Of the 410 femoral head fractures for which reduction method was described,^{2,8-27} closed reduction was attempted in 366 (89.3%) (Table 54.1). Primary open reduction was performed in the remaining cases, based on surgeon preference or presence of an associated femoral neck fracture. Of those 366 attempted reductions, successful reduction was accomplished in 312 (85.2%). Nine patients (2.5%) had an associated unrecognized femoral neck fracture that dis-

Successful closed reduction	Iatrogenic femoral neck fracture	Required open reduction
312 (85.2%)	9 (2.5%)	45 (12.3%)

placed,¹³ or sustained an iatrogenic femoral neck fracture during the reduction attempt.^{2,13,15,16,26} The remaining 45 (12.3%) were irreducible, and required open reduction. While some authors showed better outcomes with early reduction,^{15,28} others showed no difference with delay to reduction.¹⁹ There was inadequate data to draw a conclusion regarding timing of reduction.

Recommendations

- In the absence of a femoral neck fracture, a timely attempt at a closed reduction in the Emergency Department or operating room is recommended [overall quality: moderate]

Question 2: Is there a role for nonoperative treatment?

Case clarification

After successful closed reduction, CT scan reveals concentric reduction of the hip joint, but persistent displacement of the femoral head fragment. The patient wants to know if he really needs surgery.

Current opinion

Displaced femoral head fractures are typically treated with open reduction and internal fixation (ORIF).

Relevance

Historically, many fractures were managed nonoperatively. With advances in surgical techniques and implants, more fractures are now treated surgically. Has this improved the outcome of femoral head fractures?

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 11 retrospective case series^{2,12-16,19,20,22,29,30}

Findings

Eleven articles^{2,12-16,19,20,22,29,30} gave details of the outcomes, according to the classification of Thompson and Epstein,³⁰ of nonoperatively treated femoral head fractures, in addition to the results of those treated operatively (Table 54.2). Of the 57 cases managed nonoperatively, there were 8 (14.0%) excellent, 16 (28.1%) good, 16 (28.1%) fair, and 17 (29.8%) poor results. In comparison, the 139 operatively treated fractures yielded 5 (3.6%) excellent, 66 (47.5%) good, 30 (21.6%) fair, and 38 (27.3%) poor results. Very little information was provided as to the criteria used to select these cases for nonoperative treatment. There may also be some selection bias, as less severe cases may have been those chosen for nonoperative treatment.

Openmirrors.com

Table 54.2 Results of nonoperative vs. operative treatment of femoral head fractures

Results	Nonoperative(n = 57)	Operative(n = 139)
Excellent	8 (14.0%)	5 (3.6%)
Good	16 (28.1%)	66 (47.5%)
Fair	16 (28.1%)	30 (21.6%)
Poor	17 (29.8%)	38 (27.3%)

Recommendations

- In a stable hip with minimal fracture displacement, non-operative management may be a reasonable treatment option [overall quality: very low]

Question 3: Which surgical approach should I use?

Case clarification

You determine there is sufficient displacement of the head fragment to warrant surgical intervention. But how are you going to get there?

Current opinion

Femoral head fractures are currently addressed through a variety of surgical exposures, based on surgeon preference and associated fractures.

Relevance

Multiple surgical approaches are available, and each has potential advantages and disadvantages that must be considered.

Finding the evidence

See Question 1.

Quality of the evidence

Level III

- 1 retrospective case-control study¹⁸

Level IV

- 10 retrospective case series^{14,19,22-27,31,32}

Findings

While medial (Ludloff)⁸ and anterolateral (Watson-Jones)²² approaches have been described for the fixation of femoral head fractures, the most commonly utilized approaches are the anterior (Smith-Peterson), posterolateral (Kocher-Langenbeck), and the trochanteric flip osteotomy. Eleven articles provided adequate description of the surgical approach and complications in 151 cases to

Table 54.3 Complications related to surgical approach (n = 151)

Approach	Anterior (n = 45)	Posterior (n = 62)	Trochanteric flip (n = 44)
Avascular necrosis	4 (8.9%)	10 (16.1%)	4 (9.1%)
Heterotopic ossification	17 (37.8%)	22 (35.5%)	19 (43.2%)

Table 54.4 Outcomes related to surgical approach used (n = 137)

Result	Anterior (n = 38)	Posterior (n = 62)	Trochanteric flip (n = 37)
Good/excellent	25 (65.8%)	33 (53.2%)	31 (83.8%)
Fair/poor	13 (34.2%)	29 (46.8%)	6 (16.2%)

permit further analysis (Table 54.3).^{14,18,19,22-27,31,32} The anterior approach was used in 45 (29.8%), a posterolateral approach in 62 (41.1%), and a trochanteric flip in 44 (29.1%) of cases.

Poor visualization of the head fragment was noted by two authors via the posterolateral approach^{18,22} and in three of the case series^{18,22,31} excision of the fragment was performed in 18/33 (54.5%) of cases via a posterolateral approach, compared with only 4/28 (14.3%) via an anterior approach, at least in part due to impaired visualization. AVN occurred with 4/45 (8.9%) anterior, 10/62 (16.1%) posterolateral, and 4/44 (9.1%) trochanteric flip approaches. Heterotopic ossification (HO) was noted in 17/45 (37.8%) anterior, 22/62 (35.5%) posterolateral, and 19/44 (43.2%) of the trochanteric flip approaches. This occurred despite HO prophylaxis with either indomethacin or radiation therapy in 11/34 (32.4%) of cases.²³⁻²⁷

Nine articles provided functional outcomes according to Thompson and Epstein³⁰ for the various approaches in 137 cases (Table 54.4).^{14,18,19,22-25,31,32} A posterior approach was used more commonly when there was an associated fracture of the posterior acetabulum, which may have influenced these results.

Recommendations

- Isolated femoral head fractures are best approached using an anterior approach or trochanteric flip to improve visualization and minimize the risk of AVN [overall quality: low]
- Femoral head fractures with associated acetabular fractures (Pipkin IV) are best approached with a trochanteric flip osteotomy [overall quality: low]

Question 4: Should the fragment be excised or repaired?

Case clarification

Once you reach the femoral head fragment, should you attempt to fix the fragment, or simply excise it?

Current opinion

Most surgeons recommend fixation of displaced femoral head fractures.

Relevance

The size and extent of comminution of the femoral head fragment can vary. When should the fragment be preserved, and should it ever be excised?

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 8 retrospective case series^{13,14,16,19,21-23,31}

Findings

Eight papers described the outcomes of 123 patients treated by either fragment excision or fixation.^{13,14,16,19,21-23,31} Insufficient data was provided to clearly determine the indication for excision. In 53 cases where excision was performed, there were 5 (9.4%) excellent, 30 (56.6%) good, 8 (15.1%) fair, and 10 (18.9%) poor results. Better results were obtained with open reduction and internal fixation, with 16 (22.9%) excellent, 30 (42.9%) good, 9 (12.9%) fair, and 15 (21.4%) poor results (Table 54.5).

Earlier authors suggested excision of fragments up to 1/3 of the weightbearing surface of the femoral head,⁶ but most authors now advocate fixation of any fragment large enough to salvage, excising only smaller, comminuted fragments not amenable to fixation.^{18,22,31}

Recommendations

- Excision of small, comminuted fragments can yield reasonable results, but fixation of larger head fragments is recommended [overall quality: low]

Table 54.5 Outcomes observed with fragment excision or fixation (n = 123)

Result	Excision (n = 57)	Fixation (n = 70)
Excellent	5 (9.4%)	16 (22.9%)
Good	30 (56.6%)	30 (42.9%)
Fair	8 (15.1%)	9 (12.9%)
Poor	10 (18.9%)	15 (21.4%)

Question 5: What complications should be anticipated?

Case clarification

As you discuss the results of surgery with the patient's family, they ask if there are any complications to worry about.

Current opinion

Femoral head fractures are associated with complications including sciatic nerve palsy, heterotopic bone formation, AVN, arthritis, and infection.

Relevance

These potentially significant complications can lead to inferior outcomes, impaired function, and result in the need for further surgery.

Finding the evidence

See Question 1.

Quality of the evidence

Level III

- 1 retrospective case-control study¹⁸

Level IV

- 19 retrospective case series^{7-9,13-17,19,22-30,32}

Findings

Twenty papers provided data on complications in 329 femoral head fractures (Table 54.6).^{7-9,13-19,22-30,32} Traumatic sciatic nerve palsy occurred in 19 (5.8%) of cases. HO developed in 59 (17.9%) cases, 38 (11.6%) of patients went on to develop AVN, and 67 (20.4%) showed radiographic signs of arthritis. Deep infection occurred in 8 (2.4%) of cases. Length of follow-up varied significantly among studies.

Recommendations

- Long-term follow-up is recommended to monitor for the development of complications frequently observed following femoral head fractures [overall quality: low]

Table 54.6 Complications observed with femoral head fractures (n = 329)

Complication	Incidence
Sciatic nerve palsy	19 (5.8%)
Heterotopic ossification	59 (17.9%)
Avascular necrosis	38 (11.6%)
Arthritis	67 (20.4%)
Deep infection	8 (2.4%)

Question 6: What is the expected outcome?**Case clarification**

Your patient asks what kind of outcome he can expect.

Current opinion

Femoral head fractures have a significant complication rate, and often have a poor clinical outcome.

Relevance

As these injuries typically occur in young, active individuals, the potential impact of these injuries on their long-term function and productivity is significant.

Finding the evidence

See Question 1.

Quality of the evidence*Level IV*

- 19 retrospective case series^{7,12-17,19-25,28-32}

Findings

Nineteen studies described the outcome according to Thompson and Epstein³⁰ of 294 patients.^{7,12-17,19-25,28-32} Overall there were 43 (14.6%) excellent, 120 (40.8%) good, 53 (18.0%) fair, and 78 (26.5%) poor results (Table 54.7).

Fourteen of these studies further described the results by fracture type in 202 of these patients (Table 54.7).^{12-14,16,17,19,20-25,31,32} While quite similar results were reported for isolated femoral head fractures, the addition of an acetabular fracture resulted in slightly inferior outcomes, and an associated femoral neck fracture (although small numbers) resulted in significantly worse outcomes.

Recommendations

- Patients should be counseled regarding expectations following these significant articular injuries, with only slightly more than half of patients obtaining good or excellent results [overall quality: moderate]

Summary of recommendations

- In the absence of a femoral neck fracture, a timely attempt at a closed reduction in the Emergency Department or operating room is recommended
- In a stable hip with minimal fracture displacement, non-operative management may be a reasonable treatment option
- Isolated femoral head fractures are best approached using an anterior approach or trochanteric flip to improve visualization and minimize the risk of AVN
- Femoral head fractures with associated acetabular fractures (Pipkin IV) are best approached with a trochanteric flip osteotomy
- Excision of small, comminuted fragments can yield reasonable results, but fixation of larger head fragments is recommended
- Long-term follow-up is recommended to monitor for the development of complications frequently observed following femoral head fractures
- Patients should be counseled regarding expectations following these significant articular injuries, with only slightly more than half of patients obtaining good or excellent results

Conclusions

Although no high-quality studies have been published on these relatively rare injuries, an organized review of the available literature provides some useful guidance in the management of these challenging injuries. Advances in surgical technique may provide enhanced visualization, while minimizing postoperative complications. Despite our best efforts in the treatment of these high-energy injuries, the results remain unsatisfactory in many cases, and patients should be counseled with regard to potential complications and expected functional outcomes from the outset of treatment.

Table 54.7 Outcomes (Thompson and Epstein) reported for femoral head fractures

Result	Total Pipkin (n = 294)	Pipkin I (n = 68)	Pipkin II (n = 59)	Pipkin III (n = 8)	Pipkin IV (n = 65)
Excellent	43 (14.6%)	12 (17.6%)	14 (23.7%)	0 (0%)	11 (16.9%)
Good	120 (40.8%)	39 (57.4%)	30 (50.8%)	3 (37.5%)	27 (41.5%)
Fair	53 (18.0%)	11 (16.2%)	6 (10.2%)	2 (25%)	9 (13.8%)
Poor	78 (26.5%)	6 (8.8%)	9 (15.3%)	3 (37.5%)	18 (27.7%)

¹University of Ottawa, Ottawa, ON, Canada

²University of Minnesota, Minneapolis, MN, USA

³McMaster University, Hamilton, ON, Canada

Case scenario

A 75 year old woman who is currently ambulatory and living independently is brought to the Emergency Department with complaints of left hip pain after a slip in her kitchen. She is currently unable to bear weight. On examination, her left leg is shortened and externally rotated. She is neurovascularly intact.

Relevant anatomy

Hip fractures are anatomically classified in relation to the hip capsule as intracapsular fractures (i.e., femoral neck) or extracapsular fractures (intertrochanteric and subtrochanteric). This chapter focuses on management options for fractures of the femoral neck.

Importance of the problem

The disability adjusted life-years (DALYs) lost as a result of hip fractures ranks in the top 10 of all-cause disability globally. Over 4.5 million persons sustain hip fractures around the world each year. In North America, hip fractures occur in 280,000 Americans (over 5000 per week) and 36,000 (over 690 per week) Canadians annually. By the year 2040, the number of people aged 65 or older will increase from 34.8 million to 77.2 million. The number of hip fractures is likely to exceed 500,000 annually in the United States and 88,000 in Canada over the next 40 years.¹⁻³

Hip fractures are associated with a 30% mortality rate at 1 year and profound temporary, and sometimes perma-

nent, impairment of independence and quality of life. Furthermore, approximately 30% of surgically treated hip fractures require revision surgery.⁴ These revisions are associated with a large burden of morbidity and mortality. By the year 2040, the estimated annual healthcare costs will reach \$9.8 billion in the United States and \$650 million in Canada.⁵

Surgeons and patients are inundated with an ever-increasing and easily accessible body of information about hip fractures. A Google search for "hip fractures" returns over 2,000,000 hits. The variable quality and lack of filtering mandates need for preappraised evidence-based guides.

Top six questions

Treatment

1. What is the relative effect of internal fixation vs. arthroplasty in the management of displaced femoral neck fractures?
2. What is the optimal implant for fixing femoral neck fractures?
3. What is the optimal approach to fixing femoral neck fractures?
4. What is the optimal approach to replacing femoral neck fractures?
5. What is the optimal perioperative care in patients with femoral neck fractures?

Prognosis

6. What is the effect of surgical delay on morbidity and mortality after a femoral neck fracture?

Finding the evidence

The following general searches were undertaken to identify the best evidence (meta-analyses, systematic reviews, and clinical trials) on intracapsular hip fractures. In addition to this, more detailed search steps are outlined under each respective question.

- Cochrane Database, using the search term: “hip fractures”
- PubMed: (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “hip fracture” OR “femoral neck fracture”
- PubMed: Advanced search/type of article/randomized control trials: “femoral neck fractures”
- MEDLINE search: population (“femoral neck fracture”) and methodology (clinical trial)

Question 1: What is the relative effect of internal fixation vs. arthroplasty in the management of displaced femoral neck fractures?

Case clarification

The patient’s radiograph reveals a displaced femoral neck fracture (Garden type IV). You present two options for treatment to your patient: arthroplasty or internal fixation.

Garden type IV denotes a displaced femoral neck fracture; Garden types I and II are typically nondisplaced whereas types III/IV are displaced.

Relevance

Maintaining the patient’s original hip with a fixation device vs. removing the femoral head and replacing the hip with

a prosthesis has important implications for outcome and function. Current opinion is highly divergent among orthopedic surgeons on whether to fix or replace the hip.

Current opinion

Current opinion suggests that the majority of surgeons use arthroplasty for the treatment of displaced femoral neck fractures.

Finding the evidence

- Search terms: “femoral neck fracture” AND “arthroplasty” OR “internal fixation”

Quality of the evidence

Level I

- 4 systematic reviews/meta-analyses^{6,7}
- 10 randomized trials

Level II

- 5 randomized trials with methodological limitations

Findings

A meta-analysis by Bhandari et al. is summarized below.⁸

Mortality Nine trials (n = 1162 patients) provided postoperative mortality data at 4 months or less and 12 trials (n = 1767 patients) provided 1 year mortality data (Table

Revision surgery All fourteen studies (n = 1901) provided information on revision surgery (Table 55.1). Arthroplasty substantially reduced the risk of revision, and the results were consistent from study to study.

Pain, function, and infection rates Information on secondary outcomes was available for 6 studies (N = 1153 patients)

Openmirrors.com

Table 55.1 Mortality and revision surgery

	Events			RR ^a	95% CI	p value
	N	A	IF			
Mortality (<4 months)						
All arthroplasty vs. IF	1162	55/615	34/547	1.27	0.84–1.92	0.25
Mortality (1 year)						
All arthroplasty vs. IF	1767	226/984	160/783	1.04	0.84–1.29	0.68
Mortality (>1 year)						
All arthroplasty vs. IF	1596	412/895	251/701	1.12	0.90–1.43	0.30
Revision surgery						
All arthroplasty vs. IF	1901	111/1051	299/850	0.23	0.13–0.42	0.0003

A, all arthroplasty; CI, confidence interval; IF, internal fixation; N, total sample size pooled; RR, relative risk.
^aThe relative risk of outcome (i.e., mortality or revision surgery) with arthroplasty compared to internal fixation. Values >1.0 favor internal fixation, values <1.0 favor arthroplasty).

reporting on pain relief and 12 on function (N = 1179 patients). Pain relief and function were similar in patients treated with arthroplasty or internal fixation (RR of no/little pain 1.12, 95% CI 0.88–1.35 and good function 0.99, 95% CI 0.90–1.10). Arthroplasty significantly increased the risk of infection (12 studies, n = 1822) compared to internal fixation (RR 1.81, 95% CI 1.16–2.85, p = 0.009, homogeneity p = 0.16). The risk difference between the two treatments was 3.4%. This meant that for every 29 patients treated with internal fixation, 1 infection could be prevented (NNT = 1/0.034 = 29.4).

Blood loss and surgical time Four studies (N = 343 patients) reported on estimated blood loss, and 5 (N = 447 patients) and surgical time. Patients who underwent arthroplasty experienced greater blood loss than those who were treated with internal fixation (weighted mean difference = 176.4 mL, 95% CI 132.4–220.4, p < 0.05). Similarly, surgical time in the arthroplasty-treated patients was greater than the patients treated with internal fixation (weighted mean difference = 29.0 minutes, 95% CI 23.2–34.8, p < 0.05).

Recommendations

- Arthroplasty significantly reduces the risk of revision surgery at 1 year compared to internal fixation [overall quality: moderate]
- Arthroplasty does not increase the risk of mortality at 1 year compared to internal fixation [overall quality: low]
- Arthroplasty significantly increases the risk of infection, blood loss, and operating time at 1 year compared to internal fixation [overall quality: moderate]

Question 2: What is the optimal implant for fixing femoral neck fractures?

Case clarification

In considering internal fixation you need to determine whether cancellous screws or sliding hip screws will result in the best outcome for your patient.

Relevance

As much of the focus in the literature is concerned with comparing internal fixation to arthroplasty, the question of

which method of fixation generates superior results is less well understood. It is suggested that bias in certain study designs has caused outcomes for arthroplasty to fair better. For this reason, internal fixation cannot be overruled and further scrutiny of fixation methods is in order.⁹

Current opinion

Current opinion suggests that the majority of surgeons are using internal fixation with cancellous screws in undisplaced hip fractures. When internal fixation is chosen for displaced fractures, cancellous screws are also the preferred option.⁹

Finding the evidence

- Search terms: “hip OR femoral neck fracture” AND “internal fixation”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses

Level II

- 28 randomized trials with methodologic limitations

Findings

Sliding hip screw (SHS) vs. screw fixation A review by Bhandari et al. summarized results for five randomized trials comparing SHS to screw fixation (Table 55.2).⁹

A Cochrane review of internal fixation (using screws, pins and/or plates) in intracapsular hip fractures included 28 trials (N = 5547).¹⁰ The authors concluded that, due to the variability in study designs, outcomes, lack of methodological rigor, and small sample sizes, no definitive statements can be made to support the use of certain types or methods of fixation over others. While several studies did find significant results for certain outcomes, these results are questionable because of the multiple analyses performed.

Pooled results from trials comparing SHS to cancellous screws are shown in Table 55.3. Note that point estimates for AVN (avascular necrosis) favor SHS.

Table 55.2 Comparing outcomes between SHS and screw fixation

Fracture	Outcome	N	Trials	RRR ^a	95% CI	p value
Displaced	Revision surgery	516	4	27%	48 to –4	0.08
Undisplaced	Revision surgery	33	1	87%	99 to –142	>0.05

CI, confidence interval; N, total sample size pooled; RRR, relative risk reduction.

^aThe relative risk reduction of revision with SHS compared to screw fixation.

Table 55.3 Comparing outcomes in SHS vs. cancellous screw fixation

Outcome	N	Trials	SHS	Cancellous	RR ^a	95% CI	p value
Nonunion	462	4	62/226	64/236	1.02	0.76–1.37	0.88
AVN	565	5	23/227	39/288	0.62	0.38–1.01	0.053
Complications	772	6	107/378	131/394	0.86	0.70–1.05	0.13

CI, confidence interval; N, total sample size pooled; RR, relative risk.

^aThe relative risk of outcome with SHS compared to cancellous screws. Values >1.0 favor cancellous screws, values <1.0 favor SHS.

Recommendations

- Sliding screws have a tendency towards decreased rates of AVN compared to cancellous screws [overall quality: low]
- Current studies comparing different implants for fixation of femoral neck fractures lack methodological rigor. The superiority of one method of fixation over others cannot be concluded [overall quality: low]

Question 3: What is the optimal approach to fixing femoral neck fractures?

Openmirrors.com

Case clarification

You consider managing your patient’s fracture using internal fixation. You want to know if there is a superior surgical approach for this procedure.

Relevance

In addition to selecting the optimal implant for fixation of femoral neck fractures, the surgical approach and technique may influence outcome. More specifically, certain methods applied in internal fixation may enhance stability and reduction and thereby decrease rates of AVN and nonunion.¹¹

Current opinion

Opinions about compression and impaction during femoral neck fracture fixation are divergent.

Finding the evidence

- Search terms: “Femoral neck fractures” AND “internal fixation”

Level I

- 1 systematic review/meta-analysis

Level II

- 4 randomized trials with methodological limitations:

Table 55.4 Comparing femoral head vascularity in hip fracture impaction

Fracture type	Intervention	Isotope uptake	p value
Undisplaced	Impaction	1.49 ± 0.58	>0.05
	No impaction	1.67 ± 0.48	
Displaced	Impaction	1.08 ± 0.36	<0.05
	No impaction	1.34 ± 0.48	

Findings

A Cochrane review¹¹ found only four randomized controlled trials (RCTs) comparing different surgical approaches and ancillary techniques for internal fixation of intracapsular hip fractures. Due to the statistical heterogeneity of the studies, the data was not pooled. Results from individual trials are described below.

Impaction of the fracture One trial (n = 103) compared femoral head blood supply (presurgery and at 10 days postsurgery) using bone scintigraphy in femoral neck fractures randomized to impaction (with a 1 kg mallet) or no impaction (Table 55.4).

Compression of the fracture A single trial (n = 220 patients) compared compression of displaced intracapsular hip fractures with a compression screw using a sliding screw plate to no fracture compression (Table 55.5). Fracture nonunion was significantly greater in the compression group compared to the noncompression group.

Open vs. closed reduction Two trials compared outcomes in patients randomized to either closed or open internal fixation. Both studies found operating times to be significantly longer in the open reduction groups. Rates of nonunion, AVN, postoperative blood transfusions, mortality, and wound infections were not significantly different between groups in either study.¹¹

Table 55.5 Comparing outcomes in compression vs. no compression

Outcome	Compression	No compression	RR ^a	95% CI	p value
Mortality	27/112	37/108	0.75	0.46–1.07	>0.05
Fracture nonunion	28/85	13/71	1.80	1.01–3.20	<0.05
Avascular necrosis	9/37	7/36	1.25	0.52–3.00	>0.05

CI, confidence interval; RR, relative risk.

^a The relative risk of outcome with fracture compression compared to no compression. Values >1.0 favor no compression, values <1.0 favor compression.

Recommendations

- Impaction may decrease femoral head vascularity in fixation of displaced intracapsular fractures [overall quality: low]
- Compression may increase nonunion in fixation of displaced intracapsular fractures [overall quality: low]
- Operating times are significantly higher in open compared to closed internal fixation of femoral neck fractures [overall quality: low]

Question 4: What is the optimal approach to replacing femoral neck fractures?

Case clarification

You have decided to treat the fracture with arthroplasty and want to ensure that you are selecting the implant most appropriate for your patient's age and functional status.

Relevance

In making operative decisions about arthroplasty, it is important, for example, to know whether bipolar compared to unipolar hemiarthroplasty does in fact decrease acetabular wear and improve function. Also, what patient and implant risk factors should be considered when choosing between hemiarthroplasty and total hip arthroplasty (THA)?

Current opinion

THA is generally considered a better option for older, more active patients. Hemiarthroplasty is thought to be better for patients with low mobility because of the higher risk of hip dislocation in these implants.

Finding the evidence

- Search terms: "femoral neck fractures" OR "hip fractures" OR "intracapsular hip fractures" AND "arthroplasty"

Quality of the evidence

Level I

- 3 systematic reviews/meta-analyses
- 7 randomized trials

Level II

- 13 randomized trials with methodologic limitations

Findings

A Cochrane review of 19 trials (n = 2115) of arthroplasties in hip fractures provided the highest level of evidence shown below.¹²

Unipolar vs. bipolar hemiarthroplasty Seven clinical trials (n = 857) compared outcomes following unipolar and bipolar hemiarthroplasty (Table 55.6).

Cemented vs. uncemented arthroplasty Six clinical trials (n = 549 patients) compared cemented to uncemented arthroplasty in adults with hip fractures. The results revealed decreased risk of pain and failure to regain mobility in the cemented group (Table 55.7).

Hemiarthroplasty vs. THA Two trials (n = 232 patients) compared uncemented hemiarthroplasty to THA (Table 55.8).

Cemented hemiarthroplasty was compared to THA in 4 trials (n = 415 patients) (Table 55.9).

Recommendations

- There is no difference in the risk of complications, acetabular erosion, return to function, or mortality between unipolar and bipolar hemiarthroplasty in femoral neck fractures [overall quality: moderate]
- The risk of postoperative pain at 1 year after surgery is significantly increased in uncemented compared to cemented arthroplasty [overall quality: moderate]
- The risk of failure to regain mobility is increased in patients with uncemented compared to cemented arthroplasty prostheses [overall quality: low]
- No significant risk differences were found between uncemented hemiarthroplasty compared to THA for any outcome [overall quality: low]
- Patients with the Moore implant were significantly more at risk for residual pain compared to those with THA [overall quality: low]

Table 55.6 Comparing outcomes in unipolar and bipolar hemiarthroplasty

Outcome	N	Trials	Unipolar	Bipolar	RR ^a	95% CI	p value

Failure to regain mobility	187	2	20/86	20/101	1.66	0.31–8.92	0.56

CI, confidence interval; N, total sample size pooled; RR, relative risk.

^aThe relative risk of outcome with uncemented hemiarthroplasty compared to THA. Values>1.0 favor THA, values<1.0 favor hemiarthroplasty.

^bThe Austin Moore hemiarthroplasty was compared to THA in this study. A trial by Ravikumar et al.¹³ also reported high rates of pain in patients with the Moore implant (27% at 1 yr; 45% at 13 yrs) compared to hemiarthroplasty (0% at 1 yr; 6% at 13 yrs).

- No significant risk differences were found between cemented hemiarthroplasty compared to THA for any outcome [overall quality: low]
- The risk of dislocation is greater in THA compared to cemented hemiarthroplasty [overall quality: low]
- The risk of minor reoperation is higher in THA compared to cemented hemiarthroplasty [overall quality: low]
- Pain and function scores were better in patient with THA compared to cemented hemiarthroplasty [overall quality: low]

Question 5: What is the optimal perioperative care in patients with femoral neck fractures?

Case clarification

You know that perioperative factors may influence mortality in your patient and you look to the current literature on how to best care for your patient.

Table 55.9 Comparing outcomes in cemented hemiarthroplasty vs. THA

Outcome	N	Trials	Hemi	THA	RR ^a	95% CI	p value
Dislocation	4	415	4/207	13/208	0.34	0.12–0.96	0.042
Reoperations (all)	4	415	13/207	22/208	0.61	0.32–1.15	0.13
Reoperations (minor)	3	277	2/138	12/139	0.24	0.07–0.08	0.0020
Mortality (3–4 mo)	1	138	5/69	2/69	2.50	0.50–12.45	0.26
Mortality (1 yr)	2	258	9/129	8/129	1.13	0.45–2.83	0.80

CI, confidence interval; N, total sample size pooled; RR, relative risk.

^aThe relative risk of outcome with cemented hemiarthroplasty compared to THA. Values >1.0 favor THA, values <1.0 favor hemiarthroplasty.

Relevance

Perioperative management, particularly in the elderly population, requires optimal attention as certain factors may significantly impact morbidity and mortality among these patients. Anesthesia choices, deep vein thrombosis (DVT) prophylaxis, and antibiotic use may influence these outcomes.

Current opinion

Opinions concerning optimal perioperative care for elderly hip fracture patients are varied. The three topics with the highest level of evidence are considered here.

Finding the evidence

• Search terms: “femoral neck fractures” OR “hip fractures” AND “perioperative” OR “anesthesia” OR “deep vein thrombosis” OR “pulmonary embolism” OR “antibiotics”

Anesthesia in hip fractures

Level I

- 1 meta-analysis
- 7 randomized trials

Level II

- 15 randomized trials with methodologic limitations

Antibiotics in hip fractures

Level I

- 1 meta-analysis
- 7 randomized trials

Level II

- 15 randomized trials with methodologic limitations

Thromboprophylaxis in hip fractures

Level I

- 1 meta-analysis
- 8 randomized trials

Level II

- 23 randomized trials with methodologic limitations

Findings

Anesthesia A review of 22 trials (n = 2567 patients) compared outcomes of mortality and morbidity in patients randomized to either regional (spinal or epidural) or general anesthesia during operative hip fracture repair (Table 55.10).¹⁴ It must be noted that 1 month mortality was not found to be significant when a trial from 1978 was removed, and this may reflect changes in anesthesia practices over the years (RR 0.79, 95% CI 0.56–1.12).

The risks of DVT and postoperative confusion were significantly reduced in the regional anesthesia group (Table 55.10). However, the authors caution the reader about the DVT risk results as this group may have been subject to selection bias.

Antibiotics A review of 22 trials (n = 8307 patients) evaluated the effects of antibiotic prophylaxis for surgery in proximal femoral and other closed long-bone fractures.¹⁵ The effectiveness of a single antibiotic dose compared to placebo in closed fractures is shown in Table 55.11.

Four studies (n = 526) showed a significant risk reduction in deep wound infection for multiple-dose antibiotics compared to placebo in hip fracture fixation (RR 0.22, 95% CI 0.07–0.75, p = 0.015).

The results of single short-acting vs. multiple-dose antibiotics were not significant. Additionally, no significant risk reduction was found for operative day vs. longer antibiotic prophylaxis, or for oral vs. parenteral route.

Thromboprophylaxis A review of 31 trials compared the effects of unfractionated (U) heparin, low molecular weight (LMW) heparin, and mechanical pumping devices in patients with hip fractures (Table 55.12).¹⁶ All three interventions were found to be significantly effective in the prevention of DVT.

Table 55.10 Comparison of outcomes in regional and general anesthesia

Outcome	N	Trials	Regional	General	RR ^a	95% CI	p value
Mortality 1 month	1668	8	56/811 (6.9%)	86/857 (10.0%)	0.69	0.50–0.95	0.021
Mortality 3 months	1491	6	86/726 (11.8%)	98/765 (12.8%)	0.92	0.71–1.21	0.55
Mortality 6 months	1264	3	103/613 (16.8%)	115/651 (16.1%)	1.04	0.81–1.33	0.76
Mortality 12 months	726	2	80/354 (22.6%)	78/372 (21.0%)	1.07	0.82–1.41	0.61
DVT	259	4	39/129 (30.0%)	61/130 (47%)	0.64	0.48–0.86	0.0029
Acute postoperative confusion	237	5	11/117 (9.4%)	23/120 (19.2%)	0.50	0.26–0.95	0.0034

CI, confidence interval; DVT, deep vein thrombosis; N, total sample size pooled; RR, relative risk.

^aThe relative risk of outcome with regional compared to general anesthesia. Values >1.0 favor general, values <1.0 favor regional.

Table 55.11 Comparison of effect of a single antibiotic dose vs. placebo or no treatment

Outcome	N	Trials	Treatment	Placebo	RR ^a	95% CI	p value
Openmirrors.com							
Deep wound infections							
All	3500	7	20/1745	51/1755	0.40	0.24–0.67	<0.001
Unspecified hip procedure	1251	5	7/615	11/636	0.68	0.28–1.66	0.40
Superficial infections	3500	7	59/1745	87/1755	0.69	0.50–0.95	0.023
Urinary tract infections	2975	4	131/1493	212/1482	0.63	0.53–0.76	<0.001
Respiratory Infections	2975	4	41/1493	92/1482	0.46	0.33–0.65	<0.001

CI, confidence interval; N, total sample size pooled; RR, relative risk.

^aThe relative risk of outcome with single dose antibiotics compared to placebo/no treatment. Values >1.0 favor placebo, values <1.0 favor treatment.

Recommendations

- Regional compared to general anesthesia may reduce short-term postoperative mortality, DVT and postoperative confusion in adult patients treated for hip fracture [overall quality: moderate]
- A single prophylactic dose of antibiotics significantly reduces postoperative deep and superficial wound infection, UTI, and respiratory infections in hip fracture patients [overall quality: moderate]
- Heparin (U and LMW) and physical devices are effective in reducing DVT in hip fracture patients [overall quality: moderate]
- The superiority of U heparin vs. LMW heparin in preventing adverse thromboembolic events is indeterminate [overall quality: moderate]

- Physical devices are effective in reducing overall risk of PE in postoperative hip fracture patients [overall quality: moderate]
- No conclusive evidence was found to show which form of thromboprophylaxis was most effective in reducing mortality and fatal PE [overall quality: moderate]

Question 6: What is the effect of surgical delay on morbidity and mortality after a femoral neck fracture?

Case clarification

Your elderly patient is on the trauma waiting list for surgery and you are concerned about the harmful effect that delaying surgery may have.

Table 55.12. Comparing the effects of U heparin, LMW heparin, and physical devices

Outcome	Intervention	N	Trials	Treatment	Control	RR	95% CI	p value
DVT	Heparin (U or LMW) vs. placebo	993	13	124/474	219/519	0.60	0.50–0.71	<0.001
	Physical device vs. placebo	450	5	16/221	52/229	0.31	0.19–0.51	<0.001
	LMW heparin vs. U heparin	479	5	47/252	64/227	0.67	0.48–0.94	0.02
PE	Heparin (U or LMW) vs. placebo	858	10	13/404	14/454	1.0	0.49–2.02	1.0
	Physical device vs. placebo	487	5	5/238	16/249	0.40	0.17–0.96	0.041
	LMW heparin vs. U heparin	354	4	7/189	1/165	0.094	0.82–13.32	0.094
Mortality	Heparin (U or LMW) vs. placebo	730	8	42/356	38/374	1.16	0.77–1.74	0.47
	Physical device vs. placebo	256	4	7/128	15/128	0.50	0.22–1.14	0.099
	LMW heparin vs. U heparin	242	3	6/122	7/120	0.85	0.31–2.36	0.76

CI, confidence interval; DVT, deep vein thrombosis; N, total sample size pooled; PE, pulmonary embolism; RR, relative risk.

^aThe relative risk of outcome with treatment vs. control. Values >1.0 favor control, values <1.0 favor treatment. Note: LMW vs U heparin intervention: LMW heparin is allocated to treatment column.

Relevance

It has been suggested in the literature that delaying surgery in elderly hip fracture patients is associated with increased risk of morbidity and mortality. However, other studies have contradicted this finding.¹⁷

Current opinion

The effect of time to surgery on morbidity and mortality in elderly hip fracture patients remains an issue of controversy.

Finding the evidence

• Search terms: “femoral neck fractures” OR “hip fractures” OR “intracapsular hip fractures” AND “surgical delay” OR “operative delay”

Quality of the evidence

Level I

- 1 systematic review/meta-analysis

Level III and IV

- 16 prospective and retrospective cohort studies

Findings

There were no randomized trials evaluating surgical delay in hip fracture patients. This is largely a result of the unethical nature inherent in such studies. A recent systematic review and meta-analysis included 16 historical and prospective observational studies.¹⁸ Though data was significantly heterogeneous between the studies, the authors pooled the data for mortality odds ratios following “early” and “delayed” surgery. The effect of delaying surgery by more than 48 hours (cut-off used in the majority of studies) is significant for mortality within 30 days of surgery and at 1 year (Table 55.13).

Recommendations

- The risk of mortality (at 30 days and 1 year) is decreased in patients with hip fracture who undergo early (<48 hours) surgery compared to delayed [overall quality: low]

Summary of recommendations

- Arthroplasty significantly reduces the risk of revision surgery at one year compared to internal fixation
- Arthroplasty does not increase the risk of mortality at 1 year compared to internal fixation
- Arthroplasty significantly increases the risk of infection, blood loss and operating time at 1 year compared to internal fixation
- Sliding screws have a tendency towards decreased rates of AVN compared to cancellous screws
- Current studies comparing different implants for fixation of femoral neck fractures lack methodological rigor. The superiority of one method of fixation over others cannot be concluded
- Impaction may decrease femoral head vascularity in fixation of displaced intracapsular fractures
- Compression may increase nonunion in fixation of displaced intracapsular fractures
- Operating times are significantly higher in open compared to closed internal fixation of femoral neck fractures
- There is no difference in the risk of complications, acetabular erosion, return to function or mortality between unipolar and bipolar hemiarthroplasty in femoral neck fractures
- The risk of postoperative pain at 1 year post surgery is significantly increased in uncemented compared to cemented arthroplasty

Mortality(at 1 year)	93,391	9	5,991/21,773	16,547/71,618	1.33	1.22–1.44	<0.001	0.02
Prospective studies ^b	3995	2	43/274	266/3721	2.11	1.46–3.04		0.85
Retrospective studies ^c	89,396	7	5948/21,499	16,281/67,897	1.33	1.22–1.44		0.09

CI, confidence interval; N, total sample size pooled; RR, relative risk.

^a The risk of outcome with delayed vs. early surgery. Values>1.0 favor delayed, values<1.0 favor early surgery). "Delayed" for most studies is >48 hours.

^b A single study in this group used a cut-off of 24 hours for delay.

^c A single study in this group used a cut-off of 72 hours for delay.

- The risk of failure to regain mobility is increased in patients with uncemented compared to cemented arthroplasty prostheses
- No significant risk differences were found between uncemented hemiarthroplasty compared to THA for any outcome
- Patients with the Moore implant were significantly more at risk for residual pain compared to those with THA
- No significant risk differences were found between cemented hemiarthroplasty compared to THA for any outcome
- The risk of dislocation is greater in THA compared to cemented hemiarthroplasty
- The risk of minor reoperation is higher in THA compared to cemented hemiarthroplasty
- Pain and function scores were better in patient with THA compared to cemented hemiarthroplasty
- Regional compared to general anesthesia may reduce short-term postoperative mortality, DVT and postoperative confusion in adult patients treated for hip fracture
- A single prophylactic dose of antibiotics significantly reduces postoperative deep and superficial wound infection, UTI, and respiratory infections in hip fracture patients
- Heparin (U and LMW) and physical devices are effective in reducing DVT in hip fracture patients
- The superiority of U heparin vs. LMW heparin in preventing adverse thromboembolic events is indeterminate
- Physical devices are effective in reducing overall risk of PE in postoperative hip fracture patients
- No conclusive evidence was found to show which form of thromboprophylaxis was most effective in reducing mortality and fatal PE
- The risk of mortality (at 30 days and 1 year) is decreased in patients with hip fracture who undergo early (<48 hours) surgery compared to delayed surgery

Conclusions

The incidence of hip fractures is increasing as the population ages, and controversies concerning the optimal treatment of intracapsular hip fractures continue to exist. It is therefore crucial that surgeons look to the current literature and seek out the evidence for the most optimal care of their patients. This chapter provides an overview of the best evidence on several of the top issues in hip fracture management. However, the need for trials with enough power and methodological rigor to answer the questions that are still inconclusive remains a priority in this patient population.

Intertrochanteric Fractures

Ole Brink and Lars C. Borris

Department of Orthopaedics, Trauma Research Unit, Århus University Hospital, Århus, Denmark

Case scenario

A 83 year old woman lives with her husband of the same age in a large house. One evening she falls and is unable to get up. Her husband has already gone to bed and does not hear her calling for help. The next morning she is found by the housekeeper and immediately brought to the hospital. The left leg is externally rotated and shortened and she feels great pain. Radiographic examination of the left hip showed an intertrochanteric fracture (Figure 56.1). Operative fixation was conducted on the day after admission.

Relevant anatomy

Hip fractures are anatomically classified in relation to the hip capsule as intracapsular fractures (femoral neck fractures) or extracapsular fractures (intertrochanteric and subtrochanteric fractures). This chapter will focus on management options for intertrochanteric fractures (also called pertrochanteric fractures). These fractures may be either stable (two-fragment fractures) or unstable (three or four main fragments). One of the commonly used classification systems for intertrochanteric fractures (see box) is the Evans–Jensen classification system.¹ Another much used classification system is the AO/OTA classification system,² which divides the intertrochanteric fractures into three groups with each group further divided into three subgroups. This classification system is very well suited for research and documentation.

Classification of intertrochanteric fractures

Evans–Jensen classification

- I: stable, no comminution
- Type II: stable, minimally comminuted, but displaced
- Type III: unstable due to lack of lateral support
- Type IV: unstable due to lack of medial support
- Type V: unstable due to lack of medial and lateral support

AO/OTA classification

- Group 1: simple (two-part) and stable, with a single extension into the medial cortex, but with intact lateral cortex of greater trochanter
- Group 2: multifragmentary and unstable, involving the greater and lesser trochanter
- Group 3: involvement of both the medial and lateral cortices with differing fracture direction in the subgroups

Importance of the problem

Intertrochanteric fractures represent about 50% of all hip fractures in elderly people and therefore are very common. The number per year in Europe and the United States is about 300,000, with the majority in women. All these fractures need operative treatment, some of them more than once, so they place a major economic burden on society. For the patient, impaired walking ability and leg shortening are common and may influence quality of life. A substantial mortality (around 25%) is also observed following these fractures.

Figure 56.1 Left-sided intertrochanteric fracture with involvement of the lesser trochanter.

Top five questions

1. How can surgeons reliably establish when an intertrochanteric fracture is unstable?
2. Should operative treatment take place within 24 hours of admission?
3. What is the best treatment option for this fracture type?
4. In patients with unstable intertrochanteric fractures, is a long intramedullary (IM) nail better than a short nail?
5. How can shortening of the leg be avoided after intertrochanteric fracture?

Question 1: How can surgeons reliably establish when an intertrochanteric fracture is unstable?

Case clarification

The radiograph of the patient's left hip shows an intertrochanteric fracture with involvement of the lesser trochanter and displacement at the fracture site (Figure 56.1). According to the Evans–Jensen classification it is a type IV fracture because there is lack of medial support; this means it is an unstable fracture.

Relevance

Whether an intertrochanteric fracture is stable or unstable is clinically important in terms of choosing the right method of stabilization and is related to the risk of complications and the overall outcome of treatment. A valid classification system for intertrochanteric fractures is an important tool for this purpose.

Current opinion

It is believed that the existing fracture classification systems can be used to discriminate between stable and unstable fracture patterns.

Finding the evidence

- Cochrane Database, with search term: “hip fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “hip fracture or intertrochanteric fracture”
- MEDLINE search identifying the population (hip fracture or intertrochanteric fracture) and the methodology (clinical trials). Keywords: “intertrochanteric fracture” and “classification,” “hip fracture” and “classification”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords “intertrochanteric fracture” AND “classification” AND “intertrochanteric fracture” AND “classification” and “reliability”

Quality of the evidence

Level III

- 6 studies with consecutive and nonconsecutive patients without consistently applied reference gold standard

Findings

A number of studies have evaluated the observer agreement with focus on the reliability to classify fractures in accordance with the AO/OTA and/or Evans–Jensen fracture classification systems. Four of these studies comprising a total of 234 radiographs evaluated by a total of 32 reviewers found poor reproducibility and reliability of both classification systems, with kappa values ranging from 0.33 to 0.56.^{3–6} Some evidence suggests, however, that the AO/OTA system without subgroups has a higher level of agreement and reproducibility compared with Evans–Jensen and in general should be used in preference to other classification systems.^{3,4}

When the question whether a fracture is stable or unstable has to be answered, agreement between surgeons is also relatively poor. Thus, in 2 studies 10 surgeons evaluated a total of 101 radiographs and agreement on stability or instability was reported in only 57% and 65% of cases, respectively.^{7,8} Another study with 12 reviewers who assessed 56 radiographs achieved fair agreement on fracture instability (intraclass correlation coefficient 0.38, 95% CI 0.28–0.50),⁹ but the inter- and intraobserver agreement on fracture stability was poor in a study with 10 observers evaluating 50 radiographs.¹⁰

Recommendations

- There is no classification system that can be used to reliably discriminate between stable and unstable intertrochanteric fractures

- The AO/OTA classification without subgroups should be used in preference to other systems

Question 2: Should operative treatment take place within 24 hours of admission?

Case clarification

This patient fractured her hip late in the evening and was not admitted to hospital until the next morning. Surgery was performed on the following day; thus, the time delay from fracture to surgery in this case was more than 24 hours.

Relevance

Surgery for hip fracture is frequently delayed as a result of time spent on blood sampling and analyses, preoperative medical evaluation, and optimization, but also due to unavailability of surgeons, anesthesiologists, or operating rooms.

Current opinion

Delay to surgery increases mortality and morbidity after hip fracture due to associated medical complications, i.e., thromboembolic events or cardiopulmonary complications.

Finding the evidence

- See Question 1
- Additional keywords used: “delay,” “timing of surgery”

Quality of the evidence

- Level I–II: 1
- Level III: 4

Findings

A systematic review and meta-analysis of 16 prospective and retrospective studies (257,357 patients) with a cut-off of 48 hours delay from hospital admission to surgery reported an increased 30 day mortality of 41% (OR 1.41, 95% CI 1.29–1.54) and an OR for 1 year mortality of 1.32 (95% CI 1.21–1.43).¹¹ In the analysis one large study accounted for 19% of all patients, but exclusion of this study had no significant effect on the overall results.^{11,12} Another review on 52 published studies (291,413 hip fracture patients) was not able to identify a clear relation between delayed surgery, mortality, and morbidity.¹³ Many of the studies included, however, represented a mixture of retrospective and unadjusted prospective studies with conflicting results, while studies with careful methodology were more likely to show a positive relation between early surgery and lower morbidity and mortality. A prospective study including 3,707 hip fracture patients found significantly increased mortality within 6 months when surgery was delayed more than 48 hours (OR 1.63, CI 1.16–2.3).¹⁴

Most studies have focused on the time delay from hospital admission until surgery, without considering the time delay from the fracture itself until surgery. A register study of 3,754 hip fracture patients analyzed the difference between the time delay from fracture until surgery and the time delay from hospital admission until surgery, and the influence on mortality.¹⁵ The study concluded that the time delay from hospital admission until surgery can be used as a surrogate for the time delay from fracture until surgery.

Recommendation

- We recommend that operation is not delayed more than 48 hours from admission to hospital

Question 3: What is the best treatment option for this fracture type?

Case clarification

There are basically two different methods for fixation of intertrochanteric fractures: sliding hip screw (SHS) or intramedullary (IM) nails. Our patient was treated with closed reduction and internal fixation, and insertion of an IM nail locked distally with a single screw.

Relevance

The method of fixation used for intertrochanteric fractures is relevant because it may be related to the treatment outcome in terms of fracture healing, patient function, and quality of life.

Current opinion

The current opinion among orthopedic surgeons is that unstable fractures should be operated with an IM device because it is believed that this gives a more stable fixation and a reduced risk of secondary displacement and functional impairment.

Finding the evidence

- See Question 1
- Additional keywords used: “internal fixation,” “nail,” “hip screw”

Quality of the evidence

Level I

- 3 meta-analysis

Findings

The latest Cochrane review concludes that the SHS appears to be a better implant than IM nails for the more common types of intertrochanteric fractures.¹⁶ The conclusions are based on results from 30 randomized controlled trials (RCTs) comparing sliding hip screw with either the Gamma nail (22 trials and 3,871 patients), IMHS (5 trials and 623 patients), or PFN (3 trials and 394 patients). The authors

found higher complication rates for the IM nails, with increased frequency of operative and postoperative fracture of the femur and more reoperation. Another meta-analysis of 24 studies and 3,279 fractures comparing short IM nails with SHS showed significantly more complications in the IM group, and the majority of complications occurred in unstable fractures.¹⁷ The same study found no evidence of fewer complications when using newer-generation IM nails. Conversely, a more recent meta-analysis reported that there seems to be a trend towards fewer implant-related fractures with newer-generation nails, but no firm conclusion about the potential advantages of these implants can be drawn at the present time due to lack of properly dimensioned randomized clinical studies.¹⁸ Nevertheless, a change towards more use of IM devices compared with SHS to fix intertrochanteric fractures from 3% in 1999 to 67% in 2006 has been demonstrated, especially among younger surgeons, and the change seems to be based on clinical outcome evidence factors.^{19,20} Several explanations for this have been suggested in terms of a change in training to focus more on IM fixation rather than on fixation with SHS, an attraction towards new devices, concerns about medical liability in case of failure of fixation with SHS, and finally a higher resource value unit (RVU) with IM fixation relative to fixation with SHS.^{19,20} In general it could be an advantage to use the same device to fix all intertrochanteric fractures because it will result in more experienced surgeons, however, the scientific evidence does not support superiority of IM nails over SHS for the time being.

Recommendation

- SHS and IM nails seem to be equally effective for surgical fixation of unstable intertrochanteric fractures based on the current evidence and can be chosen by the individual surgeon based on personal preference. We recommend using newer-generation nails

Question 4: In patients with unstable intertrochanteric fractures, is a long IM nail better than a short nail?

Case clarification

The patient was treated with a long IM nail (IMHS Smith & Nephew) locked distally with a single screw.

Relevance

The choice of a long vs. a short IM nail has an implication for the operative procedure and the experience of the surgeon.

Current opinion

Long nails are preferred by a number of surgeons in order to avoid the occurrence of secondary fractures at the tip of the nail and to obtain better stability.

Finding the evidence

- See Question 1
- Additional keywords used: "long nail," "short nail"

Quality of the evidence

- No evidence found

Findings

A short IM nail has a working length of around 150 mm whereas long nails have working lengths of 350–400 mm depending on the brand. Biomechanical data suggest that for unstable subtrochanteric fractures with comminution or segmental bone loss, treatment with long IM nails reduces fracture site motion which may allow early weightbearing.²¹ Most surgeons prefer to use long nails for unstable subtrochanteric fractures, intertrochanteric fractures with a subtrochanteric extension, inverse oblique intertrochanteric fractures, and cases with combined fractures of the proximal femur and the femoral shaft. Long IM nails have performed acceptably with low complication rates when used to treat subtrochanteric and proximal femoral shaft fractures.^{22,23} However, no comparative studies have been conducted to answer the question whether intertrochanteric fractures are best treated with short or long IM nails.

Recommendation

- We cannot recommend using long nails instead of short nails to treat unstable intertrochanteric fractures due to the sparse clinical evidence

Question 5: How can shortening of the leg be avoided after intertrochanteric fracture?

Case clarification

Our patient was a 83 year old woman with known osteoporosis and an unstable intertrochanteric fracture and was treated with an IM nail.

Current opinion

Current opinion among surgeons is that leg shortening is of minor clinical significance and is not related to the implant used.

Finding the evidence

- See Question 1
- Additional keywords used: "leg shortening"

Quality of evidence

Level I

- 2 systematic reviews/meta-analyses
- 2 randomized trials

Level II

- 2 randomized trials with methodological limitations

Level III

- 1 study

Findings

Leg shortening due to secondary fracture collapse with lateral displacement of the proximal fragment is common after unstable intertrochanteric fractures and among elderly patients with poor bone quality.¹⁶ The consequence of leg shortening is not only cosmetic, but the fracture collapse results in a weakening of the muscles around the hip joint causing prolonged postoperative disability and decreased patient mobility.^{24,25}

A retrospective study by Platzner (57 nongeriatric patients) reported that the degree of leg shortening was rather low and depended mainly on the fracture type,²⁶ but in case of unstable fractures the shortening was significantly less in patients treated with a IM nail.

The latest Cochrane review included 3 studies comparing Gamma nail with SHS and 1 study comparing IMHS with SHS with respect to leg shortening.¹⁶ Overall there was no difference between the two treatment groups but there was a tendency towards a reduced leg shortening in favor of the nail. No study has been identified any comparing PFN with SHS with respect to postoperative leg shortening, and studies comparing different nailing systems in this respect are also lacking.

Recommendation

- Unstable fractures may be better treated with IM nails, but the evidence is sparse

Summary of recommendations

- Classification systems cannot be used to identify stable and unstable fractures [overall quality: low]
- Operative treatment should not be delayed more than 48 hours from the patient's admission to hospital [overall quality: low]
- Stable intertrochanteric fractures can be treated with SHS without an increased risk of functional impairment [overall quality: moderate]
- Unstable intertrochanteric fractures can be treated with SHS or IM nails based on the current evidence and can be chosen by the individual surgeon based on personal preference [overall quality: low]
- We cannot recommend using long nails instead of short nails due to the lacking evidence [overall quality: low]
- Unstable fractures may be better treated with IM nails because of a tendency towards a decreased risk of secondary displacement and leg shortening [overall quality: low]

Conclusion

Intertrochanteric fractures are very frequent injuries in the elderly population. The diagnosis is made by clinical and radiographic examination. The existing fracture classification systems can be used to assess the type but are not useful to assess stability. There is some evidence to suggest that the operative treatment of these fractures should be carried out within 48 hours after hospital admission. Stable intertrochanteric fractures can be treated with SHS. Unstable fractures can be treated with SHS or IM nails, based on the current evidence. It cannot be evaluated whether long nails have better results compared with short nails. Overall, we need more studies to be able to make more valid conclusions.

In unstable fractures treatment may be better with newer-generation IM nailing compared with dynamic hip screw in order to avoid fracture collapse and secondary leg shortening.

Subtrochanteric Fractures

Steven Papp, Wade Gofton, and Allan S.L. Liew

University of Ottawa, Ottawa, ON, Canada

Case scenario

A 75 year old patient, currently ambulatory and living independently, presents to the Emergency Department after a fall at home. In the Emergency Department, she is found to have an isolated injury to the left lower extremity. She has hip pain and a shortened, externally rotated lower extremity. Radiographs show a proximal femur fracture (Figure 57.1). There is significant varus, abduction and flexion deformity of the proximal fragment in relation to the distal fragment. The OTA classification is an A3.1.

Relevant anatomy

In subtrochanteric femur fractures, the deformity of the fracture is determined by the deforming forces of muscular action on the proximal and distal fragments (Figure 57.2).

When dealing with subtrochanteric femur fractures, it is also important to understand the local bony anatomy and its relevance. It has been shown that as much as 1200 psi of force (8MNm^{-2}) are present in the femur with weightbearing in an average 200 lb (90 kg) man.¹ These forces are seen along the medial side of the femur approximately 1–3 inches (2.5–7.5 cm) below the lesser trochanter. Therefore, fixation used to manage these fractures may see significant loads during the healing period (even if a patient is toe-touch weightbearing). A simple fracture pattern in which an anatomic reduction is achieved will likely have a much lower failure rate (due to bony contact) than a more medially comminuted fracture or a fracture in which an anatomic reduction is not achieved.

Importance of the problem

Subtrochanteric femur fractures are not as common as femoral neck fractures or intertrochanteric hip fractures. However, early studies showed high failure rates (20%) when treating these fractures and have therefore generated interest in improving outcomes with improved treatment.^{2,3}

Top four questions

1. Which is the better starting point for nailing a subtrochanteric femur fracture: the trochanteric fossa or the tip of the trochanter?
2. Does anatomic reduction lead to lower failure rates than nonanatomic reduction?
3. When nailing a subtrochanteric fracture, does open reduction increase the nonunion rate in comparison to closed reduction?
4. Which device leads to the lowest failure device clinically: an extramedullary or intramedullary (IM) implant?

Finding the evidence

- PubMed and Ovid (1950–2010), search terms: “subtrochanteric femur fractures” AND “extramedullary implants” and “intramedullary implants” AND “open reduction” with limits: “Humans” and “English Language”
- Cochrane Review, search terms: “fracture” and “subtrochanteric femur fracture”

Figure 57.1 AP and lateral xray of a proximal femur fracture. This is a OTA 31 A3.1 type femur fracture with typical noted deformity. A/B.

- OTA meeting abstracts search (subtrochanteric fractures) 1996–2009

Question 1: Which is the better starting point for nailing a subtrochanteric femur fracture: the trochanteric fossa or the tip of the trochanter?

Case clarification

If an IM nail is chosen as the fixation device, there has been debate over different aspects of the surgical technique, including the starting point.

Relevance

The insertion site for antegrade nailing of subtrochanteric femur fractures may be the trochanteric fossa (many refer to this as a piriformis starting point) or the tip of the trochanter. The trochanteric fossa starting point will offer “in line” access to reaming, straight nail insertion, and possibly improved fracture reduction. Fracture reduction is important when dealing with a subtrochanteric femur fracture.

Figure 57.2 Schematic diagram of the muscular forces that deform a typical subtrochanteric femur fracture.

However, this insertion site may involve more soft tissue damage than a starting point at the tip of the trochanter. Starting at the tip of the trochanter may be easier, especially in an obese patient, and operative time and fluoroscopic time may be decreased. In addition, modern nails designed for insertion at the tip of the trochanter have a proximal lateral bend to fit this insertion site.

Current opinion

A trochanteric fossa starting point leads to less varus angulation in treatment of subtrochanteric femur fractures.

Quality of the evidence

- Level II: 1
- Level IV: 7

Reduction

In 4 studies there was a total of 153 cases in which the subtrochanteric fracture was stabilized with a nail that was started at the tip of the trochanter (level IV).⁴⁻⁷ Seven cases were reported to be in more than 5° varus, and 4 out of 153 patients were reported to have clinical failures. In 2 studies in which the trochanteric fossa starting point was used, varus deformity occurred in 31 of 82 cases (level IV),^{8,9} and 4 out of 82 patients had a clinical failure. However, the trochanteric fossa studies were more recent and evaluated alignment more carefully. In the only randomized study to date, 2 of 17 patients in the trochanteric fossa group and 4 of 17 patients in the trochanteric tip group had varus malalignment on follow-

up radiographs (level II).¹⁰ This was not found to be statistically significant, but the study was underpowered for this outcome.

The type of nail used may have an impact on the reduction when considering the starting point. In one study, five nails with differing lateral bends were studied and the amount of displacement in a cadveric subtrochanteric femur fracture model was studied. It was found that a starting point at the tip of the trochanter gave the best reduction in most cases, but the results were dependent on the lateral bend in the nail. Insertion through a laterally based (very lateral) trochanteric starting point always led to varus malreduction (level IV).¹¹

Outcome

In the retrospective reviews that were available, there were 6 out of 153 failures in the trochanteric tip starting point group and 4 out of 82 in the trochanteric fossa group (level IV). In the only randomized trial, there was no statistically different outcome with respect to blood loss, incision length, or duration of surgery (level II). There were no nonunions in this study.

Recommendations

- Either starting point can be used, and varus malalignment is relatively common with both [overall quality: moderate]
- There is no conclusive evidence that one starting point leads to a better outcome with respect to blood loss, duration of surgery, healing of fracture, or assessment of hip function [overall quality: moderate]

Question 2: Does anatomic reduction lead to lower failure rates than nonanatomic reduction?

Relevance

Because of the difficulty of treating this fracture and the relatively high failure rate of fixation in early studies, there has been focus on trying to improve these results. There has also been some focus on the importance of fracture reduction.

Current opinion

Complete stripping of bony fragments to achieve perfect anatomic reduction may be detrimental to fracture healing. But there has also been a focus on alignment. Currently, it is felt that varus malalignment and flexion malalignment should be corrected, or the fixation has an increased chance of failure.

Quality of the evidence

- Level II: 3 studies
- Level IV: 24 studies

Findings

The level IV studies inconsistently reported on quality of fracture reduction. In the studies that reported on fracture reduction, there was heterogeneity in reporting style. Some studies reported on anatomic vs. nonanatomic reduction. Others calculated neck–shaft angles and some even compared the injured leg to the normal contralateral leg. In most studies, nonanatomic referred to a varus deformity greater than 5°, flexion deformity greater than 10°, or the presence of a significant gap. In a total of 312 fractures that were reported as having an anatomic reduction, 6 (2%) failures were found. In 86 patients with a nonanatomic reduction, (26%) 22 patients had failure of fixation (level IV).

There were two studies that best documented correlation of reduction and outcomes. In the study by Haidukewych et al. there were 23 hips that were judged to be anatomic and 4 failed. In 24 fractures that were reduced nonanatomically, there were 11 failures (level IV).¹² Similarly, Shukla et al. found 3 of 19 failures when more than 10° of varus was present but no failures in anatomically reduced fractures. They recommended surgeons pay particular attention to alignment during reduction and that converting a closed to open nailing is necessary if an acceptable reduction cannot be achieved (level IV).¹³ In the three randomized trials, very little data was available on fracture reduction.^{14–16}

Recommendation

- Anatomic reduction decreases failure rates (2%) in comparison to poorly reduced fractures (26%) [overall quality: low]

Question 3: When nailing a subtrochanteric fracture, does open reduction increase the nonunion rate in comparison to closed reduction?

Case clarification

Closed reduction on the fracture table is unable to achieve a satisfactory reduction. Proceeding with closed nailing may improve the reduction but may not completely reduce the fracture, resulting in a malreduction. An open reduction would be needed to obtain a more accurate reduction.

Relevance

Varus malreduction is associated with higher nonunion rates and hardware failure. (see Question 2) Open reduction can improve the reduction to acceptable parameters; however, it has been suggested that open reduction techniques may be associated with increased nonunion rates secondary to soft tissue stripping, as well as increased infection rates.

Current opinion

Current opinion suggests that most surgeons use an open reduction technique for the IM nailing of subtrochanteric femur fractures.

Quality of the evidence*Level III*

- 1 case-control study

Level IV

- 1 case series

Findings

Nonunion Limited publications specifically address the effects of open reduction techniques with subsequent IM nailing of subtrochanteric fractures with adequate stratification of the complications of infection, malreduction/malunion, and nonunion by open or closed reduction technique. In two studies in which this was specifically addressed, no infection developed.

Nonunion was reported in 1/44 cases (2.3%) in one series in which an open reduction was performed for all cases.¹⁷ In another study by Ziran et al., using cerclage cable (4/10) and cerclage wire (0/14), 4 of 24 had nonunions. In this same study, closed nailing had a nonunion rate of 14.3% (8/56) and malunion rate of 16.1% (9/56). Overall there was a nonunion or malunion in 16.7% (4/24) with an open reduction technique compared with 30.4% (17/56) for closed reduction (level IV).¹⁸

Recommendation

In patients with displaced subtrochanteric fractures where closed manipulation does not achieve a satisfactory reduction, evidence suggests:

- Open reduction reduces the risk of malunion [overall quality: very low]
- Open reduction does not increase the risk of nonunion [overall quality: very low]
- Open reduction does not increase the risk of infection [overall quality: very low]

Question 4: Which device leads to the lowest failure device clinically: an extramedullary or IM implant?**Case clarification**

In this case, the patient has a subtrochanteric fracture. The OTA classification is an OTA 31 A3.1

Relevance

IM nail fixation and extramedullary plate and screw treatment have been advocated. Nail treatment is challenging in these fractures.

Current opinion

IM nailing is the most common treatment for subtrochanteric femur fractures and leads to a lower reoperation rate when compared to extramedullary plating.

Quality of the evidence

- Level II: 3 studies
- Level IV: 24 studies

Findings

Reoperation/failure of construct Restricting consideration to the use of more modern implants, we found 24 level IV articles and 3 level II studies. Retrospective reviews included 10 nail articles,^{4-6,8,9,13,17, 19-21} 11 plate articles,²²⁻³² and 3 comparative reviews (Table 57.1).^{12,33,34} There was considerable variability in the sample population among the 23 level IV articles. Plate studies looked at the DCS, the angled blade plate, or a locking plate. The nailing articles investigated the Gamma nail, the Russell Taylor nail, the proximal femoral nail or the intramedullary hip screw. The heterogeneity of the devices used also makes it difficult to interpret pooled data. In these studies, an extramedullary implant was used in 340 patients and there were 17 failures for an overall failure rate of 5%. In a group of 1094 IM nails used for these fractures, there were 64 failures for a failure rate of 6%. It appears in more recent retrospective reviews that either nail or plate fixation is able to treat this fracture successfully, with a failure rate around 5%. However, failure rates may be higher in more comminuted fractures (Seinsheimer III–V) and one implant may be superior to the other when dealing with the more comminuted subtrochanteric femur fracture.

There are three randomized trials that compare extramedullary and IM implants for the treatment of subtrochanteric femur fractures (level II).¹⁴⁻¹⁶ In all three of these studies the patient population involved elderly patients with low-energy falls, so this data may not apply to the younger patient with the higher-energy fracture pattern which makes up a significant portion of patients with this injury. In two of three studies, the subtrochanteric femur fractures were only a subset of a bigger population of patients with pertrochanteric hip fractures. All three studies had a small number of patients randomized. An evidence-based review of these studies has been published by Kuzyk et al.³⁵ Pooled data found a reduced relative risk for reoperation but this did not reach statistical significance (0.287; 95% CI 0.062–1.327). The majority of failures in the extramedullary group came in the study by Sadowski et al.¹⁴ in which the device used was the Dynamic Compression Plate. Based on their assessment, Kuzyk made a grade B recommendation that IM fixation reduces the rate of postoperative fixation failure (Figure 57.3).

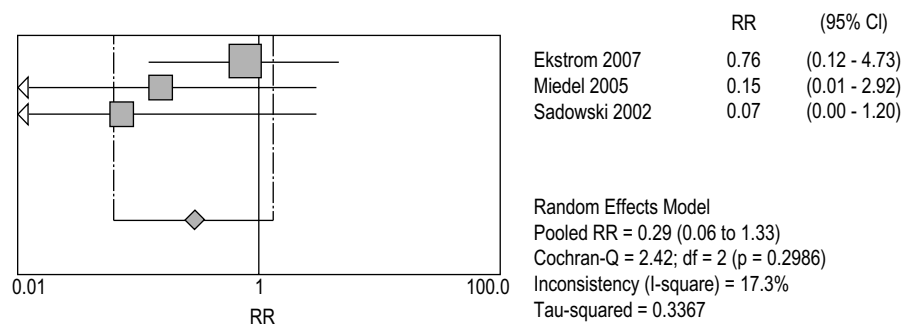

Figure 57.3 Forest plot of relative risk (RR) for failure of fixation for intramedullary compared with extramedullary implants. (Squares represent the RR for individual studies and the diamond represents the pooled RR.) (Reproduced from Kuzyk et al. Intramedullary versus extramedullary fixation for subtrochanteric femur fractures. J Orthop Trauma. 2009 Jul;23(6):465–70 with permission from Wolters Kluwer Health.)

Recommendations

- There is a reduced relative risk of fixation failure with IM fixation over extramedullary fixation when dealing with elderly patients with osteoporotic fractures [overall quality: low]
- In younger patients with a high-energy fracture, fixation failure is equivalent for both IM fixation and extramedullary fixation. Further study is needed [overall quality: very low]

Summary of recommendations

- Both starting points can be used and varus malalignment is relatively common with both
- There is no conclusive evidence that one starting point leads to a better outcome with respect to blood loss, duration of surgery, healing of fracture or assessment of hip function
- Anatomic reduction decreases failure rates (2%) in comparison to poorly reduced fractures (26%)
- In patients with displaced subtrochanteric fractures where closed manipulation does not achieve a satisfactory reduction, evidence that open reduction reduces the risk of malunion and does not increase the risk of nonunion or infection
- There is a reduced relative risk of fixation failure with intramedullary fixation over extramedullary fixation when dealing with elderly patients with osteoporotic fractures
- In younger patients with a high-energy fracture, fixation failure is equivalent for both IM and extramedullary fixation

Costas Papakostidis and Peter V. Giannoudis

University of Leeds, Leeds General Infirmary, Leeds, UK

Case scenario

A 30 year old man is transferred to the Emergency Department after being involved in a motorcycle accident. He complains of severe pain in his right thigh. On examination his right thigh is swollen, while the entire right leg is abnormally deviated and shortened. He is neurovascularly intact.

Relevant anatomy and biomechanics of the femoral shaft

A femoral shaft fracture is easily diagnosed clinically by the presence of severe local pain, axial deviation, and shortening and abnormal function of the injured limb. As the femur is the largest and strongest tubular bone of the human skeleton, significant forces are required in order for it to be fractured. Consequently, femoral fractures, especially in young individuals, are the result of high-energy trauma. Associated injuries are often present and dictate the treatment plan. The bulky soft tissue envelope surrounding the femoral bone protects from open injuries in most cases. However, the high amount of energy dissipated by the thigh in case of femoral shaft fracture can sometimes result in various degrees of injury to the soft tissue envelope, including various grades of open fractures and even closed subcutaneous degloving injuries. Therefore, neurovascular assessment should be an integral part of the clinical examination.

Importance of the problem

Very few epidemiological studies regarding diaphyseal femoral fractures exist in the literature. In one study, conducted in the population of Rochester, Minnesota (USA) over a 20 year period (1965–1984) the overall incidence of diaphyseal femoral fractures was 18.9 per 100,000 person-years.¹ Severe trauma accounted for the majority of diaphyseal femoral fractures in young patients, and showed a male preponderance.¹ In a more recent epidemiological study conducted in Finland over a 10 year period (1985–1994), the documented incidence of diaphyseal femoral fractures was 9.9 per 100,000 person-years.² The highest incidences with regard to age and gender were seen in males 15–24 years old and females above 75 years of age, and 75% of the fractures were the result of high-energy trauma.²

From the above studies, it is clear that femoral shaft fractures present a bimodal distribution. The first peak incidence is associated with high-energy trauma occurring in young men; another peak incidence is observed in elderly women and is associated with low-energy trauma within the context of osteoporosis. The two distinct patient population groups should be considered separately when comparing treatment options, complications, and outcome. High-energy femoral shaft fractures present a high incidence of associated injuries, including chest, head, pelvis, and ipsilateral leg injuries in pedestrians, and pelvic and ipsilateral leg injuries in motorcyclists.³

The internet is teeming with an enormous amount of information regarding femoral shaft fractures. A Google

search for “femoral shaft fractures” returns over 694,000 hits. However, the treating surgeon cannot easily draw useful information for optimal decision-making from this heterogeneous material, and there is a pressing need for pre-evaluated evidence-based guidelines.

Top ten questions

Diagnosis

1. What are the implications of concomitant fractures of the ipsilateral neck of femur or distal end of femur?

Therapy

2. What is the optimal entry point in antegrade nailing?
3. Do unreamed nails have the same clinical success as reamed ones?
4. Does retrograde femoral nailing yield equivalent results to antegrade nailing?
5. Is the use of manual traction on a standard table more advantageous over the fracture table in intramedullary (IM) nailing of femoral shaft fractures?
6. What is the optimal timing for IM nailing of femoral shaft fractures in patients with chest trauma?
7. What is the optimal timing for IM nailing of femoral shaft fractures in patients with head injury? Openmirrors.com
8. Is the damage control orthopedics (DCO) approach a safer alternative to early total care (ETC) in polytrauma patients with femoral shaft fractures?
9. Is femoral plating preferable to reamed IM nailing in polytrauma patients with femoral shaft fractures and concomitant head or chest injury?

Prognosis

10. Is there a functional impairment after isolated femoral shaft fracture?

Question 1: What are the implications of concomitant fractures of the ipsilateral neck of femur or distal end of femur?

Case clarification

The patient’s radiographs reveal a fracture of the femoral diaphysis and a concomitant fracture of the ipsilateral neck of femur. The combination of ipsilateral hip and femoral shaft fractures has been reported in 0.8–8.6% of femoral shaft fractures.⁴ This represents a high-energy injury with a 44% prevalence of associated multiple trauma. A high index of suspicion is required for early diagnosis and appropriate treatment, as ipsilateral femoral neck fracture may be initially missed in one third of cases of femoral

shaft fractures.⁴ Treatment options include: (1) IM nail with additional screws, (2) cephalomedullary nail, and (3) plate and screws for the fracture of the femoral diaphysis and additional screws for the fracture of the neck of femur. Although an anatomic reduction of the femoral neck fracture is considered of paramount importance, the best treatment option for this combined skeletal injury is controversial.

Finding the evidence

A systematic literature search was conducted in order to delineate the effect of the alternate treatment options of ipsilateral femoral neck and shaft fractures on union, malunion, deep infection, avascular necrosis (AVN) of the femoral head, and reoperation.

- Cochrane Database, with search term “femur fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “femoral neck” AND “femoral shaft fracture” PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: (“ipsilateral femoral neck” AND “shaft fracture”) OR (“concurrent femoral neck” AND “shaft fracture”)
- Review of references of eligible studies

Quality of the evidence

Level III

- 1 case-control study⁵

Level IV

- 1 meta-analysis of case series studies⁶

Findings

A retrospective comparison between two methods of fixation—compression plate and hip screws (n = 15 patients) vs. reconstruction IM nailing (n = 12 patients)—failed to document any statistically significant difference between the two treatment methods with respect to non-union, delayed union, loss of reduction of the femoral neck, osteonecrosis of the femoral head, and functional outcome.⁵ Although the use of a single implant was associated with a higher reoperation rate compared with the combination of compression plate and hip screws (4/12 for the reconstruction nail vs. 0/15 for the plate and hip screws), the difference did not reach statistically significant levels (p = 0.06) (Table 58.1).

Evidence from the meta-analysis of case series studies suggests that customary locked IM nails in combination with hip screws and cephalomedullary nails (reconstruction nails) may result in better union rates for the femoral shaft fracture than plate fixation. On the other hand, separate neck and shaft implants (IM nails with hip screws or femoral shaft plates with hip screws) may result in fewer reoperations than single implants (reconstruction nails) (Table 58.2).

Table 58.1 Outcomes of a retrospective comparative study (Singh et al.⁵) of two treatment options for concomitant femoral shaft and ipsilateral femoral neck fractures: femoral shaft plating with additional hip screw vs. reconstruction intramedullary nail

	Age (mean, years)	Nonunion		Delayed union		AVN	Reoperation	Good outcome
		Neck	Shaft	Neck	Shaft			
Group 1 (n = 15): Hip: screws Shaft: plate	33.2 ± 6.2	0/15	0/15	nd	2/15	0/15	0/15	13/15
Group 2 (n = 12): Recon IMN	37.9 ± 11.6	1/12	0/12	nd	3/12	1/12	4/12	10/12
P value	0.18	0.9	0.78		0.78	0.9	0.06	1.0

AVN, avascular necrosis; IMN, intramedullary nail; nd, not determined.

Table 58.2 Outcomes of various treatment methods for ipsilateral femoral neck and shaft fractures, as documented in a systematic review of the literature (n = 659 patients)⁶

	Age (mean, years)	Nonunions		Reoperation		Malunion		AVN
		Neck	Shaft	Neck	Shaft	Neck	Shaft	
Neck: screws Shaft: plate	34	nd	8/82 (10%)	0/82 (0%)	5/82 (6%)	1/82 (1.2%)	3/82 (4%)	1/82 (1.2%)
Neck: screws Shaft: IMN	34	nd	2/73 (3%)	5/72 (7%)	1/73 (1.3%)	1/72 (1.4%)	6/72 (8%)	2/72 (3%)
Cephalomedullary nail (single implant)	34	nd	0/38 (0%)	6/38 (16%)	2/38 (5%)	2/38 (5%)	1/38 (3%)	2/38 (5%)

AVN, avascular necrosis; IMN, intramedullary nail; nd, not determined.

Recommendations

- It is doubtful whether the use of a single implant (cephalomedullary nail) could result in increased likelihood for reoperation compared to the combined use of compression plate and hip screws [overall quality: low]
- Better union rates for the femoral shaft fracture may result from the use of intramedullary implants (locked intramedullary nails combined with hip screws or cephalomedullary nails) [overall quality: low]

Question 2: What is the optimal entry point in antegrade nailing?

Case clarification

Assuming, in our previous case scenario, that the patient had sustained an isolated fracture of the femoral shaft, then the treatment of choice would be antegrade IM nailing. The selection of entry point is important in antegrade nailing, since nail insertion through a wrong portal may lead to intraoperative complications.⁷

Current opinion

IM nail fixation constitutes the gold standard in femoral shaft fracture treatment. However, there still exist controversial issues related to the optimal management of these fractures. Many orthopedic surgeons prefer the piriformis fossa as the standard entry point because of its collinear relation with the long axis of the femoral shaft, while others utilize the tip of greater trochanter, although it is located more laterally with respect to the proximal projection of the medullary canal. Potential advantages of the use of the trochanteric tip as starting entry portal include less operative time, less intraoperative fluoroscopy, and a reduced risk of complications, such as AVN of the femoral head and iatrogenic fracture of the neck of femur.

Finding the evidence

In order to provide evidence as for the optimal entry portal in antegrade IM nailing we undertook a systematic literature search:

- Cochrane Database, with search terms “femur fracture,” “intramedullary nail,” “entry point”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “femoral shaft fracture,” “intramedullary nailing,” and “entry point”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/):sensitivity search using the following keywords and Boolean operators: “femoral nailing” AND “entry point”
- Review of references of eligible studies

Quality of the evidence

Level II

- 2 randomized trials with methodologic limitations^{8,9}

Findings

Pooled estimates of the key results are as follows.

Union rate Two trials (n = 125 patients) provided data regarding union rate.^{8,9} The choice of entry portal in ante-grade nailing (piriformis vs. greater trochanter entry) did not seem to affect union rate (risk ratio 1.01, CI 0.94–1.07, p = 0.82, homogeneity not applicable).

Malunion rate Both eligible trials (N = 125 patients) provided data with regard to malunion.^{8,9} No statistically significant risk of malunion was documented with either technique using different entry portals (risk ratio 0.43, 95% CI 0.11–1.76, p = 0.24, homogeneity p = 0.68).

Operative time Although both trials provided data with regard to operative time, a pooled estimate of the effect size could not be estimated due to lack of standard deviation (SD) values of the mean operative time. Consequently, the results of each study were interpreted individually. In one study⁸ the above two groups (piriformis fossa and greater trochanter) did not show statistically significant difference with respect to operative time (p = 0.26). In the other study⁹ the piriformis fossa (PF) group showed a longer mean operative time compared to the greater trochanter (GT) group, although this difference did not reach statistically significant levels (p = 0.08). This difference, however, was magnified in obese patients, where the operative time was 30% greater in the PF group than in the GT group (p < 0.05).

Fluoroscopy time Only one trial provided relevant data regarding fluoroscopy time.⁹ The PF group showed a 61% increase in fluoroscopy time with respect to the GT group and this difference was statistically significant (p < 0.05). Moreover the difference was further intensified in the subgroup of obese patients, where the fluoroscopy time was 73% higher in the PF group (p < 0.02).

Recommendations

- The union process or the risk of malunion of femoral shaft fractures does not depend on the choice of the entry

portal (piriformis or trochanteric) of the IM nail that is used for its treatment [overall quality: moderate]

- The use of piriformis entry portal in obese patients is associated with significant increase of both operative and fluoroscopy time compared with greater trochanter entry [overall quality: moderate]

Question 3: Do unreamed nails have the same clinical success as reamed ones?

Case clarification

In our case scenario the patient had a grade II open femoral shaft fracture. In addition he had suffered a chest contusion. An unreamed femoral nail is considered a more appropriate treatment option for such a situation.

Although the use of reamed IM nails for the management of femoral shaft fractures has been associated with overall excellent clinical results, concerns about the biological consequences of reaming have increased interest in the femoral nailing technique without reaming. Femoral nailing with reaming has been associated with high union and low implant failure rates, but the reaming process has been thought to generate bone marrow embolization phenomena, disrupt of cortical blood flow, and theoretically increase the risk of infection, particularly in open fractures. On the other hand, the use of smaller-diameter unreamed nails has raised concerns about rates of fracture healing and implant failure.

Finding the evidence

In order to evaluate reliably the merits of one technique over the other, we conducted a systematic literature search, using the following databases and references of retrieved articles:

- Cochrane Database, with search terms “femur fracture” AND “intramedullary nail”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “femur fracture” AND “intramedullary nail”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: “femur fracture” AND “reamed nails”, “femur fracture” AND “unreamed nails” OR “nonreamed nails”
- Review of references of eligible studies

Quality of the evidence

Level I

- 7 randomized trials^{10–16}

Level III

- 1 case-control study¹⁷

Our conclusions were based on the evidence available from higher-quality studies, i.e., randomized controlled trials (RCTs).

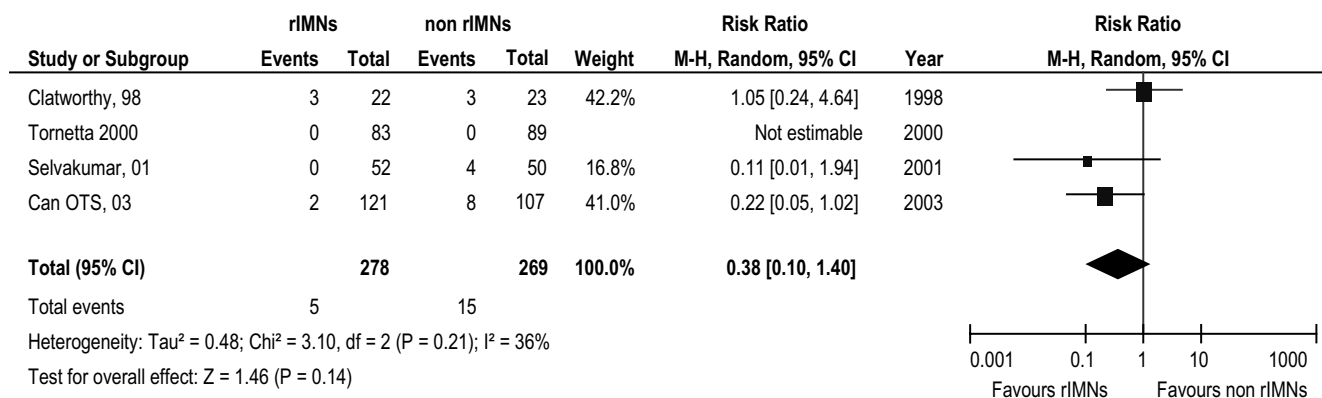

Figure 58.1 Forest plot of nonunion rates between reamed and nonreamed femoral nails.

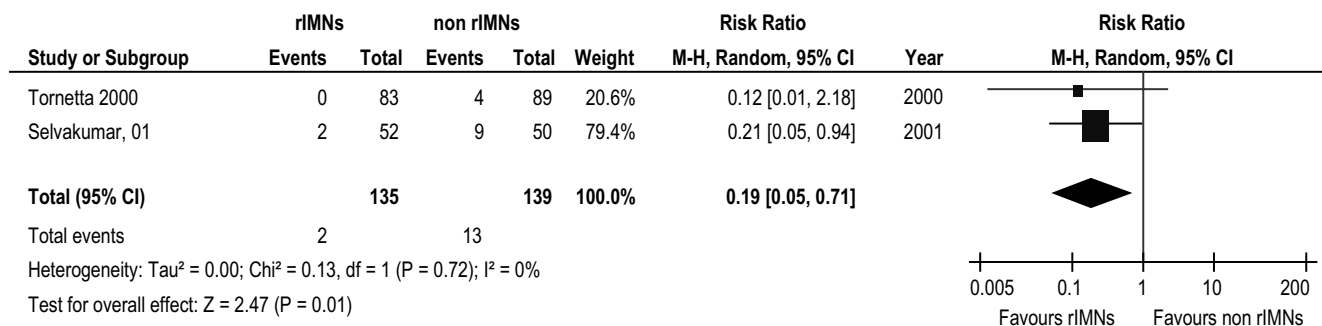

Figure 58.2 Forest tree of delayed union rates, between reamed and nonreamed femoral nails.

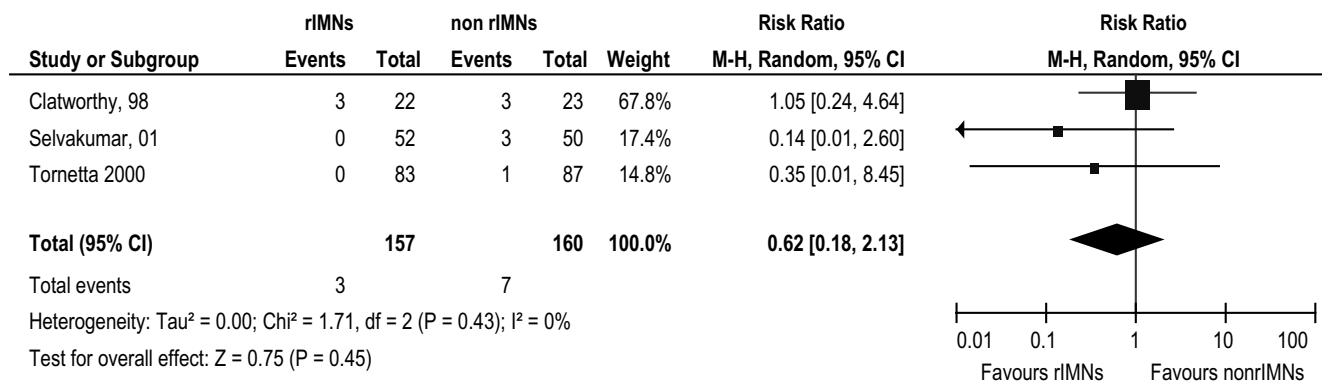

Figure 58.3 Forest plot of implant failure rates between reamed and nonreamed femoral nails.

Findings

Union complications

• **Nonunion:** Four trials^{10,11,13,15} (N = 547 patients) provided relevant data. Reamed IM nails showed a tendency for fewer nonunions compared to nonreamed nails, although this difference did not reach statistically significant levels (relative risk 0.38, 95% CI 0.10–1.40, p = 0.14, homogeneity p = 0.21) (Figure 58.1).

• **Delayed union:** Two trials^{10,15} (n = 274 patients) provided data regarding delayed union. Reamed IM nailing was associated with a statistically significant risk for delayed

union compared with nonreamed nails (risk ratio 0.19, 95% CI 0.05–0.71, p = 0.01, homogeneity p = 0.72) (Figure 58.2).

Implant failure Three trials^{10,13,15} (N = 317 patients) provided data regarding implant failure. The reamed nails were associated with a lower risk (but not statistically significant) of implant failure compared to nonreamed nails (relative risk 0.62, 95% CI 0.18–2.13), p = 0.45, homogeneity p = 0.43) (Figure 58.3).

Pulmonary complications Three trials^{10,12,16} (N = 569 patients) provided data on pulmonary complications. Reamed nails

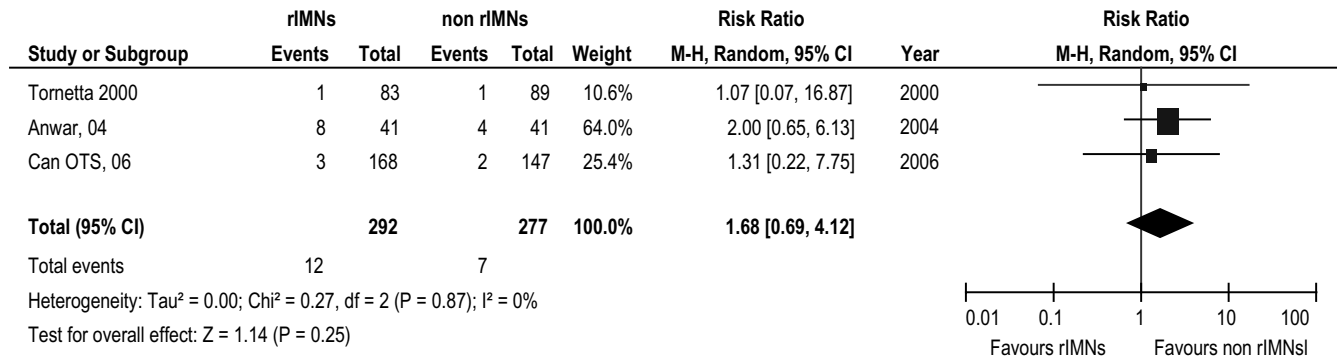

Figure 58.4 Forest plot of pulmonary complications between reamed and nonreamed femoral nails.

appeared to have a greater tendency towards developing pulmonary complications than nonreamed nails, but not to a statistically significant level (relative risk 1.68, 95% CI 0.69–4.12, $p = 0.25$, homogeneity $p = 0.87$) (Figure 58.4).

Recommendations

- The use of unreamed femoral nails is associated with a significant risk of delayed union compared with reamed nails [overall quality: high]
- With respect to other union complications (non union, implant failure), no significant superiority of the reamed over nonreamed nails was proven [overall quality: moderate]
- Reamed femoral nails were not associated with a significantly higher risk of developing pulmonary complications compared with nonreamed nails [overall quality: moderate]

Question 4: Does retrograde femoral nailing yield equivalent results to antegrade nailing?

Case clarification

In our initial case scenario the patient had suffered a femoral shaft fracture accompanied by an ipsilateral femoral neck fracture. One treatment option for the femoral shaft fracture is retrograde femoral nailing, so as to avoid interference with the fixation of the concomitant fracture of the ipsilateral femoral neck.

Antegrade nailing is the standard technique for operative management of femoral shaft fractures. It has yielded high union rates and low infection and malunion rates. However, as antegrade nail insertion in essence violates the abductor musculature; it can potentially cause abductor weakness and limp. Moreover, in certain situations retrograde nailing has appeared as a viable alternative. Such conditions include floating knee injury (as both femoral and tibial fractures can be addressed through the same skin incision), ipsilateral acetabular or pelvic fractures (where the incision for antegrade nailing is inappropriate for the fixation of the pelvic or acetabular fracture), ipsilateral frac-

ture of femoral neck (retrograde nailing of femoral shaft does not interfere with cannulated screw fixation of the concomitant fracture of the ipsilateral neck of femur), obesity, or pregnancy (retrograde nailing is associated with reduced exposure of fetus to radiation).

Finding the evidence

In order to provide a direct comparison of these two techniques in terms of clinical outcome, we undertook a systematic literature search using the following strategy:

- Cochrane Database, with search terms “femur fracture,” “retrograde nailing,” “antegrade nailing”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “femur fracture” AND “antegrade” OR “retrograde nailing”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: “femur fracture” AND “antegrade nailing” and “femur fracture” AND “retrograde nailing”
- Review of references of eligible studies

Quality of the evidence

Level II

- 2 RCTs with methodologic limitations^{18,19}

Level III

- 2 case-control studies^{20,21}

Level IV

- 1 systematic review of case series studies²²

Findings

The two RCTs (level II)^{18,19} and one case-control study (level III)²⁰ were analyzed together and a pooled estimate of effect size for each outcome of interest was obtained. Another case-control study evaluating antegrade and retrograde nailing techniques in two distinct patient populations, obese and nonobese, was analyzed separately.²¹ Lastly, the systematic review of literature provided summarized pooled estimates of various key outcomes of interest.²²

Union complications

• Nonunion: Data regarding nonunion were available in all three trials (N = 353 patients).^{18,19,20} A pooled estimate of effect size did not reveal any difference between antegrade and retrograde nailing with regard to union rate (relative risk 0.99, 95% CI 0.37–2.69, p = 0.99, homogeneity p = 0.65, I² = 0%). One systematic review of literature²² documented a combined union rate of 94.2% and a mean time to union of 3.2 ± 0.4 months for femoral shaft fractures treated with retrograde nailing.

• Malunion: Two studies provided relevant data with regard to axial malalignment (N = 267 patients).^{18,20} The risk of axial malalignment did not differ significantly between the two evaluated nailing techniques (relative risk 0.85, 95% CI 0.20–3.68, p = 0.83, homogeneity p = 0.18, I² = 45%). Two studies provided relevant data with regard to rotational malalignment.^{18,20} Although antegrade nailing showed a clear advantage on controlling correct rotational alignment of the lower limb over retrograde nailing, the respective difference was not statistically significant (relative risk = 0.57, 95CI = 0.20–1.59, p = 0.28, homogeneity p = 0.72, I² = 0%). The systematic review of literature documented an overall malunion rate of 7.4% for femoral shaft fractures treated with retrograde nailing.

Long-term pain at the entry portals Two studies reported on long-term hip pain (N = 256 patients),^{19,20} and all three studies gave information about knee pain (N = 299).^{18–20} The risk of long-term hip pain was quadruple with antegrade over retrograde technique (relative risk 4.02, 95% CI 1.27–12.70, p = 0.02, homogeneity p = 0.46, I² = 0%) (Figure 58.5). As for long-term knee pain, a clear conclusion could not be reached due to the presence of significant statistical heterogeneity (homogeneity p = 0.08, I² = 60%). The systematic review of literature documented a 24.5% rate of knee pain in femoral shaft fractures treated with retrograde nailing. This was significantly greater compared to the prevalence of knee pain in distal femoral fractures treated with retrograde nailing (16.5%), (p = 0.014, odds ratio 1.65, 95% CI 1.11–2.45).

With regard to the role of either (retrograde vs. antegrade) technique in association with increased body mass

index (BMI), one comparative study provided relevant data.²¹ Antegrade technique in the obese group of patients (OG) was associated with 53% greater average operative time than in the nonobese group (NOG) (p < 0.003). As for the retrograde nailing technique, there was no statistically significant difference in terms of mean operative time between OG and NOG. Antegrade technique in the OG was associated with 79% greater average radiation exposure time compared with the same technique in the NOG (p < 0.003). For retrograde technique, mean fluoroscopy time was similar between OG and NOG. Within the OG, antegrade technique was proved more time consuming, requiring 40% greater average operative time compared with the retrograde technique (p < 0.02). As for radiation exposure time, within the same group of obese patients, antegrade technique required three times more average fluoroscopy time than retrograde nailing (p < 0.002).

Recommendations

- Current literature does not suggest any superiority of either technique over the other in the general population with regards to union complications [overall quality: moderate]
- The risk of long-term hip pain appears to be significantly more frequent with antegrade than retrograde technique [overall quality: low]
- Existing evidence cannot document any potential association of either of these techniques with long-term knee pain [overall quality: low]
- In obese patients, antegrade technique is associated with significantly greater operative and radiation exposure times compared with nonobese patients [overall quality: low]

Question 5: Is the use of manual traction on a standard table advantageous over the fracture table in IM nailing of femoral shaft fractures?

Case clarification

The patient in our case scenario was multiply injured with concomitant abdominal injury. An exploratory laparotomy was performed and, when completed, he was hemody-

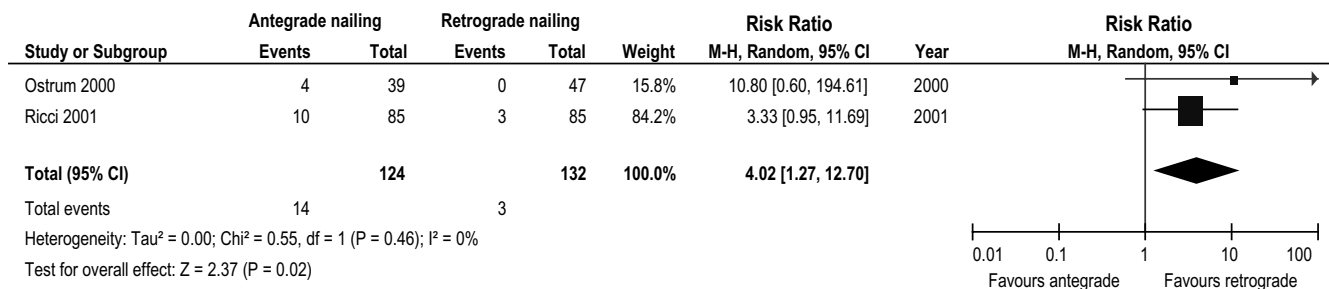

Figure 58.5 Forest plot of antegrade vs. retrograde nailing with respect to the outcome: “long-term hip pain.”

namically stable and fit for having his femur fracture fixed. In order to avoid transfer of the patient to a fracture table for a standard femoral nailing procedure, it was decided to perform the operation on the standard table.

Closed IM nailing has become the standard procedure for the management of femoral shaft fractures. The technique is usually performed on a fracture table that exerts controlled longitudinal traction to facilitate fracture reduction and nail insertion. However, the use of a fracture table presents various disadvantages, such as prolonged time for setup, and is not practical for polytrauma patients (who often require transfer to a standard table to treat other injuries). In addition, use of a fracture table has been related to certain complications such as pudendal nerve palsy, well-leg compartment syndrome, and perineal skin sloughing. As an alternative, another technique has been described for IM nailing of femoral shaft fractures, using manual traction on a standard radiolucent table.

Finding the evidence

In order to compare the above two techniques in terms of quality of reduction, operative time, complications, and functional outcome we conducted a systematic literature review using the following search strategy:

- Cochrane Database, with search term: “femur fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “femur fracture” AND “fracture table” OR “manual traction”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: “femur fracture” AND “fracture table” and “femur fracture” AND “manual traction”
- Review of references of eligible studies

Quality of the evidence

Level I

- 1 study²³

Level III

- 2 studies^{24,25}

Findings

Quality of reduction In a level I study (N = 87 patients),²³ quality of reduction was evaluated by CT measurements, using the contralateral intact femur as reference. The fracture table group (FT) was characterized by a significantly greater risk of internal malrotation (>10°) compared with the manual traction group (MT) (relative risk 0.77, 95% CI 0.62–0.94, p = 0.007). The number needed to treat (NNT) was 4.6; this means that in every 5 patients treated with manual traction on a radiolucent table, 1 excessive internal malrotation (>10°) could have been prevented. The two groups did not differ significantly with respect to leg length

discrepancy greater than 10mm (relative risk 0.31, 95% CI 0.03–2.88).

Operative time In a level I study (N = 87 patients),²³ operative time was significantly shorter in the MT group (mean 119 min, range 65–180 min) than in the FT group (mean 139 min, range 100–212 min), p < 0.05. Two other level III studies, including N1 = 83 patients and N2 = 720 patients respectively, reported on operative time,^{24,25} but pooling of their results was not possible because of missing SD values. Both these studies also documented a significantly shorter operative time in the MT group compared to the FT group (p < 0.05).

Blood loss One level I study (N = 87 patients) provided relevant data. Although estimated blood loss was significantly higher in the FT group (p = 0.004), the observed mean difference (159 mL) was not of clinical importance.

Functional outcome Functional outcome (using Short Form-36²⁶ and Musculoskeletal Function Assessment Instrument²⁷) was reported in one level I study.²³ No statistically significant difference was detected between the two groups with regard to functional status at 6 months and 1 year postoperatively.

Recommendations

Current evidence suggests that:

- The use of manual traction instead of a fracture table during IM nailing of femoral shaft fractures significantly reduces the risk of internal malrotation in excess of 15°, and shortens operative time [overall quality: high]
- The FT technique was associated with significantly higher blood losses than the MT technique, but the mean quantity of blood loss is perhaps of no clinical significance [overall quality: high]
- No statistically significant difference was documented between FT and MT with respect to functional outcome [overall quality: high]

Question 6: What is the optimal timing for IM nailing of femoral shaft fractures in patients with chest trauma?

Case clarification

Our patient, in addition to the abdominal injury, was suffering from lung contusions. What is the existing evidence in literature regarding optimal timing of femur fracture fixation?

It is well established that expeditious fixation of isolated femoral shaft fractures decreases the risk of severe pulmonary complications, allows prompt mobilization of the injured patient, and shortens hospital stay. However, femur fractures frequently occur within the context of multiple

trauma. In such situations the optimal timing of femoral fracture fixation should weigh the benefits of early fracture stabilization against the detrimental effects of an operation that may decompensate an acutely injured and potentially incompletely resuscitated patient. Concomitant thoracic injury poses additional concerns for even fatal complications, particularly when reamed IM nailing is contemplated.

Finding the evidence

In order to investigate the impact of timing of femoral shaft fracture fixation on the outcome of polytrauma patients with concomitant chest injury, we undertook a systematic literature search. Our aim was to investigate whether early (<24 hours) femoral shaft fracture fixation in polytrauma patients with concomitant chest trauma resulted in more complications compared to delayed fracture fixation. Our search strategy was conducted according to the following steps:

- Cochrane Database, with search term: "femur fracture"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "femur fracture" AND "timing of fixation"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: "femur fracture" AND "chest trauma" and "femur fracture" AND "pulmonary injury"
- Review of references of eligible studies

Quality of the evidence

Level I

- 1 study²⁸

Level III

- 6 studies²⁹⁻³⁴

Findings

We pooled the results of the above studies, including both randomized and nonrandomized trials, in the absence of

significant statistical heterogeneity. We used relative risk estimates for each outcome of interest and random effects model to estimate confidence intervals for relative risks.

Mortality Mortality rates were available in 6 studies reporting on N = 686 patients.²⁸⁻³³ Early fixation (<24 hours) of femoral shaft fractures seemed to predispose to increased mortality compared to late fracture fixation (>24 hours), although the difference was not statistically significant (relative risk 1.66, 95% CI 0.69–4.00, p = 0.26, homogeneity p = 0.35, I² = 10%).

Acute respiratory distress syndrome (ARDS) Four studies (N = 298 patients) provided data on ARDS rates.^{28,30,33,34} A pooled estimate of effect size could not be obtained due to the presence of significant statistical heterogeneity (homogeneity p = 0.01, I² = 73%). Three studies favored early (<24 hours) fracture fixation for minimizing the risk of ARDS,^{28,33,34} while another one favored late (>24 hours) fracture fixation³⁰ (Figure 58.6).

Major pulmonary complications Five studies including 571 patients reported on major pulmonary complications (i.e., at least one of the following: ARDS, pneumonia, fat embolism, pulmonary embolism). A pooled estimate of effect size could not be obtained due to the presence of significant statistical heterogeneity (homogeneity p = 0.0001, I² = 83%). The results of three studies^{28,29,33} favored early fixation for reducing the risk of major pulmonary complications, whereas another two studies^{30,31} favored late fracture fixation (Figure 58.7).

Recommendation

- Current literature is unable to provide clear guidelines with regard to the optimal timing of IM nailing of femoral shaft fractures in multiply injured patients suffering from concomitant lung injuries [overall quality: moderate]

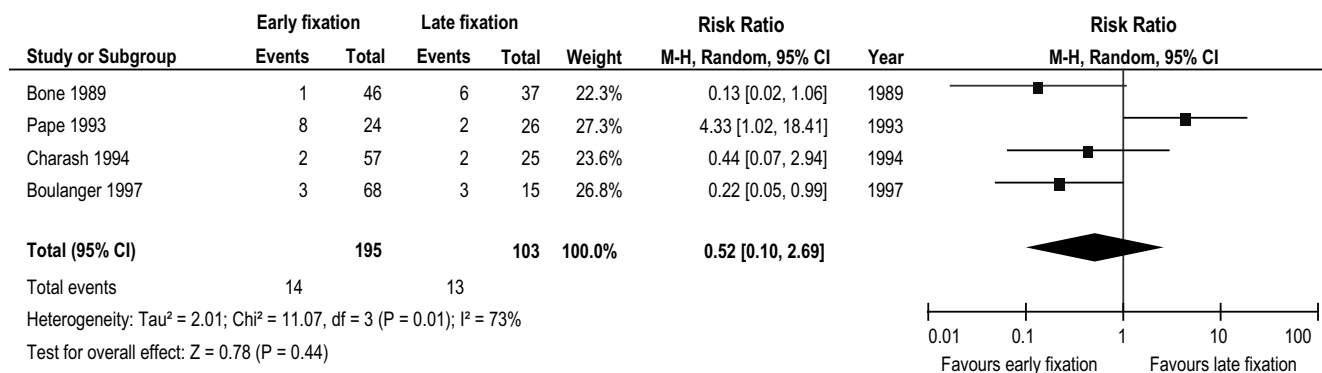

Figure 58.6 Forest plot of ARDS rate in two compared groups of patients: early IMN vs. late IMN.

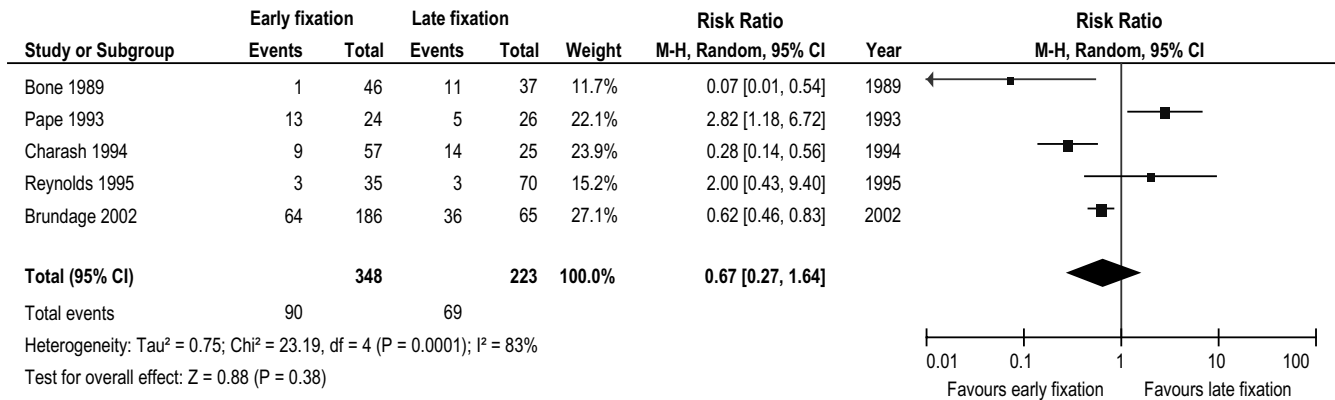

Figure 58.7 Forest tree of major pulmonary complication in two compared groups: early IMN vs. late IMN.

Question 7: What is the optimal timing for IM nailing of femoral shaft fractures in patients with head injury?

Case clarification

Assuming that the polytrauma patient, in our case scenario was additionally suffering from head injury with a Glasgow Coma Scale (GCS) of 10 points, the question that arises is: What is the optimal timing for femoral shaft fracture fixation to avoid further brain injury?

The presence of significant head injury in patients with femoral shaft fractures poses a therapeutic challenge. Inadvertent early definitive fracture fixation may cause increased blood loss, hypotension, and hypoxia, bringing about decreased cerebral perfusion and, ultimately, additional brain injury. This risk of secondary brain injury could potentially outweigh the benefits of early stabilization of a long bone fracture. Consequently, the issue of optimal timing of femoral shaft fixation in the presence of significant head trauma is of great clinical importance.

Finding the evidence

In order to find the best evidence that could provide reliable guidelines concerning the optimal timing of definitive treatment (preferably with IM nails) of femoral shaft fractures in patients with concomitant head trauma, a systematic literature search was conducted. The search strategy was as follows:

- Cochrane Database, with search terms: “femur fracture” AND “head injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “femur fracture” AND “timing of fixation”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: “femur fracture” AND “head injury” and “femur fracture” AND “cerebral injury”

- Review of references of eligible studies

Studies reporting on various long bone or pelvic fractures and not focusing exclusively on femoral fractures were excluded.

Quality of the evidence

Level III

- 4 studies^{29,31,32,35}

Openmirrors.com Findings

Mortality All four eligible studies (N = 598 patients) provided data regarding mortality rates. In the presence of head injury, early fixation (<24 hours) of femoral fractures with IM nails is probably associated with increased mortality compared to late (>24 hours) fixation, but this difference did not reach statistical significance (risk ratio 1.60, 95% CI 0.51–5.01, p = 0.42, homogeneity p = 0.29, I² = 18%).

Pulmonary complications Three studies (N = 511 patients) provided data regarding pulmonary complications.^{29,31,35} A pooled estimate of the effect size could be obtained due to moderate degree of statistical heterogeneity (I² = 52%). Early (<24 hours) fracture fixation showed a trend towards fewer pulmonary complications compared to late (>24 hours) fixation. Again, the documented difference was not statistically significant (risk ratio 0.59, 95% CI 0.21–1.62, p = 0.30, homogeneity p = 0.12).

CNS complications Two studies (N = 133 patients) provided relevant data.^{31,35} The available data documented a trend of early fracture fixation towards more frequent CNS complications, but the wide confidence interval of the pooled estimate of effect size does not document statistical significance of the result (risk ratio 1.40, 95% CI 0.21–9.49, p = 0.73, homogeneity p = 0.72, I² = 0%).

Recommendation

- No clear conclusion could be drawn from the existing literature regarding optimal timing of IM nailing of femoral shaft fractures in patients with concomitant head trauma [overall quality: low]

Question 8: Is the DCO approach a safer alternative to ETC in polytrauma patients with femoral shaft fractures?**Case clarification**

The polytrauma patient, suffering from femoral shaft fracture, bilateral lung contusions, intra-abdominal injuries and closed head injury is, in addition, haemodynamically unstable. What is the best treatment approach in such a scenario? Should the patient be stabilized haemodynamically first, and also have his long bone fracture provisionally fixed by a means of external fixation with the plan of converting it to an IM nail at a later stage, or should he be treated definitively in one stage, through a marathon surgery approach?

Expedient, definitive fixation of all long bone fractures represents the optimal management of the patient suffering from multiple orthopedic injuries. The benefits of such an approach are well documented in literature.²⁸ However, this early total care (ETC) principle may not be applicable in polytrauma patients with high injury severity score (ISS), suffering from significant head, chest, or abdominal injuries in addition to the musculoskeletal trauma and presenting to the Emergency Department with signs of hemodynamic compromise (borderline patients). In this particular subgroup of polytrauma patients, an attempt at early aggressive and definitive treatment of all musculoskeletal injuries could result in fatal complications, such as acute lung injury (ALI), ARDS, and multiple organ failure (MOF). For these patients, an alternative management concept, consisting of initial temporary stabilization of long bone fractures and secondary conversion to a definitive fixation (preferably, internal fixation) has been advocated. The term “damage control orthopedic surgery” (DCO) was coined to describe this treatment approach.³⁶ In polytrauma patients with femoral shaft fractures, DCO is translated into initial temporary external fracture fixation and later conversion to IM nailing, when the patient’s condition is deemed stable.

