, non-fatal stroke, or vascular death) is actually prevented by treating 1000 subjects with aspirin for 1 year. Reproduced with permission from Patrono *et al.*[124]

of low doses of aspirin possibly influenced by genetic polymorphism, thromboxane A2 independent pathways of thrombus formation, generation of thromboxane A2 by COX-2, and agonists of thromboxane receptors other than thromboxane A2, such as the isoprostanes which are non-enzymatically derived products of arachidonic acid.[128] The diagnosis of aspirin resistance is based on clinical suspicion as no single test has so far been prospectively and reproducibly validated. Since an alternative therapy to aspirin exists with drugs that have been shown to be at least as useful as aspirin, aspirin monotherapy should be questioned in patients clinically suspected of aspirin resistance because of recurrent ischemic events occurring on aspirin therapy. **Grade B**

Other agents acting on the cyclo-oxygenase pathway – The inhibition of prostacyclin (PGI_2) generation by aspirin does not appear to limit its protective effects significantly. Nevertheless, it was shown that an infusion of prostacyclin in unstable angina patients resulted in no benefit.[129] Analogs of PGI_1 that are more stable and that have less hemodynamic effects are now being investigated in various situations. The thromboxane synthase inhibitors and/or receptor antagonists investigated so far were not shown to be superior or

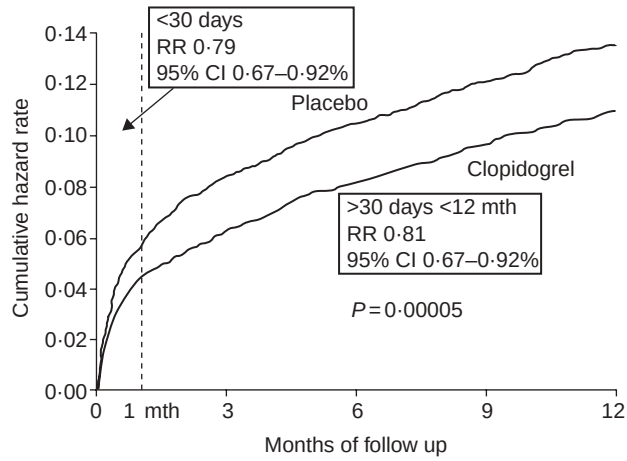
inferior to aspirin. S18886 is a new agent under clinical investigation, which blocks the thromboxane (TP) receptor and has favorable pharmacokinetic and pharmacodynamic profiles. Experimental data have suggested that the drug could be protective against progression of atherosclerosis.[130]

ADP receptor antagonists

The thienopyridines ticlopidine and clopidogrel are the two ADP receptor antagonists currently approved. Clopidogrel has replaced ticlopidine as it is devoid of the serious life-threatening adverse effects of leukopenia and thrombocytopenia found with ticlopidine. Clopidogrel is also more potent than ticlopidine and can be safely administered in loading doses to achieve full drug effects approximately 2 hours after the administration of a bolus dose of 300 mg. Clopidogrel effects are dose-related, cumulative, and irreversible, as are those of aspirin. Placebo-controlled trials with ticlopidine in unstable angina and in the secondary prevention of stroke have documented risk reductions in the range of those observed with aspirin.[131] One direct comparison trial has shown superiority of ticlopidine over aspirin in the secondary prevention of stroke.[132] Many trials in coronary stenting have confirmed the greater efficacy and safety of clopidogrel.[133]

Clopidogrel was evaluated in two large trials, in one as single therapy,[134] and in the other as combined therapy with aspirin versus aspirin alone.[135] In the CAPRIE trial, a total of 19 185 patients with atherosclerotic vascular disease manifested as recent ischemic stroke, recent myocardial infarction, or symptomatic peripheral vascular disease were randomized to aspirin, 325 mg/day, or clopidogrel, 75 mg/day.[134] The annual risk of ischemic stroke, myocardial infarction, or vascular death during a follow up of 1–3 years was reduced by 8·7% from 5·83% to 5·32% by clopidogrel ($P = 0{\cdot}043$). The risk reductions (RR) were, however, heterogeneous among the entry groups: 23·8% ($P = 0{\cdot}00028$) in patients enrolled because of peripheral vascular disease, 7·3% in patients enrolled because of stroke, and an excess of 5·03% ($P = 0{\cdot}66$) in patients enrolled because of a myocardial infarction.

In the CURE trial, 12 562 patients were randomized within 24 hours after the onset of a non-ST-segment elevation ACS to receive clopidogrel (300 mg bolus, 75 mg daily) or placebo in addition to aspirin 160–360 mg daily for 3–12 months. The primary composite outcome of cardiovascular death, non-fatal MI, or stroke occurred in 9·3% of patients in the clopidogrel group and 11·4% of patients in the placebo group (RR 0·80; 95% CI 0·72–0·90; $P < 0{\cdot}001$) (Figure 30.12).[136] Clopidogrel further reduced the rates of inhospital severe ischemia and of revascularization, the need for thrombolytic therapy or intravenous Gp IIb/IIIa-receptor antagonists, and the occurrence of heart failure. The benefits became apparent within a few hours of treatment initiation and increased throughout the follow up period to one year. These benefits were homogeneous among all secondary end points, subgroup analyses, and patients at low, medium, and high risk, enhancing the clinical relevance of the trial. Thus even patients with no ST-segment depression and patients with no elevation of cardiac markers benefit, contrasting with the benefits of enoxaparin and the Gp IIb/IIIa antagonists which are apparent only in high-risk patients. There were significantly more patients with major bleeding in the clopidogrel group than in the placebo group (3·7% *v* 2·7%; RR 1·38; $P = 0{\cdot}001$), but there was no excess in life-threatening bleeding (2·2% *v* 1·8%; $P = 0{\cdot}13$) or hemorrhagic stroke (0·1% *v* 0·1%). The risk of major bleeding was particularly increased in patients undergoing CABG surgery within the first 5 days of stopping clopidogrel (9·6% *v* 6·3%, RR 1·53; $P = 0{\cdot}06$) but not when CABG was performed after 5 days (4·4% *v* 5·3% with placebo). The CURE trial was mainly aimed at medical management, although revascularization was performed during the initial admission in 23% of the patients, among whom there was a benefit of clopidogrel. A benefit of clopidogrel was also noted in patients who received thrombolytic therapy or a Gp IIb/IIIa antagonist, but these drugs were administered in only 1·1% and 5·9% of patients respectively.