Finding the evidence

In order to elucidate whether DCO is preferable to ETC in the polytrauma setting, in terms of reducing the risk of systemic complications (pulmonary and MOF), and also to define the subgroup of polytrauma patients in which application of the staged approach is appropriate, we undertook a systematic literature search to isolate comparative studies

of these two treatment protocols (DCO vs. ETC). We conducted a literature search according to the following steps

- Cochrane Database, with search terms: “femur fracture” AND “damage control orthopedics,” or “femur fracture” AND “early total care” or “femur fracture” AND “polytrauma”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “femur fracture” AND “damage control orthopedics”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: “femur fracture” AND “damage control orthopedics,” or “femur fracture” AND “early total care” or “femur fracture” AND “polytrauma,” or “femur fracture” AND “external fixation”
- Review of references of eligible studies

The studies considered eligible were comparative ones (DCO vs. ETC, with or without randomization), reporting on at least one outcome of interest (mortality, ALI, ARDS, sepsis, MOF, pneumonia).

Quality of the evidence*Level I*

- 2 RCTs^{37,38}

Level III

- 3 studies^{36,39,40}

Findings

In most studies, the DCO group consisted of polytrauma patients with significantly higher ISS and longer stay in the intensive care unit (ICU) compared to the ETC group (Table 58.3). This reflects a trend towards applying the DCO protocol in more severe polytrauma patients and is responsible for methodological heterogeneity in our analysis which, in turn, could influence the results of pooling.

Pneumonia Three studies (N = 374 patients) reported on pneumonia.^{37,38,40} Patients in the DCO group ran a statistically significant higher risk of developing pneumonia vs. patients in the ETC group (risk ratio 1.93, 95% CI 1.28–2.92, $p = 0.002$, homogeneity $p = 0.77$, $I^2 = 0\%$) (Figure 58.8).

ARDS Four studies (N = 552 patients) provided relevant data on this outcome.^{37–40} Although patients in the DCO group had a higher ISS than patients in the ETC group, application of the DCO principle did not result in statistically significant higher risk of developing ARDS compared to the ETC principle (risk ratio 1.11, 95% CI 0.66–1.84, $p = 0.70$, homogeneity $p = 0.28$, $I^2 = 21\%$) (Figure 58.9).

MOF Two studies (N = 343 patients) reported on MOF rates.^{38,39} Although the DCO group showed an increased risk for developing MOF vs. the ETC group, the docu-

mented difference was not statistically significant (risk ratio 1.14, 95% CI 0.74–1.75, p = 0.56, homogeneity p = 0.91, I² = 0%).

Mortality Two studies (N = 498 patients) reported on mortality.^{36,40} Mortality rates were significantly higher in the DCO group than in the ETC group (risk ratio 11.68, 95% CI 2.44–55.98, p = 0.002, homogeneity p = 0.30, I² = 0%) (Figure 58.10).

One prospective RCT conducted further analyses on two distinct subgroups of multiply injured patients, namely stable and borderline patients.³⁸ In addition, regression analyses were used to control for differences between the two treatment groups (DCO vs ETC) in terms of initial injury severity. The results of this study are presented in Table 58.4. The odds of developing ALI were 6.69 times greater in borderline patients who had received ETC treatment compared to those in the DCO group.

Recommendations

- In the multiply injured patient population, in general, implementation of the DCO principle is associated with increased mortality and pneumonia rates compared with the ETC principle. This difference may, however, reflect the inherent heterogeneity of the two groups of patients in terms of severity of initial injury, as more severely injured patients are recruited into the DCO group [overall quality: moderate]
- Treatment of femoral shaft fractures, within the context of polytrauma, according to the DCO principle does not seem to result in increased risk of developing ARDS or MOF compared with the ETC principle, even in the presence of more severe injuries in the DCO group [overall quality: moderate]
- In borderline patients, the ETC principle is associated with a significantly higher risk of developing ALI compared with the DCO principle [overall quality: high]

Question 9: Is femoral plating preferable to reamed IM nailing in polytrauma patients with femoral shaft fractures and concomitant head or chest injury?

Relevance

Although reamed IM nailing has been universally recognized as the treatment of choice for femoral shaft fractures, concerns have been raised that reamed nails could potentiate additional brain or pulmonary injury when used in polytrauma patients with concomitant head or chest trauma. For this particular patient population the use of plate fixation has been advocated as a viable alternative to IM nailing.

Finding the evidence

In order to compare the above methods with respect to certain outcomes of interest, such as mortality, pulmonary complications, CNS complications, and infection, we undertook a systematic literature search aiming to isolate relevant studies comparing directly these two methods, preferably within the context of multiple trauma. The literature search was conducted as follows:

- Cochrane Database, with search terms “femur fracture” AND “plate fixation,” and “femoral plating”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “femoral plating”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using the following keywords and Boolean operators: “femur fracture” AND “plate fixation”
- Review of references of eligible studies

Quality of the evidence

Level III

- 2 studies^{41,42}

Findings

Mortality Both studies^{41,42} provided relevant data regarding mortality. A pooled estimate of effect size for mortality showed no statistically significant difference between the two treatment options (IM nailing vs. plating) for femoral shaft fractures (risk ratio 0.82, 95% CI 0.30–2.21, $p = 0.69$, homogeneity $p = 0.56$, $I^2 = 0\%$).

Pulmonary complications Both included studies reported on pulmonary complications.^{41,42} IM femoral nailing appeared equivalent to femoral plating with regards to the risk of developing pulmonary complications (risk ratio 1.38, 95% CI 0.88–2.16, $p = 0.16$, homogeneity $p = 0.45$, $I^2 = 0\%$).

CNS complications and infection One study (N = 50 patients) documented 3.4% and 0% CNS complication rate in the femoral plating and IM nailing groups, respectively.⁴² The same study documented 4.8% and 0% deep infection rates

in IM nailing and femoral plating groups, respectively. Both differences were not statistically significant.

Recommendation

- No convincing evidence exists in current literature supporting the use of plates over IM nails for the treatment of femoral shaft fractures within the context of multiple trauma [overall quality: low]

Question 10: Is there a functional impairment after isolated femoral shaft fracture?

The majority of femoral shaft fractures occur in young, otherwise healthy individuals, as a result of high-energy injury. Due to the high-energy nature of this injury and the operative intervention, resultant soft tissue trauma is common. In addition, iatrogenic muscle injury (abductor musculature) from antegrade nail insertion may further aggravate soft tissue injury. This combined soft tissue injury may predispose to impaired functional recovery even in the absence of postoperative complication such as nonunion, malunion, reoperation, or infection.

Finding the evidence

In order to assess the long-term functional consequences of femoral shaft fractures treated with antegrade IM nails, we conducted a systematic literature search using “femoral shaft fracture” and “functional outcome” as keywords. In order to avoid bias from concomitant multiple injuries or serious postoperative complications that could affect the eventual functional outcome of a femoral shaft fracture, we limited our search, posing certain inclusion and exclusion criteria. Consequently, eligible studies were those reporting on isolated femoral shaft fractures in adult population that had been treated with IM nails and healed with normal alignment, no residual leg length discrepancy, and no major complications or repeat operations in the postoperative period. Our search strategy followed these steps:

- Cochrane Database
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search
- Review of references of eligible studies

Quality of the evidence

Findings

Table 58.5 summarizes the basic results.

Table 58.5 Current evidence on functional outcome of isolated femur fractures

Study	Type of study	Inter-vention	No. of patients	Outcome measure	Control group	Follow-up	Results
Archdeacon et al. 2008 ⁴³	P	a-IMN	8	Dynamic hip abductor weakness at 2 time intervals: (1) independent ambulation without aid (~2 mo) (2) complete bone healing (~7 mo) S-MFA at 3 mo and at latest follow-up	Opposite limb	>12 mo (mean: 21.6 mo)	Dynamic hip abductor weakness resolved at 7 mo S-MFA: significant improvement (p = 0.008)
Helmy et al. 2008 ⁴⁴	R	a-IMN	21	Isokinetic muscle test of: Hip abductors, Hip extensors Knee extensors S-MFA	Controlateral uninjured limb	>12 mo (mean: 70 mo)	Muscle strength: -Hip abductors: reduced p < 0.05 -Hip extensors: reduced, p < 0.05 SF-36 / S-MFA: similar to population norms Residual pain (mild-moderate): Hip: 10/21 Knee: 9/21 Thigh: 17/21
Kapp et al. 2000 ⁴⁵	R	a-IMN	17	BMD Muscle function	Controlateral uninjured limb	>18mo	BMD, reduction (p < 0.05) Quadriceps strength: reduced (p < 0.05)
Bain et al. 2007 ⁴⁶	R	a-IMN	32	Subjective complaints (trochanter pain, thigh pain, hip stiffness) Abduction strength	Asymptomatic controls	>24 mo (mean: 47 mo)	Trochanter pain: 13/32 Thigh pain: 3/32 Abduction strength: reduced (p < 0.05)
Bednar and Ali 1993 ⁴⁷	R	a-IMN	47	Reoperation Return to work (41 pts available for analysis)	-	Mean 34.5 mo	Implant related pain: 20/47 (43%) [Implant removal: 17/20 (85%)] Return to original work: 33/41 (80%) Other full-time employment: 4/41 (10%) Part time employment: 3/41 (7%) Unable to work: 1/41 (2%)
Sanders et al. 2008 ⁴⁸	R	a-IMN	40	VAS for pain: groin, buttock, thigh, knee WOMAC S-MFA	-	>12 mo	Functional recovery and pain relief within 6 mo No difference between 6 and 12 mo Residual functional impairment at 12 mo Knee pain most common and severe source of discomfort at 12 mo

a-IMN, antegrade intramedullary nail; BMD, bone mineral density; P, prospective; R, retrospective; SF-36, short form 36; S-MFA, short musculoskeletal functional assessment; VAS, visual analog scale; WOMAC, Western Ontario and McMaster Universities Osteoarthritis index.

Recommendation

Current evidence, though incomplete and of poor quality, may indicate that persistent reduced strength of certain muscle groups (hip abductors, knee extensors) and residual pain (in the knee, thigh, or hip region) could contribute to the presence of impaired functional capacity of the injured limb even in cases of successful treatment of femoral shaft fractures. Significant soft tissue trauma partly imparted by the initial injury and partly during surgery may be responsible. Carefully conducted large prospective cohort studies could provide strong evidence for possible causes and effects [overall quality: low]

Summary of recommendations

- It is doubtful whether the use of a single implant (cephalomedullary nail) could result in increased likelihood for reoperation compared to the combined use of compression plate and hip screws
- In concomitant ipsilateral femoral neck and shaft fractures, the use of a single implant for addressing both injuries (cephalomedullary nails) is probably associated with better union rates of the femoral shaft fracture over the combined use of compression plate and hip screws
- The union process or the risk of malunion of femoral shaft fractures does not depend on the choice of the entry portal (piriformis or trochanteric) of the IM nail that is used for its treatment
- In obese patients, the use of greater trochanter entry portal appears more advantageous over piriformis entry portal as the latter is associated with significantly increased both operative and fluoroscopy times
- Unreamed femoral nails are associated with significant risk of delayed union compared with reamed nails
- Current literature does not suggest any superiority of either technique over the other in the general population with regards to union complications
- Antegrade nailing technique may be associated with significantly more frequent hip pain and, in obese patients, greater operative and radiation exposure times compared with retrograde technique
- Existing evidence cannot document any potential association of either of these techniques with long-term knee pain
- The use of manual traction instead of fracture table during nailing procedure significantly reduces the risk of internal malrotation ($>15^\circ$) and shortens operative time
- The FT technique was associated with significantly higher blood losses than the MT technique, but the mean
- No statistically significant difference was documented between FT and MT with respect to functional outcome
- Current literature is unable to provide clear guidelines with regard to the optimal timing of IM nailing of femoral

shaft fractures in multiply injured patients suffering from concomitant lung injuries

- Contradictory evidence exists in current literature with regard to optimal timing of IM nailing of femoral shaft fractures in patients with concomitant chest or head trauma
- In borderline multiply injured patients, the ETC approach is associated with significantly higher risk of developing ALI than the DCO principle
- No convincing evidence exists in current literature supporting the use of plates over IM nails for the treatment of femoral shaft fractures within the context of multiple trauma
- Long-term functional impairment may persist after isolated femur fractures and may be due to soft tissue injury occurring during initial trauma and operative procedure

Conclusions

High-quality evidence from current literature supports the following conclusions with regard to IM nailing of femoral shaft fractures:

- Use of unreamed femoral nails will probably result in increased risk of delayed union compared with reamed nails
- Performing the procedure on a standard radiolucent operative table using manual traction instead of the classical fracture table will probably protect against excessive internal malrotation and will shorten operative time
- In borderline multiply injured patients, implementation of DCO principle significantly reduces the risk of developing ALI compared with ETC.

The current literature is lacking high-quality, clear evidence with regard to the optimal timing of IM nailing in patients with femoral shaft fractures and concomitant chest or head trauma. Similarly, no substantial evidence exist supporting substitution of femoral nails with plates and screws in multiply injured patients.

¹Onze Lieve Vrouwe Gasthuis, Amsterdam, The Netherlands

²Academic Medical Center, Amsterdam, The Netherlands

Case scenario

Case 1

A 20 year old tourist was involved in a traffic accident in Amsterdam. The front wheel of his bicycle was trapped in the tram rails, after which he was hit by the tram on his right leg. He did not lose consciousness. Directly after the accident he was unable to bear weight with his right leg. There were no other obvious injuries. On examination the knee was swollen and painful. The skin was intact and the neurovascular examination was normal. Radiographs showed a distal femur fracture in the right leg.

Case 2

The patient is a 75 year old woman who had a total knee replacement 5 years ago. She has now had a fall on the sidewalk. Her radiographs show a distal femoral fracture above a total knee replacement.

Relevant anatomy

Fractures of the distal femur tend to follow the weakest planes in the femur. The main zones of weakness are first the transition from diaphysis to metaphysis, secondly the sagittal plane through the intercondylar notch, where the patella can act as a wedge, and finally the junction between the trochlear groove and medial or lateral condyle.¹ Due to high-energy trauma or osteoporosis, distal femoral fractures can be significantly comminuted.

As in every fracture, muscles play a major role in the dislocation of the fracture fragments. The most common dislocation is posterior angulation and displacement of the distal fragment with femoral shortening. The dislocating forces are produced by the quadriceps, hamstrings, and gastrocnemius muscles. The muscle pull of the quadriceps and posterior hamstrings results in shortening of the femur. The gastrocnemius pulls posteriorly, displacing and angulating the condyles posteriorly as the shaft overrides anteriorly. In intercondylar fractures, the heads of the gastrocnemius can cause a rotational malalignment and separation of the fracture. Adductor muscles may produce a varus deformity or even valgus when the fracture is located distally of the adductor tubercle.

The femoral and popliteal arteries are at risk of injury due to the close relation to the distal femur. Although a posteriorly angulated fracture could cause damage to the artery, this is a rare phenomenon.

The anatomy of the distal femur is complex and needs to be understood before restoration of the distal femur can be achieved. The cranial part of the trochlea is a shallow depression between the condyles. The patella predominantly articulates with the surface area of the lateral condyle. The lateral condyle is broader than the medial condyle. The medial condyle is longer and extends farther distally than the lateral condyle. The distal femur is trapezoidal when viewed from distal to proximal. The lateral metaphyseal surface is angulated approximately 10° while the medial surface is angulated approximately 25°. When using a lateral plate it is important to realize that the central axis of the femoral shaft normally aligns with the anterior half of the femoral condyles viewed lateral to medial (Figure 59.1).

Figure 59.1 Caudal-cranial view of the condyles of the distal femur. The lateral metaphyseal surface is angulated approximately 10° while the medial surface is angulated approximately 25°.

Classification

The classification system commonly used for distal femur fractures is the AO/OTA system.² Fractures are arranged in order of increasing severity according to the complexity of the fracture, difficulty of treatment, and worsening prognosis. Each bone segment is numbered, followed by the fracture pattern and degree of comminution. In this system, the distal femur fracture is numbered 33 and the fracture is subsequently classified based on the amount of articular involvement and comminution. Type 33 A describes an extra-articular fracture whereas type 33 B is partial articular involving one of the femoral condyles, and type 33 C is a complete articular fracture (Figure 59.2).

Importance of the problem

Fractures of the distal femur represent 4–7% of all femur fractures.^{3,4} In Sweden this corresponds to an incidence of 51 per million inhabitants older than 16 years.³ The occurrence of distal femur fractures shows a bimodal pattern with a marked variation in relation to gender and age. Low-energy trauma occurs in the elderly osteoporotic female patient (>50 years), while high-energy trauma primarily occurs in young men involved in traffic or sport accidents.⁴

Although the social and financial impact of proximal femur fractures is widely reported, this is not the case for the less common distal femur fracture. Increased life expectancy, greater participation in high-risk sports and more motor vehicle traffic will most likely lead to higher incidence. Distal femur fractures are not very forgiving and can lead to severe impairment and loss of quality of life.

Nonoperative treatment may be chosen for non- or minimally displaced fractures in low-demand elderly patients. In general, however, nonoperative treatment does not work well for displaced fractures and is reserved for those patients who cannot tolerate surgery.⁵

Top five questions

Diagnosis

1. Is there a role for standard CT scanning in choosing a treatment strategy in patients with distal femur fractures?

Therapy

2. What is the optimal type of osteosynthesis for distal femur fractures: plate or nail?
3. What is the best type of plate fixation for a distal femur fracture?
4. What is the optimal approach for operative fixation of a distal femur fracture above or around a total knee replacement?

Harm

5. What are the most important complications associated with internal fixation of distal femur fractures?

Question 1: Is there a role for standard CT scanning in choosing a treatment strategy in patients with distal femur fractures?

Case 1 clarification

The patient's radiographs show an undisplaced supracondylar fracture with possibly (inter)condylar involvement. You are trying to decide between an AO, A1, or C1 fracture, or maybe a Hoffa (B3) fracture.

Unicondylar fractures are rare and usually occur in the sagittal plane. A unicondylar fracture oriented in the coronal plane is called a Hoffa fracture.

Relevance

In planning the surgery one should not underestimate the complexity of the fracture, potentially leading to unwanted surprises during surgery. Does that imply that it is necessary to perform standard CT scanning of every distal femur fracture?

Current opinion

The *AO Principles of Fracture Management*⁶ states that AP and lateral radiographs of both the femur and the tibia should be taken, in combination with focused views of the

Figure 59.2 AO/OTA classification system for distal femur fractures.

knee joint. CT scans or MRI, as well as 3D reconstructions, offer additional information but are rarely essential.⁶ Browner and Levine, as well as Schatzker, conclude that if in doubt about intra-articular involvement CT scans help in planning the surgical approach, especially in minimally invasive techniques.^{7,8} Therefore, preoperative CT scanning is currently widely advised and used.

Finding the evidence

- Cochrane Database: no reviews available

- PubMed: no reports on the use of CT scans in planning treatment strategies in distal femur fractures

Quality of the evidence

Level V

- 3 expert opinions

Recommendation

- The use of CT scanning can be considered for standard use in the treatment planning of distal femur fractures [overall level: very low]

Question 2: What is the optimal type of osteosynthesis for distal femur fractures: plate or nail?

Case 1 clarification

You present two options to your patient: plate fixation or retrograde nailing. Your patient wants to know what the best option is.

Relevance

The articular fracture component is usually treated with closed or open reduction, followed by lag screw fixation. However, there is no consensus on the type of implant for the fixation of the metaphyseal–diaphyseal fracture component.

Current opinion

Most surgeons use an osteosynthesis technique based on their own experience.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed: 47 case reports, 2 nonrandomized comparative studies, 1 randomized controlled trial (RCT), 1 prospective cohort study, 1 review, 1 systematic review on the operative treatment of distal femur fractures.

Quality of the evidence

Level I

- 1 systematic reviews/meta-analyses/randomized trial

Level II

- 3 randomized trials with methodological limitations

Level III

- 2 case-control studies/retrospective comparative studies

Level IV

- 47 case series

Recommendation

- The use of either a nail or plate construct can be guided by surgeon experience [overall level: low]

Question 3: What is the best type of plate fixation for a distal femur fracture?

Case 1 clarification

After discussing the options of retrograde nailing and plate fixation with your patient, you both decide to use a plate fixation technique. Your patient now asks if you use the best kind of plate fixation. What is your answer?

Relevance

In addition to traditional compression plating and dynamic condylar screws, locking internal fixation plates have been

developed in the last decade. These plates have screws that lock into the plate. The plate/screw construction has the possibility of minimally invasive application.

Current opinion

Internal fixation plates are used with increasing frequency since the development of plates with locking screws.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed: 47 case reports, 2 nonrandomized comparative studies, 1 RCT, 2 prospective cohort studies, 1 review, 1 systematic review on the operative treatment of distal femur fractures

Quality of the evidence

Level I

- 1 systematic review/meta-analysis/randomized trial

Level II

- 4 randomized trials with methodologic limitations

Level III

- 2 case-control studies/retrospective comparative studies

Level IV

- 47 case series

Openmirrors.com
Despite the numerous cohort studies, there are few that compare different surgical options. Presently there are no reports on prospective, randomized trials comparing different surgical procedures for distal femoral fractures.⁹

Recommendation

- The rates of nonunion fixation failure and deep infection are not significantly different when comparing locking plate IMN or traditional plate constructs (e.g., blade plate, DCS etc.) [overall level: low]

Question 4: What is the optimal approach for operative fixation of a distal femur fracture above or around a total knee replacement?

Case 2 clarification

The patient's radiographs show a distal femoral fracture above a total knee replacement.

Relevance

With an increase in life expectancy and a growing number of total knee replacements all over the world, the incidence of a periprosthetic fracture above a total knee will increase.

Current opinion

- There is no consensus on the best treatment of periprosthetic supracondylar fractures.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed: 29 case series, 1 systematic review

Quality of the evidence*Level I*

- 1 systematic review/meta-analyses/randomized trial

Level IV

- 32 case series

Recommendation

- Surgical treatment is superior to nonoperative treatment. Retrograde intramedullary nailing and locking plates appear to be more successful than conventional (nonlocking) plating methods.¹¹ [overall level: very low]

Question 5: What are the most important complications associated with internal fixation of distal femur fractures?**Relevance**

Improvement of current or future techniques should be focused on present failures (hardware failure), complications (nonunion, infection) and functional impairment in the treatment of distal femur fractures.

Current opinion

The reported evidence on the treatment of distal femur fractures consists of a large number of case series, a few comparative studies, and three reviews.⁹⁻¹³ Unfortunately no RCTs have been performed directly comparing two or more different implants. Although the outcomes including complication rates and differences in complications are not comparable, no extreme differences in complications with respect to nonunions, fixation failure, deep infection, or secondary procedures between different treatment options have been reported. Present research should not be limited to case series and cohort studies; (large) RCTs, possibly multicentered, are necessary to assess the success of current treatment options and its flaws.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed: no reports on complications and treatment of distal femur fractures

Summary of recommendations

- Standard CT scan of a distal femur fracture may be considered, but is not mandatory
- No evidence is available for a superior implant for surgical treatment of a distal femur fracture

- Surgical treatment is superior to nonoperative treatment. Retrograde intramedullary nailing and locking plates appear to be more successful than conventional (nonlocking) plating methods.¹¹

Conclusions

The lack of RCTs or even direct (retrospective) comparative studies on the treatment of patients with distal femur fractures deprives the answers to the key questions regarding distal femoral fractures.

Knee Dislocations

James P. Stannard¹ and Allan Hammond²

¹University of Missouri Hospital, Columbia, MO, USA

²University of Manitoba Health Science Centre, Winnipeg, MB, Canada

Case scenario

A 32 year old male construction worker is involved in a motor vehicle collision on the way home from work. He sustains a right femur fracture and is noted to have mild swelling around the right knee as well. After intramedullary (IM) nailing of the femur the next day, it is noted that the patient has gross knee instability in all directions. He has a normal vascular exam with 2+ pulses bilaterally for both the dorsalis pedis and posterior tibial arteries.

Top eight questions

Openmirrors.com

Diagnosis

1. How accurate is the diagnosis of knee dislocation? Are they easily missed?
2. What diagnostic tests or physical examination tests are necessary to exclude popliteal artery injuries?

Therapy

3. Should knee dislocation be treated surgically, or with casts or braces?
4. Should torn collateral ligaments be repaired or reconstructed?

Prognosis

5. What is the incidence of arthrofibrosis and motion problems following reconstructive surgery?
6. What is the likelihood of instability following reconstruction?
7. What yields better results, reconstruction of the knee acutely (3–4 weeks after injury) or delayed reconstruction?

8. Are patients able to return to work and/or sports and recreation following a knee dislocation?

Question 1: How accurate is the diagnosis of knee dislocation and is it easily missed?

Case clarification

It is extremely difficult to examine the knee when the patient has an ipsilateral long bone fracture, prior to stabilization of the fracture.

Clinical relevance

Missed knee dislocations can result in limb-threatening complications.

Current opinion

Vigilance is key, and orthopedic surgeons must realize that knee dislocations frequently present reduced, or have associated injuries, which can cause the dislocation to be missed.

Finding the evidence

- PubMed: English language articles, 1969–2010, with the following search terms: “knee” AND “multi-ligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “epidemiology” OR “incidence” OR “diagnosis”

Quality of the evidence

- Level II: 1¹
- Level IV: 1²

Findings

Although many current textbooks and reviews acknowledge the problem of diagnosis, there are no articles that can be identified in a literature search that directly address this topic. In the past it was believed that three or four ligament

disruptions were required for knee dislocation to occur; however, Cooper presented a series of four cases (level IV) where only two ligaments were disrupted,³ and single-ligament injuries resulting in dislocation have been documented as far back as 1969 (level IV).⁴ A retrospective MRI study by Bui² (level IV) showed that in their review of 20 knee dislocations, only 25% presented with abnormal alignment on initial radiographs, and that in nearly one third of cases dislocation was not even suspected at the time the MRI was ordered. A prospective outcome study (level II) by Twaddle et al.¹ demonstrated that only one third of dislocated knees presented in the Emergency Department unreduced.

Recommendation

- Great vigilance is required to avoid missing knee dislocations in trauma patients. All patients with lower extremity trauma and pain or swelling around the knee should be carefully evaluated for knee instability [overall quality: low]

Question 2: What diagnostic tests or physical examination tests are necessary to exclude popliteal artery injury?

Case clarification

The diagnosis of a knee dislocation was not made until nearly 24 hours following the injury, when the femur fracture was stabilized.

Clinical relevance

A missed popliteal artery injury can lead to an above-knee amputation.

Current opinion

A selective arteriography protocol that employs a good vascular examination as the screening method is currently standard care. Any abnormality in the examination requires additional studies to document the integrity of the artery.

Finding the evidence

- PubMed: English language articles, 1969–2010, with the following search terms: “knee” AND “multi-ligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “vascular”

Quality of the evidence

- Level II: 3⁵⁻⁷
- Level III: 1⁸
- Level IV: 10^{9,10-18}

Findings

No prospective randomized trials have been published on this topic. However, one meta-analysis (level III),⁸ four pro-

spective studies (three level II,⁵⁻⁷ one level VI⁹) and nine retrospective studies (level IV)¹⁰⁻¹⁸ have been published regarding the use of physical examination as the primary screening tool for arterial injury. Physical examination was sufficient to rule out vascular injury in all but one study,¹⁷ and in this study ankle brachial indices were not used and even angiography had a false-negative rate of more than 40%.

Recommendation

- All patients should be carefully screened for arterial injury with serial vascular physical examinations following knee dislocation. Any abnormality should be evaluated with additional testing [overall quality: moderate]

Question 3: Should knee dislocations be treated surgically or nonoperatively?

Relevance

Surgical treatment is complex and expensive, often requiring multiple procedures. Older treatment protocols advocated cast or brace treatment, but outcomes were frequently poor.

Current opinion

Knee dislocations should be treated surgically in the vast majority of patients.

Finding the evidence

- PubMed: English language articles, 1969–2010, with the following search terms: “knee” AND “multi-ligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” OR “anterior cruciate” AND “posterior cruciate” OR “posterolateral corner”

Quality of the evidence

- Level III: 5^{19,20-23}
- Level IV: 11^{3,4,24-32}

Findings

There are no prospective randomized trials in the literature, but there is one meta-analysis with methodological flaws¹⁹ (level III), and 18 comparative studies with operatively and nonoperatively treated patients with published outcome data.^{3,4,20-34} Ten of the 18 studies, all level IV, had either too few patients or presented their data in such a manner that no conclusions could be made.^{3,4,24-31} The remaining studies, four level III²⁰⁻²³ and one level IV,³² found the Lysholm, Tegner, and IKDC outcome measures to be statistically superior in operative patients compared to those treated nonoperatively. Regarding range of motion (ROM), only two of eight studies (one level III and one level VI), showed decreased ROM in operatively treated patients, and in neither did it reach statistical significance.^{21,35} In no study

was instability, either by physical exam or via KT1000, found to be greater or more frequent in operative cases.

Recommendations

- Operative treatment of knee dislocations results in superior functional outcomes and stability with little risk of stiffness when compared to nonoperative treatment [overall quality: low]

Question 4: Should torn collateral ligaments be repaired or reconstructed?

Clinical relevance

Traditional teaching has been that the corners should be repaired if good quality tissue is present and the repair is accomplished within 3 weeks.

Current opinion

The failure rate is lower for both the posteromedial corner (PMC) and posterolateral corner (PLC) with reconstruction of the ligaments when compared with repair.

Finding the evidence for the treatment of PMC injury

- PubMed: English language articles, 1969–2010, using the search terms: “knee” AND “multi-ligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “mcl” OR “medial collateral ligament” OR “posteromedial corner” OR “pmc”

Quality of the evidence for the treatment of PMC injury

- Level II: 1³⁶
- Level III: 3^{22,37,38}
- Level IV: 21^{24,28,29,39–55}

Findings

There are currently no published studies in the literature directly comparing PMC reconstruction with repair. A systematic review was recently published on this topic (level III).³⁷ There is one level II study,³⁶ and three level VI studies which performed PMC reconstruction exclusively without synthetics,^{53–55} as well as two level III studies,^{22,38} and 18 level VI studies^{24,28,29,39–52} which performed medial collateral ligament (MCL) repair, either with or without synthetic or biologic augmentation, in the management of knee dislocation. Of the four studies in which the PMC was reconstructed, only three had interpretable data. Combined, these three studies demonstrated a very low failure rate (<2%) for PMC reconstruction (1/72).^{36,53,54} Regarding PMC/MCL repair with knee dislocation, of the 20 studies only 13 were suitable for analysis (1 level III²² and 12 level VI^{22,39–41,43–49,51}). Combining these studies gave an overall

failure rate for MCL repair of 17%. While no direct comparisons were made in the studies regarding acute vs. chronic MCL repair, analysis of individual studies suggests that acute repair may have lower failure rates (0, 11%, 16%)^{36,41,45} than chronic repair (29%, 57%, 66%).^{44–46}

Recommendations for the treatment of PMC injury

- PMC reconstruction has a low failure rate compared to repair. Acute PMC repair may have lower failure rates than chronic repair [overall quality: low]

Finding the evidence for the treatment of PLC injury

- PubMed: English language articles, 1969–2010, using the search terms: “knee” AND “multiligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “PLC” OR “posterolateral corner” OR “LCL” OR “lateral collateral”

Quality of the evidence for the treatment of PLC injury

- Level II: 1⁵⁶
- Level III: 4^{20,22,46,57}
- Level IV: 16^{31,36,39–41,43–45,47–49,58–62}

Findings

One level II study⁵⁶ and one level III study⁵⁷ directly compared PLC repair with reconstruction, while there were 3 level III studies^{20,22,46} and 16 level VI studies^{31,36,39–41,43–45,47–49,58,59–62} in which the PLC was managed surgically. The vast majority did not distinguish between repair, augmentation, or reconstruction, except for Stannard et al. and Levy et al. who found statistically significant higher failure rates in repair over reconstruction, 9% vs. 5% ($p=0.03$)⁵⁶ and 40% vs. 6% ($p=0.04$).⁵⁷ The overall combined failure rate for the surgical management of PLC injuries in knee dislocations in the literature, either by repair or reconstruction, is 89/406 (22%).

Recommendation for the treatment of PLC injury

- PLC reconstruction appears to have lower failure rate than repair [overall quality: low]

Question 5: What is the incidence of arthrofibrosis following knee dislocation?

Relevance

Many surgeons consider arthrofibrosis and painful loss of motion to be the biggest problem associated with knee dislocations.

Current opinion

Arthrofibrosis is a common complication that is decreasing as surgeons adopt more aggressive postoperative rehabilitation protocols.

Finding the evidence

- PubMed: English language articles, 1969–2010, using the search terms: “knee” AND “multiligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “arthrofibrosis” OR “stiffness” OR “manipulation” OR “arthrolysis”

Quality of the evidence

- Level II: 1⁵⁶
- Level III: 1⁶³
- Level IV: 18^{3,30,33,36,39–43,45,50–52,61,62,64–66}

Findings

No comparative studies have been performed which have looked to minimize the incidence or severity of arthrofibrosis after knee dislocation. Twenty studies have been published that report on the incidence of arthrofibrosis; except for one level II and one level III study,⁶³ they are retrospective studies with level IV evidence.^{3,30,33,36,39–43,45,50–52,61,62,64–66} The cumulative incidence of arthrofibrosis is 19% (76/403), although three recent studies^{39–41} show current rates to be much lower (8%).

Recommendation

- Arthrofibrosis is common (about 19%) but decreasing due to modern reconstruction and rehabilitation techniques [overall quality: low]

Question 6: What is the likelihood of recurrent instability following reconstruction of a dislocated knee?**Relevance**

Although many surgeons state that arthrofibrosis and motion loss is the greatest problem following knee dislocation, recurrent instability is a major problem.

Current opinion

Recurrent instability is the most common complication following the repair or reconstruction of knee dislocations.

Finding the evidence

- PubMed: English language articles, 1969–2010, using the search terms: “knee” AND “multiligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “laxity” OR “instability” OR “failure”

Quality of the evidence

- Level II: 1³⁶
- Level III: 4^{20,22,46,63}
- Level IV: 19^{31,34,39–41,43–45,48–50,58,59,61,62,66–69}

Findings

There have been 24 published studies: one level II, four level III,^{20,22,46,63} and 19 level IV,^{31,34,39–41,43–45,48–50,58,59,61,62,66–69}

which document rates of ligamentous laxity, either by physical examination or KT1000, after surgical management of knee dislocations. By pooling all the data from these studies, surgical management of anterior cruciate ligament (ACL) and posterior cruciate ligament (PCL) disruption results in recurrent instability in 19% of cases, while there is recurrent instability of the MCL/PMC and PLC respectively 17% and 22% of the time.

Recommendation

- Recurrent instability is the most common complication following dislocation reconstruction. Patients should be counseled regarding the risk, and surgeons should continue to look for strategies that decrease the problem of recurrent instability [overall quality: low]

Question 7: What yields better results, reconstruction of the knee acutely (3–4 weeks after injury) or delayed reconstruction?**Relevance**

Reconstruction during the acute phase after the injury allows patients to recover from fractures and knee reconstruction simultaneously. However, the risk of skin breakdown and arthrofibrosis may be higher during the inflammatory phase immediately following the injury.

Current opinion

Outcome results are somewhat more favorable for patients who have surgical reconstruction initiated within 1 month after the injury.

Finding the evidence

- PubMed: English language articles, 1969–2010, using the search terms: “knee” AND “multiligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “acute” OR “chronic”

Quality of the evidence

- Level III: 1³⁸
- Level IV: 2^{45,46}

Findings

Only three published studies have directly compared acute to chronic management of knee dislocations.^{38,45,46} All three report superior Lysholm scores in the acute group, but statistical significance was not reached. Meyers, IKDC and Knee Outcome Survey scores were also found to be superior in acute management, but these scores also never reached statistical significance.

Recommendation

- If the patient’s condition allows, knee reconstruction should be started acutely [overall quality: low]

Question 8: Are patients able to return to work and/or sports and recreation following a knee dislocation?

Clinical relevance

Reconstructing dislocated knees often requires multiple operations in order to maximize function. It is important for patients to know if they will be able to resume careers or leisure activities after completion of their care.

Current opinion

Most patients are able to return to employment following reconstruction of a knee dislocation. However, only about half of them are able to resume the same level of sporting activities.

Finding the evidence

- PubMed: English language articles, 1969–2010, using the search terms: “knee” AND “multiligament” OR “multiligamentous” OR “multiple ligament” OR “dislocation” AND “sport” OR “work”

Quality of the evidence

- Level II: 1⁷⁰
- Level III: 2^{21,61}
- Level IV: 18^{22,27,34,42,44,48–51,58,59,62,63,66,71–73}

Findings

There are 21 studies presenting data on these questions, with the vast majority being retrospective level VI studies.^{21,22,27,34,42,44,48–51,58,59,61–63,66,70–73} Due to the ambiguity of the terminology in the literature, it is difficult to combine all these studies into an analysis. However, by selecting studies that use similar or specific phrases, some conclusions can be made. Of the seven studies that used the term “return to work,” the combined data shows that 88% (189/215) of patients returned to work (range 75–100%).^{22,42,44,50,58,62,70} Data on return to athletic activities is even more difficult to assess, due to variability in the definition and individual activity levels. However, when the terms “same level,” “preinjury level,” or “previous level” of sport are used as the outcome measure, nine studies show a combined rate of 40/158 or 25% (range 0–81%).^{21,24,34,48,49,59,61,66,71}

Recommendation

- Patients are highly likely to be able to return to employment. Return to the same level of sporting activity is unlikely, but possible [overall quality: low]

Summary of recommendations

- Great vigilance is required to avoid missing knee dislocations in trauma patients. All patients with lower extrem-

ity trauma and pain or swelling around the knee should be carefully evaluated for knee instability

- All patients should be carefully screened for arterial injury with serial physical examinations following knee dislocation. Any abnormality should be evaluated with additional testing
- In the vast majority of instances, knee dislocations should be treated with surgical stabilization
- The failure rate of reconstruction of the PLC and PMC will be lower than the failure rate of repair
- Arthrofibrosis occurs in nearly 1/5 patients but recent literature suggests that the rate is decreasing
- If the patient’s condition allows, knee reconstruction should be started acutely
- Recurrent instability is common following dislocation reconstruction. Patients should be counseled regarding the risk, and surgeons should continue to look for strategies that decrease the problem of recurrent instability
- Patients are very likely to be able to return to their previous employment. The probability of returning to the same level of preinjury athletics is unpredictable but unlikely.

Conclusion

No level I studies have been published regarding knee dislocations. Many questions regarding the ideal treatment of these challenging patients remain unanswered. However, good guidelines can be developed by combining the data from a large number of small level IV studies.

Proximal Tibia

Richard J. Jenkinson and Hans J. Kreder

University of Toronto, Toronto, ON, Canada

Case scenario

A 48 year old man is injured in a fall from a ladder, from a height of 2m. He has sustained an isolated injury to his right proximal tibia. Clinical examination shows that there is no open wound, his compartments are soft, and his swelling is minimal. Radiographic examination shows a displaced bicondylar proximal tibia fracture.

Relevant anatomy

Fractures of the proximal tibia are also known as tibial plateau fractures. They are classified by the OTA classification, as described in Table 61.1. Another commonly used classification is that described by Schatzker,¹ as outlined in Table 61.2.

Case clarification

Careful inspection of radiographs and a CT scan show that this patient has suffered a Schatzker type 6 fracture involving both medial and lateral plateaus with metaphyseal/diaphyseal discontinuity. In terms of the OTA classification he has sustained a 41-3C injury, implying significant articular comminution.

Top five questions

Therapy

1. This patient will require surgical treatment. Are the functional outcomes different between patients treated with external fixation compared to open reduction and internal fixation (ORIF) with plates and screws?

2. I anticipate a metaphyseal bone void after reduction. Should I fill this with iliac crest autograft or a bone graft substitute.

3. How early should I allow range of motion postoperatively?

Prognosis

4. What is the effect of imperfect articular reduction on functional outcomes?

5. What is the effect of limb instability, malalignment and meniscus cartilage damage on functional outcomes?

Finding the evidence

The following general searches were undertaken to identify the best evidence (meta-analyses, systematic reviews and clinical trials). When level I evidence was lacking, studies at a lower level of evidence were reviewed.

- Cochrane Database: search term “proximal tibia fractures” and “tibial plateau fractures”
- PubMed: clinical queries search/systematic reviews: “tibial plateau fractures,” “proximal tibial fractures”
- PubMed: “tibial plateau fracture” OR “proximal tibia fracture”

Question 1: This patient will require surgical treatment. Are the complication rates and functional outcomes different between patients treated with external fixation compared to ORIF with plates and screws?

Relevance

There are a number of treatment options for complex proximal tibia fractures. External fixation, combined with limited open techniques can potentially reduce complications but

Table 61.1 OTA Classification of proximal tibia (41) fractures

Type	Group	Description
41-A Extra-articular	41-A1	Avulsion
	41-A2	Metaphyseal simple
	41-A3	Metaphyseal multifragmentary
41-B Partial articular	41-B1	Pure split
	41-B2	Pure depression
	41-B3	Split depression
41-C Complete articular	41-C1	Articular simple Metaphyseal simple
	41-C2	Articular simple Metaphyseal multifragmentary
	41-C3	Articular multifragmentary

Table 61.2 Schatzkter classification of tibial plateau fractures

Type	Description
1	Lateral plateau pure split fracture
2	Lateral plateau split and depression
3	Lateral plateau pure depression
4	Fracture of the medial plateau
5	Fracture of both medial and lateral plateau Some metaphyseal/diaphyseal continuity
6	Fracture of both medial and lateral plateau Metaphyseal/diaphyseal discontinuity

potentially limit the ability to obtain optimal reductions. Open plating techniques can allow a more precise reduction, but risk complications. When performing an ORIF, the surgeon must consider choice of incision and approach(es) to achieve surgical goals while limiting complications as well as considering the need for future procedures.

Current opinion

Treatment with ORIF with two plates inserted via an anterior or two incisions may have a higher complication and reoperation rate than limited ORIF with circular external fixator. There is insufficient evidence to definitively guide choice between open reduction and internal fixation, hybrid external fixation, and unilateral locked plating in proximal tibia fractures.

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 randomized trial with methodologic limitations

Levels III and IV

- 6+ retrospective cohort studies or case series

Findings

A straight or modified midline anterior knee incision has historically been described to treat proximal tibia fractures.¹⁻³ This has recently fallen out of favor due to reported high rates of deep infection (13–88%) in high-energy bicondylar fractures.³⁻⁵ This is thought to be due to the large amount of soft tissue dissection required to expose the proximal tibia for traditional techniques. In response to this, there has been a trend to consider the soft tissue more carefully with the introduction of less invasive surgical strategies. The literature describing these techniques consists almost entirely of retrospective and single-center cohort studies. For each technique, authors describe their surgical methods and report satisfactory results in terms of obtaining and maintaining reduction along with their low complication rates.

Two prospective comparative trials were identified in the literature. A trial from the Canadian Orthopaedic Trauma Society (COTS) compared closed/limited open reduction and circular external fixation with ORIF via midline or two-incision methods using nonlocking implants.⁶ The patients were limited to high-energy fractures classified as Schatzker 5/6 injuries (AO 41-C). The authors identified HSS knee scores at 2 years postoperatively as their primary outcome. with an a-priori power calculated to predict a 25% difference with their sample size of 82 patients. There was no significant difference in HSS knee scores at 2 years (primary outcome) between groups ($p = 0.31$). However, the external fixation group was found to have a trend to earlier functional recovery with better HSS knee scores at 6 months postoperatively ($p = 0.064$). The ORIF group was found to have a 17% (8/40) infection rate vs. 4.7% (2/43) in the external fixation group ($p = 0.032$). The ORIF group was found to have a larger number of unplanned procedures (37 vs. 16, $p = 0.001$) which were often of significant magnitude, including one above-knee amputation. Other secondary outcomes of WOMAC scores, quality of reduction, development of osteoarthritis, and SF-36 scores were similar between groups.

Jiang et al. randomized 84 patients with bicondylar tibial plateau fractures to either double plating through 2 incisions or lateral locked plating with the LISS device.⁷ Some limitations of this study include concerns that details of the

randomization process were not clear and that a-priori primary and secondary outcomes were not discussed. However, a power calculation for HSS scores was presented, which is presumably the primary outcome. This group found no significant difference in HSS score at 12 or 24 months postoperatively ($p = 0.215$ and $p = 0.84$). They also found no significant difference in infection rate (5.9% overall (5/84), $p = 0.96$) or other complications.

Recommendations

- Midline anterior exposure should be avoided when two plates are required in high-energy proximal tibia fractures [overall quality: low]
- There is insufficient evidence to recommend between ORIF, hybrid/circular external fixation, and unilateral locked plating in proximal tibia fractures [overall quality: low]

Question 2: I anticipate a metaphyseal bone void after reduction. Should I fill this with iliac crest autograft or a bone graft substitute?

Relevance

Proximal tibia fractures often are associated with a component of joint surface depression.¹ Elevation of the joint surface to its anatomic location leaves behind a metaphyseal bone void of variable size. It is common practice to fill this resultant void with supportive material to augment internal fixation and support elevated articular bone fragments. Autograft bone, usually from the iliac crest, has been used historically.¹⁻³ Several bone graft substitute materials have been introduced recently, in part due to the known morbidity of bone graft harvest.

Quality of the evidence

Level I

- 1 systematic review/meta-analysis
- 1 randomized controlled trial (RCT)

Level II

- 2 RCTs with methodologic limitations

Findings

An RCT was published comparing calcium phosphate bone substitute (alpha-BSM) to iliac crest bone graft (ICBG) in tibial plateau fractures.⁸ The authors of this study conducted a multicenter trial with patients requiring tibial plateau fracture surgery randomized to either ICBG or alpha-BSM. The primary outcome was joint subsidence as measured on follow-up radiographs. The authors defined significant articular subsidence as greater than 2 mm. They found the ICBG-treated patients to have a subsidence rate of 30% compared to a subsidence rate of 6% in the alpha-BSM treated group ($p = 0.009$). An unpublished study presented at the Orthopaedic Trauma Association meeting⁹

compared injectable calcium phosphate cement (Norian SRS™) to ICBG. The authors utilized radiostereometry with tantalum bead markers. They found less articular displacement and better functional knee scores in the group treated with bone graft substitute. These studies were included in a meta-analysis exploring the use of calcium phosphate cement in fracture surgery at multiple anatomic sites including the wrist, hip, tibial plateau, and calcaneus.¹⁰ This article described a systematic literature review and analysis of level I studies comparing calcium phosphate cements to bone graft or no grafting. They found calcium phosphate cements to be associated with less pain at the fracture site and with less loss of reduction, especially in tibial plateau patients. Calcium sulfate graft substitutes are also available, but there is minimal evidence supporting their use in tibial plateau fractures. Two case series^{11,12} describe the use of calcium sulfate products in tibial plateau fractures, and Kelly et al.¹³ describe its use in a mixed group of patients with bone defects. They report radiographic resorption of the material by 3 months; however, complications of sterile drainage (4–8%) and loss of reduction (8–12.5%) are also reported. A randomized trial of grafting anterior cruciate ligament tunnels with calcium sulfate pellets vs. no grafting was reported.¹⁴ They examined pellet resorption and bone growth with CT scans at up to 6 months after surgery. They found that resorption of the calcium sulfate pellets occurred by 6 weeks and that no significant bone growth differences were observed at any point between the treatment groups.

In fractures of the tibial plateau, level I evidence supports the use of calcium phosphate bone graft substitutes instead of ICBG to reduce harvest site related symptoms and to minimize articular collapse of the tibial plateau after surgery. Limited, inconclusive evidence is present regarding use of calcium sulfate bone graft substitutes. No data exists comparing functional outcome of patients treated with ICBG vs. bone graft substitutes. However, the relationship with residual joint incongruity and functional outcome suggests that improved maintenance of anatomic reduction with calcium phosphate bone graft substitute would also lead to a better outcome.

Recommendation

- Calcium phosphate bone substitutes, rather than ICBG or calcium sulfate, should be used when it is desirable to fill a metaphyseal bone void [overall quality: moderate–high]

Question 3: How early should I allow range of motion postoperatively?

Quality of the evidence

Levels III and IV

- 4+ retrospective cohort studies or case series

Findings

Modern fracture treatment principles prescribe early range of motion (ROM).¹⁵ The series by Lucht and Pilgaard¹⁶ noted patients have better clinical results when knee immobilization was less than 8 weeks before initiation of ROM exercises. Rasmussen¹⁷ noted a better ROM among patients immobilized for less than 6 weeks. Volpin¹⁸ showed similar results with better functional ratings and less pain in patients treated with less than 6 weeks of immobilization. Unfortunately, there is no data comparing immediate ROM with a short period of immobilization, so that it is not possible to state whether any immobilization is required at all. While these studies are limited by their retrospective design and lack of validated outcomes, the consistent finding of improved results with decreasing duration of immobilization allows us to recommend joint ROM as early as possible and preferably before 6 weeks.

Recommendation

- Joint ROM should begin as early as possible and preferably before 6 weeks [overall quality: low–moderate]

Question 4: What is the effect of imperfect articular reduction on functional outcomes?

Quality of the evidence

Level II

- 12 prospective studies with limitations and retrospective studies

Relevance

General principles of treatment for articular fractures demand anatomic reduction and stable fixation to permit early motion of the injured joint.¹⁵ This is somewhat controversial in the proximal tibia, as several authors have suggested this joint may tolerate higher ° of articular displacement than other joints.^{16,17,19–21}

Findings

Table 61.3 lists the published series which comment on a relationship between accurate joint reduction and clinical outcome. No level I prognostic studies exist (prospective cohort with >80% follow-up).²² Among the several retrospective series, comparison is difficult due to lack of consistent definitions of malreduction and varied, often nonvalidated, clinical outcome measures. One often-quoted study by Blokker et al.²³ used a composite outcome including a clinical impression and radiographic parameters (residual displacement <5mm) for their acceptable result. This meant it was impossible for a patient to have an acceptable result if they had residual displacement, regardless of their clinical outcome. Among the other studies, the majority (6 studies including 670 patients)^{2,3,24–27} suggest a

relationship between some amount of residual displacement and functional outcome. This includes three modern studies^{3,26,27} that use validated outcome measures. Five studies reporting on 562 patients showed no relationship clinical outcome and articular displacement.^{16,17,19–21} Unfortunately, the two more recent studies with validated outcomes^{20,21} were limited by the small number of patients with a malreduction, thus limiting their statistical ability to show a difference in functional outcomes. Among the more recent series using modern measurement methods,^{20,21} there is a consistent finding that residual articular displacement is associated with deterioration in clinical and functional results. However, there is insufficient evidence to support a particular threshold of displacement as an indication for surgical intervention.

Recommendations

- Articular incongruity negatively affects outcomes and should be considered in combination with other injury factors when determining the need for surgical intervention [overall quality: low–moderate]
- When surgery is undertaken the best achievable reduction should be sought but balanced against the potential complications of achieving that reduction [overall quality: low–moderate]

Question 5: What is the effect of limb instability, malalignment, and meniscus cartilage damage on functional outcomes?

Quality of the evidence

Level II

- 12 prospective studies with limitations and retrospective studies

Findings

Joint instability, particularly in the coronal plane, has been suggested to be an important predictor of outcome and thus an indication for surgical stabilization.¹⁷ Many of the studies listed in Table 61.3 regarding articular malreduction also comment on joint instability as a predictor of outcome. However, the modern series using validated outcomes^{20,21,25,27} either do not comment on joint instability or have very few patients with significant instability. The classic studies^{2,17,19} defined joint stability as less than 10° excess motion in the coronal plane in the extended knee. Instability in the sagittal and rotational planes has not been evaluated scientifically. Restoration of coronal plane stability, by bone elevation/reduction and/or ligament repair, improved clinical results and/or reduced post-traumatic osteoarthritis.^{2,11,26} A study exploring post-traumatic osteoarthritis²⁸ showed a high risk of developing osteoarthritis (69%) was associated with residual knee instability. A limitation of these findings is that all patients with radiographic

Table 61.3 Summary of studies exploring relationship of residual articular displacement on clinical outcome

Reference (publication year)	No. of patients (no.assessed/ total no.)	Association of outcome to accurate reduction (Yes/No)	Reduction threshold suggested	Outcome measure(s)	Comments
Rademakers et al. 2007	109/222	No	2 mm or 5 mm	Neer and HSS knee scores	Neither reduction threshold associated with outcome Few malreductions for comparison
Barei et al. 2006	42/83	Yes	2 mm	MFA	Regression analysis <2 mm associated with better MFA scores
Weigel et al. 2002	23/30	Yes	Linear correlation (r = 0.51; p = 0.01)	SF-36 and Iowa Knee score	Association of residual displacement with bodily pain subscale of SF-36 but not other measures
Stevens et al. 2001	46	No	4 mm	SF-36 and WOMAC	Low numbers and few malreductions for comparison
Kumar and Whittle 2000	54	Yes	Not defined	Knee society score	Better Knee society score in patients with anatomic vs. non-anatomic reduction
Moore et al. 1994	320/988	Yes	Linear correlation Objective: r = 0.42 ; p < 0.001 Subjective: r = 0.26; p < 0.001	"arbitrary" objective and subjective knee score	Nonvalidated outcomes Raw data shows similar outcomes until 5–10 mm of residual displacement
Honkonen 1994	131/212	Yes	4 mm	Vague surgeon defined grading as acceptable or not	Proportion of acceptable results lower with residual displacement >4 mm
Duwelius and Connely 1988	96	No	Not defined	Rasmussen's criteria	Vague description and nonvalidated outcomes
Lansinger et al. 1986	102/204	Yes	10 mm	Vague surgeon defined grading of acceptable or not	Longer follow-up of Rasmussen et al. Poorer results in those with >10 mm of joint depression
Blokker et al. 1984	60/64	Yes	5 mm	Vague surgeon defined grading as acceptable or not based on radiographs and clinical criteria	Defined a residual displacement of 5 mm as an unacceptable result therefore impossible for patient to have >5 mm of displacement and acceptable result
Rasmussen 1973	204/260	No	5 mm	Surgeon defined grading system	Insensitive outcome measure
Lucht et al. 1971	107	No	3 and 10 mm	Vague surgeon defined grading of acceptable or not	Insensitive outcome measure

osteoarthritis do not necessarily have severe functional problems. However, based on these retrospective studies, there is consistent level II evidence that joint instability is a significant predictor of worse outcome. Joint instability of more than 10° is an indication for surgery, and joint stabilization by articular elevation/reduction and fixation should be a goal of surgical treatment. If instability persists, ligament repair should be considered.

Proximal tibial malunion resulting in malalignment of the weightbearing axis of the lower extremity has been correlated with worse clinical results.^{16,17,19–21,24,28} Unfortunately, there are no series that use validated outcome measures to evaluate the relationship of malalignment and worse function. However, several older studies^{17,18,21,28} show increased rates of osteoarthritis in patients with residual coronal plane malalignment. Clinical results were worse in malaligned patients in the series by Honkonen.²⁴ Each of these studies shows less tolerance of varus malalignment compared to valgus malalignment. Clinical outcomes and rates of osteoarthritis worsen with even small amounts of varus, while valgus malalignment is tolerated up to 5–10°.^{17,21,24} Osteoarthritis rates increase in the setting of malalignment and meniscectomy.^{28,29} The consistency of these retrospective studies allows us to recommend articular malalignment of greater than 10° of valgus or any varus as indications for surgery, with a goal of reducing this malalignment via the surgical procedure. The meniscus is now recognized as an important structure, especially in the traumatized knee, and should be repaired when possible and not be removed.

Recommendation

- Joint instability or more than 10° is an indication for surgery and joint stabilization should be a goal of surgical treatment [overall quality: moderate]
- Articular malalignment of greater than 10° of valgus or any varus are indications for surgery with a goal of reducing this malalignment during the surgical procedure [overall quality: moderate]
- Menisci should be repaired when possible and not removed [overall quality: moderate]

Summary of recommendations

- Midline anterior exposure should be avoided when two plates are required in high-energy proximal tibia fractures
- There is insufficient evidence to recommend between open reduction internal fixation, hybrid/circular external fixation, and unilateral locked plating in proximal tibia fractures
- Calcium phosphate bone substitutes, rather than ICBG or calcium sulfate, should be used when it is desirable to fill a metaphyseal bone void

- Joint ROM should begin as early as possible and preferably before 6 weeks
- Articular incongruity negatively affects outcomes should be considered in combination with other injury factors when determining the need for surgical intervention
- When surgery is undertaken the best achievable reduction should be sought but balanced against the potential complications of achieving that reduction
- Joint instability or more than 10° is an indication for surgery and joint stabilization should be a goal of surgical treatment
- Articular malalignment of more than 10° of valgus or any varus are indications for surgery with a goal of reducing this malalignment during the surgical procedure
- Menisci should be repaired when possible and not be removed

University of Ottawa, Ottawa, ON, Canada

Case scenario

A 29 year old man is brought to the Emergency Department following a motor vehicle collision. On examination the right lower leg is swollen and deformed and an open wound is noted. He is neurovascularly intact and there are no signs of compartment syndrome on initial clinical evaluation.

Relevant anatomy

Fractures of the tibial shaft (diaphysis) are defined by the Orthopedic Trauma Association as simple, wedge, and complex.¹ A detailed classification is presented in Table 62.1. Open fractures are generally described using the Gustilo classification (Table 62.2).²

Importance of the problem

Tibial shaft fractures are one of the most common long bone fractures presenting to the Emergency Department each year. The incidence of tibial and fibular fractures is approximately 500,000 per year in the United States.^{3,4} The management of tibial fractures can be complex and complication rates high. Thus, knowledge of the evidence in current literature with respect to care of patients with these fractures is paramount.

Intramedullary (IM) nailing has become the generally accepted standard of management for displaced tibial fractures, but controversy concerning optimal treatment for these injuries continues to exist. This is largely due to the variations in degree of trauma and extent of soft tissue damage which have an impact on overall outcome. The nature of injury to the tibia may result in inadequacy of

vascular supply and tissue coverage, and can make these diaphyseal fractures particularly prone to poor healing and infection.⁴ It is the intention of this chapter to explore the best available research on areas of controversy in the management of tibial shaft fractures and provide the reader with recommendations for patient care.

Top six questions

Therapy

1. Is there any difference in outcomes between reamed and unreamed IM nails?
2. What is the best management of open tibial shaft fractures?
3. What is the best management for closed tibial shaft fractures?
4. Does low-intensity pulsed ultrasound (LIPUS) aid in the healing of tibial shaft fractures?

Prognosis

5. Is dissection of the patellar tendon in IM nailing of the tibia associated with chronic anterior knee pain?
6. What is the relative effect of reaming and intraoperative traction on the risk of compartment syndrome (CS)?

Finding the evidence

The following general searches were undertaken to identify the best evidence (meta-analyses, systematic reviews, and clinical trials) on tibial shaft fractures. More detailed search terms are outlined under each question.

- Cochrane Database: search term “tibial fractures”

Table 62.1 Classification of tibial shaft fractures

Type	Fracture pattern	Description
A	Simple	A1: Spiral A2: Oblique ($\geq 30^\circ$) A3: Transverse ($< 30^\circ$)
B	Wedge	B1: Spiral B2: Bending B3: Fragmented
C	Complex (comminuted)	C1: Spiral C2: Segmented C3: Irregular

Table 62.2 Gustilo classification of open tibial shaft fractures

Grade	Description
I	Skin opening: < 1 cm Fracture pattern: short oblique or transverse
II	Skin opening: > 1 cm Fracture pattern: short oblique or transverse, minimal comminution
III	General: high energy injury with extensive soft tissue damage (including neurovascular structures) Grade IIIA: 10 cm skin opening; soft tissue coverage of bone adequate Grade IIIB: tissue damage includes periosteal stripping and typically requires flap repair Grade IIIC: Requires vascular repair

- PubMed: (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “tibial fractures” OR “tibial shaft fractures” OR “tibial shaft”
- PubMed: advanced search/type of article/randomized control trials: “tibial fractures” OR “tibial shaft fractures”
- MEDLINE search: population (“tibial fracture” or “tibial shaft fractures”); methodology (clinical trial)

Question 1: Is there any difference in outcomes between reamed and unreamed IM nails?

Case clarification

The patient has an open fracture of the right tibia. The fracture will be treated with IM nailing and you consider whether reaming will be beneficial for your patient.

Relevance

Controversy about the superiority of the reamed over the unreamed technique in IM nailing of the tibia has been ongoing for many years. The reamed procedure has the advantage of creating space for a larger nail, which improves overall stability of the fracture. However, the process of reaming may destroy endosteal blood supply, thereby decreasing healing and increasing risk of infection.

Current opinion

IM nailing of the tibia is the preferred surgical method of treatment for displaced diaphyseal fractures. Opinions about whether or not to ream remain varied.

Finding the evidence

- Terms: “tibial fracture,” “tibial shaft fractures,” “intramedullary nailing”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses
- 4 randomized trials

Level II

- 7 randomized trials with methodologic limitations

Findings

The pooled results of a meta-analysis comparing reamed to unreamed nails in long bone fractures of the lower extremity⁵ are shown in Table 62.3. No risk differences were found for the rates of malunion, pulmonary embolism, CS, or infection.

Results of a systematic review of three trials evaluating effects of reamed and unreamed nails in tibial shaft fractures are also shown in Table 62.3 (n = 291).⁶

A large multicenter trial (n = 1319 patients) randomized patients to reamed or unreamed IM nailing of the tibia.⁷ Results are provided in Table 62.4. Note that the significant findings for the closed fracture subgroup analysis may reflect the higher rates of dynamization in this group.

Recommendations

- Reamed IM nailing reduces the risk of reoperation at 1 year in closed tibial shaft fractures compared to unreamed IM nailing [overall quality: high]
- There is no difference in reoperation risk between reamed and unreamed IM nailing of tibial shaft fractures (open and closed) [overall quality: high]
- The risk of nonunion and implant failure is higher in unreamed compared to reamed IM nailing [overall quality: moderate]

Table 62.3 Effect of reamed vs. unreamed IM nailing of the tibia

Study	Outcome	N	Trials	Risk	95% CI	p value
Bhandari et al. 2000	Nonunion	646	9	RR 0.33	0.16–0.68	0.0019
	Implant failure*	358	4	RR 0.30	0.16–0.58	<0.001
Forster et al. 2005	Nonunion	291	3	OR 2.83	1.16–6.68	0.02
	Implant failure	291	3	OR 3.57	1.92–6.66	<0.001
Bhandari et al. 2008	Reoperation at 12 months (all fractures)	1319	1	RR 0.90	0.71–1.15	0.40
	Reoperation at 12 months (closed fractures)	826	1	RR 0.67	0.47–0.96	0.03

OR, odds ratio; RR, relative risk.

Table 62.4 Comparison of risk of reoperation in treatment of open tibial fractures

Intervention	N	Trials	RR ^a	95% CI	p value
External fixator vs. plate	56	1	0.13	0.03–0.54	<0.01
External fixator vs. unreamed nails	396	5	0.51	0.37–0.69	<0.001
Reamed vs. unreamed nails	132	2	0.75	0.43–1.32	0.32
Reamed nails vs. external fixators (indirect analysis)	—	—	0.56	0.19–0.95	<0.05

95%CI, confidence interval; N, total sample size pooled; RR, relative risk.

^aThe relative risk of reoperation when first listed intervention compared to second intervention. Values <1.0 favor first intervention, values >1.0 favor second intervention.

Question 2: What is the best management of open tibial shaft fractures?

Case clarification

Your patient has an open tibial shaft fracture. Recognizing the complex nature of these fractures, you want to know the optimal treatment for decreasing complications and minimizing undesirable outcomes such as reoperation, nonunion, malunion, infection, and implant failure.

Relevance

There are several options for treatment of open tibial fractures. These include plate fixation, external fixation, unreamed IM nail, and reamed IM nails. The main concerns with open tibial shaft fractures are adequate blood supply and soft tissue coverage necessary for fracture union and infection reduction.

Current opinion

IM nailing of the tibia has been generally accepted for treatment of open tibial shaft fractures, although there are proponents of external fixation (EF).

Finding the evidence

- Search terms: “open tibial fracture,” “open tibial shaft fractures”

Quality of the evidence

Level I

- 1 systematic review/meta-analysis
- 4 randomized trials

Level II

- 4 randomized trials with methodological limitations

Findings

Bhandari et al. conducted a meta-analysis primarily evaluating rates of reoperation with different methods of treatment for open tibial shaft fractures.⁸ Eight trials were included in the analysis. Results are shown in Table 62.4 and Figure 62.1.

Secondary outcomes of nonunion, malunion, superficial and deep infection, and implant failure were also evalu-

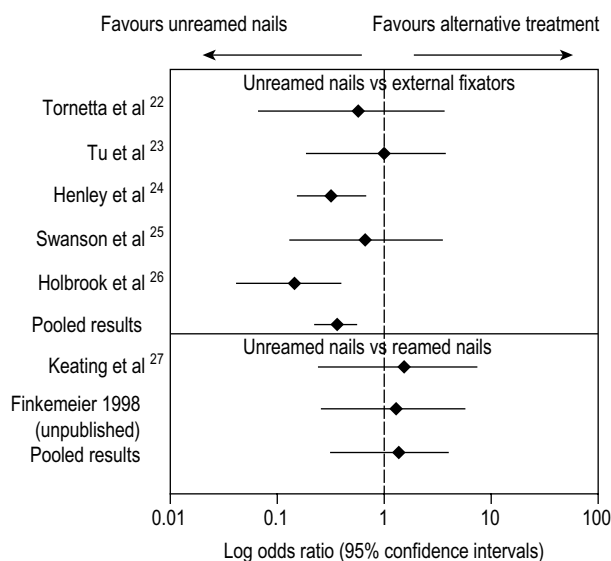

Figure 62.1 Comparing odds of reoperation between unreamed nails and external fixators, unreamed and reamed nails. Reproduced with permission and copyright © of the British Editorial Society of Bone and Joint Surgery. Bhandari M, Guyatt GH, Swiontkowski MF, Schemitsch EH. Treatment of open fractures of the shaft of the tibia: a systematic overview and meta-analysis. *J Bone Joint Surg [Br]* 2001;83-B:62-8.

ated. No significant differences were found between plate and EF for these outcomes. However, point estimates for all outcomes favored EF. Results of five trials revealed that risk of malunion (RR 0.42, 95% CI 0.25–0.71) and superficial infection (RR 0.24, 95% CI 0.08–0.73) were significantly less in unreamed nails compared to EF. Two trials comparing reamed to unreamed IM nails ($n = 156$) showed the risk of implant failure to be less in reaming of the tibia (RR 0.32, 95% CI 0.17–0.89, $p < 0.025$).

Grade IIIB fractures The meta-analysis⁸ reported outcomes comparing EF with unreamed IM nailing in grade IIIB fractures ($n = 45$ patients). The results did not reveal significant differences between unreamed nails and EF with respect to nonunion (RR 0.70, 95% CI 0.24–2.43) or deep infection (RR 1.95, 95% CI 0.39–9.89). Additionally, when reamed and unreamed IM nailing was compared in grade IIIB fractures ($n = 11$ patients), the risks of nonunion (RR 1.14, 95% CI 0.15–8.99) and deep infection (RR 1.88, 95% CI 0.09–37.63) did not significantly differ between groups.

Two-stage management With respect to two-stage management, a systematic review⁹ included a single randomized controlled trial (RCT)¹⁰ which compared outcomes in patients who had been randomized to cast or IM nailing treatment following EF. The rate of union was significantly higher in the IM nailing group (94% vs. 64%, RR 4.8, $p = 0.02$). Weighted estimates from this trial and 21 case series ($n = 504$) in the review revealed that infection rates

were reduced when the interval between removal of the external fixator to IM nailing was shorter (≤ 14 days, RRR = 85%, 95% CI 68–93%, $p < 0.001$). Additionally, short EF periods (≤ 28 days) decreased risk of infection (RRR = 83%, 95% CI 62–93%, $p < 0.001$).

Recommendations

- The risk of reoperation with EF is lower than plate fixation in open tibial shaft fractures [overall quality: low]
- The risks of reoperation, malunion, and superficial infection in unreamed nailing of open fractures is less than EF [overall quality: moderate]
- The risks of implant failure in reamed IM nails is less than unreamed IM nails [overall quality: moderate]
- The risks of reoperation is reduced in reamed IM nailing of open tibial shaft fractures compared to EF [overall quality: low]
- There is no significant difference in the risk of nonunion or deep infection in grade IIIB tibial fractures when EF is compared to unreamed IM nailing, or in the comparison of reamed to unreamed nailing [overall quality: low–moderate]
- When EF is used as a preliminary step to IM nailing, shortening the EF duration and the period between EF removal and IM nailing reduces risk of infection. Well-designed prospective clinical trials are necessary for confirmation [overall quality: low–moderate]

Question 3: What is the best management for closed tibial shaft fractures?

Case clarification

Although your patient has an open tibial shaft fracture, you are interested in knowing if current evidence supports interventions such as casting, plating, and IM nailing in the treatment of closed tibial fractures.

Relevance

Closed tibial fractures may be treated with casting, IM nailing, or plating. Results in recent literature may challenge historical management of these fractures.

Current opinion

IM nailing is becoming the preferred method of fixation for closed tibial shaft fractures.⁴

Finding the evidence

- Search terms: “closed tibial fracture,” “closed tibial shaft fracture”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses
- 3 randomized trials

Level II

- 3 randomized trials with methodologic limitations

Findings

Littenberg et al. conducted a meta-analysis evaluating three different methods of treating closed tibial shaft fractures (casting, ORIF, IM rod).¹¹ There were few studies fitting the inclusion criteria; because of the lack of randomized trials, several nonrandomized trials and case series were included in the analysis. The review found the risk of superficial infections to be lower in casting compared to ORIF (OR 0.20, 95% CI 0.08–0.50, RD –5.81, p = 0.02). Casting was associated with a lower rate of union at 20 weeks compared to ORIF (OR 0.21, 95% CI 0.06–0.68, RD –18.07, p = 0.008). No significant differences (i.e., where p < 0.05) were found in mortality rates, “deep infection”, reoperation, or nonunion following cast treatment.

The results of the meta-analysis by Coles et al. presented average values for the outcomes of the various closed reduction treatments.¹² Mean time to union was lowest in plate fixation (14.9 weeks) compared to IM nailing (19.5 weeks unreamed; 20.2 weeks reamed). Rates of delayed union and nonunion (combined) were lower in plate fixation (2.6%) compared to IM nailing (16.7% unreamed; 8.0% reamed). Reoperation rates were as follows: 4.7% plate fixation; 8.3% casting; 12.4% reamed nailing; 23.1% unreamed nailing.

Recommendations

- Treatment of closed tibial shaft fractures with casting has a lower risk of superficial infections compared to ORIF [overall quality: low]
- ORIF of closed tibial fractures has a higher rate of union compared to casting [overall quality: low]
- Evidence on the best method of closed tibial shaft fracture treatment is poor [overall quality: low]

Question 4: Does LIPUS aid in the healing of tibial shaft fractures?

Case clarification

You would like to optimize the healing process for your patient as much as possible and are interested in the efficacy of LIPUS in the management of tibial shaft fractures.

Relevance

The use of bone stimulators in fracture healing has received increasing attention over the past decade. LIPUS has been found to enhance the four stages of fracture healing (inflammation, soft callus formation, hard callus formation, remodeling) in laboratory studies.¹³ However, studies to date are conflicting and scrutiny of the current literature is

required before this method can be employed in the regular management of tibial fractures.

Current opinion

LIPUS is used by 21% of orthopedic surgeons in Canada in the management of tibial shaft fractures.⁴

Finding the evidence

- Search terms: “tibial fracture,” “tibial shaft fracture,” “fractures,” “ultrasound,” “low intensity pulsed ultrasound”

Quality of the evidence

Level I

- 4 systematic reviews/meta-analyses
- 4 randomized trials

Level II

- 3 randomized trials with methodologic limitations

Findings

A systematic review of trials evaluating healing time in fractures reported results for several studies on tibial shaft fractures.¹⁴ The pooled effect of LIPUS in healing of tibial shaft fractures managed operatively was nonsignificant. Significant results in the study of conservatively managed tibial fractures supported the use of LIPUS in fracture healing (Table 62.5).

This same study was used in a meta-analysis of three trials comparing healing time in patients (n = 158) with fractures (tibial, distal radius, and scaphoid) treated with LIPUS or placebo.¹⁷ The results for radiographic healing (3 of 4 cortices) were significant and revealed a decrease in healing time of 64 days in patients treated with LIPUS (effect size = 6.41, 95% CI 1.01–11.81). A trial evaluating healing time in tibial and radius fracture (n = 158) found that in tibial fractures, healing time was decreased in smokers treated with LIPUS by 41% (p < 0.006) and in non-smokers by 26% (p < 0.05).¹⁷

Table 62.5 Comparison of tibial shaft fracture healing with LIPUS

Method of fracture treatment	N	Trials	% reduction in healing time	95% CI
Operative (pooled)	62	2	16.6	76.8–60.7
Emami ¹⁵	32	1	–24.0	–71.9 to 10.6
Leung ¹⁶	30	1	42.5	31.7–51.6
Conservative	67	1	46.3	33.8–56.5

95%CI, confidence interval; N, total sample size pooled.

The results of two other systematic reviews^{13,18} reported similarly on the studies discussed above. The conflicting outcomes are suggested to be the result of variations in the initiation and duration of LIPUS or the type and treatment of the fractures studied.

Recommendation

- The evidence supporting the use of LIPUS in the healing of tibial shaft fractures is conflicting and inconclusive [overall quality: low]

Question 5: Is dissection of the patellar tendon in IM nailing of the tibia associated with chronic anterior knee pain?

Case clarification

You will fix the tibial shaft fracture with an IM nail, but recognize that chronic anterior knee pain may be a residual effect of the procedure. You consider a paratendinous approach in anticipation that this will reduce painful outcomes in your patient.

Relevance

While current operative management of tibial shaft fractures is through IM nailing, anterior knee pain is recognized as an adverse outcome associated with this procedure. The reasons for this outcome are not well understood and are thought to be multifactorial. Dissection of the patellar tendon in IM nailing may risk factor for the development of chronic anterior knee pain.^{19–21}

Current opinion

The causes of postoperative knee pain in IM nailing of the tibia are undetermined, and surgical approach varies among surgeons.

Finding the evidence

- Search terms: “tibial fracture,” “tibial shaft fracture,” “knee pain,” “anterior knee pain,” “intramedullary nailing”

Quality of the evidence

Level II

- 1 randomized trials with methodologic limitations

Findings

A randomized trial (n = 50 patients) comparing paratendinous (incision medial to the patellar tendon) to transtendinous (incision through the patellar tendon) in IM nailing reported outcomes at 3 and 8 years following surgery.²⁰ Anterior knee pain was evaluated in multiple ways, including a pain and impairment visual analog scale (VAS), simple functional tests, thigh muscle strength, and the Iowa knee scoring system.

No significant differences in knee pain were found between the two surgical approaches at either 3 or 8 years.^{20,21} In both groups, the prevalence of knee pain decreased from 75% (at 3 years) to 29% (at 8 years). The number of patients in this study is small may not have enough power to show the true effect of patellar dissection in IM nailing.

Recommendations

- Evidence regarding the association between anterior knee pain and dissection of the patellar tendon in IM nailing of the tibia is limited. It cannot be said that one approach has greater risks than another [overall quality: low]
- The prevalence of anterior knee pain after IM nailing of the tibia decreases with time [overall quality: low]

Question 6: What is the relative effect of reaming and intraoperative traction on the risk of CS in patients undergoing IM nailing of the tibia?

Case clarification

You are concerned about the development of postoperative CS in your patient and would like to know if intraoperative steps can be taken to reduce the risk of this complication.

Relevance

CS has been reported to have a higher incidence following intraoperative traction. Additionally, concern exists about the risks associated with reaming of the tibia and the development of CS.^{20,21}

Current opinion

Current practice is divided about the use of intraoperative traction and reaming in the treatment of tibial shaft fractures.

Finding the evidence

- Search terms: “tibial fracture,” “tibial shaft fracture,” “compartment syndrome”

Quality of the evidence

Level II

- 2 randomized trials with methodologic limitations

Findings

Does intraoperative traction increase the risk of CS? A single trial randomized patients (n = 30) with Tscherne CI fractures to traction or no traction during reamed IM nailing of the tibial shaft.²⁰ Pressures were measured in all four compartments immediately before and after surgery. Postoperative measurements in all compartments

were significantly ($p < 0.05$) higher in the traction group (6.8–8.5 mmHg).

Does reaming increase risk of CS? A small ($n = 48$) trial recorded compartment pressures preoperatively, intraoperatively, and for 24 hours postoperatively in patients who had been randomized to reamed or unreamed IM nailing of the tibia (no fracture tables or skeletal traction used).²¹ Though no patients developed CS, peak average pressures in the deep posterior compartment were significantly higher ($p < 0.05$) in the unreamed group at 10–24 hours postoperatively. Measurements at 24 hours were provided (reamed 9.5 mmHg, unreamed 19.8 mmHg, $p = 0.0143$). ΔP was significantly higher (i.e., compartment pressure was lower) in the reamed group at 14 hours (reamed 64.4 mmHg, unreamed 48.0 mmHg, $p = 0.0012$) and at 18 hours (reamed 62. mmHg, unreamed 52.1 mmHg, $p = 0.04$).

Recommendations

- Acute (≤ 3 days) reamed IM nailing of closed, displaced tibia fractures does not increase the risk of CS [overall quality: low]
- Intraoperative traction increases the risk of compartment syndrome in IM nailing of the tibial shaft [overall quality: low]

Summary of recommendations

- Reamed IM nailing in closed tibial shaft fractures reduces the risk of reoperation at 1 year compared to unreamed IM nailing
- There is no difference in risk of reoperation between reamed and unreamed IM nailing of tibial shaft fractures (open and closed)
- The risk of nonunion and implant failure is higher in unreamed compared to reamed IM nailing
- The risk of reoperation with EF is lower than plate fixation in open tibial shaft fractures
- The risk of reoperation, malunion, and superficial infection in unreamed nailing of open fractures is less than EF
- The risk of implant failure in reamed IM nails is less than unreamed IM nails
- The risk of reoperation is reduced in reamed IM nailing of open tibial shaft fractures compared to EF
- There is no significant difference in the risk of nonunion or deep infection in grade IIIB tibial fractures when EF is compared to unreamed IM nailing, or in the comparison of reamed to unreamed nailing
- When EF is used as a preliminary step to IM nailing, shortening the EF duration and the period between EF removal and IM nailing reduces risk of infection. Well-

designed prospective clinical trials are necessary for confirmation

- Treatment of closed tibial shaft fractures with casting has a lower risk of superficial infections compared to ORIF
- ORIF of closed tibial fractures has a higher rate of union compared to casting
- Evidence on the best method of closed tibial shaft fracture treatment is poor
- Evidence supporting the use of LIPUS in the healing of tibial shaft fractures is inconclusive
- No strong association between anterior knee pain and surgical approach in IM nailing of the tibia has been shown
- The prevalence of anterior knee pain after IM nailing of the tibia decreases with time
- Acute (≤ 3 days) reamed IM nailing of closed, displaced tibia fractures does not increase the risk of CS
- Intraoperative traction increases the risk of compartment syndrome in IM nailing of the tibial shaft

Conclusions

Management of tibial shaft fractures continues to be a complex and controversial issue. Levels of evidence in this area have improved over the years, but high-quality studies are still in their infancy. Certain topics have been adequately explored and have enough strength to change clinical practice. In particular, IM nailing has been shown to be the treatment of choice for tibial shaft fractures. Additionally, the use of reamed vs. unreamed nails has been an issue of controversy over the years, but there is strong evidence to support the use of reamed over unreamed nails in closed tibial shaft fractures. More large and methodologically rigorous randomized trials are required to bring clarification to the questions that still remain.

Distal Tibia/Plafond

Hossein Pakzad and Peter J. O'Brien

University of British Columbia, Vancouver, BC, Canada

Case scenario

The patient is a 30-year-old man who was involved in a motor vehicle accident. He suffered an isolated injury to his right ankle. He presented to the Emergency Department with pain, swelling, and inability to bear weight.

Relevant anatomy

The distal tibial articular surface is known as the plafond, which along with the medial and lateral malleoli forms the mortise to articulate with the talar dome. The plafond is concave in the sagittal plane and flat, or more often slightly convex, in the coronal plane. It is wider in the anterior plane to provide stability, especially while weightbearing. Ligaments providing support about the distal tibia include the tibiofibular ligament (anterior, posterior, and transverse portions), the interosseous ligament, and the strong deltoid ligament (divided into superficial and deep portions).

Pilon or plafond fractures are nonmalleolar distal tibia intra-articular fractures. They commonly occur either as a result of a high-energy axial compression load (a fall from height or motor vehicle accident) or as a result of rotational forces.

Axial compression type fractures typically have greater metaphyseal and articular comminution, greater soft tissue injury, swelling, and articular cartilage damage.

Fractures resulting from rotational forces typically have a spiral shape with minimal to moderate displacement of the fracture fragments and minimal soft tissue injury, although significant swelling may occur.

Traditionally, plafond fractures have been classified by Ruedi and Allgower¹ (level III) to three different types (Figure 63.1).

Traditional classification of plafond fractures

- Type I: simple fracture pattern without intra-articular displacement
- Type II: displaced intra-articular fracture with minimal comminution
- Type III: displaced intra-articular fracture with articular and metaphyseal comminution

The comprehensive AO/OTA classification² (level V) for long bone fractures permits more detailed information. In this classification type A is a nonarticular fracture (A1, A2, A3), type B is a partial articular fracture (B1, B2, B3), and type C is a total articular fracture (C1, C2, C3) (Figure 63.2).

AO/OTA classification of plafond fractures

Type A: Distal tibial metaphyseal injuries without intra-articular extension

- A1: simple
- A2: wedged or comminuted
- A3: complex or severely comminuted

Type B: Partial articular fractures

- B1: pure split
- B2: split-depression
- B3: multifragmentary depression

Type C: Fracture involves the entire joint surface

- C1: simple split in articular surface and metaphysis
- C2: articular simple split with a multifragmentary metaphyseal fracture
- C3: fracture with multiple fragments of the articular surface and the metaphysis

Figure 63.1 Ruedi and Allgower classification of plafond fractures.

Importance of the problem

Pilon fractures are uncommon, accounting for only approximately 10% of lower extremity fractures and are more common in men than women (level V).³ With operative treatment, high-energy pilon fractures will take 4 months on average to heal and the total time of disability will be longer. Pilon fractures have a long-lasting negative effect on ankle function, work, recreation, and health-related quality of life. Patients frequently use pain medication, change jobs, and are unable to participate in all recreational activities (level IV).⁴

Top ten questions

Diagnosis

1. How important is the history and clinical examination in the diagnosis of pilon fractures?

2. What is the role of CT scanning in the diagnosis and treatment of pilon fractures?

Treatment

3. Is there any role for nonsurgical treatment in pilon fractures?

4. When is the optimum time for surgical intervention?

5. What is the role of external fixation in the treatment of pilon fractures?

6. Is ankle-sparing external fixation superior to ankle-spanning external fixation in the treatment of pilon fracture?

7. What are the common surgical approaches for pilon fracture reduction and fixation?

8. What is appropriate postoperative care and rehabilitation after pilon fractures?

Complications and outcome

9. What are the common early and late complications of pilon fracture, and what outcome is expected?

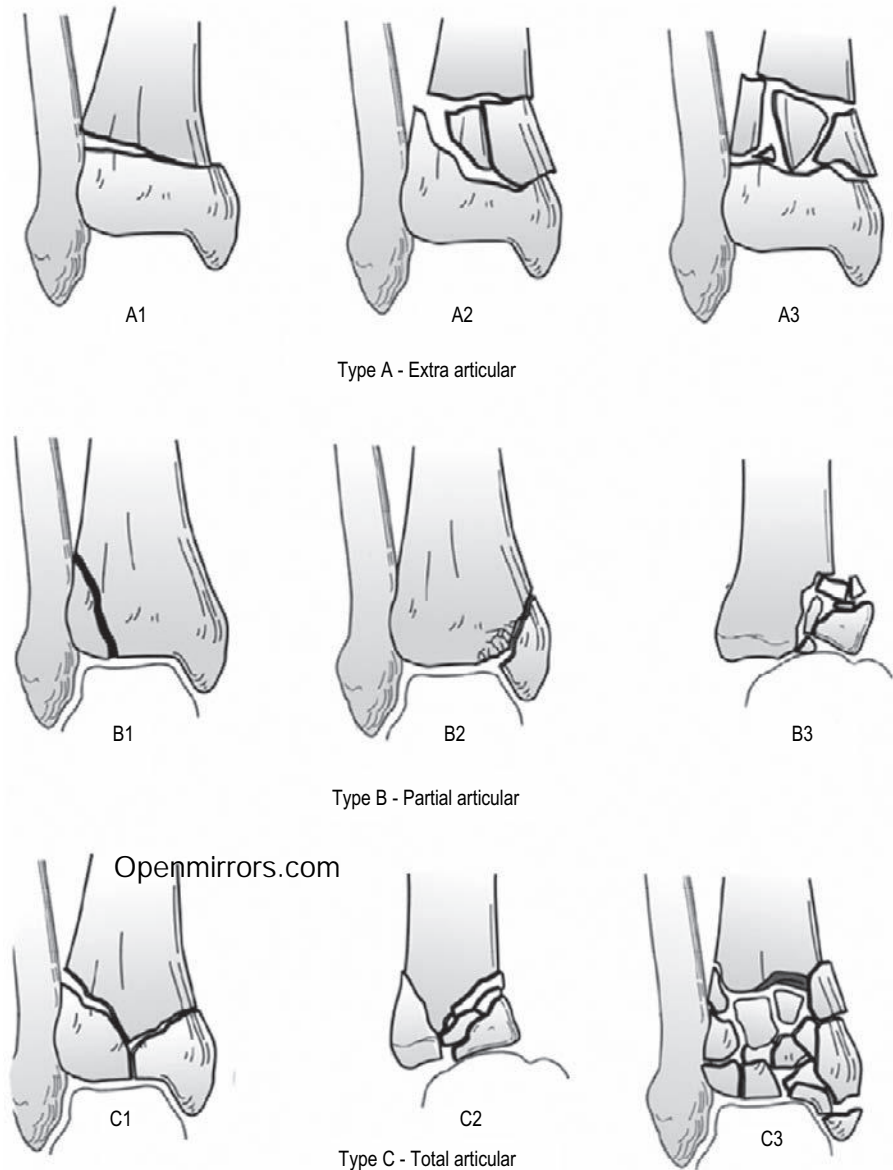

Figure 63.2 AO/OTA classification of plafond fractures.

Question 1: How important is history and clinical examination in the diagnosis of pilon fractures?

Case clarification

Clinical examination demonstrates that the patient's right foot and ankle is markedly swollen and deformed and there are tenderness and crepitus in palpation. There is no open wound injury. Neurovascular examination of his foot and ankle is normal. Radiographs in the AP, lateral and oblique views show a displaced comminuted intra-articular fracture of the distal tibia and a fracture of the distal fibula.

Relevance

Assessment starts with a careful history and a thorough physical examination along with good-quality radiographs.

Careful assessment of both the soft tissue injury and the fracture pattern are essential for successful treatment planning.

Current opinion

There are two different groups of mechanism of injury. High-energy fractures generally have a poorer outcome than do low-energy pilon fractures.

Finding the evidence

- Cochrane Database, with search terms: "plafond fracture," "pilon fracture," "distal tibia fracture," "mechanism of injury" and "physical examination"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "plafond fracture" OR

“pilon fracture” OR “distal tibia fracture” AND “mechanism of injury” AND “physical examination”

- MEDLINE search using keywords: “plafond fracture” OR “pilon fracture” OR “distal tibia fracture” AND “mechanism of injury” AND “physical examination”
- *Journal of the American Academy of Orthopaedic Surgeons*
- *Journal of Bone and Joint Surgery* (American and British volumes)

Quality of the evidence

Level II

- 2 prospective studies

Findings

Since soft tissue injury is an important component of a pilon fracture, a thorough lower extremity skin and soft tissue assessment should be performed to identify swelling, skin blister, or an open wound. Open tibial plafond fractures present with traumatic wounds typically over the medial aspect of the distal tibia or at the level of the fibular fracture (level II).⁵ Finding fracture blisters, especially bloody blisters, demonstrates the magnitude of soft tissue trauma and usually indicates a full-thickness dermal injury. A clear-filled blister usually indicates superficial epidermal injury. Blood-filled blisters are more troublesome than clear-filled blister, usually have higher rate of infection, and leave scars after recovery (level II).⁶

Assessment of the neurovascular status of the limb must also be done and documented. Alignment of deformed foot and ankle needs to be corrected especially if there is any evidence of impaired foot perfusion. Patients need to be carefully assessed for associated injuries.

Recommendation

- A thorough physical examination of the lower extremity including neurovascular examination must be done in the Emergency Department. Attention to careful assessment of the soft tissue envelope is critical [overall quality: moderate]

Question 2: What is the role of CT scan in the diagnosis and treatment of pilon fractures?

Case clarification

The patient's radiographs revealed a multifragmentary distal tibia fracture with involvement of articular surface (type C pilon fracture) with proximal displacement of talus.

A type C pilon fracture usually represents high-energy trauma with involvement of the entire joint surface.

Relevance

AP, mortise, and lateral ankle radiographs are usually sufficient for the diagnosis. Radiographs of the entire tibia and

fibula are essential for detecting extension of the fracture into the diaphysis but should not be used alone to evaluate the tibial plafond.

Current opinion

CT of the injured extremity is essential in identifying the number of articular fragments, the amount of displacement (step, gap) between the fragments, and the presence of articular and subarticular impaction.

Finding the evidence

See Question 1.

Quality of the evidence

Level II

- 1 prospective cohort study

Level IV

- 3 case series

Level V

- 1 expert opinion

Findings

CT is used to guide operative treatment to minimize soft tissue stripping while allowing articular reduction and fixation, and is essential for understanding and planning definitive treatment (level V).⁷ In one study the addition of an axial CT scan led to a change in the operative plan in 64% of patients (level IV).⁸ In a recent study (level IV),⁹ CT anatomy of 126 pilon fractures (85% type C) in 122 patients was reviewed. The authors categorized fracture patterns to be primarily coronal in 55% and primarily sagittal in 33%.

If a staged protocol is planned for a complex pilon fracture with soft tissue swelling, a distraction CT scan can be done after open reduction and internal fixation (ORIF) of fibula and length restoration with application of external fixator using the ligamentotaxis effect.⁷

The amount of information achieved in CT imaging is more precise in terms of restored length compared to a collapsed multifragmentary fracture.

In a recent prospective cohort study (level II),¹⁰ the authors intraoperatively evaluated 248 consecutive patients with intra-articular fractures including 41 tibial plafond fractures. Standard fluoroscopy and 3D imaging (Iso-C3D system) intraoperatively were performed and compared for all patients. Based on intraoperative image analysis, 19% of all cases had immediate adjustment of the reduction or hardware exchange. These revisions were based on Iso-C3D views of the articular surface that were not visible using fluoroscopy.

Recommendation

- CT scan is essential in the assessment of pilon fractures and will help surgeons to understand the anatomy of the

fracture and select the best treatment [overall quality: moderate]

Question 3: Is there any role for nonsurgical treatment in pilon fractures?

Case clarification

The patient's radiographs demonstrate a complex comminuted intra-articular distal tibia fracture. There is an associated fibular fracture. The family asks if the fracture can be managed without surgery.

Relevance

Casting is commonly used to treat stable ankle fractures but only applies to nondisplaced plafond fractures.

Current opinion

If patient medical comorbidity is not a contraindication for surgical intervention, nonsurgical intervention or casting is only appropriate for AO type A1, B1, and C1 fractures with less than 2mm of articular displacement. When in doubt, CT or plain tomography can aid in determining articular congruity.³

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 3 case series

Level V

- 1 expert opinion

Findings

In one study (level IV)¹¹ nonoperative treatment produced good functional results in all type I fractures, poor results in type II, and was not applicable to type III fractures.

Plaster immobilization may be used acutely for minimally or nondisplaced intra-articular fractures (level IV).¹²

In one study (level IV),¹³ the authors demonstrated fair to poor outcomes in 73% (22/30) of their patients who were treated with nonoperative management. They reported 13 patients with type I fractures, 9 type II, and 8 type III fractures. Follow-up examinations were performed from 4 months to 4 years. Long-term results (mean 3 years) were good in 8 cases, fair in 12, and poor in 10; 23 cases showed early ankle osteoarthritis. In 16 cases there were deviations of bone axis (15° of varus). The range of movement was limited in all patients.

The primary indications for surgical intervention are articular fragment displacement of 2mm or more, joint instability resulting from the fracture, unacceptable axial alignment of the limb, and presence of open fractures (level

V).¹⁴ Therefore, most pilon fractures are not amenable to nonoperative treatment.

Recommendation

- If the patient's medical condition is not a contraindication for surgery, nonsurgical treatment is only an option in nondisplaced plafond fractures [overall quality: low]

Question 4: What is the optimum time for surgical intervention?

Case clarification

The patient's ankle is very swollen and he has a few small amber-colored blisters anterior and medial to his ankle.

Relevance

The timing of definitive surgery depends on the condition of the soft tissues. Good surgical timing decreases the risk of wound complications, including skin slough and infection. Surgical intervention during maximum soft tissue swelling will lead to a higher risk of wound necrosis and infection. Early surgical intervention or delayed surgery as part of two-stage management is carried out when the soft tissue envelope is ready. Specific clinical signs that help the surgeon decide if the soft tissue is ready include resolution of edema and fracture blisters and the return of skin wrinkling.

Current opinion

Current treatment recommendations for pilon fractures involve a two-stage protocol in which an ankle-spanning external fixation with or without fibular reduction and fixation is used to stabilize the fracture until the soft tissue injury resolves.

Finding the evidence

See Question 1.

Quality of the evidence

Level II

- 1 prospective study

Level IV

- 4 case series

Level V

- 2 expert opinions

Findings

The decision on whether to operate and when to operate depends on multiple factors such as age, general health, soft tissue condition, current medical status, or other injuries that influence the safe administration of anesthesia. It

Openmirrors.com

also depends on the time has elapsed between the injury and the definitive evaluation of the patient (level V).¹⁵

In 1986, Mast¹⁵ stated that if surgery cannot be done before 8–12 hours have elapsed since the injury, the definitive procedure must be delayed for 7–10 days. Helfet (level IV)¹⁶ retrospectively reported the outcomes of 34 (26 type II and 8 type III) pilon fractures, including 18 open fractures with average 7.3 days from injury to operation (range 0–25 days). He concluded that the timing of pilon fracture surgery is dependent on the status of the soft tissues. Immediate postinjury swelling represents fracture hematoma. However, within 8–12 hours, the soft tissues become edematous and definitive surgery should then be delayed for 7–12 days to allow soft tissue swelling and edema to subside. If not, skin closure without undue tension will not be possible, increasing the risk of soft tissue slough and infection.

The approach most commonly used to treat high-energy pilon fractures is a two-stage procedure involving initial reduction and application of external fixator followed by definite fixation about 10–21 days later when the soft tissue envelope is ready (level IV–V).^{17–19}

Sirkin et al.¹⁷ reported on 56 fractures, including group I with 34 closed fractures and group II with 22 open fractures. The treatment protocol included immediate (<24 hours) ORIF of the fibula and application of an external fixator spanning the ankle joint followed by ORIF of the tibia with plates and screws. ORIF was performed on an average of 12.7 days after injury in group I, and 14 days after injury in group II. In the closed fracture group, 5/34 patients (15%) with closed fractures had partial skin necrosis that healed with local wound care and 1 patient had a chronic draining sinus from osteomyelitis that resolved after fracture healing. In the open fracture group, 4/22 patients (18%) had complications, with 2 only having partial skin necrosis that resolved with local wound care. One of the remaining 2 patients required a below-knee amputation.

Patterson (level IV)¹⁸ retrospectively reported the outcomes of 22 type C3 pilon fractures at 22 months treated with a two-stage procedure. He reported no infections or soft tissue complications. Objective outcome measurements were reported as 77% good and excellent results, 14% fair, and 9% poor results.

In a prospective study, Conroy et al. (level II)²⁰ reported the results of early ORIF in 32 patients who suffered from type B (21 patients) and type C pilon fractures (11 patients). They followed a “fix and flap” protocol by managing pilon fractures with early bone stabilization and flap coverage at the same time. In this study 28 patients were managed with early ORIF and early coverage using free muscle flaps (25 latissimus dorsi, 3 gracilis, 3 rectus abdominis, 1 latissimus dorsi and rectus abdominis) and split skin graft, and 4 patients were managed with application of external fixa-

tion. As a result there were 2 amputations (6.2%), 2 deep infections (6.2%), and 3 malunions (9.3%). After exclusion of the 2 amputees, all 30 remaining patients progressed to clinical and radiological union. Mean time to union was 35 weeks (range 12–78 weeks). Six patients had loss of joint congruity and demonstrated evidence of osteoarthritis on radiographs at final follow-up. They concluded their “aggressive protocol” showed excellent union rate, low rate of infection, and good functional outcome.

A recent cohort study done by Guy et al. (level IV)²¹ presented results of early primary ORIF of 95 patients with type C pilon fractures (21 open and 74 closed fractures). Primary ORIF was performed within 24 hours in 70% and within 48 hours in 88% of patients. They reported six patients with deep wound infection that required surgical irrigation and debridement, including four patients who had presented with open fractures initially. Five patients developed delayed/nonunion who subsequently had revision with ORIF and bone grafting. The authors demonstrated an acceptable deep infection rate of 2.7% for closed fractures and 19% for open fractures, with satisfactory quality of reduction in 90% of cases. Although they demonstrated a good result on those who had surgery within 48 hours after injury they did not propose a golden surgical window for ORIF of pilon fractures, but concluded that type C pilon fractures can be stabilized effectively by primary ORIF with relatively low rate of deep wound complications, a high quality of reduction, and long-term outcome comparable with all other modalities of treatment.

Recommendation

- Surgical timing is dictated by patient medical status, soft tissue envelope condition and surgeon’s experience. For most centers, a two-stage approach is appropriate. Definite internal fixation is not recommended between 2–7 days after injury [overall quality: low]

Question 5: What is the role of external fixation in the treatment of pilon fractures?

Case clarification

The patient’s ankle is now severely swollen and there are a few big bloody blisters anterior and medial to his ankle.

Relevance

In high-energy pilon fractures, the soft tissue envelope has been damaged by the injury. A second insult from surgical dissection may increase soft tissue complications. Handling of the delicate thin soft tissue envelope in tibial pilon fractures is one of the greatest challenges in the treatment of these injuries. Maintenance of fracture length and stability decreases soft tissue swelling by helping to maintain vascular flow (level V).²²

Current opinion

Fracture reduction through ligamentotaxis will maintain fracture length, provide fracture stabilization, and eventually promote soft tissue healing. With minimal dissection, the surgeon will avoid more insult to the vulnerable soft tissue envelope. The portability of the external fixator makes subsequent imaging studies easier to obtain and more informative. The fixator also provides stability for patient transfers. It is possible to use external fixation as definitive treatment for tibial plafond fractures.

Finding the evidence

See Question 1.

Quality of the evidence

Level II

- 1 randomized control trial without blinding

Level IV

- 4 case series

Findings

Historically, poor outcomes have been reported with primary ORIF of high-energy pilon fractures (level II–V),^{1,12,19,23,24} and external skeletal fixation therefore became a popular treatment alternative. Limited ORIF of the joint surface was utilized for articular fragments not anatomically reduced by ligamentotaxis.

This was well demonstrated by Bonar et al. (level IV)²⁵ in their retrospective result with the use of a unilateral external fixator for the treatment of severe pilon fractures. This retrospective review of 21 patients included two distinct treatment groups. The first group (n = 5) consisted of patients who underwent only external fixation without attempted articular reduction. The second group (n = 16) included patients who underwent limited internal fixation combined with external fixation. Four of the five patients in the first group went on to an arthrodesis, while the fifth received a late amputation. Each of the fractures in the second group healed without evidence of wound infection, skin slough, or osteomyelitis. Reflecting on the results of the patients in the second group, the authors concluded that less extensive tissue dissection, in an area prone to wound complications, may have accounted for the low rate of infection, wound complication, and nonunions.

In a randomized prospective study, Wyrsh et al. (level II)²⁶ compared 18 patients who were treated with ORIF with 20 patients who were treated with external fixation with limited internal fixation. There were 15 major complications in 7 patients who had ORIF that necessitated 28 additional operations. In the external fixation group there were 4 major complications in 4 patients, necessitating 5 additional operations. The authors found no significant

difference in post-traumatic arthritis and concluded that external fixation with limited internal fixation was a satisfactory method of treatment of pilon fractures and was associated with fewer complications than early ORIF.

In a prospective study, Watson et al. (level IV)²⁷ treated 107 pilon fractures according to a staged protocol from 1991 to 1997. All closed pilon fractures underwent stabilization with definitive fixation when patients' general health and soft tissues were ready, at an average of 5 days. They treated 26 type A, 29 type B, and 39 type C fracture patterns, 30 of which were open fractures. They treated 36 patients with ORIF and 58 patients with application of external fixation.

Clinical and radiographic evaluations were performed at an average 4.9 years after injury. For all fracture types (AO classification), 81% of the patients who were treated with external fixation and 75% of the patients who were treated with open plating had good or excellent results. The patients in the open plating group had a significantly higher rate of nonunion, malunion, and severe wound complications compared with the patients who received external fixation for type C fracture patterns. For severe fracture patterns (type C), patients in both groups had significantly poorer results than patients with type A and B fractures. They concluded that the worse the initial soft tissue injury, the poorer the overall function tended to be, regardless of the initial fracture pattern.

Recommendation

- External fixation with limited internal fixation is a widely accepted mode of definitive treatment in pilon fracture management. The existing literature suggests that the outcome is better with external fixation than with primary ORIF. There is not enough evidence to conclude whether two-stage ORIF or definitive management with an external fixator is superior [overall quality: low]

Question 6: Is ankle-sparing external fixation superior to ankle-spanning external fixation in the treatment of pilon fracture?**Case clarification**

The soft tissue of the patient's ankle is not ready for definitive ORIF. His surgeon has decided to use external fixation as the definitive treatment.

Relevance

Loss of ankle range of motion (ROM) and post-traumatic osteoarthritis are common complications after pilon fractures with disrupted articular surface. Prolonged joint immobility is associated with permanent joint stiffness.

Current opinion

Early passive and active ROM is considered beneficial to restore preinjury ROM.

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 1 randomized controlled trial without blinding

Level III

- 1 systematic review of level III studies

Level IV

- 2 case series

Findings

Early ROM provides better overall scoring and improves ROM (level IV).²⁸ Salter (level IV)²⁹ demonstrated early motion was the most important factor in promoting cartilage nutrition and healing in his animal model.

Three categories of fixator design are available: (1) joint-spanning rigid fixator, (2) joint-spanning articulated fixator, and (3) non-joint-spanning fixator.

In a systematic review (level III),³⁰ the outcomes of the use of external fixation devices for spanning or sparing the ankle joint in the treatment of fractures of the tibial plafond were compared, focusing on the complications and the rates of healing. Although there was a statistically significant difference between spanning and sparing fixation systems regarding the rates of minor infections (pin track and superficial wound infection) there were no statistically significant differences regarding the rates of deep infection, nonunion, and the time to union. Patients treated with spanning frames had a significantly greater incidence of malunion compared with patients treated with sparing frames.

Marsh et al. (level II)³¹ in a prospective multicenter study randomized pilon fractures to have either early postoperative ankle movements through a mobile articulated hinge or to have an immobile ankle with a locked hinge. All patients were treated with a uniform surgical technique, including application of a hinged transarticular external fixator with limited internal fixation. In the 31 patients (14 nonmobile and 17 mobile) who completed a 2-year follow-up, no significant differences were found between the 2 groups in any of the outcomes. The authors concluded that there was no detectable benefit of moving the ankle joint in the first 8–12 weeks after a tibial plafond fracture treated with articulated external fixation.

Recommendation

- The type of external fixation device employed is dictated by the fracture anatomy and surgeon experience. Nonspanning fixation requires large articular fragments. Use of hinged spanning external fixator has no benefit over nonhinged fixators [overall quality: moderate]

Question 7: What are the surgical approaches for pilon fracture reduction and fixation?**Case clarification**

The patient's CT scan revealed a pilon fracture with a centrally depressed fragment and about a 5 mm step. The line of fracture starts laterally and passes through the central fragment and extends medially anterior and posterior to the medial fragment (V family). There is a fibular fracture 4 cm proximal to the syndesmosis.

Relevance

The ankle soft tissue envelope is thin and vulnerable to wound complications. Extensive soft tissue dissection may result in wound breakdown. The approach that results in the least amount of dissection should be chosen.

Current opinion

The surgical approach to a pilon fracture is primarily dictated by the fracture pattern and soft tissue status. The CT scan must be reviewed carefully as part of surgical planning for both reduction and fixation strategies. The goal is to achieve anatomic reduction of the joint surface, restoration of axial alignment of the nonarticular component and application of appropriate fixation with meticulous soft tissue handling.

Finding the evidence

See Question 1.

Quality of the evidence*Level IV*

- 1 case series

Level V

- 4 expert opinions

Findings

The classic approaches to distal tibia and fibula are: (1) anteromedial (1 cm lateral to the anterior tibial crest), (2) anterolateral (between the peroneal and extensor muscles), (3) posterolateral (Harmon), (4) posteromedial, (5) anterior, and (6) direct lateral.

The traditional surgical approach, described by the AO Group (level V),³² is the *anteromedial approach* for the tibia and lateral for the fibula. A 7 cm skin bridge between the lateral incision over the fibula and the medial approach for the tibial plafond was recommended by AO pioneers (level V)³³ and others^{3,15} to avoid skin necrosis and wound complications.

A recent prospective study (level IV)³⁴ reported a low rate of wound complications in 46 pilon fractures with less than a 7 cm skin bridge between two or three skin incisions.

The authors concluded that with careful attention to soft tissue management and surgical timing, incisions for tibial plafond fractures may be placed less than 7 cm apart, allowing the surgeon to optimize exposures on the basis of the injury pattern.

Soft tissue injury or fracture pattern commonly necessitate the *anterolateral approach*. One study reported 131 pilon fractures treated with ORIF through an anterolateral surgical exposure (level V).⁷ A satisfactory reduction (<2 mm of articular incongruity) was obtained in 92% of the patients. There were 3 wound infections that required further operative treatment and no nonunions.

The well-known *posterolateral approach* is commonly used for partial articular fractures that involve the posterolateral aspect of the tibia. The posteromedial approach is occasionally useful in some fracture patterns.

There is a wide choice of implants available for ORIF of pilon fractures. The fibula fracture is generally managed with standard open reduction and fixation with a small fragment compression plate. Precontoured plates are available for the medial and anterolateral surfaces of the distal tibia. These implants reduce surgical time by eliminating the need for extensive plate contouring and facilitate minimally invasive plating techniques. There is no evidence that locked plates are superior to nonlocked plates in this application.

Wound closure is extremely important. It should be accomplished with an atraumatic technique and without soft tissue tension.

Recommendation

- The surgical approach is dictated by anatomy of fracture and the status of the soft tissue. Careful physical examination and review of the CT scan will help the surgeon to choose the most appropriate surgical approach. Most fractures can be adequately stabilized with precountoured nonlocked plates [overall quality: low]

Question 8: What is appropriate postoperative care and rehabilitation after pilon fractures?

Case clarification

The patient was discharged home 5 days after ORIF of his pilon fracture. He wants to know if he needs physiotherapy and when he is going to walk again.

Relevance

Postoperative wound care and close follow-up are necessary following treatment of pilon fractures. Wound infection and skin necrosis need to be addressed appropriately before deep infection develops. Normally weight-bearing is delayed for 12 weeks following ORIF of these fractures.

Current opinion

Most patients with pilon fracture will be observed closely after discharge for development of injury-related or post-surgical complications. If their course is uneventful they generally need to maintain non-weight-bearing status for at least 12 weeks.

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 1 expert opinion

Findings

Patients are maintained toe-touch weightbearing (TTWB) and discharged home when comfortable. The ankle is often splinted for the first week or two. Active ROM of the ankle is allowed following wound healing at approximately 2 weeks after surgery. Physiotherapy is used for ROM exercises until full motion is regained. Typically the fracture is healed by 12 weeks postoperatively and the patient can be advanced to full weightbearing.¹⁴

Recommendation

- Patients must be followed closely. Postoperatively TTWB is recommended for 10–12 weeks. Non-weight-bearing ROM exercises are recommended after the surgical incision is healed. Weightbearing status will be increased when evidence of bone healing is observed in imaging studies [overall quality: low]

Question 9: What are the common early and late complications of pilon fracture, and what outcome is expected?

Case clarification

The patient comes back to clinic after a year for follow-up. He walks with a subtle limp and had to discontinue many of his recreational activities, including tennis. Examination demonstrates decreased ankle ROM. His radiograph reveals grade II ankle arthrosis. He wants to know if he might get more clinical improvement.

Relevance

Despite progress in techniques and hardware technology, pilon fractures are associated with high rates of complications and disability.

Current opinion

Depending on the severity of their pilon fracture, patients may experience a variety of early and late complications. A fair to poor outcome is expected in at least one third of C type pilon fractures.

Finding the evidence

See Question 1.

Quality of the evidence*Level II*

- 1 prognostic study

Level IV

- 9 case series

Findings

In the 1990s, case series of early ORIF of pilon fractures reported complication rates as high as 70%.^{23,24} Early local complications were mostly related to wound dehiscence and infection. The late complications included malunion, nonunion, osteomyelitis, ankle stiffness, osteomyelitis, and osteoarthritis.

The risk of complication following the currently accepted staged treatment strategy of reduction and external fixation followed by definitive ORIF on a delayed basis has been reported.^{17,18} The technique is associated with a low risk of deep infection (0–4%), malunion, and nonunion in closed fractures.

In open fractures the risk of complication is higher. However, recently the two-stage protocol has been reported to have a low risk of complication (overall 8% infection, 8% delayed/nonunion) even in open fractures (level IV).³⁵

Pollak et al. (level II)³⁶ reported mid-term outcomes (average 3.2 year follow-up) on 80 patients with pilon fracture treated with either ORIF or external fixation. General health, as measured with the Short Form-36 (SF-36), was significantly poorer than age- and gender-matched norms. Of the 65 participants who were employed at the time of injury, 28 (43%) were not working at the time of follow-up. Approximately one third of the participants reported notable difficulty with ankle stiffness (35%), swelling (29%), or pain (33%). The only injury or treatment characteristic that was significantly related to several of the selected outcomes was treatment method. Participants treated with external fixation with or without limited internal fixation had more overall ROM impairment and reported more pain and ambulatory dysfunction than did participants treated with ORIF ($p < 0.05$).

Between 1988 and 1994, Marsh et al. (type IV)⁴ treated 56 pilon fractures (types B3, C1, C2, and C3) with a hinged external fixator with limited internal fixation. Their 5 year follow-up of 29 patients showed significantly reduced SF-36 scores compared to norms. Patients were generally satisfied with the results of treatment and perceived that they had improved for a long time after the injury. The patients reported improvement for an average of 2.4 years. Almost all patients had radiographic evidence of osteoarthritis in the ankle.

Surprisingly, radiological evidence of arthrosis had only weak correlations with clinical outcome, as measured with the Iowa Ankle Score, the Ankle Osteoarthritis Scale, and the SF-36.

Chen et al. (level IV)³⁷ published a 10 year follow-up of 128 pilon fractures treated with ORIF. Clinical outcomes were better in simple fracture patterns than they were in complex fractures, and this is a consistent finding of most studies.

Williams et al. (level IV)³⁸ found that injury severity and the quality of reduction were less important predictors of outcome than patient demographic factors (gender, age, level of education) and whether or not the injury was work related. This is not confirmed by other studies.³⁵

Recommendation

- Complications after pilon fracture treatment are common and need to be addressed accordingly [overall quality: moderate]:
 - Wound healing problems, including infection, are the commonest early local complications
 - Delayed union and nonunion can occur, especially after high-energy open fractures
 - Ankle osteoarthritis is a very common late complication
- Patients need to be advised that mid- to long-term outcomes of pilon fractures are associated with some degree of disability in most patients, especially in high-grade comminuted fractures

Summary of recommendations

- The diagnosis of a tibial pilon fracture requires a thorough history and physical examination with particular attention to careful assessment of the soft tissue envelope
- Plain radiographs are important for diagnosis and high-quality CT images are essential for operative planning
- Almost all tibial plafond fractures require surgical management
- Surgical timing is dictated by the patient's medical status, the condition of the soft tissue envelope, and the surgeon's experience. For most centers, a two-stage approach (closed reduction and external fixation ± ORIF of the fibula followed by delayed definitive internal fixation) is appropriate. Definite internal fixation is not recommended between 2 and 7 days after injury
- External fixation with limited internal fixation is a widely accepted mode of definitive treatment in pilon fracture management and is an alternative to ORIF in some settings
- The type of external fixation device employed is dictated by the fracture anatomy and surgeon experience. The use

of a hinged spanning external fixator has not been shown to have a benefit over nonhinged fixators

- For definitive ORIF, the surgical approach is dictated by the anatomy of the fracture and the status of the soft tissue. Careful physical examination and review of the CT scan will help the surgeon to choose the most appropriate surgical approach. Most fractures can be adequately stabilized with precountoured nonlocked plates
- Postoperative care involves early ankle ROM exercises. Weightbearing should be delayed until the fracture has healed (usually at about 12 weeks)
- Complications are common after pilon fractures. Early local complications often involve difficulties with wound healing and infection. Post-traumatic ankle osteoarthritis is a common late local complication
- The mid- and long-term outcome following high-energy tibial plafond fractures is guarded, with a high incidence of some degree of residual disability

Conclusions

High-energy tibial pilon fractures are challenging injuries for orthopedic surgeons to treat. Despite advances in the assessment and treatment of these complex injuries, complications do occur. The outcome is often associated with some degree of disability. Modern strategies for management that respect the soft tissue injury and provide restoration of the anatomy of the bone and joint are however, associated with lower risks of serious complication and better outcomes than have been reported historically.

Malleolar Fractures

David W. Sanders and Ajay Manjoo

London Health Sciences Centre and the University of Western Ontario, London, ON, Canada

Case scenario

An active 23 year old man employed as a laborer sustains a rotational injury to his right ankle. He is unable to bear weight and is tender over the posterior aspect of his lateral malleolus.

Importance of the problem

The ankle is the most commonly injured weightbearing joint. The incidence of fractures has doubled since the 1960s. This is believed to be due to a rise in the "open mirror" fractures. A screening tool may help determine which injuries are at high risk for fractures and will require radiological investigation.

Top five questions

Diagnosis

1. Which ankle injuries require a radiograph for diagnosis?

Treatment

2. How do you assess ankle fracture stability?
3. How are syndesmosis injuries identified and managed?
4. What is the significance of posterior malleolar injuries?

Prognosis

5. What is the role of early postoperative mobilization?

Question 1: Which ankle injuries requires a radiograph for diagnosis?

Case clarification

The patient has sustained an inversion injury to his right ankle. He is unable to bear weight and is tender over the posterior aspect of his lateral malleolus. The patient asks whether he needs a radiograph of his ankle.

Relevance

Ankle injuries are among the most common reasons for visits to the Emergency Department. Many patients do not require radiographic imaging, yet it is preferable to avoid "open mirror" fractures. A screening tool may help determine which injuries are at high risk for fractures and will require radiological investigation.

Current opinion

The most widely used screening tool to determine which ankle injuries require investigation is the Ottawa ankle rules (see box).

Ottawa ankle rules¹

Ankle radiographs are indicated if there is pain in the malleolar area and any of the following:

- Bone tenderness along the distal 6 cm of the posterior edge of the tibia or tip of the medial malleolus
- Bone tenderness along the distal 6 cm of the posterior edge of the fibula or tip of the lateral malleolus
- An inability to bear weight, both immediately and in the Emergency Department, for 4 steps

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "Ottawa ankle rules"

Evidence-Based Orthopedics, First Edition. Edited by Mohit Bhandari.
© 2012 Blackwell Publishing Ltd. Published 2012 by Blackwell Publishing Ltd.

Quality of evidence*Level I*

- 2 systematic reviews
- 1 randomized trial

Level II

- 1 prospective study

Findings

Various ankle rules have been validated in a number of prospective studies and systematic review. For the Ottawa ankle rules, a pooled analysis of 3,130 patients from 12 studies identified 671 fractures.¹ The overall sensitivity was 98.5% (95% CI 97.3–99.2). There were 10 missed fractures, of which several were deemed “insignificant.” The rate of radiographic reduction was 24.8% (95% CI 23.3–26.3%). In a prospective study of 750 patients with acute ankle injuries, a simplified version of the Ottawa ankle rules was used.² Patients who had pain near the malleoli and were age 55 years or more, or had localized bone tenderness of the posterior edge or tip of either malleolus, or were unable to bear weight both immediately after the injury and in the Emergency Department, underwent radiography. This rule was 100% sensitive and 40.1% specific for detecting malleolar fractures and would allow a reduction of 36.0% of ankle radiographic series ordered.

Recommendation

- The Ottawa ankle rules are a reliable tool to exclude fractures in patients more than 5 years of age presenting with ankle injuries. These rules decrease use of radiography with a low likelihood of missing a fracture [overall quality: high]

Question 2: How do you assess ankle fracture instability?**Case clarification**

The patient’s radiographs show a fracture of the lateral malleolus at the level of the syndesmosis with no fracture of the medial malleolus and no obvious disruption of the mortise. The patient wants to know if he needs surgery.

Relevance

For rotational ankle fractures, once the fibula is fractured, the medial restraints (i.e., the deep deltoid and medial malleolus) act as important secondary stabilizers of the ankle joint.

Current opinion

Clinical signs of medial injury are unreliable. Injury films should be examined for signs of ankle subluxation including talar shift (widening of the medial clear space >4mm).

In cases of isolated fractures of the fibula, a manual external rotation or gravity stress test can assess for medial ligamentous disruption.

Finding the evidence

- PubMed (clinical queries: systematic review), using search terms: “ankle fracture” OR “ankle injury” AND “stability” OR “operative stabilization” OR “intraoperative stress test”

Quality of the evidence*Level II*

- 6 diagnostic studies (development of diagnostic criteria on the basis of consecutive patients)

Findings

A total of 152 patients (in 2 studies) with isolated Weber B ankle fractures (see box) were assessed for medial-sided ankle tenderness, and subsequently had an external rotation stress test performed.^{3,4} There was no statistical correlation between medial-sided tenderness, ecchymoses or swelling, and deltoid ligament incompetence.

Weber classification of ankle fractures

This refers to the level of the fibula fracture:

Weber A: fracture distal to the ankle joint

Weber B: fracture at the level of the syndesmosis

Weber C: fracture proximal to the syndesmosis

Stress testing In a cadaveric study, ankles were destabilized according to the Lauge–Hansen mechanism for supination–external rotation (SER) injuries. Stress views taken in dorsiflexion and external rotation were most predictive of deep deltoid disruption.⁵ A second cadaveric study tested intact ankles, then added a Weber B fibula osteotomy, and finally with transection of the superficial or deep deltoid ligament and the fibula osteotomized or plated.⁶ The authors concluded that the gravity stress test was able to reliably diagnosed deltoid disruption.

In a pooled analysis of 54 ankle fractures there were no statistical differences in medial clear space (MCS) between the manual and the gravity stress test in either the SER II or SER IV fractures.^{7,8}

Recommendation

- Clinical signs of medial-sided injury are unreliable. External rotation and gravity stress tests are an accurate and reliable method for differentiating SER II and SER IV injuries [overall quality: moderate]

Question 3: How are syndesmosis injuries identified and managed?

Case clarification

The patient's radiographs show a fracture of his lateral malleolus at the level of the syndesmosis with no fracture of the medial malleolus, with talar shift on stress views. Your patient wants to know what fixation will be needed to stabilize his ankle.

Relevance

The distal tibiofibular syndesmosis is a primary stabilizer of the ankle joint. Instability of this articulation has been shown to significantly increase joint contact pressures and thus predispose to secondary arthrosis and poor functional outcomes. Adequate reduction and stabilization improves functional outcome.

Current opinion

An intraoperative external rotation stress test or modified Cotton test can reliably diagnose syndesmosis instability. There is no consensus with regards to the use of 3.5 mm vs. 4.5 mm screws, bioabsorbable vs. metallic screws, or quadricortical vs. tricortical fixation for syndesmosis stabilization.

Finding the evidence

- PubMed clinical queries/systematic review: "syndesmosis injuries" or "syndesmosis stabilization"

Openmirrors.com

Quality of the evidence

Level I

- 5 randomized trials

Level II

- 1 prospective cohort study

Level III

- 1 retrospective case control study

Findings

Intraoperative diagnosis of syndesmosis injury The static radiographs of 38 skeletally mature ankles were analyzed for signs of syndesmosis injury and medial instability. Intraoperatively an external rotation stress test was performed after stabilization of lateral and medial malleolar fractures.⁹ Intraoperative stress tests predicted syndesmosis injuries in 37% of patients not thought to have syndesmosis injuries on the basis of preoperative films. Rigid bimalleolar fixation did not always stabilize the syndesmosis adequately.

Size of screws A number of clinical and biomechanical studies have not detected clinically important differences between 3.5 and 4.5 mm screws.¹⁰

Number of cortices In one study, 120 ankle fractures with syndesmosis injury were randomized to stabilization with a single 3.5 mm tricortical screw (59 patients) or with a single 3.5 mm quadricortical screw (61 patients).¹¹ There were no differences between the groups with respect to hardware failure and irritation requiring screw removal at a mean follow-up of 150 days. A second study randomly assigned 64 ankles to fixation with either a single 4.5 mm cortical quadricortical screw (30 patients) or with two 3.5 mm tricortical screws (34 patients).¹² At 1 year there was no difference in functional outcome or pain scores.

Metal vs. bioabsorbable screws In one study of 38 patients, patients with bioabsorbable screws demonstrated a faster return to preinjury activity and less swelling.¹³

Functional outcome A retrospective review of 106 patients followed up for an average of 21 months, found that patients in whom the screws were either loosened, broken, or removed had a better functional outcome than those in whom the screw was intact.¹⁴ The authors theorized that restoration of normal mechanics occurs once the screw is no longer intact.

Recommendations

- Intraoperative stress tests are accurate in diagnosing syndesmosis injuries. There is no consensus with regard to the use of 3.5 mm vs. 4.5 mm screws, tricortical or quadricortical fixation, and the use of bioabsorbable implants [overall quality: high]

Question 4: What is the significance of posterior malleolar injuries?

Case clarification

The patient's radiographs show a fracture of his medial and lateral malleolus at the level of the syndesmosis with a fracture of the posterior malleolus (PM) involving 5% of the articular surface on the lateral radiographs. Your patient wants to know if he needs surgery and what fixation will be needed to stabilize his ankle.

Relevance

It is generally accepted that fractures involving the posterior malleolus have a worse prognosis than those with intact posterior malleoli. The literature remains divided with respect to the indications for surgical intervention.

Current opinion

Fractures involving more than 25% of the articular surface should be treated with operative reduction and internal fixation (ORIF). Fractures involving less than 10% of the

articular cartilage are generally not addressed operatively. There remains controversy with respect to the optimal management of intermediate-sized posterior fragments.

Finding the evidence

- PubMed clinical queries/systematic review: “posterior malleolus fractures”

Quality of the evidence

Level I

- 1 individual inception prognostic cohort study

Level II

- 2 prospective cohort studies

Findings

In a cadaveric study, the posterior malleolus was sequentially resected to include 25%, 33%, and 50% of the articular surface.¹⁵ Contact area decreased with increasing size of the resected fragment and normal congruency of the tibiotalar joint was lost. Authors recommended that fragments greater than 25% be addressed with operative stabilization.

A prospective study of 142 ankle fractures with an average of 5.7 years follow-up demonstrated that the presence of posterior malleolar fractures resulted in decreased functional scores regardless of the size of the fragment.¹⁶ Larger fragments were more likely to develop osteoarthritis. In the case of the larger fragments, patients fared better with operative stabilization.

A second retrospective study of 57 trimalleolar fractures followed for a mean of 6.9 years determined that ankles with posterior fragments of 10% or more had better functional outcome scores if joint congruity was restored.¹⁷ Restoration of congruity to fragments less than 10% did not affect outcome.

Recommendations

- Fragments less than 10% of the articular surface generally do not require fixation. Fragments greater than 25% may benefit from surgical stabilization. Fragments between 10% and 25% should be assessed on an individual basis when deciding whether surgical fixation is required [overall quality: moderate]

Question 5: What is the role of early postoperative mobilization?

Case clarification

The patient has sustained a Weber B bimalleolar fracture and undergoes ORIF. He asks about your plan for postoperative rehabilitation and how soon he could expect to go back to work.

Relevance

Early mobilization of ankle fractures should theoretically prevent postoperative stiffness and allow earlier return to work. However, early mobilization may increase wound complications. The orthopedic surgeon must weigh the risks and benefits of early mobilization when determining the optimal choice for postoperative rehabilitation.

Current opinion

Young healthy patients with high functional expectations may be ideally suited for early mobilization, whereas elderly patients with poor bone quality and those at risk for postoperative infection (i.e., diabetics, patients with rheumatoid arthritis) may benefit from longer cast immobilization.

Finding the evidence

- PubMed clinical queries/systematic review: “early mobilization” OR “early motion” AND “ankle injury” OR “ankle fracture”

Quality of the evidence

Level I

- 4 randomized controlled trials

Level II

- 1 nonrandomized control trial

Findings

In one study, 100 with isolated Weber A or B ankle fractures were randomized to either early postoperative mobilization or a conventional below-knee cast.¹⁸ Functional scores at 2 years and the time to return to work were equivalent in the two groups. However the early mobilization group had a significantly higher wound complication rate (24 patients) compared to the conventional cast immobilization group (4 patients).

In another study, 53 patients with ORIF of ankle fractures were randomized to weightbearing in either an orthosis or a walking cast. There was no difference in overall ankle function, range of motion, and pain scores at 18 months.

Following ORIF, 55 ankle fractures were randomized to either a short-leg cast (28 patients) or a removal functional brace (27 patients).¹⁹ All patients were kept non-weightbearing for 6 weeks. They were no wound complications in either group. Patients who underwent early mobilization had a faster return to work (53.3 days) compared to those who were immobilized in the cast (106.5 days). There was a tendency for higher functional scores in the braced group but this difference was only significant at 6 weeks.

In another study, 59 operatively stabilized ankle fractures were assigned to cast immobilization (19 patients) or an ankle-foot orthosis (AFO) (32 patients). There was no difference in range of motion or complication rates between

the two groups, nor was there any loss of reduction in any of the AFO patients.

Following ORIF, 62 ankle fractures were randomized to immobilization in a cast (29 patients) or to early mobilization in a custom made removable splint (33 patients).²⁰ Range of motion and functional scores were similar at 12 weeks. The early mobilization group had a faster return to work/preinjury level of function (67 days vs. 94.9 days) but demonstrated an increase in wound complication rate (9.1% vs. 0%) compared to the cast immobilization group.

Recommendations

- At 1 year there was no difference in outcome in any trial with early mobilization compared to cast immobilization. Early mobilization may allow a faster return to work/preinjury function, but may be associated with increased complication rates. The surgeon should weigh the risks and benefits individually for each patient when determining the optimal rehabilitation protocol [overall quality: high]

Summary of recommendations

- The Ottawa ankle rules are a reliable tool to exclude fractures in patients more than 5 years of age presenting with ankle and midfoot injuries. Use of the Ottawa ankle rules would significantly decrease use of radiography with a low likelihood of missing a fracture
- Clinical signs of medial-sided injury are unreliable, but external rotation and gravity stress tests are an accurate and reliable method for differentiating SER II and SER IV injuries
- Intraoperative stress tests are accurate in diagnosing syndesmosis injuries
- There is no consensus with regarding the ideal screw size, number, and material for stabilization of the tibiofibular syndesmosis
- Posterior malleolar fragments less than 10% of the articular surface generally do not require fixation, while fragments greater than 25% may benefit from surgical stabilization
- At 1 year there are no differences in outcome with early mobilization compared to cast immobilization. Early mobilization may allow a faster return to work/preinjury function, but early mobilization may be associated with increased complication rates

Conclusions

Ankle fractures are common orthopedic injuries. The ability to recognize injuries with a high probability for fracture is important in minimizing unnecessary radiography. One must be methodical in the assessment of ankle

fractures in order to identify all injuries that may contribute to ankle instability. It is important to have an organized approach to the management of these injuries and to understand the indications and the techniques available for surgical stabilization. Postoperative rehabilitation should be individually tailored for each patient.

Talus Fractures

Gregory K. Berry

McGill University, Montreal, QC, Canada

Case scenario

A healthy 25 year old woman is involved in a motor vehicle collision. She presents to the Emergency Department with a painful and deformed right hindfoot as an isolated injury. The skin and neurovascular examinations are normal.

Relevant anatomy

Two related anatomic concerns arise in the care and outcome of talar body and talar neck fractures: blood supply and cartilage coverage. The talus shares these characteristics with the carpal scaphoid bone. The intactness of the blood supply to the talus has long been recognized as a key determinant in the outcome following these injuries,¹ with osteonecrosis (ON) of the body being a frequent complication following fracture. Given that over half of the surface of the talus is covered in cartilage and that it has no tendinous or muscular insertions, direct perfusion of the neck and body by the extraosseous blood supply is limited.

Importance of the problem

Fractures of the talar body and neck are dreaded injuries for a number of reasons: they are infrequent, representing less than 0.1–0.85% of all fractures (level IV),² limiting the experience of the general orthopedic surgeon in treating them; they typically occur in a young, active patient population (level IV);^{3–7} surgical reduction and fixation is technically challenging; and outcomes remain unfavorable in a significant percentage of patients. The viability of the talus following injury has a major impact on functional outcome given its key role in hindfoot function.

Top eight questions

Diagnosis

1. Differentiating between talar body and neck fracture—does it matter in treatment strategy or outcome?
2. Does classification help in treatment or prognostication?

Therapy

3. Is the reduction and fixation of a displaced talar neck fracture a surgical emergency?
4. Should one or two incisions be used to reduce and fix talar neck fractures?
5. What is the optimal fixation construct: plates or screws; medial or lateral implants; anterior-to-posterior or posterior-to-anterior screws?
6. Talar extrusion: to keep or to discard?
7. Weightbearing in the face of ON: to protect or not?

Prognosis

8. What are the expected outcomes following fractures of the talar body and talar neck?

Question 1: Differentiating between talar body and neck fracture—does it matter in treatment strategy or outcome?

Case clarification

The patient's radiographs show a displaced type 3 talar neck fracture (Figure 65.1).

Relevance

Differentiation between body and neck fractures is important in choice of surgical approach and prognosis.

Figure 65.1 Lateral radiograph showing displaced type 3 talar neck fracture.

Finding the evidence

- Cochrane Database, with search term “talus fracture”: no systematic reviews nor randomized trials; a single review on talus osteochondral injuries
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “talus neck and talus body fracture”

Quality of the evidence

Level IV

- 60 studies

Findings

Talar body fractures are rarer injuries than those of the neck, representing 6–40% of talus fractures, depending on the series. The two fractures differ in the position of the coronal plane fracture relative to the lateral process of the talus, as described by Inokuchi (level IV).⁸ Given the fracture occurs through or posterior to the lateral process in body fractures, it by definition involves the articular surface of both the tibiotalar joint and posterior facet of the subtalar joint. Thus, any displacement will compromise load-bearing properties of both of these major weightbearing joints. Given the retrograde nature of the perfusion to the talar body from the soft tissue attachments on the talar neck, the same risks regarding ON apply to fractures of the body and the neck. In fact, in a recent review of these fractures, 40% of body fractures were associated with neck fractures (level IV).⁵ Malleolar osteotomy, more commonly

medial, is more likely to be required in body fractures to reduce and fix all fracture components.

Recommendation

- Careful attention should be paid to preoperative imaging studies to clearly define the talar injury. In particular, the differentiation between neck and body fractures is important in the choice of approach, affecting overall quality of reduction and long-term prognosis [overall quality: low]

Question 2: Does classification help in treatment or prognostication?

Relevance

Fracture classification systems often lack clinical utility. A sound classification system should help guide treatment choice and inform overall prognosis.

Finding the evidence

- Cochrane Database: see Question 1
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “fracture talus neck” AND “classification”

Quality of the evidence

Level IV

- 32 studies

Findings

The most commonly used classification system in talar neck fractures is that of Hawkins (level IV);⁹ see box.

Hawkins classification of talar neck fractures

- Type I: undisplaced fracture
- Type II: displacement with subluxation or dislocation of the subtalar joint
- Type III: dislocation of ankle and subtalar joints
- Type IV: type III plus talonavicular subluxation or dislocation

The utility of classification relates to understanding fracture displacement as well as to prognosis with regards to ON. A proper appreciation of the classification scheme helps the surgeon to understand the displacement(s) involved in the fracture, which in turn will contribute to choice of approach (see below). Numerous studies have confirmed Hawkins’ original correlation between displacement (or fracture grade) and incidence of ON (level IV).^{3,4,10–12} This information can be transmitted to the patient early on, as the onset of ON is related to a greater number of subsequent surgeries as well as worse overall outcome.

Recommendation

- Classifying the talar neck fracture using the Hawkins classification is helpful in preoperative planning and in providing prognostic information to the patient [overall quality: low]

Question 3: Is the reduction and fixation of a displaced talar neck fracture a surgical emergency?**Relevance**

Traditionally, the treatment of a displaced talar neck fracture was considered a surgical emergency.

Finding the evidence

- Cochrane Database: see Question 1
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "fracture talus neck" AND "timing to surgery"

Quality of the evidence

Level IV

- 4 studies

Findings

Another way of formulating this question is: "Is there an association between the interval from injury to reduction and the incidence of ON?" Traditionally, the answer was yes, with many authors advocating urgent restoration of anatomy to limit the risk and extent of ON (level IV).^{11,13,14} More recent data, however, has found no such correlation (level IV).^{3,4} Thus, the indications for emergent of surgery have been modified; no longer is the isolated displaced talar neck fracture, in the absence of other factors, considered a surgical emergency. Reasons for urgent operation do exist and include open fracture, impending skin necrosis, and neurovascular compromise due to tension or compression of the posteromedial neurovascular bundle.

Recommendation

- Emergent reduction of talar neck fractures does not reduce the incidence of post-traumatic ON. Indications still remain for the emergent surgical care of these injuries, however [overall quality: low]

Question 4. Should one or two incisions be used to reduce and fix talar neck fractures?**Relevance**

Soft tissue attachments to the talar neck, including perforating arteries, provide most of the blood supply to the talar body in a retrograde manner. Controversy exists whether a single or double incisions are preferable to optimize reduction quality while maintaining perfusion.

Finding the evidence

- Cochrane Database: see Question 1
- PubMed: see Question 1

Quality of the evidence

Level IV

- 60 studies

Findings

Displaced talar neck fractures typically approached through combined anteromedial and anterolateral approaches (level IV).^{3,4,7,13,15-17} This strategy limits dissection on the anterior and posterior surfaces of the talar neck, thereby minimizing disruption of the critical blood supply to the talar body.

Each approach provides visual access to key components of displaced fractures. The anteromedial approach, in the interval between the tibialis posterior and anterior tendons, exposes the medial neck where comminution is usually greatest, permitting direct reduction and screw (and more rarely, plate) fixation. Cancellous and strut bone grafting are performed as needed. Extension proximally can be carried to an anteromedial ankle arthrotomy or a medial malleolar osteotomy to address an associated talar body fracture.

The anterolateral approach exposes the lateral neck and can be extended proximally to visualize the lateral ankle joint or the lateral talar process. The subtalar joint can also be cleared of fracture debris. Rarely, a lateral malleolar osteotomy is required to deal with lateral body fractures. Plate fixation, if required, is more often performed on the lateral side of the neck as the anatomy is more conducive than the medial side. Fixed angle plates such as 2.0 and 2.7mm blade or locked plates applied to the lateral neck provide adequate stability despite there being more comminution on the medial neck.

Recommendation

- For displaced talar neck fractures, two incisions are preferable to optimize the accuracy of fracture reduction while minimizing soft tissue dissection on the anterior and posterior surfaces of the talar neck [overall quality: low]

Question 5: What is the optimal fixation construct: plates or screws; medial or lateral implants; anterior-to-posterior or posterior-to-anterior screws?**Case clarification**

The patient above underwent surgery. Her surgeon had to choose one of three fixation strategies (Figure 65.2).

Relevance

A number of fixation strategies and implants are available to the surgeon for talar neck fractures.

Figure 65.2 (a) Posterior-to-anterior screw fixation. (b) Anterior-to-posterior screw fixation. (c) Plate-and-screw construct.

Finding the evidence

- Cochrane Database: see Question 1
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “talus neck fracture and implant,” “talus neck fracture and implant fixation,” “talus neck fracture and fixation”

Quality of the evidence

- Only two level IV studies exist to answer the clinical question

Findings

The aim of fixation is the maintenance of anatomic alignment while permitting range of motion exercises during the healing period. Malunion results in uneven load distribution on the articular surfaces and perturbed motion of the hindfoot complex (level IV).^{18,19} Controversy exists as to the optimal choice of implants and their direction in talar neck fractures. Options include anterior-to-posterior screws, posterior-to-anterior screws, and plate fixation. Kirchner wires alone provide insufficient rigidity to withstand physiologic shear forces generated during active motion (level IV).²⁰

In general, in simple (noncomminuted) fracture patterns, compression provided by screws provides adequate fixation stability. Screws directed from the posterior talus (entry at the posterolateral process) toward the talar head provide superior stability when compared to screws directed in the opposite direction (level IV).²⁰ This is likely due the perpendicularity of the screws relative to the coronal plane fracture line with the former technique. However, the insertion of these screws is technically more demanding.

In comminuted fractures, posterior-to-anterior screws, and medial neck plate fixation outperformed anterior-to-

posterior screws in a biomechanical study using a comminuted fracture model. However, the differences were not statistically significant and all three techniques provided enough stability to withstand the physiologic loads of active motion (level IV).²¹ The authors concluded that all techniques provide sufficient stability to maintain reduction while permitting motion during healing, which has been borne out in clinical cohort outcomes (level IV).^{3,4,6}

Recommendation

- Simple fracture patterns can be successfully fixed with compressive lag-screw fixation using either anterior-to-posterior or posterior-to-anterior directions. In comminuted neck fractures, plate-and-screw fixation montages on the medial or lateral neck provide favorable clinical outcomes in terms of maintenance of reduction. Biomechanical data suggests screws alone, especially when directed from posterior-to-anterior, should provide adequate stability to resist physiologic loads [overall quality: low]

Question 6: Talar extrusion: to keep or to discard?

Relevance

Faced with an extruded talar body, the surgeon must balance risk of reinsertion and attendant risk of infection vs. discarding the body and dealing with a significant bone defect (Figure 65.3).

Finding the evidence

- Cochrane Database: see Question 1
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “extrusion of the talus”

Quality of the evidence

Level IV

- 24 studies

Findings

On the spectrum of injury severity, the most severe and dramatic scenario in talus fractures is that of talar body extrusion. The decision the surgeon faces is between discarding a significant portion (if not all) of the talus and being faced with a large bony deficit, and the risk of infection posed by an open wound and often extensive soft tissue stripping if the talus is reinserted. Recent evidence would support the latter strategy. In a cohort study of 19 cases of extrusion in which the talus was preserved following irrigation, debridement, reduction and rigid internal fixation, only 2 cases (10%) suffered deep infection and 12 of the 19 (63%) underwent a single surgery. Outcomes were significantly worse in those patients with talar neck fractures, with ON, collapse, and osteoarthritis (OA) occurring frequently (level IV).²²

Recommendation

- Irrigation and debridement followed by reduction of the talar body provides favorable results considering the severity of the injury, with acceptable incidences of infection and

Figure 65.3 Extruded talus.

ON/OA. The talar body should not be routinely discarded [overall quality: low]

Question 7: Weightbearing in the face of ON: to protect or not?**Relevance**

When faced with a case of ON of the body following talar neck fracture (Figure 65.4), the surgeon must decide whether to recommend weightbearing as tolerated vs. protected weightbearing.

Finding the evidence

- Cochrane Database: see Question 1.
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "talus neck fracture", "osteonecrosis", "weightbearing"

Quality of the evidence

Level IV

- 8 studies

Findings

ON results from disruption of the retrograde blood supply from the anterior and posterior talar neck to the talar body. The degree of compromise is related to amount of displacement, as supported in nearly all outcome studies, which have consistently shown a correlation between Hawkins grade and rate of ON. The revascularization process weakens support for the articular surface(s), resulting in collapse, deformity and, eventually osteoarthritis.

The patient who suffers ON following talus fracture represents a conundrum for the surgeon: allow weightbearing to simplify function and risk collapse, or limit weightbearing to minimize risk of collapse but impair function for up to 2 years. Unfortunately, no good evidence exists to guide the choice of strategies, and advocates exist both for^{13,23,24} and against^{3,25,26} (all level IV).

Recommendation

- In the case of ON following talar neck fracture, no good evidence exists to recommend protected weightbearing over weightbearing as tolerated

Figure 65.4 Lateral (a), mortise and AP (b) radiographs of patient at 6 months following her injury demonstrating osteonecrosis of the talar body.

Figure 65.5 Osteonecrosis with subsequent osteoarthritis of the ankle joint. (a) AP radiograph (b) coronal plane CT scan.

Question 8: What are the expected outcomes following fractures of the talar body and talar neck?

Relevance

Displaced talar neck fractures are associated with significant functional limitations due to a high incidence of complications (Figure 65.5).

Finding the evidence

- Cochrane Database: see Question 1.
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “talus neck fracture,” “clinical outcome”

Quality of the evidence

Level IV

- 17 studies

Findings

In general, talar neck and body fractures are life-altering injuries, especially if they occur following high-energy mechanisms such as a motor vehicle accident. Although perioperative complications occur at acceptable rates, long-term sequelae are frequent and debilitating, often requiring further surgical management.

In recent reports of the surgical care of talar neck fractures, employing dual approaches as needed, rigid internal fixation with screws and/or plates, and early range of motion rehabilitation, superficial and deep infection occurred in 3–5% of cases, and wound dehiscence in 3% (level IV).^{3,4} Late complications of delayed union (1.7%) and nonunion (3.3%) were associated with inexact reduction and open fractures in the same series.

Late sequelae were more frequent and more difficult to manage. ON occurred in 20–64% of patients and was cor-

related with degree of initial displacement (Hawkins grade), fracture comminution, and open fracture (level IV).^{3,4} To reiterate, in neither series was delay to reduction associated with increased risk of ON. Post-traumatic osteoarthritis was a common finding and occurred at the ankle (0–18%), subtalar joint (15–40%), or both (0–57%), limiting function considerably. Lastly, pain of a mild or moderate intensity was present in 80% of patients who had suffered a talar neck fracture (level IV).⁴

As for talar body fractures, long-term sequelae occur at similar or increased rates. ON rates of 38% in isolated body fractures rise to 55% when combined with neck fractures (level IV).³ Ankle (65%) and subtalar (35%) arthritis rates are higher than following neck fractures. Open fractures are associated with higher rates of ON and arthritis, and worse functional outcome can be expected in any patient experiencing ON, arthritis, open fracture, and comminution (level IV).^{3,4}

Recommendation

- Patients who have suffered a talar body and/or neck fracture should be made aware of the significant risk of postfracture complications and sequelae [overall quality: low]

Summary of recommendations

- Careful attention should be paid to preoperative imaging studies to clearly define the talar injury. In particular, the differentiation between neck and body fractures is important in the choice of approach, affecting overall quality of reduction and long-term prognosis
- Classification of the talar neck fracture using the Hawkins classification is helpful in preoperative planning and in providing prognostic information to the patient

- Emergent reduction of talar neck fractures does not reduce the incidence of post-traumatic ON. Indications still remain for the emergent surgical care of these injuries, however
- For displaced talar neck fractures, two incisions are preferable to optimize the accuracy of fracture reduction while minimizing soft tissue dissection on the anterior and posterior surfaces of the talar neck
- Simple fracture patterns can be successfully fixed with compressive lag-screw fixation using either anterior-to-posterior or posterior-to-anterior directions. In comminuted neck fractures, plate-and-screw fixation montages on the medial or lateral neck provide favorable clinical outcomes in terms of maintenance of reduction. Biomechanical data suggests screws alone, especially when directed from posterior-to-anterior, should provide adequate stability to resist physiologic loads
- Irrigation and debridement followed by reduction of the talar body provides favorable results considering the severity of the injury, with acceptable incidences of infection and ON/OA. The talar body should not be routinely discarded
- No good evidence exists to recommend protected weightbearing over weightbearing as tolerated in the case of ON following talar neck fracture
- Patients who have suffered a talar body and/or neck fracture should be made aware of the significant risk of postfracture complications and sequelae

Conclusions

Fractures of the talar body and neck remain challenging injuries for the orthopedic surgeon. The level of quality of the evidence in the literature is in general poor, consisting primarily of case series and case reports. These do, however, provide some useful information to guide the surgical and postoperative care of these injuries.

Calcaneus Fractures

Stephen J. McChesney and Richard E. Buckley

University of Calgary, Calgary, AB, Canada

Case scenario

A 35 year old male construction worker is brought to the Emergency Department following a 3m fall at work. He complains of left heel pain and is unable to bear weight on the left. Initial trauma workup reveals an isolated injury to the left calcaneus, with no spinal or ipsilateral lower limb fractures. His left foot is very swollen and tender posteriorly, with a few blisters.

Relevant anatomy

The calcaneus is the largest of the tarsal bones. It has two articulations (comprised of three facets) with the talus superiorly, and a single saddle-shaped articulation with the cuboid anteriorly. The anterior and middle facets are frequently contiguous with one another forming one articulation, and are separated from the larger posterior articulation/facet (which is the major weightbearing surface) by the floor of the tarsal canal. The sustentaculum tali is the dense bone beneath the middle facet and it is medial to the calcaneal body. The medial aspect of the calcaneus contains thicker bone than the thin lateral wall. The area posterior to the posterior facet is the tuberosity which has two processes (lateral and medial) on its plantar surface and the insertion of the Achilles tendon on the inferior two thirds of its posterior surface.¹

The soft tissue envelope surrounding the calcaneus has been problematic in the past. It is important to recognize that the lateral calcaneal artery, the lateral hindfoot artery, and the lateral tarsal artery contribute to the vascularity of the lateral skin and soft tissues of the foot. The lateral calcaneal artery is responsible for most of the blood supply to the corner of the flap in the extensile lateral approach.²

Importance of the problem

Fractures of the calcaneus are common, accounting for approximately 1.2–2% of all fractures³ and 60% of all tarsal injuries.¹ In a study from the United Kingdom using data from the year 2000 their incidence has been estimated at 13.7/100,000 of population.³ Only 5% of calcaneal fractures occur in children, and 80–90% occur in men aged 30–45 years.⁴

The displaced intra-articular fracture, which occurs in 75% of patients with calcaneal fractures, has been recognized as a fracture with poor functional outcome despite various treatment methods. Patients with this injury frequently have a significant period of time off work and away from normal recreation. One study showed that the mean time off work following a displaced intra-articular calcaneal fracture was 230 days or 7.5 months. The estimated average cost per patient was between \$32,000 and \$51,000 (Canadian) indicating a significant economic burden to society.⁵

The internet provides a significant volume of information on all medical topics and calcaneal fractures are no exception. A Google search for “calcaneal fractures” returns 500,000 hits. Given the highly variable nature of internet content, the assimilation and publication of appropriate evidence-based information to guide management of calcaneal fractures is a necessity.

Top six questions

Therapy

1. In skeletally mature patients with displaced intra-articular calcaneal fractures, is there a significant difference in outcome between nonoperative and operative treatment?

2. What preoperative factors predict outcome with nonoperative vs. operative treatment of calcaneus fractures?
3. What is the effect of minimally invasive treatment on outcome and complications compared with current established treatment techniques?
4. What is the effect of using bone graft or bone-graft substitute vs. no graft on outcome in the operative management of intra-articular calcaneal fractures?
5. In patients with severely displaced intra-articular calcaneal fractures, what is the effect of acute subtalar fusion on outcome compared to current established treatment techniques?

Harm

6. What complications are associated with nonoperative vs. operative treatment of displaced intra-articular calcaneal fractures?

Question 1: In skeletally mature patients with displaced intra-articular calcaneal fractures is there a significant difference in outcome between nonoperative and operative treatment?

Case clarification

Plain radiographs and CT scan reveal a comminuted displaced intra-articular calcaneus fracture (Figure 66.1).

Relevance of the question

Operative treatment of calcaneal fractures is associated with a significant risk of serious complications. As such, it is important that both the treating surgeon and the

Figure 66.1 Comminuted displaced intra-articular fracture of the calcaneus.

patient are aware of the expected outcome of operative treatment and nonoperative treatment so that this can be accurately balanced against the risk involved in the chosen treatment.

Current opinion

Most trauma surgeons would currently suggest operative treatment of a displaced intra-articular calcaneal fracture in an otherwise healthy young male manual worker.

Finding the evidence

- Cochrane Database, with search terms: “(calcaneus OR calcaneal OR os calcis) AND fractures”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “(calcaneus OR calcaneal OR os calcis) AND fractures”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “(calcaneus OR calcaneal OR os calcis) AND fractures”

Quality of the evidence

Level II

- 4 randomized trials with methodologic limitations⁵⁻¹⁶
- 2 meta-analyses (NB: a Cochrane Review was published in 2000 but withdrawn in 2008 and is thus excluded)^{17,18}

Findings

In 2005 Bajammal et al. performed a meta-analysis utilizing the results of four randomized trials with a total of 534 patients. These studies remain the best level of evidence available in the literature to date. Analysis of these studies fails to reveal a significant difference in pain or functional outcome between patients treated operatively or nonoperatively. Operative treatment may offer an advantage regarding earlier return to work and the patient's ability to continue wearing the same shoes. Subgroup analysis in the largest of these randomized trials revealed statistically significant differences in outcome between operative and nonoperative treatment in selected subgroups. These findings need to be interpreted with caution and are discussed in the following section.^{6,13,14,16,18}

Ibrahim et al. reported on the longer-term follow-up of surviving patients from Parmar et al.'s original cohort.¹⁵ This study also found no significant difference in functional outcome for those patients treated operatively vs. those treated nonoperatively. The authors concluded that 15 year follow-up demonstrated findings similar to those at 1 year; however, there were serious methodologic limitations.^{14,15} No new randomized trials have been reported in the literature since 2005.

Subtalar arthrodesis has been used as a surrogate endpoint for subtalar arthritis. It has been shown that those treated nonoperatively have a six times greater risk of requiring subtalar arthrodesis than those treated nonoperatively.^{6,7}

Recommendations

In patients with displaced intra-articular calcaneal fractures there is insufficient evidence to determine definitively if operative treatment is superior to nonoperative treatment. Current evidence shows:

- No statistically significant difference in pain or functional outcome between operative treatment modalities and nonoperative treatment [overall quality: moderate]
- Return to work may be improved with operative treatment [overall quality: moderate]
- Subtalar arthrodesis rates are significantly decreased with operative treatment [overall quality: moderate]

Question 2: What preoperative factors predict outcome with nonoperative vs. operative treatment of calcaneus fractures?

Case clarification

Careful history, physical examination, and radiologic examination allow the surgeon to get to know the patient. Usually the patient has 7–14 days for limb settling and soft tissue to be appropriate for surgery. Patient compliance seems most important to optimize results and minimize complications.

Relevance of the question

Only patients with appropriate variables for surgery should have surgery; other patients should have nonoperative care. Both patient and fracture variables are important when deciding on a course of treatment for an individual with a calcaneal fracture. Correctly identifying patient variables that could influence management should positively affect outcome in the individual undergoing treatment.

Current opinion

Surgeons hope to minimize complications, and by choosing patients appropriately for surgery they will predictably have the best results for the patients whether they operate or not.

Finding the evidence

- Cochrane Database, with search term: “(calcaneus OR calcaneal OR os calcis) AND fractures”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “(calcaneus OR calcaneal OR os calcis) AND fractures”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “(calcaneus OR calcaneal OR os calcis) AND fractures”

Quality of the evidence

Level II

- 4 randomized trials with methodologic limitations^{5–16}
- 3 meta-analyses: (NB: A Cochrane Review was published in 2000 but withdrawn in 2008 and is thus excluded)^{17–19}
- 1 prospective cohort study²⁰

Level III

- 1 retrospective cohort study²¹
- 1 case-control study²²

Findings

There are no well-designed studies on calcaneal fractures in which patient variables are incorporated in the main study question. Caution must be exercised when interpreting the results of subgroup analysis as sample size can often become small. It should also be noted that almost all studies relate only to displaced intra-articular calcaneal fractures. There is no level I or II evidence relating to extra-articular calcaneal fractures.

Age In skeletally immature patients, most calcaneal fractures are extra-articular and respond well to nonoperative treatment. Patients who are skeletally immature (<14 years) with displaced intra-articular calcaneal fractures do well regardless of whether they have operative or nonoperative care. Calcaneal fractures in adolescents behave much like those in adults and should be treated similarly.²¹

Once skeletal maturity is reached Tufescu reported that age did not alter outcome regardless of whether the treatment was operative or nonoperative. However, Buckley et al. demonstrated that patients less than 30 years of age had a statistically significant better outcome with operative treatment (odds ratio 20.0; relative risk 9.14). Their subgroup analysis also showed a trend towards poorer outcome with operative treatment in those more than 50 years of age, although this was not statistically significant.^{6,20}

Gender Gender is not commonly analysed as a separate variable but it has been demonstrated that female patients with displaced intra-articular fractures treated operatively had a significantly better outcome compared to those treated nonoperatively. Young (<30 years) male patients also demonstrated a similar trend.^{6,9}

Work type Patients with a light workload were significantly more likely to report a high outcome scores when treated operatively compared to nonoperative management. Patients with a heavy workload showed poor outcome scores, with no difference noted between those treated operatively and those treated nonoperatively. However, patients with a heavy workload treated operatively show a quicker return to work and a decreased incidence of subtalar arthrodesis.^{6,20}

Smoking history Smoking has not been specifically correlated with outcome but does increase the risk of complications, as discussed below.

Insurance claim Patients with a pending insurance claim have been reported to have worse outcome results regard-

Table 66.1 Treatment of displaced intra-articular calcaneal fractures

Factors	Grade of evidence	Surgery recommended	Results equivocal	Nonoperative care
Patient factors				
Age ^{6,18}	Moderate	Adolescent	Middle age (50yr)	>60yr
Sex ^{6,18}	Moderate	Adult female; young male	Middle-aged male	Older male and female
Smoking history ⁸	Poor	—	—	Recommended
Chronic medical illness ⁶	Poor	—	—	Recommended

Fracture factors				
Bilateral injury ^{6,10}	Moderate	—	+	—
Bohler's angle ⁶	Moderate	>0°	<0°	—
Fracture classification ⁶	Moderate	Sanders types II, III, IV	Type IV fractures ORIF or primary fusion	Extra-articular

less of treatment method. This group also has a higher incidence of late subtalar arthrodesis following calcaneus fracture, whether treated operatively or nonoperatively.

Bohler's angle Patients with an initial Bohler's angle less than 0° show equivocal results with operative treatment. At least one study¹³ has suggested better results with operative treatment compared to nonoperative. Those with a Bohler's angle greater than 15° at presentation tend to do better with operative intervention; however, they also do well with nonoperative treatment when compared to those with a Bohler's angle less than 0°.⁶ Patients with a flat or negative initial Bohler's angle are significantly more likely to require subtalar arthrodesis than those with a higher initial Bohler's angle.

Sanders classification Simple fracture patterns such as Sanders II have better functional outcomes with operative treatment when compared to nonoperative treatment. Patients with a higher Sanders classification (Sanders IV) showed no difference in outcome whether treated operatively or nonoperatively.⁶ However, patients with a Sanders IV fracture are 5.5 times more likely to require subtalar arthrodesis than those with a Sanders II fracture.⁷

Bilateral injury Patients with bilateral calcaneal injuries have worse outcomes than those with unilateral injuries but there is no significant difference between operative or nonoperative treatment in this group.^{6,10}

Institutional fracture load A recent systematic review of operatively treated calcaneal fractures has demonstrated a significant inverse correlation between late subtalar arthrodesis (used as surrogate for post-traumatic subtalar arthritis) and institutional fracture load. This review suggests that an institutional fracture load of less than one calcaneus fracture per month jeopardizes the outcome of operatively treated calcaneal fractures.¹⁹

Recommendations

Due to a lack of good evidence it is only possible to give recommendations with moderate to low grades.

Current evidence suggests that treatment of displaced intra-articular calcaneal fractures be tailored to the individual, as summarized in Table 66.1.

- Institutional fracture load of less than one calcaneus fracture per month jeopardizes the outcome of operatively treated calcaneal fractures [overall quality: moderate]

Question 3: What is the effect of minimally invasive treatment on outcome and complications compared with current established treatment techniques?

Case clarification

The patient's cousin had a tibial fracture treated using "keyhole surgery." He asks if his fracture can be treated in a similar fashion.

Relevance of the question

Although minimally invasive reduction and fixation techniques are becoming widely accepted in orthopedic trauma practice, the role of this technique in calcaneal fracture fixation is unclear.

Current opinion

Currently very few surgeons are routinely using minimally invasive techniques for the treatment of displaced intra-articular calcaneal fractures.

Finding the evidence

- Cochrane Database, with search term “(calcaneus OR calcaneal OR os calcis) AND fractures AND (percutaneous OR minimally invasive)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “(calcaneus OR calcaneal OR os calcis) AND fractures AND (percutaneous OR minimally invasive)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “(calcaneus OR calcaneal OR os calcis) AND fractures AND (percutaneous OR minimally invasive)”

Quality of the evidence*Level III*

- 1 study²³

Level IV

- 1 systematic review²⁴
- 21 studies^{25–45}

Findings

There are no level I or II studies comparing minimally invasive techniques to any other form of treatment. We identified 22 level III or IV studies, but these cover a heterogeneous group of procedures. It is not possible to perform a meta-analysis of these studies because of their heterogeneity and poor study designs.

Weber et al. compared a series of percutaneously treated patients with Sanders II and III fractures to another group who had undergone open reduction and internal fixation (ORIF). They found no difference in radiologic or clinical outcome.²⁹ Frohlich reported on a retrospective series of percutaneously treated patients compared to a retrospective series of patients treated with open reduction, showing a favorable outcome and low complication rate for the percutaneously treated group.²³ Tornetta has reported on the successful use of percutaneous techniques for tongue fractures (OTA 73 C1,C2) using an Essex-Lopresti maneuver, and it is these fractures that are perhaps currently most applicable for minimally invasive fixation techniques.^{43,44} Forgon has the largest series, consisting of 265 fractures with 90% good or excellent results.⁴⁵

Recommendations

- At present there is insufficient evidence to make recommendations regarding the use of minimally invasive techniques for calcaneal fracture fixation

Question 4: What is the effect of using bone graft or bone-graft substitute vs. no graft on outcome in the operative management of intra-articular calcaneal fractures?**Case clarification**

Following reduction of the fracture there is a significant void below the posterior facet.

Relevance of the question

It has been suggested that bone graft or bone graft substitute adds mechanical strength or post-fixation constructs and bone graft enhances bone healing in skeletally mature patients. However, bone graft has also been reported to increase complications, including wound breakdown and infection.

Current opinion

Currently opinion is divided on whether or not it is necessary to use some form of graft material to fill the void frequently found after reduction of an intra-articular calcaneal fracture.

Finding the evidence

- Cochrane Database, with search term “(calcaneus OR calcaneal OR os calcis) AND fractures AND (bone graft OR bone substitute OR bone cement)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “(calcaneus OR calcaneal OR os calcis) AND fractures AND (bone graft OR bone substitute OR bone cement)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “(calcaneus OR calcaneal OR os calcis) AND fractures AND (bone graft OR bone substitute OR bone cement)”

Quality of the evidence*Level I*

- 1 meta-analysis⁴⁶
- 1 randomized controlled trial⁴⁷

Levels III–IV

- 6 studies^{48–53}

Findings

The best-designed studies showed benefits with the use of calcium phosphate bone cement to fill the void left after reduction of a displaced intra-articular calcaneus fracture in terms of functional and radiologic outcomes.^{46,47} Thordarson’s group demonstrated in a cadaveric biome-

chanical study that calcium phosphate cement was superior to bone graft.⁵³ Longino showed no difference in functional or radiographic outcome when using iliac crest bone graft compared to no bone graft.⁵¹

Recommendations

- Use of calcium phosphate cement to fill a void after reduction of a displaced intra-articular calcaneal fracture improves functional and radiologic outcome [overall quality: moderate]

Question 5: In patients with severe displaced intra-articular calcaneal fractures, what is the effect of acute subtalar fusion on outcome compared to current established treatment techniques?

Case clarification

CT scan reveals a Sanders IV calcaneal fracture (Figure 66.2).

Relevance of the question

It is difficult to obtain an anatomic reduction in this type of fracture. Thus some surgeons would recommend immediate subtalar arthrodesis, given that that this fracture pattern is associated with poor functional results and a high rate of late subtalar arthrodesis.

Current opinion

Acute primary fusion is a single operation to deal with a difficult fracture. It may be reasonable to proceed with

ORIF, but late fusion after nonoperative treatment is difficult.

Finding the evidence

- Cochrane Database, with search term “(calcaneus OR calcaneal OR os calcis) AND fractures AND subtalar arthrodesis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “(calcaneus OR calcaneal OR os calcis) AND fractures AND (subtalar arthrodesis or subtalar fusion)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “(calcaneus OR calcaneal OR os calcis) AND fractures AND (subtalar arthrodesis or subtalar fusion)”

Quality of the evidence

Level IV

- 7 retrospective case series⁵⁴⁻⁶⁰

Findings

There are no studies that compare reconstruction and primary subtalar arthrodesis with reconstruction for severe (Sanders IV) fractures. Seven level IV studies were identified that suggest favorable results for primary subtalar arthrodesis in patients with severe displaced intra-articular calcaneal fractures.

A multicenter randomized trial is currently in progress in Canada to evaluate this issue.

Recommendations

- There is insufficient evidence to tell if acute subtalar arthrodesis is an appropriate treatment for severe displaced intra-articular calcaneal fractures

Question 6: What complications are associated with nonoperative vs. operative treatment of displaced intra-articular calcaneal fractures?

Case clarification

Infection and hardware issues are common after operative care. Foot morphology problems and need for late subtalar fusion are common with nonoperative care.

Relevance of the question

Both operative and nonoperative treatments carry risk. It is important that both the treating surgeon and the patient are aware of what risks are involved in a course of treatment.

Current opinion

In most healthy young patients with displaced intra-articular calcaneal fractures the risks of operative treatment are justified given improved outcomes and a decreased

Figure 66.2 Sanders IV calcaneal fracture.

need for late surgical intervention when compared to non-operative care.

Finding the evidence

- Cochrane Database, with search term “(calcaneus OR calcaneal OR os calcis) AND fractures AND complications”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “(calcaneus OR calcaneal OR os calcis) AND fractures AND complications”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) search: “(calcaneus OR calcaneal OR os calcis) AND fractures AND complications”

Quality of the evidence

Level II

- 4 randomized trials with methodologic limitations⁵⁻¹⁶
- 3 meta-analyses: (NB: A Cochrane Review was published in 2000 but withdrawn in 2008 and is thus excluded)¹⁷⁻¹⁹

Findings

Numerous studies have reported complications following treatment of calcaneal fractures; however, most of these are case series that do not compare treatment groups. Complications reported include poor wound healing/infection, pain, thromboembolism, neurologic complications, compartment syndromes, peroneal tendon problems, and shoe wear problems. Subsequent operative procedures have included arthrodesis, reoperations, fasciotomies, ostectomies, operative intervention for infection, and subsequent hardware removal.

The best evidence available comes from a large randomized controlled trial where complications of operative and nonoperatively treated patients were assessed. This study showed that complications occur regardless of the treatment. Complications caused significant morbidity, and patients who developed a complication had worse outcomes than those who did not develop complications, regardless of treatment. At least one major complication developed in 18% of fractures treated nonoperatively and in 25% of those treated operatively. Superficial wound slough was seen in 16% of patients treated operatively and there was a deep infection rate of 4.4%.⁶⁻⁸ One recent systematic review demonstrated an exponential increase in the incidence of deep infection in operatively treated fractures with decreasing institutional fracture load, and suggests that an institutional load of less than one fracture per month jeopardizes the outcome of operatively treated displaced intra-articular fractures.¹⁹ In Buckley et al.'s study the need for subsequent surgery was the most common complication in both groups (19% for nonoperatively treated patients and 18% for operatively treated patients), with the most common operation in the ORIF group being implant removal which occurred in 15%. The rate of late subtalar arthrodesis was significantly increased in the non-

operatively treated group (16% vs. 3%). Footwear modification is often discussed as a minor complication and this study showed no difference in the incidence of footwear modification between the two groups.⁶⁻⁸

Recommendations

- At this time there is insufficient evidence to calculate relative risk for complications in those treated operatively vs. nonoperatively.
- Rate of deep infection increases exponentially with decreasing institutional fracture load [overall quality: moderate]

Summary of recommendations

- No statistically significant difference in pain or functional outcome between operative treatment modalities and nonoperative treatment
- Return to work may be improved with operative treatment
- Subtalar arthrodesis rates are significantly decreased with operative treatment
- Current evidence suggests that treatment of displaced intra-articular calcaneal fractures be tailored to the individual
- Institutional fracture load of less than one calcaneus fracture per month jeopardizes the outcome of operatively treated calcaneal fractures
- Use of calcium phosphate cement to fill a void after reduction of a displaced intra-articular calcaneal fracture improves functional and radiologic outcome
- Rate of deep infection increases exponentially with decreasing institutional fracture load

Conclusions

This difficult fracture in trauma surgery is best dealt with by institutions that perform this type of surgery commonly. Complications must be avoided with either nonoperative or operative care. With careful patient/limb selection and patient compliance, operative care is the standard. However, nonoperative care is common in patients at risk for complications or with medical illness or at extremes of age. Minimally invasive surgery is possible in patients or limbs that are amenable, to minimize complications. Surgeon experience is of significance. Young skeletally mature patients benefit from surgery. It is costly to suffer this injury.

Midfoot/Metatarsal Fractures

Robin R. Elliot and Terence S. Saxby

Brisbane Foot and Ankle Centre, Brisbane, QLD, Australia

Case scenario

During a game of football, player A has to quickly turn and change direction in order to make a tackle on player B: he twists, and in doing so he sustains an injury to his right foot. Nevertheless, he makes a good tackle but lands with his body weight on the foot of player B. Both players are injured and unable to continue with the game. Both players attend the Emergency Department for a radiograph; player A is told he has a fracture of his 5th metatarsal, but player B is reassured that there is no bony injury.

Relevant anatomy

The proximal metatarsals and the cuneiform bones of the midfoot are trapezoidal shaped and together they form a Roman arch structure, the keystone being the base of the 2nd metatarsal (Figure 67.1). The 2nd tarsometatarsal joint is recessed proximally, locking the midfoot and protecting the area against medial and lateral shear forces. The arch protects the neurovascular and tendinous structures running underneath during weightbearing. The metatarsals function as supports in the stance phase of the gait cycle and as a lever during propulsion.

In assessing for a Lisfranc injury, key radiological alignments should be assessed in all cases (Figure 67.2 and Figure 67.3). Careful attention should be paid to the distances between the 1st and 2nd metatarsals and the medial and middle cuneiform and for the presence of avulsion fractures (fleck sign).¹ A weightbearing view is more sensitive in demonstrating tarsometatarsal instability, but this is often not practical in the acute setting.

Importance of the problem

Metatarsal fractures are relatively common injuries with fractures of the 5th metatarsal occurring most frequently.² A study of trauma in motorcyclists showed that metatarsal fractures were the most common injuries to the foot.³ Metatarsal fractures may be caused by inversion/avulsion injuries, direct crushing forces to the foot, and overuse injuries. These injuries can be a cause of prolonged disability and lost work productivity.⁴

Lisfranc joint injuries are uncommon, with reported incidence of 1 per 55,000 per year, accounting for approximately 0.2% of all fractures.⁵ These injuries have traditionally been associated with high-energy trauma, but it is now recognized that there is a spectrum of injuries involving this area of the foot, ranging from sprains to complete dislocations. Unfortunately, Lisfranc injury is a commonly missed diagnosis and this type of injury has the potential to lead to significant morbidity.⁶

Finding the evidence

A search of the literature was undertaken using available databases at our institution. These include MEDLINE through PubMed (citations 1950 to present), the Cochrane Database of Systematic Reviews, and CINAHL. Specific search details are listed below.

- PubMed: searches built using MeSH database controlled vocabulary. Combined searches: "Fractures, Bone" [Mesh] AND "Metatarsal Bones" [Mesh], "Fractures, Bone" [Mesh] AND Lisfranc. Word searches using "Lisfranc" AND "fracture," "metatarsal" AND "fracture"

Figure 67.1 The Roman arch configuration of the Lisfranc complex.

Figure 67.2 AP view showing alignment of the lateral borders of the first metatarsal and the medial borders of the 2nd metatarsal and the middle cuneiform.

- Cochrane Database: using text words “metatarsal,” “Lisfranc,” (“metatarsal” AND “fracture”), (“Lisfranc” AND “fracture”)
- CINAHL: Combined searches “Fractures, Bone” [Mesh] AND “Metatarsal Bones” [Mesh], “Fractures, Bone” [Mesh] AND Lisfranc

Top six questions

Diagnosis

1. What are the different types of proximal 5th metatarsal fractures?
2. What is the role of further investigations in the diagnosis of Lisfranc fractures?

Figure 67.3 30° oblique view showing alignment of the medial borders of third metatarsal and the lateral cuneiform as well as the medial borders of the fourth metatarsal and the cuboid bone.

Therapy

3. What is the role of operative vs. nonoperative management of proximal 5th metatarsal fractures?
4. In a patient with a Lisfranc injury, does an anatomic reduction and fixation result in better outcomes than conservative treatment and how does this compare to primary fusion?

Prognosis

5. What is the chance of each of these players returning to their preinjury level of sport?

Harm

6. What are the potential problems with delayed or misdiagnosis of Lisfranc injuries, and what are the long-term complications associated with this injury?

Question 1: What are the different types of proximal 5th metatarsal fractures?

Case clarification

Player A presents with plain radiographs that reveal a fracture in the proximal part of the 5th metatarsal diaphysis with associated periosteal new bone formation and some sclerotic bone within the medullary canal. He reports that he has had some discomfort over the lateral border of his foot for many months prior to this acute injury.

Figure 67.4 (Top) Dameron's three zones of the proximal 5th metatarsal. Zone I injuries are avulsion fractures of the tuberosity. Zone II injuries are fractures involving the intermetatarsal facet (as described by Jones). Zone III injuries are proximal diaphyseal fractures. (Bottom) Blood supply. ©1995 American Academy of Orthopaedic Surgeons. Reprinted with permission from Dameron TB. Fractures of the proximal fifth metatarsal: selecting the best treatment option. *J Am Acad Orthop Surg* 1995;3(2):110–14.⁸

Relevance

This patient has a proximal diaphyseal stress fracture. The classification and description of fractures of the proximal 5th metatarsal can be confusing and central to this has been the regular misuse of the term “Jones fracture.”

Sir Robert Jones was one of the forefathers of British Orthopaedics and founder of the British Orthopaedic Association. In 1902 he wrote on six cases of fractures of the proximal 5th metatarsal.⁷

The use of a clear and practical classification system such as that provided by Dameron⁸ can help in this respect (Figure 67.4).

Current opinion

Treatment should be individualized according to the type of fracture and the demands of the patient. Most zone 1 injuries heal with simple conservative management; zone 2 injuries can take longer to heal and are more likely to refracture if full activity is resumed too quickly. It is well recognized that zone 3 fractures are prone to delayed or nonunion.

Quality of the evidence

Level IV

- 3 case series

Findings

Clapper published a series of 100 patients with 5th metatarsal fractures which were followed prospectively to

determine outcomes of their injuries: three distinct subgroups were identified depending on fracture location (level IV).⁹ Dameron reported a case series of 100 tuberosity fractures treated conservatively, all but one healed clinically within 3 weeks (level IV).¹⁰ In Kavanaugh's series of 22 “Jones” fractures delayed healing was observed in 2/3 of those cases treated conservatively (level IV).¹¹

Recommendations

- For zone 1 (avulsion) fractures conservative, symptomatic treatment is sufficient and patients may resume normal activities as their symptoms permit irrespective of radiological appearance [overall quality: high]
- Zone 2 (Jones) fractures are slower to heal and more prone to refracture. A short-leg cast or a functional brace may be used and surgical fixation could be considered in the high-level athlete [overall quality: moderate]
- Zone 3 injuries (diaphyseal stress fractures) are prone to nonunion and surgical fixation results in a quicker time to union and return to sport and this may be beneficial in selected patients (see Question 5) [overall quality: moderate]

Question 2: What is the role of further investigations in the diagnosis of Lisfranc fractures?

Case clarification

Player B rests at home with his foot elevated for a week. Despite this, his foot remains swollen and he is unable to weight bear. He returns to the Emergency Department where the attending doctor notes significant swelling and an area of plantar ecchymosis. His initial radiographs are re-examined and once again no obvious malalignment of the tarsometatarsal joints is noticed. Nevertheless, there is high clinical suspicion of a midfoot injury and he is referred to the orthopedic clinic for further investigation.

Relevance

The initial mechanism of injury, the ongoing swelling and the plantar ecchymosis all raise the suspicion of a Lisfranc injury.

Jacques Lisfranc (1787–1847) was a field surgeon in the Napoleonic wars. He described an amputation performed through the midfoot because of gangrene that developed after an injury incurred when a soldier fell off a horse with his foot caught in the stirrup.

Current opinion

In suspected midfoot injuries with apparently normal plain radiographs, no widely agreed imaging algorithm exists beyond the recommendation that weightbearing views

should be obtained. Weightbearing or stress radiographs are favored because of the dynamic nature of the investigation and their ability to demonstrate instability. CT, MRI, bone scans, and ultrasound have also been reported as further investigations.^{1,12,13}

Findings

A cadaver study showed that in comparison to weightbearing radiographs, injury-specific manual stress radiographs showed qualitatively greater displacement when used to evaluate Lisfranc instability (level V).¹⁴

A study examined plain radiographs and stress radiographs in 40 normal volunteer feet and compared these with images taken in cadaveric feet, which had undergone sectioning of the Lisfranc and dorsal tarsometatarsal ligaments. Disruption of a line tangential to the medial aspect of the navicular and medial cuneiform intersecting the base of the first metatarsal (medial column line) was found to be a simple and valuable diagnostic tool for determining significant ligamentous injury (level V).¹⁵

One study of 21 feet compared MRI findings with intraoperative findings to determine whether conventional MRI is a reliable diagnostic tool; 19 (90%) of the feet were correctly diagnosed with one false positive and one false negative (level III).¹⁶

A cadaver study showed the increased sensitivity of CT scanning vs. plain radiographs in revealing minor malalignments of the metatarsal cuneiform joints (level V).¹⁷

A prospective clinical study investigated midfoot hyperextension injuries in 75 consecutive patients. All patients had plain radiographs, stress radiographs, CT, and MRI. Their findings showed that both CT and MRI were more sensitive in identifying tarsal and metatarsal fractures and malalignments than plain radiographs and stress radiographs (level IV).¹⁸

Recommendation

- Plain radiographs and weightbearing/stress radiographs are appropriate initial investigations in patients with suspected Lisfranc injuries. If these investigations are normal or equivocal and there is ongoing clinical suspicion of a Lisfranc injury then further investigation in the form of bone scans, CT or MRI should be requested depending on which imaging modality is most readily available locally [overall quality: moderate]

Question 3: What is the role of operative vs. nonoperative management of proximal 5th metatarsal fractures?

Case clarification

Player A has sustained an acute injury to his metatarsal but his history and radiographic findings suggest that he had an underlying proximal diaphyseal stress fracture. He

reports that he is the captain of his team and they have an important game in 12 weeks' time. He wants to know what treatment would offer him the best chance of playing in that game. In discussing the treatment options with player A, he asks what the alternatives are to surgery.

Relevance

The majority of 5th metatarsal fractures heal with conservative management.^{9,10} There is a small group that are prone to delayed healing and nonunion: diaphyseal stress fractures (zone 3). These fractures have been further subclassified by Torg (see box).¹⁹

Torg classification of diaphyseal stress fractures

- Torg I (acute fracture): no previous injury, no intramedullary sclerosis or cortical hypertrophy, sharp fracture margins
- Torg II (delayed union): previous injury, periosteal new bone, widened fracture line, some intramedullary sclerosis
- Torg III (nonunion): repetitive trauma, wide fracture line, periosteal new bone, obliteration of medullary canal with sclerotic bone

Current opinion

Zone 1 tuberosity fractures and distal metatarsal fractures are commonly treated symptomatically. Zone 2 and 3 proximal metatarsal injuries, when treated conservatively, should be put in an aircast boot or plaster and weightbearing can be allowed as tolerated. Prolonged absence of weightbearing may be counterproductive. In a high-demand athlete with an acute zone 2 (Jones fracture) or zone 3 fracture, most specialists would advise operative fixation to achieve a more rapid time to union and return to sport. Most surgeons use an intramedullary screw to fix these fractures. Guidelines for treatment should be individualized depending upon type of fracture and sporting demands.

Quality of the evidence (treatment methods)

The frequent, and often incorrect, use of the term Jones fracture makes interpretation of the literature difficult.

Level IIb

- 2 prospective randomized trials

Level IV

- 6 case series

Findings

A prospective randomized trial showed a significantly quicker ($p < 0.01$) time to union (7.5 weeks) and return to

sport (8 weeks) in the surgical group when compared to conservative treatment (14.5 weeks and 15 weeks). The failure rate was also noticeably higher in the conservative group (44% vs. 5%) (level II).²⁰

These findings are in keeping with the results of the various case series. Portland et al. showed time to union of 6.2 weeks for surgically treated Jones fractures (level IV)²¹ and Leumann et al. found union in 64% of patients at 6 weeks, the remainder uniting by 12 weeks with one partial union. All patients returned to their previous levels of sporting activity (level IV).²² Kavanaugh found delayed union (>6 months) in 66% patients treated conservatively, 50% having had refractures, whereas all 4 surgically treated patients united and returned to sport at 6–8 weeks (level IV).¹¹ De Lee achieved union (mean 7.5 weeks) in all patients in his series (10 patients) with screw fixation (level IV).²³ Mindrebo reports 9 patients fixed surgically with mean time to return to running of 5.5 weeks, all fractures clinically and radiologically united (level IV).²⁴

A prospective randomized study included 60 patients comparing short-leg cast and soft dressings in the treatment of tuberosity fractures. All fractures healed however those treated in a soft dressing returned to preinjury levels of activity faster (average 33 days vs. 46 days) (level II).²⁵

A case series of 38 patients with zone 1 (tuberosity) fractures showed that the most significant predictor of poor functional outcome was prolonged absence of weightbearing. Gender, age, and fracture type did not affect outcome (level IV).²⁶

Quality of the evidence (fixation methods)

- Only two clinical studies (level IV) were found, the rest relying on cadaveric models to test different fixation methods

Findings

One clinical study and one cadaveric study compared the use of 4.5mm and 5.5mm screws to fix proximal 5th metatarsal fractures and neither was unable to show a significant difference between the two. In the clinical study, three bent screws were noted in the 4.5mm group (level IV–V).^{27,28}

Reese et al. cautioned against the use of screws of 4mm and less due to the low number of cycles to failure in their cadaveric models fixed with these screws. They also found that solid screws displayed twice the number of cycles to failure when compared to cannulated screws (level V).²⁹

Sides et al. compared bending stiffness and pull-out strength of tapered variable-pitch screws and 6.5mm cancellous screws in acute Jones fractures using a cadaveric

model. There was no demonstrable difference in bending stiffness between metatarsals fixed with the two types of screws ($p = 0.688$) (level V).³⁰ The 6.5mm screw provided significantly higher resistance to pull-out ($p = 0.001$), a finding replicated in Kelly et al.'s cadaveric study (level V).³¹

The importance of torsional restraint was suggested by the findings of a cadaveric study by Vertullo et al. (level V).³² Horst et al. tested torsional resistance of 5mm and 6.5mm screws used to fix simulated Jones fractures in cadaveric models. They found that both 5.0mm or 6.5mm screws provided equal torsional rigidity, but 5.0mm screws needed to be longer to achieve stability and this could potentially cause problems in patients with curved metatarsals (level V).³³

Moshirfar et al. studied strength of fixation comparing a bicortical lag screw with an intramedullary screw. The lag screw technique resulted in a significantly greater mean (\pm SD) load to failure (150 ± 90 N) (level V).³⁴

Sarimo et al. present a series of zone 3 injuries treated successfully with a tension band wire construct. There were no refractures or hardware failures in their series (level IV).³⁵

Recommendations

- Zone 1 injuries can be treated symptomatically. Consideration should be given to operative fixation of zone 2 and zone 3 injuries leads to a quicker time to union and return to sport and this may be beneficial in selected patients [overall quality: moderate]
- A solid screw of adequate size such that the threads gain purchase in the cortical diaphyseal bone should be used (Figure 67.5). Care should be taken not to oversize the screw as complications such as stress fracture and distal cortical penetration may occur.³⁶ Use of screws smaller than 4mm risks failure/bending of the screw and refracture [overall quality: moderate]
- If Zone 2 and 3 injuries are treated conservatively they should be treated with support in a plaster or boot, and weightbearing should be encouraged as tolerated [overall quality: moderate]

Question 4: In a patient with a Lisfranc injury, does an anatomic reduction and fixation result in better outcomes than conservative treatment and how does this compare to primary fusion?

Case clarification

Player B has weightbearing radiographs of his foot taken at his outpatient follow-up. These clearly show instability of the tarsometatarsal joints and the radiographs indicate a homolateral pattern of Lisfranc injury (Figure 67.6).

Quenu and Kuss described the original classification of these injuries and this remains the most widely used today. They described three types, dependent upon the radiographic findings: homolateral, isolated, and divergent.³⁷

Figure 67.5 4.5 mm screw fixation of proximal 5th metatarsal fracture.

Relevance

Anatomical reduction and rigid internal fixation has been shown to be an important factor in the eventual outcome (level IV).³⁸ Key to this is the reduction of the articulation between the 2nd metatarsal and the middle cuneiform and fixation, which replicates the function of the Lisfranc ligament, tying the medial cuneiform to the 2nd metatarsal.

Current opinion

Lisfranc injuries require prompt anatomical reduction and surgical fixation with screws. There is some debate regarding the effectiveness of primary arthrodesis as treatment for these injuries, but this has not become mainstream treatment.

Quality of the evidence

Level II

- 2 prospective randomized studies have investigated primary arthrodesis

Level IV

- Numerous case series can be found relating to this topic

Findings

In Myerson's case series of 55 patients the major determinant of unacceptable results was identified as the quality of the initial reduction (level IV).³⁸ Goossens' case series of 20 patients showed that 70% of patients who were treated conservatively in an unreduced position had a poor outcome, compared with only 18% of those who had reduc-

Figure 67.6 Weightbearing views showing instability of the left 1st and 2nd tarsometatarsal joints and widening of the space between the 1st and 2nd rays.

tion and pinning (level IV).³⁹ Arntz showed in a consecutive series of 40 patients that good or excellent results were obtained in 95% of patients with an anatomical reduction but only 20% of those in whom the reduction was nonanatomical (level IV).⁴⁰ One case series suggested that anatomical reduction was not a guarantee of satisfactory outcome: Teng et al. reported that the subjective functional outcome in their series of 11 patients was not very good despite successful restoration of normal anatomy (level IV).⁴¹

Coetzee reported favorable outcomes for patients treated with a primary arthrodesis with a significant improvement in midfoot American Orthopaedic Foot & Ankle Society (AOFAS) scores in the arthrodesis group at 2 years (level II).⁴² These findings were not replicated by a similar study of 40 patients by Henning et al. which showed no significant difference in Short Form-36 (SF-36) and short musculoskeletal function assessment (SMFA) scores (level II).⁴³

Recommendation

- In treating Lisfranc injuries, restoration of normal anatomy and surgical fixation gives the best chance of a favorable long-term outcome [overall quality: high]

Question 5: What is the chance of each of these players returning to their preinjury level of sport?

Case clarification

Both players attend follow-up and ask for insurance forms to be completed in relation to their injuries. One question asks whether they will be able to return to their preinjury level of function.

Relevance

Managing expectations is an important aspect of treating surgical patients and a thorough knowledge of prognosis helps in this respect.

Current opinion

Return to a preinjury level of sporting activity can almost always be expected after a 5th metatarsal injury, but the outcome is less certain after a Lisfranc injury.

Quality of the evidence

Level IV

- 5 case series

Findings

Lisfranc injury Chilvers published a case series including 5 gymnasts with Lisfranc injuries: only 1 returned to full competition (level IV).⁴⁴ Curtis et al. report that 3 of 19 patients with Lisfranc injury were unable to return to their sports (level IV).⁴⁵

Nunley and Vertullo describe 15 patients with Lisfranc injuries sustained playing sport. Seven of these injuries were diagnosed as sprains (stage 1 injuries—see box) and treated conservatively. All patients in their series returned to sport (average 15.2 weeks) (level IV).¹ Nunley and Vertullo have proposed a classification system for the low-energy Lisfranc injury typically sustained playing sport.¹

Classification system for low-energy Lisfranc injuries

Stage 1 (bone scan positive): a sprain of the Lisfranc ligament with no diastasis between the medial cuneiform and the base of the 2nd metatarsal

Stage 2: diastasis 1–5 mm

Stage 3: diastasis >5 mm and loss of arch height

Proximal 5th metatarsal Porter et al. report a case series of 23 athletes treated with internal fixation of the 5th metatarsal, all of whom returned to sport (mean 7.5 weeks) (level IV).⁴⁶

Portland et al. surgically treated 22 patients with Jones fractures or proximal diaphyseal stress fractures, all fractures united (mean 6.25 weeks) with none to rare pain reported during athletic activity (level IV).²¹

Recommendation

- Patients with 5th metatarsal injuries can be reassured that they should be able to return to their preinjury sport. The outcome of Lisfranc injuries is less predictable, the recovery is slower and caution must be taken to avoid giving an overoptimistic prognosis [overall quality: moderate]

Question 6: What are the potential problems with delayed or misdiagnosis of Lisfranc injuries, and what are the long-term complications associated with this injury?

Case clarification

Player B attends his orthopedic follow-up clinic. He is unhappy that he was not referred immediately after his first attendance at the Emergency Department. He asks what effect the potential delay in diagnosing his injury might have and asks about his prognosis and possible complications.

Relevance

We live in an era where litigation is commonplace. Lisfranc injury is a commonly missed diagnosis in the acute setting,^{47,48} and although it is a rare injury the potential for a poor outcome is significant, especially if mismanaged.

Current opinion

In this case the diagnosis was not significantly delayed: surgical intervention would not be recommended before

the swelling had settled and the only evidence in the literature is that a significant delay (6 months) in treatment would affect outcome (level IV).⁴⁹ Nevertheless, clinicians who regularly attend to patients with acute foot trauma should always be alert to the possibility of a Lisfranc injury in order to expedite prompt further investigation and management. Lisfranc injuries usually occur with significant trauma to the foot. Most specialists would advocate a period of elevation, icing, and observation in the initial 24–48 hours. At the same time further investigations should be arranged, if necessary, to assess tarsometatarsal stability.

Long-term follow-up should be arranged because of the high number of delayed problems encountered.

Quality of the evidence (delayed diagnosis)

Level III

- 1 comparative cohort study

Level IV

- 1 retrospective case series

Findings

A retrospective study (46 patients) found that there was a worse outcome in terms of return to work when there was delay in diagnosis of more than 6 months ($p = 0.01$) (level IV).⁴⁹

A comparative cohort study (44 patients) compared primary open reduction with delayed, corrective arthrodesis (mean 22 months) and found that the primary fixation leads to improved functional results, earlier return to work, and greater patient satisfaction than secondary corrective arthrodesis ($p = 0.03$) (level III).⁵⁰

Quality of the evidence (complications)

- Most of the literature relating to complications consists of case reports and small case series (level IV)

Findings

Vascular injury The terminal part of the dorsalis pedis artery may be damaged as it dives down between the 1st and 2nd ray to join the plantar arterial arch (level IV).⁵¹ Gossens describes three cases in his series which were found to have vascular compromise; two of these were also open injuries and eventually required amputation due to the development of gas gangrene (level IV).³⁹

Compartment syndrome Compartment syndrome is a rare complication after Lisfranc injury sustained playing sport, and is more commonly seen in high-energy crushing type injuries. Nevertheless, Lisfranc injury is a common cause of compartment syndrome, implicated in a third of cases of foot compartment syndrome in a series reported by Myerson (level IV).⁵²

Stiffness Loss of range of movement in the midfoot is well recognized after this injury. Wilson found that almost all patients in his series displayed some degree of stiffness and this was related to the quality of the initial reduction (level IV).⁵³

Complex regional pain syndrome (CRPS) Goossens reported CRPS in 25% of the patients in his series: missed or delayed diagnosis was thought to be an important factor in many of those cases (level IV).³⁹

Deformity Disruption of the Lisfranc complex can result in a planovalgus deformity. There is conflicting evidence as to whether this is significant in terms of outcome. Aitken and Poulson report good functional outcomes in their case series despite obvious residual deformity (level IV).⁵⁴ This is contrary to the findings of Faciszewski who reports that maintenance of the longitudinal arch is a major determinant of outcome (level IV).⁵⁵

Post-traumatic arthritis Arthritis is the most common long-term complication in Lisfranc injuries. In many series this is reported to occur in a significant number of cases and is a significant cause of long-term morbidity (level IV).^{38,56}

Recommendations

- Lisfranc injuries are best treated acutely to avoid potential problems associated with missed or delayed diagnosis [overall quality: high]
- Awareness of the immediate and late complications of these injuries is essential [overall quality: high]

Summary of recommendations

- Careful attention should be paid to the anatomy and alignment of the tarsometatarsal joints when reviewing foot radiographs
- It should be appreciated that there are three types of proximal 5th metatarsal fracture that may require different treatments and which have different prognoses
- Weightbearing or stress radiographs should be obtained to assess tarsometatarsal stability if there is ongoing clinical concern of Lisfranc injury after apparently normal initial radiographs
- Lisfranc injuries are best treated acutely to avoid potential problems associated with missed or delayed diagnosis
- Operative fixation of zone 2 and zone 3 proximal metatarsal injuries leads to a quicker time to union and return to sport and this may be beneficial in selected patients
- When fixing proximal 5th metatarsal fractures, use a solid screw of adequate size such that the threads gain purchase in the cortical diaphyseal bone

- When conservatively treating proximal 5th metatarsal fractures treat zone 1 injuries symptomatically and zone 2/3 injuries in a plaster or boot: weightbearing should be encouraged as tolerated
- In treating Lisfranc injuries, restoration of normal anatomy and surgical fixation gives the best chance of a favorable long-term outcome
- The prognosis of proximal 5th metatarsal fractures is good; the prognosis of Lisfranc injuries is significantly worse and less predictable
- Awareness of the immediate and late complications of Lisfranc injuries is essential

Conclusions

This chapter has provided an insight into the investigation and management of two important injuries to the midfoot: the proximal 5th metatarsal fracture and the Lisfranc injury. Proximal 5th metatarsal fractures are common but vary in their management according to the type of patient and the fracture location. The outcome is usually satisfactory. Lisfranc injuries are rare and have the ability to deceive unsuspecting clinicians. The outcome, if misdiagnosed or mismanaged, may be extremely poor.

University of Montreal, Montreal, QC, Canada

Case scenario

A 37 year old woman is severely injured in a motor vehicle accident and is brought to the Emergency Department with complaints of pain to the pelvis. She is unresponsive to the initial volume resuscitation. On examination, her left and right thighs are swollen and bruised. A sheet is immediately wrapped around the pelvis in the Emergency Department. Her blood pressure improves to 90/60 with tachycardia of 130/min. The neurological examination, the chest radiograph, and the abdominal ultrasound are negative. An AP radiograph of the pelvis is shown in Figure 68.1.

Relevant anatomy

This chapter focuses on the initial management of pelvic fractures associated with hemodynamic instability and on the definitive management of pelvic fractures that are mechanically unstable. Pelvic fractures are classified in relation to the mechanism of injury (Table 68.1) and in relation to the instability patterns (Table 68.2).

Importance of the problem

Fractures of the pelvis are the third most commonly encountered injury in motor vehicle accident fatalities (level IV).¹ Pelvic fractures account for 3–8% of all fractures seen in the Emergency Department but are present in up to 25% of multiply injured patients. Life-threatening hemorrhage is a frequent complication of major pelvic fractures and extensive bleeding is the leading cause of death in these patients, with a mortality rate as high as 50% for patients with open pelvic fractures.

The forces needed to create a pelvic ring disruption in a young patient are extreme and often life threatening. The priority is saving the patient's life and then managing the pelvic fracture in order to reduce the high morbidity associated with pelvic ring injuries. A significant number of survivors will suffer major chronic disability with long-term problems.

Top five questions

1. What is the role of angiography in an unstable patient? Should it be performed first, before external fixation?
2. Is there any evidence to support the use of an external fixator over noninvasive stabilization (sheets or belts)?
3. Is prophylactic inferior vena cava (IVC) filter insertion recommended in pelvic trauma patients in whom surgery is likely to be delayed?
4. What is the optimal thromboprophylaxis strategy in pelvic fracture patients?
5. What is the prognosis of patients with pelvic fractures?

Question 1: What is the role of angiography in an unstable patient? Should it be performed first before external fixation?

Case clarification

Blood pressure improves to 90/60 with tachycardia of 130/min. Should the patient be sent to the operating room for emergent external fixation or to the angiography suite?

Relevance

Bleeding pelvic fractures carry mortality as high as 60%, yet controversy remains over their optimal initial management. Some surgeons prefer immediate external fixation

Figure 68.1 AP radiograph of fractured pelvis.

aimed at controlling venous bleeding. Others feel ongoing hemodynamic instability indicates arterial bleeding, and prefer early angiography before external fixation.

Current opinion

The establishment of standardized clinical treatment algorithms for patients with a bleeding pelvic injury increases the probability of rapid stabilization and survival. Two different families of algorithms can be found in the literature: fixation and packing first (level IV)^{2,3} or angiography first (level IV, III).^{4,5}

Finding the evidence

- Cochrane Database: search term: “pelvic fracture” AND “embolization”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews search for “pelvic fracture” AND “thromboembolism (pulmonary embol*, thrombosis, pelvis fracture, embolization)”

Quality of the evidence

Level III

- 1 case-control study
- 2 retrospective comparative studies

Level IV

- 3 case series with 20 or more patients

Findings

All results are from retrospective studies using variable treatment algorithm and reporting results in different

Table 68.1 The Young–Burgess classification system, based on mechanism of injury

Category	Distinguishing characteristics
LC	Transverse fracture of pubic rami, ipsilateral or contralateral to posterior injury
LC I	Sacral compression on side of impact
LC II	Crescent (iliac wing) fracture on side of impact
LC III	LC-I or LC-II injury on side of impact; contralateral open-book (APC) injury
APC	Symphyseal diastasis or longitudinal rami fractures
APC I	Slight widening of pubic symphysis; stretched but intact anterior SI, sacrotuberous, and sacrospinous ligaments; intact posterior SI ligaments
APC II	Widened anterior SI joint; disrupted anterior SI, sacrotuberous, and sacrospinous ligaments; intact posterior SI ligaments
APC III	Complete SI joint disruption with lateral displacement, disrupted anterior SI, sacrotuberous, and sacrospinous ligaments; disrupted posterior SI ligaments
VS	Symphyseal diastasis or vertical displacement anteriorly and posteriorly, usually through the SI joint, occasionally through the iliac wing or sacrum
CM	Combination of other injury patterns, LC/VS being the most common

SI, sacroiliac.

Table 68.2 Tile’s classification system, based on the instability pattern

Category	Distinguishing characteristics
Type A	Stable
A1	Fractures of the pelvis not involving the ring
A2	Stable, minimally displaced fractures of the ring
Type B	Rotationally unstable, vertically stable
B1	Open book
B2	Lateral compression: ipsilateral
B3	Lateral compression: contralateral (bucket-handle)
Type C	Rotationally and vertically unstable
C1-	Rotationally and vertically unstable
C2-	Bilateral
C3	Associated with an acetabular fracture

ways. Some patients got angiography after external fixator or pelvis packing. Data specific to cases where angiography was done first were impossible to extract from these series. The only study comparing angiography to another treatment, i.e., pelvic packing, was a case-control study with two groups of 20 patients showing no significant difference

Table 68.3 Efficacy of arterial angiography for stopping bleeding in unstable patient with pelvis fracture

ISS, Injury Severity Score.

between both groups. However, in the pelvic packing group, three patients (15%) also required embolization.²

Efficacy to stop pelvic bleeding A total of 5 cohorts with comprehensive results were identified for a total of 194 unstable patients with pelvic fracture having angiography. Of them 117 (60%) received embolization and 90–100% of them were successful (Table 68.3 and Table 68.4).

Revision intervention Fangio et al.⁶ showed that on 140 patients with pelvic fracture, 26 (18.6%) required repeat embolization for recurrent bleeding; an odds ratio of 3.22

of revision rate for superselective arterial (SSA) embolization compared to internal iliac artery embolization (IIAE) with a higher mortality rate (35% vs. 15%).

Mortality Mortality ranged from 16% to 43%, but the majority of death were secondary to the other injuries (brain, respiratory, etc.) (Table 68.5).

Recommendations

- Angiography is an effective option for bleeding control in hemodynamic unstable patients with pelvis fracture [overall quality low]

- A multidisciplinary standardized treatment algorithm must be established for unstable patients with a pelvic fracture
- The timing of angiography remains controversial and should be decided in collaboration with the trauma team
- Pelvic packing is a rapid method for controlling pelvic fracture-related hemorrhage and an alternative to emergent angiography

Question 2: Is there any evidence to support the use of an external fixator over noninvasive stabilization (sheets or belts)?

Case clarification

A few hours after successful embolization, the sheet wrapped around the patient's pelvis is carefully removed but a drop in the blood pressure is observed. The sheet is retightened over her pelvis and thighs.

Relevance

The anterior frame external fixator has gained widespread acceptance in the management of these injuries as a stabilizing frame, in the belief that this controls the fracture and reduces hemorrhage.

Current opinion

Experimental studies have shown that reduction in volume is much smaller than previously assumed,¹ and that a 'tamponade effect' of the pelvis is minimal. The external fixator will only adequately control a rotationally unstable pelvis, and may worsen a posterior injury.

Quality of the evidence

Level II

- 1 randomized trial with methodologic limitations

Level III

- 1 case-control study
- 1 systematic review (level III and IV studies)

Level IV

- 1 prospective cohort study

Findings

Immediate stabilization of unstable pelvic fractures to delayed stabilization with simple external fixation was studied by Waikakal et al. (level II).⁸ A parallel trial with 2 year follow-up included 112 patients who were allocated randomly into 2 groups (acute fixation vs. delayed fixation). Blood transfusion, postoperative pain, need for reconstructive surgery of the pelvic fractures, and late deformities were less in the delayed fixation group.

A systematic review of literature was recently published on the effectiveness of pelvic circumferential compression

Table 68.6 Retrospective case-control study on transfusion requirements in patients with exsanguinating pelvic fracture¹⁰

Variable	POD (n = 93)	EPF (n = 93)	p value
24 h, Tx	4.9	17.1	0.008
48 h, Tx	5.6	18.6	0.008
Mortality, %	26	37	0.11

EPF, external pelvic fixation; POD, pelvic orthotic device; Tx, units of blood transfused.

devices (PCCDs) for unstable pelvic fractures (level III).⁹ The authors included 17 articles with only one level III study (level III) (Table 68.6)¹⁰ and concluded that PCCDs seem to be effective but prospective data was lacking. Krieg et al. (level IV)¹¹ were the only ones to investigate prospectively the effectiveness of a PCCD in 13 patients. In the external rotation group, the PCCD closely approximated the $10.0 \pm 4.1\%$ reduction in pelvic width achieved by definitive stabilization.

Recommendations

In the hemodynamically unstable pelvic fracture, evidence suggests [overall quality: low]:

- Emergent stabilization of the pelvis is beneficial
- External fixation is not superior to noninvasive stabilization devices. We therefore recommend the immediate application of a pelvic binder in resuscitation from life-threatening hypovolemic shock in patients with unstable pelvic injuries
- A pelvic binder can effectively reduce pelvic ring injuries with minimal risk for overcompression in lateral compression injuries

Question 3: Is prophylactic IVC filter insertion recommended in pelvic trauma patients?

Case clarification

The patient's hemodynamic status has been stabilized but the CT scan shows a large retroperitoneal hematoma. The surgery to fix her pelvis has been scheduled in 5 days.

Relevance

Patients with pelvic fractures are believed to be at very high risk for venous thromboembolisms (VTEs) such as spinal cord injuries. Prophylactic IVC filter insertion prior to the definitive surgical fixation procedure has been recommended by some clinicians for patients in whom early thromboprophylaxis has not been possible.

Current opinion

With current insertion techniques performed by experienced clinicians, the short-term complication rates associ-

ated with IVC filter use are very low and we should expand our indications.

Quality of the evidence

Level I

- 3 systematic reviews/meta-analyses

Level III

- 4 case-control studies

Level IV

- 1 case series

Findings

Two meta-analysis of prospective studies in trauma patients found no statistically significant difference in the rates of pulmonary embolism (PE) among patients with and without prophylactic IVC filters (level I).^{12,13} Both PE and fatal PE still occur despite the presence of an IVC filter (level I, level II),^{13,14} see Table 68.7 and Table 68.8.

Only one small prospective cohort study reported on a subgroup of 23 pelvic fracture patients (level III).²¹ Another prospective cohort on acetabular fractures was published

by Webb et al. (level III).²² The short-term complication rates associated with an IVC filter are lower than previously reported, but very little is known about the long-term follow-up (level III).²³ Retrievable IVC filters have recently become available but the majority are never removed (level IV).²⁴

Recommendation

- For pelvic trauma patients, evidence suggests that prophylactic IVC filters do not significantly reduces the risk of pulmonary embolism or mortality. The use of an IVC filter as thromboprophylaxis is therefore not recommended [overall quality: low]

Question 4: What is the optimal thromboprophylaxis strategy in pelvic fracture patients?

Case clarification

The patient's pelvis was stabilized on the fifth day after trauma with an anterior plate and iliosacral screws. No complications occurred during surgery and bleeding was minimal.

Table 68.7 Pulmonary embolism after thromboprophylactic trials involving IVC filters after major trauma
Openmirrors.com

Study	Type of injury	Pulmonary embolism		p value
		Control	With IVC filter	
Wilson et al. ¹⁵	Major trauma	6.3% (7/111)	0% (0/15)	NA
Khansarinia et al. ¹⁶	Major trauma	6.0% (13/216)	0% (0/108)	<0.009
Rodriguez et al. ¹⁷	Major trauma	17.5% (14/80)	2.5% (1/40)	0.02
Gosin et al. ¹⁸	Major trauma	4.8% (12/249)	0% (0/99)	<0.02
Rogers et al. ¹⁹	Major trauma	0.9% (11/1150)	2.9% (1/35)	<0.05
Webb et al. ²⁰	Acetabular fracture	7.4% (2/27)	0% (0/24)	NA
Rogers et al. ²¹	Pelvic fracture	2.9% (5/168)	4.3% (1/23)	NA

IVC, inferior vena cava; NA, not available.

Table 68.8 Relative risks of PE after thromboprophylactic trials involving IVC filters after trauma

Type of injury	Pulmonary embolism		RR	95% CI
	Control	IVC filter		
Pelvic fracture studies	3.6% (7/195)	2.1% (1/47)	0.6	0.10–4.09
Major trauma studies ^a	9.1% (27/296)	0.7% (1/148)	0.11	0.02–0.74

CI, confidence interval; IVC, inferior vena cava; NNT, number needed to treat; RR, relative risk.

^aRequired that two clearly identified groups be studied, one receiving prophylactic IVC filters and the other not, and that these two groups be matched for age and risk for VTE disease.^{16,17}

Relevance

Without thromboprophylaxis, patients with a pelvic fracture have a DVT risk that exceeds 50%, and PE is the third-leading cause of death in those who survive beyond the first day (level I).²⁵

Current opinion

Current prophylaxis guidelines for thromboprophylaxis are directed towards major trauma patients but their effectiveness, especially in the patient with an injured pelvis, is still debated.

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses

Level II

- 2 randomized trials with methodologic limitations

Level III

- 1 case-control study

Findings

A systematic review of thromboprophylaxis for pelvic fracture was conducted by Slobogean et al. in 2009 (level I).²⁶ Many limitations were encountered, including small sample sizes, with only one study of more than 200 patients, and the inability to extract injury-specific data from several eligible studies that did not stratify their results. In the pelvic fracture population, the early (<24 hours) administration of low molecular weight heparin (LMWH) was the only reviewed intervention that demonstrated a clear reduction in DVT and PE (level III).²⁷

Two randomized trials (level II) were available comparing different mechanical compression devices (Table 68.9).^{28,29} Important limitations of mechanical devices include their inability to be used in many trauma patients (due to lower extremity injuries), and evidence of poor compliance with proper use of these devices. According to the American College of Chest Physicians (ACCP) guidelines,²⁵ mechanical devices are recommended in patients

with a contraindication to anticoagulant thromboprophylaxis, such as those with active bleeding or with a high risk for bleeding (grade 1A).

Recommendations

- For major trauma patients with a pelvic fracture, early administration of LMWH demonstrated a clear reduction in DVT and PE [overall quality: low]
- LMWH prophylaxis significantly protects against DVT in the major trauma patient [overall quality: moderate]
- Mechanical prophylaxis is less effective than LMWH

Question 5: What is the functional outcome of patients with pelvic injuries?

Case clarification

Two years after her injury, the patient comes back to clinic complaining of posterior back pain. She has yet to return to full-time work and has significant restrictions in her recreational activities.

Relevance

Pelvic ring injuries result in significant long-term functional disability and chronic pain. Even today, with modern management and early stabilization of the pelvic ring, morbidity remains high.

Current opinion

Patients with residual deformity and malunion seem to have the worst outcome. The literature supports the concept that the outcome depends on the fracture type and fracture stability. Restoration of a near-anatomic reduction in order to achieve a stable pelvic ring offers the best chance to return to a functional life. Improved techniques of reduction and fixation should improve outcomes and reduce complications.

Quality of the evidence

From Papakostidis et al. ³⁰				

Level III

- 1 systematic review of case series
- 1 case-control study

Findings

A systematic review (level III)³⁰ investigated the correlation of the clinical outcome of different types of pelvic ring injuries (27 case-series with 1,641 patients) to the method of treatment (Table 68.10). Few studies used validated outcome instruments, and prospective outcome studies are needed to better understand the relationship between fracture type, residual displacement, treatment modalities, and outcome.

Suzuki et al. evaluated the long-term functional outcome of patients with unstable pelvic ring fractures in 57 patients (level II).³¹ The Majeed score, the Iowa pelvic score, and the physical component summary of the SF-36 correlated with the presence of neurological injury.

Tile's C-type injuries of the pelvis are mechanically the worst injuries and may also have the worst functional outcome. According to a prospective clinical study evaluating 40 patients with Tile C-type fractures (level II),³² 72% had returned to their original jobs at the time of the last follow-up visit. There was an inverse correlation between ability to work and depression and anxiety ($r = -0.551$, $r = -0.391$). Rommens et al. found that functional outcome was worse in C-type than in B-type lesions (level III).³³ Within the B-type group, B1 lesions had a worse functional end result than B2/B3 fractures. This finding was also supported by Kreder's prospective cohort of 366 patients (level II) using validated functional outcome tools (SF-36, MFA),³⁴ and by many other case series.

Recommendations

In unstable pelvic ring fractures, evidence suggests [overall quality: low]:

- Fixation of all the injured elements of the pelvic ring yields better anatomical results.
- Functional outcome is associated with neurological injury and fracture type, C-type injuries being the worst.
- No clear relationship can be found between quality of reduction/residual displacement of the pelvis and functional outcome.

Summary of recommendations

- Angiography is an effective option for bleeding control in hemodynamic unstable patients with pelvis fracture
- The timing of angiography remains controversial and should be decided in collaboration with the trauma team
- Pelvic packing is a rapid method for controlling pelvic fracture-related hemorrhage and an alternative to emergent angiography.
- In the hemodynamic unstable pelvic fracture, emergent stabilization of the pelvis is beneficial
- External fixation is not superior to noninvasive stabilization devices. We therefore recommend the immediate application of a pelvic binder in resuscitation from life-threatening hypovolemic shock in patients with unstable pelvic injuries. A pelvic binder can effectively reduce pelvic ring injuries with minimal risk for overcompression in lateral compression injuries.
- For pelvic trauma patients, evidence suggests prophylactic IVC filters do not significantly reduce the risk of pulmonary embolism or mortality. The use of an IVC filter as thromboprophylaxis is not recommended
- For major trauma patients (with a pelvic fracture), early administration of LMWH demonstrates a clear reduction in DVT and PE and LMWH prophylaxis significantly protects against DVT in the major trauma patient
- Mechanical prophylaxis is less effective than LMWH.

- In unstable pelvic ring fractures, evidence suggests that fixation of all the injured elements of the pelvic ring yields better anatomic results
- Functional outcome is associated with neurological injury and fracture type; C-type injuries being the worst
- No clear relationship can be found between quality of reduction/residual displacement of the pelvis and function outcome.

Conclusions

The priority is saving the patient's life and then managing the pelvic fracture in order to reduce the high morbidity associated with pelvic fractures. Every Emergency Department must create and apply a simple algorithm with the onsite surgical and radiological team following available resources for unstable patient with pelvic fracture to prevent confusion and loss of precious time in life-threatening pelvic injury.

Acetabulum

Kelly A. Lefaiore¹ and Adam J. Starr²

¹University of British Columbia, Vancouver, BC, Canada

²University of Texas Southwestern Medical Center, Dallas, TX, USA

Case scenario

A 26 year old manual laborer is brought to the Emergency Department after a 20 ft (6 m) fall at work, with complaints of left pain. He is unable to weight bear, and has diffuse bruising and swelling around his left hip. The trauma team has cleared him otherwise, and this is an isolated left acetabulum fracture.

Relevant anatomy

Acetabulum fractures involve the “hip joint” portion of the pelvis—the socket side of the ball and socket hip joint. Acetabulum fractures are anatomically classified based on the parts of the bone involved in the injury. These parts are comprised of the anterior and posterior columns (structural attachments of the acetabulum to the remainder of the axial skeleton) and the anterior and posterior walls (rims that contribute to congruence of the hip joint). These structures can be seen in Figure 69.1.

Based on these anatomic components, Judet and Letournel described a widely used classification system, which divides injuries into two main categories, elementary and associated, each with subtypes.¹ Elementary fracture patterns are posterior wall, posterior column, anterior wall, anterior column and transverse (Figure 69.2a–e) Associated fracture patterns are posterior column/posterior wall, transverse posterior wall, t-type, anterior column posterior hemitransverse and associated both column (Figure 69.2f–j).

Importance of the problem

Acetabular fractures are rare and few studies have examined their epidemiology. Laird et al. reported the experience from Edinburgh in the UK, where they noted 3 fractures per 100,000 population per year.² In practice, the relative scarcity of these fractures means that few will be encountered at individual community hospitals. Usually they are managed at trauma centers, but even at a busy trauma center they are infrequent. In the authors’ opinion, 100 operative cases in a year represents a considerable caseload for a trauma center. This rarity makes it difficult to conduct research to guide treatment. To date, most of the literature on acetabular fractures consists of small retrospective series. Pioneers in the field published larger retrospective series with detailed analyses of fracture types, and more complete follow-up.^{3–5} Recent well-conducted prospective series have examined aspects of particular fracture types, and biomechanical studies have improved our understanding of the hip socket’s function.^{6–10} However, despite the number of studies, most of the treatment recommendations in the literature consist of advice from experts. Sadly, the results obtained by experts in the field—who have years or even decades of experience, and who benefit from working with teams dedicated to acetabular fracture management—may not be reproduced by less experienced surgeons. To the contrary, there is evidence that surgeons who perform acetabular fracture repair infrequently will experience higher complication rates and inferior results.¹¹

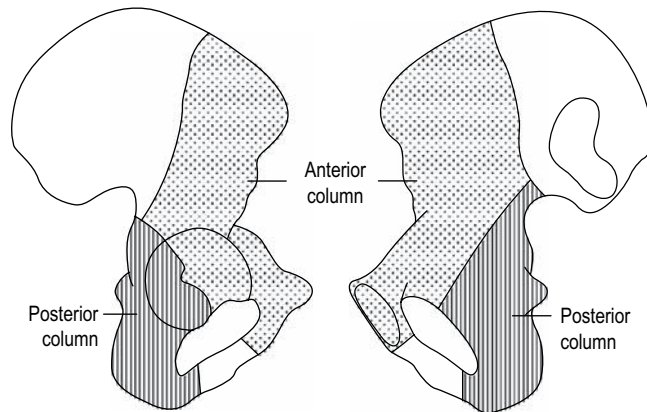

Figure 69.1 Anterior and posterior columns of the acetabulum.

It is fortunate that acetabular fractures are rare, because they can lead to devastating outcomes for patients. Post-traumatic arthritis of the hip can have a profound negative impact on a patient's life. It seems clear that operative restoration of the articular surface offers the best chance of avoiding arthritis, but the surgery to achieve joint restoration is difficult, risky, and requires dedication to master.²⁻⁵ These facts, combined with the nature of acetabular fracture research as it exists today, make these fractures among the most complex and least well understood injuries that orthopedic trauma surgeons face. As stated by Tile in the first edition of his book, published in 1984, and repeated in the latest edition, "Fractures of the acetabulum remain an enigma to the orthopaedic surgeon."⁵ Although many advances have been made in the management of these complex and disabling injuries in the last 25 years, many questions about their treatment remain.

Acetabulum fractures remain an injury with variable results and a significant complication rate.^{4,5} Important questions remain about which patients and patterns to treat surgically. Similarly, the selection of surgical approach and the use of methods to avoid complications, such as heterotopic ossification (HO) or deep vein thrombosis (DVT) remain controversial. Clearly, the treatment of acetabulum fractures has become its own specialty within orthopedics, and is best undertaken by those with subspecialty training and expertise.

DVT is the development of a blood clot in the veins of the leg, an event that trauma patients in general are at risk for. The propagation of these clots to the arteries is a significant cause of death in otherwise healthy trauma patients.

HO refers to the nonmalignant overgrowth of bone, frequently occurring after a fracture, which can lead to pain, stiffness, and compromised outcome.

Given the relative youth of this area of orthopedic trauma surgery, evidence-based practice is in evolution. Further, surgeons and patients are inundated with an ever-increasing, easily accessible body of information about acetabulum fractures. To this end, as noted above, a Google search for "acetabular fractures" returns over 867,000 hits. The variable quality of this information mandates development of evidence-based guides.

Top seven questions

Diagnosis

1. How accurate are plain radiographs vs. CT scan in the characterization of acetabulum fractures?

Therapy

2. What are the indications for surgical management of acetabulum fractures in a young person?
3. What are the treatment options in elderly patients?
4. What is the optimal deep vein thrombosis/pulmonary embolus (DVT/PE) prophylaxis in patients with acetabulum fractures?
5. What is the optimal HO prophylaxis in patients with acetabulum fractures?

Prognosis

6. What is the expected long-term functional outcome in acetabulum fractures?
7. What are the important non-surgeon-related factors that determine prognosis in acetabulum fractures?

Question 1: How accurate are plain radiographs vs. CT scan in the characterization of acetabulum fractures?

Case clarification

The patient's AP pelvis and Judet views reveal a comminuted fracture involving the anterior column and posterior column, and apparent discontinuity of the entire weight-bearing dome from the axial skeleton (an associated both column acetabulum fracture). You are faced with the question of whether CT will be helpful in definitive characterization of the fracture type and properties, and subsequently planning for surgical approach.

Judet views of the acetabulum are obtained by turning the X-ray beam 45° away from the affected side (iliac oblique view) and towards the affected side (obturator oblique view). These views each give an advantageous view of a column and a wall (iliac oblique: posterior column and anterior wall; obturator oblique: anterior column and posterior wall).

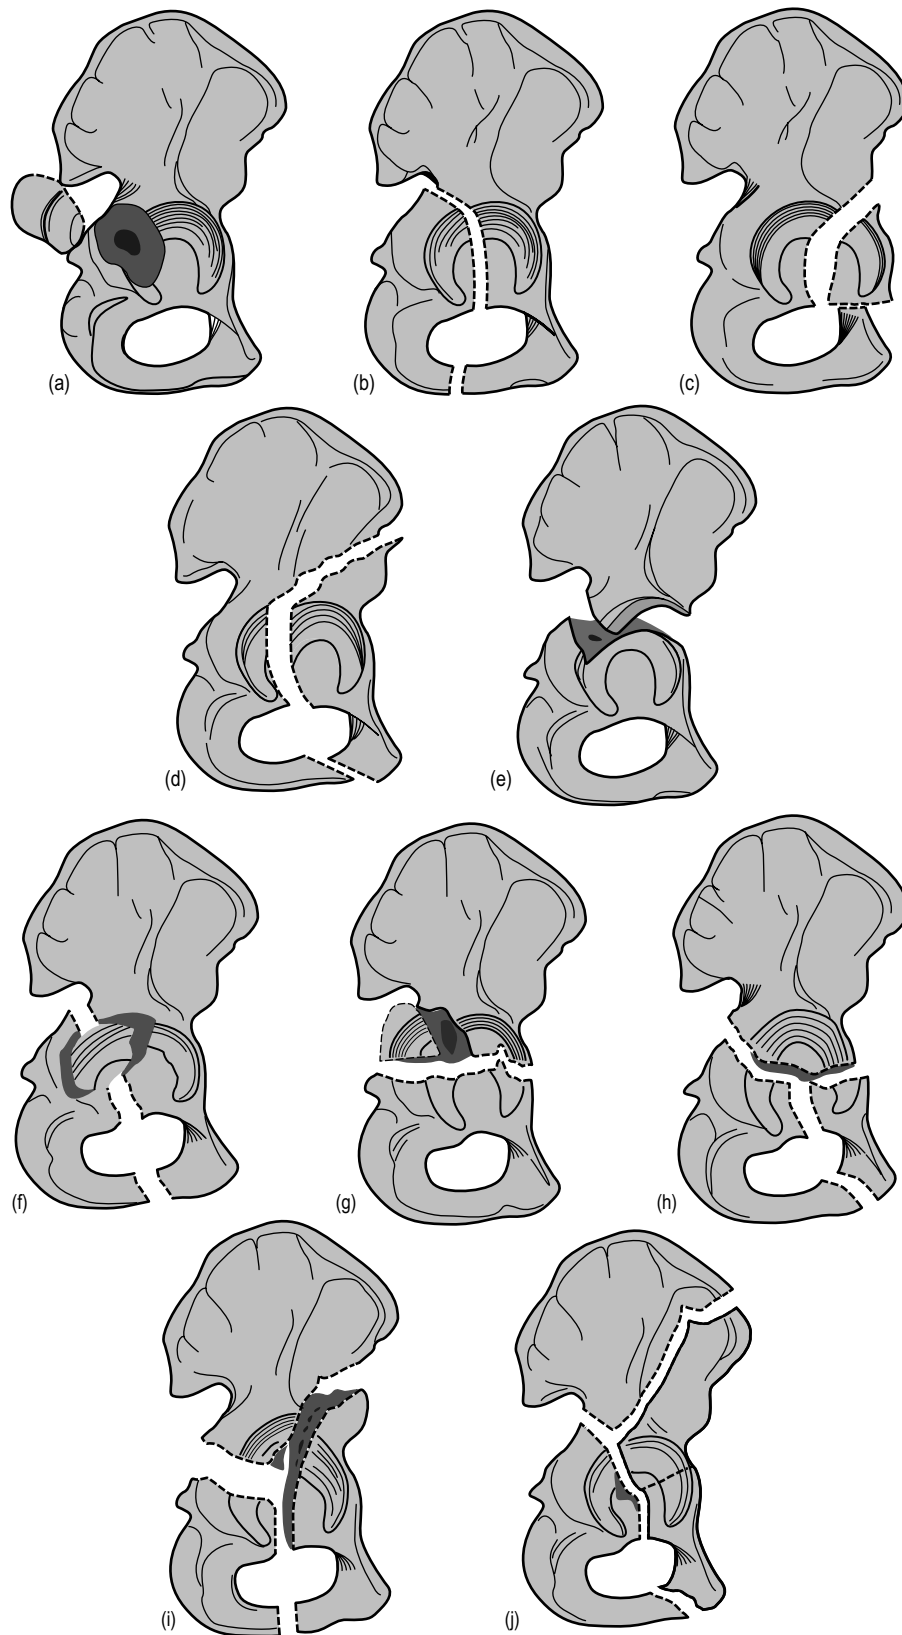

Figure 69.2 Patterns of acetabular fractures. Elementary fracture patterns: posterior wall (a), posterior column (b), anterior wall (c), anterior column (d) and transverse (e). Associated fracture patterns: posterior column/posterior wall (f), transverse posterior wall (g), t-type (h), anterior column posterior hemi-transverse (i) and associated both column (j). (Reprinted with kind permission from Springer Science+Business Media: Fractures of the Acetabulum, 1993, Letournel E, Judet R, figure 4.1).