Placebo	6303	5780	4664	3600	2388
Clopidogrel	6259	5866	4779	3644	2418

Figure 30.12 Cumulative hazard rates for the outcome of cardiovascular death, non-fatal myocardial infarction, or stroke during the 12 months of the CURE study with the use of clopidogrel versus placebo on a background of aspirin in all patients. The results demonstrate sustained benefit of clopidogrel from the time of randomization through to the end of the study. Reproduced with permission from The CURE Investigators.[136]

Gp IIb/IIIA-receptor blockers – Three Gp IIb/IIIa antagonists are approved for clinical use: abciximab, eptifibatide,

and tirofiban. Clinical trials failed to show a benefit of lamifiban, a synthetic Gp IIb/IIIa antagonist with properties similar to those of eptifibatide and tirofiban.[37,137] Abciximab is a Fab fragment of a chimeric monoclonal antibody that binds the RGD and dodecapeptide recognition sequences of the receptor. The plasma half life of the drug is approximately 10 minutes but the biologic half life extends to 6–12 hours. Abciximab has strong affinity for the receptor and receptor occupancy persists weeks after drug exposure, although platelet aggregation progressively returns to normal within 12–24 hours. Abciximab is not specific for the Gp IIb/IIIa integrin, also inhibiting the vitronectin receptor ($\alpha v\beta 3$) on the endothelium and smooth muscle cell and the MAC-1 ($\alpha m\beta 2$) integrin on neutrophils and monocytes. The clinical relevance of occupancy of these receptors involved in cell proliferation and leukocyte activation respectively remains ill defined. Eptifibatide is a cyclic heptapeptide derived from the structure of barbourin in the venom of the pigmy rattlesnake possessing a KGD sequence recognized by the receptor. Tirofiban is a non-peptide mimetic of the RGD sequence. The half life of the two small molecules is approximately 2 hours. After drug discontinuation, there is 50% recovery of receptor occupancy and platelet aggregation within 4 hours and nearly 100% within 8 hours. These drugs have no special affinity for the receptor and receptor occupancy parallels blood levels. Many trials have documented the efficacy of abciximab in reducing periprocedural MI and the need for urgent revascularization when it is administered in the cardiac catheterization laboratory before a revascularization procedure and continued for 12 hours thereafter.[138,139] In the c7E3 Fab Antiplatelet Therapy in Unstable Refractory angina (CAPTURE)[140] trial involving 1265 patients with refractory unstable angina, abciximab was administered after a first angiogram identifying a culprit lesion suitable for coronary angioplasty. The procedures were performed 20–24 hours later and abciximab was continued for one hour after the procedure.[140] Abciximab, compared with placebo, reduced the rate of death and myocardial infarction by 30 days from 15·9% to 11·3% ($P = 0{\cdot}012$). In a comparison trial, abciximab was shown to be significantly superior to tirofiban in preventing complications associated with urgent or elective stent placement.[141] The doses of tirofiban used in this study had previously been shown to be ineffective.[142] Contrasting with the benefits observed in percutaneous intervention and in stent implantation trials, the GUSTO-IV trial failed to show a benefit of abciximab in the medical management of patients with a non-ST-segment elevation ACS. In this trial, 7800 patients with chest pain and either ST-segment depression or raised troponin T or I concentrations were randomly assigned placebo, an abciximab bolus and 24 h infusion, or an abciximab bolus and 48 h infusion.[42] The primary outcome of death or myocardial infarction 30 days after randomization occurred in 8·0% of patients on placebo, 8·2% of patients on 24 h abciximab, and 9·1% of patients on 48 h abciximab (OR 1·0 between placebo and 24 h abciximab, and 1·1 (95% CI 0·94–1·39) for difference between placebo and 48 h abciximab). The lack of benefit with abciximab was consistent in most subgroups investigated including, remarkably, patients with elevated troponin T or I, although they were at a high risk of subsequent events.

Tirofiban was investigated in two ACS trials. In one, tirofiban alone with placebo heparin versus heparin with placebo tirofiban was associated with an early benefit at 72 hours, a benefit that was not, however, sustained after 30 days.[35] The second trial compared the combination of tirofiban with heparin to heparin alone. The combination reduced the occurrence of the primary end point of death, myocardial infarction, or refractory ischemia at 7 days by 32% ($P = 0{\cdot}004$) and of death or myocardial infarction by 43% ($P = 0{\cdot}006$).[36] The gain appeared early and was sustained after 6 months.

Many trials were performed with eptifibatide. In the PURSUIT trial, 9461 patients with a non-ST-segment elevation ACS were randomized to eptifibatide or placebo; the rate of death or myocardial infarction after 30 days was reduced by 10% with eptifibatide (14·2% *v* 15·7%, $P = 0{\cdot}042$).[39] In the placebo-controlled ESPRIT trial, eptifibatide used at higher doses and with a double bolus injection significantly reduced the event rate associated with coronary stenting to an extent similar to that observed with abciximab.[143]

Altogether, these trials show efficacy of abciximab and eptifibatide in reducing event rates in percutaneous coronary interventions and of tirofiban and eptifibatide in non-ST-segment elevation ACS. The benefits were additive to those of aspirin and of heparin. **Grade A**

Several meta-analyses demonstrated a benefit of intravenous Gp IIb/IIIa antagonist therapy in patients with an ACS. One meta-analysis published in 1999, before the confounding results of GUSTO-IV were known and including the data from the CAPTURE, PURSUIT, and PRISM-PLUS trials, showed event rates of 2·5% with treatment and 3·8% with placebo during the period of medical management and of 4·9% and 8·0% respectively in the 48 hours that followed PCI in the subgroups of patients who underwent a procedure (RR reduction 34%, $P < 0{\cdot}001$). An early benefit of Gp IIb/IIIa inhibitors during medical treatment was documented, and a larger benefit when PCI was performed on drug therapy.[144] A second meta-analysis with data on individual patients included trials, which enrolled at least 1000 patients and did not recommend early coronary revascularization (this criterion did not apply in PRISM-PLUS).[36,145] Among 31 402 patients from six trials, including GUSTO-IV, the Gp IIb/IIIa antagonists reduced the odds of death or MI at 30 days by 9% (10·8% *v* 11·8%; OR 0·91; 95% CI 0·84–0·98; $P = 0{\cdot}015$). The relative treatment benefit was largest in high-risk patients. Benefit was present in both males and females when the baseline troponin levels were elevated but only in males when normal.