Relevance

The accepted classification system for acetabulum fractures was based on multiplanar plain films (AP and Judet views)¹. However, current discussions of classification and surgical planning most frequently involve CT information, as well as reformats of this information.

Current opinion

Current opinion suggests that the majority of surgeons find CT to be more accurate in fracture classification, identification of additional lesions, and for surgical planning.

Finding the evidence

- Cochrane Database, with search term: “acetabulum fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “acetabulum” and “acetabular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “acetabulum fracture OR acetabular fracture” AND “radiography” “acetabulum fracture OR acetabular fracture” AND “CT”
- MEDLINE search keywords: “acetabulum fracture” or “acetabular fracture” AND “tomography”

Quality of the evidence

Level II

- 4 studies developing diagnostic criteria on basis of consecutive patients (with universally applied reference gold standard)

Level III

- 1 study of nonconsecutive patients (without consistently applied reference gold standard)

Level IV

- 1 case-control study

Findings

The best research comparing plain films and CT scans in the classification of acetabular fractures, and in the preoperative detection of fracture characteristics, represents a heterogeneous group of papers that cannot be combined to synthesize results. A review of the work is below.

Fracture classification Beaulé et al. reported on 65 cases of acetabulum fractures selected from a database, evaluated by three surgeons trained by Letournel (group 1), three acetabular specialists (group 2), and three general trauma surgeons (group 3). The interobserver reliability without and with CT during the first session was 0.70 and 0.74,

respectively, for group 1, 0.71 and 0.69 for group 2, and 0.51 and 0.51 for group 3. The overall agreement of the radiographic observation with the fracture pattern observed at surgery was 74%.¹²

Ohashi et al. reported on 101 sets of imaging reviewed by 2 musculoskeletal radiologists, first multiplanar CT followed by standard radiographs. Interobserver agreement on Letournel classification with plain films was 0.42, and 0.70 with reformatted and axial CT scans. Standard Judet films resulted in a change in classification in one case for each observer.¹³

Hufner et al. found an improvement in “correct diagnosis” of fracture type in plain films vs. 2-D CT scan 10 trainees (11–30%) 10 junior attendings (32–55%) and 10 acetabular experts (61–76%) in the review of 10 cases. The use of 3-D CT reformats increased this diagnosis rate to 65%, 64%, and 83% respectively. The diagnosis rate of additional lesions was universally based on CT (marginal impaction, head fractures, etc.), and was accurate vs. intraoperative findings in 73% of cases by acetabular experts.¹⁴

Fracture characteristics Borrelli et al. reported on 20 operatively treated acetabular fractures, and performed standardized assessment of step and gap at the articular surface using three observers (a senior resident, a junior resident, and a traumatologist). Compared to CT scan, plain films showed a sensitivity of 25% in detecting step deformity overall, and a sensitivity of 0% in fractures involving a single column of the acetabulum.¹⁵

Lang et al. used 12 sets of imaging and 3 independent observers to compare plain films and CT scans in quantifying fracture gaps, using a nonstandardized and a standardized method. The kappa statistic for interobserver (0.30 vs. 0.27) and intraobserver (0.43 vs. 0.36) agreements were superior for CT scans vs. radiographs.¹⁶

St. Pierre et al. used 67 consecutive cases, and evaluated the classification of fracture type as well as the presence of additional lesions. Although the CT information resulted in the alteration of classification in one case, the treatment plan was altered in 28 cases secondary to intra-articular fragments (20) and articular impaction (8).¹⁷

Recommendations

In surgical planning for acetabular fractures:

- While neither form of imaging is perfect when intraoperative findings are used as the gold standard, CT scan appears to offer little additional information over three plain film views in acetabular fracture classification [overall quality: moderate]
- The importance of CT in appropriate fracture classification appears to be inversely related to level of experience in acetabular fracture surgery [overall quality: moderate]
- CT imaging of acetabulum fractures is necessary to delineate additional fracture features such as impaction,

articular gap and step, and intra-articular loose bodies [overall quality: moderate]

Question 2: What are the indications for surgical management of acetabulum fractures in a young person?

Case clarification

The patient's CT scan confirms an associated both column fracture, with displacement visible on many of the CT scan cuts. You need to explain clearly to the trainees working with you what the absolute indications are for surgical treatment of acetabulum fractures are with patients this age, and apply them to this case.

Surgical indications are considered based on demand as well as life expectancy of the patient. "Young person" in this context refers to a patient in whom preservation of the native hip joint is very important.

Relevance

The decision to intervene in order to provide reduction and fixation of an acetabular fracture is one that needs to be made in the acute phase, as the results from delayed reconstruction revision of late malunions are far inferior to acute anatomic open reduction and internal fixation (ORIF).¹⁸⁻²⁰ Although a significant number of biomechanical and cadaveric studies are available to help guide clinical decision-making, solid clinical evidence has been more difficult to gather in these uncommon and complex injuries.²¹⁻²⁴

Current opinion

Articular displacement of greater than 3 mm, nonconcentric reduction of the hip joint (incongruence), and instability of the hip joint are indications for surgical management.

Finding the evidence

- Cochrane Database, with search term: "acetabulum fracture"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "acetabulum" and "acetabular"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "acetabulum fracture OR acetabular fracture" AND "surgery"
- MEDLINE search keywords: "acetabulum fracture" or "acetabular fracture" AND "surgery"

Quality of the evidence

Level III

- 4 case-control studies

Level IV

- 2 case series

Findings

Much of what guides current standards of care is based largely on retrospective case series, retrospective comparative studies, and expert opinion in these rare injuries. Although much of the evidence is of low quality by today's standards, the most compelling of it has been included below.

Displacement Matta et al. described follow-up in a retrospective case series of 64 patients, with 21 nonoperatively treated cases (traction) and 43 operatively treated cases. Overall, there were 24% good or excellent clinical results in the nonoperative group and 40% in the operative group (author generated outcome measure and radiographic measurement technique). They found 91% good or excellent clinical results in all patients with less than 3mm displacement at the weightbearing dome and congruence of the femoral head (all operative $p < 0.001$).²⁵

Recently, a series of nonoperatively treated displaced acetabulum fractures involving the weightbearing dome were reported at 2 years after injury. In these patients treated in traction, 18/32 were considered to have an adequate reduction in traction (≤ 3 mm), and 14 were considered inadequate. Those with an adequate reduction had 77.8% good or excellent results rated by the Aubigné score, and the inadequate reductions had 14.3% good or excellent results.²⁶

Incongruence In the often cited series by Rowe et al., which pre-dates the classification by Letournel, the idea of the importance of the weightbearing dome as an indication was coined. Displacement at the superior dome resulting in incongruence universally produced poor or fair radiographic and clinical outcomes exclusively in fractures involving the weightbearing dome.²⁷

In the same series described above, Matta et al. delineated the "roof arc angle" as an assessment for risk for loss of congruence. The roof arc angle is measured from the geometric center of the acetabulum to the fracture line. Matta pointed out that it can be indicated by fracture displacement, but that loss of congruence between the weightbearing dome and femoral head carries special significance. In the series of 64 patients, subluxation occurred in 69% of cases with a medial roof arc of 30° or less.²⁵

Olson and Matta again addressed the issue of roof arc measurements, and operative indications, with CT scan in 1993. This measurement does not apply to associated both column and posterior wall fractures. They describe the 10mm of axial cuts caudad to the roof of the acetabulum as being intact equivalent to a roof arc measurement of greater than 45°. They report 82% good or excellent results overall when using these criteria to decide operative vs. nonoperative treatment.²⁸

Instability Calkins et al. described the acetabular fracture index (percentage of intact acetabulum remaining) in posterior wall fractures as an assessment of stability in 31 patients. All hips with less than 34% remaining intact were unstable, and all those with 55% or greater were stable. Seven out of ten unstable hips showed at least 0.5mm of subluxation on axial CT scan.²⁹

Tornetta reported his experience with the use of dynamic stress views under anesthetic in all acetabulum patients meeting criteria for nonoperative management (roof arc angles of at least 45°, subchondral CT arc of 10mm, and displacement of less than 50% in posterior wall fractures). Of 41 patients, one had a transverse fracture with a posterior dislocation and a roof arc measurement of 45°, and two were posterior wall fractures (one with a dislocation involving 15% of the surface, one without dislocation involving 33% of the articular surface).³⁰

Recommendations

In surgical planning for acetabular fractures:

- Displacement is poorly tolerated in the weightbearing dome, and greater than 3mm is a relative operative indication [overall quality: low]
- Incongruence at the hip joint is an indication for surgical reduction in acetabulum fractures, and can be predicted by the roof arc angle [overall quality: low]
- Clinical series support cadaveric data that instability in posterior wall fractures is predicted by greater than 50% involvement, and dynamic testing can offer additional information in those with 25–50% involvement. [overall quality: low]

Question 3: What are the treatment options in elderly patients?

Case clarification

The patient was working on the roof of a private home when he fell. During the commotion of the incident, and the arrival of the ambulance, the owner of the home lost his footing, and fell 2ft (0.6m) from a step, landing on his side. He also suffered an acetabulum fracture, which appears to be a T-type, and has similar displacement and incongruence to the 26 year old, but more comminution. This patient is 78 years old, has a history of coronary artery disease and type 2 diabetes mellitus, and two low-energy fractures in the last two years. You need to consider the options for this very different patient subgroup, and apply them to this case.

Injuries in this “elderly” age group bring up important issues and goals. Decreased bone density, medical comorbidity, surgical morbidity, and life expectancy all play a role.

Relevance

In the treatment of injuries in the elderly patient one has to consider and balance the risks involved. It has been clearly outlined in the hip fracture literature that treatment with bed rest and surgical delay can be very dangerous in elderly patients, and efforts to facilitate early mobilization in these patients should therefore be made.^{31–33} In addition, bone quality in this population can be poor, and physiologic reserve for prolonged surgery may also be poor. Consideration of the entire patient, not just the acetabular injury, is paramount.

Current opinion

The options for treatment of acetabulum fractures in elderly patients include nonoperative management, ORIF, acute total hip replacement, and delayed total hip replacement.

Finding the evidence

- Cochrane Database, with search term “acetabul\$ fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “acetabulum” and “acetabular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “acetabulum fracture OR acetabular fracture” AND “treatment”
- MEDLINE search keywords: “acetabulum fracture” or “acetabular fracture” AND “treatment”

Quality of the evidence

Level III

- 3 case control studies

Level IV

- 4 case series

Findings

Conservative management Spencer reported on 25 acetabular fractures treated in traction in patients over 65 years of age. Of 23 survivors, 7 had an unacceptable functional result (able to walk only with severe pain).³⁴

ORIF Anglen et al. reported on a retrospective series of 48 patients over 60 years of age with an operatively treated acetabulum fracture. They reported 60% good or excellent radiographic results, and 40% fair, poor or, early arthroplasty. Ten patients were found to have superomedial impaction at the time of injury (Gull sign) and all had a fair or poor radiographic result. However, the functional outcomes of the group overall based on the Short Form 36 (SF-36) and Short Musculoskeletal Function Assessment (SMFA) were within a standard deviation of population age-matched norms.³⁵

Helfet et al. reported a series of 18 patients 60 or older treated with ORIF. He reported concentric reductions in all articular gap up to 3 mm. One patient had an early failure, and the remainder had Harris hip scores (HHS) of more than 90 at 2 years follow-up.³⁶

Early total hip replacement Mears et al. published a series of 57 patients with a mean age of 69 years treated with acute total hip replacement for severely displaced acetabulum fractures. The mean HHS at 2–12 year follow-up was 89, with 79% of patients having good or excellent results (level IV).³⁷

A series of 121 acetabular fractures by Sermon et al. published in 2008 were all treated with total hip replacement. These were 64 in the acute setting, and for failed primary treatment in 57 cases. The former group had a mean age of 78, and the later was 53. There was no statistical difference in HHS, but the primary group had a lower heterotopic ossification rate (28 vs. 41%) and revision rate (8 vs. 22%).³⁸

Late total hip replacement Weber et al. reported on the Mayo clinic experience in 66 total hip replacements following ORIF for acetabular fracture, although the age group was diverse, and the results of the patients over 60 were not reported separately. The 10 year survival of the components was 78%, with age being protective for need for revision.³⁹

Bellabarba compared post-traumatic arthritis treated with late total hip replacement in 30 patients to a matched cohort treated for nontraumatic osteoarthritis. The clinical results were similar, with a HHS of 88 vs. 90. Similarly, the survival of the acetabular component at 10 years was 97% (vs. 99% for the nontraumatic group).⁴⁰

Recommendation

- Management of acetabulum fractures in elderly patients requires careful consideration of patient demands and risk of surgery. Reasonable functional results after operative treatment can be obtained with ORIF, early arthroplasty, and delayed arthroplasty [overall quality: low]

Question 4: What are the optimal DVT/PE prophylaxis and screening in patients with acetabulum fractures?

Case clarification

The 26 year old patient was taken to the operating room on postinjury day 2 and underwent ORIF of the acetabulum fracture through an extensile approach. Postoperatively, you wish to make an evidence-based decision about the use of prophylaxis or screening for DVT and/or PE.

DVT is the development of a blood clot in the veins of the leg, an event that trauma patients in general are at risk for. The propagation of these clots to the arteries is a significant cause of death in otherwise healthy trauma patients.

Relevance

Pelvic and acetabulum fractures are a few of the previously identified risk factors for embolic complications among trauma patients.^{41–43} The identification of potential risk factors for venous thromboembolism has not solved the issue of prevention. Several strategies are in practice to prevent and detect venous thrombosis, and their effectiveness has been evaluated in other populations. The American College of Chest Physicians (ACCP) provides the most comprehensive thromboprophylaxis guidelines, but very few recommendations were directed toward the prophylaxis of trauma patients—specifically, patients with pelvic or acetabular fracture.⁴⁴ For major trauma patients, the ACCP authors recommend the routine use of low molecular weight heparin (LMWH) (grade 1A) or the use of mechanical prophylaxis alone if LMWH is contraindicated (grade 1B). They recommend against the routine use of duplex ultrasound for screening for asymptomatic DVT (grade 1B); however, screening of high-risk patients (including those with pelvic fractures) who had received suboptimal or no prophylaxis received a grade 1C recommendation. They also recommend against the use of inferior vena cava (IVC) filters as a method of prophylaxis (grade 1C).

Current opinion

Pelvic and acetabulum fracture patients should be receiving prophylaxis with LMWH when possible and otherwise with mechanical compression devices. Many centers routinely use IVC filters, as well as screening protocols.

Finding the evidence

- Cochrane Database, with search term “acetabulum fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “acetabulum” and “acetabular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “acetabulum fracture OR acetabular fracture” AND “thromboembolism”
- MEDLINE search keywords: “acetabulum fracture” or “acetabular fracture” AND “thromboembolism”

Quality of the evidence

Level II

- 1 systematic reviews² of 11 level II studies or level I studies with inconsistent results

Findings

Systematic reviews Slobogean et al. published a systematic review of the literature on this topic in 2009, with a goal of outlining practice guidelines. They found 11 studies with 1760 cases that met inclusion criteria, in the categories of mechanical compression, LMWH, IVC filters, ultrasound

screening, and magnetic resonance venography screening. Quantitative pooling was not possible due to heterogeneity, and only LMWH demonstrated a clear reduction in DVT and PE.⁴⁵ The studies included in this review are summarized in Table 69.1.

Recommendation

- The recommendations of the ACCP chest guidelines for trauma patients in the use of LMWH are supported in pelvis and acetabulum fractures [overall quality: moderate]

Question 5: What is the optimal HO prophylaxis in patients with acetabulum fractures?

Case clarification

In addition to the postoperative decision about DVT prophylaxis, the trainees want to know if you plan to use either nonsteroidal anti-inflammatories (NSAIDs) or irradiation for prophylaxis against HO.

Relevance

The occurrence of, and subsequent surgical treatment of, acetabular fractures is known to be associated with HO. Although there have been reports of increasing risk with increasingly extensile approaches, the relationship between approach and HO is unclear.⁵⁷⁻⁶⁰ Disabling forms of the condition occur in nonoperatively treated patients, but much more commonly in operatively treated patients. A meta-analysis finds the rate in operatively treated cases to be 25.6%.⁶¹ The two widely accepted methods of prophylaxis for this are irradiation and indomethacin treatment. Both have disadvantages—burden, transport, and cost for irradiation; bleeding, gastrointestinal complications, and nonunion for NSAIDs.^{62,63}

Current opinion

There is no difference between indomethacin and irradiation in the prevention of HO in acetabular fractures, and choice is based on surgeon preference.

Finding the evidence

- Cochrane Database, with search term: “acetabulum fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “acetabulum” and “acetabular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) -sensitivity search using keywords “acetabulum fracture OR acetabular fracture” AND “heterotopic ossification”
- MEDLINE search keywords: “acetabulum fracture” or “acetabular fracture” AND “heterotopic ossification”

Quality of the evidence

Level I

- 1 high-quality randomized controlled trial (RCT)

Level II

- 4 systematic reviews² of 3 level II studies or level I studies with inconsistent results

Findings

Systematic review Blokhuis et al. published a systematic review in 2009, evaluating all RCTs comparing these treatments either to each other, or no treatment. With synthesis of data, they found a rate of 5/160 in those treated with irradiation, and 20/224 in those treated with indomethacin ($p = 0.034$).⁶⁴⁻⁶⁸

Indomethacin Karunakar et al. published the only level I study in the above reviewed systematic review. They compared the rate of HO with indomethacin vs. placebo after a posterior approach to the acetabulum. They found no significant difference ($p = 0.722$) with Brooker III or IV in 9/59 indomethacin patients and 12/62 placebo patients.^{67,69}

Irradiation Childs et al. reported on a prospective series of 152 patients irradiated on day 1, 2, or 3. They found no statistically significant increase in HO with delay of up to 3 days in treatment. They also compared their prospective series to a retrospective cohort, and found a rate of 5.3% in those treated with radiation, and 60% in those treated without it.

Recommendation

- Irradiation is superior to indomethacin in the prevention of HO in surgically treated acetabulum fractures [overall quality: moderate]

Question 6: What is the expected long-term functional outcome in acetabulum fractures?

Case clarification

When the patient returns to your clinic 2 weeks after the surgery, he wants some clarification of what he can expect as a functional result from this injury and surgery.

Functional outcomes were classically surgeon generated, and reported as “good” or “fair” as we would in natural dialogue. In an effort to move toward the scientific, modern reports of outcomes involve the use of “outcome instruments” designed to collect relevant data and provide an “objective” basis for outcome reporting.

Relevance

Historically, the endpoint of orthopedic studies, or outcome reported, was radiographic. Over time, it was apparent that

radiographic outcome did not necessarily correspond to how patients actually felt. As such, authors began reporting functional result as reported by patients. In its most basic form, this is a simple author-generated outcome. In an attempt to move away from this to more objective measures, it is now considered standard practice to report some type of patient-reported validated functional instrument. For the hip joint, these can be generic or specific.⁷⁰ Most commonly in medicine overall, generic outcome is measured using the SF-36.⁷¹ In orthopedics, generic musculoskeletal function is often measured using the SMFA.⁷² In the hip specifically, the most common outcome measures reported for acetabulum fractures have been the HHS (pain, function deformity, and range of motion) and the Merle d'Aubigné-Postel hip score (pain, mobility, ability to walk). Both of these were designed for hip arthroplasty patients, and neither has been validated for the acetabulum fracture population.^{70,73,74}

Current opinion

The majority of patients attain good to excellent functional results after acetabulum fracture with appropriate treatment.

Level III

- 4 studies

Findings

Systematic review In 2005, Giannoudis et al. published a systematic review of displaced acetabulum fractures in adults, treated within 4 weeks, with a follow-up of at least 12 weeks. They reviewed 160 articles, and included 34 with 3639 patients.⁶¹ These were 5 prospective and 29 retrospective reviews; 16 of these studies reported functional outcome based on Merle d'Aubigné score (1610), and 5 reported functional outcome using the HHS (600). Using the former, a good or excellent clinical result was reported 79.4% of the time. With the HHS, a good

Table 69.2 Systematic review of displaced acetabulum fractures

	Satisfactory reduction Patients (%)	Unsatisfactory reduction Patients (%)
Merle d'Aubigné score		
Excellent	543 (62.4)	53 (48.2)
Good	203 (23.4)	28 (25.4)
Fair	46 (5.3)	11 (10.0)
Poor	77 (8.9)	18 (16.4)
Harris hip score		
Excellent	52 (56.5)	3 (18.8)
Good	26 (28.3)	1 (6.2)
Fair	4 (4.3)	4 (25.0)
Poor	10 (10.9)	8 (50.0)

Satisfactory, ≤ 2 mm; unsatisfactory, > 2 mm.

or excellent functional outcome was reported 73.2% of the time. There was a correlation between outcome and radiographic outcome, when considering postoperative displacement of 2 mm or less as satisfactory (Table 69.2).

Individual reports Matta published his often cited prospective series in the *Journal of Bone and Joint Surgery* in 1996.³ He reported on 262 displaced acetabulum fractures in 259 patients. Using the Merle d'Aubigné score for clinical outcome, he reported 76% good or excellent results, fair in 8%, and poor in 6%. There was a statistically significant relationship between quality of reduction (excellent, good, fair, poor) and quality of clinical outcome (excellent, good, fair, poor).

Since the publication of the meta-analysis in 2005, there have been several additional reports. Ovre et al. presented a prospective cohort of 176 fractures in 2008.⁷⁵ They reported a mean modified HHS of 99.9 (good). A multiple regression analysis was performed to delineate the independent relationship between articular step, articular gap, and roof arc angle. The strongest predictor was roof arc score ($p = 0.02$), and there was no relationship between diastasis and HHS. Articular step of 2 mm approached clinical significance ($p = 0.08$).

Moed et al. published two series in the *Journal of Bone and Joint Surgery* (American volume) highlighting weaknesses in currently used functional outcome scores for these injuries. In 2003, a series of 150 patients with all types of acetabulum fractures treated with surgery.⁷⁶ In this series they reported a modified Merle d'Aubigné score of 16.8 (good–excellent) and a SMFA of 24.9. There was a significant ceiling effect with the former. Despite good correlation, the SMFA score were significantly worse than population norms ($p < 0.001$), indicating that the Merle d'Aubigné score may not be capturing the functional level

in these patients. This performance of the Merle d'Aubigné score was reiterated in 2007 with a series of 46 patients, in whom the Merle score was 17 (good–excellent) and the SMFA was 23.17.⁷⁷ Again here, there was a ceiling effect in the merle score, and a failure of this score to capture loss of function as captured on the SMFA.

In 2006, Kreder et al. described a series of simple posterior wall fractures compared to associated patterns with posterior wall fractures (128 patients);⁷⁸ 84 of these had functional outcome follow-up with SF-36 and SMFA. The mean SMFA score was 35.75 for the group overall, and was significantly worse in the associated patterns ($p = 0.036$). The mean scores in all SF-36 domains were worse than matched population norms ($p < 0.001$). There was a trend to worse functional outcome with residual displacement of greater than 2 mm ($0.05 > p < 0.08$).

Recommendations

- Despite largely good–excellent clinical scores on frequently used hip-related outcome measures reported, expected general functional outcome after acetabulum fracture is below population age matched norms [overall quality: moderate]
- Complexity of fracture and quality of reduction are important predictors of functional outcome [overall quality: moderate]

Question 7: What are the important non-surgeon-related factors that determine prognosis in acetabulum fractures?

Case clarification

Your patient continues to have some pain and disability after 6 months, and has been unable to return to his previous employment. There is a subtle loss of joint space on plain films, and a diagnostic local anesthetic block of the hip confirms that his hip joint is the source of his pain. The trainees ask whether this outcome could have been predicted in this patient.

A diagnostic block with local anaesthetic involves injection of local anaesthetic into a particular anatomic space, and subsequent evaluation of the patient's symptoms. Resolution of symptoms indicates that the area is the source of the pain.

Relevance

As early as Rowe's review in 1961, it was becoming very apparent that there were particular factors that were important in determining patient outcomes in acetabulum fractures.²⁷ Those with articular cartilage damage, older patients with poor bone quality, more severe fractures, appear to be less likely to have a favorable outcome.^{1,4,5} However, as with many areas of orthopedic surgery, this

opinion has been largely based on expert opinion and experience, with scientific evidence being a more recent development.

Current opinion

Age, fracture type, damage to the femoral head, marginal impaction, and posterior dislocation are all important factors in determining outcome in acetabulum fractures, regardless of the quality of surgical reduction.

Level III

- 4 studies

Findings

Age Matta's series reported 81 percent good or excellent results in those less than 40, and 68% good or excellent results in those over 40 ($p = 0.02$).³ This same age cut-off used to create a binary age variable was found to be statistically significant by Liebergall et al. in their review of 60 patients.⁷⁹

Murphy et al.'s paper in injury in 2003 was aimed at determining the importance of prognostic factors on outcome (Merle d'Aubigné) using a logistic regression models in 201 patients. An increase in age of 1 year was associated with an odds ratio of having a worse outcome of 1.02 per year of increase in age ($p = 0.036$). Put simply, this means that even an increase in 1 year in age is statistically significant.⁸⁰

Fracture type The Giannoudis et al. systematic review addressed the issue of fracture type (Table 69.3). Seven of the included studies with 906 patients correlated the results of the Merle d'Aubigné score with the Letournel fracture classification. The worst outcomes were seen in fractures of the anterior wall (16 patients) and of the posterior column (27 patients) with 48% and 37% fair and poor results, respectively. The best prognostic fracture types were anterior column and transverse fractures with nearly 90%

PC	27	2.7	63.0	37.0
Anterior wall	16	1.7	56.2	47.8
AC	37	4.0	89.2	10.8
Transverse	51	5.6	86.3	13.7
All simple fracture types	335	36.6	80.9	19.1
T-shaped	128	14.0	71.1	28.9
PC–PW	47	5.1	83.0	17.0
Transverse–PW	136	14.8	71.3	28.7
AC–posterior hemitransverse	43	4.7	72.1	27.9
Associated both columns	227	24.8	71.4	28.6
All associated fracture types	581	63.4	72.3	27.7

AC, anterior column; PC, posterior column; PW, posterior wall.

of excellent and good results. As a group simple fractures showed a better functional outcome than associated fractures, with 80.9% and 72.3%, excellent and good results respectively ($p = 0.07$).⁶¹

Femoral head damage Liebergall's study outlined above found damage to the femoral head to be the strongest predictor of poor outcome, with only 35.7% of patients in the series with femoral head damage having a favorable outcome ($p = 0.001$).⁷⁹

In a review of the experience with the T-extensile modified extended iliofemoral approach, Starr et al.⁸¹ reported 14/43 "failures" with a HHS of less than 70, or total hip replacement. Ten of these patients had femoral head damage at surgery, one had known osteoarthritis, and in two the capsule was not opened. Only one patient with a poor outcome had visibly normal cartilage at surgery ($p = 0.004$).⁸¹

Dislocation Giannoudis's meta-analysis also addressed avascular necrosis (AVN) and posterior dislocation. In 18 studies with 2010 patients, the overall AVN rate was 5.6%. In patients with a posterior dislocation, this rate was 9.2% (28/303). This was statistically higher than the 5% in

those without posterior dislocation in the meta-analysis (85/1707) ($p = 0.003$).⁶¹

Moed et al. described the outcome of 108 fracture dislocation of the hip with posterior wall fractures 2 years from surgery, using the Merle d'Aubigné–Postel hip score. They found a highly significant relationship between time to reduction and fair/poor outcomes, with a progressively worse outcome at 12 hours, 12–24 hours and more than 24 hours ($p < 0.0001$). Of the 10 patients who had a poor result in this study, 5 had delayed reduction and development of osteonecrosis.⁷⁷

Recommendations

- Younger patients have a more favorable prognosis in acetabulum fractures [overall quality: moderate]
- With a few exceptions of rare simple fracture types, the prognosis of simple fractures is better than that of complex fracture types [overall quality: moderate]
- Femoral head damage is a poor prognostic indicator in acetabulum fractures [overall quality: moderate]
- The presence of posterior dislocation increases risk of AVN. Reduction should be performed as soon as possible [overall quality: moderate]

Summary of recommendations

Openmirrors.com can appear to offer little additional information over three plain film views in acetabular fracture classification, and is inversely related to level of experience in acetabular fracture surgery

- CT scan imaging of acetabulum fractures is necessary to delineate additional fracture features such as impaction, articular gap and step, and intra-articular loose bodies
- Displacement is poorly tolerated in the weightbearing dome, and greater than 3mm is a relative operative indication
- Incongruence at the hip joint is an indication for surgical reduction in acetabulum fractures, and can be predicted by the roof arc angle
- Clinical series support cadaveric data that instability in posterior wall fractures is predicted by greater than 50% involvement, and dynamic testing can offer additional information in those with 25–50% involvement
- In elderly patients, reasonable functional results after operative treatment can be obtained with open reduction and internal fixation, early arthroplasty, and delayed arthroplasty
- The recommendations of the ACCP chest guidelines for trauma patients in the use of LMWH for thromboprophylaxis are supported in pelvis and acetabulum fractures
- Irradiation is superior to indomethacin in the prevention of HO in surgically treated acetabulum fractures

- Despite largely good–excellent clinical scores on frequently used hip related outcome measures reported, expected general functional outcome after acetabulum fracture is below population age-matched norms
- Complexity of fracture and quality of reduction are important predictors of functional outcome
- Younger patients have a more favorable prognosis in acetabulum fractures
- With a few exceptions of rare simple fracture types, the prognosis of simple fractures is better than that of complex fracture types
- Femoral head damage is a poor prognostic indicator in acetabulum fractures
- The presence of posterior dislocation increases risk of AVN. Reduction should be performed as soon as possible

Case scenario

A 28 year old man is involved in a serious motorcycle accident. His injuries include a closed head injury, an anterior-posterior compression (APC) type 1 pelvic ring injury, and an open comminuted tibial shaft fracture with associated fibula fracture. He is intubated in the trauma bay and is actively undergoing resuscitation. His distal pulses are normal and he has adequate capillary refill.

Openmirrors.com

Relevant anatomy

An “open” fracture involves any injury pattern in which a breach in the soft tissue envelope has occurred, resulting in direct communication between the bone and the environment. Open fractures are more susceptible to wound infection or deeper bone infection, termed osteomyelitis. In general, the anatomic goal in open fracture care is to debride any nonviable tissue (including bone), while preserving as much of the perfused tissue as possible.

Open fractures are most commonly classified according to the Gustilo and Anderson system (see box), which considers wound size, fracture pattern, and degree of soft tissue compromise/contamination (level II, level III)^{1,2} The classification of open fractures accounts for both soft tissue and bone injury, and predicts eventual prognosis, including rates of infection (level II).¹ Open fracture classification

No grants or external sources of funding were used for this study. Authors report no conflicts of interest related to the subject matter.

can be estimated in the Emergency Department but should be definitively classified in the operating room once wound/fracture exploration and debridement have been completed.

Gustilo and Anderson classification of open fractures

- **Type I** Clean (minimally contaminated) wound smaller than 1 cm and simple fracture pattern; no skin crushing
- **Type II** Wound >1 cm but without significant soft tissue crushing; fracture pattern may be more complex but with minimal periosteal stripping
- **Type III** Segmental fracture or a single fracture with extensive soft tissue injury; subdivided into three subtypes:
 - **Type IIIA** Adequate soft tissue coverage of the fracture despite high-energy trauma or extensive soft tissue damage
 - **Type IIIB** Inadequate soft tissue coverage with periosteal stripping; requires soft tissue reconstruction
 - **Type IIIC** Open fracture associated with arterial injury requiring repair

Importance of the problem

Data from Europe demonstrate an approximate 4% rate of open fractures,^{3,4} which is likely similar to rates in other developed nations. As extrapolated in other reviews (level II),⁵ this amounts to approximately 3,400 open fractures in Canada or 250,000 open fractures in the United States every year.

Although much has been written about open fractures, very little of the literature is level I quality. Many of the

treatment recommendations that are ingrained in our everyday treatment of open fractures are based on retrospective data with low numbers of patients or simply on opinion-based literature.

Top five questions

1. What is the initial management of open fractures?
2. How soon does an open fracture need to get to the operating room?
3. What irrigation techniques afford the best results with open fractures?
4. Is there evidence for the use of negative pressure wound closure therapy (e.g., V.A.C.[®]) vs. antibiotic bead pouch placement in open fracture care?
5. What factors should be considered when performing a soft tissue closure in an open fracture?

Question 1: What is the initial management of open fractures?

Case clarification

The patient's tibia fracture is displaced and comminuted. The wound size is 10cm, and there appears to be some soft tissue loss. The wound is not grossly contaminated, but some foreign debris is noted.

Relevance

Initial management of the open fracture wound includes antibiotics, a sterile dressing, appropriate splinting, and tetanus toxoid administration.

Current opinion

Prompt antibiotic administration and a tetanus shot are priority. A sterile gauze dressing moistened with normal saline may be an appropriate choice for a wound dressing, accompanied by temporary skeletal stabilization for patient comfort.

Quality of the evidence

Level I

- 4 studies

Level II

- 5 studies

Level III

- 6 studies

Level IV

- 4 studies

Level V

- 1 study

Findings

Few articles on open fractures address the management of wounds in the field or Emergency Department. Simple debridement of any gross contamination is encouraged if possible, as well as direct pressure on active bleeding. Temporary splinting of any fracture is highly recommended. As experiments have suggested that antiseptics (such as povidone-iodine) may be toxic to the host cells (level V, level I),^{6,7} a gauze dressing moistened with normal saline may be the safest, least destructive choice for short-term coverage.

The administration of systemic antibiotics for open fractures has been the standard of care since 1974 (level I).⁸ A review by Gosselin et al. showed that antibiotics given for an open fracture reduces the infection risk by 59% (level III).⁹ The current antibiotic recommendations stem from the original Gustilo and Anderson articles,^{1,2} and no article since has challenged the basic antimicrobial approach, even with the plethora of broad-spectrum antibiotics now available. Several studies agree that the single most important factor in reducing infection is early administration of the appropriate antibiotics (level I–III).^{7–12} In current protocols a first-generation cephalosporin (usually cefazolin) is given for type I and II fractures, while an aminoglycoside (usually gentamicin) is often added for type III fractures. In a prospective randomized double-blind trial, Patzakis et al. showed that ciprofloxacin alone was as effective as cefamandole plus gentamicin for type I and II injuries but not as effective in type III injuries (level I).¹⁰ In wounds that are severely contaminated or have poor oxygenation (vascular injuries), penicillin is added for adequate anaerobic coverage (level II).¹

Some exceptions exist to the early antibiotic rule. For example, a randomized placebo-controlled trial found that flucloxacillin did not add to the prevention of infection in conjunction with routine treatment of open distal phalanx fractures with irrigation and debridement (level II).¹¹

Few articles give length of dosing recommendations for antibiotic therapy, although most surgeons agree that antibiotics should be continued for at least 24 hours after the final irrigation and debridement, similar to antibiotic prophylaxis recommendations for elective surgery (level I).¹²

Recommendations

Present recommendations for initial open fracture management are as follows [overall quality: moderate]:

- Systemic antibiotic administration is the most important factor in the initial management of open fractures
- A cephalosporin is appropriate for type I and II open fractures
- An aminoglycoside should be added for type III injuries and penicillin should be given for severely contaminated wounds
- Tetanus toxoid should be administered when appropriate
- A sterile dressing moistened with normal saline and temporary stabilization should be applied

Question 2: How soon does an open fracture need to get to the operating room?

Case clarification

The extremity is sterilely dressed and splinted. Appropriate antibiotics are administered, and a dose of tetanus toxoid is given. Full evaluation is completed by the trauma surgery team by midnight. The patient is hemodynamically and neurologically stable. The case is posted for surgery, but the operating room charge nurse reports that a room will not be available for at least 4–5 hours.

Relevance

As open fractures are at increased risk for infection, these injuries must be addressed promptly. However, the need for urgent surgical debridement must be balanced with the patient's overall physiological status, operating room availability, and reasonable demands on the surgeon.

Current opinion

Open fractures were long considered orthopedic emergencies requiring immediate debridement and fixation. Many trauma centers now reserve an operating room dedicated to orthopedic trauma. This room affords time for adequate patient workup and resuscitation, and allows the surgeon to operate during daytime hours with well-trained surgical support staff. More recent evidence supports the notion that many late-night open fractures can wait until morning with no increased risk to the patient (see below).

Quality of the evidence

Level II

- 5 studies

Level III

- 2 studies

Level V

- 1 study

Findings

Based on the Gustilo–Anderson articles, open fractures have been considered emergent cases that need to be operatively debrided within 6 hours of injury. Time to initial surgical debridement—the traditional “6 hour rule”—is rooted in both historical animal studies (level V)¹³ and more modern microbiologic analysis citing a theoretical open-fracture inoculum of 10^5 organisms (level II).¹⁴ Only one recent human study supports the idea of debriding open fractures within 6 hours of injury; Kindsfater and Jonassen reviewed 47 high-energy open tibial fractures and found a significant increase in infection rate in fractures that were delayed greater than 5 hours (level III).¹⁵ On the contrary, many are skeptical, based on the limited data, over the improved long-term outcomes with surgical intervention within 6 hours of injury (level II),¹⁶ and some have even suggested that no debridement is necessary for isolated type I open injuries (level III).¹⁷ The literature refuting the “the 6 hour rule” is summarized by Crowley et al. in their review article (level II).¹⁸ Pollak concluded in a review article that, within the modern era of antibiotics, timing to debridement is not an independent predictor of postinjury infection (level II).¹⁹ He later demonstrated, in a 2010 paper based on data from the Lower Extremity Assessment Program (LEAP), that there was no difference in development of infection outcomes when debridement occurred within the first 24 hours (level II).²⁰ This is the current thought process most often adopted at most level 1 trauma centers.

Recommendations

Present recommendations for timing of open fracture management are as follows [overall quality: high]:

- The patient should not be taken to the operating room until medically stabilized
- If possible, the patient should be taken to the operating room within 24 hours of injury

Question 3: What irrigation techniques afford the best results with open fractures?

Case clarification

The patient is admitted to the intensive care unit, resuscitation is continued, and the patient is scheduled to be first case in the dedicated trauma operating room. He goes to the operating room at 7:30 a.m. for irrigation and debridement of the open wound and stabilization of his tibial shaft fracture.

Relevance

The need for surgical debridement of open fractures to prevent infection is well established. Along with antimicrobial chemoprophylaxis and treatment, irrigation must be employed to decrease bacterial cell counts and to flush foreign matter and microorganisms from the wound.

Current opinion

Specific variables associated with the irrigation of open fractures remain controversial, including volume of irrigation, pressure of lavage, type of diluents, and any additional additives to lavage solution.

Quality of the evidence*Level I*

- 1 study

Level II

- 2 studies

Level III

- 1 study

Level IV

- 13 studies

Level V

- 17 studies

Findings

No consensus currently exists for the choice of irrigation solution or method of administration during the initial or subsequent procedures. A recent international survey found 70.5% of respondents favored normal saline as an irrigation solution, 71% of surgeons used low-pressure systems, and only 1.3% of the surgeons routinely used a soap additive (level V).²¹ Experimental data suggest some toxicity to the host cells from antiseptic solutions. Other concerns for solutions other than normal saline include allergic reactions, additional cost, promotion of resistance, and unproven efficacy.

Volume of irrigation The volume of solution used to irrigate a wound after adequate debridement has not been studied in humans, but is somewhat rooted in tradition (level II).⁵ One animal study showed increased bacterial removal with increased volume of irrigation but the correlation plateaued for normal saline alone (level V).²² The traditionally accepted minimum volume is 3 L for type I, 6 L for type II, and 9 L for type III injuries.

Irrigation additives The efficacy of antiseptic additives in eliminating bacterial loads must be weighed against the potentially toxic side effects to normal host cells in the wound bed. For example, although povidone-iodine solution has demonstrated efficacy in reducing infection in surgical wounds (level 2),²³ undiluted povidone-iodine is toxic to bone cells (level V).⁶ Furthermore, there is continued concern over local antibiotic resistance (level II)²⁴ and anaphylactic reactions (level IV).^{25,26} Bhandari et al. showed cell density decrease in vitro with solutions of 10% ethanol, 10% povidone-iodine, 10% antimicrobial wash, and 4% chlorhexidine gluconate (level V).²⁷ He found the only solutions that did not significantly decrease cell count were soap solution and normal saline alone.

Animal models have shown that irrigation with an antibiotic reduces the rate of infection compared with the use of saline solution alone (level II, level V).²⁸⁻³⁰

Anglen reported the results of a prospective randomized controlled trial of 398 lower extremity open fractures comparing castile soap with bacitracin solution (level I).³¹ Despite equivalent infection and bone-healing rates, bacitracin was more problematic in terms of wound-healing issues (9.5% vs. 4%; $p = 0.03$). Although this study provides some support for soap as the irrigation solution, it was a single-surgeon, single-site study with a relatively small sample size. Soap solutions were more effective than normal saline in removing bacteria from stainless steel screws, while antibiotic solutions showed no advantage ($p > 0.05$) (level II).²⁸

Other potential additives not systematically studied in well-controlled controls include hydrogen peroxide, hexachlorophene (pHisoHex[®]), sodium hypochlorite (Dakin's solution), benzalkonium chloride (Zephiran[®]), and various alcohol-containing solutions (level I).⁸

Method of irrigation delivery Multiple studies have promoted the superior mechanical properties of high-pressure irrigation, while many others have addressed the more tissue-friendly approach of low-pressure methods. While high-pressure lavage systems may be more effective in reducing bacterial cell counts and protective biofilm barriers (level V, level V),^{32,33} macro- and microscopic damage to both host soft tissues and bone occurs (level V)³⁴⁻³⁶ and may result in deeper seeding of bacterial colonies (level V).^{37,38} This data is limited by lack of human in-vivo testing

of lavage systems. In general, the bulk of experimental evidence suggests an inverse relationship between efficacy of removal of contamination and potential tissue damage with the various methods of wound irrigation.

While the pendulum has swung towards lower-pressure lavage systems, newer innovations, such as the Versajet™ claim to provide controlled surgical debridement of tissues.³⁹ A purported Venturi effect creates a local vacuum on the surface of the debridement area. Recent studies have suggested that it produces a lower bacterial load in burns (level IV).^{40,41} Manufacturers claim that it also prevents the diffusion of microbial contamination deeper into the wound. While applied to total joint infections and wound care, the Versajet system has yet to be systematically tested in the debridement of open fractures. Other techniques, such as tissue sonication to break up bacterial glycolyx, are still relatively nascent technologies.

Recommendations

There is a clear lack of well-controlled human clinical studies to guide clinical practice recommendations (level II, level V),^{24,42} despite decades of interest in systemic, local, and topical antibiotic wound prophylaxis (level III, level II).^{43,44} Practicing orthopedic surgeons' opinions are clearly mixed, as demonstrated in the aforementioned survey, and rightly so, based on the inconclusive literature. The Fluid Lavage of Open Wounds (FLOW) study is an ongoing, multicenter study comparing multiple variables (normal saline with or without castile soap, and high-pressure vs. low-pressure vs. gravity flow) in a prospective randomized fashion.

Recommendations

Present recommendations for open fracture management are as follows [overall quality: moderate]:

- normal saline irrigation solution
- low-pressure (generally less than 50 psi, 345 kPa) lavage system
- additives have not demonstrated clear benefit and have additional risks to host tissue

Question 4: Is there evidence for the use of negative pressure wound closure therapy (e.g., V.A.C.) vs. antibiotic bead pouch placement in open fracture care?

Case clarification

After initial debridement of nonviable and highly contaminated soft tissue in the wound bed, a large soft tissue defect remains. The surgeon has performed stabilization of the patient's tibial shaft fracture with an external fixation device and has a discussion with his surgical colleagues, the patient, and his family regarding options for eventual wound coverage.

Relevance

Temporary coverage for wounds between procedures can include a simple mesh-gauze dressing, an antibiotic bead pouch, or negative pressure therapy. The use of negative pressure wound closure therapy (NPWCT) has gained momentum since its inception and routine clinical use in the early 1990s (level V),⁴⁵ with early applications for both soft tissue closure due to trauma and in secondary wound coverage after debridement for infection (level V, level III).^{34,46}

Negative pressure wound closure therapy

Use of a sponge or foam placed over the wound bed connected to a closed suction system or vacuum device.

Antibiotic bead pouch

Polymethylmethacrylate (PMMA, a cement) mixed with powdered antibiotics; beads are fashioned while the cement is still in a doughy consistency. These beads are usually strung along a heavy suture or 24-gauge wire in a string-of-pearls configuration. The bead string or pouch may then be placed directly into the wound. Example ratio of antibiotics to cement: 3.6 g tobramycin to 40 g PMMA.

Current opinion

Negative pressure therapy and antibiotic bead pouches have proven to be effective in managing the initial soft tissue defects after high-energy injuries. Use of vacuum therapy vs. antibiotic beads may be surgeon- or institutional-based; no well-designed (level I) studies have directly compared these two treatment modalities, and there is limited data—often anecdotal evidence based on small case series—for combined modalities of therapy.

Findings

Negative pressure wound therapy Several reports have documented favorable results with the use of NPWCT, also known as vacuum-assisted closure (after the brand-name device V.A.C.,[®] in the management of orthopedic wounds (level II–III).^{47–50} NPWCT aims to reduce tissue edema, to shrink wound size, and to stimulate granulation tissue formation. This modality is also thought to increase blood flow and perhaps stimulate angiogenesis (level I).⁵¹ After each irrigation and debridement procedure, NPWCT is typically applied until the wound is considered clean; it may be changed in the operating room or at the bedside every 2–3 days. Originally used in the management of chronic wounds, its application has been extended to acute and contaminated wounds, large soft tissue defects, and even fasciotomy sites.

A retrospective analysis comparing this negative pressure technique to simple saline dressings for fasciotomy wounds of the leg demonstrated several advantages of the V.A.C technique: more rapid resolution of edema, earlier

definitive closure/coverage, and higher rate of primary closure vs. skin grafting (level III).⁵² Superior healing rates, decreased wound depths, and improved histologic profile (i.e., granulation tissue vs. inflammatory tissue/fibrosis) were all seen with NPWCT in a randomized prospective trial comparing V.A.C. to saline dressings in chronic non-healing wounds (level I).⁵³ Significant decrease in wound size with NPWCT has been demonstrated elsewhere (level IV).⁵⁴

In type IIIB open fractures, NPWCT has been shown to be safe and reliable for wound protection until definitive coverage (level III),⁵⁵ given that wound coverage occurs within 7 days. While vacuum-assisted closure appears to be a promising modality in the management of musculoskeletal wounds, additional studies are required before definitive recommendations can be made regarding the nuances of NPWCT.

Antibiotic bead pouch Local/topical antibiotics have been shown to generate high bactericidal concentrations within the wound, while maintaining low systemic concentrations (level II)⁵⁶ and resultant systemic side effects. Candidate antibiotic agents include heat-stable, powdered formulations that properly target suspected pathogens. Aminoglycosides may be preferred over vancomycin because of concerns about resistance to vancomycin.

The bead pouch technique may attain local antibiotic concentrations up to 20 times greater than systemic formulations, which may decrease the need for systemic therapy. Like NPWCT, the bead pouch affords a sealant between the environment and wound bed. Moreover, a bead pouch may elute adequate antibiotic levels for at least 1 month, decreasing the need for replacement (level V).⁵⁷

Ostermann et al. retrospectively looked at 1,085 open fractures. Patients treated with tobramycin antibiotic beads had lower infection rates than controls (3.7% vs. 12.1%; $p < 0.001$) (level III).⁵⁸ When results were stratified according to open fracture type, the reduction of infection was statistically significant in only the type III fractures (6.5% vs. 20%; $p < 0.001$). In a smaller patient group, Keating et al. conducted a retrospective analysis of 81 open tibial fractures and found tobramycin bead pouch use associated with fewer infections (4% vs. 16%) without reaching statistical significance (level II).⁵⁹

Some authors have investigated the use of local antibiotic therapy alone. Moehring et al. conducted a prospective randomized controlled trial comparing local and systemic therapy in open type II, IIIA, and IIIB fractures (level V).⁶⁰ Patients were randomized after initial treatment in the Emergency Department and preoperatively, which included prophylactic (systemic) antibiotic treatment. Similar rates of infection were reported in the two groups; the study was limited by small study size and cross-treatment effects.

Recommendations

NPWCT has a demonstrated track record for wound management after high-energy orthopedic trauma (level V, level II).^{37,39,61} There are no well-controlled human studies comparing results with V.A.C. vs. antibiotic bead pouch in open fracture wound management.⁶²

Recommendations

Recommendations for wound coverage [overall quality: moderate]:

- There is insufficient data to make a recommendation for antibiotic bead pouch over negative pressure wound therapy
- Both V.A.C. therapy and antibiotic beads are adjunctive modalities in the management of open wounds associated with fractures
- The V.A.C. method is not a substitute for adequate wound debridement

Question 5: What factors should be considered when performing a soft tissue closure in an open fracture?

Case clarification

The patient is now at postinjury day 5 and has undergone two debridements of the wound. The orthopedic surgeon, in consultation with his plastic surgery colleagues, would like to perform definitive fixation and soft tissue reconstruction for wound coverage. He plans to place an intramedullary nail; afterwards, the plastic surgeon plans to transpose a local flap for wound coverage.

For soft tissue coverage of open tibial fractures, flaps are harvested/transposed based on the location of the tibial fracture:

- For proximal-third fractures, a **medial gastrocnemius muscle flap** is used.
- For middle-third fractures, a **soleus muscle flap** is used.
- For distal-third fractures, **free tissue transfer** is often used.

Relevance

Despite controversy surrounding the appropriate time to initial debridement, the need for definitive wound coverage to prevent infection is universally accepted. After a wound is initially irrigated and debrided and the fracture stabilized, there remains an important window of time in which the wound must be covered definitively with soft tissue to prevent the sequelae of late infection.

Current opinion

Definitive soft tissue coverage is best undertaken within 5–7 days by an experienced surgeon using orthoplastic reconstructive techniques.

There are a number of methods for achieving closure, including direct suturing, skin grafting, and the use of free or local muscle flaps. Treatment and choice of definitive coverage must be tailored to the individual patient.

Quality of the evidence

Level II

- 3 studies

Level III

- 5 studies

- 2 studies

Level V

- 3 studies

Findings

Several studies have documented significantly better outcomes with early closure (within 7 days) than with late closure ($p < 0.05$) (level II–III).^{63–66} Also, a number of studies have demonstrated excellent outcomes with closure performed within 3 days after injury (level III–IV).^{67,68}

Delayed wound closure (within 3–7 days) affords the opportunity to do second-look debridements at 24- to 48-hour intervals. Any tissue of questionable viability may be removed in the interim. It may be difficult to evaluate muscle/ soft tissue viability in the acute setting or at initial debridement. Concern for clostridial infection from severe contamination is another contraindication to early closure and resulting entrapment of anaerobic bacteria.⁶⁹

The management of high-energy open fractures requires both skeletal stability and adequate soft tissue coverage. Delays beyond 7 days have been associated with increased complications related to the flap or subflap tissues (level II).⁵⁹ When comparing free muscle flaps performed within 72 hours of injury vs. 72 hours to 90 days after injury, Godina reported a failure rate of less than 1% vs. 12%,

respectively (level II).⁶² Infection rates were 1.5% vs. 17.4%, respectively. Gopal et al. examined an aggressive wound coverage protocol in type IIIB and IIIC open fractures: comparing coverage within 72 hours with that of greater than 72 hours, infection rates were 6% vs. 29%, respectively (level III).⁷⁰

Recommendations

The optimal method of closure depends on a number of host and injury factors, including wound size and location, and patient functional status and expectations.

Recommendations for definitive soft tissue wound coverage [overall quality: moderate]:

- Current trend toward earlier coverage and closure of open fracture wounds
- Exceptions to early coverage include concern for anaerobic infection or incomplete debridement of nonviable tissue
- Type IIIB and IIIC defects should be managed in a concerted effort by subspecialist teams

Summary of recommendations

- Prompt intravenous antibiotics should be given at the time of initial presentation to treat wound contamination in most open fractures
- Tetanus toxoid should be given if indicated, based on patient's immunization history
- Initial wound management should include a sterile dressing moistened with normal saline and temporary skeletal stabilization
- The timing of irrigation and debridement is not as important as the prompt administration of antibiotics but should occur within 24 hours of injury
- The wound should be irrigated with normal saline
- Additives have not demonstrated clear benefit and have additional risks to host tissue
- Pulsed lavage should not exceed 50 psi (345 kPa)
- There is insufficient data to make a recommendation for an antibiotic bead pouch over negative pressure wound therapy
- Both V.A.C. therapy and antibiotic beads are adjunctive modalities in the management of open wounds associated with fractures
- The V.A.C. method is not a substitute for adequate wound debridement
- There is a current trend toward coverage or closure of open fracture wounds within 5–7 days
- Exceptions to early coverage include concern for anaerobic infection or incomplete debridement of nonviable tissue
- Type IIIB and IIIC defects should be managed in a concerted effort by subspecialist teams

Conclusions

The factors that are of paramount importance in the treatment of open fractures are early administration of antibiotics and surgical irrigation with meticulous wound debridement. All interventions should lead toward the eradication of contamination from the wound and preservation of blood flow to the site of injury. Early fracture stabilization and wound closure/coverage are beneficial. Much of the information quoted in the orthopedic literature for open fractures, however, has inadequate scientific support and deserves further prospective investigation with appropriate sample sizes.

University of Minnesota, Minneapolis, MN, USA

Case scenarios

Case 1

A 45 year old man is brought to the Emergency Department with injuries that occurred when he was struck by an automobile moving at less than 5 miles per hour (8 km/h). He is not intoxicated and has a normal mental status examination. He has no injuries other than those to his legs. He is normotensive with a blood pressure of 140/85 mmHg. His right leg has a transverse laceration over the medial malleolus with exposed bone and an unstable fracture, with minimal soft-tissue swelling. His left leg has no wounds and is firmly swollen (much more so than the right leg), with pain over the middle of the leg but no obvious instability of the limb.

Case 2

A 24 year old man is brought in by paramedics after a high-speed motorcycle accident. He smells of alcohol, was not wearing a helmet, and was combative at the scene of the accident. The patient had swelling and deformity of the right thigh, and his left lower leg was swollen and obviously fractured with instability of the tibia. The patient had a Glasgow Coma Score of 12 at the time of admission. He was intubated immediately upon arrival in order to protect his airway. His blood pressure was 125/75. A CT of his head showed a frontal lobe contusion and punctate hemorrhage in the right hemisphere. The patient was taken to the operating room by neurosurgery for placement of a ventriculostomy. An orthopedic consult was requested just before the patient was taken to the operating room.

Relevant anatomy

Compartment syndrome is a complication of trauma or other conditions and circumstances that alter perfusion to an extremity, and can potentially involve any myofascial compartment of the extremities or trunk. It most often occurs following a fracture or a crush injury to the limb.¹ When limb swelling occurs following fracture, a crush injury, or reperfusion following a period of ischemia, the mass of the myofascial compartment increases due to accumulation of blood and fluid (which may be extra- and/or intracellular). Due to the inelastic nature of muscle fascia and other connective tissues, this accumulation of mass leads to increased pressure within the compartment. This pressure is transmitted to the thin-walled venous system, which in turn collapses, causing venous hypertension.² Progressive tissue ischemia ensues, with increasing amounts of cellular necrosis with time. Cell lysis releases osmotically active cell contents into the interstitial space, causing further accumulation of fluid and further increase in intracompartment pressure. After about 8 hours, irreversible ischemic injury to myoneural tissues within the compartment has occurred.

Importance of the problem

Although the existence of compartment syndrome is well known and most clinicians are familiar with its pathophysiology and understand its potential limb-threatening nature, there is no clear definition of when compartment syndrome is actually present and considerable variation in its clinical management is the inevitable consequence.³⁻⁵

Clinical signs and symptoms as well as direct measurements of intramuscular pressure are inaccurate as screening tests for compartment syndrome and have significant pitfalls as a means of diagnosis.⁶⁻¹⁴ Not surprisingly, compartment syndrome is one of the most common causes of litigation against orthopedic surgeons.¹⁵

The only established treatment for acute compartment syndrome is immediate surgical fasciotomy, wherein the skin and muscle fascia of the involved compartment are generously incised to release the constricting soft tissues and increase the volume of the muscle compartment, thereby effecting immediate reduction of compartment pressure. Although intramuscular pressure varies in a continuum, given the lack of specific diagnostic criteria as well as reliable methods to prevent or reduce the occurrence of compartment syndrome, compartment syndrome is presently an “all or none” diagnosis, and patients who are considered to have compartment syndrome typically receive emergent fasciotomy. It is recognized that performing early fasciotomy is critical to achieving the best possible outcomes when compartment syndrome occurs,¹⁶⁻²¹ and it is generally accepted that performing unnecessary fasciotomy is better than missing a true case of compartment syndrome, given the potential systemic risks and functional loss associated with rhabdomyolysis and myonecrosis.

Unfortunately, fasciotomy is associated with its own set of complications, including the need for further surgery for delayed wound closure or skin grafting, pain, cosmetic problems, nerve injury, permanent muscle weakness, and chronic venous insufficiency.^{9,19,22-27}

In order to minimize morbidity and optimize treatment of a patient at risk for compartment syndrome, clinicians need a clear understanding of the pathophysiology, means (and problems) of diagnosis, and treatment of compartment syndrome.

Top five questions

Risk factors

1. What factors increase the risk of compartment syndrome?

Diagnosis

2. What are the clinical signs and symptoms of compartment syndrome? Which can I rely on for diagnosis?
3. Is measurement of compartment pressure always necessary?

Treatment

4. When should fasciotomy be done in the face of positive clinical signs and symptoms?

5. Is there a pressure threshold above which fasciotomy should always be done?

Question 1: What factors increase the risk of compartment syndrome?

Case 1 clarification

Our patient is a relatively young, active man, with a potentially high-energy bumper injury. Radiographs of the right leg show transverse fractures of the tibia and fibula at the junction of the middle and distal thirds of the tibia. Radiographs of the left leg show a nondisplaced bending-wedge fracture of the midshaft of the tibia with an intact fibula.

Case 2 clarification

The patient had an associated long bone injury, which increases the risk of hypotension, although at the time of admission his vital signs remained stable.

Relevance

The only accepted treatment for compartment syndrome is immediate fasciotomy, which if performed commits the patient to further surgery, a prolonged hospital stay, increased cost of care, and increased morbidity. Understanding the risk factors for compartment syndrome will allow the surgeon to modify his or her assessment of the a-priori risk of compartment syndrome for a given patient, and potentially raise or lower the threshold for fasciotomy in a given clinical scenario.

Current opinion

Young individuals sustaining high-energy trauma, especially of the lower leg, are considered to be the most at risk for compartment syndrome. The risk of compartment syndrome in other types of patients, and in other anatomic locations, is less-well understood.

Finding the evidence

- PubMed Search: “acute compartment syndrome risk factor”

 - 81 results (only results relevant to the question are shown)

Quality of the evidence

Level II

- 2 prognostic studies^{1,28}

Level IV

- 2 retrospective case series^{29,30}

Level V

- 3 case reports, 11 review papers

Findings

The published literature documents both the demographics and risk factors for acute compartment syndrome (ACS). McQueen et al. documented 164 cases treated in their trauma unit.¹ Most patients were men younger than age 35, and fractures were present in 69% of cases. Slightly more than half of the fractures (52%) were of the tibia, and fractures of the forearm (radius and ulna shaft, plus distal radius) accounted for one quarter of the total cases. Isolated soft-tissue injuries were reasonably common, accounting for 23% of the total cases, and occurred in the leg, thigh, forearm, hand, and foot. It should be noted that this series excluded cases of postischemic ACS, which is another well-known etiology of ACS. In a later publication, the same investigators specifically studied the patients in this series who developed compartment syndrome without fracture and compared them to the patients who had ACS after fracture.¹⁷ Patients who developed ACS in the absence of fracture were older and had more medical comorbidities than those with a fracture. Importantly, in the cohort of patients with ACS without fracture the time to fasciotomy was delayed, and a greater proportion of patients had myonecrosis, suggesting a significant delay in diagnosis (possibly due to the lack of a fracture). Park et al. evaluated 414 acute tibial fractures and looked at the rate of compartment syndrome requiring fasciotomy according to fracture location.²⁸ Compartment syndrome was most common in diaphyseal tibia fractures, occurring in 8% of cases, compared to less than 2% in proximal and distal metaphyseal fractures, respectively. In the diaphyseal group, patient and injury risk factors were examined; younger age was the only potential risk factor that was independently associated with the development of compartment syndrome. Several series report an appreciable incidence of compartment syndrome in patients with tibial plateau fractures,²⁹ and these fractures must also be considered in the high-risk category. Compartment syndrome of the thigh can also occur, often (but not necessarily) associated with a fracture of the femur, and in one series led to significant morbidity.³⁰

Recommendations

- Younger age (25–35 years), male gender, and trauma are consistent risk factors for compartment syndrome in patients with fractures of the tibia and forearm [overall quality: moderate]

Question 2: What are the clinical signs and symptoms of compartment syndrome? Which can I rely on for diagnosis?

Case 1 clarification

The patient is able to actively flex and extend his great toe, lesser toes, and ankle bilaterally, although with some pain.

He has mild pain with passive plantarflexion and dorsiflexion of the ankle and great toe. He reports completely normal sensation in his first web space and over the dorsum of the foot, lateral border of the foot, and bottom of the foot, bilaterally.

Relevance

Compartment syndrome is an entity without a definitive diagnostic test. The consequences of missed diagnosis are severe for the patient, the physician, and the hospital. As a result, overtreatment (surgical fasciotomy) is common, but contributes to morbidity as well. An understanding of the value of specific clinical findings and the meaning of elevated intramuscular pressure will aid the clinician in diagnosing and managing patients at risk for compartment syndrome.

Current opinion

The diagnosis of ACS is best made on the basis of the presence of specific clinical findings that include the tenseness or firmness of the involved compartment, motor weakness and pain with passive stretch of the involved muscle, increasing pain, pain that is out of proportion to that expected, and loss of sensation in a specific neuronal distribution for a given compartment (such as the deep peroneal nerve for the anterior compartment of the leg). However, all of these clinical findings are imprecise, subjective, and easily attributable to other aspects of the injury.

Findings

The literature documents that ACS can occur in almost any muscle of the body, either following fracture, crush injury, muscle injury, overexertion, ischemia-reperfusion injury, or even without apparent provocation (acute deep vein thrombosis, spontaneous hemorrhage, etc.). The generally accepted clinical signs of compartment syndrome are worsening pain (out of proportion to what is otherwise expected), pain with passive stretch, paresthesias, and paresis. However, the published literature makes it clear that these clinical signs and symptoms are unreliable, both when they are present^{12,39} and when they are absent.^{40,41} Robinson et al. reviewed 208 consecutive patients treated with reamed nailing of a tibia fracture; 5% of the patients developed dysfunction of the common or deep peroneal nerve, with most of them exhibiting isolated weakness of the extensor hallucis longus (the “dropped hallux”) with associated numbness in the first web space. All of these patients had continuous compartment pressure monitoring and none developed compartment syndrome.³⁹ Three patients were documented as having neurologic deficits before surgery.³⁹ Ulmer performed a methodical review of the published literature through 2001 and evaluated all four of these clinical signs.¹² Of 1,932 studies found in a literature search, only 4 had adequate data with which to calculate the sensitivity and specificity of these findings in patients with lower leg injuries. The sensitivity and positive predictive value of all four clinical signs of compartment syndrome was less than 20%. In contrast, the specificity and negative predictive value were above 97%. False-positive findings were present more often than true positive findings. Using the concept of likelihood ratios, Ulmer did demonstrate that there is increasing clinical utility when multiple findings are present; if three of the four signs were present the odds of compartment syndrome are increased to above 90% (given a pretest probability of 5%).¹²

Despite these problems, careful clinical monitoring appears to be useful for minimizing morbidity due to compartment syndrome.^{31–33} Use of a specific checklist may help to formalize the clinical monitoring of patients.³³

Given the emphasis on clinical findings that exists, it is not surprising that one area of concern has been the issue of analgesia. Several case reports exist of alert, adult patients who developed compartment syndrome without pain.^{6,7,11,41} Mar et al. performed a systematic review of the literature, identifying 28 articles discussing the influence of analgesic technique on the diagnosis of compartment syndrome in 35 patients.³⁸ These authors concluded, on the basis of their review, that there is no convincing evidence that intravenous opioids or regional anesthetic blocks delays the diagnosis of compartment syndrome in “adequately monitored” patients.

Recommendations

- Due to the myriad causes of ACS, clinicians must consider this diagnosis in any patient with swelling of the limb. In an alert patient, careful and frequent (every 1–2 hour) clinical monitoring of pain (both at rest and with passive muscle stretching), limb swelling, and neurologic status is usually sufficient to make the diagnosis. The clinical findings are of greatest utility when several findings are present together. Clinicians should remember that clinical findings are positive more often in patients without ACS than in patients with compartment syndrome. The clinical diagnosis is not reliable if done infrequently, in children, or in unconscious patients in whom pain cannot be assessed. The influence of anesthetic technique on the clinical examination is uncertain; one systematic review of the topic contained mostly single case reports and a very small number of patients, such that definitive conclusions cannot be drawn. The highest available evidence is level I, but it is impossible to make conclusive statements because of the inherent nature of the treatment of compartment syndrome, in which the incidence of unneeded fasciotomy (false-positive diagnosis) and missed compartment syndrome (false-negative diagnosis) is impossible to know [overall level: low]

Question 3: Is measurement of intracompartment pressure always necessary?

Case 1 clarification

This patient has an isolated injury and a reliable physical examination.

Case 2 clarification

This patient does not have a reliable physical examination because he has been intubated; due to his traumatic brain injury this is likely to remain true for at least the next several days. Therefore all that can be used for diagnosis are serial (or continuous) measurements of intracompartment pressure.

Relevance

Recent literature has documented that the clinical findings typically associated with ACS are not reliable as a screening test (e.g., have poor sensitivity), and many patients considered to be at risk (or to have) ACS are not clinically evaluable due to head injury, intubation/sedation, or altered mental status. Making the diagnosis on the basis of clinical findings can also be particularly challenging in children.¹⁸ In these instances, measurement of intramuscular pressure is another diagnostic option, and the accuracy and reliability of such measurements should be understood by anyone treating patients at risk for ACS. The potential benefit of continuous vs. intermittent pressure monitoring remains an area of clinical controversy.

Current opinion

Measurement of intracompartment pressure is of value in patients with clinically equivocal findings or in patients who cannot be evaluated clinically. Routine continuous pressure monitoring may lead to increased rate of fasciotomy, and is of unproven benefit in centers that are accustomed to careful clinical monitoring. When measurement of intramuscular pressure is done, using a threshold for fasciotomy based on a perfusion pressure (diastolic blood pressure minus intramuscular pressure) of at least 30 mmHg will avoid missed compartment syndrome.

Findings

Although compartment syndrome may be diagnosed in an alert adult patient on the basis of positive clinical findings, many experts have recommended routine measurement of intramuscular pressure in one or more compartments.^{13,35,42,43} It has been estimated that muscle necrosis may occur within 2 hours of injury in as many as 35% of patients with ACS.⁴⁴ Therefore, early diagnosis of compartment syndrome is key to avoiding morbidity,^{16–18,21,36} and delay in diagnosis occurs often.⁹ The incidence of delayed diagnosis appears to be lessened by use of frequent or continuous measurement of intramuscular pressure.^{9,36} On the other hand, routine monitoring of intramuscular pressure could lead to increased use of fasciotomy, depending on what pressure threshold is used.^{8,45}

Whenever the clinical examination is not reliable, direct measurement of intramuscular pressure in a patient at risk is a necessity. The proper role of compartment pressure monitoring in an alert patient is unknown.^{4,8,10} There are several well-done studies that both support^{13,36,42,43} and refute^{10,31,32} the value of pressure monitoring. At issue is whether pressure monitoring improves the diagnosis of compartment syndrome (i.e., identifies cases that clinical monitoring would miss), and whether it leads to earlier diagnosis and therefore contributes to a reduction in morbidity from delayed diagnosis. The answer to these questions clearly depend on what pressure threshold is used to diagnose compartment syndrome, and this too remains a topic of controversy.^{8,10,45}

With respect to the accuracy of diagnosis, several case series report that there is little difference in the rate of fasciotomy in groups of patients who are monitored clinically compared to those that have continuous measurement of intramuscular pressure.^{31,32} However, careful review of these reports reveals that the patients that were monitored clinically were in fact followed very closely. For example, Al-Dadah et al. reported similar rates of fasciotomy and time to diagnosis of compartment syndrome in two sets of patients treated before and after adopting a protocol of continuous monitoring of anterior compartment pressure.³² However, patients in both groups were assessed by trained nurses every hour.³¹ It might be surmised that monitoring of compartment pressure would be of more value if such careful clinical monitoring were not possible, and that these results may not be generalizable to institutions that cannot offer that level of care. Harris et al. performed a trial in which 200 consecutive patients with tibia fracture were randomized to continuous monitoring for 36 hours or clinical assessment alone.³¹ There were no cases of compartment syndrome in the monitored group, and five in the nonmonitored group, leading the authors to conclude that clinical monitoring alone is adequate. However, this report did not describe how the patients were assessed clinically, and included a mixture of both postoperative cases and patients monitored after admission but before surgery, as well as alert and unconscious patients. Data regarding the distribution of these patient groups in the study is not provided in the paper, making it difficult to draw conclusions.

Recommendations

- Frequent clinical assessment of the patient considered to be at risk for developing compartment syndrome, ideally using a structured checklist, remains the cornerstone of diagnosis. When a patient is unconscious or otherwise not able to be clinically assessed, then measurement of intramuscular pressure within the anterior is of benefit. It is difficult to recommend a specific absolute measure of pressure at which fasciotomy should be done. Performing

fasciotomy whenever the intramuscular pressure is within 30mmHg of the diastolic blood pressure is not likely to result in any missed cases of compartment syndrome, but will likely lead to overtreatment if used routinely. Further research is needed to provide more sensitive and specific means to diagnose compartment syndrome. The highest available evidence is level I, but the results are conflicting and the studies showing benefit to each modality may not be generalizable [overall quality: low]

Question 4: When should fasciotomy be done in the face of positive clinical signs and symptoms?

Relevance

As a surgical procedure, fasciotomy has its own set of potential complications, and at the very least, commits the patient to a large open wound that requires a second (or more) surgical procedure to close, and increases hospital stay and costs. When facing a patient with compartment syndrome, it is important to know if there are nonoperative medical interventions that might be done, and how to understand the urgency of when to do fasciotomy (what is the relative risk of waiting vs. early intervention).

Current opinion

There are no clinically relevant medical therapies for ACS, and immediate fasciotomy is warranted as soon as the diagnosis is considered to be present.

Finding the evidence

- PubMed Search: “fasciotomy acute compartment syndrome”,
 - limited to English
 - 179 results (only results relevant to the question are shown)

Quality of the evidence

Level III

- 1 diagnostic study³⁶

Level IV

- 3 therapeutic case series^{18,46,47}

Findings

Experimental animal models indicate that irreversible muscle necrosis can occur in 8 hours or less as a consequence of elevated intramuscular pressure; the tolerance of muscle to ischemia depends on both the absolute pressure, the duration of elevated pressure, associated muscle injury, and differences in muscle metabolic demands between individuals. In one clinical series in which operative reports and pathologic specimens from fasciotomy were scrutinized, the authors concluded that appreciable muscle

necrosis can occur in over one third of patients in as little as 3 hours.⁴⁴

Numerous series document the efficacy of early fasciotomy^{18,27,46-48} and the complications associated with late fasciotomy.^{17,47} Although all are level IV studies, it clearly would not be ethical to undertake any sort of prospective study of the effects of delayed fasciotomy in patients with compartment syndrome. Despite the universal acceptance that compartment syndrome is an “orthopedic emergency,” Vaillancourt et al. documented frequent delays both in the time from initial assessment to diagnosis and in the time from diagnosis to surgery.²¹ Interestingly, one study that specifically evaluated time from diagnosis to fasciotomy in two hospitals could not determine any statistical correlation between the time from diagnosis to fasciotomy and residual functional defects.⁴⁹

Sheridan and Matsen found that fasciotomy performed within 12 hours of the onset of compartment syndrome, as defined by the first appearance of any clinical sign (motor weakness, stretch pain, or hyperesthesia in the appropriate nerve), resulted in normal function in 68% of patients, compared to only 8% of those who had delayed fasciotomy.⁴⁷ In addition, patients undergoing late fasciotomy had a 10-fold increase in the rate of complications (4.5% vs. 54%).⁴⁷ In a series of pediatric upper extremity compartment syndromes, a statistically significant difference in outcomes were found if surgery was delayed more than 6 hours.¹⁸

Recommendation

- When compartment syndrome is going to occur, early fasciotomy can avoid myonecrosis or ischemic neuropathy. However, the challenges in diagnosis, and the fact that compartment syndrome does not begin at a well-defined point in time, make it impossible to make draw specific conclusions about when fasciotomy is needed that apply to every case [overall quality: low]

Question 5: Is there a pressure threshold above which fasciotomy should always be done?

Case 2 clarification

While the patient was in surgery, his intracompartment pressures were measured in the left leg and found to be: anterior compartment, 77mmHg; lateral compartment, 55mmHg; deep posterior compartment, 35mmHg; superficial posterior compartment, 15mmHg.

Relevance

It is not clear how accurate recommended thresholds for fasciotomy are, and how such thresholds should be applied in a given clinical situation.

Current opinion

The use of a pressure threshold for fasciotomy that is based on an assessment of perfusion pressure rather than an

absolute intracompartment pressure is more relevant physiologically, and less likely to lead to unnecessary fasciotomy. The best indicator of the need for fasciotomy is the perfusion pressure (also referred to as the “Delta-P”), which is defined as the difference between the patient’s diastolic blood pressure and the intracompartment pressure. Fasciotomy may be safely avoided as long as the perfusion pressure remains greater than 30 mmHg.

Finding the evidence

- PubMed Search: “threshold fasciotomy acute compartment syndrome”
 - limited to English
 - 7 results (only results relevant to the question are shown)

Quality of the evidence

- No new articles identified.

Findings

Decisions for fasciotomy may be based on absolute compartment pressure,^{37,45} or the so-called differential pressure (also called perfusion pressure or “Delta-P”), which represents the difference between the intramuscular pressure and some measure of the patient’s blood pressure.⁵⁰ Although many definitions of perfusion pressure have been considered, the one proposed by McQueen et al. is most commonly used:

$$\text{perfusion pressure} = \text{diastolic blood pressure} - \text{intramuscular pressure}$$

with a threshold for fasciotomy when the perfusion pressure (so defined) is less than 30 mmHg when averaged over a 12-hour period.^{13,35,43} Multiple studies demonstrate that perfusion pressure is a better diagnostic criteria for compartment syndrome than absolute pressure,^{13,43} and that fasciotomy can be safely avoided whenever the limb perfusion pressure is greater than 30 mmHg.^{13,34,35,43} Typically, the anterior compartment is monitored since the pressures within it are typically highest.⁴⁷

The difficulty in using specific thresholds for fasciotomy was highlighted by Prayson et al, who carefully followed blood pressure and compartment pressure in 19 patients with isolated lower extremity fractures who did not have compartment syndrome by clinical criteria, or at follow-up.¹⁰ In this series, 84% of the patients had at least one reading in which their perfusion pressure was within 30 mmHg of their diastolic blood pressure, and 58% had a reading within 20 mmHg. Thus, single pressure measurements alone are not representative, and serial or continuous measurements demonstrating rising compartment pressure or falling perfusion pressure are likely to be more specific for patients that truly have compartment syndrome. Similar findings were noted by Janzing and Broos,

who reviewed 95 patients treated with continuous pressure monitoring, and after reviewing their patients at follow-up, could not identify a threshold that was both sensitive and specific for diagnosing compartment syndrome.⁸

There are several potential pitfalls with use of pressure measurements for decision-making in patients suspected of compartment syndrome. First, it has been shown that there is spatial variation in the pressure within a given compartment, with pressures being highest within 5 cm of the fracture⁵¹ and more centrally in the muscle.⁵² It is not known whether one should obtain pressures near the fracture to obtain the highest pressure, or measure further away (outside the zone of injury) to obtain a pressure that may be more representative of the compartment as a whole.³¹ Another source of uncertainty when calculating perfusion pressure is what blood pressure value to use, especially if the patient is under general anesthesia. Tornetta and colleagues evaluated 242 patients undergoing tibial nailing, and recorded preoperative, intraoperative, and postoperative blood pressures.⁵³ During surgery, there was a statistically significant decrease in diastolic blood pressure comparing intraoperative to preoperative values (average decrease 18 mmHg), whereas postoperative diastolic pressure was within 2 mmHg of the preoperative value. Thus, use of intraoperative diastolic blood pressure measurements for calculation of perfusion pressure may give a spuriously low perfusion pressure and lead to unnecessary fasciotomy. These authors recommend using preoperative blood pressure values when calculating perfusion pressure in a patient under general anesthesia, except when the patient is going to remain under anesthesia for several more hours.⁵³

Recommendations

- The concept of perfusion pressure has reduced the need for fasciotomy by avoiding unnecessary fasciotomy in patients with high absolute pressures but maintained perfusion. Setting the threshold for fasciotomy at a perfusion pressure of 30 mmHg, as defined by McQueen et al.,³⁶ can be considered to be safe, but still may lead to overtreatment if used routinely [overall quality: moderate]
- Transient intraoperative hypotension should be considered when making decisions about perfusion pressure.⁵³ The current literature does not contain recommendations for fasciotomy based on any measurement of pressure that can be relied upon in every situation [overall quality: low]

Summary of recommendations

- Younger age (25–35 years), male gender, and trauma are consistent risk factors for compartment syndrome in patients with fractures of the tibia and forearm.

- Careful and frequent (every 1–2 hour) clinical monitoring of pain (both at rest and with passive muscle stretching), limb swelling, and neurologic status is usually sufficient to make the diagnosis.
- Clinical diagnosis is not reliable if done infrequently, in children, or in unconscious patients in whom pain cannot be assessed. The influence of anesthetic technique on the clinical examination is uncertain.
- Performing fasciotomy whenever the intramuscular pressure is within 30 mmHg of the diastolic blood pressure is not likely to result in any missed cases of compartment syndrome, but will likely lead to overtreatment if used routinely.
- The concept of perfusion pressure has reduced the need for fasciotomy. Setting the threshold for fasciotomy at a perfusion pressure of 30 mmHg can be considered safe, but still may lead to overtreatment if used routinely.

Noninvasive Technologies for Fracture Repair

Yoshinobu Watanabe, Makoto Kobayashi, and Takashi Matsushita

Teikyo University School of Medicine, Tokyo, Japan

Case scenario

A 32 year old man, who was otherwise healthy, sustained a comminuted open tibial shaft fracture as a result of a motor vehicle accident. After initial debridement and irrigation, the fracture was fixed by an unreamed interlocking nail. Radiographs showed no sign of callus formation 6 months after surgery (Figure 72.1). There was no clinical, biochemical, or radiographic evidence of deep infection or osteomyelitis.

Relevant anatomy

Fracture healing of locked tibial nailing is controlled by many factors such as stability, gap, and vascularity of fracture site (level II–V).^{1–4} Therefore comminuted open tibial shaft fractures are potentially at risk of developing delayed healing (level II).^{1,5}

Importance of the problem

Of the estimated 5.6 million fractures occurring annually in the United States, it is believed that 5–10% demonstrated delayed union or nonunion (level II).⁶ Acceleration of fracture healing is important to reduce the socioeconomic loss by shortening the period of fracture treatment.

Top five questions

1. What are the predictors of nonunion?
2. What kinds of noninvasive biophysical technologies can be available for noninfected delayed union and nonunion?

3. Does low-intensity pulsed ultrasound (LIPUS) accelerate fracture healing and improve the patient's health-related quality of life (QOL)?

4. Does pulsed electromagnetic fields (PEMF) accelerate fracture healing and improve the patient's health-related QOL?

5. Does extracorporeal shock wave therapy (ESWT) accelerate fracture healing and improve the patient's health-related QOL?

Question 1: What are the predictors of nonunion?

Case clarification

The patient's radiograph reveals a comminuted tibial shaft fracture fixed by a relatively small unreamed intramedullary (IM) nail. Subsequent radiographs showed no bridging callus with existence of visible fracture line (Figure 72.1). If we know the probability of this open tibial fracture developing to established nonunion, this information will help us to determine when additional treatment or therapy is needed to achieve union.

Relevance

Evaluation of predictors for nonunion will help us to recognize the risk of delayed union or nonunion earlier, and early treatment can help patients avoid prolonged periods of pain and disability.

Current opinion

Predictors of nonunion of open tibial fracture treated by using IM nail are Gustilo grades, postoperative fracture gap, unreamed IM nailing, and dynamization.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search with meta-analysis, clinical trial, randomized

Figure 72.1 Delayed union or nonunion?

Openmirrors.com

clinical trial, and review: search term: “(tibia*) AND (fracture*)”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search with meta-analysis, clinical trial, randomized clinical trial, and review: search term “((tibia*) AND (fracture*)) AND ((nonunion*) OR (delay*))”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search with meta-analysis, clinical trial, randomized clinical trial, and review: search term “((fracture*) AND ((nonunion*) OR (delay*))) AND ((ultrasound*) OR (electromag*) OR (shock wave*) OR (LIPUS) OR (PEMF) OR (ESW*))”

Quality of the evidence

Level I

- 1 meta-analysis for reaming
- 5 randomized clinical trials (RCTs) for reaming

Level II

- 3 cohort studies for postoperative fracture gap, and 1 for dynamization

Level IV (case series) or II (cohort)

- There are over 500 case series for Gustilo grades of open fracture. Among these articles some one-group cohort studies must be included, but the exact numbers of these

could not be determined because of the inadequate description

Findings

Court-Brown et al. have analyzed the mean time to union for different Gustilo grades of open fracture. These results indicated that the risk of nonunion increased with Gustilo grades (level II).^{5,7,8}

Drosos et al. studied factors affecting fracture healing after tibial nailing for closed and grade I open fractures, and reported that the risk of failure of union increased by 2.38 times for highly comminuted fractures, by 3.14 times when nail dynamization was applied, and by 1.65 times when the locking screws failed (level II).¹ They also showed that the risk of nonunion increased if the postreduction gap was 3mm or more in fractures with no or only minimal comminution (level II).¹ Bhandari et al. identified that postoperative fracture gap is one of the predictors of reoperation following operative treatment of tibial shaft fracture (level II).⁹

Meta-analyses of prospective RCTs have suggested large reductions in the risk of nonunion in association with the use of reamed IM nailing (RR 0.44; 95% CI 0.21–0.93) (level I– II).^{10–13} A well-designed randomized trial with a large number of participants demonstrated that overall nonunion rate was 4.6% and there is a possible benefit for reamed IM nailing in patients with closed fractures (RR 0.67; 95% CI 0.47–0.96) (level I).¹⁴

Recommendations

- Risk factors for nonunion in tibial shaft fractures include: (1) open fractures with high-grade Gustilo classification [overall quality: moderate]; (2) fixation with unreamed nails [overall quality: moderate]; and (3) fixation with large fracture gap between main fragments [overall quality: moderate]
- In these situations, some sort of additional intervention would be needed to avoid nonunion [overall quality: moderate]

Question 2: What kinds of noninvasive biophysical technologies can be available for noninfected delayed union and nonunion?

Case clarification

Some noninvasive technologies would be worth trying before surgical interventions for delayed union and nonunion.

Relevance

Some type of bone growth stimulation can be widely applied for acceleration of fracture healing as an adjuvant therapy and/or alternative therapy.

Current opinion

LIPUS, PEMF, and ESWT have been widely used to enhance fracture healing.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 3 meta-analyses (2 for LIPUS and 1 for PEMF)
- 1 RCT for ESWT

Findings

LIPUS and PEMF have been most popular devices for the adjuvant and/or alternative treatment of choice for surgical intervention to enhance fracture healing (level I–III).^{15–17} Currently the effectiveness of ESWT for hypertrophic non-unions has been confirmed by RCT.

Recommendation

- Noninvasive biophysical stimulation may be available for possible tibial nonunion, and LIPUS, PEMF, and ESWT are recommended methods

Question 3: Does LIPUS accelerate fracture healing and improve the patient's health-related QOL?**Case clarification**

Before surgical intervention is considered for delayed or nonunion after tibial fracture, there is a chance to achieve union by LIPUS.

Relevance

How much is fracture healing accelerated by using LIPUS? What is the overall union rate for delayed union/nonunion by LIPUS? Does LIPUS improve QOL of the patient with a tibial fracture?

Current opinion

The use of LIPUS is considered to augment fracture healing in those fracture types at risk for nonunion such as open or comminuted fracture and/or compromised patients with smoking and malnutrition.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 7 meta-analyses

Findings

Most meta-analyses included several kinds of bone and fractures, not focusing on tibial nonunion. Heckman et al.

Figure 72.2 Effect of low-intensity pulsed ultrasound on radiographic healing of tibial fractures.

concluded that LIPUS shortened the time to healing fracture by 38% and significantly reduced the incidence of delayed union for the relatively simple closed or Gustilo I open tibial shaft fracture immobilized by a cast (level I).¹⁸ Leung et al. investigated the effect of LIPUS on fracture healing for open and/or severely comminuted tibial shaft fractures immobilized by IM nail or external fixator (level I).¹⁹ They concluded that the LIPUS-treated group showed statistically significant better healing, as demonstrated by all assessments. Emami et al., however, concluded that LIPUS did not shorten healing time in fresh tibial fractures treated with a reamed and statically locked IM nail (level I).²⁰ Limited information for tibial shaft fracture from these three RCTs suggested that LIPUS probably enhances or accelerates fracture healing in tibial fracture (Figure 72.2), although the results of these three trials were heterogeneous (level I).¹⁷

The benefits of LIPUS for delayed and nonunion were also investigated by cohort studies, which revealed that the overall success rate of LIPUS for delayed union and non-unions of tibia/tibia-fibula or fibula is approximately 88% (Table 72.1) (level II).^{21–24} Unfortunately, there is little literature that studies the improvement of health-related QOL of the patient (level II).²⁵

Recommendation

- LIPUS is likely to accelerate fracture healing in a fresh fracture as well as in delayed union or nonunion [overall quality: high]

Question 4: Does PEMF accelerate fracture healing and improve the patient's health-related QOL?**Case clarification**

Before surgical intervention is considered for delayed or nonunion after tibial fracture, there is a chance to achieve union by PEMF.

Relevance

How much does the use of PEMF accelerate fracture healing? What is the overall union rate for delayed union/

Table 72.1 Success rate of LIPUS for long bone fractures

Study	Delayed or nonunion	Overall of long bones		Humerus		Radius/radius-ulna		Femur		Tibia/tibia-fibula or fibula

nonunion by PEMF? Does PEMF improve QOL of the patient with tibial fractures?

Current opinion

The use of PEMF is considered to augment fracture healing in those fracture types at risk for nonunion such as open or comminuted fractures and/or compromised patients with smoking and malnutrition.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 4 meta-analyses

Findings

For fracture healing, three types of electrical stimulation are available: (1) direct current stimulation using electrodes; (2) electromagnetic stimulation by inductive coupling; (3) capacitive coupling stimulation (level II).²⁶

Sharrard (level I)²⁷ and Simonis et al. (level I),²⁸ in a placebo-controlled randomized trial, examined the efficacy of PEMF on tibial delayed or nonunions. Both reports indicated that a greater proportion of patients in the treatment group achieved union (Table 72.2), and PEMF increased the chance of union by 3.8 or 1.8 times. However, the 95% confidence interval suggested that the increase could be as low as 1.1-fold (level III).²⁹ Baker et al., in a placebo-controlled randomized trial, showed a negative effect of PEMF for tibial nonunion conservatively treated by cast (Table 72.2) (level II);³⁰ however, the number of participants seemed to be too small.

Cohort studies or case series without control group showed that PEMF showed a high union rate (87–93%) of long-bone nonunions with non-weight-bearing treatment (level IV).^{31,32}

No evidence was available for improvement of the patient’s QOL.

Table 72.2 Effect of pulsed electromagnetic fields on increasing chance of union for tibial nonunion

	Active		Placebo		Increased chance of union	
	United	Not united	United	Not united	Times	95% CI
Sharrard 1990	9	11	3	22	3.8	1.09–16.2
Simonis 2006	16	2	8	8	1.8	1.06–2.98
		Active		Placebo		Decreased chance of union
	United	Not united	United	Not united	Times	95% CI
Barker 1984	5	4	5	2	1.2	0.61–2.72

Openmirrors.com

Recommendation

- PEMF is likely to improve healing rate in delayed union or nonunion [overall quality: high], but no evidence was available for acceleration of fracture healing in fresh fracture

Question 5: Does ESWT accelerate fracture healing and improve the patient health-related QOL?

Case clarification

Before surgical intervention is considered for delayed or nonunion after tibial fracture, there is a chance to achieve union by ESWT.

Relevance

How much is fracture healing accelerated by using ESWT? What is the overall union rate for delayed union/nonunion by ESWT? Does ESWT improve QOL of the patient with tibial fractures?

Current opinion

Predictors of open tibial fracture treated by IM nailing are Gustilo grades, postoperative fracture gap, unreamed IM nailing, and dynamization.

Finding the evidence

See Question 1.

Quality of the evidence

Level II

- 1 systematic review of case series

Findings

A shock wave is defined as a sonic pulse characterized by a high peak pressure (500 bar = 100 kPa), a short life cycle (10 ms), fast pressure rise (<10 ns), and broad frequency spectrum (16–20 MHz) (level IV).³³

Elster et al. currently reported the result of 192 tibial nonunions treated by ESWT coupled with post-treatment immobilization, external fixation, or ESWT alone (level IV).³⁴ They stated that 138 of 172 (80.2%) patients demonstrated complete fracture healing at the time of last follow-up, and that mean time from first shock wave therapy to complete healing of the tibia nonunion was 4.8 ± 4.0 months.

Cacchio et al. prospectively compared the results of ESWT produced by two different devices (with 4000 impulses of shock waves with an energy flux density of 0.40 mJ/mm² (group 1) or 0.70 mJ/mm² (group 2) with those of surgical treatment for long-bone hypertrophic nonunions (group 3) (level IV).³⁵ At 6 months, 70% of the nonunions in group 1, 71% of the nonunions in group 2, and 73% of the nonunions in group 3 had healed. They concluded that ESWT is as effective as surgery in stimulating union of long-bone hypertrophic nonunions.

Zelle et al. reviewed 10 case series and reported that the overall union rate in patients with delayed union/nonunion was 76% (95% CI 73–79%) and ranged from 41% to 85%. The union rate in atrophic nonunions was 29% as compared with 76% in hypertrophic nonunions (RR 2.6; 95% CI 1.6–4.7; $p < 0.0001$).

Recommendation

- ESWT is likely to be the alternative treatment of choice for hypertrophic long-bone nonunion [overall quality: low]

Summary of recommendations

- Risk factors for nonunion in tibial shaft fractures include (1) open fractures with high-grade Gustilo classification, (2) fixation with unreamed nails, and (3) fixation with large fracture gap between main fragments. In these situations, some sort of additional intervention would be needed to avoid nonunion
- Noninvasive biophysical stimulation may be available for possible tibial nonunion, and LIPUS, PEMF, and ESWT are among the recommended methods
- LIPUS is likely to accelerate fracture healing in fresh fracture as well as in delayed union or nonunion
- PEMF is likely to improve healing rate in delayed union or nonunion, but no evidence was available for acceleration of fracture healing in fresh fracture
- ESWT is likely to be the alternative treatment of choice for hypertrophic long-bone nonunion

Case scenarios

Case 1

A 54 year old woman presents with a fractured tibial plateau following a low-energy injury at home. The patient's radiographs indicate a split depression injury laterally, with an associated medial condylar injury with a posterior medial split (Schatzker V) (Figure 73.1).

Case 2

A 42 year old man presents with a significant tibial plateau fracture (Figure 73.2).

Case 3

A 72 year old woman presents with a fracture of the distal radius with significant posterior comminution (Figure 73.3).

Importance of the problem

Metaphyseal fractures are among the most difficult fractures to treat. Depressed articular fragments can crush the underlying weak subchondral cancellous bone, leaving a void when the articular segments are reduced surgically. Potential long-term problems including pain, post-traumatic arthritis, and limitation of motion and function may occur if joint surface subsidence cannot be prevented or at least limited.

Definitions

- **Articular:** bone close to and including the joint surface
- **Metaphyseal:** bone adjacent to the joint consisting of cancellous bone with a weak cortical layer and extending to the shaft of the long bone
- **Diaphyseal:** bone located in the narrow part of the long bone, generally consists of hard cortical bone with a narrow medullary canal

Top five questions

Diagnosis

1. What types of fractures lend themselves to fixation with calcium phosphate bone substitutes?

Therapy

2. What type of bone graft should be used to treat subchondral contained defects: autograft, allograft, or a calcium phosphate bone substitute?
3. What are the features of calcium phosphate that make it suitable as a bone substitute?

Prognosis

4. When does the calcium phosphate resorb?
5. Are there any other benefits to using calcium phosphate?

Figure 73.1 Case 1: Schatzker V tibial plateau fracture before fixation.

Figure 73.2 Case 2: preoperative AP (a) and lateral (b) views of a Schatzker V fracture.

Figure 73.3 Case 3: distal radius fracture with dorsal comminution.

Finding the evidence

Bajammal et al. employed a comprehensive search strategy for a 2008 meta-analysis,¹ which we expanded to locate articles published more recently. We selected the most relevant articles for this review.

Quality of the evidence

Level I

- 4 randomized trials and meta-analyses¹⁻⁴

Level II

- 7 retrospective reviews and prospective cohorts⁵⁻¹¹

Level IV

- Case reports, review articles, animal and laboratory studies

Question 1: What types of fractures lend themselves to fixation with calcium phosphate bone substitutes?

Case 1 clarification

Provisional fixation of this patient's fracture is obtained with wires (Figure 73.4). Open reduction with a lateral locking plate plus the use of calcium phosphate (alpha-BSM) allowed for rigid fixation (Figure 73.5).

Figure 73.4 Case 1: provisional fixation with wires.

Figure 73.5 Case 1: postoperative AP (a) and lateral (b) views of postoperative fixation with calcium phosphate in place.

Relevance

Periarticular fractures are common injuries that result from indirect coronal and/or direct axial compressive forces. As the patient ages, the fracture pattern is usually a split depression type without associated ligamentous injury. Surgical guidelines advocate anatomic reduction, re-establishment of the long bone alignment, subchondral bone grafting to support the articular cartilage, and stable internal fixation.²

Findings

Two recent prospective, randomized, multicenter trials have studied the use of calcium phosphate bone substitutes in periarticular fractures. Russell et al. compared the treatment of subarticular bone defects in tibial plateau fractures with conventional autogenous iliac bone graft (AIBG) to bioabsorbable calcium phosphate paste (alpha-BSM, EteX Corporation).² All fractures united in both groups within the same time periods.

There was an unexpected statistically significant ($p = 0.009$, Fisher's exact two-tailed test) higher rate of articular subsidence in the AIBG group compared to the alpha-BSM group. Subsidence of 2mm or more on the AP radiographs was found in 31% of patients in the AIBG group compared to 8% in the alpha-BSM group in the final evaluation. This provided level I evidence that bioabsorbable calcium phosphate material, such as alpha-BSM, appeared to be a better choice for treatment of subarticular defects than AIBG in tibial plateau fractures.

Johal et al. performed a similar randomized controlled trial (RCT) on os calcis fractures comparing open reduction and internal fixation (ORIF) plus alpha-BSM to ORIF alone

in the treatment of calcaneal bone voids encountered after operative treatment of displaced intraarticular fractures of the calcaneus.³ There was no difference between the groups in the degree of collapse of Bohler's angle at 6 weeks and 3 months when compared to initial postoperative values. However, at 6 months the mean collapse of the alpha-BSM and ORIF group was 5.6° and ORIF alone was 10.6° . This was statistically significant ($p < 0.01$).

Recommendations

- For a subarticular defect in metaphyseal bone, ORIF plus calcium phosphate provides better support for the elevated subarticular bone and prevents late subsidence [overall quality: high]
- There is no evidence to support the use of calcium phosphate in acute diaphyseal fractures or nonunions

Question 2: What type of bone graft should be used: autograft, allograft, or a calcium phosphate bone substitute?

Autogenous bone graft, typically from the iliac crest, has been stated in the past to be the gold standard of bone grafting. However, it is associated with donor site morbidity, including chronic pain and wound complications.^{5-9,12,13} Alternative grafting materials for filling fracture voids include allograft and synthetic bone materials. Although using allograft avoids the donor site morbidity associated with autograft, it also can lead to complications including potential disease transmission, histoincompatibility, and possibly lower union rates.^{10,14,15} Synthetic bone materials, such as calcium phosphate bone cement therefore appear

to be an attractive alternative. They perform better acutely and over the first year, and lack the disadvantage of bone site morbidity or the potential for infection and disease transmission associated with allograft.

There are several narrative review articles that address the use of bone grafting in fractures and trauma situations.^{16–19} In addition Bajammal et al. have completed a meta-analysis of studies comparing calcium phosphate bone cement to bone graft.¹ The meta-analysis included 15 RCTs. The studies had documented outcomes that included pain, maintenance of fracture reduction, infection, and functional outcomes.

The meta-analysis suggested that the use of calcium phosphate bone cement in treatment of fractures in adult patients is associated with lower incidences of pain and loss of fracture reduction; lower infection rates in radius fractures; and likely improved functional outcomes.

Recommendation

- Calcium phosphate avoids the need for a second incision to harvest autograft and results in a reduction in assessed pain and better maintenance of subarticular reduction

Question 3: What are the features of calcium phosphate that make it suitable as a bone substitute?

Findings

Calcium phosphate synthetic bone substitutes have been investigated as devices by the U.S. Food and Drug Authority (FDA) and by industry over the last number of years. Initially animal studies were done with critical defects in rats, dogs, and sheep.²⁰ Biomechanical studies were then undertaken, such as Trenholm et al.'s paper,²¹ indicating that calcium phosphate (alpha-BSM) in proximal tibias was stronger than the cancellous bone graft used to repair periarticular fractures (Figure 73.6).

Similar substances such as calcium sulfate and calcium phosphate resins have not been as successful. A study by Petruskevicius looking at Osteoset (Wright Medical) vs. no bone graft showed no difference in the amount of bone in the defect.⁴ The Osteoset pellets were almost resorbed after 6 weeks. A study looking at the use of calcium sulfate in nonunions demonstrated no improvement in bone healing, an increased infection rate, and increased wound drainage.¹¹ Calcium sulfate cement does not perform in the same way as calcium phosphate cement. Because of its early resorption it has also been noted to cause an early drainage in the wound that resembles very liquid white fluid. This has been confused with pus in some cases, so it has to be evaluated very carefully if used in cases prone to infection.

Kryptonite (Doctor's Research Group, Inc.), a calcium phosphate resin, has been mostly evaluated in the spine. It

Figure 73.6 Load–displacement curves showing the stiffness of calcium phosphate (alpha-BSM) compared to solid bone, cancellous bone, and a tibial plateau defect with no fill. Reproduced with permission from Trenholm A, Landry S, McLaughlin K, et al. Comparative fixation of tibial plateau fractures using a-BSM, a calcium phosphate cement, versus cancellous bone graft. *J Orthop Trauma* 2005;19:698–702.²¹

seems to work as an adhesive material. Unfortunately, for subarticular fractures it does not resorb at all. Bone does seem to grow around it and perhaps into the pores, but very little if any resorption occurs. Its use therefore appears to be in those areas where one might normally use polymethylmethacrylate cement. There are many ongoing on- and off-label studies, but no compelling level I information to date. This substance should only be used in acute fractures where prospective studies are being performed at this time.

Recommendations

- Calcium sulfate is not recommended for nonunions or periarticular fractures [overall quality: high]
- Osteoset T may be used carefully to allow a depot of tobramycin in the local area [overall quality: high]
- There is not enough evidence to support the use of calcium phosphate resins; therefore, these should only be used for acute fractures as part of a clinical trial.

Question 4: When does the calcium phosphate resorb?

Case 2 clarification

Initial management consists of plating the posterior medial plateau fragment to buttress it in place. This is followed by a lateral approach with a plate and the use of calcium phosphate to prevent late collapse (Figure 73.7). Beta-BSM putty was placed into the subarticular defect (Figure 73.8). The final radiographs illustrate resorption of the calcium phosphate (Figure 73.9). Figure 73.10 illustrates the correct position for the skin incisions for this simultaneous approach.

Figure 73.7 Case 2: postoperative AP (a) and lateral (b) views showing fixation and the graft in place laterally.

Figure 73.9 Case 2: postoperative AP (a) and lateral (b) views showing the graft nearly resorbed.

Figure 73.8 Case 2: insertion of calcium phosphate into the lateral defect.

Findings

According to Russell et al., gradual reduction in density of alpha-BSM was observed on successive radiographs, but approximately 10% of the material was still visible at 1 year in the majority of patients.² At 2 years it is no longer visible on plain radiographs. However, CT scans were not done on these patients so it could still be present in a microscopic sense.

Recommendation

- Calcium phosphate is clinically resorbed by 1 year [overall quality: high]

Question 5: Are there any other benefits to using calcium phosphate?

Case 3 clarification

A closed reduction was performed and the radius pinned with two crossed Kirchner wires (K-wires). Gamma-BSM putty was injected into the dorsal comminuted area (Figure 73.11).

Findings

According to the meta-analysis by Bajammal et al., the use of calcium phosphate reduces the risk of infection in distal radius fractures.¹ This is in addition to better maintenance of the articular reduction. Calcium phosphate by itself will not provide stability. It must be only used as addition to the usual fixation.

The cost of autogenous bone graft harvesting was investigated in a study by St. John et al.²² The direct and indirect costs involved in harvesting iliac crest were gathered from a cross-section of hospitals in the United States by means of a questionnaire completed by both finance and surgical staff. The study concluded the mean cost of autologous bone graft is estimated to be \$4,154, assuming a hospital stay extended by 1 day. In comparison, 10mL of alpha-BSM, an amount commonly used in Russell’s trial,² has an average cost of US\$1270. Additional cost savings include no additional tray instrumentation and a reduction in operating time.

Recommendations

- Calcium phosphate reduces infection risk in distal radius fractures when used in addition to fixation [overall quality: moderate]

Figure 73.10 Case 2: location of the skin incision for the posterior medial approach (a) and the lateral approach (b).

Figure 73.11 Postoperative radiograph of the wrist with fixation (crossed Kirschner wires) and calcium phosphate to fill the dorsal defect.

- Inclusive healthcare costs are actually less with calcium phosphate than iliac crest autograft if it saves the patient a day or more in hospital [overall quality: moderate]

Summary of recommendations

- For a subarticular defect in metaphyseal bone, using fixation plus calcium phosphate provides better support for the elevated bone and prevents late subsidence
- There is no evidence to support the use of calcium phosphate in acute diaphyseal fractures or nonunions
- Calcium phosphate avoids the need for a second incision to harvest autograft and results in less pain and less loss of fracture reduction
- Calcium sulfate is not recommended for nonunions or peri-articular fractures
- Osteoset T may be used carefully to allow a depot of tobramycin in the local area
- There is not enough evidence to support the use of calcium phosphate resins; therefore, these should only be used for acute fractures as part of a clinical trial
- Calcium phosphate is clinically resorbed by 1 year
- Calcium phosphate reduces infection risk in distal radius fractures when used in addition to fixation
- Inclusive healthcare costs are actually less with calcium phosphate than iliac crest autograft if it saves the patient a day or more in hospital

Conclusion

When dealing with a fresh periarticular fracture with a contained defect in the metaphysis of the bone, it appears

that the literature would support the following: if two techniques are equally successful, it seems logical that the simpler procedure should be the surgeon's first choice. Bone grafting for subarticular defects in periarticular fractures should be discouraged in favor of bioresorbable calcium phosphate material in order to improve the early maintenance of the subchondral reduction, improve pain and prevent late collapse.

Philipp Kobbe and Hans-Christoph Pape

University Hospital, Aachen, Germany

Case scenario

A young man was involved in a severe motor vehicle accident. Rescue time was approximately 65 minutes. Upon admission the patient is mechanically ventilated, hemodynamically unstable with a systolic blood pressure of 85 mmHg and has a core body temperature of 33°C. Obvious findings are diminished ventilation of the right thorax, an extended abdomen, an unstable pelvis, a bilaterally displaced femur, and a displaced right tibia.

- Early total care (ETC): a concept implying the primary definitive management of all major injuries within 24 hours after trauma
- Damage control orthopedics (DCO): minimally invasive surgical techniques are used for the primary stabilization of all major fractures. Based upon the patient's physiological status, temporary stabilization with external fixation for certain fractures is used.

Patient's condition determined by physiology

Relevant definitions

Polytrauma

The term polytrauma defines a patient with multiple injuries of which at least one injury or the combination of several injuries is life-threatening. When scoring systems are used, patients with an Injury Severity Score (ISS) of 16 points or more are classified as polytrauma.¹

Openmirrors.com *Stable patients* have no immediately life-threatening injuries and respond to initial therapy.

- *Borderline patients* have stabilized in response to initial resuscitative attempts but sustained injuries that put them at risk of rapid deterioration (Table 74.1).
- *Unstable patients* remain hemodynamically unstable despite initial intervention and are at high risk for clinical complications.
- *Patients in extremis* have ongoing uncontrolled blood loss despite resuscitation and may succumb if blood loss is not immediately stopped.

Definitions

- Injury Severity Score (ISS): an anatomical scoring system that provides an overall score for patients with multiple injuries
- New Injury Severity Score (NISS): a modification of the ISS. In contrast to the ISS, which considers at most one injury per body region, the NISS takes the three most severe injuries regardless of the body region into account

Importance of the problem

During the last decade there has been a debate on whether severely injured patients should be managed by definitive operative care or whether a staged management is favorable. In patients under 45 years of age, trauma is the leading cause of death worldwide, with about 5.8 million deaths/year.² Today, motor vehicle accidents account for approximately 1.2 million deaths/year³ and it has been estimated that this will increase to 8.4 million deaths/year by 2020.⁴

Table 74.1 Clinical features or injuries defining the borderline patient^{2,8}

ISS >40
Hypothermia below 35°C
Patients with bilateral femoral fracture
Multiple injuries (ISS >20) in association with thoracic trauma (AIS >2)
Multiple injuries in association with severe abdominal or pelvic injury and hemorrhagic shock at presentation (systolic BP <90 mmHg)
Radiographic evidence of pulmonary contusion
Patients with moderate or severe head injuries (AIS ≥3)
Initial mean pulmonary arterial pressure >24 mmHg or a >6 mmHg rise in pulmonary artery pressure during intramedullary nailing or other operative intervention

AIS, Abbreviated Injury Scale; BP, blood pressure; ISS, Injury Severity Score.

Severe traumatic injuries have a higher socioeconomic impact in the age group under 45 years than cardiovascular or neoplastic diseases.⁵

Top four questions

1. Does DCO reduce primary operation time and blood loss?
2. Does DCO reduce systemic complications and mortality in the severely injured patient?
3. Does DCO influence the posttraumatic inflammatory response?
4. Is DCO associated with an increased risk of local infection?

Question 1: Does DCO reduce primary operation time and blood loss?

Case clarification

The question arises whether this patient's fractures should be managed with definitive operation right away or whether they should be stabilized with external fixation and minimally invasive techniques.

Relevance

Lengthy operations with increased blood loss after trauma are a heavy burden for the polytraumatized patient.

Current opinion

DCO reduces initial operation time and blood loss.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search using [Text Word]: "damage control" AND "blood loss" as well as "damage control" AND "operation time"

Quality of the evidence

Level II

- 1 prospective controlled trial⁶

Level III

- 2 retrospective cohorts^{7,8}

Findings

In their retrospective study, Scalea et al. compared blood loss and operation time in patients with fractures of the femur either managed with ETC (n = 284) or DCO (n = 43).⁷ Median operating room time for patients managed with DCO was 35 minutes with an estimated blood loss of 90 mL. In patients managed with ETC the median operating room time was 135 minutes with an estimated blood loss of 400 mL. Similar results have been reported by Tuttle et al., who found a significantly reduced operation time (22 minutes vs. 125 minutes) and blood loss (37 mL vs. 330 mL) in patients with femoral shaft fractures managed with DCO (n = 55) as compared to ETC (n = 42).⁸

These findings have been confirmed by Taeger et al. who managed 75 patients with DCO of which they converted 57 patients in the course of surgery (hypothetical ETC).⁶ Operation time for DCO was 62 ± 30 minutes as compared to a significantly higher mean operation time for conversion (hypothetical ETC) of 233 ± 19 minutes. Also, blood loss was significantly reduced for DCO (<50 mL) as compared to hypothetical ETC (472 mL).

Recommendation

- In critical patients DCO is useful to perform fracture stabilization faster and less bloodily than ETC [overall quality: moderate]

Question 2: Does DCO reduce systemic complications and mortality in the severely injured patient?

Case clarification

The patient is managed according to DCO principles. Although severely injured, he survives and develops no signs of organ failure.

Relevance

A subset of polytraumatized patients does not tolerate ETC right after trauma and dies during the lengthy primary surgery.

Current opinion

The trauma population is a very heterogenic group and the application of the DCO concept does not make sense in all patients. Most patients (~85%) can be treated with ETC without complications; however, a subset of severely injured patients, especially those with severe thoracic and head injuries, appears to benefit from DCO.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search using time interval from 1990 to present in English language with the following [Text Word]:
 - “timing of stabilization” OR “timing of fixation” AND “mortality” OR “morbidity”
 - “damage control” AND “mortality” OR “morbidity”
 - “delayed stabilization” OR “delayed fixation” AND “mortality” OR “morbidity”
 - “early stabilization” OR “early fixation” AND “mortality” OR “morbidity”

Quality of the evidence

Level I

- 1 study investigating systemic complications⁹

Level III

- Several retrospective studies^{7,10-21}

Findings

Including all suitable studies in the analysis it appears that DCO principles have no benefit in terms of mortality as compared to ETC; however, several included studies have major limitations, e.g., a significantly higher ISS in the DCO group (Figure 74.1).^{7,10,13,16,19} Analyzing the effect of DCO

without these biased studies shows a trend towards a reduced mortality in the overall trauma population managed with DCO as compared to ETC (Figure 74.2). The benefit of DCO becomes even more obvious once the heterogenic trauma population is divided into subgroups (stable, borderline, unstable, in extremis). This is supported by Morshed et al. with their retrospective study including 3,069 patients and by the only available prospective study investigating the incidence of acute lung injury, showing that ETC is fine in stable patients but has a higher risk of mortality and acute lung injury (ALI) in more severely injured patients (borderline patients) than DCO.^{9,17} Prospective randomized clinical trials (RCTs) for the management of femur fractures in polytraumatized patients are listed in Table 74.2.

Nonetheless, the evidence for DCO is difficult to establish since most studies are retrospective cohorts which are not matched for ISS. Further, the impact of several studies is limited due to selection bias: in many countries the patient is cleared for surgery either by the Emergency Department or intensive care unit (ICU) physician, thus these studies only investigate the method of primary stabilization in stable patients who usually do not benefit from DCO; some studies even equate DCO with plaster stabilization of long-bone fractures.

Openmirrors.com Recommendation

- So far there is no evidence that the concept of DCO reduces mortality in the overall polytrauma population; however, there is growing evidence that severely injured patients (categorized as borderline, unstable, or in extremis) benefit from DCO [overall quality: moderate]

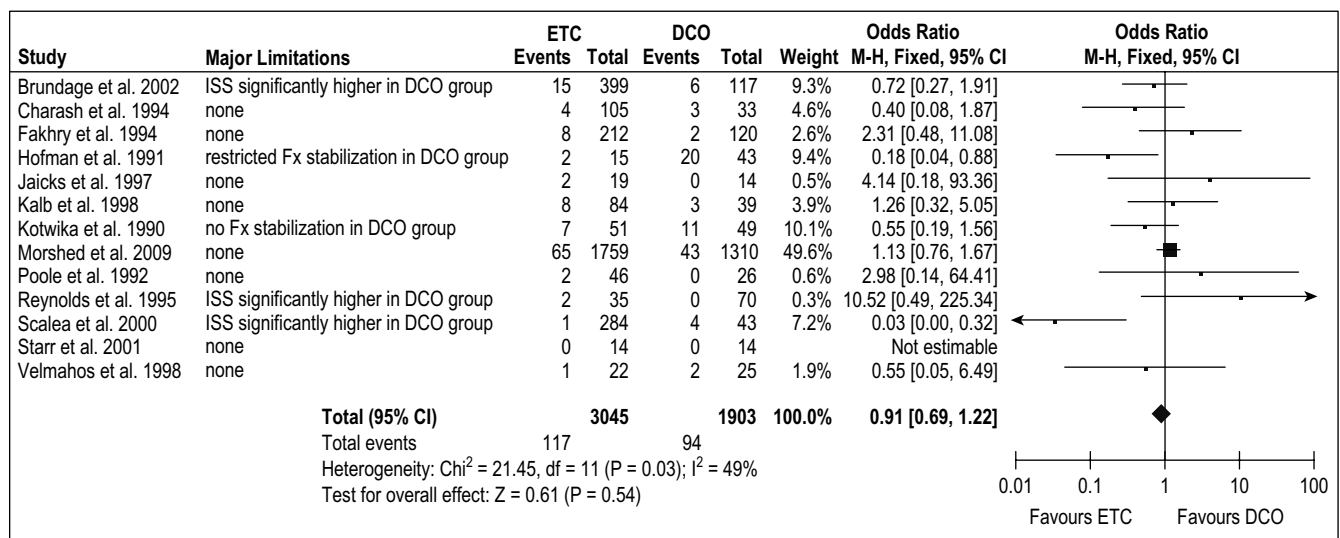

Figure 74.1 Overview of cohort studies investigating the incidence of mortality depending on the initial surgical approach (ETC vs. DCO).

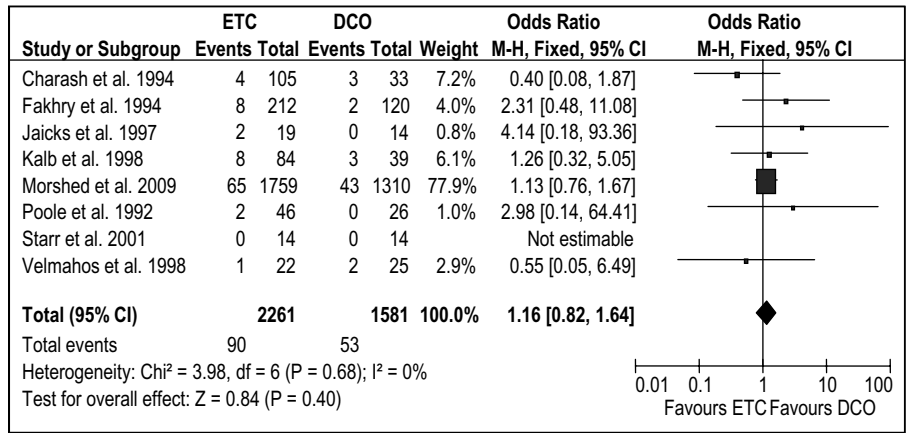

Figure 74.2 Exclusion of studies with major limitations shows a trend towards a favorable DCO treatment in the overall trauma population.

Table 74.2 Prospective randomized trials for the management of femur fractures in severely injured patients^{23,29,30}

Study	Year	Level of evidence
Bone et al.	1989	II (moderate)
Pape et al.	2003	I (high)
Can. Orthop. Trauma Soc.	2006	I (high)

Question 3: Does DCO influence the posttraumatic inflammatory response?

Case clarification

A major risk factor for systemic complications is an overwhelming posttraumatic inflammatory response.

Relevance

The systemic inflammatory response after trauma is recognized as a part of the physiologic reaction and called the “first-hit” phenomenon.²² The “second hit” is observed to be compounded by factors such as the type of surgical procedure, blood loss, sepsis, and ischemia, all of which can increase the inflammatory response.²² The overriding principle of damage control surgery is therefore to minimize subsequent stresses imposed upon unstable patients with high risk of posttraumatic complications.

Current opinion

The DCO concept reduces the second-hit phenomenon and lowers the inflammatory response.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search using [Text Word]: “inflammation” AND “fracture stabilization” as well as “inflammatory response” AND “damage control orthopedics” OR “early total care”

Quality of the evidence

Level I

- 1 prospective randomized multicenter study²³

Level III

- 1 retrospective clinical investigation²⁴

Findings

In a prospective randomized multicenter study, 35 poly-traumatized patients (ISS >16) with long-bone shaft fractures were included.²³ Patients were either managed with ETC (n = 17) or with DCO (n = 18) and serum inflammatory markers were measured pre-, peri-, and postoperatively. The main findings are that a sustained increase in the inflammatory burden was only obvious in the patients managed with ETC, but not after initial external fixation and secondary conversion to an intramedullary implant. These data are supported by a cohort of 174 patients with femoral shaft fractures and a NISS of 20 or more.²⁴ Patients in the DCO group (n = 97) had a significantly higher NISS than those in the ETC group (n = 77), but patients managed with ETC showed a significantly higher systemic inflammatory response.

Recommendation

- There is some evidence that DCO minimizes the second-hit phenomenon, and these findings may become clinically relevant in patients at high risk of developing systemic complications [overall quality: moderate]

Question 4: Is DCO associated with an increased risk of local infection?

Case clarification

The patient’s fractures were converted to intramedullary implants between days 8–20 after trauma. The patient developed osteomyelitis of his right tibia, resulting in lower leg amputation.

Relevance

Pin tract infection can be the source of severe complications, such as osteomyelitis and sepsis.

Current opinion

We perform a conversion to definitive implants once the systemic inflammatory response has been resolved, which is usually around days 5–7 after trauma. In cases of an unknown inflammatory status, inflammatory mediators such as serum interleukin-6 (IL-6) can be measured.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search using [Text Word]: “damage control” OR “external fixation” AND “infection”

Quality of the evidence

Level III

- 3 retrospective studies directly comparing the incidence of infection between groups of early vs. delayed definitive care^{7,25,26}
- Several studies reporting on the incidence of infection following external fixation in polytrauma patients

Findings

Van den Bossche et al. showed that external fixation for femoral shaft fractures in severely injured patients is a safe option in terms of infectious complications (neither superficial nor deep infections).²⁷ Harwood et al. showed that the risk of infection following DCO was equivalent as compared with primary definitive care (~4.5%).²⁵ Equivalent results have been reported by Scalea et al. and Nowotarski et al., who found no significant differences in infectious complications comparing DCO with ETC.^{7,26} Although no increased risk of infection following external fixation could be shown, contamination of pin sites was significantly more likely when conversion to intramedullary nailing occurred later than 14 days after trauma.²⁵

Recommendation

- There is some evidence that DCO is associated with an increased risk of local infection. In view of the inflammatory burden, conversion to a definitive, biomechanical superior implant should not be performed before days 5–7 after trauma. However, due to an increased risk of local pin site contamination it is recommended that the conversion should be performed before day 14 [overall quality: low]

Summary of recommendations

Overall there is a moderate level of evidence for the following recommendations:

- DCO should be applied in patients who fail to tolerate primary lengthy operations with an associated increase of intraoperative inflammation and blood loss. Typically, these are patients who have been defined as unstable or in extremis
- Patients defined as borderline should be re-evaluated during surgery
- When in doubt about the patient’s condition, treat according to DCO principles, because DCO is a safer initial approach, significantly decreasing the initial operative exposure and blood loss

Conclusions

DCO reduces the primary operative burden by reducing intraoperative inflammation, blood loss, and operation time. This is of minor importance in stable patients but has clinical relevance for critical patients in the initial treatment phase. These patients should be managed with external fixators which should be converted to a definitive fixation method within 14 days after trauma.

Ted V. Tufescu

University of Manitoba, Winnipeg, MB, Canada

Case scenario

A motorcyclist collides with a car at highway speed. He is brought to the Emergency Department with a severe open injury of his leg.

Relevant anatomy

Any extremity may be mangled. At least three out of four tissue groups are affected (integument/soft tissue, nerve, vessels and bone).¹ Lower extremities are more commonly involved, with 63% tibia and 23% femur fractures.²

Arterial injuries can determine the prognosis of the limb,³ while nerve injury is less important.⁴ The most frequent vascular injury is to the popliteal artery,^{2,5} which enters the popliteal fossa via the adductor canal, at the distal femur. Here it travels immediately posterior to the knee. It then exits the popliteal fossa and enters the posterior compartment of the leg under the origin of the soleus muscle. The popliteal artery is therefore fixed at the adductor canal and soleus origin. This places it at risk of being torn with displaced fractures and dislocations about the knee.

Importance of the problem

Although uncommon, this is the most severe limb injury short of traumatic amputation. It frequently results in severe disability and loss of work.^{6,7}

In addition, the physician is faced with one of the toughest decisions in medicine: whether the limb should undergo salvage or amputation. Salvage may require multiple, costly procedures,⁶ and may result in failure rates as high as

40%.⁸⁻¹¹ Patients with failed salvage would not do it again;^{8,11} however, at the time of injury 92% prefer an attempt at salvage.⁹ This chapter reviews factors that influence the decision to salvage or amputate the mangled extremity.

Top five questions

Diagnosis

1. When does an open fracture (Gustilo–Anderson grade III) become a mangled extremity?

Therapy

2. What is the expected resource investment for salvage vs. amputation?
3. What patient factors affect success of therapy and return to work?
4. What is the utility of scoring systems in choosing between salvage and amputation?

Prognosis

5. What is the outcome after salvage and amputation?

Question 1: When does an open fracture (Gustilo–Anderson grade III) become a mangled extremity?

Gustilo graded open fractures I through III based on increasing involvement of soft tissue and bone². Grade III fractures are subdivided, with III B requiring soft tissue reconstruction and III C requiring vascular bypass¹².

SECTION IV Trauma / IV.IV General**Case clarification**

The emergency physician diagnoses a Gustilo–Anderson IIIB open tibia fracture. He counsels the patient that with current technology, there is little risk of amputation.

Relevance

Understanding when in the spectrum of open fractures amputation becomes a real possibility allows better management decisions.

Current opinion

Current opinion suggests Gustilo–Anderson grade IIIB and IIIC injuries have substantial amputation rates.

Finding the evidence

The search strategy employed was based on a recent systematic review.¹²

- MEDLINE: “leg injuries” AND “(amputation OR limb salvage OR reconstructive surgical procedures)”
- CINAHL: “leg injuries” AND “(amputation OR limb salvage OR reconstructive surgical procedures)”
- EMBASE: “leg injuries” AND “(amputation OR limb salvage OR reconstructive surgical procedures)”

Quality of the evidence

Level III

- 8 studies^{3,9,10,13–17}

Findings

Gustilo reported overall amputation rates of 0% for IIIA, 16% for IIIB, and 42% for IIIC fractures.¹²

Primary amputation rate Amputation is primary when it is the planned initial treatment. Data was pooled from five studies.^{3,14,15,16,18} The average primary amputation rate was 0% for IIIA fractures (0 of 82), 7% for IIIB (11 of 149) and 44% for IIIC (28 of 63). See Table 75.1.

Delayed amputation rate Delayed amputation follows attempted salvage. Depending on follow-up duration, it is possible that some delayed amputations were missed. Data was pooled from seven studies.^{3,9,10,14–17} The average delayed amputation rate was 1% for IIIA fractures (1 of 93), 9% for IIIB (23 of 256), and 36% for IIIC (23 of 64). See Table 75.2.

Recommendations

- Gustilo IIIA fractures are unlikely to require amputation [overall quality: low]
- Gustilo IIIB and IIIC fractures may require amputation [overall quality: low]

Table 75.1 Primary amputation rate (raw data and calculated averages)

	Gustilo–Anderson grade			Reference
	IIIA	IIIB	IIIC	
Primary amputation rate	0% (0 of 42)	7% (5 of 67)		14
	0% (0 of 40)	0% (0 of 18)	45% (10 of 22)	16
		2% (1 of 43)		15
		24% (5 of 21)	72% (13 of 18)	17
			22% (5 of 23)	3
Average primary amputation rate	0% (0 of 82)	7% (11 of 149)	44% (28 of 63)	

Table 75.2 Delayed amputation rate (raw data and calculated averages)

	Gustilo–Anderson grade			Reference
	IIIA	IIIB	IIIC	
Delayed amputation rate	0% (0 of 42)	3% (2 of 67)		14
	0% (0 of 11)	16% (7 of 43)	78% (7 of 9)	15
	2.5% (1 of 40)	6% (1 of 18)	14% (3 of 22)	16
		9% (2 of 22)	60% (3 of 5)	10
		10% (4 of 41)	20% (1 of 5)	9
		11% (7 of 65)		18
			39% (9 of 23)	3
Average delayed amputation rate	1% (1 of 93)	9% (23 of 256)	36% (23 of 64)	

Question 2: What is the expected resource investment for salvage vs. amputation?**Case clarification**

This man lives in a remote location 8 hours from the hospital. He would prefer a short hospitalization time so he can rejoin his family.

Relevance

Salvage and amputation place different requirements on the patient and the surgeon. This should be considered before initiating treatment.

Current opinion

Current opinion suggests that limb salvage requires greater resource investment.

Finding the evidence

See Question 1.

Quality of the evidence*Level II*

- 1 study¹⁹

Level III

- 4 studies^{9,10,16,20}

Findings

Cost Georgiadis reported a lower acute hospitalization charge (\$65,624) for amputation than for salvage (\$109,044) ($p < 0.006$).¹⁰ Hertel reported equal mean annual hospital cost, based on 4 years, for amputation (15,112 Swiss francs) and salvage (17,365 Swiss francs).¹⁶ MacKenzie reported equal long-term hospital costs for amputation (\$78,221) and salvage (\$81,091).¹⁹ Hertel reported a higher total cost, including pension and loss of wage benefits for amputation (64,000 Swiss francs) than salvage (33,000 Swiss francs) ($p < 0.01$).¹⁶ Including lifetime prosthesis-related costs, amputation is three times more costly (\$509,275) than salvage (\$163,282).¹⁹

Hospitalization and rehabilitation time Georgiadis reported a shorter acute hospitalization for amputation (48 days) than salvage (71 days) ($p < 0.05$).¹⁰ Dagum reported equal stays for amputation (28 days) and salvage (25 days).⁹ Georgiadis reported shorter readmission for amputation (5 days) than for salvage (18 days).¹⁰ Hutchins reported equal total hospital stays, including readmission, for amputation (14 weeks) and for salvage (14.8 weeks).²⁰ Hertel emphasized the importance of rehabilitation center admission.¹⁶ Total acute and rehabilitation admission times were equal for amputation (101 days) and for salvage (129 days).²⁰ Hutchins reported shorter outpatient rehabilitation time for amputation (12 months) than for salvage (30 months), although this was self-reported by patients ($p < 0.009$).²⁰

Recommendation

- The cost of salvage and amputation is:
 - probably equal, for in-hospital charges [overall quality: low]

- higher for amputation, when considering lost wages, pension, and lifetime prosthesis-related charges [overall quality: moderate]

- The duration of hospitalization for salvage and amputation is probably equal [overall quality: low]
- The duration of rehabilitation for salvage and amputation is equal for inpatient and probably shorter for outpatient rehabilitation of amputation patients [overall quality: low]

Question 3: What patient factors affect success of therapy and return to work?**Case clarification**

The physician inquires whether the patient's family should be notified. This man divorced after his family business failed. He was unable to find other employment due to poor education, and has no other social support.

Relevance

Patient factors are often overshadowed by the urgency of the situation, but they have an important influence on success of therapy, and may guide necessary counseling.

Current opinion

Current opinion suggests that certain patient factors, such as education level and presence of social support, can affect success of therapy.⁶

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 2 studies^{6,21}

Level II

- 1 study⁷

Level III

- 2 studies^{9,20}

Findings

Predictors of outcome Dagum reported patient involvement with legal action was not associated to SF-36 mental component scores or WOMAC pain scores,⁹ in a small study. The LEAP (Lower Extremity Assessment Project) studies analyzed a large body of prospectively collected data and measured outcome with the Sickness Impact Profile (SIP).^{6,7} The following patient characteristics predicted poor outcome at 2 years:⁶ less than high school education, household income below poverty level, being nonwhite, lack of insurance, poor social support network, low level of self-efficacy (confidence in one's ability to resume chief life

activities), smoking, and involvement with the legal system for injury compensation. The following predicted poor outcome at 7 years:⁷ low education level, older age, female gender, being nonwhite, household income below poverty line, smoking, low self-efficacy, poor self-reported health status before injury, and involvement with the legal system for injury compensation. Success of salvage and amputation was equally influenced.

Predictors of return to work Hutchins reported older age to be inversely related to return to work (RTW).²⁰ The LEAP study found the following predictors of RTW:²¹ age less than 55, being white, high school or college education, being a nonsmoker, average to high self-efficacy and motivation (high job involvement and being in a preinjury job for one or more years). Involvement with the legal system for compensation predicted lower RTW.²¹

Recommendation

- Patient characteristics predicting poor outcome and difficulty with RTW are: older age, being nonwhite, lack of education, poverty, smoking, involvement in disability-compensation litigation, and low self-efficacy [overall level: moderate]

Question 4: What is the utility of scoring systems in choosing between salvage and amputation?

Case clarification

A junior physician calculates a Mangled Extremity Severity Score (MESS) greater than 7.²² She suggests amputation is warranted.

Scoring systems grade the injury based on physical findings. A score higher than a set threshold is predictive of amputation. MESS is based on injury findings, ischemia time, shock, and age. The threshold for amputation is 7.

Relevance

A limb may be inappropriately amputated if a scoring system is applied without understanding the supporting evidence and its role in clinical practice.

Current opinion

Current opinion suggests that scoring systems should not be considered in isolation, but rather in combination with clinical judgment.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 4 studies^{22,25,29,30}

Level II

- 6 studies^{1,23,24,26,27,28}

Findings

The Mangled Extremity Syndrome Index (MESI) was created in 1985. The authors reported 100% accuracy,¹ but Bonanni reported only 6% sensitivity and 90% specificity.²³ The Predictive Salvage Index (PSI) was created in 1987. The authors reported 78% sensitivity and 100% specificity,²⁴ while Bonanni reported only 33% sensitivity and 70% specificity.²³ The MESS was created in 1990. Multiple studies reported 100% sensitivity and 100% specificity,^{22,25-27} but Bonanni reported only 22% sensitivity and 53% specificity.²³ The Limb Salvage Index (LSI) was created in 1991. The authors reported 100% sensitivity and 100% specificity,²⁸ while Bonanni reported only 61% sensitivity and 43% specificity.²³ The Nerve injury, Ischemia, Soft tissue injury, Skeletal injury, Shock and Age of patient score (NISSA) was created in 1994. The authors reported improved sensitivity and specificity compared to the MESS, at the cost of increased complexity.²⁷ The LEAP study looked at all scoring systems prospectively and found that low scores predicted salvage,²⁹ but high scores did not predict amputation, as some of these limbs were successfully salvaged.²⁹ The LEAP group also showed that scoring systems are not predictive of function after salvage.³⁰

Recommendation

- Scoring systems predict limb salvage [overall level: high]
- Scoring systems do not predict amputation [overall level: high]
- Scoring systems do not predict function of salvaged limbs [overall level: high]

Question 5: What is the outcome after salvage and amputation?

Case clarification

At 2 year follow-up the patient has ongoing pain and has not returned to work. He wonders if further recovery is expected.

Relevance

Ultimately, patients and physicians must be aware of the outcomes of both limb salvage and amputation. The longest prospective record and measure of outcome is provided by the LEAP study.

Current opinion

Current opinion suggests that patients suffer significant disability after a mangled extremity, regardless of treatment type.⁶

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 2 studies^{4,6}

Level II

- 2 studies^{7,31}

Level III

- 5 studies^{3,8-11}

Findings

Outcome At 2 years the SIP was the same for salvage and amputation;⁶ 42% of all patients had a SIP greater than 10, indicating severe disability.⁶ RTW was 49% after salvage and 53% after amputation.⁶ At 7 years, 49.4% of all patients had a SIP greater than 10.⁷ Between 2 year and 7 year follow-up, rehospitalization was 39.4% for salvage and 33.3% for amputation patients.⁷ Through-the-knee amputees had a worse outcome.⁷ Most studies support these findings,⁸⁻¹¹ with minor exceptions.^{3,9,10} Dagum reported better SF-36 physical function scores after salvage.⁹ Georgiadis reported longer time to weightbearing, and more interference of health on work and recreation for salvage.¹⁰ Lange reported greater walking distances after salvage.³

Outcome after insensate foot At 2 year follow-up, 55% of patients with an insensate foot had normal plantar sensation.⁴ An insensate foot did not lead to worse function at 2 years.⁴

Complications The most common complication after salvage is nonunion (31.5%), usually diagnosed at 6 months.³¹ The most common complication after amputation is wound infection (34.2%), which usually occurs at 3 months.³¹ Salvage patients have more complications, longer time to complication, and require more interventions.³¹

Recommendation

- Outcome of salvage and amputation is equal [overall level: high]
- Outcome does not improve from 2 to 7 years after injury [overall level: high]
- Lack of plantar sensation is not predictive of long-term sensory status or function [overall level: high]
- Salvage patients have a higher risk of complications [overall level: moderate]

Summary of recommendations

- Gustilo IIIA fractures are unlikely to require amputation, while Gustilo IIIB and IIIC fractures may require amputation

- The cost of salvage and amputation is probably equal for in-hospital charges, but higher for amputation, when considering lost wages, pension and lifetime prosthesis-related charges
- The duration of hospitalization for salvage and amputation is probably equal
- The duration of rehabilitation for salvage and amputation is equal for inpatient and probably shorter for outpatient rehabilitation of amputation patients
- Patient characteristics predicting poor outcome and difficulty with RTW are: older age, being nonwhite, lack of education, poverty, smoking, involvement in disability-compensation litigation, and low self-efficacy
- Scoring systems predict limb salvage but they do not predict amputation or function of salvaged limbs
- Outcome of salvage and amputation is equal, and outcome does not improve from 2 to 7 years after injury
- Lack of plantar sensation is not predictive of long-term sensory status or function
- Limb salvage patients have a higher risk of complications

Conclusions

The decision to salvage or amputate remains difficult. Outcomes are poor with both options. Patient characteristics are not helpful in choosing treatment, and scoring systems provide little guidance. Amputation is more costly, due to prosthesis-related charges, and salvage leads to more complications.

Adult Spine

Openmirrors.com

Gabrielle van der Velde

Toronto Health Economics and Technology Assessment (THETA) Collaborative, University of Toronto, and Institute for Work & Health, Toronto, ON, Canada

Case scenario

A 50 year old woman presents with acute neck pain which she attributes to sleeping in an awkward position. The pain is sharp and tight, and located over the right posterolateral aspect of her neck. The patient also describes a generalized ache involving her right upper back and arm.

Relevant anatomy

Nonspecific (mechanical) neck pain is a symptom-based diagnosis of exclusion that is assigned once serious, observable cervical spinal pathology has been ruled out. In the United States, patients presenting with neck pain are assigned symptom-based rather than pathology-based diagnoses in 64% of physician office or hospital outpatient visits.¹

The Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders (Neck Pain Task Force) has proposed a clinical grading system for neck pain (Table 76.1), similar to the severity grading for whiplash-associated disorders proposed by the Québec Task Force on Whiplash-associated Disorders.^{2,3} In most settings, a simple descriptive clinical diagnosis is preferable to a speculative assignment of causation with respect to the origin of pain (e.g., cervical facet irritation, cervical facet joint dysfunction), since there is no definitively identifiable tissue lesion associated with nonspecific neck pain. This chapter focuses on the nonoperative management of acute neck pain without structural pathology or radiculopathy: grade I–II neck pain.

Importance of the problem

Neck pain is common: 30–50% of adults in the general population experience neck pain in any given year.⁴ Neck pain prevalence rises with increasing age and peaks in middle-aged individuals.⁴ On average, women are affected twice as often as men.⁴ The incidence of self-reported neck pain in the general population is estimated to be 146–213 per 1,000 persons.⁴ During 2000 and 2001 in the United States, 10.2 million visits for neck pain were made to physician offices and hospital Outpatient/Emergency Departments.¹ These numbers underestimate the total number of visits to all practitioners because visits to complementary and alternative medicine providers (e.g., chiropractors, massage therapists, physiotherapists) were not included.

Top five questions

History

1. What are the “red flags” that are used during history-taking to rule out serious pathology underlying neck pain?

Treatment

2. Have physical electro-modalities been demonstrated to be effective compared to placebo, or other treatments, for nonspecific neck pain?
3. Has acupuncture been demonstrated to be effective compared to placebo, or other treatments, for nonspecific neck pain?

Table 76.1 The Bone and Joint 2000–2010 Task Force on Neck Pain and Its Associated Disorders clinical grading system for neck pain²

Grade	Clinical presentation
I	No signs of major pathology. No or little interference with daily activities. This is frequently the case. Reassurance is typically all that is required
II	No signs of major pathology, but interference with daily activities. This occurs less frequently (<10% of people report having experienced this severity of pain during the previous year). Clinical intervention may be provided to decrease symptoms
III	Neck pain with neurological signs ^a or symptoms (radiculopathy). This is uncommon, but may require specific tests and treatments
IV	Neck pain with signs of major pathology (e.g., serious instability or spinal infection). Rare, but might require urgent tests and treatments

^aNeurologic signs include decreased or absence of deep tendon reflexes, weakness, and sensory deficits.

4. Have nonsteroidal anti-inflammatories (NSAIDs), muscle relaxants, or analgesics been demonstrated to be effective compared to placebo, or other treatments for non-specific neck pain?

Harm

5. What is the risk of stroke associated with cervical manipulation?

Question 1: What are the “red flags” that are used during history-taking to rule out serious pathology underlying neck pain?

Case clarification

During history-taking, the patient states that she was previously diagnosed with melanoma in situ 7 years ago, which was successfully excised. She was monitored for 5 years following surgical resection with no recurrence.

Relevance

The presence of red flags raise the suspicion of serious underlying spinal pathology; their absence rules out the need for special investigations.

Current opinion

Clinicians who treat neck pain should use a collection of red flags during assessment similar to those formally pro-

Table 76.2 System of “red flags” for triage of neck pain patients seeking care in nonemergency settings suggested by the Bone and Joint Decade 2000–2010 Task Force on Neck Pain and Its Associated Disorders⁸

Suggested red flag	Definition
Trauma	Minor or no trauma, but potential for bone loss due to osteoporosis or corticosteroid treatment
Tumour, cancer, malignancy	Previous history of cancer, unexplained weight loss, failure to improve after a month of therapy
Spinal cord compromise	Cervical myelopathy (where about half of patients with cervical myelopathy have pain in their neck or arms, most have symptoms of arm, leg or, uncommonly bowel and bladder dysfunction)
Systemic diseases	Ankylosing spondylitis, inflammatory arthritis or other
Infections	Intravenous drug abuse, urinary tract infection or skin infection
Pain	Intractable pain, tenderness over vertebral body
Prior medical history	Previous neck surgery

posed for the examination of acute low back pain by professional organizations worldwide.⁵⁻⁷

Finding the evidence

- MEDLINE: suggested search terms: “neck pain” (MeSH term, exploded), combined with “assessment” or “examination” or “history” or “guideline” (search as keywords), combined with “red flags” (search as keyword), and limited to “English” (publication language).

Quality of the evidence

- 1 best-evidence synthesis⁸

Findings

There are currently no formal systems of red flags for the assessment of neck pain as there are for the assessment of low back pain.⁵⁻⁸ The Neck Pain Task Force has therefore suggested a list of red flags for patients with no exposure to blunt trauma, similar to those currently used in the assessment of low back pain (Table 76.2).

Recommendations

- Serious underlying pathology must be considered during assessment of neck pain
- A suggested system of red flags can be used during patient history until a formal system is validated for neck pain

Question 2: Have physical electro-modalities been demonstrated to be effective compared to placebo, or other treatments, for nonspecific neck pain?

Case clarification

The patient denies symptoms suggestive of radiculopathy. Active cervical range of motion is mildly reduced. She is neurologically intact. The clinical presentation is consistent with grade II neck pain (Table 76.1). She would like maintain her usual work activities and asks whether she should buy a transcutaneous electrical nerve stimulation (TENS) unit to provide relief while she works at her sedentary job.

Relevance

There are numerous electro-modalities available for neck pain treatment. It is important to select treatments with demonstrated effectiveness.

Current opinion

The effectiveness of physical electro-modalities remains unclear and opinions are mixed regarding their effectiveness.

Finding the evidence

- Cochrane Library: “by topic” > “back” > “cervical spine” > “nonspecific neck pain”
- MEDLINE: suggested search terms: “neck pain” (MeSH term, exploded), combined with “electric stimulation therapy” (MeSH term, exploded), or “physical modalities” (search as keyword), and limit to “English” (publication language) and 1) “review” (publication type), and 2) “clinical trial” (publication type).

Quality of the evidence

- 1 systematic review⁹
- 1 best-evidence synthesis¹⁰

Findings

The preponderance of evidence does not support the effectiveness of physical electro-modalities for neck pain, nor has their effectiveness been demonstrated in high-quality trials.^{9,10} A 2009 Cochrane review concluded that there is very low-quality evidence that pulsed electromagnetic field therapy, repetitive magnetic stimulation, and TENS are more effective than placebo.⁹ The review also concluded that there is low-quality evidence that necklace magnets, modulated galvanic current, iontophoresis, and electric muscle stimulation are not more effective than placebo. The Neck Pain Task Force concluded that physical modalities have not been proven effective for nonspecific neck pain.¹⁰ Note that the Neck Pain Task Force only considered evidence provided by studies that were judged to be scientifically admissible.¹⁰

Recommendation

- Physical electro-modalities are not more effective than placebo [overall quality: low]

Question 3: Has acupuncture been demonstrated to be effective compared to placebo, or other treatments, for nonspecific neck pain?

Case clarification

After you advise that physical electro-modalities do not have demonstrated effectiveness, the patient asks whether she should consult with a Chinese traditional medicine practitioner for acupuncture to relieve her neck pain.

Relevance

Visits to complementary and alternative medicine providers for neck pain are common. A 1997 United States survey estimated that 42.1% of adults (83 million persons) reported complementary–alternative medicine use.¹¹

Current opinion

There are conflicting opinions on the effectiveness of acupuncture for nonspecific neck pain.

Finding the evidence

- Cochrane Library: “by topic” > “back” > “cervical spine” > “nonspecific neck pain”
- MEDLINE: suggested search terms: “neck pain” (MeSH term, exploded), combined with “acupuncture therapy” (MeSH term, exploded) or “acupuncture” (MeSH term, exploded), and limit to “English” (publication language) and 1) “review” (publication type), and 2) “clinical trial” (publication type).

Quality of the evidence

- 1 systematic review^{12,13}
- 1 best-evidence synthesis¹⁰
- 2 randomized trials^{14,15}

Findings

The search identified two systematic reviews,^{12,13} a best-evidence synthesis,¹⁰ and two randomized trials^{14,15} published subsequent to the reviews and best-evidence synthesis. The Neck Pain Task Force accepted six trials as scientifically admissible for its best-evidence synthesis, and concluded that the evidence was conflicting on the effectiveness of acupuncture compared to placebo.¹⁰ A Cochrane review accepted 10 trials and found moderate evidence that acupuncture was more effective than sham treatments, and limited evidence that acupuncture was more effective than massage, both at short-term follow-up.¹² One trial, published subsequent to these reviews, found acupuncture to be more effective than deactivated TENS.¹⁴ Another,

large trial concluded that acupuncture added to routine care was more effective than routine care alone in patients with chronic neck pain.¹⁵

Recommendations

- There is conflicting evidence that acupuncture provides short-term relief of neck pain compared to placebo
- Limited evidence suggests that acupuncture may be superior to massage
- A single trial supports the use of acupuncture in addition to primary care in patients with chronic neck pain

Question 4: Have NSAIDs, muscle relaxants, or analgesics been demonstrated to be effective compared to placebo, or other treatments for nonspecific neck pain?

Case clarification

The patient expresses concern that her neck pain will interfere with her work-related activities. She asks whether an analgesic would be helpful.

Relevance

Interventions that provide symptomatic relief are widely recommended for neck pain. To justify their use, these interventions should allow patients to maintain activities related to work and daily living.

Current opinion

NSAIDs, muscle relaxants, and analgesics are considered effective treatments and are widely prescribed.

Finding the evidence

- Cochrane Library: "by topic" > "back" > "cervical spine" > "nonspecific neck pain"
- MEDLINE: suggested search terms: "neck pain" (MeSH term, exploded), combined with "anti-inflammatory agents, nonsteroidal" (MeSH term, exploded) or "analgesics, non-narcotic" (MeSH, exploded) or "analgesics (MeSH, exploded) or "analgesics, opioid" (MeSH, exploded) or "NSAIDs" or "muscle relaxants" (search as keywords), and limit to "English" (publication language) and 1) "review" (publication type), and 2) "clinical trial" (publication type).

Quality of the evidence

- 1 systematic review¹⁶
- 1 best-evidence synthesis¹⁰
- 1 randomized trial¹⁷

Findings

A Cochrane review concluded that muscle relaxants, opioid analgesics, and NSAIDs have limited evidence and unclear benefits for nonspecific neck pain.¹⁶ The Neck Pain Task

Force found no evidence to suggest that one medication is superior to any other medication or nonmedication intervention.¹⁰ Based on six clinical trials considered to be scientifically admissible, the Neck Pain Task Force concluded that the short-term management of symptoms with non-narcotic analgesics may be helpful for grade II neck pain.²

A subsequent trial found that oxycodone (an opioid analgesic) was effective for recurrent episodes of neck pain.¹⁷ However, the use of oxycodone for noncancer pain is controversial due to limited evidence for long-term efficacy, side effects, and potential for abuse and addiction.¹⁸

Recommendation

- A short course of nonopioid analgesics or NSAIDs may be helpful for the short-term management of grade II neck pain symptoms

Question 5: What is the risk of stroke associated with cervical manipulation?

Case clarification

The patient advises that another clinician has suggested that she consider a short course of mobilization or manipulation for symptomatic relief. The patient expresses concern about the risk of stroke associated with neck manipulation.

Relevance

Current evidence suggests that mobilization or manipulation are likely to be helpful for in decreasing symptoms in grade II neck pain;² however, there is concern about the risk of vertebrobasilar artery (VBA) stroke associated with neck manipulation.

Current opinion

Opinions are mixed on the risk of stroke associated with neck manipulation, with widely varying judgments on the magnitude of risk.

Finding the evidence

- MEDLINE: suggested search terms: "stroke" (MeSH term, exploded), combined with "manipulation, orthopedic" (MeSH term, exploded) or "manipulation, chiropractic" (MeSH term, exploded), or "manipulation, spinal" (MeSH term, exploded) or "manipulation, osteopathic" (MeSH, exploded), and limit to "English" (publication language).

Quality of the evidence

One ranking system for prognostic studies distinguishes between types of studies that provide increasing strength of evidence (see box).¹⁹⁻²¹

Ranking of prognostic studies

- *Phase I* studies are exploratory, hypothesis-generating studies characterized by descriptive exploration and demonstration of crude (unadjusted) associations
- *Phase II* studies are also exploratory, but use multivariable techniques/stratification to identify risk factors related to the outcome of interest, while adjusting for other factors
- *Phase III* studies are hypothesis-driven and confirmatory. The goal is to confirm or refute the independence of a relationship between a prognostic factor and outcome of interest, after adjusting for confounding^{4,22}

Best evidence

- 2 systematic reviews^{10,23}
- 2 case-control studies (phase III)^{24,25}
- 1 case-crossover study (phase III)²⁴

Findings

Trials of neck manipulation are too small to evaluate the risk of rare, treatment-related complications. There are three phase III population-based studies that have investigated the risk of VBA stroke following neck manipulation.^{10,23} Rothwell et al. showed an increased risk of vertebralbasilar dissection within a week of a chiropractic visit in patients <45 years of age (OR 5.03; 95% CI 1.32,43.87).²⁵ No significant associations were found in patients aged 45 years or more. Cassidy et al. extended these findings using a case-control and a case-crossover design.²⁴ There was a strong association between chiropractic visits and subsequent stroke, but also a similar increase in the risk of stroke after visiting a primary care physician for neck pain.²⁴ The authors proposed that a plausible explanation for the increased risk of VBA stroke associated with chiropractic and physician visits is that patients with VBA dissection-related neck pain and headache consult with chiropractors and physicians during the prodromal stage of a VBA stroke.²⁴

Recommendation

- Since several nonoperative treatments seem to be roughly equivalent in efficacy and the overall risk of serious side effects is minimal, patient preference should be an important guide in choice of treatment for the short-term relief of neck pain

Summary of recommendations

- A suggested system of red flags should be used to screen for serious pathology underlying a complaint of neck pain
- The preponderance of evidence does not support the effectiveness of physical electro-modalities

- There is conflicting evidence on the effectiveness of acupuncture for neck pain
- A course of nonopioid analgesics may be helpful for short-term management of neck pain symptoms
- Since several nonoperative treatments seem roughly equivalent in efficacy and the overall risk of significant side effects is minimal, patient preference should be an important guide in choice of treatment for short-term relief of neck pain

Conclusions

Once serious underlying pathology has been reasonably ruled out, it is preferable to use a simple, descriptive clinical diagnosis (such as the grading system proposed by the Bone and Joint Decade 2000–2010 Task Force on Neck Pain), rather than a speculative assignment of causation, for nonspecific neck pain. For grade I–II nonspecific neck pain, the patient should be reassured about the absence of serious pathology. A short course of treatment using an intervention shown to provide some degree of short-term relief (e.g., exercise training, nonopioid analgesics, or mobilization) is appropriate. This approach will assist patients to adhere to their clinician's encouragement to maintain activities related to work and daily living.

Whiplash

Gabrielle van der Velde

Toronto Health Economics and Technology Assessment (THETA) Collaborative, University of Toronto, and Institute for Work & Health, Toronto, ON, Canada

Case scenario

A 45 year old man presents to your office with a complaint of neck pain following a traffic accident the previous day. He describes generalized pain and stiffness in the neck and upper back. He denies radiating pain into the upper limbs.

Relevant anatomy

Whiplash defined by the Québec Task Force on Whiplash-associated Disorders is an “acceleration-deceleration mechanism of energy transferred to the neck that results in soft tissue injury that may lead to a variety of clinical manifestations including neck pain and associated symptoms”.¹ “Whiplash-associated disorder” (WAD) describes the clinical syndrome characterized by neck pain and clusters of physical and psychological symptoms, and is classified into five grades of severity (Table 77.1). This chapter focuses on the nonoperative management of the most prevalent grades of WAD in nonemergency settings: grade I–II.

Importance of the problem

Whiplash affects 83% of individuals involved in traffic accidents.² Most Western countries have seen a rise in the annual cumulative incidence of emergency visits for traffic-related WAD. A Dutch study found a 10-fold increase, from an average annual incidence of 3.4 visits per 100,000 inhabitants in 1970–1974 to 40.2 visits per 100,000 in 1990–1994.³ An American study reported the weighted annual incidence of Emergency Department visits to be 328 visits per 100,000 inhabitants, based on the population of the United States in 2000.⁴ WAD represents a significant burden in

terms of pain, disability, and healthcare utilization,^{1,2,5,6} and increases the risk of future health complaints.^{2,7,8}

Top five questions

Assessment

1. When is it appropriate to use radiography when assessing whiplash injury in nonemergency settings?

Course

2. What is the expected rate of recovery for acute whiplash injury?

Prognosis

3. Is initial pain severity and WAD grading predictive of a patient’s recovery?

Treatment

4. What is the most effective nonoperative treatment for grade I–II WAD?
5. What is the appropriate frequency and duration of treatment?

Question 1: When is it appropriate to use radiography when assessing whiplash injury in nonemergency settings?

Case clarification

The patient describes being involved in a traffic collision in which his vehicle was rear-ended by another vehicle travelling at approximately 60km/hour. He was not

Table 77.1 The Québec classification of whiplash-associated disorders¹

Grade	Clinical presentation
0	No neck symptoms, no physical sign(s)
I	Neck pain, stiffness or tenderness only, no physical sign(s)
II	Neck symptoms and musculoskeletal sign(s) ^a
III	Neck symptoms and neurologic sign(s) ^b
IV	Neck symptoms and fracture or dislocation

^aMusculoskeletal signs include decreased range of motion and point tenderness.

^bNeurologic signs include decreased or absence of deep tendon reflexes, weakness, and sensory deficits.

Symptoms and disorders that can be manifested in all grades include deafness, dizziness, tinnitus, headache, memory loss, dysphagia, and temporomandibular pain.

intoxicated and did not lose consciousness. Active cervical range of motion is moderately decreased by pain and stiffness; rotation is 70° right and left. There is generalized tenderness in the neck and upper back and the patient is neurologically intact.

Relevance

Even in nonemergency settings, cervical instability can be a concern in patients with secondary trauma to the neck.

Current opinion

Current opinion is divergent. While many practitioners believe that the majority of patients presenting with WAD I or WAD II do not require radiographic assessment in nonemergency settings, there is considerable variation among clinicians with respect to the use of radiography to rule out cervical instability.

Finding the evidence

- MEDLINE: suggested search terms: “cervical vertebrae” (MesH term, exploded) and “blunt trauma” (search as keyword), combined with “screening” or “criteria” or “decision” or “rule” (search as keywords), and limit to “English” (publication language).

Quality of the evidence

Sackett and Haynes proposed a ranking system for studies that provide evidence for diagnostic tests (see Chapter 76).⁹ In this system, phase III studies establish the validity of a test by answering the question: “Do test results distinguish patients with and without the target disorder among those in whom it is clinically sensible to suspect the disorder?” and are required for the widespread adoption of a test. Phase IV studies provide evidence of the test’s utility (i.e., a test may be valid, but have not impact on outcome).

Table 77.2 The NEXUS low-risk criteria¹²

Cervical spine radiography is indicated for patients with trauma unless they meet all of the following criteria:	
1.	No posterior midline cervical spine tenderness
2.	No evidence of intoxication
3.	A normal level of alertness
4.	No focal neurologic deficit
5.	No painful distracting injuries

Best evidence

- 1 best-evidence synthesis¹⁰
- 3 cohort studies (phase III)¹¹⁻¹³

Findings

There are no formal screening criteria for determining the appropriateness of diagnostic imaging of patients with secondary trauma to the neck in nonemergency settings.^{10,14,15} In the emergency setting, there are two decision rules for identifying low-risk patients that do not require imaging: the National Emergency X-Radiography Utilization Study (NEXUS) low-risk criteria (NLC) (Table 77.2),^{11,12} and the Canadian C-spine rule (CCR) (Figure 77.1).¹³ Both rules are validated by phase III studies and widely used. Although developed for emergency settings, they also inform the need for radiography in nonemergency settings.

Although the American College of Radiology does not take a stand on their relative merits,¹⁷ a recent comparison of the NLC and CCR concluded that for alert patients with trauma who are in stable condition, the CCR is superior to the NLC with respect to sensitivity and specificity.¹⁶

Recommendation

- In adults with an acute whiplash injury presenting to nonemergency settings, the NLC and/or CCR can be used to provide clues of significant cervical trauma in low-risk WAD patients that should be followed up with acquisition of plain films.

Question 2: What is the expected rate of recovery for acute whiplash injury?

Case clarification

The patient’s presentation based on history and physical examination is consistent with grade II WAD. He would like to know when he will recover.

Relevance

The likelihood of recovery from whiplash injury is of essential interest to patients, and their families and employers.

Current opinion

Opinions are widely divergent on the rate of recovery from WAD.

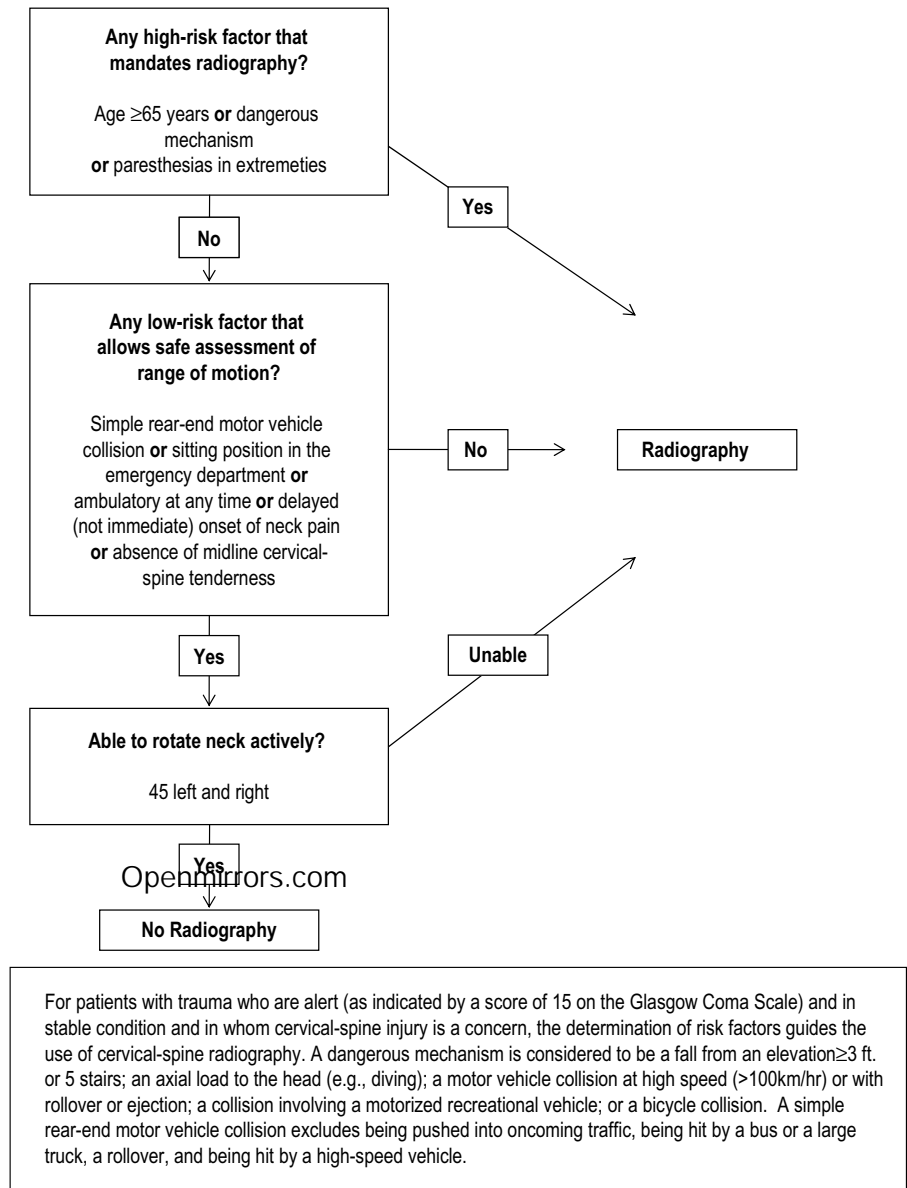

Figure 77.1 The Canadian C-spine rule.^{13,16}

Finding the evidence

- MEDLINE: suggested search terms: “whiplash injuries” (MeSH term, exploded), combined with “course” or “recovery” (search as keywords), and limit to “English” (publication language) and 1) “review” (publication type), and 2) “2007-current” (publication year).

Quality of the evidence

- 1 systematic review¹⁸
- 1 best-evidence synthesis¹⁹
- 1 cohort study²⁰

Findings

The preponderance of evidence identified by a recent review and a best-evidence synthesis suggests that recovery from WAD is prolonged. Approximately 40–56% of indi-

viduals with acute whiplash injury recover in 3 months.^{18,19}

The proportion recovering then declines over time, with 50–71% recovering by 12 months.^{18,19} However, these estimates should be interpreted with two points in mind. First, 20–40% of the general population report neck pain in the previous month.²¹ Second, sampling frames in half of the studies accepted by one review were emergency departments.¹⁹ Patients in these studies likely had more severe whiplash injuries, and therefore a poorer prognosis for recovery. A recent cohort study, published subsequent to these reviews, reported estimates within the above ranges.²⁰

Recommendations

- A substantial proportion of patients with acute whiplash injuries recover within 3 months after injury

- Most patients will have recovered at 1 year, though periodic symptoms may persist

Question 3: Are initial pain severity and WAD grading predictive of a patient's rate of recovery?

Case clarification

The patient's neck pain intensity, measured on a 10-point visual analog scale, is 5. WAD severity grading is II. Neck pain-related disability, measured by the Neck Disability Index, is 45%.²²

Relevance

Clinicians should understand the role of initial symptom severity on recovery, in order to guide the expectations of patients, and their families and employers.

Current opinion

Patients with more severe initial symptoms recover more slowly.

Finding the evidence

- MEDLINE: suggested search terms: "whiplash injuries" (MeSH term, exploded), combined with "prognosis" (MeSH term, exploded) or "prognosis" (search as a keyword), and limit to "English" (publication language) and 1) "review" (publication type), and 2) "2007-current" (publication year).

Quality of the evidence

A ranking system for prognostic studies distinguishes between studies that provide increasing strength of evidence and ranks them as phase I–IV (see Chapter 76).^{23–25}

Best evidence

- 2 systematic reviews^{18,26}
- 1 best-evidence synthesis¹⁹
- 1 cohort study (phase II)²⁷

Findings

On average, patients with more severe symptoms have a poorer prognosis. An association between high initial neck pain intensity and poor outcome was reported in 7 of 10 cohort studies identified by one review.¹⁸ Similarly, high initial neck pain intensity and disability were associated with late whiplash syndrome.²⁶ The Bone and Joint Decade 2000–2010 Task Force on Neck Pain identified three cohorts (one phase I, two phase II) that examined WAD grading as a prognostic factor.¹⁹ Individuals with more severe WAD grades were more likely to report work or leisure limitations at long-term follow-up.¹⁹ Results of a prospective cohort (phase II) published subsequent to these reviews

and best-evidence synthesis found that higher initial pain was associated with delayed recovery.²⁷

Recommendation

- Recovery from whiplash injury is slower in patients with greater initial symptom severity
- Recovery is delayed with increasing WAD severity grading

Question 4: What is the most effective nonoperative approach for grade I–II WAD?

Case clarification

There are numerous noninvasive WAD treatments that are commonly provided to patients, including heat and ice, traction, massage, exercise, manual therapies, electro-modalities, and combined approaches.

Relevance

Clinicians should choose treatments with demonstrated effectiveness, based on the best available evidence.

Current opinion

Opinions are conflicting about the most effective treatment approaches.

Finding the evidence

- Cochrane Library: "by topic" > "back" > "cervical spine" > "whiplash-associated disorders"
- MEDLINE: Suggested search terms: "whiplash injuries" (MeSH term, exploded), combined with "therapeutics" (MeSH term, exploded) or "treatment" (search as a keyword), and limit to "review" (publication type) and "English" (publication language).

Quality of the evidence

- 1 systematic review²⁸
- 1 best-evidence synthesis²⁹

Findings

Both the Cochrane review by Verhagen (2007) and the best-evidence synthesis by the Bone and Joint Decade 2000–2010 Task Force on Neck Pain concluded that evidence is limited and conflicting.^{28,29} The reviews did not statistically pool effectiveness estimates due to clinical and statistical heterogeneity. The Neck Pain Task Force found support for the short-term effectiveness of interventions that involve mobilization and exercises, or supervised training and rehabilitation. Educational videos that included exercises and recommendations to return to work and activities of daily living were also effective.²⁹ In contrast, the Cochrane review did not draw conclusions about the most effective therapy for grade I–II WAD given methodological limitations of the identified studies. The authors did note a trend that sug-

gested active treatments, such as exercise, may be more effective than passive treatments.²⁸

Recommendations

- Patients should be encouraged to a timely return to work and activities of daily living
- Active treatment should be used rather than passive treatments such as electro-modalities, neck collars, or traction

Question 5: What is the appropriate frequency and duration of treatment?

Case clarification

The patient's employer is flexible with respect to time off for treatment visits, but would like to know how often the patient will be treated and for how long.

Relevance

Deciding on the frequency and duration of treatment is complicated. Besides uncertainty of the impact of patterns of care on recovery, there is much at stake, including time and resources of stakeholders (patients, clinicians, employers).

Current opinion

There is considerable divergence in opinion, as demonstrated by wide variations in patterns of care; however, it is broadly believed that early, aggressive, intervention leads to faster recovery.

Finding the evidence

- MEDLINE: suggested search terms: "whiplash injuries" (MeSH term, exploded), combined with "patterns of care" or "frequency" or "treatment" or "duration" (search as keywords), and limit to "English" (publication language).

Quality of the evidence

- 1 best-evidence synthesis¹⁹
- 3 cohort studies (phase III)^{30,31}

Findings

Contrary to current opinion, on average, frequent, early healthcare utilization leads to delayed recovery.¹⁹ Two phase III prognostic studies found that more frequent healthcare visits were associated with slower recovery.^{31,32} Patients who increased their frequency of care beyond two visits to general practitioners and six visits to chiropractors, or added chiropractic to medical care, had slower recovery. High healthcare utilization also appears to be associated with poorer recovery from WAD. A phase III prognostic cohort found that attendance at a community-based multidisciplinary rehabilitation program did not enhance patients' recovery.^{19,30} Attendees of these programs recovered 30–50% more slowly than those who did not attend.³⁰

Recommendation

- The optimal frequency and duration of care has not been determined, but clinicians should avoid intensive treatment of patients after whiplash injury

Summary of recommendations

- Radiographic assessment is not necessary for most grade I–II WAD
- The NEXUS LRC or CCS rule can be used to identify clues of serious cervical trauma
- Recovery from acute whiplash injury is slower in patients with more severe symptoms and higher WAD grade
- Clinicians should promote a timely return to work and resumption of activities of daily living
- Active rather than passive treatments appear to be more effective for treating grade I–II WAD
- Intensive treatment shortly after whiplash injury should be avoided

Conclusions

The evidence suggests that grade I–II WAD requires less healthcare intervention (including radiographic assessment and early intensive treatment) than has been the standard of care in many jurisdictions. It is important to promote a timely return to work and activities of daily living, and to provide active rather than passive approaches to treatment.

Mechanical Low Back Pain: Operative Treatment—Fusion

Rahul Basho¹, Alex Gitelman¹, and Jeffrey C. Wang²

¹UCLA Medical Center, Santa Monica, CA, USA

²UCLA School of Medicine, Los Angeles, CA, USA

Case scenario

A 60 year old man with a 2 year history of lower back pain presents to your clinic. He describes the pain as being located entirely in his lower back, with no symptoms of leg pain. Sitting for long periods of time exacerbates his pain, as does prolonged standing. He is most comfortable when he is lying down. The pain has gradually worsened over the course of the past few months. He has tried multiple conservative treatment modalities, including physical therapy and epidural steroid injections, each with minimal benefit. He indicates that he recently had a discogram performed by his pain management specialist, the results of which show concordant pain at L5–S1 with normal controls at L3–L4 and L4–L5. Physical examination shows the patient has slightly decreased motion in flexion and extension, normal gait, and a normal neurovascular examination in his lower extremities

Relevant anatomy

In order to understand the changes occurring in a degenerative disc, one must understand the relevant anatomy of a normal, healthy disc. Intervertebral discs which make up approximately 30% of the height of the lumbar spine, are composed of three primary structures: the cartilaginous endplates, the annulus fibrosus, and the nucleus pulposus. The outer layer, known as the annulus fibrosus, has a sparse vascular supply along its periphery. It is composed of type I collagen fibrils arranged in concentric lamellae. Each lamina has fibrils arranged obliquely relative to the vertebral endplates, with the direction of the fibrils alternating from one lamina to the next. This arrangement con-

tributes to the tensile strength of a spinal unit. The inner gelatinous layer, known as the nucleus pulposus, is composed primarily of type II collagen, proteoglycans, and mucopolysaccharides. The compressive strength of the spinal unit is conferred by the proteoglycans within the nucleus pulposus. They provide an osmotic gradient for water to enter the disk. Axial loading of the disk due to a patient's upright posture, forces water out of the disc, creating a cycle of flow seen in normal disks.¹ Hyaline cartilage connects the endplates of the vertebral bodies to the disks and permits diffusion between the two. Because the disk is a relatively avascular structure, this is the major mechanism of providing nutrition to the disk.

Importance of the problem

Chronic low back pain places a tremendous burden on the patient, society, and resources allocated to health care. Data indicates that 70–85% of all people experience an episode of back pain at some point in their lifetime, and that patients with back pain for a period of more than 3 months use health services more often than most patient groups.² Patients suffering from low back pain who have not been able to return to work for a period of 2 years are unlikely ever to return.² In addition, a large percentage of healthcare resources are used to treat chronic low back pain. European studies estimate the cost of low back pain to be 1.7% of the gross national product, and in the United States the figure is between 0.5% and 6%.² There is a huge amount of literature available to both practitioners and patients regarding to low back pain. In fact, an internet search for “chronic low back pain” results in 51 million hits. Even with all of this data, there is unfortunately only a handful of randomized, prospective, multicenter studies comparing

treatment options for low back pain. These studies themselves are not perfect, but they provide the most scientific data available and they assist clinicians in making evidence-based decisions.

Top question

1. Does lumbar fusion provide improved pain relief for patients with mechanical low back compared to nonoperative treatment?

Question 1: Does lumbar fusion provide improved pain relief for patients with mechanical low back compared to nonoperative treatment?

Case clarification

The presenting patient has clinical and radiographic findings consistent with degenerative disk disease. He has exhausted conservative measures and wishes to know if a fusion can reliably improve his lower back pain.

Relevance

There is a great deal of controversy among orthopedic surgeons regarding treatment of mechanical low back pain. Whether the intervertebral disk is the true pain generator and the efficacy of an operative fusion for treating mechanical low back remain controversial in both the literature and in clinical practice.

Current opinion

Current opinion suggests that operative fusion for the treatment of mechanical low back pain is one of the less reliable surgical options in spine surgery.

Finding the evidence

- Cochrane Database, with search term: "lumbar fusion"
- PubMed clinical queries search/systematic reviews "lumbar operative fusion"
- MEDLINE search for "low back pain" with subheading "surgical"

Quality of the evidence

Level I

- 1 systematic review/meta-analysis³
- 4 randomized trials

Findings

Oswestry Disability Index The common measurement outcome amongst the four randomized trials was the Oswestry Disability Index (ODI), a validated outcome measure specific for lumbar degenerative disorders.⁸ This index is measured from 1 to 100, with higher scores

indicating a higher level of disability. The developers of the ODI indicate that a clinically relevant change is 4 points, whereas other studies have suggested thresholds of up to 18 points corresponding to a clinically relevant change.⁴

All four of the randomized trials compared surgical treatment of mechanical low back pain with nonoperative treatment. Of the four randomized trials reviewed, three had structured nonoperative regimens.⁵⁻⁷ The Fritzell 2002 study² did not have a structured regimen of physical therapy, instead using physical therapy as the main component, which could be supplemented with "information and education, TENS, acupuncture, injections, cognitive and functional training, and coping strategies."²

All four studies showed a similar improvement in the surgical arm of patients, with improvement from baseline ranging from 8.9 to 15.6 points (percentage improvement 18.9–37.1%).³ In the nonoperative arm, improvements ranged from 2.8 to 12.8 (percentage improvements from baseline were 5.8–30.1%). Only in the Fritzell et al. study was the improvement in nonoperative treatment below the clinically relevant threshold of 4 points on the ODI, whereas in the other three studies the improvement seen in the nonoperative patients was similar to that of the operative patients. These three studies used a structured nonoperative treatment regimen incorporating cognitive behavioral therapy, whereas the Fritzell et al study did not.

The greatest improvement in surgical patients when compared to their nonsurgical counterparts was seen in the Fritzell et al. study (Δ ODI surgery group – Δ ODI nonsurgical group) at 8.8. The Fairbank et al. study showed improvement in the surgical group of patients as well, with a lesser improvement at 4.1 (95% CI 0.1–8.1), but this value was not considered statistically significant.⁵ Neither Brox et al.^{6,7} study showed a statistically significant difference between surgical and nonsurgical intervention for the ODI. The first study, looking at patients without prior surgery, the improvement seen with surgery for this study was 2.3 (95% CI –6.8 to 11.4).⁶ In the second Brox et al study, looking at patients with a prior discectomy, greater improvements in the ODI were seen with nonsurgical treatment. When adjusted for gender and treatment expectations, this value was –9.7 (95% CI –21.7 to 1.7).⁷

Recommendations

- Compared with an unstructured nonoperative treatment regimen, lumbar fusion can be expected to reduce pain by about 63% and improve ODI by about 25% [overall quality: moderate]
- Structured nonoperative treatment regimens that incorporate cognitive behavioral therapy can provide pain relief and improvements in the ODI that are comparable if not better than lumbar fusion [overall quality: moderate]
- Nonoperative treatment for mechanical back pain should be strongly considered [overall quality: high]

Conclusions

The studies discussed above are not without limitations: Fritzell et al. did not use a structured nonoperative treatment regimen, Fairbanks et al. had a high crossover rate and included patients with spondylolisthesis, and both Brox et al. studies had wide confidence intervals. However, these studies provide the best available data for surgeons to make clinical decisions in regards to lower back pain. Though these studies are not standardized and contain different treatment arms, time points, and patient populations, their conflicting results indicate that lumbar fusion for chronic low back pain should be recommended only as a last resort in a group of well-informed patients with realistic expectations.

⁵Mount Sinai Hospital, Toronto, ON, Canada

Case scenario

A 45 year old man is brought to the Emergency Department with a 2 day history of insidious and incapacitating low back pain (LBP). Because of his pain, he has been unable to return to work at the post office where he works as a mail handler. On examination, the range of motion of the lumbar spine is difficult to examine because of severe pain; deep tendon reflexes are present and symmetrically equal, and straight leg raise is full to 90° bilaterally. Babinski reflexes are down-going bilaterally.

Relevant anatomy

Low back pain is defined as pain localized from the costal margin or 12th rib to the inferior gluteal fold. "Nonspecific" indicates that objective causes for symptoms, such as infection, neoplasm, metastasis, osteoporosis, fracture, inflammatory process, or radicular syndrome have been ruled out.

Importance of the problem

Low back pain affects 70–85% of people at some point in their lives.¹ A national telephone survey of the United States workforce found that the 2-week period prevalence of back pain was 15.1%; the cost to employers was esti-

mated as \$7.4 billion/year.² A recent review of cost of illness identified 27 studies reporting data from Australia, Belgium, Japan, Korea, the Netherlands, Sweden, the UK, and the US. They found that the largest proportion of direct medical costs for LBP was spent on physical therapy (17%) and inpatient services (17%), followed by pharmacy (13%) and primary care (13%). Among studies providing estimates of total costs, indirect costs resulting from lost work productivity represented a majority of overall costs associated with LBP.³

Patients are inundated with a variety of potential treatment modalities, all claiming efficacy in the treatment of LBP. Haldeman and Dagenais termed this situation the "supermarket approach."⁴ They presented a partial list of treatment options available to patients with chronic LBP that contained 96 options divided into "supermarket aisles": storefront window shopping (activity modification, coping and acceptance, reassurance, rest, etc.), pharmacological, manual therapies, exercise, physical modalities, educational and psychological therapies, treatment and interventions, injections, minimally invasive interventions, surgery, lifestyle therapies, and complementary and alternative therapies.⁴

Approximately 63 million hits appear on Google when the search term "low back pain" is entered, and 19,834 citations are identified in PubMed. One of the goals of the Cochrane Back Review Group (established in 1996) is to synthesize the evidence from randomized trials of interventions for neck and LBP. As of the Cochrane Library 2011, issue 8, this group has published 50 reviews, including 1

review of diagnostic test accuracy and 13 protocols. (www.cochrane.iwh.on.ca) Fifty-two reviews were co-published in peer-reviewed journals.

Top five questions

Diagnosis

1. What is the role of lumbar imaging studies in the diagnosis of LBP?

Therapy 1

2. What is the optimal nonoperative approach for the treatment of acute LBP?

Prognosis

3. Are there prognostic indicators for the development of chronic LBP?

Therapy 2

4. What is the optimal nonoperative approach for the treatment of chronic LBP?

Harm

5. What are the complications associated with epidural injections and facet blocks for the treatment of LBP?

Question 1: What is the role of lumbar imaging studies in the diagnosis of LBP?

Case clarification

The patient presents with an episode of acute LBP.

LBP is usually classified according to duration:

- **Acute LBP:** duration of 4 weeks or less
- **Subacute LBP:** duration between 4 and 12 weeks
- **Chronic LBP:** constant pain for 12 weeks or longer
- **Recurrent LBP:** recurrent episodes of acute LBP with asymptomatic periods between episodes

Relevance

The use of imaging (radiography, CT scan and MRI) in patients with LBP should be judicious and discriminating. Decisions should be based on the presence of clinical features (risk factors) in the history and physical examination that significantly raise the suspicion of underlying serious

conditions. Serious disease is rare in patients with LBP. Once serious disease is ruled out, the patient is considered to have nonspecific LBP. However, making the diagnosis of nonspecific LBP is often challenging in the acute care setting or during a single visit to a specialist.

Finding the evidence

- Cochrane Database of Systematic Reviews (April 2010) for reviews published by the Cochrane Back Review Group (query: hm-back in 'all text')
- PubMed (www.pubmed.com) query: "(low back pain) AND (imaging) AND (systematic review OR meta-analysis)"

Quality of the evidence

Level I

- 1 systematic review/meta-analysis⁵

Findings

Immediate lumbar imaging (radiography, CT scan or MRI) was compared to usual care without immediate imaging in six randomized trials (1,804 patients). Most patients had acute or subacute LBP and all trials were conducted in primary care or urgent care settings. These trials were summarized in a meta-analysis⁵ and no significant differences were found between the two groups at either 3 month follow-up (standardized mean difference 0.19, 95% CI -0.01 to 0.39 for pain; and 0.11, 95% CI -0.29 to 0.30 for function) or 6–12 month follow-up (SMD -0.04, 95% CI -0.15 to 0.07 for pain and 0.01, 95% CI -0.17 to 0.19 for function).

Adults with LBP should be assessed by taking a focused history and conducting a physical examination, evaluating the duration of symptoms, risk factors for potentially serious conditions, symptoms suggesting radiculopathy or spinal stenosis, presence and severity of neurological deficits, and psychosocial risk factors. If potentially serious conditions are suspected, then the clinician should perform diagnostic studies to identify the cause. In the absence of symptoms or signs suggesting a serious condition, the clinician should avoid ordering diagnostic imaging tests. The indicators of a serious underlying condition in patients with LBP were summarized in a systematic review conducted for the American Pain Society for the development of the clinical practice guidelines for diagnosis and treatment of LBP.⁶ Figure 79.1 shows the diagnostic workup to rule out possible serious underlying conditions recommended by the American Pain Society.

Recommendations

- Lumbar imaging for LBP without indications of serious underlying conditions does not improve clinical outcomes [overall quality: high]
- Clinicians should refrain from routine, immediate lumbar imaging in patients with acute or subacute LBP

Image not available in the electronic edition

Figure 79.1 Diagnostic workup. Reproduced with permission from Chou R, Qaseem A, Snow V, Casey D, Cross JT, Jr, Shekelle P, Owens DK. Diagnosis and treatment of low back pain: a joint clinical practice guideline from the American College of Physicians and the American Pain Society. *Ann Intern Med*, 2007; 147: 478–491.

without features suggesting a serious underlying condition [overall quality: high]

Question 2: What is the optimal nonoperative approach for the treatment of acute LBP?

Case clarification

The patient's focused history and physical examination did not reveal signs of radiculopathy, spinal stenosis, or any specific spinal cause, therefore there is no need to order imaging studies. The patient receives the diagnosis of "acute nonspecific LBP."

LBP can be classified according to the underlying cause:⁶

- **Nonspecific low back pain:** more than 85% of patients who present to primary care have LBP that cannot reliably be attributed to a specific disease or spinal abnormality.¹⁰
- In a minority of patients presenting for initial evaluation in a primary care setting, LBP is **caused by a specific disorder**, such as cancer (0.7%), compression fracture (4%), spinal infection (0.01%), ankylosing spondylitis (0.3–5%), spinal stenosis (3%), and symptomatic herniated disc (4%). Cauda equina syndrome is most commonly associated with a massive midline disc herniation but is rare, with an estimated prevalence of 0.04% among patients with LBP.^{7–9}

The goal of therapy is to help the patient manage their symptoms with minimal disruption in their normal life.

Finding the evidence

- Cochrane Database of Systematic Reviews (April 2010) for reviews published by the Cochrane Back Review Group (query: hm-back in 'all text')
- PubMed (www.pubmed.com) query: "(low back pain) AND (intervention OR treatment OR therapy) AND (systematic review OR meta-analysis OR guideline)"

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses

Findings

A Cochrane review of individual patient education strategies found 24 randomized trials.¹⁰ The results showed that intensive patient education (lasting 2 hours) seems to be effective for pain relief and global improvement for patients with acute or subacute LBP. Providing the patient with pamphlets, booklets, or a 20-minute session resulted in little or no difference compared to no intervention.

A Cochrane review of bed rest included 10 randomized trials.¹¹ They found high-quality evidence that people with acute LBP who are advised to rest in bed have more pain (standardized mean difference 0.22; 95% CI 0.02–0.41) and less functional recovery (SMD 0.31; 95% CI 0.06–0.55) than those advised to stay active.

A Cochrane review of nonsteroidal anti-inflammatory drugs (NSAIDs) for LBP included 65 randomized trials (11,237 patients); 28 trials were considered to have a low risk of bias.¹² The authors found 11 trials comparing NSAIDs with placebo for acute LBP, and statistical pooling was possible for 6 of the 11 trials: the mean difference (MD) in pain reduction was -8.39 (95% CI -12.68 to -4.10), indicating an effect in favor of NSAIDs. Six trials compared some type of NSAID with acetaminophen (paracetamol). The statistical pooling showed an SMD of -0.21 (95% CI -0.43 to 0.02) which indicates that NSAIDs and acetaminophen are equally effective for pain relief and global improvement for acute nonspecific LBP. However, NSAIDs were associated with more adverse effects than paracetamol (relative risk [RR] 1.76; 95% CI 1.12–2.76).

A Cochrane review of muscle relaxants for LBP included 24 trials of acute LBP.¹³ Results showed that muscle relaxants were more effective than placebo on short-term pain relief, but adverse effects were also more prevalent, (especially dizziness and drowsiness) with an RR of 2.04 (95% CI 1.23–3.37). The various muscle relaxants were found to be similar in performance.

A meta-analysis of 76 trials reporting on 34 different treatments for LBP was conducted to estimate the treatment effects in placebo-controlled trials. Fifty percent of the investigated treatments had statistically significant effects, but for

most the effects were small or moderate: 47% had point estimates of effects of less than 10 points on a 100-point scale, 38% had point estimates of 10–20 points, and 15% had point estimates of more than 20 points. Treatments reported to have large effects (>20 points) had only been investigated in a single trial (electroacupuncture, immunoglobulins, infrared, vitamin B₁₂, and neuroreflexotherapy) (Figure 79.2). This meta-analysis found that the analgesic effects of many treatments for nonspecific LBP are small and that they do not differ in populations with acute or chronic symptoms.

Recommendations

Based on systematic reviews^{10–13} and existing clinical practice guidelines,^{6,14} practitioners should start with the following, when treating patients with acute nonspecific low back pain:

- Provide patient education and reassurance [overall quality: high]
- Avoid bed rest as a treatment [overall quality: high]
- Advise patients to stay active and continue normal daily activities, including work if possible [overall quality: high]
- Prescribe medications as necessary for pain relief; preferably to be taken at regular intervals; first choice paracetamol, second choice NSAIDs [overall quality: high]
- Consider adding a short course of muscle relaxants on its own or added to NSAIDs, if paracetamol or NSAIDs fail to reduce pain and promote functional gains [overall quality: high]

Question 3: Are there prognostic indicators for the development of chronic LBP?

Case clarification

The patient is seen again at 6 months: he now has constant daily pain and is on long-term disability leave from his job. This patient has progressed from an acute episode of nonspecific LBP to chronic nonspecific LBP.

There are flags in the acute and subacute phases that may have indicated that this patient was at risk of developing chronic pain. "Yellow flags" are psychosocial factors that may be associated with delayed recovery.¹⁵

Yellow flags

Psychosocial "yellow flags" are factors associated with increased risk of developing, or perpetuating chronic pain and long-term disability (including) work-loss associated with LBP. Identification of 'yellow flags' should lead to appropriate cognitive and behavioral management. Examples of yellow flags are:

- Inappropriate attitudes and beliefs about back pain
- Inappropriate pain behavior
- Work related problems or compensation issues
- Emotional problems (depression, anxiety, stress, withdrawal from social interactions)

Figure 79.2 Analgesic effects of treatments for LBP. Reproduced from Machado LAC, Kamper SJ, Herbert RD, Maher CG, McAuley JH. Analgesic effects of treatments for non-specific low back pain: a meta-analysis of placebo-controlled randomized trials. *Rheumatology*, 2009; 48: 520–527, by permission of Oxford University Press.

Finding the evidence

- Cochrane Database of Systematic Reviews (April 2010) for reviews published by the Cochrane Back Review Group (query: hm-back in 'all text')
- PubMed (www.pubmed.com) query: "(low back pain) AND (broad prognosis clinical query) AND (systematic review OR meta-analysis)"

Quality of the evidence

Level I

- 1 systematic review

Findings

Chou and Shekelle systematically reviewed the usefulness of individual prognostic factors or outcome prediction tools for identifying patients more likely to develop persistent disabling LBP.¹⁶ This review identified 20 studies evaluating 10,842 patients. Considering evidence from these studies, the following factors are identified as predictors of persistent LBP.

Demographic and work-related factors Age, sex, educational level, smoking status, and being overweight did not predict worse outcomes. Receiving compensation at baseline was associated with a slightly increased likelihood of worse

outcomes at 1 year (median likelihood ratio (LR) 1.4; range 1.2–0.8). Higher work dissatisfaction and higher physical work demands did not predict worse outcomes at 3 months, but did at 1 year (median LR 1.4; range 1.2–1.7).

Health status at the onset of LBP Worse general health status before the onset of LBP was associated with worse outcomes at 3–6 months (median LR 1.6; range 1.1–1.7) and at 1 year (median LR 1.8; range 1.1–2.0). Higher psychiatric comorbidity was associated with worse outcomes at 3–6 months (median LR 1.9; range 1.4–2.1) and at 1 year (median LR 2.2; range 1.9–2.3). A history of previous LBP was not associated with persistent disabling LBP at 3–6 months or 1 year.

LBP episode signs and symptoms High baseline pain intensity was found to be associated with worse outcomes at 3–6 months (median LR 1.7; range 1.1–3.7), but was less useful at 1 year. High baseline functional impairment was associated with increased likelihood of poor outcome at 3–6 months (median LR 1.4; range 1.3–3.5) and at 1 year (median LR 2.1; range: 1.2–2.7). Radiculopathy or leg pain was associated with worse outcomes at 3–6 months (median LR 1.4; range 1.1–1.7) and 1 year (median LR 1.4; range 1.2–2.4). Patients with maladaptive pain coping behaviors,

such as fear-avoidance beliefs had more persistent LBP at 3–6 months (median LR 2.2; range 1.5–4.9) and 1 year (median LR 2.5; range 2.2–2.8). High somatization/nonorganic signs (exaggerated pain symptoms) were associated with poor work outcomes at 1 year (median LR 3.0; range 1.7–4.6).

Recommendations

Current evidence on the prognosis of acute nonspecific LBP supports the following:

- The majority of patients with acute nonspecific LBP will recover, although recurrences are common [overall quality: low]
- Helpful characteristics for predicting persistent disabling LBP are maladaptive pain coping behaviors, somatization/nonorganic signs, increased functional impairment, poor general health status, and presence of psychiatric comorbidities [overall quality: high]

Question 4: What is the optimal nonoperative approach for the treatment of chronic LBP?

Case clarification

The patient's LBP is severe and debilitating.

Severity of pain is usually measured with a numerical pain rating scale from 0 (no pain) to 10 (most severe pain).

- **Mild pain** is when the average pain is 4 or less
- **Moderate pain** is between 5 and 7
- **Severe pain** is 8 or greater

Openmirrors.com

Finding the evidence

- Cochrane Database of Systematic Reviews (April 2010) for reviews published by the Cochrane Back Review Group (query: hm-back in 'all text')
- PubMed (www.pubmed.com) query: "(low back pain) AND (intervention OR treatment OR therapy) AND (systematic review OR meta-analysis OR guideline)"

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses

Findings

In 2007, the American Pain Society's clinical practice guideline¹⁷ found the following interventions for chronic LBP that were of moderate or small benefit and supported by at least fair-quality evidence: advice to remain active, patient education, acetaminophen, NSAIDs, antidepressants, benzodiazepines, tramadol (opioid), spinal manipulation, exercise therapy, massage, acupuncture, yoga, cognitive-behavioral therapy, progressive relaxation, and intensive interdisciplinary rehabilitation. They found no intervention that was supported by high-quality evidence (Figure 79.3).

Image not available in the electronic edition

Figure 79.3 Conservative interventions for LBP. Reproduced with permission from Chou R, Qaseem A, Snow V, Casey D, Cross JT, Jr, Shekelle P, Owens DK. Diagnosis and treatment of low back pain: a joint clinical practice guideline from the American College of Physicians and the American Pain Society, *Ann Intern Med* 2007; 147: 478–491.

Henschke et al reviewed 27 RCTs, 14 on injection therapy and 13 on denervation procedures.¹⁸ Eighteen (66%) of the studies were determined to have a low risk of bias. Because of clinical heterogeneity, only two comparisons could be pooled. Overall, there is only low to very low quality evidence to support the use of injection therapy and denervation procedures over placebo or other treatments for patients with chronic LBP.

A Cochrane review of injection therapies for LBP included 18 trials (1179 patients).¹⁹ Statistical pooling was not possible due to clinical heterogeneity amongst the trials. Overall the results indicate that there is no strong evidence for or against the use of any type of injection therapy for subacute or chronic LBP. The injection sites varied from epidural and facet joints to local sites (tender and trigger points). The drugs injected were corticosteroids, local anesthetics, and a variety of other drugs.

In 2004, the European guidelines for chronic LBP systematically reviewed the evidence for various treatment

options.²⁰ They found no evidence to support epidural steroids, intra-articular injections of steroids or facet nerve blocks in patients with nonspecific chronic LBP.²⁰

In 2009, the American Pain Society published a clinical practice guideline on the use of interventional therapies for chronic nonspecific LBP.⁵ They concluded that there is no convincing evidence from randomized trials that injections and other interventional therapies are effective for non-radicular LBP. Facet joint steroid injection, prolotherapy, and intradiscal steroid injections were no more effective than sham therapies. For local injections, there was insufficient evidence to accurately judge the benefits because available trials were small, had a high risk of bias, and evaluated heterogeneous populations and interventions.

Recommendations

- The following nonoperative treatments for chronic nonspecific LBP have been found to show some evidence of benefit with minimal risk of harm: advice to remain active, patient education, acetaminophen, NSAIDs, antidepressants, spinal manipulation, exercise, massage, acupuncture, yoga, cognitive-behavioral therapy, and intensive interdisciplinary rehabilitation [overall quality: low to moderate]
- Tramadol and benzodiazepines have some evidence of benefit, but are also associated with adverse events [overall quality: low to moderate]

Question 5: What are the complications associated with epidural injections and facet blocks for the treatment of LBP?

Relevance

Although the use of epidural steroids and facet blocks for nonspecific LBP is not supported by current evidence, many patients end up receiving these interventions. Patients should be aware of the potential complications of these procedures.

Finding the evidence

- Cochrane Database of Systematic Reviews (April 2010) for reviews published by the Cochrane Back Review Group (query: hm-back in 'all text')
- PubMed (www.pubmed.com) query: "(low back pain) AND (epidural steroids OR facet blocks)"

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses

Findings

In the Cochrane review of injections for LBP, adverse effects such as headache, dizziness, transient local pain, paresthesia, and nausea were reported in a small number of patients in 9 of the 18 included trials.

The American Pain Society guideline development panel found insufficient evidence from randomized trials to reliably judge harms of these interventional therapies for LBP.

Rare complications are usually not reported in randomized trials due to the small sample sizes and relatively short follow-up duration. As such, a review of case reports and epidemiological studies is necessary. The 2004 European guidelines for LBP used this approach to summarize the evidence regarding complications and harms of these interventions:

- Technical complications: accidental dural puncture (5% of the cases) with consequent postdural puncture headache; and epidural hematoma (very rare)
- Infectious complications: several cases of epidural abscess after epidural steroid injection have been documented, most of which occurred in diabetic patients; however, the incidence is very rare
- Neurological complications: neurological sequelae (chemical meningitis) can occur after intrathecal application of steroids. Arachnoiditis after epidural injection of steroids is very rare
- There is one report of septic facet joint arthritis after facet injection,²¹ but the rate of such an event is unknown and seems likely to be rare

Recommendation

- Epidural steroid injections, intra-articular injections and facet blocks have potential complications, but the incidence is rare [overall quality: very low]

Summary of recommendations

- Clinicians should refrain from routine, immediate lumbar imaging in patients with acute or subacute LBP and without features suggesting a serious underlying condition
- Avoid bed rest as a treatment
- Advise patients to stay active and continue normal daily activities including work if possible. Provide information on back-care and self-care
- Prescribe medications, if necessary for pain relief; preferably to be taken at regular intervals; first choice paracetamol, second choice NSAIDs
- Consider adding a short course of muscle relaxants on its own or added to NSAIDs, if acetaminophen or NSAIDs have failed to reduce pain and promote function
- Patients with acute nonspecific LBP will likely recover although recurrences are common
- Helpful characteristics for predicting persistent disabling LBP are maladaptive pain coping behaviors, somatization/nonorganic signs, increased functional impairment, poor general health status, and presence of psychiatric comorbidities

- The following nonoperative treatments for chronic non-specific LBP have been found to show some evidence of benefit with minimal risk of harm: advice to remain active, patient education, acetaminophen, NSAIDs, antidepressants, spinal manipulation, exercise, massage, acupuncture, yoga, cognitive-behavioral therapy, and intensive interdisciplinary rehabilitation
- Tramadol and benzodiazepines also have shown some evidence of effectiveness, but are associated with adverse events
- Use of epidural steroid injections, intra-articular injections and facet blocks is not evidence-based and these therapies have potential complications, but the incidence is rare.

Neurogenic Claudication—Operative Management (Decompression and Fusion)

Hormuzdiyar H. Dasenbrock, Reza Yassari, and Timothy F. Witham

Johns Hopkins University, Baltimore, MD, USA

Case scenario

A 59 year old woman presented with buttock and leg pain that developed upon ambulation. Her pain appeared after walking a distance of one block (200m) or more, was accompanied by lower extremity numbness, and was relieved by sitting down. The patient also noted that she did not normally experience this pain while grocery shopping. Neurological examination was normal but MRI of the lumbar spine revealed severe spinal stenosis (Figure 80.1). Flexion and extension radiographs demonstrated evidence of instability with spondylolisthesis (Figure 80.2). After failure to improve with conservative therapy (including physical therapy and epidural steroid injections), surgery was recommended. The patient underwent L3–4 and L4–5 decompression and interbody arthrodesis with transpedicular instrumentation from L3 to L5 (Figure 80.3). The patient noted significant reduction in her pain at 1 year follow-up.

Relevant anatomy and pathophysiology

Spinal stenosis describes a spinal canal with a diminished caliber causing compression of neural structures, including the thecal sac and the nerve roots.^{1–2} Coexisting foraminal stenosis and/or spinal instability may further exacerbate neural compression. Patients may have pre-existing narrowing of the spinal canal due to congenital stenosis with short pedicles, excessive lordosis, or scoliosis.³ Superimposed upon any pre-existing narrowing of the canal that may be present are degenerative and arthritic changes associated with aging, including the development of osteophytes,

hypertrophy of the ligamentum flavum, degeneration of the intervertebral disc (with bulging and/or herniation), and hypertrophy of the facet joint and its capsule.⁴ The narrowed diameter of the spinal canal leads to compression of the neural structures and the microvasculature. Symptoms are hypothesized to be due to direct neural compression as well as to ischemia from microvascular compression.^{5–6}

Spinal stenosis may be accompanied by degenerative spondylolisthesis, which describes the anterior slippage of one vertebral body relative to the adjacent one and is indicative of an unstable spinal unit.⁷ Although displacement can occur posteriorly or laterally, spondylolisthesis is synonymous with anterior slippage.⁸ Degenerative spondylolisthesis is due to a combination of arthritic and degenerative changes in the disc and facet joints that leads to spinal stenosis and vertebral body displacement.⁹

Importance of the problem

The importance of the surgical treatment of lumbar spinal stenosis was evaluated in a study of more than 1000 patients in South Korea. The authors compared those who underwent surgical decompression to age- and sex-matched controls in the general population. Using a Cox multivariable regression analysis, the authors calculated standardized mortality ratios for different age groups: patients treated surgically had lower mortality compared to the general population. The mortality ratios were 0.53 for patients who were aged 60–69 and 0.45 for patients who were aged 70–79 at the time of the operation.¹⁰ The authors concluded that the improvement in mortality may be due to superior mobility and the ability to exercise regularly.

Figure 80.1 A 59 year old woman presented with neurogenic claudication. Sagittal T2-weighted MRI images (a) reveals severe spinal stenosis at the levels of the L3–4 and L4–5 intervertebral discs. Axial T2-weighted MRI images at the level of the L3–4 (b) and L4–5 (c) discs also demonstrate severe stenosis with impingement of the thecal sac, as well as low epidural fat and cerebrospinal fluid (CSF) signal.

Figure 80.2 Preoperative flexion (left) and extension (right) radiographs reveal low-grade spondylolisthesis at L3–4 and L4–5 that is visible on flexion, but reduces upon extension. Because of the evidence of instability, the patient underwent a fusion operation: decompression with interbody arthrodesis and adjunct L3–L5 transpedicular instrumentation was performed.

Figure 80.3 Postoperative lateral (left) and AP (right) radiographs reveal appropriate placement of the transpedicular instrumentation, with no progression of the spondylolisthesis.

Top 6 questions

Diagnosis

1. What are the typical presentation, examination findings, and imaging characteristics of patients with lumbar spinal stenosis?

Therapy

2. What is the evidence for surgical treatment compared to conservative management for patients with lumbar spinal stenosis *without* spondylolisthesis?
3. What is the evidence that there is a benefit to surgical treatment compared to conservative management for patients with lumbar spinal stenosis *with* spondylolisthesis?
4. What is the evidence for lumbar fusion with decompression compared to decompression alone for patients with lumbar spinal stenosis *without* spondylolisthesis?

5. What is the evidence for lumbar fusion with decompression compared to decompression alone for patients with lumbar spinal stenosis *with* accompanying spondylolisthesis?

Harm

6. What are the perioperative and long-term complications associated with decompression alone or decompression and fusion for patients with spinal stenosis?

Question 1: What are the typical presentation, examination findings, and imaging characteristics of patients with lumbar spinal stenosis?

Relevance

An understanding of the presentation and findings of spinal stenosis is important in order to evaluate patients who may benefit from treatment.

Current opinion

Neurogenic claudication may be seen in patients who have underlying spinal stenosis with or without accompanying spondylolisthesis.

Finding the evidence

- MEDLINE, with search terms: “lumbar spinal stenosis,” as well as “lumbar spinal stenosis” AND “magnetic resonance imaging” OR “computed tomography”

Quality of the evidence

Level I

- 1 meta-analysis

Findings

Patients with lumbar spinal stenosis typically present with neurogenic claudication, radiculopathy, paresthesias, and/or low back pain.¹¹ Less commonly, patients may also present with sensory deficits, lower extremity weakness, or bowel and bladder dysfunction. Neurogenic claudication describes pain in the buttocks and along the proximal thigh that occurs when standing or walking. The pain may be accompanied by paresthesias or weakness in the lower extremities and it is typically relieved by resting, sitting down, or assuming a flexed position of the spine (such as leaning on a shopping cart). Neurological examination may be normal, although radicular signs, including a positive straight leg raise test, may be elicited.¹²⁻¹³ Signs and symptoms may be exacerbated if the examination is repeated after a brief period of exercise.¹⁴

Patients with symptoms consistent with neurogenic claudication should have a thorough evaluation performed to exclude other conditions that may present similarly, including peripheral vascular disease. Vascular claudica-

tion is due to atherosclerosis of the pelvofemoral vasculature leading to hypoperfusion of the lower extremities upon ambulation. Patients with claudication will typically describe pain that is produced by walking but not by standing; the pain will not be relieved by flexion of the spine.

The accuracy of different imaging modalities to diagnose lumbar stenosis was evaluated in a 2006 systematic review: the authors concluded that the literature does not permit strong conclusions about the diagnostic accuracies of MRI or CT, primarily because of the heterogeneity and overall poor quality of the studies.¹⁵ However, MRI may be useful to visualize neural compression, and CT may determine the presence of additional bony pathology, such as osteophytes.¹⁶ Dynamic flexion-extension radiographs will demonstrate spondylolisthesis or subtle instability.

Recommendation

- Patients who have a presentation concerning for spinal stenosis should also be evaluated for peripheral vascular disease and their spinal anatomy imaged by MRI with or without additional CT [overall quality: very low]

Question 2: What is the evidence for surgical treatment compared to conservative management for patients with lumbar spinal stenosis without spondylolisthesis?

Relevance

The quality of life of patients with lumbar spinal stenosis may be improved with surgery. However, operative intervention should be reserved for patients who are likely to experience a greater benefit from the procedure than they would from conservative treatment.

Current opinion

Surgery is generally preferred for patients with spinal stenosis whose symptoms have persisted despite a reasonable trial of conservative therapy or who have evidence of neurological motor deficits.

Finding the evidence

- MEDLINE, using the search term: “lumbar spinal stenosis” AND “surgery”

Quality of the evidence

Level I

- 2 randomized controlled trials (RCTs)

Findings

The role of conservative therapy for patients with lumbar spinal stenosis is debated.¹⁷⁻¹⁸ A trial of nonsurgical management is typically attempted, which may consist of nonsteroidal anti-inflammatory drugs (NSAIDs), activity modification, and physical therapy—including core muscle

and lower extremity stretching and strengthening exercises. Operative treatment is pursued in patients who continue to remain symptomatic despite a reasonable trial of conservative management (typically defined as at least 3 months). Surgery is the preferred treatment for patients with neurological motor deficits. The goals of surgery include pain relief, improved mobility, prevention of the development of neurological deficits, or restoration of neurological function.¹⁹

The Spine Patient Outcomes Research Trial (SPORT) was a large prospective randomized multicenter trial (with an additional observational cohort) that compared surgical decompression (with or without fusion) to usual nonsurgical care. The study included 289 randomized (and 356 observational) patients from 13 centers in 11 US states. The primary inclusion criteria were at least 12 weeks of symptoms that persisted despite conservative treatment and evidence of spinal stenosis without spondylolisthesis on imaging.²⁰

At the 2 year follow-up, there was a significant crossover between cohorts: only 67% of those assigned to surgery had undergone an operation, while 43% of patients who had been assigned to nonsurgical care had surgery performed. The intention-to-treat analysis found a significant improvement in one primary outcome measure favoring surgery—SF-36 bodily pain score. However, the associated measure of precision included both clinically relevant and clinically unimportant differences (mean increase in 7.8 points, 95% CI 1.5–14.1 points), and there was no significant difference in scores on the two other primary outcome measures assessing disability—SF-36 physical function or Oswestry Disability Index (ODI) scores. The as-treated analysis, which negated the benefits of randomization, showed a significant improvement in all outcome measures at both 2 year and 4 year follow-up.²⁰⁻²¹

Another RCT that compared surgical decompression to standard nonoperative care for 94 patients with lumbar spinal stenosis was conducted by the Finnish lumbar spine research group. At 1 year follow-up the study found a statistically significant benefit to surgery for their primary outcome measure, the ODI (mean improvement 11.3 points, 95% CI 4.3–18.4 points) and the associated measure of precision included both clinically important and trivial changes. However, at 2 year follow-up this difference failed to meet the minimal important difference—the smallest change in ODI score that patients perceive is important—of 10 points²² (mean improvement 7.8; 95% CI 0.8–14.9).²³

Recommendation

- Surgery may lead to a significant improvement in pain in patients with symptomatic spinal stenosis who have not substantially improved despite a reasonable trial (at least 3 months) of conservative therapy. The effect of surgery on disability is uncertain [overall quality: moderate]

Question 3: What is the evidence that there is a benefit to surgical treatment compared to conservative management for patients with lumbar spinal stenosis with spondylolisthesis?

Relevance

Operative intervention should be reserved for patients who are likely to have a greater benefit from the procedure than from nonsurgical care.

Current opinion

Surgery is generally preferred for patients with lumbar spondylolisthesis with spinal stenosis whose symptoms have persisted despite a reasonable trial of conservative therapy or who have evidence of neurological deficits.

Finding the evidence

- MEDLINE, with search term: “lumbar spondylolisthesis” AND “surgery”

Quality of the evidence

Level I

- 1 RCT

Findings

The optimal treatment for patients with degenerative spondylolisthesis was examined by a different arm of the SPORT trial, which compared surgical to usual nonoperative care. Inclusion criteria were persistent symptoms (neurogenic claudication or radiculopathy) for more than 12 weeks and evidence of degenerative spondylolisthesis on lateral static radiographs. Enrollment was in either a randomized cohort (304 patients) or an observational cohort (303 patients), outcomes were evaluated quantitatively using the ODI and SF-36, and patients were followed for 2 years.²⁴

As was the case with the SPORT trial evaluating patients with lumbar spinal stenosis, there was substantial crossover from the initial assignment: 66% of those randomized to receive surgery and 54% of those randomized to conservative treatment had an operation performed within 4 years. The intention-to-treat analysis for the randomized cohort showed no statistically significant effects for the primary outcomes. However, the as-treated analysis showed a substantial and significant benefit to surgery that was sustained 4 years later in the three primary outcome measures: ODI (mean improvement 14.3 points, 95% CI 11.1–17.5 points), SF-36 bodily pain (mean increase 15.3 points, 95% CI 11–19.7 points), and SF-36 physical function (mean increase 18.9 points, 95% CI 14.8–23.0 points).²⁴⁻²⁵

Recommendation

- Surgery may lead to a greater improvement in pain and disability than usual nonsurgical care alone in patients

with symptomatic lumbar spinal stenosis with spondylolisthesis who have failed to substantially improve with conservative management [overall quality: moderate]

Question 4: What is the evidence for lumbar fusion with decompression compared to decompression alone for patients with lumbar spinal stenosis without spondylolisthesis?

Relevance

While a fusion operation may be important for patients who have evidence of instability, its utility for patients with spinal stenosis without spondylolisthesis is debated.

Current opinion

A fusion operation is not routinely added to a decompression for patients with lumbar spinal stenosis. However, in certain situations—such as coexisting spinal deformity or where there are concerns about postoperative iatrogenic instability—a posterolateral fusion may be preferred.

Finding the evidence

- MEDLINE, using the search term: “lumbar spinal stenosis” AND “fusion”

Quality of the evidence

Level II

- 1 prospective nonrandomized study

Findings

The benefit to the addition of a (primarily posterolateral) fusion to a decompressive surgery in patients with spinal stenosis has been debated.²⁶ Patients with evidence of preoperative instability,^{27–28} concerns for the development of postoperative instability (due to extensive resection of the facet joints),¹⁹ or coexisting spinal deformity (including degenerative scoliosis or loss of lordosis)^{29–31} may benefit from a fusion operation. However, a fusion may increase operative times, blood loss, complication rates, and cost.³²

One prospective (but nonrandomized) study examined 272 patients undergoing laminectomy with or without non-instrumented arthrodesis for lumbar spinal stenosis. Primary outcomes were health status, walking capacity, back and leg pain, and satisfaction with surgery was assessed 6 and 24 months postoperatively. Loss to follow-up was 13% at 6 months and 27% at 24 months. Adjusted models showed that arthrodesis was associated with greater improvement in back pain at 6 months ($p = 0.05$) and 24 months ($p = 0.02$), and in walking capacity at 6 months ($p = 0.02$) and 24 months ($p = 0.03$); however, the authors noted that given the adjustment for multiple comparisons, these results are of borderline statistical significance. For all other outcome measures, there was no benefit to the addition of a fusion and total hospital cost was sig-

nificantly greater for a fusion procedure ($p = 0.0001$).³³ Moreover, recent guidelines on the management of patients with spinal stenosis without spondylolisthesis recommend decompression without additional fusion in patients who do not have evidence of instability.²

Recommendation

- When operative treatment of lumbar spinal stenosis without spondylolisthesis is pursued, a decompression and fusion may not lead to superior outcomes compared with decompression alone [overall quality: low]

Question 5: What is the evidence for lumbar fusion with decompression compared to decompression alone for patients with lumbar spinal stenosis with accompanying spondylolisthesis?

Relevance

Decompression without a fusion may exacerbate the instability of patients with spinal stenosis and accompanying spondylolisthesis postoperatively.

Current opinion

When surgical treatment is pursued for patients with lumbar spinal stenosis with accompanying spondylolisthesis, a fusion is typically performed.

Finding the evidence

- MEDLINE, using the search term: “lumbar spondylolisthesis” AND “fusion”

Quality of the evidence

Level I

- 1 systematic review

Findings

The utility of spinal fusion (compared with decompression alone) to improve clinical outcomes in patients with degenerative spondylolisthesis has also been investigated.³⁴ While some retrospective studies have reported good outcomes in patients treated with decompression alone,^{35–36} a laminectomy is likely to further destabilize an already unstable spinal segment.^{37–38} A 2007 systematic review found that decompression and fusion is significantly more likely to produce a satisfactory clinical outcome than decompression alone (relative risk 1.40, CI 1.04–1.89).⁹

Recommendation

- When surgery is performed for symptomatic lumbar spondylolisthesis, a fusion procedure may lead to superior clinical outcomes than decompression alone [overall quality: low]

Question 6: What are the perioperative and long-term complications associated with decompression alone or decompression and fusion for patients with spinal stenosis?

Relevance

A number of perioperative and long-term complications may occur after decompression and fusion of the lumbar spine.

Current opinion

Perioperative mortality after lumbar fusion is rare, but surgical site infections and neurologic injury can occur.

Finding the evidence

• Medline, using the search term: “lumbar fusion” OR “lumbar laminectomy” AND “complications”

Quality of the evidence

Level III

• Many retrospective studies

Findings

Perioperative mortality after posterior lumbar decompression with or without additional fusion is rare.^{39–41} Data from the national inpatient sample (NIS) from 1993–2002 on 66,601 hospitalizations across America for patients undergoing a fusion operation where degenerative spondylolisthesis was the primary admitting diagnosis showed in-hospital mortality as 0.15%. Complication rates were also low (5.4%), of which more than half were cardiac, pulmonary, or renal in nature, manifesting in patients with chronic comorbidities.⁴²

Surgical site infections are one of the most common complications, especially after a fusion: reported rates range from 0.65% to 12%.^{43–48} Risk factors include obesity (especially morbid obesity),^{43,45,47,49} diabetes,^{45,47} a prior surgical site infection,^{45,47} alcohol abuse,⁴⁷ greater operative blood loss,⁴⁵ longer operation times,^{45,49} and the use of instrumentation.⁴⁹ Other known complications include nerve root injury due to instrumentation misplacement, incidental durotomy leading to the development of a cerebrospinal fluid leak,⁵⁰ spinal epidural hematoma (and other postoperative causes of cauda equina syndrome),^{51–52} rhabdomyolysis,⁵³ venous thromboembolic events⁵⁴ and sudden visual loss.⁵⁵ Long-term complications after spinal fusion include sacral stress fractures,^{56–58} adjacent level disease,^{59–61} pseudoarthrosis,⁶² sexual dysfunction,⁶³ and chronic donor allograft site pain.⁶⁴

Recommendation

• Patients with recurrent postoperative pain who have undergone a fusion should be examined with imaging for the possibility of sacral stress fractures, adjacent level

disease, or instrumentation complications [overall quality: very low]

Summary of recommendations

- Patients who have a presentation consistent with spinal stenosis should be evaluated for the presence of peripheral vascular disease and their spinal anatomy imaged by MRI
- Patients with spinal stenosis (with or without accompanying spondylolisthesis) who remain symptomatic despite a trial of conservative management may have a greater improvement with surgical treatment than with continued nonsurgical care
- If there is no evidence of spondylolisthesis, deformity, preoperative instability, or concern about postoperative iatrogenic instability, there may be no benefit to the addition of a fusion to decompression
- When there is evidence of spinal stenosis and spondylolisthesis, patients may have a greater degree of pain relief with a decompression and fusion

Conclusions

Neurogenic claudication is a common presenting symptom for patients with lumbar spinal stenosis. Those who fail an adequate trial (typically at least 3 months) of nonsurgical therapy may be considered for surgical intervention. The standard surgical approach supported by the literature is decompression alone. Patients who have concomitant spondylolisthesis or instability, spinal deformity, or concerns for iatrogenic postoperative instability (due to extensive resection of the facet joints) should be considered for decompression with fusion.

Neurogenic Claudication: Nonoperative Management

Carlo Ammendolia

Mount Sinai Hospital, University of Toronto and Institute for Work & Health, Toronto, ON, Canada

Case scenario

A 71 year old woman presents with a 5 month history of insidious lower back pain with radiating pain and numbness bilaterally into the buttock and lateral thighs. The pain comes on after several minutes of standing. When she tries to walk, the pain becomes progressive worse and she needs to stop after walking no more than a block (200m). Sitting reduces the pain significantly. On examination, she has a stooped posture with moderate limitation of lumbar spine extension. There is decreased sensation to light touch over the dorsum of the feet and large toes.

Relevant anatomy

Lumbar spinal stenosis (LSS) causing neurogenic claudication is one of the most commonly diagnosed and treated pathological spinal conditions and frequently afflicts the elderly population.¹ It is characterized by narrowing of the lateral and central vertebral canals with concomitant neural compression and clinical symptoms. Symptoms include pain, paresthesias and/or weakness of the back, buttock, and legs usually precipitated by walking and/or prolonged standing.² Degenerative changes in the spine are the most common cause of LSS characterized by osteoarthritic thickening of the articulating facet joints, infolding of the ligamentum flavum, and degenerative bulging of the intervertebral discs.³

Importance of the problem

Neurogenic claudication can have a significant impact on functional ability, quality of life, and independence in

elderly people. Those afflicted have greater physical limitations than patients with congestive heart failure, chronic obstructive pulmonary disease, or systemic lupus erythematosus.⁴

In primary care 3–4% of low back pain (LBP) patients are diagnosed with LSS. This prevalence increases to 13–14% among LBP patients seeking care from specialists.⁵ In the general population LSS is estimated to affect up to 6% of individuals over the age of 65.⁶

Currently in Canada individuals over the age of 65 represent 13% of the population. In 2031 this proportion is expected to rise to 23–25%.⁷ This will significantly impact future healthcare resources, and new cases of LSS are expected to increase dramatically over the next 20 years.

Top nine questions

Diagnosis

1. How accurate is the history and clinical examination in the diagnosis of neurogenic claudication?
2. What is the role of imaging in the diagnosis of neurogenic claudication?
3. What are the key differential diagnoses of neurogenic claudication?

Therapy

4. What is the effectiveness of epidural steroid injections for the treatment of neurogenic claudication?
5. What is the effectiveness of other nonoperative treatment for neurogenic claudication?
6. What medications have been found to be effective for patients with neurogenic claudication?

Harms

7. What are the complications related to epidural injections for neurogenic claudication?

Prognosis

8. What is the long-term prognosis of patients with neurogenic claudication treated nonoperatively, and what factors are prognostic in these patients?

Cost

9. How does the cost of nonsurgical treatment compare to that of surgical treatment?

Question 1: How accurate is the history and clinical examination in the diagnosis of neurogenic claudication?**Question 2: What is the role of imaging in the diagnosis of neurogenic claudication?****Question 3: What are the key differential diagnoses of neurogenic claudication?****Case clarification**

On examination, our patient walks with a wide stance gait. Standing lumbar spine extension reproduces her symptoms, whereas lumbar flexion provides immediate relief. MRI reveals moderate to severe central and bilateral lateral canal stenosis at the levels L4–L5 and L5–S1. Making a diagnosis of neurogenic claudication is often challenging in elderly patients because other comorbidities are often present, some of which give rise to similar symptoms.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/diagnosis and sensitive: “neurogenic claudication AND lumbar spinal stenosis,” “neurogenic claudication,” and “lumbar spinal stenosis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using terms “diagnosis AND lumbar spinal stenosis,” “diagnosis AND neurogenic claudication” as well as “imaging OR magnetic resonance imaging OR computerized tomography OR myelography AND lumbar spinal stenosis”

Quality of the evidence*Level I*

- 3 systematic reviews^{8,10,15}

Findings

A systematic review on the accuracy of diagnostic tests for LSS identified 12 diagnostic imaging studies and 7 studies evaluating clinical tests.⁸ Firm conclusions about the accuracy of diagnostic tests could not be made because of the overall poor quality and high heterogeneity of studies. This review highlighted one study that found 21% of asymptomatic subjects over the age of 60 years to have evidence of LSS on MRI.⁹ The systematic review by Kent et al. emphasized the importance of corroborating both clinical and imaging findings in order to make an accurate diagnosis.¹⁰

Diagnostic accuracy is typically expressed using values of sensitivity, specificity, and likelihood ratios. Sensitivity is the proportion of patients with the disorder of interest who have a positive diagnostic test, and specificity is the proportion of patients without the condition of interest who have a negative diagnostic test result.¹¹

A likelihood ratio (LR) combines the information contained within sensitivity and specificity values into a concise and meaningful expression of diagnostic usefulness.¹¹ A positive LR (sensitivity/[1 – specificity]) expresses the odds that a positive test result would be expected in a patient with the disorder of interest. A negative LR ([1 – sensitivity]/specificity) expresses the odds that a negative test result would be expected in a patient with the disorder of interest.¹² LRs close to 1 indicate a test which does little to alter diagnostic probability. A high positive LR (e.g., >5.0) indicates a test in which a positive result is helpful for ruling in the diagnosis, whereas a small negative LR (e.g., <0.30) is associated with tests in which a negative result is helpful in ruling out the diagnosis.¹³

Fritz et al. compared studies evaluating the diagnostic accuracy of myelography, CT scan, and MRI for the diagnosis of LSS. These authors demonstrated that MRI had the largest positive LR, ranging from 8.1 to 16.2, and lowest negative LR, ranging from 0.03 to 0.19, and concluded that MRI is the diagnostic imaging of choice for suspected LSS. Similarly, these authors compared the LRs of findings from the history and physical examination and concluded that findings from the history were most useful. Specifically, the absence of pain when seated (positive LR = 6.6), improvement of pain when sitting (positive LR = 3.1), sitting being the best posture for reducing symptoms (negative LR = 0.28), and standing/ walking being the worse postures for symptoms (negative LR = 0.33) were the most useful diagnostic factors.¹⁴ Patients with signs and symptoms highly suggestive of LSS require imaging only if they are possible candidates for surgery or other invasive interventions or if the patient presents with clinical features (“red flags”) suggestive of other underlying pathology.¹⁵

Other potential causes of our patient’s symptoms include peripheral vascular insufficiency, osteoarthritis of the hips, trochanteric bursitis, and peripheral neuropathy.^{3,14}

Openmirrors.com

Recommendations

- Findings in the history are most important in the diagnosis of neurogenic claudication. Key diagnostic features include the presence of lower extremity symptoms that worsen when standing and/or walking and improve with sitting and forward flexion
- Imaging (MRI) should be restricted to patients with neurogenic claudication who are potential candidates for invasive procedures or have signs and symptoms suggestive of other underlying serious disease. The use of imaging alone without corroborating the findings with presenting clinical features poses a considerable risk for inaccurate diagnosis

Question 4: What is the effectiveness of epidural steroid injections for the treatment of neurogenic claudication?

Question 5: What is the effectiveness of other nonoperative treatment for neurogenic claudication?

Question 6: What medications have been found to be effective for patients with neurogenic claudication?

Relevance

Although surgery may be a therapeutic option, evidence-based reviews suggest an initial course of conservative treatment prior to surgical intervention.^{16,17} An epidural steroid injection introduces a mixture of corticosteroids into the epidural space with the aim of reducing inflammation at the level of neural compression. Various approaches are used to access the epidural space including interlaminar, caudal, and transforaminal. The use of epidural steroid injections is a rapidly growing treatment in the elderly population for spine-related leg pain,¹⁸ and approximately a quarter of all epidural steroid injections are administered for symptoms ascribed to LSS.¹⁵ Other common nonoperative treatments include analgesic and anti-inflammatory medication, patient education, spinal manipulation and mobilization, therapeutic exercises, and the use of therapeutic modalities.^{19–21} Exercises and instruction in body repositioning techniques are aimed at improving back and lower limb strength and flexibility and teaching patients how to position their body to reduce symptoms.²⁰ Commonly prescribed medications include acetaminophen (paracetamol), narcotic analgesics, and anti-inflammatory drugs.^{3,16}

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries/systematic reviews (including meta-analysis, evidence-based reports, reviews of clinical trials, consensus development conferences and guidelines) using the search term: “neurogenic claudication OR lumbar spinal stenosis”

Quality of the evidence

Level I

- 3 systematic reviews^{15,25,32}
- 4 randomized controlled trials (RCTs)^{30,31,38,39}

Findings

Epidural steroid injections Three RCTs^{22–24} were identified from one systematic review²⁵ that included only patients with neurogenic claudication with confirmatory lumbar stenosis on imaging. Table 81.1 summarizes the trials and Table 81.2 provides GRADE evidence profiles for the trials.