A third meta-analysis examined more specifically the 6458 diabetic patients enrolled in the six trials. In these patients,

the Gp IIb/IIIa inhibitors reduced the mortality at 30 days from 6·2% to 4·6% (OR 0·74; 95% CI 0·59–0·92; $P < 0·007$) with a statistically significant interaction between treatment and diabetic status ($P = 0·036$). Mortality at 30 days among the 1279 who underwent PCI was reduced from 4·0% to 1·2% (OR 0·30; 95% CI 0·14–0·69; $P < 0·002$).[146]

Puzzling observations with the use of Gp IIb/IIIa antagonists include the absence of benefit in patients with prolonged use of abciximab not referred for invasive management, the failure of lamifiban to show a significant benefit, and, as will be seen below, the excess mortality observed with the prolonged use of orally active agents.

Oral Gp IIb/IIIa antagonists – In an attempt to extend the benefit of intravenous Gp IIb/IIIa antagonists to the subacute and chronic phases of the disease, orally active inhibitors were developed. Four different agents – xemilofiban, orbofiban, sibrafiban and latrofiban – were investigated in five large trials. These agents have rapid on and off binding to the receptor. No single trial showed a benefit in reducing ischemic events and two were prematurely interrupted because of excess mortality. A meta-analysis of four of these trials totaling 33 326 patients showed a statistically significant increase in mortality with therapy (OR 1·37; $P = 0·001$) and trends to more MI. There was a twofold increase in the rate of major bleeding and a high rate of less severe bleeding leading to study drug discontinuation.[147]

Anticoagulants

Anticoagulants evaluated during the acute phase of non-ST-segment elevation ACS have been unfractionated heparin, direct thrombin inhibitors including recombinant hirudin and small molecules, and the low molecular weight heparins. New and promising agents such as r-tissue factor pathway inhibitor, r-protein C, and pentasaccharide and other specific inhibitors of factor Xa are under investigation (Figure 30.13). Documentation of reactivation of the disease

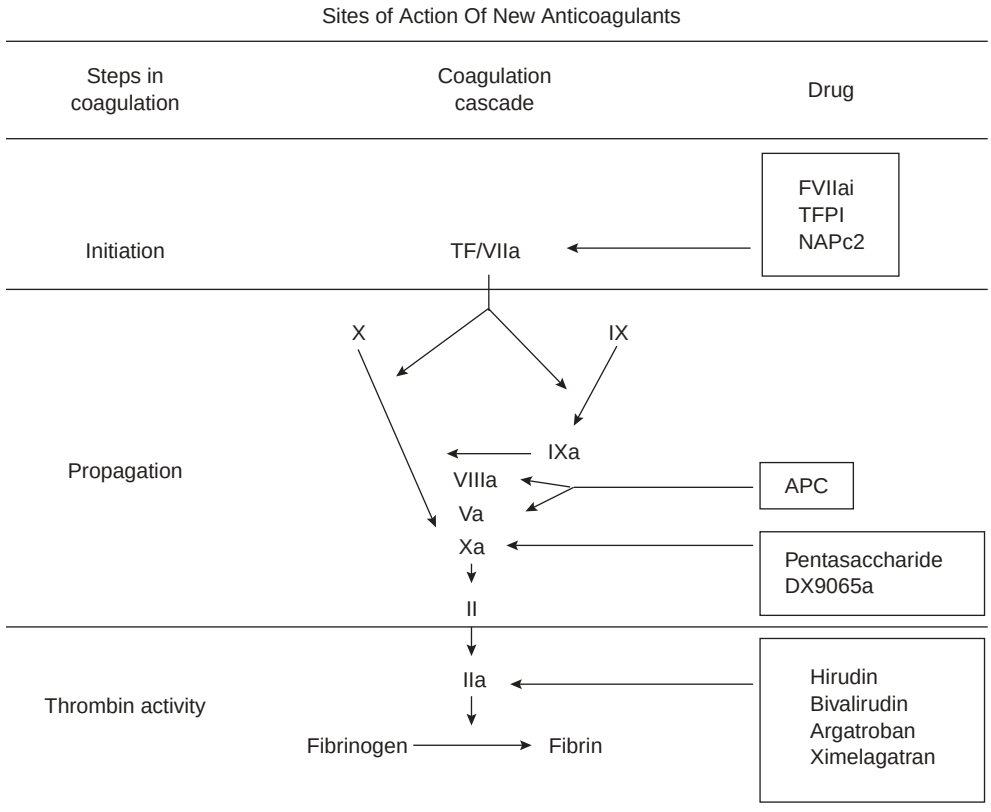


Figure 30.13 The coagulation cascade and sites of action of new anticoagulants. Initiation of coagulation is triggered by the tissue factor/factor VIIa complex (TF/VIIa), which activates factor IX (IX) and factor X (X). Activated factor IX (IXa) propagates coagulation by activating factor X in a reaction that utilizes activated factor VIII (VIIIa) as a cofactor. Activated factor X (Xa), with activated factor V (Va) as a cofactor, converts prothrombin (II) to thrombin (IIa). Thrombin then converts fibrinogen to fibrin. Active site-blocked VIIa (VIIai) competes with VIIa for TF, whereas tissue factor pathway inhibitor (TFPI) and nematode anticoagulant peptide (NAPc2) target VIIa bound to TF. Synthetic pentasaccharide and DX-9065a inactivate Xa, activated protein C (APC) inactivates Va and VIIIa, and hirudin, bivalirudin, argatroban, and ximelagatran target thrombin. Reproduced with permission from Weitz and Buller.[154]