Cuckler et al. compared the proportion of patients who self-reported at least 75% improvement from preinjection status among 37 patients randomized to receive either a translaminal steroid injection or placebo injection. The investigators found no differences in self-reported improvement in symptoms among the two groups 24 hours after the injection or after a mean of 21 months.²²

Zahaar used similar outcome measures and randomized 33 patients to receive either a prone caudal epidural steroid injection or a placebo injection. There were no differences in treatment outcomes between the groups 24 hours after the injection or after a mean of 20 months.²⁴

Fukusaki et al. evaluated walking distance among 53 patients randomized to receive an epidural block, an epidural block with methylprednisolone, or an epidural saline injection. At 1 week after the injection the groups who received either the epidural block or epidural block with methylprednisolone had a greater proportion of patients with good or excellent walking distance (55.5% and 63.2% respectively) compared to the group receiving the placebo injection (12.5%, $p < 0.05$). However, at one and 3 months post injection there were no differences in walking distance among the three groups.²³

Other medications There are no placebo controlled RCTs evaluating anti-inflammatory medication or narcotics for treatment of LSS. A pilot RCT ($n = 55$) assessed the effectiveness of gabapentin plus physiotherapy compared to physiotherapy alone and demonstrated positive benefit in

Table 81.1 Description of studies on epidural injections for neurogenic claudication due to lumbar spinal stenosis

Study	Participants	Intervention	Control	Outcomes	Results
Fukusaki 1998	53 patients with pseudoclaudication, all of the patients in the three groups had unilateral or bilateral pseudoclaudication with less than 20 m in walking distance because of intolerable leg pain	Gr 1-Epidural injection with 8 mL of 1% mepivacaine. The same epidural injection was repeated twice during the first 1-week period in all groups Gr 2-Epidural injection with a mixture of 8 mL of 1% mepivacaine and 40 mg of methylprednisolone. The same epidural injection was repeated twice during the first 1-week period in all groups	Gr 3- Epidural injection with 8 mL of saline. The same epidural injection was repeated twice during the first 1-week period in all groups	Walking distance was evaluated as follows: excellent effect, more than a mean of 100 m in walking distance; good effect, mean of 20–100 m in walking distance; poor effect, less than a mean of 20 m in walking distance	At 1 week Gr 2 and Gr 3 significantly greater number of patients with good or excellent results compared to Gr 1. At 1 and 3 months no difference in the groups
Cuckler 1985	73 patients from private clinic practice with clinical features (neurogenic claudication or sciatica) and confirmatory imaging for either spinal stenosis (n = 37) or herniated disc (n = 36)	2 mL of sterile water containing 80 mg of methylprednisolone acetate combined with 5 mL of 1% procaine was injected into the epidural space of the region between the 3rd and 4th lumbar vertebrae with the patient in the lateral decubitus position lying on the side of the painful limb	2 mL of saline with 5 mL of 1% procaine was injected into the epidural space in the region between the 3rd and 4th lumbar vertebrae with the patient in the lateral decubitus position lying on the side of the painful limb	Short-term successful result was defined as subjective improvement of 75% or more 24 hours after injection. Short-term failure was defined as less than 75% improvement during this time. Long-term success was defined as improvement of 75% or more in the preinjection symptoms at 13–36 months (mean 20.85 months) Other outcomes were re-injection rates and need for surgery	No significant difference in the short or long term between the steroid or control group
Zahaar 1991	63 patients with clinical features of neurogenic claudication (n = 30) or sciatica (n = 33) and confirmatory imaging for either acute herniated nucleus pulposus or spinal stenosis	Using a caudal route with patient prone, 2 mL of carbocaine, 4% were injected into the epidural after infiltration at the site of injection. This was immediately followed by injection of one ampule of 5 mL of hydrocortisone acetate suspension, combined with another ampule (2 mL) of carbocaine, 4%: the volume was completed with sterile saline to 30 mL	Using a caudal route with patient prone, 2 mL of carbocaine, 4% were injected into the epidural after infiltration at the site of injection. This was immediately followed by injection of one ampule (2 mL) of carbocaine, 4%: the volume was completed with sterile saline to 30 mL	Short-term successful result was defined as subjective improvement of 75% or more 24 hours after injection. Short-term failure was defined as less than 75% improvement during this time. Long-term success was defined as improvement of 75% or more in the preinjection symptoms at 13–36 months (mean 20.85 months)	No significant difference in the short or long term between the steroid or control group

CI, confidence interval; RCT, randomized controlled trial.

^aHigh risk of bias (unsure of method of randomization or concealment, blinding of patient and care provider and cointerventions).

walking distance ($p < 0.001$), pain scores ($p < 0.006$), and recovery of sensory deficits ($p < 0.04$) over a 4 month period.³¹ One RCT ($n = 79$), demonstrated that prostaglandin E1 is more effective than etodolac in improving walking distance ($p < 0.01$) and leg numbness ($p < 0.01$) at eight weeks follow-up. [Matsudaira 2009][38]. Another single RCT ($n = 152$) showed that Vitamin B12 when added to conservative treatment improved walking ability ($p < 0.05$) compared to conservative treatment alone at six months, 12 months and 18 months follow-up. [Waikakul 2000][39]. In a recent systematic review of RCTs, the use of calcitonin was found to be of no benefit for neurogenic claudication in patients with LSS.³²

Other conservative care Various conservative treatments have been used as controls for surgical trials; however, the type, frequency, treatment combination, and provider varied significantly among the trials, limiting the ability to make conclusions about effectiveness.²⁹

Whitman et al. randomized 58 patients with neurogenic claudication and LSS to receive either flexion exercises, manual therapy (thrust and nonthrust manipulation of the spine and lower extremity joints) and body-supported treadmill walking or flexion exercises, treadmill walking, and subtherapeutic ultrasound. After 12 treatment sessions, over 6 weeks, both groups achieved clinically important improvements at the completion of each treatment program and at 1 year. However, the group that received manual therapy showed significantly greater self-reported improvement in perceived recovery (79% vs. 41%, $p = 0.0015$) and on the Satisfaction Subscale of the Spinal Stenosis Scale at 6 weeks (1.57; 95% CI 1.36–1.78 vs. 2.03; 95% CI 1.8–2.31) but not at 1 year or long-term follow-up (a mean of 29 months).³⁰ There were no significant differences in other outcomes: Oswestry Disability Index, treadmill walking distance, and Numeric Pain Rating Scale for lower extremity symptoms.

Recommendations

- Low-quality evidence does not support the use of epidural steroid injections for neurogenic claudication. Manual therapy with exercise may provide short-term (up to 6 weeks) improvement in perceived recovery and patient satisfaction over exercise alone [overall quality: low];³⁰ however, there is insufficient evidence to support the use of other conservative care including analgesics or anti-inflammatory drugs. Gabapentin may be helpful; however the benefits noted were based on pilot data.³¹ Any potential benefit of gabapentin should be weighed against potential risk for adverse effects, including dizziness and drowsiness [overall quality: low]. Vitamin B12 and Prostaglandin E1 may be useful in improving walking ability. [overall quality: low]
- Although high-quality evidence is lacking to guide specific self-management strategies, providing patients with

neurogenic claudication advice to keep active and perform regular nonaggravating exercise, and use acetaminophen or anti-inflammatory medication, similar to advice for nonspecific LBP, may be a reasonable initial approach. This is the position of a recent clinical practice guideline from the American College of Physicians and the American Pain Society with the rationale that recommendations from high-quality systematic reviews for nonspecific LBP include RCTs that enrolled patients with low back related leg symptoms.¹⁵ With respect to which types of exercise are likely to be helpful, evidence from observational studies suggest that body repositioning techniques and performing flexion exercises including stationary cycling and abdominal strengthening exercises may be beneficial in reducing symptoms of neurogenic claudication.^{3,20,33–36}

Question 7: What are the complications related to epidural injections for neurogenic claudication?

Finding the evidence

See Questions 4–6.

Findings

Only one of the included trials on epidural steroid injection²³ provided information on adverse events following the intervention. This trial reported no incidence of dural puncture, hypotension, or subarchnoid injection. There have been case reports of serious adverse events including paralysis and infection following epidural steroid injection.^{26–28}

Recommendation

- There is insufficient evidence to provide a recommendation.

Question 8: What is the long-term prognosis of patients with neurogenic claudication treated nonoperatively, and what factors are prognostic in these patients?

Case clarification

We want to inform our patient on the long-term prognosis of nonoperative treatment. We also want to examine factors that may impact success of nonoperative treatment.

Finding the evidence

- PubMed: we repeated the search for therapy replacing the word “therapy” with “prognosis”

Quality of the evidence

Level II

- 1 prospective cohort study³⁷

Findings

Atlas et al. followed 148 patients with lumbar spinal stenosis over an 8–10 year period managed either surgically ($n = 81$) or non-surgically ($n = 67$) in a community-based setting.³⁷ Nonsurgical treatment varied and included epidural steroid (18%), spinal manipulation (23%), physical therapy (23%), bed rest (29%), exercises (39%), narcotics (21%), and other modalities, such as TENS, traction, and bracing (39%). When surgical intervention was compared to nonsurgical treatment, improvement in predominant symptom (lower back or leg pain) from baseline was reported by 77% and 44% of patients at 1 year ($p < 0.05$), 70% and 52% of patients at 4 years ($p < 0.05$), and 54% and 42% of patients at 8–10 year follow-up ($p > 0.05$), respectively. Symptoms of nonsurgical patients were unchanged in 36%, 18%, and 22% of patients at year 1, 4, and 8–10 years respectively. Follow-up rates at 1, 4, and 8–10 years were 87.8%, 80.4%, and 65.5% respectively. It was not possible to identify predictors of outcome among nonsurgical patients in this study because of the limited number of individuals at long-term follow-up.

Recommendation

- A large proportion of patients receiving nonoperative management either improve or remain stable, making this a reasonable initial management option for our patient. It is unknown what patient factors predict favourable nonoperative outcomes

Question 9: How does the cost of nonsurgical treatment compare to that of surgical treatment?

There are no cost-effectiveness studies evaluating nonoperative treatment for neurogenic claudication.¹³

Summary of recommendations

- Findings in the history are most important in the diagnosis of neurogenic claudication. Key diagnostic features include the presence of lower extremity symptoms that worsen when standing and/or walking and improve with sitting and forward flexion
- Imaging (MRI) should be restricted to patients with neurogenic claudication who are potential candidates for invasive procedures or have signs and symptoms suggestive of other underlying serious disease
- Low-quality evidence does not support the use of epidural steroid injections for neurogenic claudication. Low quality evidence suggests that manual therapy with exercise may provide short-term improvement in perceived recovery and patient satisfaction over exercise alone; low quality evidence suggests that gabapentin, prostaglandins and Vitamin B12 may improve walking ability. There is

insufficient evidence to support the use of other conservative care including analgesics or anti-inflammatory drugs

- Although low quality evidence limits the ability to provide recommendations for clinical practice, advising patients to keep active and perform regular nonaggravating exercise, and use acetaminophen or anti-inflammatory medication, may be a reasonable initial approach
- Body repositioning techniques and flexion exercises including stationary cycling and abdominal strengthening exercises may be beneficial in reducing symptoms of neurogenic claudication
- A large proportion of patients receiving nonoperative management either improve or remain stable, making this a reasonable initial management option

Conclusions

A comprehensive history is essential in the diagnosis of neurogenic claudication. Advanced imaging should be restricted to patients with persistent symptoms who may be candidates for invasive procedures. Low-quality evidence suggests that epidural steroid injections are ineffective, and that gabapentin, prostaglandins, Vitamin B12 and manual therapy in addition to exercise may provide improvement. High-quality randomized controlled studies are needed to further evaluate nonoperative treatment for neurogenic claudication. Most patients do not have progressive deterioration of symptoms and a conservative approach that includes self-management strategies is a reasonable first step in the treatment of neurogenic claudication. Large studies on the natural history of neurogenic claudication are needed to enable early identification of high-risk patients who may require more aggressive interventions.

Adolescent Idiopathic Scoliosis— Nonoperative Management

Calvin T. Hu and James O. Sanders

University of Rochester Medical Center, Rochester, NY, USA

Case scenario

An asymptomatic 12 year-old Risser 0 premenarchal girl presents with a spinal deformity. Radiographs demonstrate a right thoracic curve measuring 32° Cobb angle from T6 to T12. Her examination is normal with the exception of a right thoracic deformity on forward flexion.

Relevant anatomy

Idiopathic scoliosis is a deforming condition of the spine with coronal plane deviation typically associated with apical rotation. Progression during adolescence can be marked. The Cobb angle is a radiographic measurement of severity. Curves can appear in several areas of the spine but are stereotypic in their location and direction. Detection is usually by trunk asymmetry on forward bend. The Risser iliac apophyseal ossification sign is a common maturity measurement.

Risser iliac apophyseal ossification sign

- Stage 0: No ossification of iliac crest apophysis
- Stage 1: Up to 25% ossification
- Stage 2: 25–50% ossification
- Stage 3: 50–75% ossification
- Stage 4: 75–100% ossification
- Stage 5: Fusion of apophysis to iliac crest

Importance of the problem

The prevalence of scoliosis is 1–3% in the United States. Adolescent onset scoliosis is not life threatening, but consequences to the patient may include deformity and pain.

A Google search in August 2010 for “scoliosis” returned more than 17 million results. In 1995, there were 602,884 visits¹ in the U.S. for adolescent idiopathic scoliosis (AIS), with more than 4,500 surgeries performed in 2000. A functional outcome measurement, the Scoliosis Research Society (SRS) instrument was developed from the Short Form 50 (SF-50) and several scoliosis-specific issues. It has been well tested in adults^{2,3} but, like other deforming conditions in childhood where the treatment goal is prevention of presumed long-term effects, outcome instruments show a significant ceiling effect in the short run.

Top six questions

Diagnosis

1. Are school scoliosis screening programs beneficial to children?

Therapy

2. Do exercise programs prevent curve progression?
3. Does bracing prevent curve progression?

Prognosis—curve progression

4. Is it possible to predict which curves will progress markedly during the adolescent growth spurt?

Prognosis—functional outcomes

5. What is the association between nonoperatively managed scoliosis and back pain or functional impairment?
6. What is the association between nonoperatively managed scoliosis and pulmonary compromise?

Question 1: Are school scoliosis screening programs beneficial to children?

Case clarification

School screening programs are commonly used to identify children with potential scoliosis.

Relevance

The benefits of scoliosis school screening are controversial.

Current opinion

The U.S. Preventive Services Task Force (USPSTF) recommends against schools screening, but several physician groups recommend the contrary.

Finding the evidence

- Cochrane Database: “scoliosis”
- PubMed Clinical Queries:
 - Systematic Reviews: “(adolescent idiopathic scoliosis anterior posterior) AND systematic[sb]”
 - MeSH: “mass screening”[Majr] AND (“scoliosis/diagnosis”[Mesh] OR “scoliosis/epidemiology”[Mesh] OR “scoliosis/therapy”[Mesh])

Quality of the evidence

Level III

- 2 case-control studies

Findings

In 2004, the USPSTF⁴ recommended against school scoliosis screening, finding poor accuracy of the forward bending test, poor follow-up from screening programs, and poor evidence that screening detects scoliosis at an earlier age than without screening. They found fair evidence that treatment leads to health benefits in only a small proportion of cases, since few progress to require aggressive treatment, such as surgery, and these subjects are likely to be detected without screening. The USPSTF also found fair evidence that screening leads to moderate harms, including unnecessary brace wear and specialty care referral. Several physician societies issued a statement^{5,6} supporting school screening, as earlier referral can identify those who are at high risk for progression, allowing earlier nonoperative treatment. Only one recent higher-evidence study evaluated the efficacy of scoliosis screening⁷ and found an 86% probability that screening did not prevent surgery.

The utility of school screening depends upon identifying those most likely to have scoliosis and relies on proxies rather than radiographs. The sensitivity and specificity of the simple tests are low, making multistage screening more effective. However, this increases cost.^{8–11} Various ages have been recommended for school screening. Potentially, screening at age 10 will identify all patients with high curve

progression potential.¹² In order to justify school screening programs, children who screen positive should derive some benefit, such as improved treatment outcomes or a reduced likelihood of surgery. Likewise, screening should minimize harms such as unnecessary radiation exposure, costs, and misdiagnosis. Ultimately, schools may not be the proper place for screening since proper follow-up is problematic.¹³

Recommendations

- Until the completion of studies evaluating the effectiveness of bracing for adolescent idiopathic scoliosis, we are unable to identify substantial benefit from current school screening programs [overall quality: low]

Question 2: Does exercise prevent curve progression?

Case clarification

Bracing is confining, and exercise makes sense to many patients as a potential treatment or adjunct for scoliosis.

Relevance

Many patients are hesitant to wear a brace to school or do not tolerate wearing a brace at night.

Current opinion

Openmirrors.com Exercise is ineffective in preventing scoliosis progression.

Finding the evidence

- Cochrane Database: 1 protocol for review
- PubMed Clinical Queries:
 - Clinical Studies Category: “(adolescent idiopathic scoliosis exercise) AND (Therapy/Broad[filter])”
 - Systematic Reviews: “(adolescent idiopathic scoliosis exercise) AND systematic[sb]”

Quality of the evidence

Level III

- 3 systematic reviews
- 1 comparative study

Findings

Exercises used in the treatment of AIS are diverse and can be classified into four program types (Table 82.1). A recent systematic review¹⁴ found the overall methodological quality of existing studies low. Most had no controls and heterogeneity prevented a meta-analysis. Overall, decreased Cobb angle progression was seen primarily near the beginning of the adolescent growth spurt, while Cobb angle improvement was seen after growth completion. We identified one level III study¹⁵ showing a statistically significant difference in progression between an exercise-treated group (Schroth method) and observed patients. The

Table 82.1 Exercises used in the treatment of adolescent idiopathic scoliosis

Program type	Definition
Scoliosis inpatient or outpatient rehabilitation (Schroth method)	Uses exercises to correct scoliotic posture through elongation and realignment of trunk segments, positioning of the arms, as well as the use of specific breathing patterns. Proprioceptive and exteroceptive stimulation and mirror control is used
Extrinsic autocorrection (side-shift method)	Introduced by Mehta, uses a lateral trunk shift exercise which is then incorporated into the activities of daily living
Intrinsic autocorrection	Based on auto-elongation exercises, intrinsic autocorrection utilizes the intrinsic back muscles to correct spinal alignment. These principles are now taught as a three-dimensional autocorrection in the SEAS (Scientific Exercises Approach to Scoliosis) program. Also known as active self-correction
No autocorrection, asymmetric exercises	Studies classified in this category used a particular fitness machine to strengthen torso muscles. This machine is also marketed for general resistance training

patients were controlled for age but not physiological maturity. Closer examination of the systematic reviews shows the reported studies were not properly stratified by maturity in conjunction with curve magnitude and pattern. Although it is plausible that exercise may improve scoliosis, absent properly designed studies, evidence is weak that exercise therapy alters the natural history.

Recommendations

In patients with adolescent idiopathic scoliosis who are treated primarily with exercises, the evidence suggests:

- Only weak evidence exists that exercise therapy alters the natural history of idiopathic scoliosis [overall quality: very low]

Question 3: Does bracing prevent curve progression?

Case clarification

The patient's parents ask if a brace will keep their daughter's curve from worsening.

Relevance

A real benefit (stabilization of curve, avoidance of surgery) should be attainable if a patient is to commit to brace treatment.

Current opinion

Bracing is recommended for curves of 25–40° in patients Risser 2 or less, or in curves 20° or more with documented progression.

Finding the evidence

- Cochrane Database: 1 protocol filed
- PubMed Clinical Queries:
 - Systematic Reviews: “((scoliosis braces) AND systematic[sb]) OR ((scoliosis bracing) AND systematic[sb])”
 - Clinical Studies Category: “scoliosis AND brace AND ‘clinical trial’”

Quality of the evidence

Level II

- 2 systematic reviews/meta-analyses
- 1 prospective study with treatment determined by individual centers
- 1 prospective study with results compared by compliance with bracing

Level III

- 1 systematic review/meta-analysis
- 1 retrospective cohort comparison

Findings

A 1995 multicenter prospective study¹⁶ is often considered the definitive study showing brace effectiveness. This study compared observation and bracing for girls with curve apices T8–L1 and Cobb angles 25–35°. With progression defined as 6° change or more, 74% of braced patients and 34% of observed patients did not progress. Danielsson, et al.¹⁷ used some of this earlier study's subjects and compared longer-term follow-up of two sites, one bracing all eligible patients and the other only bracing progressing curves. None of 41 initially braced patients progressed 6°, while 26 of 65 (40%) initially observed patients progressed with 6 (10%) of them undergoing surgery. There was no difference in progression between the two groups after maturity (5.7° for braced and 7.0° for observed patients). Assuming these results are generalizable, bracing prevents surgery in 10% of eligible patients.

Of two systematic reviews, one¹⁸ found overall methodologically poor-quality studies without strong evidence that bracing was effective and the other¹ found no difference in surgical rates between braced and observed patients.

A recent observational study¹⁹ examined the dose response curve of patients with idiopathic scoliosis based upon the amount of time the brace was worn, the Risser sign, and the status of the triradiate cartilage. Again, curve progression was defined by 6° change. The authors found that more time wearing the brace resulted in less likelihood of curve progression more than 6°. Less mature patients

(open triadiate cartilage) required more time in the brace for the same effect. Methodologically, the study has important limitations including not documenting the specific curve pattern, using the orthotist to measure radiographs, lack of a functional endpoint such as surgery, and inability to distinguish whether compliance led to better results or vice versa.

A basic critique of prior studies is that different curve patterns behave differently and that far better maturity assessments exist than the Risser sign. Future studies must stratify by curve pattern, magnitude and sex, and use quality maturity indicators. Understanding whether bracing prevents progression to a surgical range and which patients are likely to benefit must await higher level studies which are currently in progress.²⁰

Recommendations

- There is weak evidence that bracing can prevent curve progression of 6° or more in adolescent idiopathic scoliosis curves [overall quality: low]
- There is no evidence that bracing can prevent curve progression to a surgical range in moderate-sized adolescent idiopathic scoliosis curves [overall quality: low]

Question 4: Is it possible to predict which curves will progress markedly during the adolescent growth spurt?

Case clarification

The patient's mother knows of other children whose curves increased significantly despite bracing and required surgery and is concerned about this risk for her daughter.

Relevance

With knowledge that curves tend to progress more rapidly during the adolescent growth spurt, it is helpful to know which patients can be observed and which patients may require intervention.

Current opinion

Scoliosis progresses primarily during the adolescent growth spurt centered about the timing of maximum growth velocity (peak height velocity, PHV). Small curves at the PHV tend to remain small, while larger curves can progress substantially.

Finding the evidence

- Cochrane Database: "scoliosis"
- PubMed Clinical Queries:
 - Clinical Studies Category: "(idiopathic scoliosis progression adolescence) AND (Prognosis/Narrow[filter]), and (idiopathic scoliosis progression growth) AND (Prognosis/Narrow[filter])"
 - Systematic Reviews: "scoliosis progression"

- PubMed sensitivity search: "Scoliosis"[Mesh] AND (Prognosis/Broad[filter])

Quality of the evidence

Level I

- 3 studies (2 of same series)

Level II

- 14 studies (2 of same series)

Findings

A number of primarily retrospective level II studies^{21–32} examining prognostic factors for scoliosis consistently show:

- curve progression is more common in patients with larger curves and less skeletal maturity
- thoracic and thoracic predominant double curves progress more than thoracolumbar curves or lumbar curves^{21,24,27,28,30–32}
- the timing of progression is during the adolescent growth spurt and then slows markedly as maturity is reached

Most of these studies have important weaknesses, including not controlling for the important variables of curve pattern, magnitude, and maturity, and defining progressive curves as a change of 5 or 6° rather than functional endpoints.

The most commonly used maturity indicators in the literature are the Risser sign and chronological maturity. Several other indicators have been proposed which correlate more highly with scoliosis progression. One indicator is curve magnitude at the time of the growth spurt, with curves of less than 30° at the peak growth highly unlikely to progress to surgery and conversely for larger curves.^{22,23} Skeletal maturity also highly correlates with curve progression and is a superior maturity indicator to Risser sign, chronological age, menarche, and other commonly used maturity indicators.³³ Both the hand³⁴ and the elbow^{35,36} have useful maturity markers. Studies of curve progression using nonphysiological endpoints provide very little information to the clinician. It is quite clear that the studies must also separate curves based upon their pattern, since differing curve patterns behave quite differently.

Recent presentations have identified potential genetic markers as highly indicative of scoliosis progression.³⁷ At this time, there is too little literature to assess whether this is a viable alternative to the combination of maturity, curve pattern, and curve magnitude.

Recommendations

- Studies looking at skeletal maturity in conjunction with pattern and magnitude provide a reasonable method of ascertaining curve prognosis for progression. Larger studies must be completed before clinicians have accurate predictive value for many curve types [overall quality: moderate]

- There is insufficient evidence on genetic predictors to make recommendations for or against their use [overall quality: very low]

Question 5: What is the association between nonoperatively managed scoliosis and back pain or functional impairment?

Case clarification

Many people believe scoliosis looks as if it should become painful.

Relevance

With back pain common and sometimes debilitating in the general population, patients may be concerned that their future quality of life will be diminished by chronic back pain due to untreated scoliosis.

Current opinion

Patients with adolescent idiopathic scoliosis experience chronic back pain at a higher rate, but without any higher rate of disability.

Finding the evidence

- Cochrane Database: "scoliosis"
- PubMed Clinical Queries
 - Clinical Studies Category: "(adolescent idiopathic scoliosis back pain) AND (Prognosis/Broad[filter])"
 - Systematic Reviews: "(adolescent idiopathic scoliosis back pain) AND systematic[sb]"
- PubMed sensitivity search: "Scoliosis"[Mesh] AND "Back Pain"[Mesh]

Quality of the evidence

Level III

- 6 comparative studies

Level IV

- 1 case series

Findings

Untreated Weinstein, et al.³⁸ reported on 117 AIS patients with minimum follow-up of 50 years compared to matched controls. Sixty-one percent of patients reported chronic back pain at any level compared to 35% of controls ($p = 0.003$) with no correlation between pain scores and thoracic or lumbar spine radiographic osteoarthritis. Cordover et al.³⁹ studied 34 patients with average follow-up of 22 years and average age of 36 years, compared to controls. The rate of back pain in this cohort was 65% in scoliosis patients compared to 32% of controls. Ascani et al.⁴⁰ studied a cohort of 187 untreated patients with 15–47 year follow-up without a control group. The rate of back pain was 61%, similar to the other studies.

Brace-treated Danielsson and Nachemson⁴¹ reported on 127 Swedish brace-treated patients with an average 22 year follow-up compared to controls. Seventy-six percent of patients reported back pain in the last year compared to 58% of controls ($p = 0.0076$). Functional outcome measures (Oswestry Disability Index and Short Form-36) demonstrated that back pain had a minimal effect on daily life and function. Other studies of this Swedish cohort indicated that pain intensity correlated with reduced lumbar range of motion⁴² and was a minor reason for limitation in social activities, compared to physical difficulties or self-consciousness.⁴³

Recommendations

- Scoliosis patients are more likely than controls to experience back pain over the long term [overall quality: high]
- Back pain for most untreated patients with scoliosis is typically neither disabling nor restricts daily activities [overall quality: moderate]

Question 6: What is the association between nonoperatively managed scoliosis and pulmonary compromise?

Case clarification

The patient asks if she will end up like her aunt with scoliosis, who was unable to walk up a flight of stairs without becoming short of breath.

Relevance

Thoracic curves can affect the geometry of the thoracic cage and possibly pulmonary function.

Current opinion

While infantile and juvenile curves may affect pulmonary development and function, only severe cases of adolescent idiopathic scoliosis impact on long-term pulmonary function.

Finding the evidence

- Cochrane Database: "scoliosis"
- PubMed Clinical Queries
 - Clinical Studies Category: "(adolescent idiopathic scoliosis pulmonary) AND (Prognosis/Broad[filter])"
 - Systematic Reviews: "(adolescent idiopathic scoliosis pulmonary) AND systematic[sb]"
- PubMed sensitivity search: "adolescent idiopathic scoliosis pulmonary"

Quality of the evidence

Level III

- 4 comparative studies

Findings

Weinstein et al.³⁸ in 51 year follow-up compared to controls found no significant difference in rates of shortness of breath (SOB) with daily activities or walking. Among patients with large curves (defined as $>80^\circ$ thoracic or $>50^\circ$ lumbar), those with thoracic curves had greater odds of SOB than patients with lumbar curves (OR 9.75, 95% CI 1.15–82.98). Those with curves $>50^\circ$ at maturity had greater odds of SOB at all three time-points in the study (OR 3.67 in 1992, 95% CI 1.11–12.12). Correlation was found between pulmonary function test (PFT) results and curve angles only for patients with single thoracic curves, and severe pulmonary impairment in a nonsmoker occurred only in patients with curve angles greater than 120° .⁴⁴ Pehrsson et al.⁴⁵ compared 141 surgically treated patients and 110 brace-treated patients with 100 randomly selected controls at mean follow-up of 25 years. There were no significant differences in dyspnea or wheezing among all groups. The authors also found 20 year unchanged mean vital capacity (VC) in untreated patients (65% predicted in 1968, 64% predicted in 1988), despite curves progressing from 79° to 86° , although six patients developed respiratory failure, and two had died.⁴⁶ Multivariate analysis indicated that low VC ($<45\%$ predicted) and large curve angle ($>110^\circ$) were the strongest predictors of respiratory failure.

Recommendations

In patients with adolescent idiopathic scoliosis who are treated nonoperatively, evidence suggests:

- Untreated and braced scoliosis patients report no statistically significant increased rate of SOB or dyspnea when compared to controls [overall quality: moderate]
- In untreated patients with thoracic curves, VC is inversely related to curve angle, but only patients with severe thoracic curves ($>110^\circ$) will experience severe impairment [overall quality: high]
- In moderate-sized curves, braced patients do not have statistically significant differences in PFTs when compared to surgically treated patients or controls [overall quality: low]

Summary of recommendations

- Until the completion of studies evaluating the effectiveness of bracing for adolescent idiopathic scoliosis, we are unable to identify substantial benefit from current school screening programs
- Only weak evidence exists that exercise therapy alters the natural history of idiopathic scoliosis
- Although there is weak evidence that bracing can prevent some curve progression, there is no evidence that bracing can prevent curve progression to a surgical range

in moderate-sized adolescent idiopathic scoliosis curves during immaturity

- The studies looking at skeletal maturity in conjunction with pattern and magnitude provide a reasonable method of ascertaining curve prognosis for progression. Larger studies must be completed before clinicians have accurate predictive value for many curve types
- There is insufficient evidence on genetic predictors to make recommendations for or against their use
- Scoliosis patients are more likely than controls to experience back pain over the long term
- Back pain for most untreated scoliosis patients is typically neither disabling nor restricts daily activities
- Untreated and braced patients report no statistically significant increased rate of SOB or dyspnea when compared to controls
- In untreated patients with thoracic curves, VC is inversely related to curve angle, but only patients with severe thoracic curves ($>110^\circ$) will experience severe impairment

Conclusions

Limited high-quality evidence relevant to nonoperative treatment of scoliosis precludes strong recommendations. Large trials of high methodological quality focusing on patient-important outcomes such as quality of life and risk of surgery are urgently needed to better inform the diagnosis, treatment, and prognosis of conservatively managed scoliosis.

Adolescent Idiopathic Scoliosis— Operative Management

Calvin T. Hu and James O. Sanders

University of Rochester Medical Center, Rochester, NY, USA

Case scenario

A 14-year-old boy presents with a Risser 1 spinal deformity associated with a 75° left thoracic curve and a 45° right lumbar curve. His neurological examination shows slight asymmetry in his abdominal reflexes.

Relevant anatomy

Absence of the superficial abdominal reflex is a risk factor for spinal cord abnormalities such as syringomyelia.

Importance of the problem

The issues involved with idiopathic scoliosis are outlined in the introduction to the previous chapter on nonoperative treatment. Once the curve reaches a surgical range (50° at skeletal maturity), other questions assume importance, and some of the major questions are discussed in this chapter.

Top six questions

Diagnosis

1. Which patients with presumed adolescent idiopathic scoliosis (AIS) should have MRI imaging preoperatively?

Therapy

2. When do patients with AIS benefit from anterior surgery compared to posterior surgery?

3. What are the criteria for determining the cranial/caudal extent of fusion?

4. Does the amount of curve correction correlate with patient satisfaction?

5. Does the type of bone graft material affect fusion rates?

6. Is intraoperative neuromonitoring effective in preventing neurologic injury?

Question 1: Which patients with presumed AIS should have MRI imaging preoperatively?

Case clarification

The patient above has been followed for scoliosis and is referred to you for surgical evaluation.

Relevance

There is controversy regarding the necessity of routine preoperative MRI for patients with presumed AIS. Some surgeons have reported neurological complications in patients with spinal cord abnormalities (e.g., syringomyelia) who undergo surgery for curve correction.¹⁻³ These spinal cord abnormalities may be subclinical. With this in mind, several case series have reported on the results of screening MRI of the spine for patients with normal physical examination who are about to undergo spinal fusion for AIS (Table 83.1). Combining the results of these studies, there is an overall 4% rate (33 of 791) of spinal cord abnormalities, with 9% of these patients (0.4% of all patients) requiring neurosurgical procedures to treat the abnormality (e.g., decompression of syringomyelia). But, both the highest rate of spinal cord abnormalities (8%) and the only neurosurgical procedures required came from a single study. No neurological complications were reported in any of the studies.

Table 83.1 Summary of studies reporting on the use of routine preoperative MRI

Reference	AIS, normal physical exam?	Number of patients	Number of abnormalities (%)	Type of abnormality found (n)	Number requiring neurosurgical procedure	Neurological complications
Ozturk et al. ⁸	Yes	249	20 (8%)	Syrinx (15) Arnold–Chiari type I with syrinx (3) Arnold–Chiari type I (2)	3 (those with Arnold–Chiari type I with syrinx)	0
Do et al. ⁹	Yes	327	7 (2%)	Syrinx (2) Arnold–Chiari type I (4) Vertebral body anomaly (1)	0	0
Maiocco et al. ¹⁰	Yes	45	2 (2%) (one patient was juvenile onset)	Syrinx (1) Arnold–Chiari type I with syrinx (1)	0	0
Winter et al. ¹¹	Yes	140	4 (3%)	Syrinx (3) Arnold–Chiari type I (1)	0	0
O’Brien et al. ¹²	Yes, with curve >70°	30	0 (0%)	n/a	n/a	0

Current opinion

At the time of initial evaluation, if a patient is male, has a left thoracic curve, thoracic kyphosis, or any abnormality on neurologic exam, MRI should be obtained. Routine MRI is not necessary.

Finding the evidence

- Cochrane Database, with search term: “scoliosis”
- PubMed clinical queries:
 - Clinical Studies category, with search term: “(scoliosis magnetic resonance imaging) AND (Diagnosis/Broad[filter])”
 - Systematic Reviews, with search term: “(scoliosis magnetic resonance imaging) AND systematic[sb]”
- PubMed sensitivity search, with search term: “scoliosis magnetic resonance imaging”

Quality of the evidence

Level III

- 1 observational study
- 2 case-control studies

Level IV

- 6 case series

Findings

Left thoracic curve Davids et al.⁴ studied 1,280 patients with presumed AIS who had MRI performed based on the examination findings listed in Table 83.2 and found no association between curve direction and MRI abnormality. Goldberg et al.⁵ reviewed 666 cases of AIS and found no correlation between left-sided curves and CNS abnormal-

Table 83.2 Examination findings that were tested for an association with preoperative abnormal MRI findings

Pain	Neurological findings	Atypical curve pattern
Back	Clonus	Left thoracic
Neck	Abnormal abdominal reflexes	Short segment (4–6 levels)
Radicular	Weakness	Decreased vertebral rotation
Headache	Urinary dysfunction (urinary tract infection)	Absence of thoracic apical segment lordosis
	Hyperreflexia	Rapid progression
	Asymmetric deep tendon reflexes	
	Paresthesias	
	Diminished rectal tone	
	Cavus foot deformity	
	Skin lesions	

ity. In contrast, Loder et al.⁶ in a much smaller study compared radiographic findings of 30 patients with Arnold–Chiari I malformation with or without syringomyelia to 26 patients with normal MRI and found a positive relationship with left-sided curves (40% vs. 0%, $p = 0.0002$).

Thoracic kyphosis on sagittal plain radiograph In the study by Davids et al.,⁴ of all the atypical curve pattern findings listed as an indication for MRI, the absence of apical segment lordosis (or hyperkyphosis, as defined by sagittal plane thoracic kyphosis $\geq 20^\circ$) was associated most frequently with abnormal findings on MRI. Ouellet et al.⁷ conducted a case-control study comparing radiographs of 30 patients with syringomyelia to 54 patients with normal MRI to examine the importance of apical segment lordosis and found apical segment lordosis present in 97% of those with normal MRI but only 25% of those with syringomyelia ($p < 0.00001$).

Abnormality on neurological exam In the study by Davids et al.,⁴ clonus (7 of 42 patients), weakness (7 of 46 patients), and abnormal abdominal reflexes (5 of 42 patients) were the abnormal neurological findings most frequently associated with MRI abnormalities. The presence of more than one abnormal finding on neurological examination did not increase the frequency of MRI abnormalities. However, the combination of a neurological abnormality and an atypical curve pattern was associated with a higher rate of MRI abnormalities.

Male sex Loder et al.⁶ found that 37% of cases vs. 8% of controls ($p = 0.01$) were males, suggesting an association. But the much larger study by Davids et al.⁴ failed to confirm a relationship between gender and preoperative MRI abnormalities.

Pain Davids et al.⁴ found that when pain alone was used as an indication for MRI, no MRI abnormalities were found.

Recommendations

Only a small proportion of AIS patients have been found to have spinal cord abnormalities. In patients with presumed AIS, evidence suggests:

- Absence of apical segment lordosis or abnormality on neurological exam are indicators for MRI [overall quality: low]
- Pain, left thoracic curve, and male sex are not indicators for MRI [overall quality: low]

There is low-quality information arguing for the use of a preoperative MRI in the case of our patient.

Question 2: When do patients with AIS benefit from anterior surgery compared to posterior surgery?

Case clarification

Consider a patient with a single structural 80° thoracic curve with considerable clinical deformity. Supine lateral bending films demonstrate only 20° correction of the curve.

Frontal radiograph of the patient's pelvis reveals closed triradiate cartilage.

Relevance

Anterior surgery involving thoracotomy and disc excision has several purposes. If used in lieu of a posterior approach for instrumentation and fusion, anterior surgery may spare motion segments. In large curves, anterior discectomy may enhance correction. Or, it may prevent the crankshaft phenomenon,¹³ which is deforming anterior growth in younger children following a posterior fusion.^{14,15} However, anterior surgery may cause adverse pulmonary effects, and combined anterior-posterior surgery takes longer than posterior-only surgery.

Current opinion

Anterior surgery for thoracic curve correction has decreased due to reports of long-term adverse effects on pulmonary function and improved curve correction with pedicle screw instrumentation compared to older techniques.

Finding the evidence

- Cochrane Database, with search term: "scoliosis"
- PubMed Clinical Queries:
 - Clinical Studies Categories, with search term: "(adolescent idiopathic scoliosis anterior posterior) AND (Therapy/Narrow[filter])" and "scoliosis surgery anterior posterior Limits Activated: Clinical Trial, Meta-Analysis, Randomized Controlled Trial"
 - Systematic Reviews, with search term: "(adolescent idiopathic scoliosis anterior posterior) AND systematic[sb]"
- PubMed sensitivity search, with search term: "adolescent idiopathic scoliosis anterior posterior"

Quality of the evidence

Level I

- 2 prospective cohort studies

Level II

- 1 prospective cohort study

Level III

- 6 comparative studies

Findings

Very skeletally immature patients, defined as those with open triradiate cartilages of the pelvis at the time of surgery, treated with either an isolated anterior or posterior instrumentation and fusion rather than a combined procedure, experience a higher incidence of adding more levels to the curve or of main curve progression postoperatively (8 of 28 patients vs. 0 of 16 patients).¹⁶ The results are mixed for curve correction and maintenance. A level II study of 32

patients comparing single rod anterior instrumentation with posterior pedicle screw instrumentation¹⁷ found the anterior approach superior in terms of blood loss (also seen in a level I study¹⁸) and curve correction. However, a larger level III study¹⁹ of 62 patients found worse curve correction and maintenance of correction with dual rod anterior instrumentation compared to posterior pedicle screw instrumentation. Several level III studies^{20–22} found posterior pedicle screw constructs as effective as anterior–posterior fusions for curve correction.

No studies compare functional outcomes based upon surgical approach. A level I²³ and a level III²⁴ study each documented decreased pulmonary function in patients treated with anterior surgery when compared to patients treated with posterior procedures. The previously mentioned level I study²³ found surgical approach to be only a small contributor to decreased pulmonary function, with preoperative pulmonary function test (PFT) results being a stronger predictor of decreased postoperative function. Unfortunately, the minimal clinically important difference (MCID) for PFTs is not well delineated, making this information difficult to interpret.

Recommendations

- For most cases of AIS, including large curves, posterior pedicle screw instrumentation and fusion alone is as effective as anterior–posterior surgery [overall quality: low]
- Anterior fusion in conjunction with posterior fusion results in a lower incidence of adding on and curve progression in patients with open triradiate cartilages [overall quality: low]
- Pulmonary function is adversely affected by an anterior approach, but its clinical significance is uncertain [overall quality: moderate]

There is low-quality evidence that posterior pedicle screw instrumentation would be best for this patient.

Question 3: What are the criteria for determining the cranial/caudal extent of fusion?

Case clarification

A patient has a 65° right thoracic, 50° left lumbar curve, and a 30° left upper thoracic curve with even shoulders. She has elected to have posterior surgery, but the specific spinal vertebra to include in the fusion must be decided upon.

Relevance

The selection of fusion levels is of importance because the more levels included in the fusion, the straighter and more centered the spine can become. However, more levels included in the fusion may also lead to stress on the remaining open spinal segments.

Current opinion

The selection of fusion levels is generally based upon expert opinion, originally with the goal to provide a harmoniously “balanced” spine, improving both appearance and curvature. Early evidence in the late 1960s indicated fusion into the lumbar spine might be associated with early degenerative arthritis of the lower spine, with subsequent recommendations to limit the amount of lumbar spine fusion. Another concern arose with the development of powerful posterior correction systems in whether or not to include upper thoracic curves, or lower lumbar curves in the fusion. Upper thoracic curves are typically included if they are likely to cause poor appearance if not included.

A number of terms require definition to properly discuss fusion levels. These terms are used freely here, and we recommend consulting the *Spinal Deformity Study Group Radiographic Measurement Manual*²⁵ or the Scoliosis Research Society (SRS) website (<http://www.srs.org/professionals/glossary/>) for term definitions. Fusion recommendations typically relate to the curve’s end vertebra (EV), neutrally rotated vertebra (NV), and the stable vertebra (SV), which is that vertebra bisected by the center sacral vertical line (CSVL). Recommendations typically are to fuse entire structural curves and leave secondary curves alone. Defining these secondary curves has been problematic, with several classification schemes devised for this purpose, particularly the King and Lenke classifications.

S. King²⁶ described follow-up of patients treated with fusion using Harrington instrumentation from the neutral vertebra above to the SV below. For double major curves with the lumbar curve larger than the thoracic spine, the fusion extended to L4. If the lumbar curve is smaller, it was not included in the fusion which was stopped at the SV above. Following the development of multiple hook implants, some patients were found to “decompensate” by shifting to the side if the lumbar curve was not included. Suggested reasons included “overcorrection” in the thoracic spine, which the lumbar spine could not accommodate or persistent obliquity of L4 leading to this shift.²⁷ Lenke developed his classification in an attempt to define which curves required fusion.²⁸ The Lenke classification has become widely used. In this classification, only curves defined as structural require fusion. Other criteria, such as those by Burton and Asher²⁹ or Suk,^{30–32} also attempt to straighten the spine while retaining lumbar motion segments.

Finding the evidence

- Cochrane Database, with search term: “scoliosis”
- PubMed Clinical Queries:
 - Clinical Studies Category, with search term: “(adolescentscoliosisfusionlevels)AND(Therapy/Broad[filter])”
 - Systematic Reviews, with search term: “(adolescent scoliosis fusion levels) AND systematic[sb]”

- PubMed sensitivity search, with search term: “Scoliosis/surgery”[Mesh] AND “Spinal Fusion/adverse effects”[Mesh]

Quality of the evidence

Level III

- 5 comparative studies

Level IV

- 8 case series

Level V

- 3 opinion studies

Findings

One level III study³³ compared patients treated by surgeon judgment to those treated using the Lenke criteria and found superior radiographic outcomes in those treated according to the Lenke criteria. Three studies^{34–36} compared what different surgeons would do for various curve patterns and patient scenarios and found marked variation between surgeons in the selection of fusion levels. Although a few studies have attempted to address the upper level of fusion, they are uncontrolled.^{37–39}

We performed a systematic review of the effects of fusion into the lower lumbar spine and found a marked degree of heterogeneity in the length of follow-up, the outcomes measured, and the use of controls. No studies compared fused and unfused scoliosis patients, and all controls were nonscoliotic adults. Most studies used an early, non-validated measure to determine pain;⁴⁰ however, recent studies have used validated outcomes measures. All except a few studies report Harrington instrumentation results. There is only one report⁴¹ of later-generation (CD) instrumentation with short follow-up. We performed a meta-analysis of those studies with sufficient data to determine odds ratios of severe back pain for fusion into the lower lumbar spine compared to stopping at L3 or above^{41–48} which excluded many well-known studies.^{40,49–60} When several articles were found from the same cohort, only the most complete data set was used. Our meta-analysis (Figure 83.1) and the highest-quality study⁴⁸ found no significant difference in severe lumbar pain between patients fused to L3 or above compared to L4 or below. This same higher-quality series found no substantial difference in back pain or disc degeneration based upon the amount of residual lumbar lordosis.⁶¹ We found that disc degeneration was most severe at the lowest lumbar motion segment rather than just below the instrumentation. Unfortunately, the lack of controls in this literature is problematic because without comparing untreated scoliosis controls to similar scoliosis patients, it is not possible to say that the fusion level rather than the scoliosis itself caused the disc degeneration.

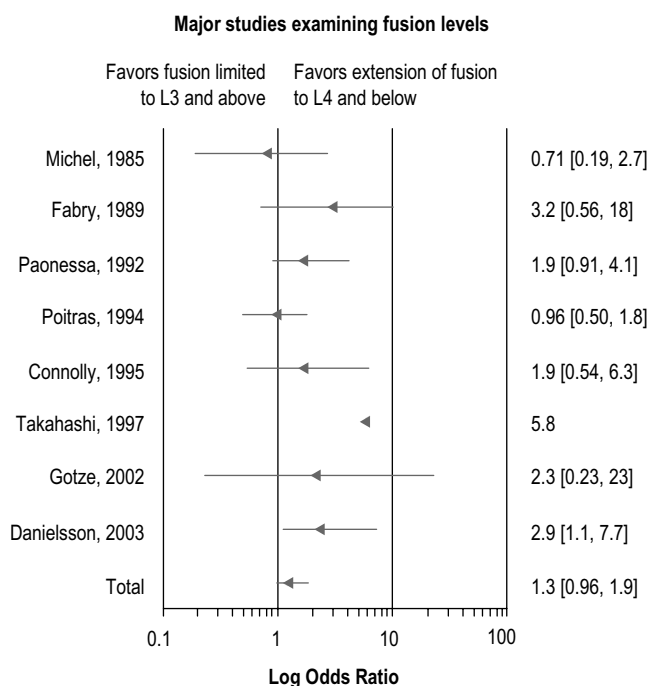

Figure 83.1 Major studies examining fusion levels.

Recommendations

There is considerable variation in recommendations for fusion levels in idiopathic scoliosis. Established criteria for instrumentation are based upon expert opinion (level V evidence) with weak support from level IV evidence. Because these types of studies are very difficult to randomize and require evaluating function several decades after instrumentation with controls consisting of either patients with similar curves fused to different levels or unfused scoliosis, it is likely that recommendations for instrumentation and fusion levels will continue to be based upon expert opinion for the foreseeable future. That is, unless nonfusion treatments replace instrumentation and fusion.

- There is very weak evidence that extending instrumentation and fusion into the lower lumbar spine for scoliosis results in long-term disability compared to fusion into the thoracic or upper lumbar spine [overall quality: very low]

Based on the available evidence, extending instrumentation into the lower lumbar spine is not contraindicated.

Question 4: Does the amount of curve correction correlate with patient satisfaction?

Case clarification

Your AIS patient asks if his back will look straight after surgery.

Relevance

There is evidence that successful radiographic outcomes do not always correlate with patient-centered outcomes. The patient's responses on quality of life measures may correlate more strongly with physical appearance as opposed to radiographic parameters.

Current opinion

Current opinion suggests that the magnitude of curve correction correlates to patient satisfaction.

Finding the evidence

- Cochrane Database, with search term: "scoliosis"
- PubMed Clinical Queries:
 - Clinical Studies Category, with search term: "(adolescent scoliosis surgery quality of life) AND (Therapy/Broad[filter])"
 - Systematic Reviews, with search term: "adolescent scoliosis surgery quality of life"
- PubMed sensitivity search, with search terms: "adolescent idiopathic scoliosis curve correction patient outcomes surgical," "adolescent scoliosis surgery quality of life surgery"

Quality of the evidence*Level II*

- 4 prospective comparative studies

Level III

- 7 retrospective comparative studies

Level IV

- 1 case series

Findings

There are few studies that investigate the relationship between curve correction and patient-important outcome measures. The most commonly used patient based outcome measure in scoliosis surgery is the SRS Patient Questionnaire. Studies have shown that patients' self-image scores on the SRS Patient Questionnaire are affected by curve severity.⁶²⁻⁶⁷ Four prospective studies compared SRS measurements both before and after surgery and found improvements, particularly in the self-image domain from preoperatively to postoperatively⁶⁸⁻⁷¹, with the largest of these studies⁷¹ finding more improvement in self-image scores in patients with greater curve correction (correlation coefficient 0.288, $p = 0.000$). It should be noted that the MCID for the SRS instrument has not been reported. From these studies, it is apparent that patients who have surgical treatment of scoliosis generally improve their self-image but the association with curve correction is not clear at this time.

Other factors may play a role in patients' self-image and satisfaction with surgery. Patients treated with different surgical approaches or instrumentation but with similar magnitudes of curve correction can have differences in SRS scores.^{69,72,73} So, although patient self-image and satisfaction will likely improve after surgery, the improvement is likely multifactorial and cannot be attributed solely to the postoperative curve magnitude.

Recommendations

- Patient self-image and satisfaction will likely improve after surgery, but the improvement is multifactorial and cannot be solely attributed to the postoperative magnitude of the curve [overall quality: low]

The patient can be told that his back will look straighter after surgery, but his parents should be informed that there are other factors that determine a patient's satisfaction with the outcome of surgery for AIS.

Question 5: Does the type of bone graft material affect fusion rates?**Case clarification**

Your patient's mother states she had iliac crest bone graft harvest performed for her scoliosis surgery, and that she still has bothersome pain at the donor site. She inquires about alternatives to iliac crest bone graft.

Openmirrors.com

Relevance

Iliac crest bone graft is the gold standard for bone grafting, but donor site morbidity can affect a patient's quality of life. Thus, alternatives to iliac crest bone graft deserve consideration if they offer advantages.

Current opinion

Adolescent patients can achieve high rates of fusion when cancellous allograft is used. There is no consensus regarding synthetic bone graft substitutes.

Finding the evidence

- Cochrane Database, using search term: "scoliosis"
- PubMed Clinical Queries
 - Clinical Studies Categories, using search term: "(scoliosis bone graft substitute) AND (Therapy/Broad[filter]), (scoliosis allograft) AND (Therapy/Broad[filter])"
 - Systematic Reviews: none
- PubMed sensitivity search, using search terms: "scoliosis AND allograft," "Scoliosis"[Mesh] AND "Bone Substitutes"[Mesh]

Quality of the evidence*Level I*

- 3 randomized trials

Level III

- 8 case-control studies

Findings

The interpretation of these studies is difficult for many reasons. The definition of pseudoarthrosis is not universally agreed upon, with several different definitions being used in the literature. Also, because it is a relatively rare complication often not becoming clinically evident until prolonged follow-up, randomized controlled trials (RCTs) or observational studies require large sample sizes and long follow-up periods to detect this complication. Case-control studies are therefore a reasonable study design to explore factors associated with pseudoarthrosis. One recent systematic review of pedicle screw instrumentation reported the incidence of pseudoarthrosis at 0.5%.⁷⁴ Because pseudoarthrosis may be related to surgical technique, surgeon ability and experience as well as the bone graft material may be important variables.

Iliac crest autograft vs. allograft Five retrospective studies directly compared the use of iliac crest autograft to bone bank allograft.⁷⁵⁻⁷⁹ The instrumentation techniques varied from Harrington–Luque to Cotrel–Dubousset to Texas Scottish Rite Hospital systems. Follow-up ranged from 6 to 24 months. The combined rate of pseudoarthrosis was similar, with 5 pseudoarthroses in 269 patients receiving autograft, compared to 6 in 274 patients receiving allograft. Two studies reported that operative times (141 vs. 176 minutes, $p < 0.001$ and 221 vs. 259 minutes, $p < 0.01$) and were less with allograft than autograft,^{78,79} while one of these showed blood loss was less with allograft compared to autograft (1,485 vs. 1,815 mL, $p < 0.01$).⁷⁹ A randomized prospective trial by Betz et al.⁸⁰ compared allograft to no bone graft material, including local bone, and failed to detect a significant difference between groups.

Bone substitutes Two randomized prospective trials^{81,82} compared the use of beta-tricalcium phosphate (β -TCP) to iliac crest autograft, with one study supplementing β -TCP with hydroxyapatite. A range of instrumentation systems were used. At minimum 18 month follow-up, there was one pseudoarthrosis in 190 patients receiving β -TCP, while none were reported in 191 patients receiving iliac crest. The authors claimed inadequate instrumentation as the cause of the pseudoarthrosis. Two smaller retrospective studies compared β -TCP to allograft, finding no pseudoarthroses in either group.^{83,84}

Demineralized bone matrix (DBM) was compared with allograft and iliac crest autograft in a 88 consecutive patients.⁷⁵ One pseudoarthrosis each was reported in the allograft and iliac crest groups, with none in the DBM group during an average follow-up period ranging from 35 to 56 months. When loss of correction of 10° was used to

define “possible pseudoarthrosis,” the rates in each group were 24%, 12%, and 11% respectively. Unfortunately, no statistical analysis was performed in this study. Finally, another consecutive series of 88 patients⁸⁵ evaluated the use of bioactive glass compared to iliac crest autograft and found three reported cases of pseudoarthrosis in the iliac crest group and none with the bioglass group at mean 40 month follow-up.

Recommendations

- To date, there are no clear differences in the rates of pseudoarthrosis for various bone graft materials [overall quality: low]

In the case of our patient, the mother can be informed that because there is no clear evidence to support the use of iliac crest autograft or its alternatives over one another, an alternative is a reasonable choice, especially given her concerns about postoperative iliac crest pain

Question 6: Is intraoperative neuromonitoring effective in preventing neurologic injury?**Case clarification**

The patient asks what the chances are he will become paralyzed as a result of surgery and what you can do minimize the risk.

Relevance

While the risk of spinal cord injury during scoliosis surgery is relatively rare, the consequences can be devastating.

Current opinion

Multimodality neuromonitoring with both sensory and motor evoked potentials is effective in detecting impending injury to the spinal cord during curve correction.

Finding the evidence

- Cochrane Database, using search term: “scoliosis”
- PubMed Clinical Queries:
 - Clinical Studies Category, using search term: “scoliosis neuromonitoring”
 - Systematic Reviews, using search term: “neuromonitoring”
- PubMed sensitivity search, using search term: “Scoliosis”[Mesh] AND “Monitoring, Intraoperative”[Mesh]

Quality of the evidence*Level I*

- 1 systematic review
- 1 cohort study

Findings

Curve correction can place traction on the spinal cord and lead to changes in neuromonitoring. Reversal of the curve

correction by removal of the rod can potentially reverse the onset of a permanent spinal cord injury. In contrast, screw misplacement into the spinal cord or nerve root is likely to cause irreversible damage. A recent systematic review of level II and level III studies⁸⁶ focused on the use of intraoperative neuromonitoring primarily in adult spine surgery. High-level evidence supported the use of multimodal (somatosensory evoked potentials, or SSEP and motor evoked potentials, or MEP) neuromonitoring as a sensitive and specific means to detect potentially reversible intraoperative neurological injury. High-level evidence also confirmed that if used alone, MEPs are more sensitive than SSEPs; however, these two tests are similar in specificity. This recommendation included one study evaluating MEP and SSEP monitoring in AIS, whose results were in agreement.⁸⁷ The systematic review also found low-level evidence that intraoperative neuromonitoring could reduce the rate of neurological injury during curve correction

Recommendations

- SSEP and MEP neuromonitoring is a sensitive and specific means to detect intraoperative neurological injury. MEPs are more sensitive than SSEPs in detecting injury, but the two modalities should continue to be used together [overall quality: high]
- Intraoperative neuromonitoring can reduce the rate of neurological injury [overall quality: low]

The patient is told there is low probability that he will become paralyzed as a result of scoliosis surgery and that there is low-quality evidence that the use of intraoperative neuromonitoring can help detect potentially reversible neurological injury.

Summary of recommendations

- MRI is recommended for patients with atypical curves, particularly with kyphosis rather than lordosis at the apex as well as in patients with abnormal neurological evaluations
- For most AIS, including large curves, posterior pedicle screw instrumentation and fusion alone is as effective as anterior–posterior surgery
- Anterior fusion in conjunction with posterior fusion results in a lower incidence of adding on and curve progression in patients with open triradiate cartilages
- Pulmonary function is adversely affected by an anterior approach, but clinical significance is uncertain
- There is very weak evidence that extending instrumentation and fusion into the lower lumbar spine for scoliosis results in long-term disability compared to fusion into the thoracic or upper lumbar spine
- Patient self-image and satisfaction will likely improve after surgery, but the improvement is multifactorial and cannot be solely attributed to the postoperative magnitude of the curve

- There are no published differences in the rates of pseudoarthrosis for various bone graft materials
- SSEP and MEP neuromonitoring is a sensitive and specific means to detect intraoperative neurological injury. MEPs are more sensitive than SSEPs in detecting injury, but the two modalities should continue to be used together
- Intraoperative neuromonitoring can reduce the rate of neurological injury

Conclusions

High-quality evidence to inform clinical decision making for scoliosis surgery is currently limited, which precludes strong recommendations. The long-term follow-up required to assess patient outcomes and rare complications, and difficulty randomizing patients are methodological challenges in this area of study.

Metastatic/Myeloma Disease— Operative Management

Harsha Malempati¹, Erion Qamirani¹, and Albert J.M. Yee²

¹University of Toronto, Toronto, ON, Canada

²Sunnybrook Health Sciences Centre, Toronto, ON, Canada

Case scenario

A 65 year old man presents to the Emergency Department with significant back pain that has been progressively worsening over the past 3 months. He has a history of prostate cancer. An MRI reveals multiple spinal lesions.

Relevant anatomy

General indications for surgical management of spinal metastases include: (1) establishing a tissue diagnosis, (2) failure of radiation therapy, (3) spinal instability, and (4) neurological deficits. One proposed scoring system was developed by Tokuhashi et al.,¹ whereby six different parameters are scored from 0 to 2 points with a maximum of 12. Aggressive surgery is recommended for patients having a score of greater than 9 and palliative surgery is reserved for those with scores less than 5. The six parameters are: (1) general condition of the patient, (2) number of extraspinal metastases, (3) number of vertebral metastases, (4) metastases to internal organs, (5) the primary tumor site, and (6) severity of neurological deficits.

Some authors have attempted to use the three-column model originally proposed by Denis² for thoracolumbar trauma to assess stability in the setting of spinal metastases.³ For spine metastasis, each of the three columns of the spine (anterior, middle, and posterior) is divided into two halves, creating a total of six zones. Instability is then defined as destruction of three or more zones by the tumor. Other authors have proposed a number of criteria that contribute to spinal instability in the setting of spinal metastases: (1) anterior and middle-column involvement or more than 50% loss of vertebral height, (2) middle and posterior-column or shearing deformity, (3) three-column

involvement, (4) involvement of the same column in two or more adjacent vertebrae, and (5) iatrogenic, defined as laminectomy in the setting of anterior and/or middle-column disease or resection of more than 50% of the vertebral body.⁴

Importance of the problem

Metastatic tumors are the most common spinal tumors. The most common sites of origin for spinal metastases are breast, lung, prostate, and the hematopoietic system. In most clinical series, these primary sites alone account for 50–66% of all metastases to the spine.⁵ Although most patients with spinal metastases present with pain as their chief complaint, the natural history of untreated spinal metastasis is generally one of relentless progression towards paralysis and loss of bowel and bladder function.⁶ Therefore, early diagnosis and appropriate treatment are necessary. The surgical management of spinal metastasis has gone through an extensive evolution over the past few decades.

Top five questions

1. What is the role of corticosteroids in the initial management of spinal metastases causing cord compression?
2. What is the efficacy of kyphoplasty in the management of spinal metastases?
3. What is the role of vertebroplasty in the management of spinal metastases? Is it more efficacious than kyphoplasty?
4. Does surgical decompression followed by radiotherapy have better outcomes than radiotherapy alone for the management of spinal metastases causing cord compression?
5. Is there a role for en-bloc tumor resection for spinal metastases?

Systematic reviews and meta-analyses that were relevant to the topic in question were referenced in isolation for the purpose of this review. Randomized controlled trials (RCTs) and other important studies pertinent to the topic that were published after (or not included in) systematic reviews were evaluated and discussed separately.

Question 1: What is the role of corticosteroids in the initial management of spinal metastases causing cord compression?

Case clarification

The patient complains of progressive muscle weakness and decreased sensation of the lower extremities. MRI confirms metastatic spinal cord compression.

Relevance

Although this chapter is devoted to the operative management of spinal cord metastases, a discussion of the use of corticosteroids is warranted because they have been shown to improve outcomes when administered before surgery in other cases involving spinal cord compression.

Finding the evidence

- Cochrane Database, search term: “corticosteroids AND spine”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “spinal metastasis AND steroids”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “spinal metastasis AND steroids”

Quality of the evidence

Level I

- 2 systematic reviews of RCTs

Findings

A systematic review found that although corticosteroids have been used for the treatment of metastatic epidural spinal cord compression (MESCC) for many years, there were only three inadequately powered RCTs designed to determine clinical benefit and optimal dosage.⁶ The review of these three RCTs did not show significant benefit for high-dose corticosteroids in improving patient ambulation (total patients 105, RR 0.91, 95% CI 0.68–1.23). The trials also showed no difference between high-dose vs. moderate or no corticosteroids for 2 year survival, pain relief, or urinary incontinence.⁶ Furthermore, there was a significant increase in the incidence of serious drug-related adverse events such as perforated gastric ulcers, psychoses, and deaths due to infection in patients who received high-dose corticosteroids.⁶ The results are summarized in Table 84.1. The authors concluded that the extent of benefit from corticosteroids, and the optimal dosage, is unclear. The three RCTs evaluated in this systematic review were underpowered given their low number of enrolled patients; therefore the grade of recommendation is moderate.

Another systematic review included two RCTs, one phase II study, and an observational study.⁷ One of the randomized trials included 57 patients with MESCC and found that 81% of the patients were ambulatory 3 months after receiving radiation and high-dose dexamethasone, while only 63% of the patients treated with radiation alone

Table 84.1 High-dose corticosteroids vs. no or moderate-dose corticosteroids

Parameters	Results
Overall ambulatory rates (short term)	RR 0.91; 95% CI 0.68–1.23 (n = 105, three trials)
Proportion of pretreatment ambulant participants maintaining ambulation (short term)	17/17 (100%) vs. 17/19 (90%) RR 0.90; 95% CI 0.75–1.08 (n = 36, one trial)
Proportion of pretreatment nonambulant participants regaining ambulation (short term)	5/10 (50%) vs. 2/11 (18%) RR 0.36; 95% CI 0.09–1.47 (n = 21, one trial)
Survival (long term)	5/10 (50%) vs. 2/11 (18%) RR 0.36; 95% CI 0.09–1.47 (n = 21, one trial)
Pain relief	11/14 (79%) vs. 10/11 (91%) RR 1.16; 95% CI 0.83–1.61 (n = 25, one trial)
Urinary continence	12/19 (63%) vs. 8/15 (53%) RR 0.84; 95% CI 0.47–1.52 (n = 34, one trial)
Adverse effects	High-dose corticosteroids vs. no or moderate-dose corticosteroids RR 0.12; 95% CI 0.02–0.97 (n = 77, two trials)
	High-dose vs. no corticosteroids RR 0.10; 95% CI 0.01–1.78 (n = 57, one trial)
	High-dose vs. moderate-dose corticosteroids RR 0.17; 95% CI 0.01–3.08 (n = 20, one trial)
Outcomes not reported	Quality of life, participant rated and caregiver satisfaction

Adapted from George R, Jeba J, Ramkumar G, et al. Interventions for the treatment of metastatic extradural spinal cord compression in adults. Cochrane Database Syst Rev 2010;1.

were ambulatory ($p = 0.046$). However, 11% of patients treated with dexamethasone had significant adverse events including psychoses and gastric ulcers requiring surgery.⁷ The other RCT in this systematic review included 37 patients and found no difference in improvement of neurological status in patients with MESCC receiving high vs. moderate corticosteroids (25% vs. 8% respectively, $p = 0.22$). Although these RCTs had good randomization and follow-up, the low number of patients makes the grade of recommendation moderate at best.

Recommendations

- There is no significant benefits of using corticosteroids for improving patient ambulation in patients with MESCC [overall quality: moderate]
- Treatment with corticosteroids for MESCC can result in severe adverse effects [overall quality: moderate]
- When combined with radiation treatment, corticosteroid therapy can result in modest improvement in patient ambulatory rates [overall quality: moderate]
- High-dose corticosteroids do not improve patient outcomes compared to moderate-dose corticosteroids in the setting of MESCC [overall quality: moderate]

Question 2: What is the efficacy of kyphoplasty in the management of spinal metastases?

Case clarification

The patient does not have any neurological deficits but MRI confirms a pathologic fracture. He asks if there are any surgical options for his condition.

Relevance

Kyphoplasty is a percutaneous cement augmentation technique that involves inflation of a balloon within the vertebral body to create a cavitory space and potentially reduce the fracture deformity before injection of polymethylmethacrylate cement under fluoroscopy. The cement reinforces and stabilizes the fracture. This percutaneous procedure has been used to treat hemangiomas, osteoporotic fractures, and lytic spinal tumors including multiple myeloma and lytic spinal metastases.

Finding the evidence

- Cochrane Database, search term “kyphoplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “spinal metastasis AND kyphoplasty”

Quality of the evidence

Level II

- 1 systematic review of prospective observational studies

Level III

- 1 systematic review of retrospective observational studies, 1 retrospective study

Findings

A systematic review of 26 studies (including both controlled prospective and observational studies) that evaluated kyphoplasty for treatment of vertebral compression fractures found that there was a significant reduction in pain measured on a visual analog scale (VAS) postoperatively (weighted mean difference (WMD) -5.11 , 95% CI -5.72 to -4.49 , $p = 0.000$; based on 0–10 VAS scores from 11 studies), at 1 year (WMD -6.10 , 95% CI -7.47 to -4.48 , $p = 0.000$; based on 0–10 VAS scores from 5 studies), and 2 years (WMD -9.3 , 95% CI -10.65 to -7.94 , $p = 0.000$; based on 0–20 VAS scores from 1 study) as compared with baseline.⁸ There was also a significant percentage increase in vertebral height compared to baseline in all three regions (anterior, middle, and posterior) of the spine. Compared to baseline, there was a significant percentage reduction in Cobb’s angle after balloon kyphoplasty (WMD -7.68 , 95% CI -9.34 to -6.03 , $p = 0.00$; based on 7 studies). Finally, there was a significant improvement in quality of life and functional capacity, measured by the Oswestry Disability Index as compared to baseline after balloon kyphoplasty (WMD -23.8 , 95% CI -34.0 to -13.55 , $p = 0.00$; based on 4 studies). The majority of patients in the included studies were women over 65 years with painful vertebral compression fracture secondary to osteoporosis, metastases, or multiple myeloma between levels T4 and L5. Although these results suggest that kyphoplasty improves pain associated with metastatic spine fractures, the grade of recommendation is low because of the nonrandomized nature of the studies reviewed and the fact that pathologies other than metastatic disease were also included in the analysis.

Another systematic review of kyphoplasty for the treatment of pathologic fractures in patients with spinal tumors included 12 prospective and retrospective observational studies with a total of 333 patients and 481 treated levels.⁹ The review found statistically significant success rates in terms of pain relief and functional outcome for kyphoplasty. However, since other pathologies (multiple myeloma, hemangioma) were also included in the final analysis for 9 of the 12 studies, these findings are indirect. Therefore the grade of recommendation from this systematic review is low given the indirect findings and observational nature of the studies reviewed.

Recommendation

- Balloon kyphoplasty is effective in providing pain relief and improving functional outcome in patients with vertebral compression fractures due to spinal metastases [overall quality: low]

Question 3: What is the role of vertebroplasty in the management of spinal metastases? Is it more efficacious than kyphoplasty?

Case clarification

You explain to the patient that one of the treatment options available includes a minimally invasive procedure called kyphoplasty/vertebroplasty. He then asks if one is better than the other.

Relevance

Vertebroplasty is a percutaneous technique where radiopaque polymethylmethacrylate cement is injected under fluoroscopy. It is commonly employed in treating osteoporotic fractures and is now increasingly used for pain management in patients with lytic spine tumors.

Finding the evidence

- Cochrane Database, search term: “vertebroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “spinal metastasis AND vertebroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “spinal metastasis AND vertebroplasty AND kyphoplasty”

Quality of the evidence

Level II

- 1 systematic review of prospective observational studies

Level III

- 1 systematic review of retrospective observational studies, 1 observational retrospective study

Level IV

- 1 systematic review of case series studies

Findings

No studies that prospectively compared kyphoplasty to vertebroplasty for the treatment of spinal metastase resulting in pathologic fractures were found. A retrospective review of 56 patients with painful pathologic vertebral fractures that compared balloon kyphoplasty and vertebroplasty demonstrated no significant difference between these two treatments in terms of pain (OR 0.89, 95% CI 0.29–2.67) or functional improvement.¹⁰ Balloon kyphoplasty resulted in a significant increase in vertebral height (4.5mm) and significant improvement in local kyphosis (WMD -5.2, 95% CI -9.71, -0.89, $p = 0.02$) from baseline; however this change was not compared to vertebroplasty.¹⁰ The spine tumors evaluated in this retrospective study included both multiple myeloma and other metastatic spine tumors, thus making the findings indirect in regards

to the topic of this question. Therefore the grade of recommendation is low.

A systematic review of 18 case series studies for tumor vertebral compression fractures found that vertebroplasty and kyphoplasty results in less pain, less disability, and greater improvement in general health compared with optimal medical management within the first 3 months after the procedure; however, no significant differences were found by 2 years after the intervention.¹¹ The grade of recommendation from this review is very low, based on the low level of the studies.

Another systematic review that performed an indirect comparison of vertebroplasty and kyphoplasty for the treatment of all vertebral compression fractures (osteoporotic and pathologic) from four observational comparative studies found that both balloon kyphoplasty and vertebroplasty provided similar levels of pain relief after surgery.¹² In 70 noncomparative case series studies, the same systematic review found a significant reduction in the pooled level of pain ($p < 0.0001$) following both balloon kyphoplasty and vertebroplasty. Lastly, they reported a significantly higher rate of cement leakages for vertebroplasty compared to balloon kyphoplasty ($p < 0.0001$). No leaks were reported to be symptomatic with balloon kyphoplasty, while some 3% of leaks with vertebroplasty were reported to be symptomatic. The grade of recommendation from this systematic review is very low given the indirect findings in relation to spine metastases combined with the observational nature of the studies reviewed.

Finally, a systematic review of 11 prospective observational studies that evaluated percutaneous techniques in the treatment of spine tumors found that both vertebroplasty and balloon kyphoplasty were successful at providing pain relief.⁹ For vertebroplasty, the rate of radiologic extravasation was 9.2–139% (multiple areas of extravasations occurred per level), whereas the range was 0–26.3% in kyphoplasty. The reported range of symptomatic extravasation in vertebroplasty was 0–13.5%, while there was none in kyphoplasty. Complications for vertebroplasty and kyphoplasty are summarized in Table 84.2. The grade of recommendation from this systematic review is low since the nonrandomized studies reviewed here also included non-metastatic spine tumors in their evaluation.

Recommendations

- Vertebroplasty is as effective as balloon kyphoplasty in providing pain relief and improved functional outcome for patients with metastatic spine disease [overall quality: low]
- Vertebroplasty has a higher rate of surgical complications (such as symptomatic cement extravasation) as compared to kyphoplasty [overall quality: low]

Table 84.2 Summary of prospective studies using vertebroplasty and kyphoplasty for symptomatic spine tumors

Prospective studies	Vertebroplasty	Kyphoplasty
No. of studies	5	6
No. of tumor patients	98	204
No. of tumor levels	152	330
Tumor types per patient		
Metastases	73 (74.5%)	91 (44.6%)
Multiple myeloma	23 (23.5%)	113 (55.4%)
Hemangioma	2 (2.0%)	0
Complications		
Medical	0	1/204 (0.5%)
Neurological	4 (4.1%)	0
Corrective surgery	3 (3.1%)	0
Extravasation		
Total per level	59/101 (58.4%)	12/239 (12.1%)
Symptomatic patients	3/98 (3.1%)	0
Adjacent vertebral fracture	0	6/204 (2.9%)
Corrective surgery	0	3/204 (1.5%)

Question 4: Does surgical decompression followed by radiotherapy have better outcomes than radiotherapy alone for the management of spinal metastases causing cord compression?

Case clarification

The patient does have neurological compromise on presentation to the Emergency Department. He states that he has noticed a rapid progression in the loss of strength to his legs and decreased sensation in the lower extremities. After initiating corticosteroids, a decision has to be made whether the patient should be given radiation or have surgical decompression.

Relevance

MESCC can lead to pain, progressive motor and sensory loss, incontinence, and disability (including paraplegia). Corticosteroids, radiotherapy, and surgical options have all been used to treat this problem.

Finding the evidence

- Cochrane Database, search term: “spinal cord compression”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “metastatic epidural spinal cord compression”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “metastatic epidural spinal cord compression”

Quality of the evidence

Level I

- 1 RCT

Level II

- 3 systematic reviews of prospective observational studies

Level III

- 1 meta-analysis of prospective and retrospective observational studies

Findings

A randomized, multi-institutional, nonblinded trial of patients with spinal metastases causing spinal cord compression assigned patients to either decompressive surgery followed by radiotherapy (n = 50) or radiotherapy alone (n = 51).¹³ The study found that significantly more patients were able to ambulate after surgery compared to radiotherapy alone (84% vs. 57% respectively, OR 6.2, 95% CI 2.0–19.8, p = 0.001). Also, those patients treated with surgery retained the ability to walk significantly longer than those with radiotherapy alone (median 122 days vs. 13 days, p = 0.003). For those patients who were unable to walk initially, significantly more patients who received surgery regained the ability to walk than those who received radiotherapy alone (62% vs. 19%, p = 0.01). In the patients who could walk initially, 94% in the surgery group continued to walk compared to 74% in the radiation-alone group (p = 0.024). The grade of recommendation based on this well-conducted RCT is high.

A meta-analysis of 28 observational (both prospective and retrospective in nature) studies that evaluated surgical decompression (24 studies) vs. conventional radiotherapy (4 studies) for the treatment of metastatic epidural spinal cord compression found that surgical patients were 1.3 times more likely to be ambulatory after treatment and twice as likely to regain ambulatory function (RR 1.28, 95% CI 1.20–1.37).¹⁴ Overall the ambulatory success rates for surgery and radiation were 85% and 64% respectively. The study therefore concludes that surgery should usually be the primary treatment, with radiation given as adjuvant therapy for metastatic disease causing spinal cord compression. However, since all studies evaluated in this meta-analysis were observational, the grade of recommendation is moderate.

Lastly, systematic reviews of other prospective observational studies have also found that, with respect to ambulation and preservation of neurological function, operative decompression followed by adjuvant radiation is superior to radiotherapy alone.^{15,16}

Recommendation

- In patients with symptomatic spinal cord compression from metastatic disease, surgical decompression should be

performed, followed by adjuvant radiotherapy [overall quality: high]

Question 5: Is there a role for en-bloc tumor resection for spinal metastases?

Case clarification

The patient's MRI shows only a single metastasis to the spine. He asks if you can remove the metastasis surgically.

Relevance

In some situations, particularly in the case of a solitary spine metastasis from certain primary tumors, en-bloc tumor evacuation has been advocated.

Finding the evidence

- Cochrane Database, search term: "spine metastasis"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "spinal metastasis AND surgery"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "spinal metastasis AND surgery"

Quality of the evidence

Level IV

- 1 systematic review of retrospective/case-control observational studies

Findings

A systematic review of solitary spine metastatic renal cell carcinoma revealed 15 patients among 6 retrospective observational studies.¹⁵ Local recurrence was observed in 2 patients (13%) at 9 and 24 months after en-bloc resection. The remaining 13 patients had no local recurrence of disease with follow-up ranging from 2 to 84 months. The review also cites unpublished data in 25 patients undergoing en-bloc resection with a 4% recurrence at a median follow-up of 30 months. Given the retrospective nature of these studies and the low number of patients, the grade of recommendation is very low.

Recommendation

- There is insufficient evidence to recommend en-bloc tumor resection as a surgical option to prevent disease progression of solitary spine metastasis [overall quality: very low]

Summary of recommendations

- There is no significant benefits of using corticosteroids for improving patient ambulation in patients with MESCC
- Treatment with corticosteroids for MESCC can result in severe adverse effects

- When combined with radiation treatment, corticosteroid therapy can result in modest improvement in patient ambulatory rates
- High-dose corticosteroids do not improve patient outcomes compared to moderate-dose corticosteroids in the setting of MESCC
- Balloon kyphoplasty is effective in providing pain relief and improving functional outcome in patients with vertebral compression fractures due to spinal metastases
- Vertebroplasty is as effective as balloon kyphoplasty in providing pain relief and improved functional outcome for patients with metastatic spine disease
- Vertebroplasty has a higher rate of surgical complications (such as symptomatic cement extravasation) as compared to kyphoplasty
- In patients with symptomatic spinal cord compression from metastatic disease, surgical decompression should be performed, followed by adjuvant radiotherapy
- There is insufficient evidence to recommend en-bloc tumor resection as a surgical option to prevent disease progression of solitary spine metastasis

Conclusions

Balloon kyphoplasty and vertebroplasty are effective therapeutic options in patients with pathological fractures and painful spinal metastases. Corticosteroids have a limited role in the treatment of patients with neurological compromise from spinal metastases. In patients with significant neurological deficits, surgical decompression should be performed before radiotherapy.

Metastatic/Myeloma Disease— Nonoperative Management

Harsha Malempati¹, Erion Qamirani¹, and Albert J.M. Yee²

¹University of Toronto, Toronto, ON, Canada

²Sunnybrook Health Sciences Centre, Toronto, ON, Canada

Case scenario

A 50-year-old woman with a history of metastatic breast cancer is referred to the office. She presents with a recent MRI that shows multiple lytic lesions in the vertebral bodies of the thoracic and lumbar spine.

Relevant anatomy

There are four potential pathways for bone metastases: venous, arterial, direct extension, and lymphatic. The venous system is the most common pathway for spinal metastases via Batson's plexus, a network of veins located in the epidural space, situated between the bony spinal column and the dura mater covering the spinal cord. This plexus is connected to the major veins that return blood to the heart via the inferior and superior vena cavae. This plexus has no blood flow control valves, and any increased pressure in the vena cavae system results in increased flow backwards into Batson's plexus, leading to spread of metastases along the axial skeleton.

Importance of the problem

Over the past decade approximately 1 million people per year were diagnosed with cancer in the United States alone,¹ with metastases developing in approximately two-thirds of patients.² The skeletal system is the third most common site of cancer metastases, after the lung and liver, and metastatic lesions of the spine represent the most common site of skeletal involvement.³⁻⁵

Top five questions

1. What is the efficacy of bisphosphonates in the treatment of spinal metastases?
2. Do radiopharmaceuticals play a role in the treatment of metastatic spine disease?
3. Can radiation alone play a role in the palliative management of myeloma/metastatic disease of the spine?
4. Do different radiation schedules affect outcomes in the treatment of myeloma/metastatic disease of the spine?
5. What is the efficacy of stereotactic radiosurgery in treating symptomatic spinal metastases?

Systematic reviews and metanalyses that were relevant to the topic in question were referenced in isolation for the purpose of this review. Randomized controlled trials (RCTs) and other important studies pertinent to the topic that were published after (or not included in) systematic reviews were evaluated and discussed separately.

Question 1: What is the efficacy of bisphosphonates in the treatment of spinal metastases?

Case clarification

The patient complains of pain in her back but is otherwise asymptomatic. She asks if there are any "anticancer" medications that would help her spine.

Relevance

Axial pain is a common clinical presentation of spinal metastases. It is often progressive and can occur both at rest and with weightbearing, and may be related to pathologic fractures caused by loss of the structural integrity of the vertebrae due to a lytic lesion.

Finding the evidence

- Cochrane Database, search term: “spinal metastasis AND bisphosphonates”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “spinal metastasis AND bisphosphonates”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “bisphosphonates AND spinal metastasis”

Quality of the evidence

Level I

- 1 meta-analysis of RCTs, 3 RCTs

Level II

- 1 meta-analysis of observational studies, 2 observational studies

Findings

Several studies have examined the use of bisphosphonates in the treatment of metastatic disease.⁶⁻¹⁰ Pavlakis et al.⁶ conducted a meta-analysis of randomized studies comparing bisphosphonates and placebo, or different bisphosphonates, in women with metastatic breast cancer. In nine studies of women with advanced metastatic breast cancer and existing bone metastases, bisphosphonates reduced risk of skeletal events such as pathologic fracture by 17% (RR 0.83; 95% CI 0.78–0.89; $p < 0.00001$).⁶ Furthermore, women with advanced breast cancer and clinically evident bone metastases had improved bone pain and significant delays in median time to pathologic fractures. Overall strength of evidence from this study is high. Another meta-analysis of randomized trials comparing the effectiveness of bisphosphonates to placebo in metastatic prostate cancer found that bisphosphonates decreased the risk of skeletal events (OR 0.79; 95% CI 0.62–1.00; $p = 0.05$); however, the associated measure of precision includes no effect.⁷ There was also a trend towards improved pain relief, but this was not statistically significant. Overall strength of evidence from this study is moderate.

A guideline by the American Society of Clinical Oncology on the role of bisphosphonates in controlling pain resulting from breast cancer bony metastases recommends that there is insufficient evidence to support the use of intravenous bisphosphonates alone for pain control.⁸ Although multiple trials of bisphosphonates compared to placebo have shown modest pain control benefit with bisphosphonates, many of these results were not statistically significant.⁹⁻¹¹ For example, one randomized study of intravenous clondronate vs. placebo found a mean difference in pain score of 0.89 (95% CI 1.43 to –0.35) in favor of clondronate.⁹ These are well-conducted studies, therefore the grade of recommendation is high.

Lastly, bisphosphonate therapy does increase bone mineral density (BMD) in the spine. One study of oral

clondronate on BMD of the lumbar spine showed statistically significant increases in the clondronate-treated group compared to placebo at multiple intervals after initiation of treatment (Table 85.1).¹² However, due to the significant loss to follow-up of patients in both treatment group and the minimal increase on BMD in the lumbar spine, the grade of recommendation from this study is low. Multiple trials have shown significant increases in lumbar spine BMD after initiation of bisphosphonate treatment; however, BMD is a surrogate for the patient-important outcome of fracture, and the improvements in BMD are associated with estimates of precision that include clinically trivial effects (Table 85.2). Another study showed a palliative benefit of significantly increased bone density (+19.6 Hounsfield Units, 95% CI: +0.685 to +38.4) and osteoblastic volume (+6.49 cm³, 95% CI +1.20 to +11.8) when switching

Table 85.1 Changes in lumbar spine bone mineral density in patients with metastatic breast cancer (% of baseline)

Follow-up time (months)		10.5 ± 0.4	17.3 ± 0.9	24.7 ± 1.4
Number of patients	Placebo	18	15	12
	Clondronate	20	12	9
Bone mineral density changes (%)	Placebo	+7.1 ± 5.4	+4.5 ± 3.2	+0.5 ± 1.9
	Clondronate	+8.2 ± 3.2	+7.8 ± 4.6	+0.8 ± 2.9

BMD, bone mineral density.

Table 85.2 Results of bone mineral density studies of bisphosphonate therapy

Study	Description	No. of patients (No. included at last follow-up)	Follow-up	Change in BMD at the spine (%)
Delmas et al. ³⁰	Randomized trial	53 (53)	2 years	2.5% (95% CI 0.2–4.9)
Powles et al. ³¹	Randomized trial	414 (311)	2 years	1.7% (95% CI 0.12–3.34)
Saarto et al. ³²	Randomized trial	93 (89)	2 years	2.9% (no measure of precision reported)

BMD, bone mineral density.

from first-line bisphosphonates to more potent agents such as zoledronic acid.¹³ Even though there was no loss to follow-up, this non-randomized prospective observational study had a small numbers of patients (15). Therefore, the grade of recommendation is moderate at best.

Recommendations

With respect to the use of bisphosphonates for the treatment of metastatic disease of the spine:

- There is good evidence that supports bisphosphonate therapy to prevent adverse outcomes such as pathologic fractures in breast cancer patients with metastatic vertebral lesions [overall quality: high]
- Limited evidence exists to suggest that similar benefits of bisphosphonate therapy may be realized in patients with metastatic prostate cancer [overall quality: moderate]
- Bisphosphonates are not effective for pain control in patients with metastatic disease of the spine [overall quality: high]
- Bisphosphonate therapy increases lumbar BMD in patients with metastatic disease of the spine as determined by multiple well-conducted RCTs [overall quality: moderate]

Question 2: Do radiopharmaceuticals play a role in the treatment of metastatic spine disease?

Case clarification

The patient states that she has tried chemotherapy and pain medications including opiates. She asks if there are any new medications that might improve her pain.

Relevance

In patients with metastatic disease, systemic radiopharmaceutical therapy (RPT) has increasingly been recognized as an important contributor to the improvement of quality of life. Using this modality, all painful osseous sites can be addressed simultaneously with little long-term toxicity.

Finding the evidence

- Cochrane Database, search term: "radiopharmaceutical AND metastasis"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "radiopharmaceutical AND metastasis"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "radiopharmaceutical AND metastasis"

Quality of the evidence

Level I

- 1 RCT, 2 systematic reviews of RCTs

Findings

Radionuclides have so far been used mainly as an adjuvant to external beam radiation for the management of metastatic disease. We were unable to find studies of radionuclides used for treatment of spine metastasis specifically, but there have been several studies evaluating the use of radionuclides for management of bone metastases.¹⁴⁻¹⁷ An RCT comparing the effectiveness of strontium-89 to placebo as an adjunct to local field radiotherapy in patients with metastatic prostate cancer to bone found a statistically significant improvement in quality of life ($p = 0.006$), alleviation of pain ($p < 0.05$), and physical activity ($p < 0.05$).¹⁴ No estimate of effect was calculated for any of these parameters. A systematic review of three RCTs studying the role of strontium-89 in palliative pain relief for patients with stage D endocrine-refractory prostate cancer and multiple bone metastases (including but not specific to spine) found that strontium-89 demonstrated palliative efficacy compared to placebo ($p < 0.01$) in two of the three studies.¹⁵ None of the studies mentioned showed any significant difference in patient survival. Hemotoxicity was found to be mild, and limited evidence suggested a decrease in treatment costs. Finally, a thorough systematic review of nine RCTs studying the role of radiopharmaceuticals in the palliation of bone pain in adults with uncomplicated, multifocal painful bone metastases from breast, prostate, and lung cancer found that single-agent radiopharmaceuticals (strontium-89 and samarium-153, whether used alone or in conjunction with radiation) provided significantly greater pain relief (30–40% strontium-89 vs. 20–23% placebo, and 31–73% samarium-153 vs. 14% placebo, $p < 0.05$) and a decreased need for opiates (17% decrease for strontium-89 vs. 2% placebo, and 37–60% decrease for samarium-153 vs. 26% increase for placebo, $p < 0.05$).¹⁶ Although the quality of studies evaluating the effects of strontium-89 and samarium-153 on pain relief from bony metastases was good (appropriate randomization, acceptable follow-up), none of these studies specifically evaluated spine metastases. Therefore, the evidence presented in these studies is limited due to indirect findings.

Recommendation

- Radiopharmaceuticals (strontium-89 and samarium-153) should be considered as an option for palliation of multiple sites of bone pain from metastatic disease involving the spine [overall quality: moderate]

Question 3: Can radiation alone play a role in the palliative management of spinal metastases?

Case clarification

In addition to the chemotherapy suggested above, the patient would like to know if radiation might help her current condition.

Table 85.3 Summary of results from a systematic review for conventional radiotherapy as a stand-alone therapy for spinal metastases

Author	N	Ambulatory status	Pain status	Median patient survival	Quality of evidence
Patchell et al.	51	74% remained ambulatory/19% regained ambulation		3 months	High
Maranzano et al.	276	67% remained ambulatory/26% regained ambulation	57% improved	4 months	High
Young et al.	13	60% remained ambulatory/33% regained ambulation	46% improved	5 months	High

Modified from the systematic review by Nair N. (1999) Relative efficacy of 32P and 89Sr in palliation in skeletal metastases. *J Nucl Med* 40(2), 256–61.¹⁷

Relevance

Radiation therapy is an important modality in the management of both primary and metastatic tumors involving the spine and spinal cord. Radiation therapy has evolved with better pretreatment imaging, improved dosing regimens, and more flexible treatment schedules.

Finding the evidence

- Cochrane Database, search term: “spine metastasis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/therapy, narrow specific search: “radiation AND metastasis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “radiation AND metastasis”

Quality of the evidence

Level I

- 2 systematic reviews of RCTs

Level III

- 1 systematic review of observational studies

Findings:

Several systematic reviews have examined the use radiotherapy for palliative pain management, local pain control, and improved quality of life in patients with metastatic disease and myeloma of the spine.^{18–21} A systematic review of 16 RCTs comparing single- vs. multiple-fraction radiotherapy for bone metastases demonstrated that overall response to pain was 58% for single-fraction and 59% for multiple-fraction therapy (measures of precision not reported).¹⁸ This is a well-conducted review of good quality RCTs, therefore the grade of recommendation regarding radiotherapy for pain control in bony metastases is high. This finding has been confirmed by other studies as well.^{19,20} Unfortunately, no uniform method of reporting pain has been used and the length of follow-up varied from one study to another. Despite these shortcomings, the data suggests that palliative radiotherapy is an important treatment modality for spine metastases. Local control of metastases, defined as the absence of recurrent cord compression after conventional radiotherapy, has been achieved at rates of

61–89% in one systematic review of several observational studies.²⁰ However, given the observational nature of these studies, the grade of recommendation regarding radiotherapy for local control of spine metastases is low.

With respect to ambulatory status, a systematic review of three well-designed RCTs demonstrated that 60–74% of patients remain ambulatory after conventional radiation in the setting of cord compression, whereas 19–33% of non-ambulatory patients are able to walk after radiation.²¹ Several other observational studies (both prospective and retrospective in nature) were evaluated in the same systematic review but are not included here because of their lower quality. A selected summary of the three RCTs included in this systematic review demonstrating an improvement in ambulatory status and pain control is shown in Table 85.3. Given the good quality of evidence presented in these three RCTs, the overall grade of recommendation is high.

There will be variation in radiotherapy response based on the histology of the primary tumor. In general, lymphomas, myelomas, seminomas, breast cancer, and prostate cancer are considered radiosensitive, whereas sarcomas, melanomas, renal cell carcinomas, gastrointestinal carcinomas, and non-small-cell lung cancer (NSCLC) are considered radioresistant.²¹

Recommendations

- Conventional radiotherapy alone is beneficial for the treatment of spinal metastases. It is particularly effective in palliative pain management [overall quality: high]
- Conventional radiotherapy is effective in achieving local control of radiosensitive spinal metastases [overall quality: low]
- Conventional radiotherapy is effective in maintaining ambulatory function in a select group of patients with spinal metastases [overall quality: high]

Question 4: Do different fractionation schedules of radiotherapy affect efficacy in the management of spinal metastases?

Case clarification

The patient would like to go ahead with radiation for the treatment of her painful spine metastases. She would like

to know if she will be receiving one or multiple doses of radiation.

Relevance

There has been much interest in investigating radiotherapy fractionation schedules for bone metastases. Several patterns-of-practice studies suggest that physician training or bias, resource availability, and/or reimbursement system are some of the factors that can influence the choice of fractionation prescribed.¹⁸

Finding the evidence

- Cochrane Database, search term “spine metastasis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/therapy, narrow specific search: “radiation AND metastasis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “radiation AND metastasis”

Quality of the evidence

Level I

- 2 meta-analyses of RCTs, 6 RCTs

Level II

- 3 systematic reviews

Findings

A meta-analysis of 8 RCTs by Wu et al.²² including 3260 randomized patients with painful bone metastases showed similar overall pain response rates for single-fraction and multifraction radiotherapy at 72.7% and 72.5% respectively (risk ratio 1.00; 95% CI 0.95–1.04). Furthermore, exploratory analyses by biologic effective dose did not reveal any dose–response relationship among fractionation schedules used (single 8 Gy to 40 Gy in 15 fractions) and only the reirradiation rates were consistently different between the treatment arms (more frequent reirradiation in lower-dose arms among trials reporting reirradiation rates).²² In addition, a systematic review of 11 RCTs including 3435 patients with bone metastases demonstrated no difference in pain

response rates between single-fraction and multiple-fraction radiotherapy (OR 1.03, 95% CI 0.89–1.19).²³ Other RCTs and systematic reviews also confirm these findings.^{18,24–29} The studies listed above are of good quality, but the site of metastases is not exclusively limited to spine, thus making the findings indirect with regard to the topic of this question. The grade of recommendation based on these studies is therefore moderate. The rates of pathologic fractures were shown to be significantly higher with single-fraction treatment in only one study,²³ while reirradiation rates were higher in the single-fraction group as compared to the multiple-fraction group across multiple studies.^{18,23,24} Therefore, the grade of recommendation regarding pathologic fractures in single- vs. multiple-fraction radiotherapy is low, given that the findings are not directly related to spine and differences were found in only one study. In contrast, multiple studies found a significant difference between single and multiple fractions with regards to reirradiation rates, thus the grade of recommendation is moderate (lack of spine-specific metastases prevents a higher grade recommendation). The findings of some of these studies are summarized in Table 85.4.

Recommendations

- For the purposes of pain relief in the palliation of spinal metastases, there is no significant difference among different fractionation schedules for localized radiotherapy [overall quality: moderate]
- Single-fraction radiotherapy for spinal metastases results in higher reirradiation rates [overall quality: moderate] and higher rates of pathological fractures [overall quality: low]

Question 5: What is the efficacy of stereotactic radiosurgery in treating symptomatic spinal metastases?

Case clarification

The patient states that she has read on the internet about a new type of radiation surgery. She asks whether this would help with her condition.

Table 85.4 Effects of radiotherapy on bone metastases

	Single-dose radiotherapy			Fractionated radiotherapy		
	Sze et al.	Chow et al.	Arnalot et al.	Sze et al.	Chow et al.	Arnalot et al.
Pain reduction (%)	60	58	75	59	59	86
Complete pain remission (%)	34	23	15	32	24	13
Reirradiation (%)	21.5 ^a	20 ^a	28 ^a	7.4 ^a	8 ^a	2 ^a
Pathologic fractures (%)	3 ^a	3.2	Not stated	1.6 ^a	2.8	Not stated

^aStatistically significant

Reproduced with kind permission from Springer Science+Business Media: Strahlenther Onkol, DEGRO practice guidelines for palliative radiotherapy of metastatic breast cancer-bone metastases and metastatic spinal cord compression, 185, 2009,417–24, Souchon R, Wenz F, Sedlmayer F, et al.

Relevance

With new advances in radiotherapy techniques, greater doses of radiation can be administered to the tumor with fewer side effects on the surrounding structures including the spinal cord.

Finding the evidence

- Cochrane Database, search term: “spine metastasis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/therapy, narrow specific search: “radiosurgery AND metastasis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “radiosurgery AND metastasis”

Quality of the evidence

Level III

- 2 systematic reviews of observational studies

Findings

A systematic review of 29 observational studies (1655 patients, only 27 of the studies assessed clinical outcomes measures) that included prospective cohort, retrospective reviews, and case series found that radiosurgery was highly effective at decreasing pain associated with symptomatic spine metastases regardless of prior treatment with conventional fractionated radiotherapy, with an overall reported improvement rate of approximately 82% (no measures of precision reported).²¹ Although this improvement rate is slightly higher than that of conventional radiotherapy (reported as 50–70% in the same systematic review, no measures of precision given), the overall low quality of studies reviewed makes the grade of recommendation low. Durable pain improvement of spinal metastases was demonstrated in metastatic breast cancer, melanoma, lung cancer, and renal cell carcinoma. Pain was reported to decrease within weeks of treatment and quality of life was maintained up to 48 months after treatment.²¹ Another systematic review of 3 studies (retrospective reviews) of patients with renal cell metastases found a radiographic tumor control rate of approximately 87% with pain control being achieved in 89% of patients presenting with axial or radicular pain (no measures of precision reported).²⁰ Again, given the observational nature of the studies reviewed, the overall grade of recommendation is low.

Recommendations

- Radiosurgery is effective in achieving symptomatic response and local control for radioresistant histologies, regardless of prior fractional radiotherapy. [overall quality: low]
- Radiosurgery achieves slightly higher pain improvement rates for spine metastases as compared to conventional radiotherapy [overall quality: low]

Summary of recommendations

- There is good evidence that supports bisphosphonate therapy to prevent adverse outcomes such as pathologic fractures in breast cancer patients with metastatic vertebral lesions, but limited evidence exists to suggest that similar benefits may be realized in patients with metastatic prostate cancer
- Bisphosphonates are not effective for pain control in patients with metastatic disease of the spine
- Bisphosphonate therapy increases lumbar BMD in patients with metastatic disease of the spine as determined by multiple well-conducted RCTs
- Radiopharmaceuticals (strontium-89 and samarium-153) should be considered as an option for palliation of multiple sites of bone pain from metastatic disease involving the spine
- Conventional radiotherapy alone is beneficial for the treatment of spinal metastases. It is particularly effective in palliative pain management
- Conventional radiotherapy is effective in achieving local control of radiosensitive spinal metastases
- Conventional radiotherapy is effective in maintaining ambulatory function in a select group of patients with spinal metastases
- For the purposes of pain relief in the palliation of spinal metastases, there is no significant difference among different fractionation schedules for localized radiotherapy
- Single-fraction radiotherapy for spinal metastases results in higher reirradiation rates and higher rates of pathological fractures
- Radiosurgery is effective in achieving symptomatic response and local control for radioresistant histologies, regardless of prior fractional radiotherapy
- Radiosurgery achieves slightly higher pain improvement rates for spine metastases as compared to conventional radiotherapy

Conclusions

Bisphosphonates, radiopharmaceuticals, and radiotherapy play an important role in the nonsurgical management of metastatic disease of the spine. Radiosurgery is a relatively new therapeutic modality that shows promising preliminary results but requires further investigation to assess its true treatment effect and potential limitations.

Sports Medicine

Openmirrors.com

Charles L. Cox and John E. Kuhn

Vanderbilt University School of Medicine, Nashville, TN, USA

Case scenario

A 21 year old collegiate athlete sustains an injury to his dominant shoulder and reports a sudden forceful, posteriorly directed force on his forearm while his arm was in a position of abduction and external rotation. On examination, he holds the affected arm at his side and refuses any attempts at range of motion assessment. He is neurovascularly intact distally.

Relevant anatomy

The diagnosis of shoulder instability represents a broad range of injury patterns to the glenohumeral joint. Injuries are frequently classified on the basis of several clinical factors including frequency (initial vs. recurrent event), etiology (traumatic vs. nontraumatic mechanism), direction (anterior vs. posterior instability), and severity (joint dislocation vs. subluxation). Anatomical evaluation generally reveals an injury to the labrum and the adjacent joint capsule, and treatment options are based upon attempts to restore preinjury tension and alignment of injured structures.

Importance of the problem

Based upon previous studies, shoulder instability rates range from 8.2–23.9/100,000 person-years in the general population with a prevalence of 1.7%, but these values are based upon presentation to medical facilities and are there-

fore likely low estimates due to failure to capture subtle events such as subluxations.^{1–3} These values are also representative of the general population, leading to a decreased external validity when extrapolating these estimates to predict numbers for younger individuals. In analyzing a younger subset of the population, the United States Military Academy followed over 4,100 students for 9 months capturing 117 events for an incidence of 2.8%. The vast majority of these injuries were subluxations (85%) and anterior in orientation (80%). In evaluating etiology, 44% were related to contact injuries.⁴ This data again indicates that frank glenohumeral dislocation likely represents only a small subset of the actual instability injury patterns seen in relation to the glenohumeral joint.

At present, definitive recommendations are lacking regarding optimal treatment strategies for those presenting with first-time dislocation events as published recurrence rates are extremely variable across broad levels of study quality, and risk factors for repeat injury are unclear. Owens et al. queried the United States Defense Medical Epidemiology Database for ICD-9 codes related to shoulder instability for a period from 1998 to 2006 determining risks factors for recurrence were male gender, age less than 30 years, being white, junior enlisted rank, and army position.⁵ Although this data assists the treating clinician when counseling a patient with a first-time shoulder dislocation, numerous questions remain surrounding treatment options ranging from choice of method of joint reduction to position of initial immobilization to decision for operative vs. nonoperative management. Knowledge of current published literature offers insight into maximizing clinical outcomes and can be used to individualize treatment for each patient.

Top five questions

Therapy

1. What premedication regimen works best for reducing a glenohumeral dislocation?
2. Is there an ideal reduction method?
3. Does position of the extremity in immobilization reduce recurrence rates?
4. Does surgical treatment reduce recurrence compared with nonoperative management for patients with a first-time dislocation?

Prognosis

5. What is the long-term prognosis for the patient with a first-time glenohumeral dislocation?

Question 1: What premedication regimen works best for reducing a glenohumeral dislocation?

Case clarification

The athlete's radiographs reveal an anterior dislocation of the glenohumeral joint. He is in obvious discomfort and resists any attempts at closed reduction of the extremity due to pain. You must decide upon the best method of premedication to achieve a successful reduction.

Relevance

The treating clinician must decide upon the best method of sedation to maximize patient safety while achieving reduction and minimizing complications. In the medical care setting, current options range from intravenous sedation to intra-articular anesthetic to regional block.

Current opinion

At present, intravenous sedation is the most commonly utilized strategy to alleviate pain allowing for closed reduction.

Finding the evidence

- Cochrane Database, with search term "shoulder reduction"

- PUBMED (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "shoulder OR glenohumeral reduction"

- PUBMED (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "shoulder" AND "reduction" as well as "glenohumeral" AND "reduction"

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses⁶⁻⁷
- 6 randomized trials⁸⁻¹³

Findings

The included trials compared various outcome measures amongst two techniques: intravenous sedation vs. intra-articular lidocaine injection. Trial outcomes can be compared based upon reduction success, complications, pain level, time to reduction, and overall time in the Emergency Department (Table 86.1). No differences were seen in rates of reduction amongst the techniques with 92% (103/111) overall success reported for intra-articular lidocaine vs. 92% (101/110) for intravenous sedation. This was found despite slight differences between the trials in patient population and utilized manual reduction techniques. Regarding complications, the intra-articular technique resulted in a 0.9% (1/111) overall rate compared with 16.4% (18/110) in the intravenous sedation group. The most common complication associated with intravenous sedation was respiratory depression. No significant differences were noted in any of the trials regarding pain level associated with each technique. Three of the studies compared time to reduction, with 2/3 significantly favoring intravenous sedation as the quicker method for achieving reduction. Three trials compared overall time spent in the Emergency Department, with 2/3 trials significantly favoring intra-articular lidocaine as the preferred method.

Recommendations

In patients with glenohumeral dislocations, evidence pertaining to premedication prior to reduction suggests:

- No difference exists between the two techniques regarding success rate for reduction and patient pain level [overall quality: high]

Table 86.1 Comparison of premedication techniques

	Success rate	Complication rate	Pain	Time to reduction	Time in Emergency Department
Intra-articular lidocaine	92%	0.9%	NS	2/3 significantly favored	2/3 significantly favored
Intravenous sedation	92%	16.4%		intravenous sedation	intra-articular lidocaine

NS, not significant.

- Intra-articular lidocaine significantly reduces the risk of complications, mainly in the form of respiratory depression associated with intravenous sedation [overall quality: high]
- Data is variable amongst the two techniques regarding time required for reduction (2/3 in favor of intravenous sedation) and time spent in the Emergency Department (2/3 in favor of intra-articular lidocaine) [overall quality: high]

Question 2: Is there an ideal reduction method?

Case clarification

The athlete clearly has a dislocated glenohumeral joint. The standard of care is expeditious reduction. You must decide upon the best technique to achieve reduction.

Relevance

Numerous described techniques for achieving reduction exist. Many utilize different strategies to overcome muscular forces and allow the humeral head to slide back into the face of the glenoid. It is important to avoid potential iatrogenic injury to the anatomic structures as reduction is attempted.

Current opinion

At present, there is no consensus as to the best technique for reduction, and many regional variations exist.

Finding the evidence

- Cochrane Database, with search term “shoulder reduction”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “shoulder OR glenohumeral reduction”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “shoulder” AND “reduction” as well as “glenohumeral” AND “reduction”

Quality of the evidence

Level I

- 2 randomized trials¹⁴⁻¹⁵

Findings

Both trials compare various reduction techniques for success rate without the use of analgesia or sedation. The first trial involves a comparison of the Milch and Kocher techniques for reduction.¹⁴ No difference in success rate was noted amongst the two techniques. The second trial compares the hippocratic, Kocher, and FARES (Fast, Reliable, and Safe) methods of reduction and includes patient visual analog pain ratings as an outcome measure (Table 86.2).¹⁵ The FARES method was significantly more successful, quicker, and less painful to the patients than the other two techniques.

Table 86.2 Comparison of the FARES, hippocratic, and Kocher reduction methods

	Success rate	Complication rate	Visual analog pain score	Time to reduction (min)
FARES	88.7%	NS	1.57	2.36
Hippocratic	72.5%		4.88	5.55
Kocher	68%		5.44	4.32

NS, not significant.

Recommendations

In patients with glenohumeral dislocations, evidence pertaining to choice of reduction technique in a patient without sedation or analgesia suggests:

- No difference exists in success rate between the Milch and Kocher techniques [overall quality: high]
- The FARES technique is associated with a significantly higher success rate, quicker time to reduction, and lower visual analog pain score than the hippocratic and Kocher techniques [overall quality: high]
- Despite a large number of described techniques for reducing the dislocated glenohumeral joint, only two high-level studies were identified. Therefore, it is recommended that the clinician obtain experience with multiple techniques [overall quality: low]

Question 3: Does the position of the extremity in immobilization reduce recurrence rates?

Case clarification

Once the reduction has been achieved, the arm must be placed in a position of relative stability to maintain anatomical congruence and avoid redislocation. You must decide upon the position of the arm in immobilization.

Relevance

Classically the arm was placed in a sling in a position of glenohumeral joint internal rotation, but some now advocate immobilization in external rotation to place tension upon the anterior capsulolabral structures and thereby reapproximate the areas of injury. This is theorized to improve restoration of preinjury anatomy and decrease likelihood of recurrence.

Current opinion

At present, most acute care settings employ a sling and/or swathe following reduction maintaining the arm in a position of internal rotation.

Finding the evidence

- Cochrane Database, with search term “shoulder dislocation”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “shoulder OR glenohumeral dislocation”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “shoulder” AND “dislocation” as well as “glenohumeral” AND “dislocation”

Quality of the evidence

Level I

- 1 systematic review/meta-analysis¹⁶
- 5 randomized trials¹⁷⁻²¹

Level II

- 1 observational cohort study²²
- 2 randomized trials with methodologic limitations²³⁻²⁴

Findings

Internal rotation In comparing length of time immobilized in internal rotation for over 500 patients combined, no significant differences in recurrence were noted amongst the various studies.^{17-20,22} Hovelius et al. followed the same cohort of patients over a 25-year period in a level I prognosis study and reported that recurrence rates progressively increased with time (29% at 2 years, 45% at 5 years, 48% at 10 years) but plateau at approximately 5 years after the initial injury.¹⁷⁻²⁰ Younger age at initial dislocation and the presence of a Hill Sachs lesion were noted to be risk factors for recurrence.

External rotation Finestone et al. compared a cohort of 51 patients immobilized for 4 weeks in internal or external rotation for an average of 33 months and found no significant difference in rates of recurrence amongst the groups (42% internal rotation group vs. 37% external rotation group).²¹ This is in contrast to two level II studies (representing the same cohort) that found a decreased recurrence rate in the external rotation group as compared to the internal rotation group (26% vs. 42%, respectively).²³⁻²⁴

Recommendations

In patients with initial glenohumeral dislocations, evidence pertaining to length and method of immobilization (internal vs. external) on recurrence rate suggests:

- No significant difference exists in recurrence rate between immobilization for several weeks in internal rotation vs. early motion [overall quality: high]
- Immobilization for several weeks in external rotation compared with internal rotation revealed no significant difference in recurrence in the level I study but did find a significant difference in the level II studies [overall quality: moderate]

Question 4: Does surgical treatment reduce recurrence compared with nonoperative management for patients with a first-time dislocation?

Case clarification

After reduction, the athlete inquires as to the best method to prevent future recurrence. Specifically, he inquires as to whether surgery is necessary to reduce risk in a clinically significant manner.

Relevance

Definitive treatment strategy generally requires a choice between a variable period of immobilization vs. surgical intervention in the setting of a first-time dislocation. Current opinion is mixed based upon high recurrence rates reported across the literature when nonoperative management is chosen.

Current opinion

At present, surgery is felt to decrease the overall risk of recurrence.

Finding the evidence

- Cochrane Database, with search term “shoulder dislocation”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “shoulder OR glenohumeral dislocation”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “shoulder” AND “dislocation” as well as “glenohumeral” AND “dislocation”

Quality of the evidence

Level I

- 1 systematic review/meta-analysis²⁵
- 5 randomized trials²⁶⁻³²

Level II

- 1 observational cohort study³³

Findings

Three of the level I studies and the included level II cohort compare surgical stabilization to nonoperative treatment (immobilization or sling or early motion) and report a significant decrease in recurrence rates in the operatively stabilized group.^{26-28,33} Two of the included level I studies compare initial arthroscopic lavage to nonoperative treatment and display a significant decrease in recurrence rates in the lavage group.²⁹⁻³⁰ Two of the level I studies utilize initial arthroscopic diagnosis followed by nonoperative treatment or surgical stabilization and again report a significant decrease in recurrence in the surgically repaired group.³¹⁻³² In the systematic review by Handoll et al., results

were pooled among included trials revealing a significant decrease in recurrence in the operative group compared to the nonoperative group (RR 0.20; 95% CI 0.11–0.33).²⁵ Of note, the systematic review included an abstract rated as level I evidence although it was not available as a published trial.

Recommendations

In patients with initial glenohumeral dislocations, evidence pertaining to the effect of operative vs. nonoperative treatment on recurrence rate suggests:

- Surgical stabilization results in a decreased risk of recurrence compared with arthroscopic lavage alone or nonoperative management techniques [overall quality: high]
- Arthroscopic lavage alone displays a decreased risk of recurrence compared with strictly nonoperative management strategies [overall quality: high]

Question 5: What is the long-term prognosis for the patient with a first-time glenohumeral dislocation?

Case clarification

The athlete inquires about the future ramifications for shoulder function later in life as a result of this primary dislocation event.

Relevance

The bulk of the current literature is focused upon strategies to reduce recurrence and restore preinjury anatomical integrity. However, most of the published data is centered on relatively short-term results (1–10 years after treatment). Long-term outcomes and effects of initial dislocation on future function are generally unknown.

Current opinion

At present, dislocation of the glenohumeral joint is presumed to increase the risk of future arthritis and resultant dysfunction.

Finding the evidence

- Cochrane Database, with search term “shoulder dislocation”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “shoulder OR glenohumeral dislocation”
- PUBMED (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “shoulder” AND “dislocation” as well as “glenohumeral” AND “dislocation”

Quality of the evidence

Level I

- 1 randomized trials²⁰

Findings

In reviewing the available published literature, only one high-level study was found that followed patients on average for more than 10 years. Hovelius et al. followed 227 patients for 25 years after an initial glenohumeral dislocation event treated nonoperatively, many of which went on to display recurrence and opt for surgical intervention. In comparing scores on the Disabilities of the Arm, Shoulder and Hand (DASH) outcome questionnaire at the end of this time period, values were similar for shoulders classified as nonrecurrent, stable over time, or surgically stabilized, but patients with persistent, recurrent dislocations fared statistically worse than the aforementioned groups. Women also displayed statistically worse scores as compared to men.²⁰

Recommendations

In patients with an initial glenohumeral dislocation, evidence pertaining to long-term outcome suggests:

- Long-term DASH scores are comparable amongst groups regardless of treatment as long as stability is displayed over time, manifested by a lack of persistent recurrence. Women tend to score statistically worse than men over time [overall quality: high]

Summary of recommendations

Openmirrors.com • Intra-articular lidocaine significantly reduces the risk of complications during shoulder reduction compared with intravenous sedation, but no difference exists between the two techniques regarding success rate for reduction and patient pain level

- Despite a large number of described techniques for reducing the dislocated glenohumeral joint, only two high-level studies were identified. Therefore, it is recommended that the clinician obtain experience with multiple techniques. Evidence exists suggesting that the FARES technique is superior to the hippocratic and Kocher techniques
- The highest-level evidence indicates that there is no difference in recurrence rate amongst choice of initial immobilization in internal vs. external rotation following a first-time shoulder dislocation
- Surgical treatment results in a decreased risk of recurrence compared with nonoperative management of first-time shoulder dislocations
- 25 year DASH score outcomes following a primary dislocation event are comparable amongst treatment strategies as long as shoulder stability is achieved over time

Conclusions

Shoulder dislocation is a relatively common clinical event, and review of the best available evidence provides

guidelines for management ranging from initial encounter with the patient (premedication decisions prior to reduction, choice of reduction technique, method of immobilization) to definitive treatment decision (operative vs. nonoperative management) to counseling on long-term prognosis.

Case scenario

A 35 year old man presents in the clinic with a history of shoulder instability. He had frequent dislocations until the age of 25, followed by a period without recurrence after adaptation of his lifestyle. Recently he started windsurfing and again experienced a sensation of instability. He is now looking for advice about his shoulder problem and a possible treatment for his instability.

Relevant anatomy

The majority (>90%) of traumatic shoulder dislocations occur in the anterior–inferior direction. A small minority of shoulders dislocate in posterior direction. Dislocation in the superior direction is extremely rare. Multidirectional instability is also extremely rare, unlike multidirectional laxity.

In nearly all anterior cases a disruption of the labrum takes place, the so-called Bankart lesion (Figure 87.1). Other eponyms are Perthes or anterior labro-periosteal sleeve avulsion (ALPSA) lesion. Sometimes this occurs in combination with a tear of the capsule; sometimes an isolated lesion of the capsule is the only soft tissue defect. When the capsule is detached from the humeral head, the acronym HAGL (humeral avulsion of the glenohumeral ligaments) is used.

In most cases of chronic instability a posterolateral impression fracture of the head, the so-called Hill–Sachs lesion, is seen (Figure 87.2). At the glenoid side an erosion of the glenoid frequently arises, either due to impaction of bone or due to avulsion of a bony fragment at the anterior glenoid together with the labrum avulsion, a so-called

bony Bankart lesion (Figure 87.3). In posterior instability sometimes a posterior Bankart lesion, a reversed Hill–Sachs on the anterior aspect of the head, or a posterior erosion of the glenoid can be seen.

Top six questions

1. Which clinical tests are accurate and necessary to perform in the diagnosis of chronic shoulder instability?
2. What is the role of imaging in the diagnosis of chronic shoulder instability?
3. What is the best surgical approach to treat chronic shoulder instability?
4. What is the role of bone defects in the treatment of chronic unstable shoulder?
5. What is the role of rehabilitation in chronic shoulder instability?
6. What is the natural history in chronic unstable shoulders?

Question 1: Which clinical tests are accurate and necessary to perform in the diagnosis of chronic shoulder instability?

Finding the evidence

We performed a literature search of literature published between 1990 and December 2009 in the online resources MEDLINE and Embase with combinations of the following search terms:

- “Clinical tests,” “apprehension test,” “clunk test,” “load and shift test,” “drawer test,” “relocation test,” “release test,” “hyperabduction test,” “jerk test,” “crank test,” “posterior drawer test,” “Kim test,” “sensitivity,” “specificity,” “diagnosis,” “chronic,” “recurrent,” “shoulder instability,”

Figure 87.1 Arthroscopic view of a labrum avulsion from the glenoid.

Figure 87.2 3-D CT scan of the right humeral head with an impression fracture on the postero-superior aspect, a so-called Hill-Sachs lesion.

Figure 87.3 3-D CT scan of the right glenoid, with an erosion of the anterior aspect of the glenoid with a detached bony fragment.

“glenohumeral instability,” “shoulder dislocation,” “shoulder subluxation”

Quality of the evidence

See Tables 87.1 and 87.2.

Findings

Chronic anterior instability In the past many tests have been developed to diagnose anterior shoulder instability. We have reviewed the tests that have been evaluated and rated them for their evidence in proving anterior instability (Table 87.1). As shown in Table 87.1, only Farber et al.⁴ and

errors.com

Guanche et al.⁵ reported publications with good evidence of level Ib and IIb respectively. Considering these studies, we can conclude that the relocation test is the only test providing a sensitivity and specificity higher than 80%, making it a clinically important test. Although specificity is high for the apprehension, release, and clunk tests, they do not give reliable results.

Chronic posterior instability Posterior instability is far less frequent than anterior instability. This explains why only a small number of tests have been developed to diagnose posterior instability (Table 87.2). The evidence of tests in chronic posterior instability is very sparse. This is most likely due to its low occurrence in daily practice. Results show a high sensitivity and specificity for the Kim test, which makes this test clinically relevant. Only Kim et al.¹² have published an evaluation of this test, making it more susceptible to bias.

Recommendations

- The relocation test is the only test providing a sensitivity and specificity higher than 80% for chronic anterior instability [overall quality: moderate]
- The Kim test for chronic posterior instability is clinically relevant although it is susceptible to bias [overall quality: moderate]

Question 2: What is the role of imaging in the diagnosis of chronic shoulder instability?

Finding the evidence

We performed a literature search of literature published between 1980 and December 2009 in the online resources MEDLINE and Embase with combinations of the following search terms:

- “diagnosis,” “imaging,” “radiology,” “MRI,” “MRA,” “arthrography,” “CT,” “conventional radiographs,” “ABER,” “chronic,” “recurrent,” “shoulder instability,” “glenohumeral instability,” “shoulder dislocation,” “shoulder subluxation”

Quality of the evidence

Level II

- 4 studies^{16,18,19,20}

Level III

- 3 studies^{14,15,17}

Level IV

- 1 study²¹

Level V

- 2 studies^{13,22}

Findings

Radiography In the chronic unstable shoulder, conventional radiographs are useful in the acute phase of a recurrence or if the patient had no previous experience of total dislocation. They are useful in detecting bony lesions such as Hill–Sachs lesions, an impression fracture in the posterolateral humerus, and bony Bankart lesions, an avulsion of the anterior inferior part of the glenoid, or other bony abnormalities, such as fractures of the greater tuberosity.¹³

MRI For two decades, MRI and MRA have been the gold standard in diagnosing any soft tissue abnormalities in chronic shoulder instability. Cartilage, rotator cuff, ligamentous and labral status can be detected by MRI. MRI can also be used to evaluate the acuteness of bony lesions, because of its ability to identify edema. Studies have shown sensitivity of 44–100% and specificity of 66–100% of MRI in identification of labral tears associated with anterior shoulder instability.¹⁴

MRA is used to increase the performance of detecting labral lesions. Two types of arthrography are available: MRA using direct contrast injection in the joint, or MRA using indirect contrast injection intravenously. In a comparison of MRI and MRA findings with surgical findings, Chandnani et al.¹⁵ found the two techniques to be roughly equivalent in ability to detect labral tears, at 96% and 93%, respectively. However, MRA was significantly more accu-

rate in detecting detached labral fragments (96% vs. 46%) and correctly identifying labral degeneration (56% vs. 11%). Waldt et al.¹⁶ found the accuracy of direct MRA to be 89% in detection, and 84% in classification of all labroligamentous pathology compared with arthroscopic findings. Overall, 80% of Bankart lesions, 77% of ALPSA lesions, and 50% of Perthes lesions were correctly identified. In studies by Palmer^{17,18} MRA demonstrated sensitivity of 91% and 92%, and specificity of 93% and 92%, respectively, in detection of labral pathology associated with anterior shoulder instability.¹⁵ Accurate quantification of glenoid defects by MRI has been demonstrated by Huijsmans et al.¹⁹ when compared with CT and direct measurement in cadavers. As MRI is usually performed in the workup of symptomatic instability, this should obviate the need to obtain a CT for this purpose.

ABER view Imaging in the ABER position (abduction external rotation) improves the accuracy of labral interpretation and recognition of undersurface cuff tears (Figure 87.4). Cvitanic et al.,²⁰ in a study comparing MR and operative findings in 92 patients, demonstrated 89% sensitivity and 95% specificity in the diagnosis of anterior labral injuries

Figure 87.4 MRI-A with ABER view, showing a detached labrum, a glenoid erosion, and a Hill–Sachs lesion.

with MRA in the ABER position, compared with 48% sensitivity and 91% specificity with MRA in the conventional position. Using both in conjunction increased sensitivity to 96% and specificity to 97%.²⁰ In a cadaver study, Kwak²¹ found that MRA in the ABER position achieved the best visualization of the inferior glenohumeral ligament. Clinicians should consider obtaining MRA in the ABER position for patients who are suspected to having a lesion of the anterior capsulolabral complex.

CT CT imaging provides a good view of bony defects as well as small glenoid fractures, glenoid version, intra-articular bodies, and the cartilage surface. It also provides the possibility to create a 3-D image of the bone. CT imaging alone is not sufficient for detection of soft tissue lesions.

An approach using contrast-injected CT arthrography (CTA) shows it to be useful in identifying labral lesions. In 1983, Shuman et al.²² were the first to describe a good result in double-contrast CTA of the shoulder. CTA can also show lesions of the labrum, making this a good second choice when MRI is not available.

Recommendations

In the chronic unstable shoulder:

- Conventional radiography can detect bony lesions but does not supply quantitative information on the size of these lesions. It is not useful for detecting concomitant soft tissue lesions [overall quality: high]
- MRI/MRA is useful for soft tissue lesions but not for bony lesions [overall quality: high]
- The accuracy of MRA is improved in the ABER view [overall quality: high]
- CT is useful for bony lesions but not for soft tissue lesions [overall quality: high]

Question 3: What is the best surgical approach to treat chronic shoulder instability?

Finding the evidence

We performed a literature search of literature published between 2000 and December 2009 in the online resources MEDLINE and Embase with combinations of the following search terms:

- "treatment," "therapy," "surgical technique," "chronic," "recurrent," "shoulder instability," "glenohumeral instability," "shoulder dislocation," "shoulder subluxation," "open treatment," "arthroscopic"

Quality of the evidence

Level III

- 2 studies^{23,24}

Findings

No consensus has so far been achieved on the surgical approach to chronic shoulder instability. Whether the tech-

nique should be open or arthroscopic has been the subject of many recent studies. Even within those two types of surgery there seems to be no consensus. For the treatment of anterior instability Hobby et al.²³ published a systematic review including a meta-analysis involving 62 studies, of which only 19 were comparative and of the comparative studies only 2 were randomized controlled trials (RCTs). Nine studies compared an open Bankart repair with or without capsular shift with arthroscopic stabilization using suture anchors or bioabsorbable tacks. There was no significant heterogeneity ($p = 0.72$). The meta-analysis provided a risk ratio estimate of 1.3 in favor of open surgery (95% CI 0.8–2.1) which was not statistically significant ($p = 0.33$). Six studies compared open techniques with arthroscopic stabilization using transglenoid sutures. The studies did not show significant heterogeneity ($p = 0.42$). Meta-analysis showed a statistically significant risk ratio estimate of 2.9 in favor of open surgery (95% CI 1.6–5.2; $p < 0.01$). The other four comparisons were of arthroscopic stabilization using transglenoid sutures with that using suture anchors. No significant heterogeneity was reported ($p = 0.64$), and meta-analysis showed a statistically significant risk ratio estimate of 2.0 (95% CI 1.3–3.1; $p < 0.01$) in favor of the use of anchors. On the basis of this meta-analysis, it appears that arthroscopic stabilization with suture anchors or bioabsorbable tacks may be as effective as open surgery, whereas transglenoid sutures should be avoided.²³

Also for anterior instability, Lenters et al.²⁴ published a systematic review consisting of 4 RCTs, 10 controlled clinical trials, and 4 other comparative studies. His meta-analysis revealed that, compared with open methods, arthroscopic repairs were associated with significantly higher risks of recurrent instability (RR 2.37; 95% CI 1.66–3.38; $p < 0.00001$), recurrent dislocation (RR 2.74; 95% CI 1.75–4.28; $p < 0.0001$), and a reoperation (RR 2.32; 95% CI 1.35–3.99; $p = 0.002$). When considered alone, arthroscopic suture anchor techniques were associated with significantly higher risks of recurrent instability (RR 2.25; 95% CI 1.21–4.17; $p = 0.01$) and recurrent dislocation (RR 2.57; 95% CI 1.35–4.92; $p = 0.004$) than were open methods. Arthroscopic approaches were also less effective than open methods with regard to enabling patients to return to work and/or sports (RR 0.87; 95% CI 0.77–0.99; $p = 0.03$).

On the other hand, analysis of the randomized clinical trials indicated that arthroscopic repairs were associated with higher Rowe scores (standardized mean difference 0.43; 95% CI 0.16–0.70; $p = 0.002$) than were open methods. Similarly, analysis of the arthroscopic suture anchor techniques alone showed the Rowe scores to be higher (standardized mean difference 0.29, 95% CI 0.01–0.56; $p = 0.04$) than those associated with open methods. Although the higher Rowe scores in the arthroscopic repairs suggest a better function and motion of the shoulder, this is not proven in this review.²⁴

The conclusion of these meta-analyses is that at the present state the open methods provide better results with respect to recurrence compared to all possible arthroscopic methods. However, at present anchors are mostly used and the results of arthroscopic repair with anchors can compete with the standard open methods. In these meta-analyses the influence of other aspects, like the extent of bony lesions at the glenoid or humeral side are not considered.

Recommendation

- The results of arthroscopic repair with anchors are comparable to the standard open methods [overall quality: moderate]

Question 4: What is the role of bone defects in the treatment of chronic unstable shoulder?

Finding the evidence

We performed a literature search of literature published between 2000 and December 2009 in the online resources MEDLINE and Embase with combinations of the following search terms:

- “bone defect,” “bony lesion,” “bone avulsion,” “bony Bankart,” “glenoid,” “humeral,” “chronic,” “recurrent,” “shoulder instability,” “glenohumeral instability,” “shoulder dislocation,” “shoulder subluxation”

Quality of the evidence

Level II

- 2 studies^{27,28}

Level III

- 5 studies^{25,26,29–31}

Findings

Since Burkhart et al.²⁵ showed an important role of the glenoid defect on the results of arthroscopic repair there has been an ongoing discussion about the limit of soft tissue repair in chronic instability.

The incidence of bone defects varies widely in the literature. The reported prevalence of fracture or erosion of the anteroinferior part of the glenoid rim among shoulders with recurrent anterior dislocation has been reported to range from 8% to 73%.²⁶ The prevalence of a Hill-Sachs lesion in patients with recurrent anterior dislocation of the shoulder ranges from 47% to 100%.²⁷

There are now adequate ways to measure the glenoid defect, following the finding that the inferior part of the glenoid is circular,^{28,29} but the only precise and quantitative way is with CT or MRI. Humeral head defects are measured in different ways, focusing on either the depth or the width of the defect. The interplay of the defects at either side of the joint is also under investigation.³⁰

Recommendation

- No studies are available showing the relation of the results of soft tissue repair, either arthroscopically or open, with an exactly measured defect of either the humeral head or the glenoid cavity³¹ [overall quality: low]

Question 5: What is the role of rehabilitation in chronic shoulder instability?

Finding the evidence

We performed a literature search of literature published between 1990 and December 2009 in the online resources MEDLINE and Embase with combinations of the following search terms:

- “rehabilitation,” “physiotherapy,” “conservative treatment,” “nonsurgical treatment,” “chronic,” “recurrent,” “shoulder instability,” “glenohumeral instability,” “shoulder dislocation,” “shoulder subluxation”

Quality of the evidence

Level II

- 1 study³⁴

Level III

- 1 study³²

Level IV

Openmirrors.com

Findings

In a systematic review of 14 studies (3 RCTs, 3 moderate quality cohorts, 5 poor quality cohorts and 3 case series) Gibson has shown that evidence is weak for the statement that physical therapy enables the athlete to return to premorbid activity level.³² Physiotherapy plays no role in prevention of recurrences in chronic shoulder instability.³³

After repair of a chronic unstable shoulder, a protocol is generally recommended that includes immobilization and exercises in a restricted range of motion during 6 weeks, especially regarding external rotation. This is based on the presumption that soft tissue heals to bone in about this period of time.

One level IIb study, comparing a group of patients after arthroscopic instability repair with either immobilization or accelerated rehabilitation postoperatively with a follow-up of a mean of 31 months shows that an accelerated program, including immediate staged exercises and strengthening, does not influence the results.³⁴

Recommendation

- Physiotherapy plays no role in prevention of recurrences in chronic shoulder instability, and an accelerated rehabilitation program, including immediate staged exercises and

strengthening, does not influence the results [overall quality: low]

Question 6: What is the natural history in chronic unstable shoulders?

Finding the evidence

We performed a literature search of literature published between 1990 and December 2009 in the online resources MEDLINE and Embase with combinations of the following search terms:

- “natural history,” “conservative treatment,” “non-surgical treatment,” “prognosis,” “chronic,” “recurrence,” “shoulder instability,” “glenohumeral instability,” “shoulder dislocation,” “shoulder subluxation”

Quality of the evidence

Level I

- 2 studies^{35,36}

Findings

Few studies are available to demonstrate the natural history of a chronic unstable shoulder. Hovelius³⁵ showed, that at 25 years, the total number of shoulders that became stable over time had increased, when compared with the 10 year follow-up, from 49% to 65%.

In another study by Hovelius³⁶ with a 25 year follow-up it was shown that, among other factors, recurrence is associated with the development of arthropathy. Shoulders without a recurrence were also associated with arthropathy. Thirty-nine per cent of the shoulders that redislocated once or more (without surgery) and 26% of the surgically stabilized shoulders showed moderate to severe arthropathy after 25 years of follow-up after the first dislocation.

Recommendation

- Recurrence is associated with the development of arthropathy, but shoulders without a recurrence were also associated with arthropathy [overall quality: moderate]

Summary of recommendations

- The relocation test is the only test providing a sensitivity and specificity higher than 80% for chronic anterior instability
- The Kim test for chronic posterior instability is clinically relevant although it is susceptible to bias
- Conventional radiography can detect bony lesions but does not supply quantitative information on the size of these lesions. It is not useful for detecting concomitant soft tissue lesions
- MRI/MRA is useful for soft tissue lesions but not for bony lesions

- The accuracy of MRA is improved in the ABER view
- CT is useful for bony lesions but not for soft tissue lesions
- The results of arthroscopic repair with anchors are comparable to the standard open methods
- No studies are available showing the relation of the results of soft tissue repair, either arthroscopically or open, with an exactly measured defect of either the humeral head or the glenoid cavity
- Physiotherapy plays no role in prevention of recurrences in chronic shoulder instability, and an accelerated rehabilitation program, including immediate staged exercises and strengthening, does not influence the results
- Recurrence is associated with the development of arthropathy, but shoulders without a recurrence were also associated with arthropathy

John E. Kuhn

Vanderbilt University School of Medicine, Nashville, TN, USA

Case scenario

A 75 year old woman presents to the office with a complaint of right shoulder pain of insidious onset. She describes difficulty sleeping at night, pain with activity, and crepitus in the shoulder. Physical examination demonstrates full active range of motion except in external rotation with the arm at the side, atrophy in the supraspinatus and infraspinatus fossae, pain with supraspinatus strength testing, and weakness in external rotation.

Relevant anatomy

The rotator cuff consists of four muscles (subscapularis, supraspinatus, infraspinatus, and teres major) whose origins are on the scapular body and insertions are on the lesser (subscapularis) and greater (supra and infraspinatus, teres major) tuberosities. The upper two thirds of the subscapularis is mostly tendon—much more so than the other rotator cuff muscles. The suprascapular nerve innervates the supraspinatus and infraspinatus. The tendon has layers with different mechanical properties—the articular side of the rotator cuff is more like glenohumeral joint capsule, whereas the middle portion is more like tendon. Tears generally start in the supraspinatus, and propagate posterior to involve the infraspinatus.

Importance of the problem

Rotator cuff disease is a common cause of disability and pain. Approximately one third of subjects over the age of

65 report shoulder pain with some degree of disability,^{1,2} and in the workplace, rotator cuff disease is common and seen in 54.0 per 10,000 full time employees in Washington State worker's compensation claims,³ second only to carpal tunnel syndrome for upper extremity disorders.⁴

Rotator cuff tears are extremely prevalent in symptomatic and asymptomatic individuals⁵ (Table 88.1), but are more common in symptomatic people⁵ and older people,⁶ and are often bilateral.⁷

Between 1998 and 2004 over 5 million physician visits in the United States were attributed to rotator cuff problems,⁸ a figure that will increase as the population ages. In New York State, rotator cuff repairs increased by 50% over a 5 year span.⁹

Most rotator cuff repairs are performed in an outpatient setting, and although accurate numbers are not available, estimates for outpatient rotator cuff repair range from 75,000/year⁴ to 250,000/year.¹⁰

Although the cost per patient for rotator cuff repairs in US averaged \$17,427 in 2004,¹¹ rotator cuff repair is considered a cost-effective procedure by Health Utility Index (\$13,092.84/QALY) and by the EuroQol (3,091.90/QALY)—values that compare favorably with other common interventions, and reach cost-effective benchmarks currently in use.¹²

Top five questions

Diagnosis

1. What are the best physical examination tests to identify a rotator cuff tear?
2. What is the best way to image the rotator cuff tear?

Table 88.1 Prevalence of rotator cuff tears⁵

	Asymptomatic		Symptomatic	
	Partial thickness tears (%)	Full thickness tears (%)	Partial thickness tears (%)	Full thickness tears (%)
Cadaver studies	10.39	12.68	NA	
Ultrasound	17.2	21.7	6.7	34.7
MRI	15.87	10.33	49.38	40.8

NA, data not available.

Treatment

- Does nonoperative treatment have a role?
- What are the best techniques for rotator cuff repair?

Harm

- What are the complications of rotator cuff surgery?

Question 1: What are the best physical examination tests to find a rotator cuff tear?

Case clarification

The patient has night pain, crepitus, and full motion. Does this patient have a rotator cuff tear?

Relevance

Some physical examination tests may be helpful to identify if a rotator cuff tear exists, which may prompt the health-care provider to consider imaging or other measures before initiating treatment.

Current opinion

Most physicians consider the physical examination to be only moderately helpful in finding rotator cuff tears.

Finding the evidence

The following literature databases were searched using the search terms “(rotator cuff tear AND physical exam\$)”:

- Cochrane Database of Systematic Reviews
- ACP Journal Club
- DARE
- PubMed (clinical queries and systematic reviews)
- PubMed 1950–April 2010
- Embase

This produced 67 potential references. Of these 51 were excluded as they did not study physical examination techniques, 2 were excluded as they were not studies of rotator cuff disease, and 8 were excluded as they were review

papers. This left 6 articles for thorough review; an additional 13 were found using the references cited in these manuscripts, to give a total of 19 on which this review is based.

Quality of evidence

Level I

- 8 studies^{13–20}

Level II

- 1 study²¹

Level III

- 7 studies^{22–28}

Level IV

- 2 systematic reviews/meta-analyses^{29,30}
- 1 study³¹

Findings

Surprising variation is noted when different researchers evaluate the same test (Table 88.2). This may relate to problems in reproducibility of physical examination tests for rotator cuff disease.^{32,33} One of the best tests for identifying rotator cuff tears is the “rent test” where the defect in the supraspinatus is palpated through the deltoid muscle. This test has a positive likelihood ratio (+LR) approaching that of MRI imaging. Lag signs, when present, are also helpful to identify rotator cuff tears. Unfortunately, as evidenced by negative likelihood ratio (–LR) close to 1.0, a rotator cuff tear may still be present if the test is negative (Table 88.2).

Recommendation

- When examining patients with suspected rotator cuff tears, lag signs and the rent test, when positive, are helpful to diagnose a rotator cuff tear. If the history suggests a rotator cuff tear when these tests are negative, imaging modalities may be required [overall quality: moderate]

Question 2: What is the best imaging study to diagnose rotator cuff tears?

Case clarification

The patient has a full range of motion, pain with supraspinatus strength testing, a positive rent test, and a negative lag sign. You suspect a rotator cuff tear. What imaging test should you order?

Relevance

A number of imaging tests are available to identify rotator cuff tears. Some patients with advanced cuff disease have radiographs that can identify cuff tears. MRI is used commonly, but is expensive. MRI arthrogram may improve accuracy. Ultrasound is gaining in popularity.

Table 88.2 Data from level I studies of physical examination techniques to diagnose full thickness rotator cuff tears

Test	Authors	N	Sens	Spec	PPV	NPV	LR+	LR-

LR, likelihood ratio; NPV, negative predictive value; PPV, positive predictive value; Sens, sensitivity; Spec, specificity.

Current opinion

Plain radiographs can identify rotator cuff tears by superior humeral head migration. MRI is very useful, but ultrasound is gaining in popularity.

Finding the evidence

The following literature databases were searched using the search terms: "(rotator cuff tear AND (imaging or magnetic resonance imaging OR arthrography OR arthrogram OR ultrasound OR ultrasonography)":

- Cochrane Database of Systematic Reviews
- ACP Journal Club
- DARE
- PubMed (clinical queries: systematic reviews)
- PubMed 1950–April 2010
- Embase

This search produced 648 references. Of these 265 were excluded for not dealing with rotator cuff tears; 190 were excluded for not studying imaging techniques; 57 were review papers or abstracts; 12 were excluded for imaging of post-operative shoulders. This left 124 articles for review. Of this group 20 were excluded for not involving rotator cuff tears; 13 were excluded as they were comparisons of different MRI techniques; 18 were excluded as they were studies of cadavers or normal subjects; 23 were excluded as they were published before 1995; 19 were excluded as they were not in English. This left 30 manuscripts for thorough review which were broken down as follows.

Quality of evidence

Level I

- 16 studies^{34–49}

Level II

- 3 studies^{50–52}

Level III

- 2 systematic reviews/meta-analysis^{53–54}
- 5 studies^{55–59}

Level IV

- 4 case control studies^{60–63}

Findings

AP radiographs used to measure superior humeral head migration are accurate compared to CT imaging.⁴⁷ When superior humeral head migration is seen it has been associated with multiple tendon rotator cuff tears^{60,62,63} and fatty degeneration of the rotator cuff muscle.⁵¹ A decreased acromiohumeral interval is also seen in patients with impingement when compared to normal subjects.⁶¹

Arthrography, or digital subtraction arthrography may be helpful to diagnose a full thickness tear,⁵⁵ but cannot accurately determine the size of the tear.³⁶

CT arthrography has sensitivities and specificities above 95% for diagnosis of supraspinatus and infraspinatus tears.⁵⁰ MRI sensitivities and specificities are generally above 85%.^{46,49,52,59} Ultrasound sensitivities and specificities are generally above 85% for full thickness tears,^{35,42,43,45} with some variation.⁵⁸ Ultrasound is less sensitive or specific for the diagnosis of partial thickness tears.^{40,43–45,54,57}

Studies that compare different imaging techniques have shown that double contrast arthrography cannot diagnose or determine the size of a rotator cuff tear as well as ultrasound or CT arthrography.³⁷ Ultrasound compares well to

CT arthrography³⁷ in evaluating the size and site of rotator cuff tears.

MRI and ultrasound are not very different in their ability to diagnose full thickness rotator cuff tears and determine the size of the tear.^{34,38–41,45,53,56} MRI arthrography is more sensitive and specific than MRI or ultrasound in diagnosing a full or partial thickness rotator cuff tear.⁵³

Recommendations

- When superior humeral head migration is seen on AP radiographs it usually is diagnostic for a large rotator cuff tear with fatty infiltration. MRI or ultrasound may be used for identification of smaller tears and to assess the size of the rotator cuff tear equally well. MRI arthrography may add information, particularly when a partial rotator cuff tear is suspected [overall quality: moderate]

Question 3: Does nonoperative treatment have a role in rotator cuff tears?

Case clarification

The patient has a rotator cuff tear. How should you manage it? What is the role of nonoperative treatment?

Relevance

There is great geographic variation in how rotator cuff tears are managed.⁶⁴ The indications for surgical intervention are not agreed upon or clear.^{65,66}

A conservative estimate of prevalence suggests that 10% of people over the age of 60 have rotator cuff tears.⁵ Using data from the 2006 US census, this equates to more than 5 million people. In the USA approximately 75,000 rotator cuff surgeries are performed each year.¹² This means that over 98% of the population with rotator cuff tears do not have surgery, suggesting very few are symptomatic.

In addition, patients who undergo surgery often fail their repairs (Table 88.3), yet report satisfaction and pain relief after treatment.⁶⁷ This data suggests that there is a role for nonoperative treatment of patients with rotator cuff tears.

Table 88.3 Failure of repair

Author	Failures (%)	Features related to failures
Galatz 2004	94	All massive tears
Boileau 2005	25	Age, size of tear
Liu 1994	24	Size of tear
Cole 2007	22	Age, size of tear
Levy 2008	18.6	Age
Fuchs 2006	13	Not reported
Paulos 1994	5.5	Size of tear

Current opinion

Rotator cuff repairs should be performed in select patients.

Finding the evidence

The following literature databases were searched using the search terms: “(rotator cuff tear AND non-operative OR physical therapy OR rehabilitation)”

- Cochrane Database of Systematic Reviews
- ACP Journal Club
- DARE
- PubMed (clinical queries: systematic reviews)
- PubMed 1950–April 2010
- Embase

This search produced 378 hits. Of these 366 were excluded: 66 were review manuscripts; 170 did not related to rotator cuff tears; 98 involved surgical treatment; 11 were in-vitro or outcome tool development studies; 12 were imaging studies; 5 assessed comorbidities, indications for surgery, or surgeons’ perceptions; and 4 assessed topical or injectable treatments for shoulder pain, leaving 12 studies for more thorough review.

Quality of the evidence

Level I

- 1 study⁶⁸

Level III

- 1 study⁶⁹

Level IV

- 1 systematic review / meta-analysis⁷⁰
- 9 studies^{71–79}

Findings

Multiple case series report success with nonoperative treatment to range between 59–85%; however, these studies are subject to selection bias and generally include only those patients with massive tears in whom surgery cannot be performed, and data was collected retrospectively.⁷⁰

One randomized trial compared open surgery (N = 52) to physical therapy (N = 51) in patients with traumatic and atraumatic tears less than 3 cm.⁶⁸ ASES and Constant scores were significantly different after 6 months, favoring surgery (suggesting the improvement in strength influences scores). Interestingly 24% of repairs did not heal completely, and only 9 of 51 (18%) of the physical therapy group decided to have surgery.

A level IV systematic review of the literature suggests that acute rotator cuff tears with functional loss and weakness may benefit from earlier surgical intervention.⁶⁵

Rotator cuff tears may progress after nonoperative treatment, with increases in size, and fatty infiltration.^{80–83} It is unknown if these increases in disease produce patient difficulties later; however, asymptomatic tears may progress and become symptomatic.⁸⁴

Openmirrors.com

Recommendations

- Currently the evidence is weak to make recommendations regarding indications for surgery, and deciding who would do well with nonoperative treatment. Low-level evidence suggests that traumatic tears with loss of function, or weakness are reasonable indications for surgery. Other patients may be managed nonoperatively, but should be counseled that their tear may progress in size [overall quality: low]

Question 4: What surgical treatments are best?

Case clarification

The patient has a rotator cuff tear. She would like to have surgery. What approaches might work best?

Relevance

Rotator cuff repairs are common and technology is evolving

Current opinion

Rotator cuff repairs should be performed in select patients; opinions vary on indications and technical aspects of the approach.

Finding the evidence

The following literature databases were searched using the search terms: “(rotator cuff repair)” and a separate search for “(rotator cuff trial)”

- Cochrane Database of Systematic Reviews
- ACP Journal Club
- DARE
- PubMed (clinical queries: systematic reviews)
- PubMed 1950–April 2010
- Embase

This search produced 273 hits. Of these, 120 were not comparative trials and were excluded, 55 were not pertaining to rotator cuff tears, 24 were not clinical studies, 24 were not in English, and 14 were reviews or abstracts, 2 systematic reviews were withdrawn as they were not up to date, leaving 34 for thorough review.

Quality of the evidence

Level I

- 16 studies^{68,85–99}

Level II

- 6 studies^{100–105}

Level III

- 2 systematic reviews/meta-analysis^{106,107}
- 9 studies^{108–116}

Level IV

- 1 systematic review/meta-analysis¹¹⁷

Findings

Evidence on comparative effectiveness for different surgical treatments is limited and somewhat inconclusive,¹⁰⁷ and it may not be appropriate to generalize the results of single-site studies of technical aspects of surgery to other surgeons; however, comparative trials have concluded the following.

Patients who have failed rotator cuff repairs report outcome scores that are not significantly different than patients whose repairs have healed,^{95,112,117} unless the outcome score includes a large component for strength (e.g., the Constant score), in which case healed repairs have better scores.^{68,117}

With regard to the approach used, open repairs improve strength, function, and outcome scores compared to arthroscopic debridement of rotator cuff tears, but patient satisfaction does not differ.¹⁰⁴ Patients with massive tears who undergo a partial repair have better Constant scores than tears that are debrided.⁸⁵ Mini-open rotator cuff repair has similar outcome scores^{107,110} and improved active forward elevation compared to open repair.¹¹⁰ Mini-open rotator cuff repairs have improved short-term scores (3 months), but scores at 28 months or 2 years are comparable to open repairs.⁹⁸ Arthroscopic repairs (with both knot tying and knotless systems) have improved outcomes compared to open repairs;¹¹⁴ however, rotator cuff repair failure is more common for large tears repaired arthroscopically compared to open repair.¹⁰² Arthroscopic rotator cuff repair techniques produce similar outcome scores^{107,111,113,115} and healing rates¹¹³ when compared to mini-open repairs.

With regard to open techniques, transosseous repair using No. 3 Ethibond and modified Mason-Allen sutures had similar Constant scores, failure rates, and complications compared to transosseous repair with 1.0 mm polydioxanone cord and modified Kessler sutures.⁸⁷ Porcine small intestine submucosa augmentation of large and massive rotator cuff tear repairs produced lower outcome scores,⁹⁴ greater strength deficits,¹¹⁶ and did not improve healing rates⁹⁴ compared to controls.

With regard to arthroscopic techniques, arthroscopic subacromial decompression has not been shown to improve outcome scores after rotator cuff repair.^{92,97,107} Rotator cuff repairs using a suture anchor to the greater tuberosity have better Constant scores and strength than repairs performed side to side without fixation to the tuberosity.⁸⁶ Double row repairs do not seem to improve outcomes over single row repairs;^{101,103,105–107} however, healing rates¹⁰³ and improvements in strength for larger tears¹⁰⁵ may favor double row techniques. Failures of single row repairs were more likely to occur at the repair site than with the suture bridge technique, which failed at the musculotendinous junction.¹⁰⁸ A massive cuff stitch method of arthroscopic rotator cuff repair had significantly improved healing rates compared to an arthroscopic simple stitch repair.¹¹²

Patients with rotator cuff repairs have outcomes similar to patients who have rotator cuff repairs and concomitant SLAP (superior labrum from anterior to posterior) lesion repairs,¹⁰⁹ but patients with concomitant rotator cuff repairs and SLAP lesions have better outcomes and motion if the SLAP tear is debrided than if it is repaired.^{89,100}

There is conflicting evidence regarding continuous passive motion compared to passive self-assisted range of motion exercises for 4 weeks, with some studies suggesting continuous passive motion may reduce pain and improve range of motion,⁹¹ and others finding no differences.⁹⁶

Recommendations

- The data suggests that rotator cuff repairs can improve patient reported outcomes, even if the repairs fail. Strength and functional improvements are greater if the repair heals [overall quality: high]
- Open, mini-open, and arthroscopic approaches are similar, but patients who have open approaches may have lower outcome scores at 3 months [overall quality: high]
- Arthroscopic approaches should include anchor fixation to the greater tuberosity. However, the double row technique does not seem to affect outcome scores, but may improve healing, especially for larger tears [overall quality: high]
- Acromioplasty has not been shown to affect outcome scores, but has not been studied to see if it has an effect on healing [overall quality: high]
- Porcine small intestine mucosa should not be used to augment repairs [overall quality: high]

Question 5: What are the complications after rotator cuff repair?

Case clarification

The patient is interested in undergoing surgery. What are the risks of rotator cuff repair surgery?

Relevance

Patient should understand risks of rotator cuff repair surgery.

Current opinion

Risks are small.

Finding the evidence

The following literature databases were searched using the search terms “(rotator cuff repair AND (complications OR risk))”

- Cochrane Database of Systematic Reviews
- ACP Journal Club
- DARE
- PubMed (clinical queries: systematic reviews)
- PubMed 1950–April 2010
- Embase

418 hits were reviewed. Of these, 49 were reviews, editorials, or letters; 39 were in-vivo studies or technical reports; 59 were describing surgeries other than rotator cuff repair for cuff tears; 23 were reports for subscapularis tears, partial tears, tendonosis, or revision repairs; 15 were not in English; 151 were reports on conditions other than the treatment of rotator cuff tears; leaving 82 manuscripts for more thorough review. Of these, 23 offered data on complications after rotator cuff repair.

Quality of the evidence

Level III

- 2 studies^{118–119}

Level IV

- 21 studies^{120–140}

Findings

Complications included failure of repair (Table 88.3), and infection, stiffness, hardware failure, nerve injury, deltoid disruption (Table 88.4), and technical aspects such as the creation of dog-ear deformity using suture bridge technique.¹³² Case reports included anchor penetration through

articular cartilage,¹⁴⁰ unrecognized breakage of nitinol needle in shoulder,¹³⁸ heterotopic ossification,^{124,133} and persistent fistula.^{125,139} Patients with diabetes are at higher risk for failure and infection.¹¹⁸

Recommendations

- Patients who are considering surgery to treat rotator cuff tears should be made aware of all complications, including failure, stiffness, infection, and failure of hardware, all of which have been reported to occur in more than 1% of rotator cuff repairs. Failure is the highest complication [overall quality: low]

Summary of recommendations

- When evaluating a patient with a suspected rotator cuff tear, the rent test and lag signs can identify a torn rotator cuff, but when these signs are absent imaging in the form of ultrasound or MRI may be indicated.
- Nonoperative treatment may be effective for relief of pain, but high-level evidence is lacking in the literature
- Weakness or loss of function, and acute injuries are indications for repair, but even if repairs fail, patient outcomes are improved and may be difficult to distinguish from healed repairs
- A variety of repair techniques have been described in the literature. Acromioplasty at the time of rotator cuff repair does not seem to change outcomes. The tendon should be anchored to the tuberosity, yet double row techniques do not seem to improve outcomes compared to single row techniques, except perhaps for larger tears where healing may be better with double row techniques. Porcine submucosa graft should not be used to augment rotator cuff repair. Many complications have been described, but failure of the repair is most common

Conclusions

Rotator cuff tears are extremely common and most are presumably asymptomatic. The evidence suggests that physical examination tests may detect tears, but cannot rule out tears. Ultrasound and MRI are fairly equivalent in detecting full thickness tears. More work is needed to identify who would be treated best with surgery, and which surgical techniques improve healing rates.

Ron L. Diercks and Oscar Dorrestijn

University Medical Center Groningen, University of Groningen, The Netherlands

Case scenario

A 48 year old man employed in a hardware store has been suffering from progressive pain in his right shoulder for 5 months. The pain is located over the anterolateral part of his shoulder and radiates to the upper arm. There is no history of trauma. Overhead activities are painful and sleeping on the right shoulder is disturbed. At examination he experiences a painful arc during active abduction between 70 and 120°. Neer, Hawkins–Kennedy, and Jobe signs are positive. The impingement test, which is based on the Neer sign after subacromial injection with a local anesthetic, confirms the suspected diagnosis of subacromial impingement syndrome. Radiographs show a small calcification just proximal to the major tubercle. Ultrasound (US) examination shows an intact rotator cuff with tendinopathic changes at the insertion and small calcifications.

Relevant anatomy

Shoulder impingement syndrome (SIS) is characterized by pain, exacerbated by arm elevation or overhead activities. Neer was the first to describe the concept of impingement as mechanical impingement of the rotator cuff tendon beneath the anteroinferior acromion when the shoulder was placed in forward flexion and internal rotation.¹

The impingement implies compression of the subacromial bursa and rotator cuff fibers. The syndrome includes cuff and/or biceps tendon tendinopathy, calcifying tendinosis, subacromial bursitis, and rotator cuff tears.² Overuse and overload induce microtraumas in the tendon. As rotator cuff tendinopathy is a degenerative process, the syndrome has an increasing prevalence in the adult popu-

lation, and in people with overhead activities in work or sports.^{3,4}

Importance of the problem

Shoulder pain is responsible for 16–21% of all musculoskeletal complaints in general practice. A recently published review has summarized 18 studies on the prevalence of shoulder complaints among the general population.⁵ Prevalence figures ranged from 6.7% to 66.7% for lifetime prevalence. The cumulative incidence of shoulder problems was estimated at 19 per 1,000 person-years.⁶ SIS is the most frequently recorded disorder (44%).⁷

This syndrome has been shown to have a substantial impact on the ability to work: 73% of SIS patients are unable to work at their usual job, and return to heavy overhand work is not common.⁸ Also, differences in outcome are seen for patients on workers' compensation, therefore SIS has a high socioeconomic impact.⁹

Top nine questions

Diagnosis

1. How accurate is clinical examination in diagnosing SIS?
2. What is the role of imaging in the diagnosis of SIS?

Therapy (effectiveness assessed in terms of improvement of shoulder function or reduction of pain)

3. What is the effect of subacromial anesthetic and/or corticosteroid injections on SIS?

4. What is the effect of physical therapy interventions on SIS?
5. Is there a place for extracorporeal shockwave therapy (ESWT), acupuncture, topical agents, or US in SIS?
6. What is the indication for surgery to treat SIS?
7. If surgery is chosen for SIS, what is the optimal surgical technique?

Prognosis

8. What is the effect of treatment on shoulder function and recovery?

Harm

9. What are the complications associated with interventions for SIS?

Question 1: How accurate is clinical examination in diagnosing SIS?

Case clarification

Upon examination, the patient experiences a painful arc during abduction between 70 and 120°. Hawkins and Jobe signs are positive. Neer sign with passive abduction is positive, and the impingement test, which is based on the Neer sign after a subacromial injection with a local anesthetic, confirms the suspected diagnosis of SIS.

Relevance

This is a clinical diagnosis of impingement syndrome. Numerous tests have been described since Neer's original publication.¹⁰ The method of execution of most tests is not always clear, nor is the technique. Sensitivity, specificity, and reliability have been tested in recent years.

Current opinion

Pain with abduction of the arm, the "painful arc syndrome," and an abnormal rhythm of movement between glenohumeral and scapulothoracic motion between 60° and 120° of abduction is the foremost sign of impingement syndrome.

Finding the evidence

- Cochrane Database, search term: "shoulder tests"
- PubMed clinical queries search/ systematic reviews: "diagnostic test impingement shoulder"

Quality of the evidence

Level II

- 6 systematic reviews/meta-analyses

Findings

The sensitivity, specificity, positive predictive value, negative predictive value, and overall accuracy of the tests vary

considerably. The pooled sensitivity and specificity for the Neer test were 0.79 (95% CI 0.75–0.82) and 0.53 (95% CI 0.48–0.58), respectively, and for the Hawkins–Kennedy test 0.79 (95% CI 0.75–0.82) and 0.59 (95% CI 0.53–0.64).¹¹ A recent systematic review concluded that some tests show good sensitivity with somewhat lower specificity when weakness is used to assess the test result.¹² Test reliability is poorer when pain is the response criterion. The right way to execute these tests differs essentially in some publications. This problem also has been addressed in a number of articles.^{12–16}

The Neer test is performed with the examiner standing behind a seated or standing patient. The ipsilateral scapula should be fixated to prevent protraction. The test consists of passive forward elevation. If the patient experiences pain in the shoulder, the test is positive. The Hawkins–Kennedy test is performed with the examiner facing the seated or standing patient. The patient has his/her arm 90° in forward elevation in the scapular plane and 90° flexed in the elbow. The test consists of passive internal rotation until pain occurs.¹⁷

Recommendations

- The Hawkins–Kennedy test is a useful and reliable screening test for SIS [overall quality: moderate]
- The supraspinatus/empty can or infraspinatus test is as a confirmatory test for impingement [overall quality: moderate]
- The supine impingement test, when negative, is a valuable screen for any rotator cuff tear [overall quality: low]
- The hornblower's sign may be diagnostic of severe degeneration or absence of the teres minor muscle [overall quality: low]
- The external rotation lag sign may be diagnostic of an infraspinatus muscle tear [overall quality: low]

Question 2. What is the role of imaging in the diagnosis of SIS?

Case clarification

The patient's radiographs show a small calcification just proximal to the major tubercle. US examination shows an intact rotator cuff with tendinopathic changes at the insertion and small calcifications.

Relevance

As SIS is predominantly a soft tissue disorder, imaging of those structures is important in evaluating the problem and planning interventions.

Current opinion

US or MRI imaging of the integrity of the rotator cuff support clinical decision-making and choice of therapeutic intervention, and help establish a prognosis.

Finding the evidence

- Cochrane Database, with search term “impingement syndrome”
- PubMed: “imaging shoulder,” “impingement syndrome shoulder,” “imaging subacromial impingement syndrome”

Quality of the evidence*Level I*

- 3 systematic reviews/meta-analyses

The value of US US combined with radiography is accepted as the primary investigation for shoulder impingement and suspected partial and full thickness rotator cuff tear. US is a cost-effective diagnostic tool for rotator cuff tears with a sensitivity of 94% and a specificity of 93%, but is operator-dependent. In experienced hands US of the rotator cuff is a reproducible diagnostic test ($\kappa > 0.60$, $p < 0.01$), but agreement is poor when there is marked disparity between operators’ experience levels.¹⁸ There is only a 41% detection rate of partial thickness tears.¹⁹

The value of MRI A recent meta-analysis summarized 10 studies using conventional MRI for detection of rotator cuff tears.²⁰ Overall sensitivity and specificity were high for full thickness tears, 0.89 (95% CI 0.86–0.92) and 0.93 (95% CI 0.91–0.95) respectively. For detection of partial thickness tears, sensitivity rates were much lower (0.44, 95% CI 0.36–0.51) although specificity remained high (0.90, 95% CI 0.87–0.92). For full thickness tears MR arthrography (MRA) has a sensitivity of 0.95 (95% CI 0.82–0.98) and a specificity of 0.93 (95% CI 0.84–0.97). MRI offers the advantage of diagnosing concomitant abnormalities.

Three studies compared MRI and US to surgery prospectively and found higher sensitivity and accuracy rates for MRI. A negative MRI would rule out the presence of a tear with more certainty than a negative US.²⁰ MRI seems to be more accurate than US in detecting partial tears. Overall, MRI is a useful tool in the identification of shoulder pathology.^{21–23}

Recommendations

- US may be the more cost-effective diagnostic method [overall quality: very low]
- MRI or US could be equally used for impingement syndrome and full thickness tears rotator cuff tears [overall quality: moderate]
- All imaging modalities were less accurate for partial thickness tears [overall quality: moderate]
- US has operator dependency, leading to variable results in daily practice [overall quality: low grade]
- The clinical correlation of imaging and the assessment of outcomes remains unknown [overall quality: very low]

Question 3: What is the effect of subacromial anesthetic and/or corticosteroid injections on SIS?**Case clarification**

The impingement test, which is based on the Neer sign after subacromial injection with a local anesthetic, confirms the suspected diagnosis of SIS.

Relevance

By judging the effect of a subacromial anesthetic and corticosteroid injection, a definite diagnosis of SIS can be made.

Current opinion

Subacromial injections of corticosteroids are effective for SIS.

Finding the evidence

- PubMed clinical queries search/systematic reviews, with search terms: “subacromial injection,” “local infiltration shoulder”

Quality of the evidence

- 1 level I meta-analysis
- 1 Cochrane Database entry
- 11 reviews and randomized controlled trials (RCTs)

Findings

Subacromial infiltration as a diagnostic procedure In the hands of experienced orthopedic surgeons, subacromial injections through standard approaches often fail to infiltrate the subacromial space.^{24,25} This can create both false-positive and false-negative results. The evaluation of the effect appears to be time-dependent: rapid responders show more than 50% pain relief at 10 minutes, delayed responders after 10 minutes or more.²⁶

Subacromial infiltration as a therapeutic intervention In a Cochrane review (three pooled trials), Buchbinder et al. state that subacromial steroid injections have a small benefit over placebo in some trials, but no benefit over NSAIDs was demonstrated.²⁷ There is some evidence that corticosteroid injections are superior to physical therapy. A recent meta-analysis (seven trials) by Arroll et al. underlines a significant benefit of steroid injections above placebos.²⁸ They found a large benefit, with a number needed to treat of 2.5, when compared with NSAIDs. The reported duration of the effect of subacromial corticosteroid injections is up to 32 weeks. Conflicting evidence was found about the benefit of adding corticosteroids to local anesthetics, and the doses that should be used. In the study that showed no effect, the lowest dose of corticosteroids was given.²⁹ Higher doses of corticosteroids (50 mg equivalent

of prednisone or greater) may be more effective than lower doses. Pooling of three high-quality studies resulted in a relative risk of 5.9 (95% CI 2.8–12.6).²⁸

All this evidence is put in a different light in a recent RCT by Ekeberg et al., showing no important differences in short-term outcomes for rotator cuff disease between local US-guided corticosteroid injections and systemic corticosteroid injections.³⁰

Recommendations

- There is conflicting evidence on the benefit of subacromial corticosteroid injections above placebo, NSAIDs, and physical therapy [overall quality: low]
- Higher doses of corticosteroids seem to be more effective than lower doses [overall quality: high]
- The duration of the effect can be as long as 32 weeks [overall quality: high]
- As nonguided subacromial injections often fail to infiltrate the subacromial space, imaging-guided subacromial steroid injections are to be preferred [overall quality: high]
- There should be serious doubt about the placebo effect of “puncturing the painful area” vs. the systemic effect of corticosteroids [overall quality: moderate]

Question 4: What is the effect of physical therapy interventions on SIS?

Relevance

The first line of treatment for SIS in most cases is physical therapy.

Current opinion

Exercise and instruction can be helpful in the rehabilitation of SIS.

Finding the evidence

- PubMed clinical queries search/systematic reviews, with search terms: “physiotherapy interventions for shoulder pain”

Quality of the evidence

Level I

- 1 Cochrane systematic review
- 1 systematic review
- 3 RCTs

Findings

In a Cochrane review, including 26 trials, little evidence to guide treatment was found.³¹ There is some evidence that exercise is effective in terms of short-term recovery for rotator cuff disease (RR 7.74, 1.97–30.32). Another systematic review, which included 16 RCTs, shows an equal effectiveness of physiotherapist-led exercises compared with surgery and of home-based exercises compared with physi-

otherapy.³² An RCT showed that self-training after instruction showed no difference in outcomes with physiotherapist-supervised exercises.³³ Another RCT reported that addition of manual therapy resulted in an improvement at follow-up.³⁴

A recent RCT comparing surgery with physical therapy found no clinically important effects in terms of subjective outcome at 24 months of follow-up.³⁵ The effect of eccentric training, used nowadays for a number of tendinopathies, has only been published as a pilot study.³⁶

Recommendations

- Systematic reviews and RCTs show no differences in outcome between patients treated with physical therapy and surgery [overall quality: high]
- There is limited evidence that exercise is more effective than no intervention [overall quality: high]
- Combining manual therapy with exercises can have additional benefits [overall quality: moderate]
- No difference is noted between physiotherapist-supervised exercises and self-training after instruction [overall quality: moderate]
- The effect of eccentric training in SIS has not yet been shown [overall quality: very low]

Question 5: Is there a place for Extracorporeal Shockwave Therapy (ESWT), acupuncture, or ultrasound for the treatment of SIS?

Relevance

Shoulder complaints, including SIS, are often treated with different modalities.

Current opinion

ESWT can have an effect on acute calcific tendinosis; no other therapeutic modalities have been proven worthwhile.

Finding the evidence

- PubMed clinical queries search/systematic reviews, with search terms: “treatment modalities tendinopathy,” “extracorporeal shockwave therapy and SIS”

Quality of the evidence

- 2 Cochrane systemic reviews
- 1 review

Findings

ESWT There is evidence for the effectiveness of ESWT in the treatment of calcific tendinosis compared with placebo, with a reported improvement in pain scores and a decrease in the size of calcific deposits.^{37,38} Two RCTs report no major benefit with ESWT compared with placebo for the treatment of noncalcific tendinopathy of the supraspinatus.^{39,40}

Supervised exercises were more effective than radial ESWT for short-term improvement in patients with subacromial shoulder pain.⁴¹

Acupuncture Acupuncture was of benefit over placebo in shoulder function (measured with Constant–Murley score) at 4 weeks. However, by 4 months the difference was not clinically significant.⁴²

Topical glyceryl nitrate There is some evidence that topical glyceryl trinitrate is more effective than placebo for rotator cuff disease among patients with acute symptoms (<7 days duration). Any benefits of treatment need to be balanced against the risk of headaches.⁴³

Ultrasound There is no evidence that US therapy has any effect on SIS.^{44,45}

Recommendations

- ESWT has an effect on radiologic calcific tendinosis [overall quality: high]
- There is no reported effect of extracorporeal shockwave therapy on SIS without calcific tendinosis [overall quality: high]
- There is some effect described of acupuncture in SIS [overall quality: moderate]
- There could be a very short time effect of topical glyceryl nitrate on SIS [overall quality: low]
- There is evidence that US therapy has no effect on SIS [overall quality: moderate]

Question 6: What is the indication for surgery to treat SIS?

Relevance

Surgical therapy for SIS is a very common procedure. The indication is mostly persistent impingement syndrome after a period of conservative therapy.

Current opinion

Surgical therapy (arthroscopic or open subacromial decompression) is the therapy of choice after failed physical therapy and steroid injections.

Finding the evidence

- PubMed clinical queries search/systematic reviews, with search terms: “shoulder impingement syndrome,” “subacromial impingement,” “rotator cuff” AND “surgical procedures” OR “arthroscopy” AND “therapy” AND “nonoperative” OR “nonsurgical” OR “conservative”

Quality of the evidence

Level I

- 1 Cochrane review

- 1 systematic review/meta-analysis
- 2 RCTs

Findings

In a Cochrane review published in 2008,⁴⁶ a systematic review published in 2009,⁴⁷ and a recent RCT,³⁵ no differences in reduction of pain or improvement of shoulder function were found between surgery and nonsurgical treatments. Coghlan et al. found a “silver” level of evidence that there are no significant differences in outcome between subacromial decompression and active nonoperative treatment for impingement.⁴⁶ Dorrestijn et al. found four RCTs comparing effects of conservative and surgical treatment,^{47–52} showing no difference in outcome. In an RCT, Ketola et al. found no clinically important effects in terms of self-reported pain when measured at 24 months of follow-up.³⁵ However, the mean healthcare costs in the combined treatment group (€2,961), which consisted of an arthroscopic acromioplasty followed by an exercise program, were considerably higher (160%) than those for the exercise group (€1,864) alone.

Recommendation

- Surgical treatment of patients with SIS is not superior to conservative treatment [overall quality: high]

Question 7: If surgery is chosen for SIS, what is the optimal surgical technique?

Relevance

Open vs. arthroscopic acromioplasty, bursectomy only, and whether to leave the coracoacromial ligament intact are issues much debated in shoulder surgery.

Current opinion

Arthroscopic subacromial decompression with resection of the coracoacromial ligament and abrasion of the anteroinferior part of the acromion is the current standard of surgical treatment.

Finding the evidence

- PubMed clinical queries search/systematic reviews, with search terms: “shoulder impingement syndrome,” “subacromial impingement,” “rotator cuff” AND “surgery” AND “open surgery” AND “arthroscopy”

Quality of the evidence

Level I

- 1 Cochrane review
- 1 systematic review/meta-analysis
- 2 RCTs

Findings

Coghlan et al. found a “silver” level of evidence from six trials that there are no significant differences in outcome

between arthroscopic and open subacromial decompression, although four trials reported earlier recovery with arthroscopic decompression.⁴⁶ A more recent meta-analysis by Davis et al. (nine studies) came to the same conclusion.⁵³ Open arthroscopy, however, was associated with longer hospital stays (2.3 days, $p = 0.05$) and a greater length in time until return to work (65.1 days) compared with the arthroscopic technique (48.6 days, $p < 0.05$). In an RCT published by Henkus et al., arthroscopic subacromial bursectomy alone was compared with debridement of the subacromial bursa followed by acromioplasty. At a mean follow-up of 2.5 years no significant differences were found between the two treatments.⁵⁴ There was no significant difference in occurrence of adverse events between the various techniques. Only mobility was sometimes reported to return earlier after arthroscopic surgery.⁵⁵⁻⁶¹

Recommendations

- There is no evidence supporting a difference in long-term outcome of arthroscopic over open subacromial decompression [overall quality: moderate]
- Arthroscopic subacromial decompression may lead to earlier recovery than open acromioplasty [overall quality: moderate]
- Bursectomy alone has an effect equal to decompression with acromioplasty [overall quality: moderate]

Question 8: What is the effect of treatment on shoulder function and recovery?

Relevance

SIS can have a profound impact on quality of life as well as on working ability. Many studies show a negative effect of workers' compensation on the outcome of interventions.

Current opinion

Pain and impairment diminish significantly after therapy for SIS, but heavy overhead work increases chances of recurrence.

Finding the evidence

- PubMed search: "shoulder", "rotator cuff", "impingement", "work", "sick leave", "disability"

Quality of the evidence

Level I

- 4 systematic reviews

Findings

Chronic shoulder impingement results in significant functional disability and a reduction in quality of life.⁶² Many articles demonstrate that compensation status of individuals who underwent shoulder surgery continues to be a

positive predictor of poor functional outcome. However, cohort studies of workers with shoulder complaints in occupational settings show strong evidence for predicting poorer outcome for the middle-aged (45–54 years).⁶³ Although 30% of all workers with shoulder pain reported sick leave during follow-up, for most workers the duration of sick leave was only a few days. There is limited evidence that arthroscopic acromioplasty is more effective than open acromioplasty in terms of time to return to work.⁵⁹ A systematic review summarizing 28 studies showed a strong link between workers' compensation status and poor outcome after shoulder surgery.⁶⁴ Faber et al. found a low correlation between functional outcomes and limitations for returning to work, and found that duration of sick leave was seldom included in the outcome scores.⁴⁵

Recommendations

- The effect of workers' compensation on the outcome of interventions for SIS is influenced by countries' social security systems and outcome measures [overall quality: moderate]⁴⁵
- Studies with duration of sick leave or work status as outcome measures provide evidence with regard to effectiveness similar to studies using functional limitations as outcome measure [overall quality: moderate]⁴⁵
- There is a strong link between workers' compensation status and poor outcome after shoulder surgery [overall quality: moderate]

Question 9: What are the complications associated with interventions for SIS?

Relevance

As there is no evidence supporting the use of one therapy or intervention above another, the chances of adverse effects can be an important factor in choice of therapy.

Current opinion

Side effects of surgery include prolonged pain, infection, difficulty moving the shoulder after the operation, wasting of the shoulder muscle, and the need to have another surgical procedure. Side effects for subacromial steroid injections could be degeneration and rupture of the rotator cuff and septic arthritis.

Finding the evidence

- PubMed, using search terms: "septic arthritis shoulder", "glenohumeral joint", "adverse outcome impingement surgery"

Quality of the evidence

- 1 Cochrane review
- 1 meta-analysis

Findings

Complications of surgical therapy A Cochrane review summarized adverse events of three trials comparing open with arthroscopic acromioplasty (arthroscopy group n = 74, open group n = 75).⁴⁶ The most-reported adverse event was postoperative pain (12% each group, n = 9), followed by stiffness/capsulitis (12% arthroscopy group, n = 9) and 4% open group, n = 3). Atrophy of the deltoid muscle was reported for 3% of patients in the arthroscopy group (n = 2). One deep wound infection was reported for the arthroscopy group and one superficial wound infection for the open group. In a meta-analysis performed by Davis et al. (nine studies) no significant differences were found in complications between the open and arthroscopic acromioplasty groups.⁵³

Other surgical pitfalls include not addressing the entire pathology and doing an incomplete or excessive decompression. Spanghel et al. published the results of a randomized controlled trial which compared arthroscopic (n = 32) with open (n = 30) acromioplasty.⁶⁰ Repeat (open) acromioplasty was performed in five patients (16%) in the unsuccessful arthroscopic group without improvement. Unsatisfactory results were reported up to 52% for arthroscopic subacromial decompression.⁶⁵ Inadequate decompression was noted in 14 of 20 failed patients. Rehabilitation pitfalls include prescribing the wrong exercises at the wrong time and omitting steps in the rehabilitation process.⁶⁶

Complications of injection therapy It is probably not possible to identify safety issues such as tendon rupture in a series of clinical trials. Iatrogenic septic arthritis has an estimated incidence of 1 in 14,000–50,000 injections, with sometimes dramatic consequences.^{67,68} Aseptic procedures are advised when injecting corticosteroids.

Recommendations

- There is only low evidence concerning the complications of surgical treatment of SIS [overall quality: low]
- A 4%–12% incidence of postoperative stiffness is mentioned in studies [overall quality: low]
- There is conflicting evidence of the complication rates in arthroscopic compared to open surgery [overall quality: low]
- Poor outcome or recurrence is mentioned most often (up to 52%) [overall quality: moderate]
- Septic arthritis after steroid injections has dramatic consequences [overall quality: low]
- An aseptic technique is advised [overall quality: very low grade]

Summary of recommendations

- The Hawkins–Kennedy test is a useful and reliable screening test for SIS

- US may be the most cost-effective diagnostic method
- MRI or US could be equally used for impingement syndrome and rotator cuff tears
- There should be serious doubt about the placebo effect of “puncturing the painful area” versus the systemic effect of corticosteroids
- ESWT can have an effect on radiologic calcific tendinosis
- Surgical treatment of patients with SIS is not superior to conservative treatment
- There is no evidence supporting a difference in outcome after arthroscopic over open subacromial decompression or arthroscopic bursectomy

Conclusions

SIS is a common disorder, with an impact on quality of life and ability to work. Although patients are offered different treatment modalities sequentially during the period of the disability, no evidence for a difference in outcome between those modalities, i.e., physical therapy, subacromial steroid injection, and surgery (acromioplasty), can be found. Although the association of workers' compensation cases with inferior outcomes can be influenced by the different outcome measures and different social systems, there seems to be no evidence for the effect of therapeutic interventions on return to work. From a cost-effectiveness perspective, steroid injections, and home exercises are to be preferred to physical therapy and surgery.

Pathology of the Long Head of the Biceps

Paul W.L. ten Berg, Luke S. Oh, and David Ring

Massachusetts General Hospital, Boston, MA, USA

Case scenario

A 58 year old self-employed electrician who was diagnosed with long head of biceps brachii (LHB) tendinopathy 6 months ago on his dominant shoulder now presents with increased pain after putting together a swing set in his back yard. On examination, he is tender over the bicipital groove and has a positive Speed's test, Yergason's, O'Brien's, Neer, and Hawkins signs, and no lag signs or weakness of the rotator cuff.

Relevant anatomy

The LHB tendon originates from the posterosuperior labrum and the supraglenoid tubercle. The proximal portion of the LHB tendon is intra-articular but extrasynovial. It passes obliquely within the shoulder joint, arching anteriorly over the humeral head before entering the bicipital groove. The exact role of the LHB in the glenohumeral joint is debated. Some believe that the biceps muscle is an important depressor of the humeral head against proximal migration.

Importance of the problem

LHB tendinopathy is a common cause of shoulder pain, although its incidence remains unknown.¹ It is generally

encountered in concert with rotator cuff tendinopathy in older individuals or overhead athletes.

Top seven questions

Diagnosis

1. How accurate are clinical examination maneuvers for the diagnosis of biceps tendinitis?
2. What is the role of images studies in the diagnosis of proximal biceps pathology?

Therapy

3. Is there a role for nonoperative treatment?
4. What are the indications for surgical treatment?
5. What is involved in the decision-making to perform a biceps tendon debridement vs. tenodesis vs. tenotomy?
6. Is there an advantage to arthroscopic over open biceps tenodesis?
7. Is any one operative technique superior to another?

Question 1: How accurate are clinical examination maneuvers for the diagnosis of biceps tendinitis?

Clinical examination maneuvers used in the office setting for the diagnosis of biceps tendinitis include bicipital groove palpation and the Speed, Yergason, and O'Brien tests (see box).

Physical examination tests

- **Bicipital groove palpation:** In case of LHB pathology patients are usually tender directly over the biceps tendon, as it exits the intra-articular space, through the intertubercular groove, and down to a point approximately 7 cm below the acromion while the arm is internally rotated 10°.²
- **Speed test:** The externally rotated (supinated) arm with an extended elbow is forward elevated. The examiner resists this forward elevation of the arm while palpating the patient's biceps tendon over the anterior aspect of the shoulder. Pain felt in the bicipital groove indicates biceps tendon pathology.³
- **Yergason test:** A test for evaluation of biceps tendon pathology in which supination of the forearm is resisted. The elbow is flexed to 90° and the patient is asked to resist while externally rotating the arm. The test is considered positive if this resistance produces pain referred to the bicipital groove.⁴
- **O'Brien test:** O'Brien's active compression test is designed to maximally load and compress the acromioclavicular joint and bicipital labral complex. The patient is instructed to flex their arm to 90° with the elbow fully extended and then adduct the arm 10–15° medial to the sagittal plane. The arm is then internally rotated (pronated) and the patient resists the examiner's downward force. The procedure is reiterated in supination. The test is positive if pain appears in maximal internal rotation, then disappears in external rotation. It is a common test for detecting acromioclavicular joint and superior labral pathology.⁵

Relevance

It can be difficult to isolate the precise cause of shoulder pain.

Current opinion

Most shoulder surgeons believe they can distinguish pain from the LHB from other types of shoulder pain.

Finding evidence

- Cochrane Database, with search term: "shoulder examination"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: "biceps tendon" AND "tests", "biceps tendon" AND "speed"/"Yergason"/"O'Brien"/"groove test"
- Bibliography of eligible articles

Quality of the evidence*Level I*

- 1 prospective blinded study of consecutive patients¹¹

Level II

- 1 randomized cohort study⁹
- 3 prospective nonrandomized clinical trials^{7,12,15}
- 4 cohort studies^{6,8,13,14,16}

Level IV

- 1 diagnostic study with poor reference standard¹⁰

Findings

Table 90.1 summarizes the findings in the literature. For diagnosis of LHB pathology, tenderness in the bicipital groove has a sensitivity of 53 and a specificity of 54; Speed's test has a sensitivity from 32 to 69 (with one outlier of 90) and a specificity from 48 to 75 (with one outlier of 14); Yergason's test has a sensitivity of 43 and a specificity of 79; and O'Brien's test has an average sensitivity of 48 and a specificity of 47.

Recommendation

- Physical examination maneuvers have limited ability to diagnose biceps pathology [overall quality: moderate]

Question 2: What is the role of imaging in the diagnosis of proximal biceps pathology?**Case clarification**

The patient's MRI demonstrated fluid surrounding the biceps tendon in the bicipital groove, with signal changes interpreted as tendinopathy and possible partial tear. There was no evidence of rotator cuff tear.

Relevance

Ultrasound and MRI are often used to diagnose LHB tendinopathy.

Current opinion

Management decisions are often based on the findings of radiological tests.

Finding the evidence

- Cochrane Database, with search term: "shoulder" AND "imaging"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "biceps tendon" AND "ultrasound"/"MRI"/"MRA"; "shoulder" AND "ultrasound"/"MRI"/"MRA"
- Bibliography of eligible articles

Quality of the evidence*Level I*

- 2 independent, blinded comparisons with a reference standard among consecutive patients with a defined clinical presentation^{20,21}

Speed combined with Yergason test				
<i>LHB tendon pathology combined with superior labrum pathology</i>				
Holtby 2004 ¹¹	152 patients	56/63	Arthroscopy	42 biceps pathology or SLAP lesions

LHB, long head of biceps; SIS, subacromial impingement syndrome; SLAP, superior labrum anterior–posterior.

Level II

- 7 independent blinded comparisons with a reference standard among nonconsecutive patients or confined to a narrow population of study patients^{9,24–27,29,30}

Level IV

- 1 independent unblinded comparison with a reference standard²²
- 1 independent unblinded comparison with poor reference standard²³

Level V

- 3 expert opinions^{17–19}

Findings

Table 90.2 summarizes the literature regarding imaging diagnosis of LHB pathology. Ultrasound has a sensitivity of 53–100% and a specificity of 97–100% for diagnosis of dislocation, subluxation, and rupture of the LHB tendon. Intracapsular partial tears of the LHB tendon are not detectable. Biceps tendon sheath effusions detected sonographically are not specific to LHB pathology.^{17,18}

The oblique sagittal plane MRI gives the best image of the intra-articular portion of the biceps tendon in the rotator cuff interval. Ruptures are easier to detect than partial tears.¹⁹ Mohtadi et al. (level I) found 60% of the patients whose findings were identified by arthroscopy and MRI as normal or abnormal and 38% of the patients in whom structures were identified exactly according to the classification of pathology on both MRI and arthroscopy.²⁰ MR arthrography has a sensitivity of 67–100% and a specificity of 56–100% for LHB pathology.

Recommendation

- Diagnostic imaging has limited and variable sensitivity and specificity for LHB tendon pathology [overall quality: moderate]

Question 3: Is there a role for nonoperative treatment?

Relevance

Physical therapy and selective cortisone injections are commonly used to treat LHB pathology.

Current option

Physical therapy and associated modalities may offer symptom relief as well as exercises and patient education regarding activity modification. Selective cortisone injections offer the advantage of providing useful diagnostic information regarding the location of pain as well as therapeutic benefit.

Finding the evidence

- Cochrane Database, with search term: “shoulder” and “physiotherapy”/“injections”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords as above

Quality of the evidence

Level II

- 2 reviews using randomized or pseudo-randomized controlled trials^{31,32}

Level IV

- 1 case series³³

Findings

There is no data on physical therapy or selective cortisone injections in the treatment of LHB tendon pathologies.

A review of the Cochrane collaboration (level II) using 26 trials of physiotherapy for shoulder conditions stated that there was some evidence for combining mobilization with exercise in rotator cuff disorders, but did not find any studies specific to LHB pathology.³¹

Another Cochrane review (Level II) including 26 trials showed some weak evidence for rotator cuff disease that corticosteroid injections were superior to physiotherapy.³²

A case series (level IV) from 1979 reported seven LHB tendon ruptures in patients with an average age of 65 years after local steroid injection (triamcinolone hexacetonide) for bicipital tendinitis (average interval injection to rupture was 3 weeks). However, the author mentioned that it is likely that the tendons which ruptured were already in a state of degeneration that predisposed to their rupture.³³

Recommendation

- There is no evidence of superiority of one nonoperative treatment over other treatment modalities [overall quality: very low]

Question 4: What are the indications for surgical treatment of a LHB rupture?

Relevance

There is no consensus regarding when to offer surgical treatment.

Current option

Tenodesis may be considered for an acute LHB rupture in an active individual

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “tenodesis” AND “biceps” AND “rupture”; “biceps” AND “rupture”
- Bibliography of eligible articles

Quality of the evidence

Level III

- 2 case-control studies^{35,36}

Table 90.2 Imaging trials for tendon pathologies and sensitivity/specificity rates

Test, author, and year	Examiner/overall	Sample size	Sensitivity/specificity%	Criterion standard	Positive by criterion standard
Ultrasound in LHB tendon pathology					
Kayser 2005 ²¹	Average	239 patients	53/97		8 LHB dislocations, 15 LHB ruptures
Teefey 2000 ²²		100 shoulders	64/99	Arthroscopy	11 LHB ruptures
			83/100		6 LHB dislocations
Read 1998 ²³		42 patients	80/100	Open surgery / arthroscopy	10 LHB tendinitis (extracapsular)
			100/100		2 LHB dislocations
			75/100		4 LHB ruptures
Armstrong 2006 ²⁴		71 patients	0.0/92	Arthroscopy	23 LHB partial tears (intracapsular)

Level IV

- 1 case series³⁴

Findings

Evaluation (level IV) of 25 patients (all >40 years of age) an average of 7.9 years after complete rupture of the LHB tendon found few differences between those treated nonoperatively and those treated operatively.³⁴ Only one patient complained about a cosmetic deformity. Muscle examination (with the Cybex II testing machine) of 19 patients found no significant differences in supination or elbow flexion strength in the two groups.

A similar study (level III) investigated the strength difference by using the Cybex II testing machine in 10 conservatively treated patients and 5 surgically treated patients after LHB tendon rupture, compared to 20 healthy individuals.³⁵ Nonoperatively treated patients had an average of 16% less elbow flexion strength, 11% less supination strength, and 16% less shoulder abduction compared to the healthy controls. The surgically treated patients lost 8% elbow flexion strength, 7% supination strength, and 20% of shoulder abduction strength.

In third study (level III), 26 patients treated operatively were compared to 30 patients treated nonoperatively a mean of 13 and 4.6 years respectively after LHB tendon rupture.³⁶ Biomechanical testing was performed on 10 patients in the surgical group and 13 in the nonsurgical group. Residual subjective weakness at the elbow was reported in 15.4% (4) of the surgical group and in 66.7% (20) of the nonsurgical group. Of the nonsurgical patients 36.7% (11) were not able to return to full work capacity, vs. only 7.7% (2) in the surgical group. The nonsurgical group had lost a mean of 21% of supination strength and 8% of elbow flexion strength but had no weakness in grip, pronation, or elbow extension. The surgical group had lost no significant strength in any of these testing modes.

Recommendation

- The role of surgery for LHB rupture is unclear [overall quality: very low]

Question 5: When operative treatment is elected for LHB tendinosis, which is better: biceps tenotomy or tenodesis?

Relevance

The optimal treatment of tendinosis of the LHB is debated.

Current opinion

Tenotomy or tenodesis are considered when there is a partial tear, significant tenosynovitis, subluxation, or dislocation. Tenotomy is a good option in the less active patient and in those patients who would accept having a "Popeye" sign. Tenodesis is becoming a more popular option, particularly in the younger and more active patient population.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "biceps" AND "tenotomy" AND "tenodesis"
- Bibliography of eligible articles

Quality of the evidence*Level III*

- 3 case-control studies⁴⁰⁻⁴²

Level IV

- 4 case series^{37-39,43}

Findings

Data from three retrospective case series that assessed tenotomy were pooled together (N = 377), with 73% of the patients achieving good/excellent outcome or satisfaction, but in 58% a Popeye sign (deformity of the biceps) was visible and 16% of the patients had a poor outcome.³⁷⁻³⁹

In case-control studies comparing both treatments, there were no significant differences between tenotomy and tenodesis in clinical assessment (N = 281, with mean follow-up interval >15 months) except for greater deformity in the tenotomy group.⁴⁰⁻⁴² Within a total group of 129 patients with tenotomy, 30% had a severe cosmetic deformity or noticeable Popeye sign vs. less than 5% in the tenodesis group (N = 152). However, Boileau (level III) mentioned that the Popeye sign was not a concern for any patient.⁴¹

In one case series (level IV) 40 patients were treated with tenotomy and the muscle force for elbow flexion-supination was decreased by 40% compared with age-, sex-, and dominance-matched controls. Nevertheless, 86% of the patients were satisfied with the outcome.⁴³

Paulos and Franklin (level III) noted for 20% within the tenotomy group (N = 39) a near normal strength in the affected arm, and 64% within the tenodesis (N = 33) group.⁴¹ Boileau et al. (Level III) compared the preoperative Constant strength score with the final Constant strength score and noticed no significant difference between both tenotomy and tenodesis groups.⁴²

Recommendation

- There are insufficient data to determine the optimal operative treatment for LHB tendinopathy [overall quality: low]

Question 6: Is there an advantage to arthroscopic over open biceps tenodesis?

Relevance

The optimal tenodesis approach is debated, i.e., arthroscopic biceps tenodesis (proximal) vs. open biceps tenodesis (distal).

Current opinion

The surgical approach is based on the physician's preferences and skills.

Findings in evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "biceps" and "tenodesis"
- Bibliography of eligible articles

Quality of the evidence

Level III

- 1 case-control study⁴¹

Level IV

- 4 case series⁴⁴⁻⁴⁷

Findings

Paulos and Franklin (level III) compared 22 patients treated with arthroscopic wedge tenodesis and 17 treated with open keyhole tenodesis. All patients were satisfied and 68% of the wedge group and 59% of the keyhole group had near normal strength. Tenderness to palpation in the proximal biceps groove was present in 23% and 6% of each group respectively.⁴¹

Case series of patients treated with arthroscopic tenodesis including bioabsorbable interference screw, suture, and subdeltoid transfer shows an overall rate for good results of 88%.⁴⁴⁻⁴⁷ The highest rate of poor outcome is 5%.

Recommendation

- There are insufficient data regarding tenodesis techniques to determine the optimal approach [overall quality: low]

Question 7: Is one operative technique superior to another?

Relevance

The optimal tenodesis technique is debated: e.g., deltopectoral approach vs. subpectoral approach for an open biceps tenodesis; "keyhole" technique vs. soft tissue tenodesis vs. metal suture anchor vs. bioabsorbable suture anchor.

Current opinion

Several tenodesis techniques are described in the treatment of LHB pathologies and are related to the preference and skills of the surgeon.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/)—sensitivity search using keywords "biceps tenodesis"; "bicep*" AND "tenodesis" AND "tendon"
- Bibliography of eligible articles

Quality of the evidence

Level III

- 2 case-control studies^{44,48}

Level IV

- 6 case series^{45-47,49-51}

Findings

A comparative study (level III) investigated the results after open subpectoral biceps tenodesis with either interference screw fixation (N = 34) or suture anchor fixation (N = 54) (mean follow-up interval 13 months). No significant difference between the two procedures was noted. There were no failures of fixation and no complications postoperatively.⁴⁸

Franceschi et al. (level III) compared two cohorts: soft tissue tenodesis incorporated with rotator cuff suture (N = 11) and the same treatment with an extra resection of the remaining intra-articular tendon stump of the biceps from glenoid tubercle (N = 11). Both groups had a 100% good to excellent outcome and no significant difference in the total UCLA scores was found when comparing treatments performed with or without additional tenotomy.⁴⁴

Two studies included respectively 40 and 15 patients for two different soft tissue tenodesis techniques: arthroscopic subdeltoid transfer of the LHB tendon to its conjoint tendon and arthroscopic stay suture integrated with the rotator cuff (mean interval of respectively 28 and 32 months). Good to excellent results were noted in over 80% and poor outcomes in less than 5%.^{46,47}

Mazzocca et al. and Boileau et al. both used bioabsorbable interference screws but different approaches: open subpectoral (N = 41, mean follow-up interval of 29 months) and arthroscopic (N = 43, mean follow-up interval of 17 months).^{49,50} Mozzocca et al. (level IV) noticed one case of tendon pulled out from the bone tunnel. However of the 56% of patients who had completed preoperative and postoperative assessments, all clinical outcome measures demonstrated statistically significant improvement at follow-up when compared with the preoperative scores. Boileau et al. (level IV) observed an average significant postoperative improvement of the Constant score and only 5% of the patients had a poor result. There was no loss of elbow movement and biceps strength was 90% of the strength of the other side.

A study (level IV) including 10 patients investigated the suture anchor technique (mean follow-up interval of 24 months).⁴⁵ In this study 90% had good to excellent outcome and there was 100% satisfaction with cosmetic results.

With a relatively large mean follow-up interval of 84 months, Berlemann and Bayley (level IV) noticed a 60% rate of good to excellent outcome in 15 patients treated with keyhole tenodesis;⁵¹ 13% had a poor outcome at final follow-up.

Recommendation

- Clinical data does not show large differences between attachments techniques [overall quality: low]

Summary of recommendations

- Physical examination maneuvers have limited ability to diagnose biceps pathology
- Diagnostic imaging has limited and variable sensitivity and specificity for LHB tendon pathology
- There is no evidence that any one nonoperative treatment modality is superior to any other
- The role of surgery for LHB rupture is unclear
- There are insufficient data to determine the optimal operative treatment for LHB tendinopathy
- There are insufficient data regarding tenodesis techniques to determine the optimal approach
- Clinical data does not show large differences between attachments techniques

Conclusions

Physical examination and imaging have low sensitivity in the detection of LHB tendon pathologies, and therefore have less diagnostic value. At present, there is a paucity of high-quality evidence with regard to surgical approach and treatment. Trials with long follow-up interval are desirable for decision-making about treatment. No significant differences can be found, except for the cosmetic deformity which is more likely to occur after tenotomy.

Denise Eygendaal¹ and Laurens Kaas²

¹Amphia Hospital, Breda, The Netherlands

²Orthopaedic Research Center Amsterdam, Academic Medical Center, Amsterdam, The Netherlands

Case scenario

A 23 year old professional athlete (baseball pitcher) has been complaining about his right elbow for 6 months. The pain is medial sided and the onset of the symptoms was gradual. A wrong pitch 5 months ago has severely increased the pain, resulting in an inability to pitch. At physical examination there is a slight extension deficit of 10°, a positive moving valgus test and a positive milking test.¹ This test can identify partial tears of the ulnar collateral ligament (UCL) by extending the elbow from the fully flexed position, while the examiner exerts a valgus moment by grasping the thumb and resisting extension. The patient has no neurovascular symptoms.

Relevant anatomy

Stability of the elbow is attained by dynamic and static constraints. Static or passive constraints are provided by both the bones and the soft tissues of the elbow. The role of the muscles as dynamic constraints is becoming increasingly clear and is probably larger than previously postulated. The relative role of the osseous and soft tissue restraints are shown in Table 91.1.

The UCL consists of an anterior and a posterior bundle, and a transverse ligament (also known as the Cooper ligament). The anterior and posterior bundles originate from a broad anteroinferior surface of the medial humeral epicondyle. The anterior bundle inserts the base of the coronoid process of the ulna and the posterior bundle inserts the medial part of the semilunar notch of the ulna. The mean length of the anterior UCL is 27.1 mm and that of

posterior UCL 24.2 mm, and the mean widths are about 4.7 mm and 5.3 mm respectively. The function of these ligaments is to restrain valgus stress during extension (anterior bundle) and during flexion (posterior bundle). Studies reveal that the anterior medial collateral ligament can be subdivided into three regions or bands according to their function (see Figure 91.1).³⁻⁵

Importance of the problem

Injury to the UCL was first recognized in 1946 in javelin throwers.⁶ The injury has since become well recognized in baseball pitchers and other overhead throwing athletes. However, exact numbers or incidence of this injury in athletes or in the general population are not known. The three most common causes of UCL injury are elbow dislocation, chronic attenuation in athletes, or acute valgus injury. The elbow joint is the second most commonly dislocated major joint after the shoulder. In children it is the most commonly dislocated joint.⁷ The incidence of this dislocation is estimated to be 6/100,000 in the general population, usually in the posterior or posterolateral direction.⁸ Josefsson⁹ showed that elbow dislocation induced injury in the lateral as well as the medial ligamentous structures, whereas O'Driscoll¹⁰ demonstrated that the joint could be dislocated experimentally with preservation of the medial ligaments. During dislocation ligamentous injury occurs in a lateral to medial circle. In stage 1, the radial collateral ligament is disrupted; in stage 2, the other lateral ligamentous structures as well as the anterior and posterior capsule are disrupted. In stage 3, disruption of the medial collateral ligament can be partial with disruption of the posterior bundle only (3A) or complete (3B).¹⁰ The UCL can therefore

Table 91.1 Relative contribution to valgus stress resistance (%)²

	Extended	90° elbow flexion
MCL	31	56
Soft tissue, capsule	38	10
Osseous articulation	31	34

**Figure 91.1** The UCL complex consists of an anterior (1) and a posterior (2) bundle, and a transverse ligament.

be disrupted after dislocation of the elbow joint. Persistent valgus instability after conservative treatment of elbow dislocation has been described in up to 50% of cases. It is related to degenerative changes of the elbow joint after an average follow-up of 9 years.¹¹

Top five questions

Diagnosis

1. Is UCL insufficiency a problem frequently encountered in general orthopedic practice?
2. As the clinical instability of the elbow is underestimated in most cases, what is the gold standard for the evaluation of the UCL?

Treatment

3. Should (professional) athletes with an acute injury of the UCL always be treated surgically?
4. What are the surgical treatment options?

Prognosis

5. Does surgical reconstruction of the UCL prevent accelerated degeneration of the elbow joint?

Question 1: Is UCL insufficiency a problem frequently encountered in general orthopedic practice?

Case clarification

The patient was treated in an upper limb unit specializing in sports medicine. In a general orthopedic practice with a small number of sports-related injuries or post-traumatic deformities of the elbow, the incidence is low. In those situations the “doctor’s delay,” due to unfamiliarity with UCL injury, can be an issue.

Finding the evidence

- Cochrane Database: No reviews available
- PubMed: No reports on incidence on UCL injury of the elbow in the general population or in throwing athletes.

Findings

There are no scientific reports on the incidence of UCL injury in throwing athletes or the general population. One study found an incidence of UCL lesions in 33% of 490 baseball players who underwent rehabilitation for any kind of injury of the upper extremity.¹² As previously mentioned, persistent valgus instability after conservatively treated elbow dislocations has been described in up to 50% of cases.¹¹ In up to 54% of patients with a radial head fracture a UCL lesion is diagnosed with MRI, although the incidence of clinical relevant UCL injuries is much lower (1–8%).^{13–16} Orthopedic surgeons should think of UCL insufficiency in patients with medial-sided elbow pain, especially in athletes and in patients with post-traumatic conditions of the elbow as a posterolateral dislocation.

Recommendations

- UCL insufficiency of the elbow has been mainly reported in athletes and in patients with post-traumatic conditions of the elbow as a posterolateral dislocation, although the incidence in the general (or athlete) population is unknown [overall quality very low]

Question 2: As the clinical instability of the elbow is underestimated in most cases, what is the gold standard for the evaluation of UCL injury?

Case clarification

In the case described above, the history was very suggestive for UCL injury. Apparently this athlete had ruptured the UCL 5 months ago, but this injury had subsided; after a new event, the “chronic rupture” of the UCL

became symptomatic again. Physical examination revealed a positive milking maneuver; the MRI with arthrogram (MRA) revealed a detachment of the UCL on the humeral side.

Current opinion

AP, lateral, and axillary views of the elbow are assessed for degenerative changes such as joint space narrowing, ossification of the UCL, and loose bodies. A small bony avulsion fragment might be identified when a UCL bony avulsion exists.

Finding the evidence

- Cochrane Database: No reviews available
- PubMed: 7 reports on MRA in UCL pathology and 2 reports on CTA in UCL pathology

Quality of the evidence

Level IV

- 6 case series

Level V

- 2 expert opinion

Findings

Dynamic radiographs under valgus load have been described in the past as a useful diagnostic tool; however, mild valgus laxity has been observed in uninjured overhead athletes, and dynamic radiographs in symptomatic elbows seems to be inconsistent.^{17,18} Another imaging modality is CT with arthrogram (CTA), with a sensitivity of 86% and a specificity of 91%.¹⁹ However, the preferred imaging technique for UCL injuries of the elbow is MRA. MRI is capable of identifying full thickness tears, and MRA improves the diagnosis of partial tears.^{18,20-23} Another advantage of MRI/MRA is the ability to identify associated pathology, such as medial epicondylitis and chondral lesions. The sensitivity of MRA is reported to be up to 97% in detecting UCL injury, including partial undersurface UCL tears, with a specificity of up to 100%.^{19,24,25} No comparative studies of CTA and MRA are currently available.

Recommendation

- MRA is the preferred imaging technique for detection of UCL injuries of the elbow [overall quality: very low]

Question 3: Should (professional) athletes with an acute injury of UCL always be treated surgically?

Case clarification

Treatment of UCL of the elbow injuries is based on the patient's athletic demands and the degree of UCL injury.

In this case, initial conservative treatment consisted of rest, anti-inflammatory measures, and physical therapy.

Finding the evidence

- Cochrane Database: No reviews on conservative treatment of UCL available
- PubMed: 1 report on conservative treatment of UCL injury of the elbow

Quality of the evidence

Level IV

- 1 case series

Findings

Rettig et al.²⁶ was the first to report on the results of conservative treatment in throwing athletes. Phase I of the conservative treatment consisted of rest and modalities to treat symptoms for 2–3 months. If pain free, the athlete began with phase II which consisted of muscle strengthening and throwing. Thirteen of 31 athletes (42%) returned to same level of play, with an average return of 24 weeks after injury after conservative treatment. This rehabilitation period is shorter than the rehabilitation period after UCL reconstruction. No history or physical examination features are predictive for athletes who will respond to no nonoperative treatment.

Recommendations

- Treatment of UCL injuries is based on the patient's athletic demands and the degree of UCL injury. [overall quality: very low]

Question 4: What are the surgical treatment options?

Current opinion

Persistent symptomatic UCL instability after initial conservative treatment is an indication for reconstruction.

Finding the evidence

- Cochrane Database: Noreviews available on results of UCL reconstruction
- PubMed: 17 reports available on results of UCL reconstruction

Quality of the evidence

Level I

- 2 systematic reviews

Level IV

- 14 case series

Level V

- 1 expert opinion

Findings

The first successful UCL reconstruction was performed in 1974 by Dr. Frank Jobe and colleagues. They published their initial results in throwing athletes in 1986, using the palmaris longus tendon as an autograft, with detachment of the flexor-pronator musculature, submuscular transposition of the ulnar nerve, and a figure-of-eight graft fixation technique. In this fixation technique the autograft is placed through two drill holes in the ulna and three in the medial epicondyle in a figure-of-eight fashion, going through the posterior humeral cortex and suturing the graft to itself.²⁷ Several modifications of this original technique have been introduced over the past 35 years. Muscle splitting instead of detachment, and abandoning the obligatory ulnar nerve transposition, have improved clinical results and decreased the complication rate.^{28,29} The introduction of the docking technique by Rohrbough et al.³⁰ allows easier graft passing, tensioning, and fixation. It uses the same ulnar tunnels as in the Jobe technique, but the humeral tunnels are created with one single inferior tunnel, with two small superior and one anterior exit tunnels. The graft is positioned in the inferior tunnel, and tensioned with sutures that exit the superior tunnels. The graft is fixated by tying the sutures over a bony bridge. Another graft fixation technique is interference screw fixation, where one or both graft endings are fixed with a bioabsorbable interference screw.^{24,31} Different autografts have been described: the palmaris longus tendon, plantaris tendon, hamstrings tendon, tendon allografts, or triceps tendon can be used.^{28,31} Ulnar decompression or transposition can be indicated in patients with symptoms of ulnar nerve irritation, which is present in more than 40% of patients with UCL insufficiency.¹⁷ Additional diagnostic arthroscopy can be performed if intra-articular pathology is suspected.^{24,30} After surgery a long-arm cast is applied for 1–2 weeks to allow wound healing. Some authors use an additional hinged brace during mobilization for 2–6 weeks. Strengthening exercises (with or without brace) are initiated after 4–6 weeks. Throwing is usually allowed after 2–5 months. Return to competition varies from “when ready” to 12 months after surgery.^{24,32–36} The original report on UCL reconstruction by Jobe et al. reported excellent results in 63%.²⁷ With the improvement of the surgical technique, success rates increased: 74–95% of all athletes returned to their previous level of injury or higher.^{17,35,37} Previous surgery for UCL insufficiency is associated with poorer results.^{17,18} The most frequent reported complication is a transient ulnar neuropathy, which occurs in 1–21% of patients, with a mean of 6%. About 1% of patients experience graft site complications.²⁸ In this case UCL reconstruction is advised, if conservative treatment under supervision of a specialized physiotherapist for 3 months is not successful.

Recommendations

- Symptomatic UCL insufficiency is indication for reconstruction. Reconstruction of a nonsymptomatic UCL injury is not indicated [overall quality: very low]
- The preferred surgical techniques are the docking technique or interference screw fixation [overall quality: very low]
- Injury to the UCL of the elbow was once a career-ending injury in overhead athletes, but UCL reconstruction has made return to previous or higher level of athlete participation in sports likely [overall quality: very low]

Question 5: Does surgical reconstruction of the UCL prevent accelerated degeneration of the elbow joint?

Current opinion

Persistent valgus instability can be related to accelerated degeneration of the elbow joint. The question of whether surgical reconstruction of the UCL can prevent accelerated degeneration of the elbow has not yet been answered.

Finding the evidence

- Cochrane Database: No reviews available on prevention of degeneration with UCL reconstruction
- PubMed: No reports available on prevention of degeneration with UCL reconstruction

Findings

Symptomatic UCL insufficiency is indication for reconstruction; a reconstruction of UCL to prevent further damage to the joint in the future is not indicated. Reconstruction of a nonsymptomatic UCL injury is not indicated.¹¹

Recommendations

- A reconstruction of the UCL to prevent further damage to the joint in the future is not indicated [Overall quality very low]

Summary of recommendations

- UCL insufficiency of the elbow has mainly been reported in athletes and in patients with post-traumatic conditions of the elbow as a posterolateral dislocation, although the incidence in the general (or athlete) population is unknown
- MRA is the preferred imaging technique for detection of UCL injuries of the elbow
- Treatment of UCL injuries is based on the patient's athletic demands and the degree of UCL injury
- Symptomatic UCL insufficiency is indication for reconstruction. Reconstruction of a nonsymptomatic UCL injury is not indicated

- The preferred surgical techniques are the docking technique or interference screw fixation
- Injury to the UCL of the elbow was once a career-ending injury in overhead athletes, but UCL reconstruction has made return to previous of higher level of athlete participation in sports likely
- A reconstruction of the UCL to prevent further damage to the joint in the future is not indicated

Conclusions

Research on diagnosis and treatment of UCL injury should continue to find higher levels of evidence. Prospective studies to determine preferable diagnostic technique, best graft fixation techniques, and long-term results of conservative and surgical treatment are in demand.

Case scenario

Case 1

A 45 year old woman who generally works at a supermarket is unable to do her job any more. She comes to your orthopedic practice with complaints of pain at the lateral side of her right, dominant, elbow. The complaints have been present for 3 months and do not seem to decrease in intensity. The strength in her right arm seems decreased, possibly due to pain. At physical examination she has pain with pressure on the origin of the common extensor tendon of the wrist at the lateral epicondyle of the humerus. There is pain on active dorsiflexion of the wrist. She is neurovascularly intact.

Case 2

A 48 year old man presents to your orthopedic outpatient clinic with pain at the lateral side of his elbow.

Relevant anatomy

Tennis elbow is characterized by pain and tenderness over the lateral epicondyle of the humerus, and pain on resisted dorsiflexion of the wrist, middle finger, or both. Pain is located over the origin of common extensor tendon of the wrist, which is a combined origin of the extensor carpi radialis brevis, the extensor digitorum communis, the extensor digiti minimi, and the extensor carpi ulnaris muscles.

Importance of the problem

Lateral elbow pain is a common entity, with a population prevalence of 1–3%.¹ Its peak incidence occurs at 40–50 years of age. In women aged 42–46 years, incidence increases to 10%.^{2,3} In the UK, the Netherlands, and Scandinavia the incidence of lateral elbow pain in general practice is 4–7/1,000 people per year.^{3–5}

In approximately 10% of the patients the complaint will result in sick leave, for a mean period of 11 weeks.⁶ Untreated, the complaint is estimated to last from 6 months to 2 years.^{7–9} Several treatment options are available,¹⁰ including an expectant policy, corticosteroid injections, orthotic devices, surgery, and physiotherapeutic modalities such as exercises, ultrasound, laser, massage, electrotherapy, and manipulations.

The number of Google hits for “tennis elbow” is over 2,500,000.

Top eight questions

Diagnosis

1. Is there a role for additional imaging in tennis elbow?

Therapy

2. What is the effect of a wait-and-see policy?
3. What is the effect of corticosteroid injections?

4. What is the effect of acupuncture?
5. What is the effect of physical therapy?
6. What is the effect of nonsteroidal anti-inflammatory drugs (NSAIDs)?
7. What is the effect of orthotic devices?
8. What is the effect of surgery?

Question 1: Is there a role for additional imaging in tennis elbow?

Case 2 clarification

A 48 year old man presents to your orthopedic outpatient clinic with pain at the lateral side of his elbow. When you tell him it is most likely a tennis elbow he asks you whether he needs a “scan.”

Relevance

Patients in our clinics are becoming more demanding, and will more frequently ask for additional imaging when you confront them with a diagnosis. Knowledge of the usefulness of additional imaging is helpful for healthcare providers in this context. Additional imaging might have diagnostic, prognostic, or therapeutic implications.

Current opinion

No additional imaging is usually performed when a patient presents with tennis elbow.

Finding the evidence

- Cochrane Database of Systematic Reviews, with search term: “tennis elbow”
- PubMed: clinical queries: systematic reviews: “tennis elbow”
- PubMed, using keywords “tennis elbow” AND “ultrasound”; “tennis elbow” AND “MRI”

Quality of the evidence

Level I

- 1 systematic review¹¹
- 5 descriptive studies¹²⁻¹⁵

Findings

MRI A systematic review¹¹ of 7 studies including 148 patients with epicondylitis comprehensively reviewed the literature to identify studies on MRI findings in epicondylitis. The MRI technique was divergent, and the observed pathological changes also varied. The most frequent alteration was a change in the common extensor tendon signal in 90% of the patients (95% CI 84–94%); 14% of the healthy volunteers and 50% of the contralateral elbows showed similar alterations.

One study compared MRI with ultrasound findings in 11 patients with clinically diagnosed tennis elbow.¹² Two readers compared the findings in two sessions, 1 week

apart. Sensitivity for detecting epicondylitis ranged from 64% to 82% for sonography and from 90% to 100% for MRI. Sensitivity ranged from 67% to 100% for sonography and from 83% to 100% for MRI.

Ultrasound Four studies on ultrasound and tennis elbow were identified. The first compared the prognostic and diagnostic value of ultrasound in tennis elbow patients. This randomized controlled trial (RCT) compared the effectiveness of physical therapy, a brace, and a combination of both. No prognostic value was found and diagnostic value showed to be limited: abnormal findings were found in only 75% of the patients.¹³

The second study compared 37 elbows of 22 patients with a clinically diagnosed tennis elbow with 20 elbows of 10 healthy volunteers.¹⁴ Three sonographers/skeletal radiologists performed two sessions. Sensitivity ranged from 72% to 88% and specificities from 36% to 48.5%. A third study¹⁵ compared sonoelastography with clinical examination in 32 consecutively registered patients with symptoms of lateral epicondylitis and 44 asymptomatic elbows of 28 healthy volunteers. The sensitivity of real-time sonoelastography was 100%, the specificity 89%, and the accuracy 94%, with clinical examination as the reference standard. The fourth study compared 26 monosymptomatic, otherwise healthy patients with lateral elbow pain and a diagnosis of lateral epicondylitis and 16 asymptomatic controls. An investigator blinded to study group performed ultrasound. A sensitivity of 95% (95% CI 73–100%) and a specificity of 88% (CI 54–99%) was found for diagnosing lateral epicondylitis.¹⁶

Recommendations

- MRI and ultrasound may support the clinical diagnosis of lateral epicondylitis [overall quality: low]

Question 2: What is the effect of a wait-and-see policy?

Case 1 clarification

A 52 year old female shop assistant presents with a tennis elbow at your orthopedic outpatient clinic. Her family doctor told her the complaint is self-limiting but the problem has now been bothering her for more than 3 months. She asks you if there is no treatment for the complaint that is more effective than her doctor’s wait-and-see policy.

Relevance

Patients do not generally accept a wait-and-see policy and are usually willing to try anything that will relieve their complaints faster. As a physician, it is important to know what treatment option is best for treating the complaints and what the effectiveness of a certain treatment strategy is compared to other strategies.

Current opinion

Several treatment strategies can be used for tennis elbow complaints. Corticosteroid injections, physical therapy, and orthotic devices (braces) are the most commonly used. Newer and/or alternative strategies include acupuncture and extracorporeal shockwave treatment (ESWT). As tennis elbow is a self-limiting condition, a wait-and-see policy *could* be applied. However, if other treatment strategies have advantages for the patient, these *should* be applied.

Finding the evidence

- Cochrane Database, with search terms “tennis elbow,” “epicondylitis,” “epicondylalgia”
- PubMed (<http://www.ncbi.nlm.nih.gov/pubmed/>), clinical queries: “tennis elbow,” “epicondylitis,” “epicondylalgia”
- PubMed (<http://www.ncbi.nlm.nih.gov/pubmed/>): sensitivity search: “tennis elbow”; “epicondylitis”; “lateral humeral epicondylitis,” combined with AND treatment; AND corticosteroid; AND injections; AND brace; AND orthotic device; AND extracorporeal; AND ESWT; AND acupuncture; AND physical therapy; AND physiotherapy; AND surgery

Quality of the evidence

See question 3–8.

Findings

See question 3–8.

Recommendations

A wait-and-see policy can be applied, since tennis elbow is usually a self limiting disease. However, some treatment strategies might have advantages over the wait-and-see policy. For details per treatment: see question 3-8.

Question 3: What is the effect of corticosteroid injections?

We found two systematic reviews (search dates 1999¹⁷ and 2003¹⁸) and three additional RCTs.^{19–21} None of the RCTs evaluated the effects of corticosteroid injections on quality of life or return to work.

Finding the evidence

- See Question 2.

Quality of the evidence

Level I

- 2 RCTs
- 1 systematic review

Level II

- 1 RCT
- 1 systematic review

Findings

Corticosteroid injections vs. placebo/no treatment The first review identified two RCTs comparing corticosteroid injection (1 mL methylprednisoloneacetate) vs. injection of saline solution.¹⁷ The first RCT (29 people in smallest group) found that corticosteroid injection significantly increased short-term global improvement compared with placebo (timescale not further specified; absolute numbers not reported; RR 0.11, 95% CI 0.04–0.33; RR <1 favors corticosteroid injections).¹⁷ This RCT did not measure pain or grip strength. The second RCT (10 people in smallest group) found no significant difference in short-term pain, global improvement, or grip strength. The second review¹⁸ identified one RCT (59 people in the smallest group),²² which compared corticosteroid injection vs. watchful waiting vs. physiotherapy. It found that corticosteroid injection significantly improved people’s “main complaint” and functional disability at 3 and 6 weeks compared with watchful waiting (mean difference in “main complaint” at 6 weeks: 24%, 95% CI 14–35%). It found no significant difference between groups at 12, 26, or 52 weeks (at 52 weeks, mean difference in “main complaint” –9%, 95% CI –19% to +2%).²² The first additional RCT (39 people with symptoms for less than 4 weeks) compared corticosteroid injection vs. a control injection.¹⁹ All patients received rehabilitation. It found that corticosteroid injection significantly improved pain compared with control from 8 weeks to 6 months (improvement on 100-point visual analogue scale was 24.3 with corticosteroid injection vs. 8.9 with control injection; $p = 0.04$; CI not reported). It found no significant difference in other pain outcomes or in grip strength.

Corticosteroid injections vs. physiotherapy We found one systematic review (search date 1999),¹⁷ which included one RCT (53 people in the smallest group; see comment below) comparing corticosteroid injections (1 mL triamcinoloneacetate 1% plus 1 mL lidocaine) vs. physiotherapy (friction massage plus a manipulation technique). It found that corticosteroid injection significantly increased global improvement and pain scores at 6 weeks compared with physiotherapy (global improvement: RR 0.45, 95% CI 0.29–0.69; pain: RR 0.61, 95% CI 0.48–0.78), but found no significant difference in global improvement, pain, or grip strength at 52 weeks.¹⁷ The second review¹² identified one RCT (59 people in the smallest group)²² comparing corticosteroid injection vs. physiotherapy (consisting of nine sessions of ultrasound, deep friction massage, and an exercise program over 6 weeks) vs. no treatment. It found that corticosteroid injection significantly improved the “main complaint” and functional disability at 3 and 6 weeks compared with physiotherapy (at 6 weeks, mean difference in “main complaint” 20%, 95% CI 10–31%). However, there was no significant difference at 12 weeks. At 26 and 52 weeks, corticosteroid injections were significantly less

effective at improving the “main complaint” compared with physiotherapy (at 52 weeks, mean difference in “main complaint” 15%, 95% CI 5–25%).²²

Corticosteroid injections vs. orthoses A review²³ identified one RCT comparing orthoses with corticosteroid injections.²⁴ It found that corticosteroid injection significantly increased the proportion of people rating global improvement as “good” or “excellent” at 2 weeks, but found no significant difference at 6 or 12 months (global improvement rated as “good” or “excellent,” at 2 weeks: 3/37 [8%] pooled results for splint and elbow band vs. 13/19 [68%] with injection, RR 2.9, 95% CI 1.8–5.7; 6 months: 19/37 [51%] vs. 14/19 [74%], RR 0.70, 95% CI 0.46–1.05; 12 months: 22/37 [59%] vs. 13/19 [68%], RR 0.90, 95% CI 0.60–1.03).

Corticosteroid injections vs. oral NSAIDs The review included three RCTs, but because of incomplete reporting of results, only two RCTs were included in the meta-analysis. The first of these RCTs compared naproxen 500mg vs. methylprednisolone 20mg plus lidocaine; and the second RCT compared naproxen 500mg (initial high dose, then 250mg) vs. betamethasone 6mg plus pilocaine plus placebo tablets. Meta-analysis of self-reported perception of benefit found a significant difference at 4 weeks in favor of corticosteroid injection (2 RCTs, subjective assessment of improvement at 4 weeks: RR 3.06, 95% CI 1.55–6.06).²⁵ The third RCT, which was not included in the meta-analysis because of skewed data, found lower pain and functional impairment at 4 weeks in the corticosteroid injection group than in the NSAIDs group (median pain measured from 0 = lowest to 9 = highest [baseline]: 1 with corticosteroids vs. 4 with NSAIDs; significance not reported; median functional impairment measured from 0 = lowest to 9 = highest [baseline]: 0 with corticosteroids vs. 3 with NSAIDs; significance not reported).²⁶ The greater benefit of corticosteroid injection compared with NSAID (naproxen) was only found in the short term (up to 4 weeks). The largest RCT (53 people in smallest group; see comments) found significantly greater improvement in pain at 26 weeks with an NSAID (RR 1.71, 95% CI 1.17–2.51). It found no significant difference in grip strength, and results were not reported for global improvement.