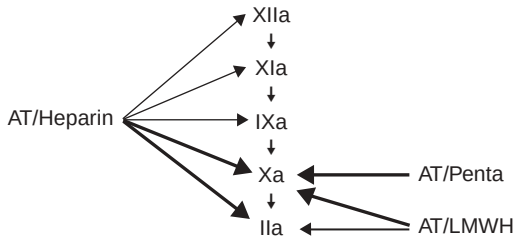

Figure 30.14 Antithrombin (AT)-mediated inhibition of coagulation factors. The complex heparin/AT inhibits especially factor Xa and thrombin (IIa) and also factor XIIa, factor XIa, and factor IXa. The shorter saccharide chains contained in the low molecular weight heparins (LMWH) allow more selective inhibition of factor Xa than factor IIa. The unique pentasaccharide chain of fondaparinux allows highly specific inhibition of factor Xa. Adapted with permission from Hirsh *et al*.[149]

following the discontinuation of heparin[148] and persisting prothrombotic activity past the acute phase have led to the evaluation of long-term therapy with coumadin and the low molecular weight heparins.

Unfractionated and low molecular weight heparins – Unfractionated heparin, low molecular weight heparins, and the heparin pentasaccharide inhibit coagulation factors by greatly enhancing the physiologic properties of circulating antithrombin, with differential effects on factor Xa and thrombin related to the molecular weight of the various heparins (Figure 30.14).[149] In the study by Theroux *et al* of 479 patients, the incidence of fatal and non-fatal myocardial infarction was reduced from 7·5% to 1·2% (RR 85%; $P = 0{\cdot}007$) with unfractionated heparin compared with placebo, and of recurrent refractory ischemia from 19·7% to 9·6% (RR 51%; $P = 0{\cdot}02$).[32] In the RISC study, which enrolled 945 men, the combination of aspirin and heparin resulted in a significant risk reduction in death and myocardial infarction at 5 days.[31] In the FRISC study, 1506 patients were randomized to subcutaneous dalteparin twice daily for 6 days followed by once a day for 35–45 days or placebo.[150] During the first 6 days the rate of death or MI was reduced with dalteparin (1·8% *v* 4·8%; RR = 0·37; 95% CI 0·20–0·68). Survival analysis showed a risk of reactivation and re-infarction when the dose was decreased; the benefit persisted at 40 days but not at 4–5 months.[150] A meta-analysis of 12 trials that compared unfractionated heparin or a low molecular weight heparin to placebo in a total of 17 157 patients showed an odds ratio for myocardial infarction or death during the short term (up to 7 days) of 0·53 (95% CI 0·38–0·73; $P = 0{\cdot}0001$) in favor of the anticoagulant. These results validate the use of unfractionated heparin or of a low molecular weight heparin in combination with aspirin in patients with a non-ST-segment elevation ACS. **Grade A**

Low molecular weight heparins present distinct advantages over unfractionated heparin. They can be administered subcutaneously once or twice a day. They bind plasma proteins and endothelial cells less avidly than unfractionated heparin resulting in more predictable anticoagulation, with no need for monitoring. The ratio of inhibition factor Xa/thrombin is greater. Low molecular weight heparins also stimulate platelets less and are less often associated with heparin-induced thrombocytopenia.

Four trials have directly compared a low molecular weight heparin with unfractionated heparin. No advantages were observed with dalteparin in a trial involving 1482 patients[151] and with nadroparin in a trial of 3468 patients.[152] Enoxaparin was shown to be superior to unfractionated heparin in the two trials that evaluated the drug. In the ESSENCE trial, enoxaparin, 1 mg/kg administered twice daily for 48 hours to 8 days (median 2·6 days) in 3171 patients, reduced the composite outcome of death, MI or recurrent angina by 16·2% at 14 days (16·6% *v* 19·8%; $P = 0{\cdot}019$), and by 19% at 30 days (19·8% *v* 23·3%; $P = 0{\cdot}017$) compared to unfractionated heparin. The rate of death was unaffected, but the rate of myocardial infarction was reduced by 29% (3·2% *v* 4·5%; $P = 0{\cdot}06$) at 14 days, and by 26% (3·9% *v* 5·2%) at 30 days ($P = 0{\cdot}08$).[34] The TIMI-11B trial showed in 3910 patients a reduction in the composite outcome of death, myocardial infarction or refractory ischemia requiring an urgent revascularization from 16·6% to 14·2% at 14 days ($P = 0{\cdot}04$) and from 19·6% to 17·3% at 43 days ($P = 0{\cdot}06$).[41] A meta-analysis of trials that directly compared any low molecular weight heparin to unfractionated heparin showed no statistically significant difference in the odds of death or MI (OR 0·88; 95% CI 0·69–1·12; $P = 0{\cdot}34$). On the other hand, a combined analysis of the data from ESSENCE and TIMI-11B showed a statistically significant reduction in the rate of death or myocardial infarction in favor of enoxaparin.[153]

The pentasaccharide binds antithrombin to inhibit factor Xa with high specificity. It does not produce thrombocytopenia. The drug is now approved for the prevention of deep vein thrombosis in orthopedic surgery and is under investigation in ST-segment elevation and non-ST-segment elevation acute coronary syndromes.

Direct thrombin inhibitors – These drugs are potent anticoagulants that specifically inhibit thrombin (Figure 30.13); they require a cofactor for their effects and have a highly predictable response. Hirudin, now produced by recombinant technology, is the prototype of these agents. Various other inhibitors have been synthesized with different binding properties to the active site and substrate-binding site of thrombin that affect their relative potency and bleeding risk.[154]

Hirudin tightly binds the active and substrate-binding sites of thrombin. The drug has been investigated in four major trials. The dose regimen of 0·6 mg/kg bolus followed

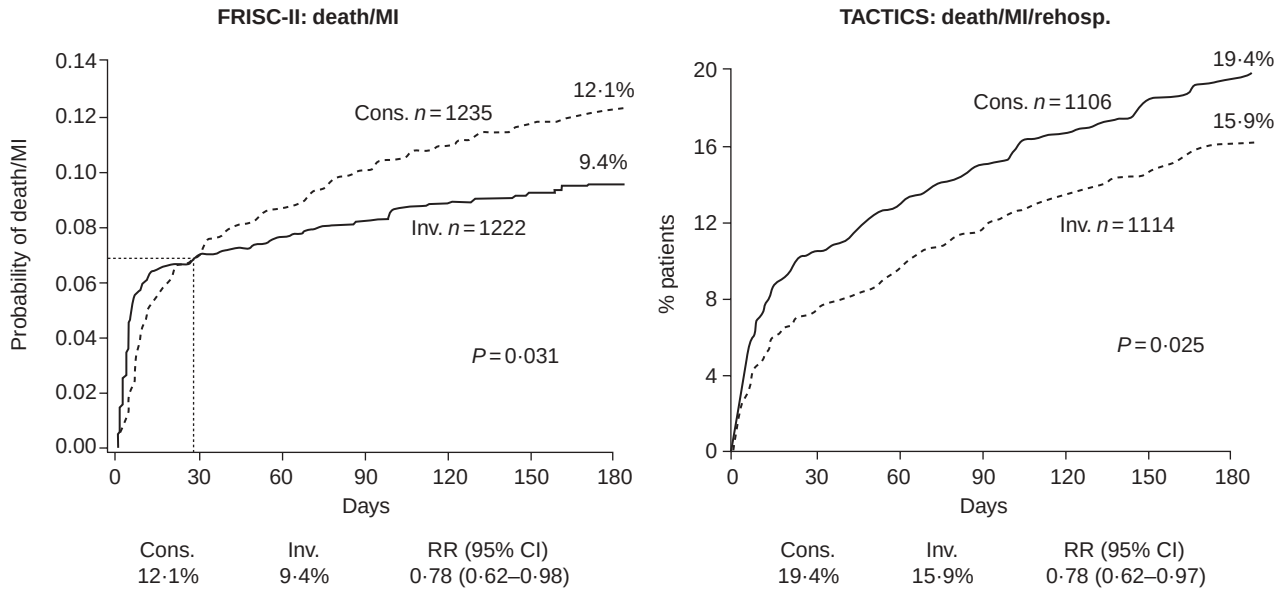

Figure 30.15 Invasive versus non-invasive management of non-ST-segment elevation ACS. Results of the two most recent trials that have compared an early routine invasive management strategy to an early routine medical management strategy. The intervention was performed relatively late in the FRISC-II study after a course of treatment with aspirin and dalteparin and relatively early after a median of 22 hours in TACTICS on treatment with aspirin, heparin, and tirofiban. The two trials show a definitive gain with the early invasive approach in patients with high-risk features as documented by ST-segment shifts and/or an elevation of cardiac markers. Adapted with permission from the FRISC-II Investigators[43] and Cannon *et al.*[44]

by 0·2 mg/kg/hour infusion initially evaluated had to be dropped because of excess bleeding.[155] A dose of 0·2 mg/kg bolus with infusion of 0·1 mg/kg/hour was used in the GUSTO-IIb, which enrolled 12 142 patients, two thirds of them with a non-ST-segment elevation ACS and one third with ST-segment elevation MI,[33] and in the TIMI-9B trial, which enrolled 3002 patients with ST-segment elevation MI.[156] Among patients with no ST-segment elevation in GUSTO-IIb, the composite end point of death or MI at 30 days occurred in 8·3% of the patients on hirudin and in 9·1% of patients on heparin (OR 0·90; 95% CI 0·78–1·06; $P = 0·22$); at 24 h, the risk of death or MI was significantly lower in the patients who received hirudin (2·1% *v* 1·3%; $P = 0·001$). The OASIS pilot study suggested a greater benefit with an intermediate dose of 0·4 mg/kg bolus and 0·15 mg/kg/hour infusion.[157] This dose was used in the large OASIS-2 trial, which randomized 10 141 patients to UFH (5000 IU bolus plus 15 U/kg/h) or recombinant hirudin for 72 h.[40] The primary end point of cardiovascular death or new MI at 7 days was reduced with hirudin from 4·2% to 3·6% ($P = 0·064$); there was an excess of major bleeds requiring transfusions (1·2% *v* 0·7%; $P = 0·014$). A meta-analysis of the GUSTO-IIb, TIMI-9B, OASIS pilot and OASIS-2 showed that the risk of death or MI at 35 days was significantly reduced with hirudin compared with heparin (RR 0·90; $P = 0·015$).[40]

Bivalirudin, argatroban, efegatran, and inogatran have been evaluated in smaller trials in acute coronary syndromes and in coronary angioplasty. A meta-analysis of 35 970 patients in 11 trials, including the hirudin trials, showed an overall reduction in the risk of death or MI at the end of the treatment period with the direct antithrombin (4·3% *v* 5·1%; OR 0·85; 95% CI 0·77–0·94; $P = 0·001$) and after 30 days (7·4% *v* 8·2%; OR 0·91; 95% CI 0·84–0·99; $P = 0·02$).[158] The benefit was, however, restricted to hirudin and bivalirudin, the two agents inhibiting the two active sites of thrombin, and was not present with agents inhibiting only the catalytic or exosite binding site of thrombin. Hirudin increased the risk of major bleeding compared with heparin but bivalirudin reduced it.[158] Hirudin, bivalirudin, and argatroban are approved for use in patients with heparin-induced thrombocytopenia. Hirudin is also approved for the prevention of deep vein thrombosis in patients undergoing orthopedic surgery and bivalirudin for use in percutaneous interventions.

Long-term anticoagulation – Prolonged administration of low molecular weight heparins and of warfarin has been evaluated to prolong the benefit of anticoagulants past the acute phase and prevent reactivation of the disease. In the ATACS trial, 214 patients were randomized to ASA alone or the combination of ASA plus UFH followed by warfarin. At 14 days, there was a reduction in the composite outcome of death, MI, and recurrent ischemia with the combination therapy (27·0% *v* 10·5%; $P = 0·004$). In a small randomized pilot study of 57 patients allocated to warfarin or placebo in

addition to ASA, there was less progression and more regression in the severity of the culprit lesion after a few weeks of treatment with warfarin. The OASIS pilot study[157] compared a fixed dosage of 3 mg of warfarin with a moderate dose titrated to an international normalized ratio (INR) of 2 to 2·5 administered for 7 months. Low-intensity warfarin had no benefit, whereas the moderate-intensity regimen reduced the risk of death, MI, or refractory angina by 58% and the need for rehospitalization for unstable angina by 58%. These results were not reproduced in the larger OASIS-2 trial[40] which randomized 3712 patients to the moderate-intensity regimen. The rate of cardiovascular death, MI, or stroke after 5 months was 7·65% with the anticoagulant and 8·4% without ($P = 0·37$). The authors suggested that poor compliance with treatment in some countries could have explained the negative results. A meta-analysis of 30 randomized studies published between 1960 and July 1999 among patients with CAD showed that high-intensity and moderate-intensity anticoagulation were effective in reducing MI and stroke but increased the risk of bleeding. In the presence of aspirin, low-intensity anticoagulation was not superior to aspirin alone, while moderate- to high-intensity anticoagulation and aspirin versus aspirin alone appeared promising with a modest increase in bleeding risk.[159]

A meta-analysis of prolonged use of low molecular weight heparin for up to 3 months after hospital discharge showed no consistent benefit (OR 0·98; 95% CI 0·81–1·17; $P = 0·80$) but an excess risk of major bleeding (OR 2·26; 95% CI 1·63–3·14; $P < 0·0001$).[160] In FRISC-II, dalteparin was administrated double-blind for 3 months following 5 days of open label administration. A significant reduction in rates of death, MI, and revascularization was observed after 30 days (3·1% *v* 5·9%; RR 0·53; $P = 0·02$) and 3 months (29·1% *v* 33·4%; $P = 0·03$), which was not sustained at 6 months.[161]

Coronary reperfusion procedures

Reperfusion therapy is increasingly successful as expertise, adjunctive pharmacotherapies, and technology are improving. It is a common clinical experience that reperfusion is the only effective means to control the unstable patient. It has also been long recognized that interventions are associated with a higher risk of complications when performed early during an unstable coronary condition and which are attenuated when interventions can be delayed past a period of medical stabilization. This early hazard can now be minimized with the use of coronary stenting and of ticlopidine or clopidogrel, and of the Gp IIb/IIIa antagonists. Modern trials are comparing treatment strategies randomizing patients to an early invasive or an early conservative management strategy. In the early invasive approach, coronary angiography is routinely performed followed by revascularization with either PCI or CABG; the choice of procedures is governed by expert judgment. In the early non-invasive approach, coronary angiography is performed only when there is evidence of recurrent spontaneous ischemia or when the ischemia can be induced by a provocative test, the criteria for evaluation being more or less stringent. Earlier trials that had compared CABG to medical therapy failed to show a difference in mortality with the two treatment strategies but succeeded in identifying subgroups of patients with depressed ejection fraction and with three vessel disease that benefitted significantly from surgery. Short- and long-term quality of life was also generally improved with reperfusion, and crossovers from medical therapy to CABG were frequent.[162–164]

The results of four major recent trials and of a few smaller trials comparing early invasive management to early conservative management were reported. The TIMI-3b randomized 1473 patients. The primary outcome of death, MI or an unsatisfactory symptom-limited exercise stress test performed at 6 weeks occurred in 18·1% of patients assigned to the early conservative strategy and 16·2% of patients assigned to the early invasive strategy (NS). The average length of initial hospitalization, the incidence of rehospitalization within 6 weeks, and days of rehospitalization were all decreased in the early invasive group.[165]

In the VANQWISH trial, 920 patients with a NSTEMI on the basis of CK-MB elevation were randomized within 72 hours of admission. More patients in the early invasive group experienced inhospital death (21 *v* 6; $P = 0·007$) or a composite of death or MI (36 *v* 15; $P = 0·004$); statistically significant differences persisted at 1 year and a trend towards higher mortality was still observed at 2 years.[166] The results of this study were questioned on the basis of the high mortality associated with CABG; no mortality was seen with PCI.

The MATE trial assigned 201 ACS patients ineligible for thrombolytic therapy to triage angiography within 24 hours, or early conservative strategy. Follow up at a median of 21 months showed no significant difference in the cumulative incidence of death, MI, rehospitalization, or revascularization between the two groups.[167] In the VINO study, 131 patients were randomized to first day angiography/angioplasty or conservative strategy. Death by 6 months occurred in 3·1% of invasive patients versus 13·4% of conservative patients ($P < 0·03$) and non-fatal MI in 3·1% and 14·9% ($P < 0·02$) respectively.[168]

More recently, the FRISC-II study enrolled 2457 patients with chest pain within the previous 48 hours and ST or T wave changes or elevated troponin T or CK-MB.[43] All patients received dalteparin in addition to aspirin in the first 5 days and were thereafter randomized to placebo or continued dalteparin administration for 3 months. Coronary angiography was done within the first 7 days in 96% of patients in the invasive arm and in 10% in the non-invasive arm, and revascularization was performed within the first

10 days in 71% and 9% of patients respectively. After 6 months there was a decrease in the composite end point of death or MI in the invasive group (9·4% *v* 12·1%; RR 0·78; 95% CI 0·62–0·98; $P < 0·031$) (Figure 30.15). At 1 year the mortality rate in the invasive strategy group was 2·2% compared with 3·9% in the non-invasive strategy group ($P = 0·016$).[169] There was a heterogeneous effect of the invasive strategies, which provided greater advantages at older age, in men, and with longer duration of angina, chest pain at rest, and ST-segment depression or Troponin-T elevation. The frequencies of symptomatic angina and readmission were halved by the invasive strategy. It was concluded that patients who first received an average of 6 days of treatment with LMWH, ASA, nitrates, and β blockers have a better outcome at 6 months.

The TACTICS trial enrolled 2220 patients with non-ST-segment elevation ACS characterized by ST-T changes suggestive of ischemia or elevated levels of cardiac markers or a history of coronary artery disease.[44] All patients received aspirin, heparin, and tirofiban. In the invasive arm, routine coronary angiography was performed within 4 to 48 hours and revascularization as appropriate. The primary outcome of death, non-fatal MI, or rehospitalization for an acute coronary syndrome at 6 months was 15·9% with use of the early invasive strategy and 19·4% with use of the conservative strategy (OR 0·78; 95% CI 0·62–0·97; $P = 0·025$). The rate of death or non-fatal MI at 6 months was similarly reduced (7·3% *v* 9·5%; OR 0·74; 95% CI 0·54–1·00; $P < 0·05$) (Figure 30.15). As in the FRISC-II trial, the patients who benefitted were those at medium or high risk, as defined by an elevation of TnT greater than 0·01 ng/ml, the presence of ST-segment deviation, or a TIMI risk score of greater than 3. In the absence of these high-risk features, outcomes in patients assigned to the two strategies were similar. Women in the FRISC-II trial derived no benefit from invasive management.[48] They were older, yet had less severe CAD and a better prognosis compared with men. Such a gender difference was not present in the TACTICS trial,[48] suggesting that the differences were related to baseline risk. Rates of major bleeding were similar, and lengths of hospital stay were reduced in patients assigned to the invasive strategy.

Thus, the two most recent trials comparing invasive versus conservative strategies in patients with non-ST-segment elevation ACS showed a benefit in patients assigned to the invasive strategy using state-of-the-art pharmacologic therapy and stenting in the majority of cases. In FRISC-II, the invasive strategy involved treatment for an average of 6 days in the hospital with ASA and dalteparin. In TACTICS–TIMI-18, treatment included ASA, unfractionated heparin, and tirofiban and interventions were performed earlier (mean 22 h). A routine invasive management strategy is therefore recommended in patients with a non-ST-segment elevation ACS with high-risk features characterized by elevation of troponin levels, ST-segment ischemic changes or a high risk score determined by the global clinical evaluation. **Grade A** These patients also require aggressive antithrombotic therapy. **Grade A** Drugs that have been shown to be useful in randomized placebo-controlled studies include aspirin, clopidogrel, heparin, dalteparin, bivaluridin, and the Gp IIb/IIa antagonists eptifibatide and tirofiban in medical management and abciximab and eptifibatide in patients undergoing percutaneous intervention. **Grade A** Direct comparisons of the various drugs have shown superiority of enoxaparin over unfractionated heparin,[34,44] and over tinzaparin,[170] and of abciximab over tirofiban when administered in the cardiac catheterization laboratory before procedures. The combination of enoxaparin with eptifibatide[171] and with tirofiban[172] has been shown to be at least as effective and safe as the combination with unfractionated heparin. No direct comparisons, however, have been conducted between the various regimens that have been shown to be useful in non-ST-segment elevation ACS. Thus, the relative benefits of the combination of aspirin and clopidogrel (CURE regimen) versus the combination of aspirin and a Gp IIb/IIa antagonist (PURSUIT and PRISM-PLUS regimen), versus the combination of enoxaparin and ASA (ESSENCE regimen), are unknown. Further, the potential benefits of various drug combinations, such as for example ASA and enoxaparin with clopidogrel or with a Gp IIb/IIIa antagonist, have not been studied. Also, uncertainties exist as to the optimal timing for performing interventions. FRISC-II employed a delayed intervention strategy and TACTICS an accelerated strategy. Many centers used an immediate intervention strategy. On the other hand, no early routine invasive procedure was used in the CURE trial. The PCI–CURE study was designed to characterize prospectively the event rates in patients who underwent PCI in the trial. A total of 1313 patients, 21·2% of the total population, had such an intervention a median of 10 days after randomization; in 65% of patients, it was performed during the initial hospitalization, a median of 6 days after randomization. Open labeled ticlopidine or clopidogrel was administered during PCI and for 4 weeks thereafter. The primary end point of cardiovascular death, MI, or urgent target vessel revascularization within 30 days of PCI occurred in 4·5% of patients in the clopidogrel group compared with 6·4% in the placebo group (RR 0·70; 95% CI 0·50–0·97; $P = 0·03$). There was also less use of Gp IIb/IIIa inhibitor in the clopidogrel group ($P = 0·001$).[173] These results may suggest that more prolonged administration of clopidogrel before percutaneous interventions could amplify the benefit, possibly by more complete plaque passivation. Thus, much evidence remains to be acquired to define the optimal modalities for medical and invasive management of patients with non-ST-segment elevation ACS. In the mean time, the best current evidence dictates the use of a combination of ASA and clopidogrel, **Grade A** plus unfractionated heparin or low

molecular weight heparin, **Grade A** plus a Gp IIb/IIIa antagonist in the patients remaining unstable and referred for an interventional procedure. **Grade A** An early invasive management approach is recommended for patients with ST-segment shifts or an elevation of troponin T or I. **Grade A** Enoxaparin is preferred over unfractionated heparin when the primary emphasis is placed on medical management with no immediate intervention planned, **Grade A** and caution is advised in the use of clopidogrel in patients with immediate PCI and a possibility of rapid CABG. **Grade A** In the low-risk patients with no ischemic changes, no troponin elevation and no recurrent ischemia, risk stratification with a treadmill or another provocative test is recommended. **Grade A**

Case series support the use of the intra-aortic balloon pump as a bridge to PCI or CABG to stabilize hemodynamically unstable patients and patients with severe recurrent ischemia on treatment. **Grade B**

Cell protection

Cell necrosis is a significant problem in patients with a non-ST-segment elevation acute coronary syndrome, as close to 50% of patients have some degree of necrosis at admission and 5–15% develop a new myocardial infarction within a few weeks (Figure 30.5). Reperfusion procedures are frequently associated with myocardial infarction and there is a correlation between subsequent mortality and elevation of blood markers of necrosis, even within the range of only one and three times normal.[174] Measures that could prevent or halt the progression of myocardial cell ischemia to necrosis could therefore optimize the benefit of current treatment strategies (see Figure 30.9).[91] These have been investigated mainly in evolving ST-segment elevation MI, with the goal of reducing infarct size. A number of interventions have been shown to be protective in experimental models of ischemia reperfusion. None of these interventions, however, have translated into relevant benefit in humans. Beta blockers were shown in a meta-analysis to be of moderate benefit to prevent myocardial infarction in patients with threatened myocardial infarction.[108] A recent trial with cariporide, an inhibitor of the Na^+/H^+ exchanger that prevents the accumulation of anions within the ischemic cell, failed to prevent myocardial infarction in patients with a non-ST-segment elevation ACS and in patients undergoing high-risk percutaneous interventions.[175] Pilot studies with antibodies against leukocyte integrins and against the cytokine tissue necrosis factor α (TNF-α) suggested no reductions of infarct size.[176]

Plaque passivation

An attractive treatment strategy for acute coronary syndromes is control of inflammatory processes associated with plaque degradation that result in plaque rupture and thrombus formation (see Figure 30·9). In principle, these therapies could be applied before, during or after the rupture. Since there are no means to easily and reliably identify vulnerable plaques, administration of these therapies before the clinical manifestations of acute coronary syndromes is not practicable. On the other hand, secondary preventive measures applied past the very acute phase, as will be discussed in the next section, are rewarding, particularly statin therapy and control of risk factors. Percutaneous interventions including stent implantation are very effective during the acute process, possibly by interrupting some of the processes implicated in the disease. A 48 hour course of methylprednisone in a small pilot study in patients with unstable angina was ineffective to prevent ischemic events and even accelerated their manifestations.[177] Statins and ACE inhibitors can promote plaque stabilization by their anti-inflammatory, antioxidant, anti-cell proliferative and anticoagulant properties.[178]

Many trials and registries have shown that statins started 2–10 days after an ACS are well tolerated and associated with reductions in total and low density lipoprotein cholesterol. In pooled observational data of 20 809 ACS patients enrolled in clinical trials, the presence of lipid lowering therapy at hospital discharge was associated with a 56% reduction in risk of mortality at 1 month ($P = 0{\cdot}001$).[179] A Swedish registry of 5528 AMI survivors reported a 1 year mortality of 9·3% in the 14 071 patients who had no statin at hospital discharge and of 4·0% in the 5528 patients with a statin.[180]

In a small randomized trial, the initiation of pravastatin 6 days after the acute phase was associated with a significant reduction in the incidence of major cardiovascular events at 2 years ($P < 0{\cdot}03$).[181] The MIRACL study was the first large-scale clinical trial to investigate early treatment with a statin in patients with an ACS.[182] A total of 3086 patients with no interventions anticipated were randomized within 24–96 hours of hospital admission to high-dose atorvastatin or placebo. The primary outcome of death, non-fatal MI, resuscitated cardiac arrest or worsening angina requiring urgent rehospitalization occurred at 16 weeks in 14·8% of treated patients and 17·4% of placebo patients (RR 0·84; $P = 0{\cdot}048$). The benefit was limited to the reduction of the outcome of worsening angina and there were no significant differences in the risk of death, non-fatal MI, or cardiac arrest. The survival curves diverged after a few weeks. The MIRACL trial showed no definitive evidence of an early benefit for statins. Nevertheless, until the results of ongoing trials are known, it is recommended to initiate statin therapy in hospital, before hospital discharge. **Grade B** This approach increases the likelihood that patients will continue to comply with statin therapy and results in a greater percentage of patients using a statin after one year.[183] Numerous large-scale trials have documented marked benefits of statins used in primary and secondary prevention.

Subacute therapy

Those patients who respond quickly to optimal medical therapy in hospital, and who are found to be at relatively low risk based upon a variety of prognostic factors and non-invasive testing, require long-term follow up. Once they have stabilized for about 24–48 hours in hospital, with no ischemic pain recurrence, intravenous nitrate therapy is generally tapered with the substitution of oral or topical nitrates. The early efficacy of β blockers, and evidence for long-term benefits in patients following MI[184] and with stable ischemia, suggest that the therapy should be continued indefinitely. Similar analogies appear reasonable if a rate-limiting calcium antagonist was chosen because of contraindications to a β blocker, although there is no good evidence for long-term benefit in terms of major cardiovascular outcomes. If large doses of β blocker or calcium antagonists, or combined therapy, were required for control of the ischemic episodes, judicious decrements of intensity are likely to be appropriate once the patient is fully mobilized and non-invasive testing has indicated that revascularization is not obligatory. **Grade A**

The evidence from the initial trials of aspirin for unstable angina[121] demonstrated ongoing benefit for up to 2 years, consistent with evidence in survivors of MI and patients with stable angina.[123] Accordingly, aspirin should be continued indefinitely. Clopidogrel, 75 mg daily should be started on admission, and continued for at least 9–12 months, in conjunction with aspirin. **Grade A1b** For those patients intolerant of aspirin, clopidogrel alone is likely to be efficacious. **Grade A** Heparin should be sustained for at least 48 hours following the resolution of acute ischemic episodes.[148] Low molecular weight heparins appear to be at least as efficacious as unfractionated heparin and may be preferable in terms of ease of use and cost–benefit considerations. They have generally been used in clinical trials for longer periods of time than unfractionated heparin and can therefore be administered until hospital discharge. **Grade C** Clinical trials of oral Gp IIb/IIIa receptor antagonists have demonstrated no benefit and potential harm from these agents. **Grade A**

Early attention to optimal management of coronary risk factors is mandatory as their control is definitively of benefit. **Grade A** It is recommended to initiate a statin in hospital. **Grade A1c** The HPS study showed benefit independently of initial cholesterol levels.[185]

Recent evidence indicates that tight control of glucose in patients with type 2 diabetes reduces the risk of death following MI and among patients with newly detected type 2 diabetes.[186–188] The recurrence of an unstable phase of coronary artery disease or poor symptomatic control in patients being managed on medical therapy generally mandates reconsideration of the option of revascularization **Grade A** and, if not feasible, alternative medical therapy and the consideration of possible aspirin failure. **Grade B** Risk factor management is of great importance in those patients who have undergone revascularization and is focused on limiting progression of disease in non-revascularized vessels and in areas of percutaneous intervention and bypass conduits. The long-term use of an ACE inhibitor is likely to be beneficial in all but the lowest-risk patients who have experienced non-ST-segment elevation acute coronary syndromes.[189] **Grade A**