Corticosteroid injections vs. ESWT The second review¹⁸ identified one RCT (93 people),²⁷ which compared a single corticosteroid plus local anesthetic injection (20mg triamcinolone made up to 1.5mL with 1% lidocaine) vs. three sessions weekly of ESWT.²⁷ Self-reported pain was measured at 6 weeks and 3 months, and treatment success was defined as over 50% reduction in pain from baseline. It found that corticosteroid plus local anesthetic injections were significantly more effective at reducing pain at 6 weeks and at 3 months compared with ESWT (treatment

success rates: 21/25 [84%] vs. 29/48 [60%] with ESWT; $p < 0.05$).²⁷

Recommendations

Pain relief

- Corticosteroid injections may be more effective at improving pain at 8 weeks and 6 months in people who have had symptoms for less than 4 weeks compared to placebo treatment [overall quality: very low quality]
- Corticosteroid injection may be more effective than physiotherapy at improving pain scores at 6 weeks, but not at 52 weeks [overall quality: very low]
- Corticosteroid injection may be less effective than oral NSAIDs at improving pain at 26 weeks. It is unclear whether corticosteroid injection is more effective at improving pain at 4 weeks [overall quality: very low]
- A single corticosteroid injection plus local anesthetic injection may be more effective at improving pain at 6 weeks and 3 months compared to ESWT [overall quality: low]

Global improvement

- Corticosteroid injections may be more effective than placebo at increasing “short-term” global improvement (timescale not defined), and at improving people’s “main complaint” at 3 and 6 weeks compared with watchful waiting. It is not clear whether injections are more effective than watchful waiting at improving people’s “main complaint” in the longer term (12–52 weeks) [overall quality: very low]
- Corticosteroid injection may be more effective than physiotherapy at increasing global improvement scores at 6 weeks, but not at 52 weeks We don’t know whether corticosteroid injection is more effective than physiotherapy at improving the “main complaint” [overall quality: very low]
- Corticosteroid injection may be more effective than orthoses at increasing the proportion of people who rate their global improvement as “good” or “excellent” at 2 weeks, but not at 6 or 12 months [overall quality: low]
- Corticosteroid injection may be more effective than oral NSAIDs at increasing self-reported perception of benefit at 4 weeks [overall quality: very low]

Functional improvement

- Corticosteroid injection may be more effective than no treatment at improving functional disability at 3 and 6 weeks, but not in the longer term (from 12–52 weeks). It is unclear whether it is more effective than placebo at improving grip strength [overall quality: very low]
- It is unclear whether corticosteroid injection is more effective than physiotherapy at improving functional disability at 12 weeks [overall quality: low]

Question 4: What is the effect of acupuncture?**Finding the evidence**

We found three systematic reviews (search dates 2001,²⁸ 2003,¹⁸ and 2004²⁹) about the effects of acupuncture on tennis elbow. The systematic reviews did not pool results of the RCTs because of considerable heterogeneity among trials. We found no RCTs assessing the effects of acupuncture on quality of life, strength, or return to work.

Quality of the evidence*Level I*

- 3 systematic reviews including 5 RCTs^{25,30–33}

Findings

The first RCT (45 people) found that 10 acupuncture treatments significantly improved pain and functional outcomes at 2 weeks compared with sham treatment.³⁰ The second RCT (48 people) found that needle acupuncture significantly increased the duration of pain relief and the proportion of people with at least 50% reduction in pain after one treatment compared with sham acupuncture where needles were not inserted.³¹ The third RCT (82 people) found that, compared with sham treatment, needle acupuncture significantly increased the proportion of self-reported “good” or “excellent” results, and the pain threshold on gripping after 10 treatments, but found no significant difference at 3 or 12 months.²⁵ A fourth RCT (49 people) found no significant difference in the proportion of people reporting either no improvement or a worsening of symptoms, after 10 sessions, and at 3 or 12 months, between laser acupuncture and sham treatment. It found a smaller proportion of “excellent” or “good” results in the laser group compared with the placebo group after 10 treatments, but not at 3 and 10 months; none of the differences was significant.³² A fifth RCT found no significant difference in cure rate (definition of cure not reported) between vitamin B₁₂ injection plus acupuncture and vitamin B₁₂ injection alone.³³

Recommendations*Pain relief*

- Needle acupuncture may be more effective than sham treatment at increasing pain relief duration after one treatment, or at improving pain after 10 acupuncture sessions at 2 weeks, but may not be more effective at improving pain at 3 or 12 months [overall quality: low]

Global improvement

- It is not clear whether needle or laser acupuncture is more effective at increasing the proportion of people who report “good” or “excellent” results or “cure” at 3–12 months, or whether it is more effective at decreasing the proportion of people who report “no improvement” or “worse” outcome at 3–12 months [overall quality: very low]

Functional improvement

- Needle acupuncture may be more effective than sham treatment at improving functional impairment at 2 weeks [overall quality: low]

Question 5: What is the effect of physical therapy?**Finding the evidence**

- See Question 2.

Quality of the evidence*Level I*

- 2 RCTs^{34,35}
- One systematic review¹⁸ including 5 RCTs

Findings

Exercise vs. control We found one RCT (62 people) comparing eccentric exercises plus proprioceptive neuromuscular facilitation plus counseling vs. sham ultrasound plus counseling.³⁴ All participants were allowed to use an orthosis during painful activities. It found that exercise significantly improved pain and function scores after treatment and at 11 months compared with control (pain at end of treatment [baseline: 16 vs. 16]: 36.3 with exercise vs. 17.4 with placebo, $p = 0.0001$; pain at 11 months: 34.9 with exercise vs. 15.7 with placebo, $p = 0.0001$; function at end of treatment [baseline range: 14.4–14.9] 27.8 with exercise vs. 15.7 with placebo, $p = 0.0001$; function at 11 months: 26.7 with exercise vs. 14.9 with placebo, $p = 0.0001$).³⁴

Exercise vs. ultrasound plus friction massage We found one systematic review (search date 2003, 1 RCT).¹⁸ The small RCT (36 people) identified by the review found that exercise significantly improved pain at 6–8 weeks compared with ultrasound plus friction massage (SMD 0.66, 95% CI 0.01 to 1.31).¹⁸

Exercise plus massage plus ultrasound vs. no treatment We found one systematic review (search date 2003, 1 RCT).¹⁸ The RCT (183 people) included in the review was a three-arm trial comparing 6 weeks of combined physical intervention (exercise plus massage plus ultrasound) vs. corticosteroid injection vs. watchful waiting. It found no significant difference between combined physical intervention and watchful waiting at 6 weeks (global improvement: RR 1.46, 95% CI 0.93–2.29; pain: SMD 0.26, 95% CI –0.10 to +0.61) or at 52 weeks (global improvement: RR 1.09, 95% CI 0.95–1.25; pain: SMD 0.26, 95% CI –0.10 to +0.61).¹⁸

Eccentric strengthening with stretching vs. concentric strengthening with stretching vs. stretching alone We found one RCT (94 people, lateral elbow pain of more than 3 months) comparing eccentric strengthening plus stretching vs. concentric strengthening plus stretching vs. stretching alone.³⁵

It found no significant difference between groups at 6 weeks in pain-free grip strength, pain, or function (difference from baseline to 6 weeks in pain-free grip strength, SD -4.2 ± 6.1 with eccentric strengthening plus stretching vs. -7.4 ± 8.3 with concentric strengthening plus stretching vs. -6.7 ± 7.0 with stretching alone, difference among groups $p = 0.44$; difference from baseline to 6 weeks in pain [visual analogue scale] SD 23 ± 24 with eccentric strengthening plus stretching vs. 14 ± 27 with concentric strengthening plus stretching vs. 23 ± 21 with stretching alone, difference among groups $p = 0.33$; difference from baseline to 6 weeks in Patient-rated Forearm Evaluation Questionnaire [PRFEQ] SD 1.2 ± 1.7 with eccentric strengthening plus stretching vs. 1.3 ± 1.8 with concentric strengthening plus stretching vs. 1.5 ± 1.6 with stretching alone, difference among groups $p = 0.87$; difference from baseline to 6 weeks in Disability of the Arm, Shoulder and Hand Scale [DASH] SD 9.3 ± 14 with eccentric strengthening plus stretching vs. 8.4 ± 10 with concentric strengthening plus stretching vs. 11 ± 12 with stretching alone, difference among groups $p = 0.66$).³⁵

Different manipulation techniques for mobilization The review identified four small RCTs on cervical, wrist, and elbow manipulation, one of which (in 15 people) was too small to meet our inclusion criteria for this review.¹⁸ Pooled results for two RCTs (total of 48 people) investigating elbow manipulation vs. control found a positive immediate effect on pain-free grip strength (SMD 1.28, 95% CI 0.84–1.73). One RCT (28 people) found no significant benefit from wrist manipulation vs. friction massage plus ultrasound plus exercise (pain-free grip strength: SMD 0.43, 95% CI -0.32 to $+1.19$).

Recommendations

Pain

- Exercise plus counseling may be more effective than sham ultrasound plus counseling at improving pain scores at 11 months [overall quality: very low]
- Exercise may be more effective than ultrasound and friction massage at improving pain at 6–8 weeks [overall quality: very low]
- Combined physical intervention (exercise plus massage plus ultrasound) may be no more effective than watchful waiting at improving pain at 6 weeks or at 52 weeks [overall quality: very low-quality]
- It is unclear whether eccentric strengthening with stretching is more effective at 6 weeks at improving pain-free grip strength or pain when compared to concentric strengthening with stretching and with stretching alone [overall quality: low]
- It is not clear whether manipulation (of wrist or elbow) is more effective than control at improving pain-free grip strength [overall quality: very low]

Global improvement

- Combined physical intervention (exercise plus massage plus ultrasound) may be no more effective than watchful waiting at increasing global improvement at 6 weeks or at 52 weeks [overall quality: very low]

Functional improvement

- Exercise plus counseling may be more effective at 11 months than sham ultrasound plus counseling at improving function scores [overall quality: very low]
- Eccentric strengthening with stretching, concentric strengthening with stretching, and stretching alone seem equally effective at improving function at 6 weeks [overall quality: moderate]

Question 6: What is the effect of NSAIDs?

Finding the evidence

We found one systematic review (search date 2001)³⁶ and no subsequent RCTs. None of the RCTs in the review evaluated the effect of NSAIDs on return to work or quality of life.

Quality of the evidence

Level I

- One systematic review³⁶ including two RCTs

Findings

The review³⁶ included two RCTs. The RCTs were not pooled, because one reported means and standard deviations and the other reported medians and ranges. One RCT (129 people) found limited evidence that an NSAID (diclofenac) improved pain in the short term compared with placebo, but did not assess long-term results (pain WMD -13.9 , 95% CI -23.2 to -4.6 on 100-point scale).³⁶ The second RCT (164 people) found no significant difference between NSAIDs (naproxen) and vitamin C placebo in pain over 4 weeks, 6 months, or 1 year, or in functional impairment at 6 months or 1 year (median pain measured from 0 = lowest to 9 = highest [baseline], at 4 weeks: 4 with NSAIDs vs. 3.5 with placebo; 6 months: 1 with NSAIDs vs. 1 with placebo; 12 months: 0 with NSAIDs vs. 0 with placebo; median functional impairment measured from 0 = lowest to 9 = highest [baseline = 4 for both groups]: at 4 weeks: 3 with NSAIDs vs. 2 with placebo; at 6 months: 0 with NSAIDs vs. 0.5 with placebo; at 12 months: 0 with NSAIDs vs. 0 with placebo; significance not reported).³⁶

Recommendations

Pain relief

- Oral NSAIDs may be more effective than placebo at improving pain in the short term, but it is unclear whether they are more effective at improving pain at 4 weeks, 6 months, or 1 year [overall quality: very low]

Functional improvement

- Oral NSAIDs may be no more effective than placebo at improving functional impairment [overall quality: very low]

Question 7: What is the effect of orthotic devices?**Finding the evidence**

We found one systematic review (search date 1999)³⁷ and one additional RCT.³⁸

Quality of the evidence*Level I*

- One RCT³⁸

Findings

We found one RCT (180 people), a three-arm trial comparing orthoses vs. physiotherapy (ultrasound plus friction massage plus exercise) vs. a combination of orthoses plus physiotherapy.³⁸ It found that, over the short term, orthosis was less effective at reducing pain among people with pain as their main complaint (34–45% of the study population at 6 weeks) compared with physiotherapy (mean pain score on a scale of 0 = no complaint to 100 = severe complaints among people with pain as main complaint at 6 weeks: mean difference in improvement 18 with orthosis vs. 31 with physiotherapy; mean difference 13, 95% CI 3–21), improving Pain Free Function Questionnaire³⁷ scores (mean improvement [scale of 0–100; baseline range 48–51]: mean difference in improvement 10 with orthoses vs. 17 with physiotherapy; mean difference 7, 95% CI 1–12), and improving patient satisfaction scores (mean improvement [scale of 0–100; baseline range not reported]: mean difference in improvement 66 with orthoses vs. 75 with physiotherapy; mean difference 9, 95% CI 1–18). However, it found that orthoses were more effective than physiotherapy at improving ability to perform daily activities (mean improvement [scale of 0–100; baseline range 59–64]: mean difference in improvement 26 with orthoses vs. 15 with physiotherapy; mean difference 11, 95% CI 1–21). It found no significant difference between orthoses and physiotherapy at 6 months and 12 months.³⁸

Recommendations*Pain relief*

- Orthoses may be less effective at 6 weeks than physiotherapy at improving pain in people who have pain as their main complaint [overall quality: very low]

Global improvement

- Orthoses may be less effective at improving patient satisfaction scores at 6 weeks compared with physiotherapy [overall quality: low]

Functional improvement

- Orthoses may be more effective than physiotherapy at improving the ability to perform daily activities at 6 weeks [overall quality: low]

Question 8: What is the effect of open vs. percutaneous release surgery?**Finding the evidence**

We found one systematic review (search date 2001),³⁹ which identified no RCTs, and one subsequent RCT.⁴⁰

Quality of the evidence*Level II*

- 1 RCT with methodologic limitations⁴⁰

Findings

The RCT (not blinded, 47 people who had failed 12 months of conservative treatment) compared open release surgery (removal of the damaged portion of the common extensor origin) vs. percutaneous release surgery (tenotomy).⁴⁰ The RCT measured function and pain using the DASH scale. It found that percutaneous release significantly improved DASH scores at 1 year compared with open release (improvement in median DASH score: 20 with percutaneous release vs. 17 with open release; $p = 0.001$).⁴⁰ The clinical importance of this 3-point difference has been questioned, because the minimum clinically important difference has been reported to be 10–15 points.⁴¹ The RCT also found that percutaneous release significantly reduced median time to return to work compared with open release (2 weeks with percutaneous release vs. 5 weeks with open release; $p = 0.0001$) and significantly improved measures of subjective satisfaction ($p = 0.012$).⁴⁰

Recommendations*Functional improvement*

- Percutaneous release surgery may be more effective than open release at improving function at 1 year, and may be more effective at reducing the median time to return to work, in people who had not improved with 12 months of conservative treatment [overall quality: very low]

Summary of recommendations

- Tennis elbow affects up to 3% of the population, and is usually an overload injury that often follows minor trauma to extensor forearm muscles. Although usually self-limiting, symptoms may persist for over 1 year in up to 20% of people.
- MRI and ultrasound may be useful in confirming the diagnosis tennis elbow.

- Corticosteroid injections improve pain from tennis elbow in the short term compared with placebo, local anesthetic, orthoses, physiotherapy, and oral NSAIDs.
- It is not certain which corticosteroid regimen leads to greatest pain relief.
- Over the long term, physiotherapy or oral NSAIDs may be more effective than corticosteroid injections at reducing pain.
- Topical NSAIDs lead to short-term pain relief, but long-term effects are unknown.
- Extracorporeal shock wave therapy is unlikely to be more effective than placebo at improving pain, and may be less effective than corticosteroid injections.
- It is not sure whether acupuncture or exercise and mobilization reduce symptoms of tennis elbow as few studies have been found, and they gave conflicting results.
- It is not sure whether orthoses (braces) reduce symptoms compared with no treatment or other treatments, as few studies have been found.
- It is uncertain whether open or percutaneous surgical techniques improve pain and function, as no good-quality studies have been identified.

Initial Management of the Sports Injured Knee

Jaskarndip Chahal¹, Christopher Peskun¹, and Daniel B. Whelan^{1,2}

¹University of Toronto, Toronto, ON, Canada

²St. Michael's Hospital, Toronto, ON, Canada

Case scenario

A 25 year old female soccer player presents to your outpatient sports medicine clinic 2 days after sustaining a twisting injury to her right knee. A workup in the Emergency Department on the day of injury revealed no fractures.

Relevant anatomy

Most acute knee injuries with intra-articular pathology are associated with a hemarthrosis. The most common lesion causing a hemarthrosis is rupture of the anterior cruciate ligament (ACL). Other lesions include patellar dislocation, meniscal tears, chondral or osteochondral injuries, capsular tears, or rupture of the deep medial collateral ligament or other ligaments.

Importance of the problem

The annual incidence of knee injuries has been estimated to be 110 per 10,000 individuals, with 10% of these injuries leading to a surgical consultation.¹

Top five questions

Diagnosis

1. What is the relative frequency of various injuries when patients present with a knee hemarthrosis?
2. What is the effectiveness of physical examination in diagnosing an ACL rupture in an acutely injured knee?

3. What is the role of MRI vs. arthroscopy in the diagnosis of acute knee injury?

Therapy

4. What is the role for aspiration in the acutely injured knee with hemarthrosis?
5. Is there evidence in favor of surgical reconstruction of an acute (<3 weeks) ACL injury?

Finding the evidence

Where there were recently published systematic reviews/meta-analyses that spoke directly to the questions above, those reviews were considered in isolation without referencing the index studies.

Question 1: What is the relative frequency of various injuries when patients present with a knee hemarthrosis?

Case clarification

The clinical examination of the knee initially reveals a hemarthrosis. The patient asks you what your differential diagnosis is.

Relevance

Given the relative frequency of acute knee injuries, it is important to have a grasp of the possible intra-articular pathoanatomy. Most experts would agree that the ACL is the most common presenting cause of an acute hemarthrosis in patients with athletic injuries. Other injuries that can present as hemarthrosis include meniscus tears, osteochon-

dral defects, patellar dislocations, and medial collateral ligament injuries.

Finding the evidence

- Cochrane Database, with search term: “knee injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “knee injury AND hemarthrosis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: “knee injury AND hemarthrosis AND arthroscopy OR MRI” Exclusions: <16 years old, atraumatic injury, road traffic accidents

Quality of the evidence

Level II

- 13 prospective diagnostic studies using arthroscopy or MRI

Level IV

- 1 retrospective study

Findings

O’Conner² and Jackson³ initially reported that arthroscopy might be of value in acute injuries. Since then, many other investigators have conducted retrospective and prospective diagnostic studies using arthroscopy as a diagnostic modality to analyze acute patterns of pathoanatomy giving rise to traumatic hemarthrosis.^{1,4-14} Based on our pooled statistical analyses of 12 diagnostic studies (n = 1468) from 1977 to 2002, it is evident that injuries to the ACL are the most common cause of an acute hemarthroses occurring in approximately 57.5% (n = 844) of cases. This observation was consistent over time and across various studies. Meniscus injuries and medial collateral ligament injuries occurred in approximately 32.5% (n = 477) and 18.8% (n = 276) of cases, respectively. Osteochondral defects were observed in 13.0% (n = 191) of cases.^{1,4-14} The results are presented in Table 93.1. The possibility of patellar dislocation leading to a hemarthrosis is unclear since most studies did not report this data. According to a recent review, this injury has been diagnosed in 4–23% of cases presenting with a hemarthrosis.¹⁵

A recent prospective MRI study conducted by LaPrade et al.¹⁶ analyzed ligament injuries alone as a cause for hemarthrosis. The authors demonstrated that in the setting of an acute hemarthroses, 18.4% of patients have multiple-ligament injuries. Of patients with posterior cruciate ligament (PCL) and posterolateral corner injury (PLC), multiple ligaments were injured in 52% and 87% of cases, respectively. The most commonly observed combined patterns included ACL–MCL (medial collateral ligament) and ACL–PLC injuries.

Recommendations

- ACL injuries are the most common cause of an acute knee hemarthroses [overall quality: high]

- PCL and PLC injury should increase suspicion for a multiple-ligament knee injury [overall quality: moderate]

Question 2: What is the effectiveness of physical examination in diagnosing an ACL rupture in an acutely injured knee?

Case clarification

The patient would like to know the likelihood of her having an ACL rupture based on your physical examination findings.

Relevance

Knowledge of the diagnostic accuracy of the anterior drawer test, Lachman’s test, and the pivot-shift test, has implications in terms of generating differential diagnoses, ordering imaging studies, and planning for operative intervention.

Finding the evidence

- Cochrane Database, with search term: “anterior cruciate ligament”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “anterior cruciate ligament injury AND diagnosis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “anterior cruciate ligament injury AND diagnosis AND physical examination”

Quality of the evidence

Level I

- 5 meta-analyses

Findings

Several meta-analyses have examined the diagnosis of ACL rupture via physical examination.¹⁷⁻²¹ These meta-analyses have included between 17 and 28 studies, the majority of which have included young patients with an average age of 28.6 years. Although most studies involved examination by a senior surgeon with experience in knee injury treatment, not all studies were explicit. In most of the studies the gold standard for diagnosis was arthroscopy, which may have selected for more severe knee injuries as the booking of the arthroscopic procedure was a determining factor for inclusion in most studies. The findings indicate that the Lachman test is the most sensitive test and the pivot-shift is the most specific test for diagnosis of an ACL injury. Benjaminse et al.¹⁷ stratified patients based on the chronicity (acute or chronic) of the injury and whether or not the tests were performed with the benefit of anesthesia. In the acute setting, anesthesia drastically improves the sensitivity of the pivot-shift test and modestly improves the accuracy of the anterior drawer test (Table 93.2).¹⁷ Anesthesia does not alter the diagnostic accuracy of the

Table 93.1 Pooled statistical analysis of 12 diagnostic studies

ACL, anterior cruciate ligament; MCL, medial collateral ligament; PCL, posterior cruciate ligament.

Lachman test. The notion of combining the three tests into a composite assessment was examined by Solomon et al.²¹ The combination of the three tests resulted in a positive likelihood ratio (LR+) of 25.0 (range 2.1–306.0) and a negative likelihood ratio (LR–) of 0.04 (range 0.01–0.50) for the diagnosis of ACL rupture. These results must be tempered by the fact that the pivot-shift examination lacks perfect reproducibility and is dependent on many patient factors.

Recommendations

- The Lachman test is the most sensitive test for ACL rupture in an acutely injured knee while the pivot-shift test is the most specific [overall quality: high]
- Anesthesia improves the diagnostic accuracy of the pivot-shift test in the acutely injured knee [overall quality: high]
- Composite physical examination improves the diagnostic accuracy of physical examination for ACL rupture in the acutely injured knee [overall quality: high]

Question 3: What is the role of MRI vs. arthroscopy in the diagnosis of acute knee injury?

Case clarification

The physical examination remains indeterminate due to pain and spasm. Although you suggest a MRI investigation

to your patient, she would like to proceed with arthroscopy to clarify the diagnosis.

Relevance

In some institutions, the availability of MRI is limited and a patient may have to wait for weeks before an evaluation. In current practice, the majority of surgeons would order an MRI and decide whether or not to proceed with arthroscopy based its results. Although this is not a formal cost-effectiveness assessment, determining whether it is more practical to obtain an MRI or proceed with arthroscopy for diagnostic purposes would be of importance in the clinical realm.

Finding the evidence

- Cochrane Database, with search term: “knee injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “knee injury AND hemarthrosis AND diagnosis”

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 systematic review, 3 prospective studies

Findings

Crawford et al.²² performed a systematic review of largely level II evidence (47 prospective studies of a total of 59 articles) to assess the difference between MRI and arthroscopy in the diagnosis of knee pathology. The findings indicate that MRI is highly accurate in diagnosing ligament and meniscal pathology. The results are presented in Table 93.3. Furthermore, performing an early MRI prior to diagnostic arthroscopy has been reported to avoid unnecessary surgical intervention in 22–51% of cases.^{12,23–25} A randomized trial also demonstrated that there are no differences in functional outcome 1 year after comparing early (<48 hours) and delayed (3–21 days) arthroscopy for acute knee

Table 93.2 Pooled data for physical examination test with and without anesthesia

Test		No anesthesia	Anesthesia
Anterior drawer test	Sensitivity	49 (43–55)	78 (73–82)
	Specificity	58 (39–76)	75 (64–83)
Lachman test	Sensitivity	94 (91–96)	97 (95–99)
	Specificity	97 (93–99)	(82–97)
Pivot-shift test	Sensitivity	32 (25–38)	85 (80–90)
	Specificity	100 (48–100)	97 (91–100)

Modified from Benjaminse et al.¹⁷

NPV, negative predictive value; PPV, positive predictive value.
 Adapted from Crawford, R., et al., Magnetic resonance imaging versus arthroscopy in the diagnosis of knee pathology, concentrating on meniscal lesions and ACL tears: a systematic review. Br Med Bull, 2007. 84: p. 5–23, by permission of Oxford University Press.²²

injuries.²⁶ Avoiding unnecessary arthroscopic procedures will help minimize associated complications such as ecchymoses, infection, deep venous thrombosis, iatrogenic cartilage injury, and the need for anesthesia.

Recommendations

- Early MRI is recommended to elucidate an equivocal physical exam as opposed to a diagnostic arthroscopy [overall quality: moderate]
- Routine MRI avoids unnecessary diagnostic arthroscopy in over 20% of cases [overall quality: moderate]

Question 4: What is the role for aspiration in the acutely injured knee with hemarthrosis?

Case clarification

The results of the MRI confirm the presence of an isolated ACL rupture. However, the patient is suffering from pain and a fixed flexion deformity due to the presence of a large hemarthrosis. You are considering an aspiration of the knee. The patient would like to know the associated risks and benefits.

Relevance

Aspiration of an acute hemarthrosis is a procedure which was initially used as a diagnostic aid. With the advent and availability of MRI, diagnostic aspiration has largely been supplanted, although many practitioners continue to rely on aspiration to offer their patients pain relief and increased function. However, the risks of iatrogenic infection and reaccumulation of the hemarthrosis must be considered before undertaking aspiration.

Finding the evidence

- Cochrane Database, with search term: "knee aspiration"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: "knee aspiration AND hemarthrosis"

Quality of the evidence

Level IV

- 5 retrospective case series

Findings

Several studies have examined the diagnostic utility of aspiration for an acute hemarthrosis. However, to the authors' knowledge there are no known studies examining the utility of aspiration for pain relief or improved functionality. Five retrospective studies, with a total of 889 patients, have included routine aspiration of acutely injured knees as part of a larger management protocol.^{11,27-30} None of these studies quantified the degree of pain relief or improved functionality after aspiration. The cumulative incidence of iatrogenic infection was zero, although this

was not always indicated as a study endpoint. One study (n = 510) consistently sent the aspirated fluid for culture.²⁷ This study returned nine positive aspirates, all of which were thought to be clinically insignificant in that no patient developed symptoms consistent with septic arthritis. Overall there is a paucity of literature to help guide the utility of aspiration in the acutely injured knee with hemarthrosis. This is highlighted by a recent short-cut review that returned zero relevant studies.³¹ This remains an important issue which requires investigation to help clarify indications and safety.

Recommendations

- The available literature cannot recommend or dissuade the use of aspiration for symptomatic relief or functional improvement in the acutely injured knee with hemarthrosis

Question 5: Is there evidence in favor of surgical reconstruction of an acute (<3 weeks) ACL injury?

Case clarification

You have suggested an acute period of rehabilitation and quads strengthening, but the patient would like to proceed with surgery immediately so she can return to her activities before the upcoming skiing season.

Relevance

There has been some recent controversy on whether it is safe to proceed with an ACL reconstruction in the acute setting and whether early surgical reconstruction should be routinely offered to patients. Current opinion dictates that is preferable to initiate an early structured rehabilitation program to optimize range of motion and quadriceps strength in order to avoid arthrofibrosis, and to offer surgery to patients who experience symptomatic instability.

Finding the evidence

- Cochrane Database, with search term: "anterior cruciate ligament" AND "surgery" AND "timing"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "early anterior cruciate ligament reconstruction"

Quality of the evidence

Level I

- 1 randomized controlled trial (2010)

Level II

- 1 systematic review (2009)

Findings

A recent systematic review by Smith et al.³² compared outcomes following the ACL reconstruction in patients with

early (<3 weeks) and delayed surgery (>6 weeks). There were 161 patients in the “early” group compared with 209 patients in the “delayed” group. There were no statistically significant differences with regard to various functional outcome measures or perceived patient satisfaction. One study also investigated return to sport; there was no difference between the early and delayed groups. There was also no difference between the two groups in instrumented laxity testing, range of motion, and rates of arthrofibrosis. One caveat made by the authors states that the quality of literature pertaining to ACL reconstruction is quite heterogeneous and that the cost–benefit analysis of early vs. delayed surgery requires further assessment.

In a recent randomized controlled trial (RCT) for acute ACL tears,³³ it was demonstrated that for young active adults, a strategy of rehabilitation plus early ACL reconstruction (<10 weeks) was not superior to a strategy of optional delayed reconstruction in those with symptomatic instability. The absolute change in the mean Knee Injury and Osteoarthritis Outcome Score (KOOS) from baseline to 2 years was equivalent in both groups. There were also no reported differences in Short Form-36, Tegner activity scores, and return to pre-injury activity at 2 years. Additionally, it was demonstrated that more than half of the ACL reconstructions can be avoided without adversely affecting outcomes. Nevertheless, further longitudinal follow-up is required to ascertain whether the comparable results in the intervention and control groups are maintained over time and to assess longer-term outcomes such as the risk of knee osteoarthritis.³³ Furthermore, since the participants in this study were not stratified according to activity level or age, these results may not be generalizable to professional athletes and young children as these groups have an exceptionally high risk of a pivoting episode (and resultant meniscal injury). Any treatment protocol which involves delayed optional reconstruction should caution patients about the potential risk to the menisci with pivoting.

Recommendations

- There is no difference in surgeon and patient-based outcomes when comparing early and delayed ACL reconstruction. Early structured rehabilitation and delayed optional reconstruction for the symptomatic patient is recommended for the acutely injured patient as opposed to *routine* early reconstruction [overall quality: high]

Summary of recommendations

- ACL injuries are the most common cause of an acute knee hemarthroses
- PCL and PLC injury should increase suspicion for a multiple-ligament knee injury

- The Lachman test is the most sensitive test for ACL rupture in an acutely injured knee while the pivot-shift test is the most specific
- Anesthesia improves the diagnostic accuracy of the pivot-shift test in the acutely injured knee
- Composite physical examination improves the diagnostic accuracy of physical examination for ACL rupture in the acutely injured knee
- Early MRI is recommended to elucidate an equivocal physical exam as opposed to a diagnostic arthroscopy
- Routine MRI avoids unnecessary diagnostic arthroscopy in over 20% of cases
- The available literature cannot recommend or dissuade the use of aspiration for symptomatic relief or functional improvement in the acutely injured knee with hemarthrosis
- There is no difference in surgeon and patient-based outcomes when comparing early and delayed ACL reconstruction. Early structured rehabilitation and delayed optional reconstruction for the symptomatic patient is recommended for the acutely injured patient as opposed to *routine* early reconstruction

Conclusions

While clinical examination, imaging and examination under anesthesia are able to accurately diagnosis acute traumatic knee injuries, there are many aspects of the management of these injuries that requires further investigation. Well-designed RCTs are required in order to elucidate the benefit of early stabilization of acute ACL injury as well the benefit of knee aspiration in the setting of acute traumatic knee hemarthroses.

Meniscal Tears (Meniscectomy, Meniscopexy, Meniscal Transplants/Scaffolds)

Nicola Maffulli¹, Umile Giuseppe Longo², Stefano Campi², and Vincenzo Denaro²

¹Barts and The London School of Medicine and Dentistry, London, UK

²Campus Bio-Medico University, Rome, Italy

Case scenario

A 28 year old soccer player comes to the Emergency Department with right knee pain after a trauma during a match. Clinical examination reveals effusion, locking, tenderness and painful flexo-extension of the knee. He has no neurovascular deficits.

Relevant anatomy

Meniscal tear patterns include vertical (longitudinal and radial), oblique, complex (or degenerative),¹⁻³ and horizontal^{4,5} tears. Oblique and vertical longitudinal tears constitute about 80% of meniscal tears.⁴ Degenerative complex tears occur in multiple planes and are more common in older age groups. They occur most commonly in the posterior horns.^{2,3}

Importance of the problem

The mean annual incidence of meniscal tears is about 60–70 per 100,000,^{6,7} with a male to female ratio ranging from 2.5:1 to 4:1. Meniscal pathology in younger patients is likely consequent to an acute traumatic event, while degenerative changes are more frequent at an older age.⁵

More than one third of all meniscal tears are associated with an anterior cruciate ligament (ACL) injury,⁸ with a peak incidence in men 21–30 years old and in girls and

women 11–20 years old. Degenerative types of meniscal tears commonly occur in men between 40 and 60.

A Google search for “meniscal injuries” returns over 1,200,000 hits.

Top six questions

Openmirror **Diagnosis**

1. What is the accuracy of clinical examination in the diagnosis of meniscal tears?
2. What is the best diagnostic tool for meniscal lesions? MRI vs. arthroscopy

Therapy

3. Does the repair technique influence the surgical outcome?
4. Does meniscal transplantation prevent osteoarthritis development after total meniscectomy?
5. Is there a role for synthetic materials in meniscal reconstruction?
6. What is the best rehabilitation protocol?

Question 1: What is the accuracy of clinical examination in the diagnosis of meniscal tears?

Case clarification

At clinical examination, medial joint line tenderness is present. McMurray's test is positive. The Apley test elicits pain with rotation of the tibia in the flexed knee joint.

Relevance

A variety of clinical diagnostic tests are available for meniscal tears. Therefore, clinicians need to select diagnostic tests that are the most specific to confirm meniscal tears and the most sensitive to establish that meniscal tears is unlikely.

Current opinion

Most health care professionals use the joint line tenderness, McMurray's test, Apley test, and the Thessaly test as clinical diagnostic tests for meniscal tears.

Finding the evidence

- Cochrane Database, with search terms: "meniscus," "meniscal injury," "meniscal tears," "knee clinical examination," "McMurray's test," "Apley test," "Thessaly test"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "meniscus," "meniscal injury," "meniscal tears," "knee clinical examination," "McMurray's test," "Apley test," "Thessaly test"
- MEDLINE search identifying the population (meniscal tears) and the methodology (diagnosis). We used the keywords "meniscus" AND "clinical examination" as well as "meniscal tears" AND "diagnosis"

Quality of the evidence

Level I

- 4 meta-analyses⁹⁻¹²
- 1 systematic reviews¹³
- 4 randomized trials¹⁴⁻¹⁷

Level II

- 1 systematic review¹⁸

Findings

Sensitivity and specificity Four trials¹⁴⁻¹⁷ (n = 668 patients) provided the accuracy of clinical tests for assessing meniscal lesions of the knee (Table 94.1). According to a systematic review by Meserve¹¹ the overall average sensitivity for meniscal tears is 0.76 (95% CI 0.73, 0.80) for joint line tenderness, 0.55 (95% CI 0.50, 0.60) for McMurray's test, and 0.22 (95% CI 0.17, 0.28) for the Apley test (Table 94.1). According to a meta-analysis by Ockert,¹² the overall average sensitivity for meniscal tears is 0.91% (95% CI 0.98-0.94) for the Thessaly test.

The overall average specificity for meniscal tears is 0.76 (95% CI 0.64, 0.87) for joint line tenderness, 0.77 (95% CI 0.62, 0.87) for McMurray's test, 0.88 (95% CI 0.72, 0.96) for

Table 94.1 Accuracy of clinical tests for assessing meniscal lesions of the knee

A, Apley; JLT, joint line tenderness; LM, lateral meniscus; LR+, likelihood ratio of a positive test; LR-, likelihood ratio of a negative test; M, Mc Murray; MM, medial meniscus; T, Thessaly.

the Apley test, and 0.97 (95% CI 0.95, 0.99) for the Thessaly test.

Recommendations

- The most sensitive clinical diagnostic test for meniscal tears is joint line tenderness at 76% [overall quality: moderate]
- The McMurray and Apley tests could be considered high specificity but low sensitivity tests [overall quality: low]
- The Thessaly test in isolation is not useful for the detection of meniscal tears, but it helps to increase diagnostic certainty when combined with other standard tests¹⁹ [overall quality: low]

Question 2: What is the best diagnostic tool for meniscal lesions? MRI vs. arthroscopy

Case clarification

Clinical examination suggests a meniscal tear. MRI should be useful to confirm the diagnosis before surgical management.

Relevance

Arthroscopy is the gold standard for the diagnosis of meniscal tears. However, this procedure carries an unquantifiable surgical risks.²⁰ MRI is a suitable noninvasive and safe alternative tool to establish a diagnosis of meniscal tear.

Current opinion

Current opinion suggests that most healthcare professionals consider MRI as an appropriate screening tool before therapeutic arthroscopy

Finding the evidence

- Cochrane Database, with search term “meniscus,” “meniscal injury,” “meniscal tears,” “MRI,” “magnetic resonance imaging,” “arthroscopy”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “meniscus,” “meniscal injury,” “meniscal tears,” “MRI,” “Magnetic resonance imaging,” “arthroscopy”
- MEDLINE search identifying the population (meniscal tears) the intervention (diagnosis) and the methodology (MRI). We used the keywords “meniscus” AND “diagnosis” as well as “meniscal tears” AND “MRI”

Quality of the evidence

Level I

- 13 randomized trials^{21–33}

Level II

- 2 systematic reviews^{13,18}

Findings

Correlation between MRI and arthroscopy Thirteen trials (n = 1162 patients) provided correlation between MRI and arthroscopy (Table 94.2). According to the systematic review by Oei,¹³ the overall average sensitivity for medial meniscal tears is 93.3 (95% CI 91.7, 95.0) and 79.3 (95% CI 74.3, 84.2) for lateral meniscal tears. The overall average specificity for medial meniscal tears is 88.4 (95% CI 85.4, 91.4) and 95.7 (95% CI 94.6, 96.8) for lateral meniscal tears.

Recommendation

- MRI is preferable to diagnostic arthroscopy in most patients because it avoids the surgical risks of arthroscopy with high accuracy in diagnosing meniscal and ACL tears²⁰ [overall quality: high]

Question 3: Does the repair technique influence the surgical outcome?

Case clarification

MRI shows an extended vertical longitudinal meniscal tear. Meniscal repair could represent an option for this patient. Arthroscopic meniscal repair surgery includes inside-out, outside-in, and all-inside techniques.

Relevance

Several techniques have been proposed to optimize the healing of a repairable meniscal tear. However, the long-term follow-up of the different techniques is not well defined. Also, the percentage of meniscal healing and its correlation with the clinical outcome is not clear.

Current opinion

All-inside meniscal repair devices are an attractive option owing to cosmesis, surgical time, and decreased risk of injury to neurovascular structures. However, the clinical outcome of the different devices has not been clarified. The newer self-adjusting suture device repairs do not have the length of follow-up of suture repair, but are showing promising initial results.

Finding the evidence

- Cochrane Database, with search term “meniscal repair,” “arthroscopy,” “meniscal sutures,” “inside-out meniscal repair,” “outside-in meniscal repair,” “all-inside meniscal repair”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “meniscal repair,” “arthroscopy,” “meniscal sutures,” “inside-out meniscal repair,” “outside-in meniscal repair,” “all-inside meniscal repair”
- MEDLINE search identifying the population (meniscal tears) the intervention (meniscal repair) and the methodology (clinical trial). We used the keywords “meniscal tear”

AND “meniscal repair,” “meniscal suture,” as well as “meniscal tear” AND “inside-out meniscal repair,” “outside-in meniscal repair” and “all-inside meniscal repair”

Quality of the evidence

Level I

- 3 randomized trials^{34–36}

Level II

- 2 systematic reviews^{37,38}
- 2 randomized trials with methodologic limitations^{39,40}

Findings

Clinical outcome In a randomized controlled trial (RCT) of 100 patients, Bryant³⁵ compared the effectiveness of inside-out suturing to bioabsorbable arrows. They reported 22

failed meniscal repairs (11 in each group), with no significant difference in the failure rate between the two groups ($p = 0.92$). There was no significant difference in mean quality of life scores and side-to-side differences in extension and flexion measurements. They concluded that, at intermediate follow-up, there are no statistically significant differences in measured outcomes between meniscal suturing and arrows.

According to a systematic review by Lozano et al.,³⁸ no substantial differences in failure rate were found among various meniscus devices. No substantial differences in failure rates were found with length of follow-up. Given the paucity of RCTs comparing different all-inside meniscal repairs, no definite conclusions could be made regarding the difference in clinical outcomes of various all-inside meniscal repair devices.³⁷

Recommendation

- There is currently no scientifically substantiated reason to believe that the choice of a particular repair technique would improve the outcome [overall quality: low]

Question 4: What is the overall success of meniscal transplantation?

Case clarification

After a failed meniscal repair, the patient underwent a near complete meniscectomy. Meniscal allograft transplant could be an option to avoid development of osteoarthritis at long-term follow-up.

Relevance

Unfortunately, not all the meniscal lesions are reparable, and often a complete or near complete meniscectomy is required to alleviate the patient’s symptoms. A complete or near complete meniscectomy predictably results in deterioration and subsequent degenerative joint disease.

Current opinion

Meniscal transplantation offers a potential alternative to the negative consequences of a total meniscectomy.

Finding the evidence

- Cochrane Database, with search term “meniscal allograft transplantation”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “meniscal tear,” “meniscal transplantation,” “meniscal allograft transplantation”
- MEDLINE search identifying the population (meniscal tears, complete meniscectomy) the intervention (meniscal allograft transplantation) and the methodology (clinical trial). We used the keywords “meniscectomy,” “meniscal tear” AND “meniscal allograft transplantation”

Quality of the evidence

Level II

- Randomized trials with methodologic limitations 1⁴²

Level III

- 1 systematic review/meta-analysis⁴¹

Findings

The available literature about meniscal allograft transplantation lacks prospective RCTs. A prospective clinical study on 101 patients showed an overall failure in 11 of 39 (28%) medial allograft and 10 on 61 (16%) lateral allograft. The cumulative survival rates at 10 years were 74.2% and 69.8% for the medial and lateral allografts respectively, producing a beneficial effect in approximately 70% of the patients at 10 years. Transplantation of a viable meniscal allograft can

significantly relieve pain and improve function of the knee joint.⁴²

According to a systematic review by Matava,⁴¹ a meta-analysis of clinical studies evaluating meniscal transplantation is not feasible because of a lack of randomization, the absence of control groups, and variable outcome measures in the published studies. Most studies providing outcome data show that over 60% of patients exhibit a successful result. However, the range of “successful” results varied between 12.5% and 100%. Also, the more recent series utilizing modern methods of graft insertion with attention to associated pathology have described favorable outcomes in approximately 85% of their patient cohorts.

Recommendations

- Meniscal transplantation will likely provide short- or medium-term symptomatic improvement in knee function, based on subjective as well as objective measures, at least in the short term [overall quality: low]
- The ideal patient for this procedure would appear be a young to middle-aged adult with joint line pain and limited degenerative joint disease, following a complete or near complete meniscectomy [overall quality: low]

Question 5: Is there a role for synthetic materials in meniscal reconstruction?

Case clarification

The patient refuses to undergo cadaveric allograft meniscal transplantation. After searching the internet for treatment options, he requires the surgeon to perform a synthetic meniscal reconstruction.

Relevance

Synthetic materials could have low risk of transmission of infective diseases, and solve the problems with the availability of human cadaveric allograft. However, before using such modalities, clinicians must make sure of their effectiveness for meniscal reconstruction.

Current opinion

Synthetic materials are sometimes used as meniscal transplants.

Finding the evidence

- Cochrane Database, with search terms: “meniscal scaffold,” “meniscus synthetic materials,” “meniscus regeneration,” “meniscus substitution”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “meniscal scaffold,” “meniscus synthetic materials,” “meniscus regeneration,” “meniscus substitution”
- MEDLINE search identifying the population (complete meniscectomy) the intervention (meniscal substitution)

and the methodology (clinical trial). We used the keywords “meniscal substitution” AND “scaffold,” “synthetic materials”

Quality of the evidence

Level I

- 1 randomized trial⁴³

Level IV

- 2 case series^{44,45}

Findings

Rodkey et al.⁴³ conducted a RCT to compare a collagen meniscus implant and partial medial meniscectomy alone. This study enrolled 311 patients with an irreparable injury of the medial meniscus or a previous partial medial meniscectomy. The collagen meniscus implants had resulted in significantly increased meniscal tissue compared with that seen after the original index partial meniscectomy. Only other small case series studies are available.^{44,45}

Recommendation

- There is no evidence to justify a meniscal reconstruction [overall quality: low]

Question 6: What is the best rehabilitation after arthroscopic meniscectomy?

Case clarification

After undergoing arthroscopic partial meniscectomy, the patient asks for indications about the best way to recover knee function and muscle strength in the operated leg.

Relevance

An appropriate rehabilitation program is a key point for the overall success of surgery.

Current opinion

Home exercise under surgeon's indications is a satisfactory rehabilitation program to obtain the best recovery after arthroscopic partial meniscectomy.

Finding the evidence

- Cochrane Database, with search terms: “meniscal tear,” “knee arthroscopy,” “rehabilitation,” “physiotherapy,” “physical therapy”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “meniscus rehabilitation,” “meniscus physiotherapy,” “meniscus physical therapy”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “meniscal tears” AND “rehabilitation” or “physiotherapy” or “physical therapy”. as well as “knee arthroscopy” AND “rehabilitation” or “physiotherapy” or “physical therapy”

- MEDLINE search identifying the population (meniscal tears) the intervention (rehabilitation, physiotherapy, physical therapy) and the methodology (clinical trial). We used the keywords “meniscal tear,” “knee arthroscopy” AND “rehabilitation,” “physiotherapy,” “physical therapy”

Quality of the evidence

Level I

- 9 RCTs⁴⁶⁻⁵⁴

Findings

Supervised physical therapy vs. home program Four randomized trials (n = 165)^{48-50,52} compared supervised physical therapy and home programs. Goodwin⁵⁰ reported the results in 84 patients, indicating that the supervised physical therapy used in the study was not beneficial for patients in the early period after uncomplicated arthroscopic partial meniscectomy. In a prospective randomized study, Jokl⁵² compared 30 patients assigned to a home exercise program or supervised physical therapy after arthroscopic partial medial meniscectomy. Evaluation was performed 2, 4, and 8 weeks after surgery. The two groups showed no statistically significant differences in strength at any evaluation time, and similar results were reported with regard to the patient's subjective evaluations of knee function and ability to resume usual activities. Nevertheless, in an RCT on 20 patients, Vervest⁴⁹ concludes that the physical therapy under the supervision of a physiotherapist led to high patient satisfaction and good functional rehabilitation after partial arthroscopic meniscectomy with regard to SARS score, hop test, and distance jumps. In another RCT on 31 patients, Moffet⁴⁸ compared supervised physical therapy plus home exercises to home exercises alone. Patients in the supervised physical therapy group had better recovery of the knee extensor strength than patients allocated to the home exercises group, highlighting the importance of an early intensive and supervised rehabilitation program.

NSAIDs Two RCTs (n = 207)^{46,47} compared the use of non-steroidal anti-inflammatory drugs (NSAIDs) in the postoperative period to no treatment (or placebo). In an RCT on 139 patients, Ogilvie-Harris⁴⁶ concluded that patients undergoing NSAID therapy after arthroscopic partial meniscectomy had significantly less pain, less synovitis, and less effusion. They had significantly more rapid return of movement and of quadriceps function, with a faster return to work and sport. In contrast, a randomized study by Birch⁴⁷ on 68 patients indicates no significant benefits from postoperative administration of diclofenac sodium compared with the control group. Complications attributable to the anti-inflammatory drug occurred in 9.6% of the patients, advising against the routine administration of NSAIDs after arthroscopy of the knee.

Electrical stimulation In an RCT on 21 patients, Williams⁵³ compared electrical stimulation and exercise to exercise alone in increasing quadriceps strength after arthroscopic meniscectomy. Twenty-one postmeniscectomy patients were randomly assigned to one of the two groups. Electrical stimulation combined with a regular program of quadriceps exercise produces a significant beneficial effect in strengthening the quadriceps at four different contraction speeds. Jensen⁵⁴ performed a prospective study of the use of transcutaneous neural stimulation (TNS) in 90 arthroscopic knee surgery patients to determine whether TNS is as effective as traditional pain medication in postoperative knee pain, and whether patients that had received TNS regain preoperative motion and strength quicker than the control population. The use of a TNS unit is an effective adjunct in decreasing postoperative pain in 93% of patients. The TNS group regained isokinetic power in flexion and extension, range of motion, and leg volume sooner than the control group.

Recommendations

- There is no evidence to recommend supervised physical therapy vs. home program [overall quality: low]
- There is no evidence to prescribe NSAIDs postoperatively [overall quality: low]
- Electrical stimulation combined with a regular program of quadriceps exercise can have a significant effect in strengthening the quadriceps [overall quality: low]

Summary of recommendations

- The most sensitive clinical diagnostic test for meniscal tears is joint line tenderness at 76%
- The McMurray and Apley tests could be considered high specificity but low sensitivity tests
- The Thessaly test in isolation was not useful for the detection of meniscal tears but it helps to increase diagnostic certainty when combined with other standard tests
- MRI is preferable to diagnostic arthroscopy in most patients because it avoids the surgical risks of arthroscopy with high accuracy in diagnosing meniscal and ACL tears
- There is currently no scientifically substantiated reason to believe that the choice of a particular repair technique would improve the outcome
- Meniscal transplantation will likely provide short- or medium-term symptomatic improvement in knee function, based on subjective as well as objective measures, at least in the short term
- The ideal patient for this procedure would appear be a young to middle-aged adult with joint line pain and limited arthrosis, following a complete or near complete meniscectomy
- There is no evidence to justify a meniscal reconstruction

- There is no evidence to recommend supervised physical therapy vs. home program
- There is no evidence to prescribe NSAIDs postoperatively
- Electrical stimulation combined with a regular program of quadriceps exercise can have a significant effect in strengthening the quadriceps

Conclusions

Even though meniscal tears are frequent, and are responsible for high healthcare costs, the quality of the available studies is generally low, and, given methodologic limitations, pooling of data is almost always impossible. There is an urgent need for large, well-conducted RCTs to improve the science around meniscal injuries.

Anterior Cruciate Ligament Injury

Verena M. Schreiber¹, Kenneth D. Illingworth¹, Hector A. Mejia²,
and Freddie H. Fu¹

¹University of Pittsburgh Medical Center, Pittsburgh, PA, USA

²Florida State University Medical School, Tallahassee, FL, USA

Case scenario

A 20 year old college student presents to the office complaining of right knee pain and instability after sustaining an injury while playing soccer 1 month ago. The patient describes how he planted his foot on the turf and sustained a twisting injury.

Relevant anatomy

The anterior cruciate ligament (ACL) is made up of the anteromedial (AM) and the posterolateral (PL) bundles, which are named for the orientation of their tibial insertion. In addition, two osseous structures can be found on the femoral side that delineate the location of the AM and PL bundles: the lateral intercondylar ridge and the lateral bifurcate ridge.¹⁻³

Importance of the problem

Rupture of the ACL is one of the most frequent types of knee injuries, with a yearly incidence of 35 out of 100,000 people.⁴ Its predominant occurrence is during sports activities, which can put extreme forces on the ACL.⁵ Although recent studies have called into question the benefit of surgical management vs. conservative treatment for ACL injuries,⁶ reconstruction of the ACL continues to be one of the most often performed orthopedic operations in the United States, with approximately 105,000 procedures performed each year, and can be performed with either single- or double-bundle reconstructions.

Top five questions

1. How accurate is the clinical examination in the diagnosis of ACL injury?
2. Which procedure provides the patient with the best clinical outcome, single- or double-bundle ACL reconstruction?
3. What is the better graft choice in ACL reconstruction, autograft vs. allograft?
4. Which autograft provides the better outcome, patellar tendon vs. hamstring tendons?
5. What influence does ACL rupture/ACL reconstruction have on the development of knee osteoarthritis?

Question 1: How accurate is the clinical examination in the diagnosis of ACL injury?

Case clarification

During the clinical exam, a Lachman and anterior drawer test of the patient shows signs of pathological laxity. The pivot shift test is inconclusive due to guarding by the patient. KT-1000 shows a side-to-side difference of 5 mm. No medial or lateral joint line tenderness or opening on varus and valgus stress can be appreciated. Posterior drawer test is negative.

Relevance

Often the knee clinical examination is the only method used to make the diagnosis of an ACL rupture and therefore the validity of these tests is of importance.

Current opinion

The diagnosis of ACL rupture by clinical examination is thought of as a reliable method; however secondary

methods of diagnosis, such as MRI, continue to be commonplace.

Finding the evidence

- Cochrane Database of systematic reviews, search term: “(anterior cruciate ligament*) AND (injury*)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews with search term: “(anterior cruciate ligament*) AND (injury*)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) advanced search with meta-analysis, randomized clinical trial, and review: search terms “(anterior cruciate ligament*) AND (injury*)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): search terms “(anterior cruciate ligament*) AND (injury*) AND (treatment*) OR (*outcome)

Articles that were not in the English language were excluded. Data from abstracts and book chapters were not included.

Quality of the evidence

Level I

- 3 systematic reviews/meta-analyses
- 1 randomized controlled trial (RCT)

Level II

- 8 prospective cohort studies
- 3 retrospective cohort studies
- 1 exploratory cohort study

Findings

Three systematic reviews/meta-analyses evaluated 53 studies in total, and all three of them concluded that the Lachman test seemed to be most accurate in diagnosing ACL tears in the clinical setting.⁷⁻⁹

Twelve level II cohort studies could be identified that matched the search criteria.¹⁰⁻²¹ 6 studies (n = 355) provided data on the Lachman test preoperatively. The Lachman test was able to diagnose an ACL tear in 296 cases (sensitivity 83.3%, 95% CI 0.79–0.87). Six studies (n = 355) evaluated the use of the pivot shift test for the diagnosis of ACL tears and it was positive in 176 cases (sensitivity 49.4%, CI 0.34–0.55). The KT-1000 was evaluated in 5 studies (n = 352, Table 95.1). In addition, 5 studies also used the anterior drawer test when examining the ACL (n = 310). A positive anterior drawer test could be found in 177 cases (sensitivity 57.1%. CI 0.51–0.63).

Recommendation

- In comparison to arthroscopy as gold standard for diagnosing ACL tears, the Lachman test has been shown to be the most accurate of all the diagnostic clinical examinations [overall quality: moderate].

Question 2: Which procedure provides the patient with the best clinical outcome, single- or double-bundle ACL reconstruction?

Case clarification

As previously mentioned, the patient is a 20 year old college student who plays competitive soccer. The MRI shows a complete rupture of the ACL. The patient tells you that he would like to continue playing competitive sports after surgery.

Relevance

Single-bundle reconstruction is the traditional way of reconstructing the ACL. Double-bundle reconstruction has gained increased interest as it is theorized to more closely restore the native anatomy of the ACL.

Current opinion

Current opinion suggests that a double-bundle reconstruction better restores the native knee kinematics when compared to a traditional single-bundle reconstruction.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 5 RCTs

Level II

- 5 cohort studies

Findings

Five RCTs and five level II cohort studies compared single- vs. double-bundle reconstruction by evaluating knee laxity exams, KT-1000 and, common knee score, i.e., International Knee Documentation Committee (IKDC) (Table 95.1).

Recommendations

- Double-bundle ACL reconstruction seems to restore rotation and laxity better than single-bundle ACL reconstruction [overall quality: moderate]
- Subjective knee scores seem to be overall equal for both reconstruction techniques [overall quality: moderate]

Question 3: Which is the better graft choice in ACL reconstruction, autograft vs. allograft?

Case clarification

The patient wishes to continue playing collegiate-level soccer and thus would like to proceed with an anterior cruciate ligament reconstruction. You present him with two options for choice of graft: allograft or autograft.

Sadoghi et al. ⁴³	92	2	41 single 51 double	No significant difference for SB and DB for IKDC	Equal pivot shift SB: 49% DB: 84% (p < 0.001)

DB, double bundle; IKDC, International Knee Documentation Committee; n, number of patients evaluated on particular outcome; SB, single bundle.

Relevance

The choice of graft can have important implications for outcome and function after ACL reconstruction. Both allograft and autograft have their respective advantages and disadvantages, which need to be discussed with the patient.

Current opinion

Current opinion suggests that the majority of surgeons choose autograft in ACL reconstruction for young active patients.

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 1 systematic review/meta-analysis

Level II

- 6 prospective cohort studies

Findings

One systematic review met the search criteria for a level I systematic review.²² No statistical significant difference between allograft and autograft could be found in the majority of outcome measures (Table 95.2).

Six prospective cohort studies could be identified.^{23–28} Five studies evaluated the outcome of allograft vs. autograft reconstruction with respect to long-term follow-up (Table 95.3). Another study by Greenberg et al. (n = 861) looked at the infection rate of allograft vs. autograft and could not show a significant difference in the rate of superficial infec-

tions between allograft and autograft (95% CI allograft group 0–0.57% and autograft group 0–1.66%).

Recommendation

- Graft choice does not appear to play a major role with respect to long-term outcome and infection in ACL reconstruction [overall quality: moderate]

Question 4: Which autograft provides the better outcome, patellar tendon vs. hamstring tendons?**Case clarification**

If the patient decides to proceed with autograft ACL reconstruction, the two most commonly used tendons are the patellar tendon and the hamstring tendon.

Relevance

It is important to have options for the patient regarding graft choice and therefore both patellar tendon and hamstring tendon should be discussed with the patient.

Current opinion

Current opinion suggests that outcomes after patellar tendon and hamstring tendons are equivocal.

Finding the evidence

See Question 1.

F/U, follow-up; IKDC, International Knee Documentation Committee, N, number of patients evaluated on particular outcome.

Level II

- 1 systematic review

Findings

Six systematic reviews evaluated patellar tendon vs. hamstring tendon (Table 95.4). Two studies reported a significant increase in graft failure, anterior knee laxity, and increased pivot shift with hamstring tendon compared to patellar tendon.^{28,29} A study by Poolman et al.³⁰ investigated the overlap of systematic reviews of ACL reconstruction

comparing hamstring autograft with bone–patellar tendon–bone (BPTB) autograft to evaluate reviewed systematic reviews of ACL reconstruction in order to assess quality of reporting and internal validity. The authors came to the conclusion that hamstring autografts have better outcome regarding anterior knee pain when evaluating the best evidence. However, they also advise that these reviews can only be applied as a guide for clinical decision-making or policy-making if each review is looked upon critically with respect to its methodological quality.

Table 95.4 Subjective and objective outcome measures

Systematic review	Group	Graft failure	Anterior knee laxity	Anterior drawer	Lachman	Pivot shift	IKDC
Reinhardt et al. ⁴⁴	PT vs. HT	Increase with HT ($p = 0.02$)	Increase absolute laxity in HT group 3/5 studies ($p < 0.05$)	—	—	—	Higher score in 1/5 studies favoring PT ($p = 0.02$)
Samuelsson et al. ⁴⁵	PT vs. HT	—	NS	NS	NS	NS	NS
Biau et al. ²⁹	PT vs. HT	—	—	—	NS ($p = 0.93$)	Decrease Pivot shift in PT ($p = 0.016$)	—
Goldblatt et al. ⁴⁶	PT vs. HT	—	NS ($p = 0.84$)	—	NS ($p = 0.22$)	NS ($p = 0.83$)	—
Forster et al. ⁴⁷	PT vs. HT	NS	—	—	NS	NS ($p = 0.12$)	NS
Spindler et al. ⁴⁸	PT vs. HT	NS	NS	—	—	—	—

DB, double bundle; HT, hamstring tendon; IKDC, International Knee Documentation Committee; NS, not significant; PT, patellar tendon; SB, single bundle.

Recommendation

- Based on the following outcome measures (graft failure, anterior knee laxity, anterior drawer, Lachman, pivot shift, IKDC) no overall significant difference could be found between patellar tendon and hamstring tendon [overall quality: moderate]

Question 5: What influence does ACL rupture/ACL reconstruction have on the development of knee osteoarthritis?

Case clarification

There are two main goals after ACL reconstruction for the patient: the short-term goal of restoration of knee stability and return to athletic activity and the restoration of normal knee kinematics in order to prevent osteoarthritis (OA) and promote long-term knee health.

Relevance

The development of knee OA in both ACL reconstruction and ACL-deficient patients has been documented in the literature.

Current opinion

Current opinion suggests that there is an accelerated progression of OA after traditional single-bundle ACL reconstruction. The goal of long-term knee health following ACL injury should be the restoration of normal knee kinematics; which is hypothesized to be the biggest determining factor in prevention of OA progression.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses
- 4 RCTs

Level II

- 3 prospective cohort studies

Findings

The natural history of an isolated ACL-deficient knee shows development of OA in 0–16% of patients. Without taking into account graft choice, the development of OA after ACL reconstruction is 16–70% at 5–15 years. The literature showed an increase in OA in BPTB autografts when compared with hamstring tendon autografts (Tables 95.5 and 95.6)

Recommendations

- Current ACL reconstruction techniques lead to an accelerated progression of OA [overall quality: moderate]
- Concomitant meniscus injury leads to an accelerated progression of OA [overall quality: high]

Summary of recommendations

In the treatment of ACL injury, there is moderate or high evidence to support the following recommendations:

- Of the clinical examinations, the Lachman test has been shown to be the most accurate test to diagnose ACL tears in the clinic setting
- Double-bundle ACL reconstruction better restores rotation and anterior laxity. Overall, there is no difference in

Table 95.5 Systematic reviews on development of knee osteoarthritis after ACL injury/reconstruction

Systematic review	Result
Samuelson et al. ⁴⁵	BPTB vs. OA—possible correlation between BPTB and OA
Risberg ⁴⁹	Isolated ACL tear—OA prevalence (0–13%) ACL tear plus meniscus injury—OA prevalence (21–48%)
Andersson ⁵⁰	Isolated ACL tear—OA prevalence 50% ACL tear plus meniscus injury—increased risk of OA
Lewis ⁵¹	SB ACL-R—tricompartamental disease at 5 years
Roos ⁵²	All ACL reconstructions—10–20yr s/p ACL recon 50% prevalence OA

ACL, anterior cruciate ligament; ACL-R, ACL reconstruction; BPTP, bone–patellar tendon–bone; OA, osteoarthritis; SB, single bundle; s/p, status post.

subjective knee scores for single- and double-bundle reconstruction

- Successful long-term outcome in ACL reconstruction does not depend on the graft source
- No significant difference in outcome measures exists between hamstring tendon and patellar tendon in ACL reconstruction. Patellar tendon may decrease anterior knee laxity and pivot shift tests, but this is not clinically significant
- The currently studied ACL reconstruction techniques lead to an increased progression of knee OA, with concomitant meniscal injuries leading to an even greater increase in progression

Conclusions

Numerous reports on the diagnosis, treatment and outcome of ACL tears have been published. However, only few recommendations for the management of ACL tears are supported by high-level evidence.

Table 95.6 Studies on development of knee osteoarthritis after ACL injury/reconstruction

Study	Design	Group(s)	OA classification	Results
Ahlden et al. ⁵³	RCT	BPTB vs. HT autografts	Ahlbäck and Fairbank rating system	Ahlbäck rating system 7yr 16% OA (BPTB 19%; ST 13%; n.s.) Fairbank rating system 7yr 68% OA (BPTB 67%; ST 70%; n.s.)

³Hamlet Private Hospital, Aarhus, Denmark

Case scenario

A 19-year-old man seeks medical help at the Emergency Department after a game of soccer. He is the team's goal-keeper and was injured when an opponent hit him on his left shinbone while he jumped forward on flexed knees trying to catch the ball. He felt a sudden onset pain in the hollow of the knee and could not continue playing. In the Emergency Department the trauma doctor reveals an effusion of the left knee with lack of full extension. Standard radiographs reveal no fractures, and the patient is scheduled for a follow-up appointment with the orthopedic department.

Relevant anatomy

The posterior cruciate ligament (PCL) is the main stabilizer in the knee against posterior translation of the tibia.¹ Secondly it is a restraint to external rotation of the tibia.² Approximately 38mm in length, the PCL consist of two main bundles, the anterolateral and the posteromedial, both originating from approximately 10mm inferior to the posterior tibial joint line and running anteromedial to attach to the lateral aspect of the medial femoral condyle.³ The anterolateral bundle is tight with the knee in flexion and the posteromedial when the knee is extended.² Injuries to the PCL are classified as either isolated or combined as part of a multiligament injury including the posterolateral or posteromedial corner (PLC or PMC). There may be either a total rupture of the ligament (most often the mid-

substance), a bony avulsion injury, or a partial tear. This chapter focuses on the evidence for diagnosis, treatment, and prognosis relating to isolated PCL tears.

Importance of the problem

There is great variability in the reported incidence of injury to the PCL with numbers ranging between 1% and 44% of all acute knee injuries depending on the population studied.⁴⁻⁶ In a cohort study of 46,500 adolescents the incidence of cruciate ligament injury was found to be 60.9 per 100,000 life years, of which about 8% were likely to be PCL tears.⁷ Arguably much less common than the ACL (anterior cruciate ligament) tear, the risk of sustaining an injury to the PCL is highly sport-specific with increasing incidence in contact sports. The incidence has been studied in hockey, team handball, soccer, wrestling, and rugby and has retrospectively been found to vary from 1% to 4% of the total number of injuries.⁸⁻¹¹ The archetypical injury mechanism is described as the dashboard injury, with a blow to the anterior of the tibia. In the sports setting a fall onto a flexed knee, hyperflexion, or hyperextension are typical mechanisms.¹² In patients with isolated PCL tears that are treated nonoperatively only about 50% return to sport at the same or higher level; however, in general the patients report good subjective knee function regardless of objective laxity.¹³ It is generally believed that damage to the internal structures of the knee leads to progressive secondary osteoarthritis (OA), but whether this is the case with isolated PCL tears is still a matter of debate.¹³⁻¹⁶ As with every subject in medicine, an increasing amount of information is readily avail-

able online and a Google search for *posterior cruciate ligament injury* returns more than 134,000 hits. This stresses the need for guidelines based on critically appraised evidence.

Top five questions

Diagnosis

1. How accurate is clinical examination in the diagnosis of PCL injury, and is additional imaging needed?

Therapy

2. Should reconstruction be performed?
3. What is the optimal reconstruction technique?
4. Which type of graft should be used?

Prognosis

5. Does an isolated PCL tear lead to increased OA?

Question 1: How accurate is clinical examination in the diagnosis of PCL injury, and is additional imaging needed?

Case clarification

The patient is seen at the outpatient clinic the day after the injury. He is not able to fully bear weight without pain. He keeps his knee in slight flexion. Examination reveals a slight AP laxity without posterior sag sign and a slight effusion but is otherwise unremarkable.

Relevance

The ability to accurately diagnose a PCL tear in both the acute and the chronic setting is paramount for the orthopedic surgeon in guiding the further treatment. The finding that a PCL injury is often overlooked by both patient and clinician underlines the importance of using sensitive and specific tools in the diagnostic process.¹⁷

Current opinion

Current opinion suggests that clinical examination should be sufficient in diagnosing a PCL tear; however, a MRI is often needed to evaluate concomitant injury.

Finding the evidence

- Cochrane Database with search term: "knee examination"
- PubMed, with search terms: "clinical," "examination," "knee," "accuracy"

Quality of the evidence¹⁸

Level I

- 1 randomized trial

Level II

- 4 exploratory cohort studies
- 1 systematic review of level II or better

Level III

- 4 nonconsecutive studies

Level IV

- 2 studies not fulfilling criteria for level I–III

Clinical examination

We found a total of 11 studies and 1 systematic review reporting on the performance of clinical examination for PCL injuries (Table 96.1). Only one study, which focused entirely on chronic injuries, could be deemed to be of level I evidence. Due to heterogeneity, pooled statistical analysis is not presented. Summarizing, based on level I and II evidence: in chronic injuries the posterior drawer test has a satisfactory sensitivity and excellent specificity, and when combined with other tests the composite examination yields a sensitivity of 97–100% in chronic injuries. The specificity of the composite clinical examination for chronic injuries is approximately 100%. In acute injuries the sensitivity of the posterior drawer test drops substantially, to between 22% and 67%, and for the composite examination the sensitivity is reported to be between 44% and 100% (the latter study including only four PCL injuries), and a specificity of 90–98%. These findings indicate why PCL injuries are often overlooked in the acute phase.

Recommendations

- In acute injuries evidence suggests that clinical examination is not sufficient and if the trauma mechanism is compatible with injury to the PCL clinical re-evaluation and/or additional imaging with MRI is recommended [overall quality: moderate]
- In chronic injuries evidence suggests that clinical examination should be sufficient for diagnosing a rupture of the PCL [overall quality: moderate]
- Concomitant injury to the PLC should always be considered and evaluated when an injury to the PCL is considered [overall quality: moderate]

Question 2: Should reconstruction be performed?

Case clarification

A faculty-level orthopedic surgeon repeats the clinical examination 6 weeks later. The patient states that the pain is now manageable and he has actually started to walk without crutches. The effusion is reduced but he now has a grade III posterior laxity and shows a posterior sag sign.

Table 96.1 Sensitivity and specificity of clinical tests for PCL insufficiency

Test	Test performance	Comments	Level of evidence
Posterior sag sign	Rubinstein et al. 1994: Sensitivity 79% Specificity 100%	Double-blinded, randomized controlled study (39 subjects, 75 knees, chronic injuries)	Ib
	Staubli and Jakob. 1990: Sensitivity 83% Specificity N/A	Nonrandomized, unblinded, uncontrolled (24 PCL-deficient knees, acute injuries)	III
Posterior drawer test	Baker et al. 1984: Sensitivity 86% Specificity N/A	Nonrandomized, unblinded, uncontrolled (7 knees preanesthesia, acute injuries)	III
	Sensitivity 77% Specificity N/A	As above (13 knees, under anesthesia)	
	Staubli and Jakob 1990: Sensitivity 83% Specificity N/A	As above (under anesthesia)	III
	Rubinstein et al. 1994: Sensitivity 90% Specificity 99%	As above	Ib
	Loos et al. 1981: Sensitivity 51% Specificity N/A	Nonrandomized, unblinded, uncontrolled (59 knees, acute injuries)	III
	Hughston et al. 1976: Sensitivity 22% Specificity 100%	Nonrandomized, unblinded, controlled (68 knees, acute injuries, anesthesia unclear)	IIb
	Moore and Larson. 1980: Sensitivity 67% Specificity N/A	Nonrandomized, unblinded, uncontrolled (18 knees, acute)	IV
	Harilainen et al. 1987: Sensitivity 33% Specificity N/A	Nonrandomized, unblinded, uncontrolled (9 knees, acute)	III
Abduction stress test	Sensitivity 100% Specificity N/A	As above (under anesthesia)	
	Clendenin et al. 1980: Sensitivity 100% Specificity N/A	Nonrandomized, unblinded, uncontrolled (10 knees)	IV
	Hughston et al. 1976: Sensitivity 94% Specificity 100%	As above	III
	Daniel et al. 1988: Sensitivity 98% Specificity 100%	Nonrandomized, unblinded, controlled (92 knees, acute and chronic injuries)	IIb
Composite exam	Rubinstein et al. 1994: Sensitivity 54% Specificity 97%	As above	Ib
	Rubinstein et al. 1994: Sensitivity 97% Specificity 100%	As above (grade II and III)	Ib
Composite exam	Simonsen et al. 1984: Sensitivity 44% Specificity 98%	Nonrandomized, unblinded, controlled (118 knees, acute, IIb note: authors calculate predictive values, not sensitivity/specificity)	IIb

Without anesthesia unless stated.

Adapted from Malanga et al. (2003), Arch Phys Med Rehabil 84(4):592–603, expanded and restructured with relevant studies from the present literature search.

A grade I posterior laxity measures 1–5mm of posterior translation of the tibia as compared to the contralateral knee, grade II 6–10mm, and grade III >10mm.

Relevance

All surgical procedures pose a risk to the patient. The orthopedic surgeon needs relevant evidence-based data on long-term outcome and risks in order to determine whether the benefit of a reconstruction is greater than of conservative treatment and whether the risk/benefit ratio is justifiable.

Current opinion

The isolated posterior cruciate lesion with less than 10mm side-to-side difference compared to the contralateral normal knee may be treated conservatively. Patients with grade III lesions (see box) or patients primarily treated conservatively who develop pain or instability are strong candidates for reconstruction.

Finding the evidence

The following search strategy was used for Questions 2–6.

- Cochrane Database with search term: “posterior cruciate ligament”
- PubMed search with search terms “posterior cruciate ligament” [MeSH Terms] OR (“posterior” [All Fields] AND “cruciate” [All Fields] AND “ligament” [All Fields]) OR “posterior cruciate ligament” [All Fields]

Quality of the evidence

Level I

- 1 prognostic cohort study

Level II

- 2 randomized trials with methodologic limitations
- 3 prospective comparative studies

Level III

- 14 retrospective comparative studies

Level IV

- 52 case series

Findings

We found and reviewed a total of 72 studies (N = 2552, median = 35 patients). Only one study could be classified as a level I prognostic study (N = 271 patients) and five studies were classified as level II (N = 215 patients). Twelve studies reported on conservatively treated patients, 57 reported on only surgically treated patients, and only two studies (level III) looked at surgically vs. conservatively treated patients. We found large variations in inclusion criteria, choice of surgical technique, and type of graft in

the reviewed studies. This large variation and the lack of proper randomized controlled trials (RCTs) make it inappropriate to present pooled statistics. We base our recommendations primarily on the level I–III studies, which are briefly summarized in Table 96.2 and 96.3. Level IV studies are listed in Table 96.4 with only minimal details, acknowledging the fact that valuable information can be deduced from this type of study. The overall heterogeneity of included studies is reflected in the generally poor overall quality scores of each recommendation.

Recommendations

- Isolated grade I and II PCL injuries (<10mm posterior laxity) should be treated conservatively [overall quality: moderate]
- Isolated acute grade III injuries may be treated conservatively with good results but in some patients without adequately defined characteristics at time of injury, instability persists which hinder sports and/or daily activities and reconstruction should be performed [overall quality: low]
- Dislocated tibial avulsion fractures should be reattached with anchors or screw fixation within 3 weeks; however, there is no clear evidence of what determines the minimum size of fragment for fixation to be an appropriate option [overall quality: low]
- Chronic isolated grade I and II injuries should be treated conservatively with physiotherapy and activity modification [overall quality: very low]
- Chronic isolated grade III injuries should be reconstructed if pain and instability persist after adequate rehabilitation with physiotherapy. It should be evaluated whether there is injury to the PLC [overall quality: low]

Question 3. What is the optimal reconstruction technique?

Case clarification

After 4 months of intensive physiotherapy and rehabilitation the patient has not been able to fully return to sport at his previous level, and returns to the clinic. Posterior laxity is still grade III and a reconstruction is planned. He has been surfing the web and asks questions about the double-bundle technique.

Relevance

Several techniques are used for reconstructing the PCL. It is necessary to be critically aware of the technical and biomechanical strengths and weaknesses of these techniques and, most importantly, know the documented outcome from each technique.

Current opinion

Expert opinions on PCL treatment suggest that reconstructions should be performed arthroscopically by a skilled

Table 96.2 Identified level I and level II studies with summary of intervention and results

Study	No. of patients	Surgery or conservative	Level of evidence	Treatment and results summary
Shelbourne and Muthukaruppan ¹⁹	271	Conservative	I	Conservatively treated grade I and II, mean follow-up of 7,8 years (215 patients) with a modified Noyes score of 85,6 ± 15. Greater PCL laxity was not associated with poorer scores
Chen et al. ²⁰	49	Surgery	II	Prospective comparison between isolated grade III lesions treated with either hamstring or quadriceps autograft reconstruction. At mean follow-up of app. 28 months there was no significant difference between groups with Lysholm scores of 90,6 ± 7,7 and 91,44 ± 6,2 in quadriceps and hamstring groups respectively. 3 patients (14%) in the quadriceps group and 2 patients in the hamstring group (8%) showed radiographic changes, 1 in each group with joint space narrowing
Houe and Jørgensen ²¹	16	Surgery	II	Prospective comparison between single-bundle patellar bone-tendon-bone or double-bundle hamstring autograft reconstructed isolated chronic grade III lesions. At median follow-up of 35 months there was no significant difference between group with median Lysholm scores of 100 and 95 in single- and double-bundle groups respectively
Wang et al. ²²	55	Surgery	II	Prospective comparison of subacute isolated grade III lesions treated with single-bundle reconstruction with either allo- (Achilles or anterior tibial tendon) or autograft (quadriceps or hamstring). At mean follow-up of 34 months there was no significant difference with Lysholm scores of 87.8 ± 9.6 and 92.3 ± 6.8 in the autograft and allograft groups respectively. More minor complications in the autograft group (7 patients) including 4 patients with donor site pain and 2 infections
Wang et al. ²³	35	Surgery	II	Prospective randomized (improperly described randomization procedure) comparison between single-bundle versus double-bundle reconstruction of subacute isolated grade III lesions with hamstring autografts. At mean follow-up of 41 months in the single-bundle and 28 months in the double-bundle group there was no significant difference between groups with Lysholm scores of 88 ± 10 and 89 ± 9 in the single- and double-bundle groups respectively
Wong et al. ²⁴	60	Surgery	II	Prospective randomized (less-than-optimal randomization procedure) comparison of isolated grade III lesion reconstructed with single-bundle hamstring autograft with either a transtibial anterolateral or anteromedial approach. At average follow-up of app. 45 months there was no significant difference with Lysholm scores of 88 ± 10 and 91 ± 8 in the anteromedial and anterolateral group respectively. In both groups ~60% showed radiographic stage 1 changes

knee surgeon with a considerable number of PCL procedures per year. Biomechanically the two-bundle technique is superior to the single-bundle technique,³⁹ but it is surgically more demanding, and has clinically not demonstrated superior results.

Recommendations

- Reconstruction may be performed arthroscopically using single- or double-bundle technique with tibial inlay or onlay/transtibial technique [overall quality: low]

- Fixation methods are numerous and none has shown superiority [overall quality: very low]

Question 4: Which type of graft should be used?

Case clarification

The surgery is scheduled a few weeks later. A week before surgery the surgical coordinator calls you and asks whether they need to order allograft for the surgery? And if so,

Table 96.3 Identified level III studies with summary of intervention and results

Study	No. of patients	Surgery or conservative	Treatment
Ahn et al. ²⁵	36	Surgery	Retrospective comparison of chronic isolated grade III lesions reconstructed with either single-bundle double-loop hamstring tendon autograft or Achilles tendon allograft. At mean follow-up of 35 months for the autograft group and 27 months for the allograft group there was no significant difference between IKDC scores but a significant difference between Lysholm scores of 90.1 and 85.8 in favor of the hamstring autograft
Hatayama et al. ²⁶	20	Surgery	Retrospective comparison of isolated and combined grade 3 lesions reconstructed with hamstring autograft either with single-bundle or double-bundle technique. At follow-up at 2 years there was no significant difference between groups neither in IKDC scores, nor in biomechanical measurements. 3 tears of posteromedial bundle at second-look arthroscopy at 1 year
Kim et al. ²⁷	60	Surgery	Retrospective comparison of subacute and chronic combined and isolated grade III lesions reconstructed via either an anteromedial (AM) or anterolateral (AL) tibial approach with a variety of grafts (Achilles and tibialis posterior allografts, patellar bone-tendon-bone autograft). At mean follow-up of 58.6 months in the AL group and 56.9 in the AM group there was no significant difference with Lysholm scores of 88.6 ± 7.1 and 88.4 ± 6.4 respectively
Kim et al. ²⁸	29	Surgery	Retrospective comparison of chronic isolated grade III lesions reconstructed with Achilles tendon allograft using either transtibial single-bundle, arthroscopic tibial inlay single-bundle or arthroscopic tibial inlay double-bundle technique. At mean follow-up of 46.4, 36.3 and 29.4 months respectively there was no clinical significant difference with Lysholms scores of 86.8 ± 7.5 , 79.7 ± 11.7 and 84.3 ± 9.7 , however biomechanically there was significantly less posterior translation in the double-bundle inlay vs. transtibial technique (3.6 vs. 5.6 mm)
Kim et al. ²⁹	55	Surgery	Retrospective comparison of isolated subacute and chronic grade III lesions reconstructed with patellar bone-tendon-bone auto- or allograft using either a one- or a two-incision technique. At a mean follow-up of 36 months and 45 months in the one-incision and the two-incision group respectively there was no significant difference with Lysholm scores of 90.6 and 90.0 respectively
Li et al. ³⁰	36	Surgery	Retrospective comparison of isolated chronic grade III lesions with either four-strand hamstring autograft or a LARS artificial ligament. At mean follow-up of 29 months and 26 months in the autograft and artificial ligament group respectively there was a significant difference in the Lysholm scores in favour of the artificial ligament (85 vs. 93)
MacGillivray et al. ³¹	29	Surgery	Retrospective comparison of chronic isolated lesions (tibia flush with or offset posteriorly at 90°) reconstructed with either transtibial or tibial inlay single-bundle using a variety of grafts (patellar bone-tendon-bone auto- and allograft and Achilles tendon autograft). At mean follow-up of 75 months and 57 months in transtibial and inlay groups respectively there was no significant difference with Lysholm scores of 81 and 76 respectively
Noyes and Barber-Westin ³²	25	Surgery	Retrospective comparison of isolated acute and chronic grade III lesions reconstructed with either single-bundle allograft (Achilles tendon or patellar bone-tendon-bone) or a combined allograft-ligament augmentation device. At mean follow-up of 45 months there was no benefit of augmentation. Cartilage deterioration was noted in all patients with chronic lesions
Ohkoshi et al. ³³	51	Surgery	Retrospective comparison of subacute and chronic grade III lesions reconstructed with hamstring autografts using either a 2-incision technique or an endoscopic transtibial technique. At mean follow-up of 19.2 months there was no significant difference in the IKDC ratings, significantly shorter rehabilitation period in the endoscopic group
Patel et al. ³⁴	58	Conservative	Retrospective cohort prognosis study of nonoperatively treated isolated partial and complete lesions. Preinjury Tegner score was 7. At mean follow-up of 6.9 years the Lysholm score was 85.2, Tegner score was 6.6., on the IKDC form 6 patients had a nearly normal result, 50 patients had an abnormal result and 1 patient had a severely abnormal result, radiographic OA was seen in the medial compartment of 17% (grade I and II), in the patellafemoral joint of 7% (grade I) and in the lateral compartment of 5% of patients. No significant correlations existed between subjective and objective findings

(Continued)

Table 96.3 (Continued)

Study	No. of patients	Surgery or conservative	Treatment
Roth et al. ³⁵	39	Surgery/ Conservative	Retrospective comparison of combined and isolated grade III mainly chronic lesions treated either conservatively or with medial gastrocnemius tendon transfer. At mean follow-up of 53 months there were no significant changes biomechanically nor was there subjective improvement in the operated group as compared to the conservative group
Seon and Song ³⁶	43	Surgery	Retrospective comparison of chronic grade III lesions reconstructed with either transtibial hamstring autograft or tibial inlay patellar bone-tendon-bone autograft. At mean follow-up of 31.8 months there was no significant difference between groups with Lysholm scores of 91.3 and 92.8 in the transtibial and the tibial inlay groups respectively
Shirakura et al. ³⁷	40	Surgery/ conservative	Retrospective comparison of isolated grade III lesions (midsubstance tears) treated with either primary repair or nonoperatively. At mean follow-up of 80 months in the surgery group and 52 months in the conservative group the operated knees were significantly more stable though not on par with a group of un-injured controls. No significant change existed on a knee rating score with 92.9 ± 5.1 and 90.9 ± 2.8 respectively. Grade I degenerative radiographic findings in 3 patients in the operated group and 1 in the conservative group
Zhao and Huangfu ³⁸	51	Surgery	Retrospective comparison of isolated chronic grade III lesions reconstructed transtibially with either 4 -strand or 7-strand hamstring autograft. At mean follow-up of 31 months in the 4-strand group and 30 months in the 7 strand group there was significant difference between the groups in favor of the 7-strand technique with Lysholm scores of 83 ± 4 and 92 ± 4

which type? You remember that it was discussed with the patient but you forgot to put it down on the note that was sent to the surgical coordinator.

Relevance

Several types of grafts are used for PCL reconstruction, both autografts and allografts. The chosen graft may have implications for surgical technique and time, donor site morbidity, risk of disease transmission, and, most important, outcome.

Current opinion

The most commonly used autografts are four-strand hamstring graft, quadriceps tendon or bone-patellar tendon-bone (BPTB) grafts. These are also commonly used as allografts with the addition of Achilles tendon grafts.

Recommendations

- Reliable results have been demonstrated with a variety of auto- and allograft choices including BPTB, hamstring tendons (quadruple and 7-double), quadriceps tendon, Achilles tendon. There are no data indicating superiority of any graft type [overall quality: low]
- Allografts have the advantage of shorter durations of surgery, no donor site morbidity, and potentially stronger grafts by choosing specific types of grafts. However, availability, potential risk of disease transmission, and tissue quality are essential factors that need to be considered and

which may vary depending on geographical location [overall quality: low]

Question 5: Does an isolated PCL tear lead to increased osteoarthritis?

Case clarification

You see the patient at regular follow-ups and at 9 months he is doing very well subjectively, having been able to return to his previous level of activity. Posterior laxity is now grade I. Occasionally, he has a little aching from the knee after a hard game and he asks whether he is likely to develop OA.

Relevance

Knowledge of the longtime risk of developing secondary OA is important both in the decision process of opting for surgery or not, and in the long-term follow-up of PCL-deficient and/or reconstructed patients.

Current opinion

A cruciate ligament injury is generally believed to lead to secondary OA and there is conflicting evidence whether reconstruction of ligaments halts this development. Current opinion suggests that isolated PCL ruptures may be treated conservatively with minor risk of patellofemoral or medial compartment OA.

Recommendations

- An injury to the PCL is a significant injury to the knee and the index injury itself is likely to damage the cartilage [overall quality: moderate]
- In injuries to the PCL with concomitant injury to the cartilage progressive OA may occur, but early reconstruction has not been shown to have an impact on this development [overall quality: low]
- An isolated injury to the PCL without concomitant cartilage injury does not necessarily lead to progressive OA of the knee and there is no clear evidence that a reconstruction prevents OA from occurring [overall quality: low]
- Successfully conservatively treated knees do not show progressive OA at long-term follow-up [overall quality: low]

Summary of recommendations

- In acute injuries evidence suggests that clinical examination is not sufficient and if the trauma mechanism is compatible with injury to the PCL clinical re-evaluation and/or additional imaging with MRI is recommended
- In chronic injuries evidence suggests that clinical examination should be sufficient for diagnosing a rupture of the PCL
- Concomitant injury to the PLC should always be considered and evaluated when an injury to the PCL is considered
- Isolated grade I and II PCL injuries (<10mm posterior laxity) should be treated conservatively
- Isolated acute grade III injuries may be treated conservatively with good results but in some patients without adequately defined characteristics at time of injury instability persists which hinder sports and/or daily activities and reconstruction should be performed
- Dislocated tibial avulsion fractures should be reattached with anchors or screw fixation within 3 weeks; however, there is no clear evidence of what determines the minimum size of fragment for fixation to be an appropriate option
- Chronic isolated grade I and II injuries should be treated conservatively with physiotherapy and activity modification
- Chronic isolated grade III injury should be reconstructed if pain and instability persist after adequate rehabilitation with physiotherapy. It should be evaluated whether there is injury to the PLC
- Reconstruction may be performed arthroscopically using single or double bundle with tibial inlay or onlay/trans tibial technique
- Fixation methods are numerous and none has shown superiority
- Reliable results have been demonstrated with a variety of auto-and allograft choices including BPTB, hamstring

tendons (quadruple and 7-double), quadriceps tendon, Achilles tendon. There are no data indicating superiority of any graft type

- Allografts have the advantage of shorter durations of surgery, no donor site morbidity, and potentially stronger grafts by choosing specific types of grafts. However, availability, potential risk of disease transmission, and tissue quality are essential factors that need to be considered and which may vary depending on geographical location

- An injury to the PCL is a significant injury to the knee and the index injury itself is likely to damage the cartilage

- In injuries to the PCL with concomitant injury to the cartilage progressive OA may occur, but early reconstruction has not been shown to have an impact on this development

- An isolated injury to the PCL without concomitant cartilage injury does not necessarily lead to progressive OA of the knee and there is not clear evidence that a reconstruction prevents OA from occurring

- Successfully conservatively treated knees do not show progressive OA at long-term follow-up

Conclusion

Unfortunately, the overall quality of the evidence for the diagnosis, treatment, and prognosis for PCL tears is poor, which is reflected in our recommendations.⁴⁰ There is a need for more studies on the management of PCL injuries. It is likely that a multicenter approach may be needed for RCTs with adequate statistical power to be feasible.

Operative vs. Nonoperative Treatment of Combined Anterior Cruciate Ligament and Medial Collateral Ligament Injuries

Rocco Papalia¹, Sebastiano Vasta¹, Vincenzo Denaro¹, and Nicola Maffulli²

¹Campus Bio-Medico University, Rome, Italy

²Barts and The London School of Medicine and Dentistry, London, UK

Case scenario

A 27 year old woman came to the outpatient clinic describing symptoms of her left knee giving out from under her and pain.

Relevant anatomy

There are four major ligaments in the knee. Ligaments are elastic bands of tissue that connect bones to each other and provide stability and strength to the joint. The four main ligaments in the knee, connecting the femur to the tibia, are:

- *anterior cruciate ligament* (ACL): the ligament that controls rotation and forward movement of the tibia; located in the center of the knee
- *posterior cruciate ligament* (PCL): the ligament that controls backward movement of the tibia; located in the center of the knee
- *medial collateral ligament* (MCL): the ligament that gives stability to the inner knee. The MCL provides the primary restraint to valgus stress at both 5° and 25° of flexion from full hyperextension while the cruciate ligaments, primary the ACL, are important secondary restraints to lateral opening of the knee joint, especially at 5° of flexion¹
- *lateral collateral ligament* (LCL): the ligament that gives stability to the outer knee

Importance of the problem

The incidence of knee ligament ruptures, primarily involving the ACL and MCL, is estimated to be 2 per 1,000 people

per year in the general population.^{2,3} The incidence of combined ACL–MCL tears range from 20%⁴ to 38%⁵ of all knee ligament injuries. From 60,000 to 175,000 ACL tears occur annually in the United States.^{2,3} A Google search for “combined ACL MCL injuries” returned a total of 128,000 hits.

Top six questions

1. How does an ACL–MCL tear occur?
2. What are the risk factors?
3. What is the accuracy of clinical examination in the diagnosis of ACL–MCL tears?
4. What is the best diagnostic tool for ACL–MCL tears?
5. What is the treatment for ACL–MCL tears?
6. What about the use of prophylactic devices?

Question 1: How does an ACL–MCL tear occur?

Case clarification

The patient mentions having fallen while skiing 2 months before. At the time of the injury she heard a “pop” followed by about 4 days of knee pain and swelling, which forced her to remain immobile.

Relevance

The majority of ACL–MCL disruptions are sustained during sport activities.

Finding the evidence

- Cochrane Database, with search terms: “ACL–MCL injury mechanism,” “ACL injury,” “ACL–MCL rupture biomechanics”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “ACL–MCL injury

mechanism," "ACL injury," "ACL-MCL rupture biomechanics"

Quality of the evidence

Level I

- 1 clinical trial⁶
- 1 systematic review⁷
- 1 book¹

Findings

Ligament injuries are closely related to sport traumas.⁶ Combined ACL-MCL injuries are often the result of concomitant rotational and valgus stress. Combination injuries involving both the ACL and the MCL may occur during contact sports such as a football, soccer, or rugby tackle, or in noncontact situations, particularly in an athlete who is making an abrupt pivot in which the tibia goes into valgus relatively to the femur. This type of injury results from a deceleration maneuver in which the forces can be substantial.^{1,7}

Recommendation

- A combined ACL-MCL lesion rather than an isolated ACL lesion should be suspected in patients playing sports that put them at risk of knee rotational and valgus stress maneuvers [overall quality: high]

Question 2: What are the risk factors?

Case clarification

Two weeks after the trauma, feeling good, the patient resumed playing sports, and while playing basketball she had the first episode of her knee giving out.

Relevance

Sport is an important risk factor for ACL-MCL injuries, but many recent studies have showed that sex and anatomical features can favor ligament rupture.

Finding the evidence

- Cochrane Database, with search term "ACL AND MCL AND risk factors," "sex AND ligament injury," "femoral notch stenosis AND ACL injuries"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "ACL AND MCL AND risk factors," "sex AND ligament injury," "femoral notch stenosis AND ACL injuries"

Quality of the evidence

Level I

- 1 meta-analysis⁸

Level II

- 7 prospective comparative studies^{9-12,14-16}

Level V

- 1 expert opinion¹³

Findings

High-risk sports for ACL injuries are basketball, soccer, alpine skiing, lacrosse, football, handball, Australian rules football, rugby, volleyball, and wrestling.⁸

Female athletes have a higher risk of tearing the ACL,⁹⁻¹¹ as a result of multiple factors such as biomechanical, neuromuscular, physiologic, hormonal, and anatomical mechanisms.^{11,12} In particular, with maturity, women experience worsening of their neuromuscular joint control.¹³

Some studies have demonstrated a relation between a narrow femoral intercondylar notch, measured as a smaller notch width index (NWI) on radiographs and CT scans, and a higher risk of ACL injuries.¹⁴⁻¹⁶

Recommendation

- A combined ACL-MCL lesion should be suspected in female athletes, in patients playing sports that have a high risk for ligament injuries, and in patients with a previous diagnosis of narrow femoral intercondylar notch or in whom the radiographs or CT scans show a smaller NWI during the diagnostic process [overall quality: moderate]

Question 3: How can we diagnose ACL-MCL injury?

Case clarification

On examination, performing the anterior drawer and the Lachman tests on both knees, abnormal anterior laxity was detected in the injured left knee. Also, there was a grade III positive valgus stress test.

Relevance

Many clinical diagnostic tests are available to diagnose ligament injuries.

Finding the evidence

- Cochrane Database, with search terms: "clinical test ACL injury," "clinical test MCL injury," "physical diagnostic tests ACL MCL injury," "accuracy ligament diagnostic test"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "clinical test ACL injury," "clinical test MCL injury," "physical diagnostic tests ACL MCL injury," "accuracy ligament diagnostic test"

Quality of the evidence

Level I

- 1 meta-analysis²⁴

Level II

- 1 descriptive study²³
- 1 book²²

Findings

Generally the diagnostic process includes history-taking, physical examination, and MRI of the knee. Accurate history-taking must be done to investigate the symptoms and the mechanism of the injury. Physical examination follows, and includes the assessment of range of motion (ROM), the palpation of the bony structure to exclude associated tibial plateau fractures, palpation of the joint lines to evaluate a possible associated meniscal tear (the frequency of meniscal injuries range from 16% to 82% in acute ligament tears and 96% in knees with chronic ligament tears^{17–21}), and finally tests to assess knee laxity. The most commonly used are the valgus stress test, Lachman's test, and the anterior drawer test.

The valgus stress test assesses the integrity of the MCL complex (superficial and deep MCL fibers), and makes it possible to establish the degree of the lesion (see box).²² A study by Kastelein et al. evaluated the reliability of "pain valgus stress test (PVST)" and "laxity valgus stress test (LVST)" comparing them with MRI data. The sensitivity and specificity were 0.78 (0.64–0.92) and 0.67 (0.57–0.76) respectively for the PVST, and 0.91 (0.81–1.00) and 0.49 (0.39–0.59) respectively for the LVST.²³

Classical method of grading MCL injuries using the valgus stress test²²

- **Grade I:** The MCL is tender and swollen but exhibits no increased laxity, it signifies an injury without elongation of ligament
- **Grade II:** The MCL is elongated but not completely disrupted; there is increased laxity to the valgus stress test but with a firm endpoint
- **Grade III:** The MCL has lost all structural integrity so there is laxity without an endpoint

Lachman's test and the anterior drawer test are the two most basic tests for abnormal anterior knee laxity that is related to ACL injury.²² A meta-analysis by Scholten et al. has shown good reliability of these tests in diagnosing ACL injuries. The Lachman's test sensitivity ranges from 0.63 to 0.93 and its specificity from 0.55 to 0.99. According to the bivariate random effects model, the pooled sensitivity is 0.86 and the specificity 0.91. The sensitivity of the anterior drawer test ranges from 0.18 to 0.92 and its specificity from 0.78 to 0.9. According to the bivariate random effects model, the pooled sensitivity is 0.62 and the specificity 0.88.²⁴

The pivot shift test is a dynamic test that demonstrates the subluxation occurring when the ACL is nonfunctional.²² The sensitivity of the pivot shift test ranges from 0.18 to 0.48 and its specificity from 0.97 to 0.99.²⁴

Recommendations

In patients with suspected ACL–MCL injury, the evidence suggests [overall quality: high]:

- The diagnostic process should include accurate history-taking
- Physical examination should assess ROM
- Suspected MCL lesions should be addressed by the valgus stress test for the MCL
- Suspected ACL lesions should be addressed by the Lachman's test, the anterior drawer test, and the pivot shift test

Question 4: What is the best diagnostic tool for ACL–MCL tears?

Case clarification

An MRI was prescribed for a suspected diagnosis of ACL and MCL injury.

Relevance

A diagnostic tool is useful to confirm clinical suspicion of a ligament injury. MRI is a noninvasive and safe tool to establish the diagnosis.

Finding the evidence

- Cochrane Database, with search terms: "diagnosis MCL injury," "MRI AND MCL injury diagnosis"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "diagnosis MCL injury," "MRI AND MCL injury diagnosis"

Quality of the evidence

Level II

- 2 descriptive studies^{25,26}

Findings

MRI is an appropriate diagnostic tool for the evaluation of internal derangement of the knee. It is very useful in assessing the location and the severity of the injury (Table 97.1). A descriptive study by Halinen et al.²⁵ has shown MRI to have an accuracy and sensitivity of 93.2% for ACL tears and 86.4% for MCL tears.

Recommendation

- In patients with suspected ACL–MCL injury, MRI is a reliable diagnostic tool [overall quality: high]

Question 5: What is the treatment for ACL–MCL tears?

Case clarification

Because MRI confirmed the diagnosis of an ACL–MCL injury, the patient was surgically treated with an arthroscopic reconstruction of the ACL and MCL.

Table 97.1 Method of grading MCL injury by MRI²⁶

Grade	MRI findings
I (minor tearing of ligament fibers)	Periligamentous swelling without complete disruption of superficial or deep layer
II (complete disruption of superficial layer)	Periligamentous swelling with complete disruption of superficial layer
III (complete disruption of superficial and deep layer)	Same as grade II but with fluid extravasating from the joint into the periligamentous tissue

Relevance

The management of combined ACL–MCL injuries is widely debated. The possible options are: full conservative MCL–ACL treatment, full surgical MCL–ACL treatment, combined surgical MCL and conservative ACL treatment, and combined conservative MCL and surgical ACL treatment (Table 97.2).

Finding the evidence

• Cochrane Database, with search terms: “ACL” and “MCL” in combination with “surgery treatment,” “conservative treatment,” “surgery management,” “conservative management,” “surgical treatment,” and “surgical management”

Table 97.2 Relevant data of each study on ACL–MCL combined tears

Author	n	MCL		Treatment		Outcome
		Grade	Diagnosis	MCL injury	ACL injury	
Osti et al. ³⁷	22	II	MVST at 30° and valgus stress radiograph at 20°	Surgery	Surgery	After 24 months from surgery, clinical and functional variables were significantly improved and 90% of patients returns to preinjury sport activity level
Andersson et al. ⁴²	167	—	—	Combined	Combined	The score distributions showed that 82% of surgically treated groups of patients had a total score of 84 points or more, compared to 64% in the nonsurgically treated
Andersson and Gillquist ⁴³	107	II–III	MVST at 30°	Surgery	Combined	Patients who had primary ACL repair returned to a higher level of competitive sports than patients who had undergone conservative ACL treatment
Schierl et al. ⁵³	28	I–II	MVST at 30° and valgus stress radiograph	Conservative	Surgery	The mean Lyshom score was 95.0 ranging from 79 to 100. Subjective findings and functional outcome in patients with ACL instability or combined ACL–MCL lesions were the same
Shelbourne and Porter ⁴⁴	84	—	MVST at 30°	Conservative	Surgery	Patients regained ROM, strenght equal to uninjured leg and ligamentous instability
Zaffagnini et al. ³⁵	57	II	IKDC grading	Conservative	Surgery	Postoperative varus-valgus laxity at 30° of flexion was approximately 1° greater in patients with ACL–MCL combined lesions than in patients with ACL lesion
Hara et al. ³⁶	342	II	IKDC grading	Conservative	Surgery	No clinically significant difference regarding outcome between patient with ACL–MCL combined lesion and patients with isolated ACL lesion
Jokl et al. ³²	28	III	Medial joint opening at valgus stress radiograph	Conservative	Conservative	68% of patients returns to pre injury sport activity level and no significant change in the Hospital for Special Surgery Knee assessment form was noted with the passage of the time
Frolke et al. ⁴¹	22	III	MVST at 25° (medial joint opening .10 mm)	Surgery	Conservative	After surgical treatment of MCL and conservative treatment of ACL a considerable improvement was observed in pivot shift, Lachman, and total AP translation
Robins et al. ⁴⁵	20	I		Surgery	Surgery	Patients with a distal lesion of MCL had a more rapid return to motion both for flexion and extension than patient with proximal MCL lesion

(Continued)

Table 97.2 (Continued)

Author	n	MCL		Treatment		Outcome
		Grade	Diagnosis	MCL injury	ACL injury	
Nakamura et al. ⁴⁶	17	II–III	MRI	Combined	Surgery	There was no significant difference between patients who underwent ACL surgical repair and patient who underwent ACL–MCL surgical group
Petersen and Laprell ⁴⁰	64	III	MVST without endpoint	Conservative	Surgery	The Lysholm score was significantly better in the group with late ACL reconstruction than in the group with early ACL reconstruction
Halinen ³⁹	47	III	—	Combined	Surgery	There were no significant differences in IKDC scores of the patients who underwent surgically repair of MCL and patient who underwent nonoperative treatment of MCL
Hillard et al. ⁴⁷	66	II–III	MVST at 20°(medial joint opening, 3–5 mm side to side difference for grade II)	Conservative	Surgery	There was no differences in stability or function
Lundberg and Messner ⁶	40	I–III	Valgus stress test	Combined	Combined	There was no significant differences in Lysholm score among patients with isolated MCL tear and patients with combined ACL–MCL tear
Ballmer et al. ⁴⁸	14	—	Medial joint opening at valgus stress radiograph	Conservative	Surgery	Both clinical and radiological stability were almost normal and all patient had returned to their preinjury activities
Yoshiya et al. ³⁴	24	III	Medial joint opening at valgus stress radiograph	Surgery	Surgery	Statistically significant improvement in medial stability and ROM were observed in postoperative follow-up and they graded almost normal in all patients according to IKDC evaluation system
Shirakura et al. ⁵⁴	25	II–III	Manual valgus stress test at 0° and 30° Grade I–III)	Combined	Conservative	Higher functional levels were observed in patients treated with surgical MCL repair
Sankar et al. ⁴⁹	180	II–III	Medial joint opening at valgus stress test (5–10 mm Grade II)	Conservative	Surgery	No significant differences were shown in Lysholm score between patients with ACL/MCL combined injury and patients with isolated ACL injury. All patients returned to their preinjury sport activity level
Noyes and Barber-Westin ⁵⁰	46	I–III	MVST at 5° and 25° (medial joint opening, side to side difference)	Combined	Surgery	Overall rating was 58% excellent or good and 42% fair or poor for operatively treated MCL tear patients while it was 91% excellent or good and 9% fair for nonoperatively treated MCL tear patients
Hughston JC ³⁸	41	III	MVST at 30°	Surgery	Surgery	38 on 41 patients had good stability and normal ROM as well as little or no muscle atrophy and most of the patients had maintained a high level of physical fitness and athletic activity
Mok and Good ⁵¹	25	III	—	Conservative	Conservative	All 25 patients had good or excellent results, with return to the preinjury level of sporting activities by 1 year and with restoration of medial stability
Millet et al. ⁵²	18	—	—	Conservative	Surgery	Patients showed a mean Lysholm score of 94.5 and a mean Tegner activity score of 8.4. Serial clinical examinations demonstrated good functional outcomes,ROM, and strength

IKDC, International Knee Documentation Committee score; MVST, manual valgus stress test; ROM, range of motion.

• PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries: “ACL” and “MCL” in combination with “surgery treatment,” “conservative treatment,” “surgery management,” “conservative management,” “surgical treatment,” and “surgical management”

Quality of the evidence

Level I

- 23 clinical trials^{3,32,34–52}

Current opinion

Isolated and partial injuries of the MCL can be treated nonoperatively given the good healing properties of this ligament.^{27–34} In contrast, the management of MCL injuries combined with other ligaments is still controversial.

Grade II MCL lesions Zaffagnini et al.³⁵ showed that residual laxity remain in patients with injured ACL–MCL successively treated with operative ACL reconstruction, raising the question of addressing the MCL.

In the study by Hara et al.,³⁶ 90% of patients with ACL injury associated with grade II valgus laxity in whom the ACL was operatively reconstructed regained medial stability with nonoperative management of MCL. The authors believed that it was not necessary to implement a combined ACL–MCL operative treatment.

Osti et al.³⁷ treated operatively, in the same surgical setting, 22 patients with chronic ACL injury and chronic grade II valgus instability. After 24 months from surgery, clinical and functional variables were significantly improved, and 90% of patients returned to preinjury sport activity level. For these reasons, the authors recommend surgical management of both ACL and MCL as a safe and reliable option.

Grade III MCL lesions In the series of Hughston et al.,³⁸ of the 41 patients with grade III valgus instability managed surgically with repair of the posterior oblique ligament and the semimembranosus complex, only 3 continued to have mild or moderate instability which impaired function. In two of these patients, the original repair had been a technical failure. This technique provides good long-term results.

Yoshiya et al.³⁴ used autogenous hamstring tendons to surgically repair injured MCL on 24 patients. At follow-up, 20 patients were stable to valgus stress test, while 4 were mildly unstable.

Halinen et al.³⁹ treated 47 patients with combined ACL and grade III MCL injury. The follow-up data suggest that nonsurgical and surgical management of MCL tears leads to equivalent results, and that the MCL does not need to be surgically repaired when the ACL undergoes early reconstruction.

In the study of Petersen et Laprell,⁴⁰ on 64 patients with combined ACL–MCL injury, 37 patients had late operative

ACL reconstruction and 27 had early operative ACL. All had nonoperative MCL treatment. At 22 months from surgery, no difference in the frequency of anterior or medial instabilities or in the loss of motion were seen, but a lower rate of motion complications in the early postoperative period, lower rate of rearthroscopies, and significantly better results in the Lysholm score were seen in the group treated with late ACL reconstruction. The authors prefer late ACL reconstruction in combined injuries of the ACL and the MCL.

Frolke et al.⁴¹ undertook primary operative repair of the MCL and conservative management of the ACL injury on 22 patients. In a follow-up at 2.5 years, testing of the MCL showed a change from 22 severely abnormal knees to 17 normal and 5 nearly normal knees.

In the study of Jokl et al.,³² 28 patients with an ACL–MCL combined injury were managed conservatively. After a mean follow-up of 3 years (ranging from 8 months to 11 years), 68% of patients had returned to preinjury sport activity levels, with significant changes in the Hospital for Special Surgery Knee assessment form with the passage of time. No data are available on valgus stability. The authors support conservative management as a valid therapeutic option.

Given the lack of standardization in the selection process of patients, outcome criteria, and outcome assessment, the question about which is the best treatment for ACL–MCL combined injuries still remains open.

Recommendations

- In patients with suspected ACL–MCL injury, isolated partial injuries of the MCL can be managed nonoperatively [overall quality: moderate]
- There are no differences in outcomes when an ACL injury associated with grade II valgus laxity is addressed by surgical reconstruction of ACL and conservative measures or surgical repair of MCL [overall quality: moderate]
- Comparable results are achieved with conservative measure or with surgical repair in combined ACL–MCL injuries with grade III valgus laxity. Early or late ACL reconstruction is still controversial [overall quality: moderate]

Question 6: What about the use of prophylactic devices?

Relevance

For the last 30 years, knee braces have been used to assist individuals with ACL deficiency and ACL-reconstructed knees. Knee bracing may have a prophylactic role in preventing knee ligament injuries.

Finding the evidence

- Cochrane Database, with search term “knee ligament injury prophylactic devices”

• PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: knee ligament injury prophylactic devices"

Quality of the evidence

Level I

- 1 systematic review⁵⁵

Findings

Rishiraj et al.⁵⁵ reviewed several studies with a protective effect of functional knee bracing (FKB) on knee ligaments injuries. However, the exact mechanism that may protect the knee ligaments is unknown, because of a lack of studies on FKB worn during competitive sport, probably because of the fear of performance hindrance.

Recommendation

• In patients with suspected ACL–MCL injury, there is evidence for a protective role of knee bracing devices but only in the noninjured population [overall quality: low]

Summary of recommendations

- A combined ACL–MCL lesion rather than an isolated ACL lesion should be suspected in patients playing sports that put them at risk of knee rotational and valgus stress maneuvers
- A combined ACL–MCL lesion should be suspected in female athletes, in patients playing sports that have a high risk for ligament injuries, and in patients with a previous diagnosis of narrow femoral intercondylar notch or in whom the radiographs or CT scans show a smaller NWI during the diagnostic process
- In patients with suspected ACL–MCL injury, the diagnostic process should include accurate history-taking and physical examination should assess ROM
- Suspected MCL lesions should be addressed by the valgus stress test for the MCL
- Suspected ACL lesions should be addressed by the Lachman's test, the anterior drawer test, and the pivot shift test
- MRI is a reliable diagnostic tool
- Isolated partial injuries of the MCL can be managed nonoperatively
- There are no differences in outcomes when an ACL injury associated with grade II valgus laxity is addressed by surgical reconstruction of ACL and conservative measures or surgical repair of MCL
- Comparable results are achieved with conservative measure or with surgical repair in combined ACL–MCL injuries with grade III valgus laxity. Early or late ACL reconstruction is still controversial

• In patients with suspected ACL–MCL injury, there is evidence for a protective role of knee bracing devices but only in the noninjured population

Case scenario

A 32 year old hockey player injured his knee 8 months ago. He now complains of posterolateral knee pain, and is unable to play hockey. His knee hyperextends when going up and down stairs, and gives way with twisting and pivoting activities.

Relevant anatomy

Posterolateral corner (PLC) anatomy is complex, and has only recently been fully elucidated. Historically, confusion surrounded the anatomical relationship of PLC structures secondary to the use of inconsistent terminology.

Seebacher et al.¹ performed a cadaveric study of 35 knees, which helped delineate the complex structural arrangement of the PLC. They described a three-layered arrangement in which the most superficial layer is composed of the iliotibial band and the superficial portion of biceps femoris. The middle layer is made up of the patelomeniscal ligament along with the quadriceps retinaculum anteriorly and the two patellofemoral ligaments posteriorly. The third and deepest layer is divided into a superficial lamina composed of the lateral collateral ligament (LCL) and the fabellofibular ligament. The deep lamina contains the popliteofibular ligament (PFL), the arcuate ligament, and the popliteus muscle. However, significant anatomical variability exists, which confuses matters further. One study demonstrated that only 68% of 50 cadaveric knees had a fabellofibular ligament and the arcuate ligament was present in just 24% of cases.²

The main stabilizers of the PLC are the LCL, PFL, and the popliteus muscle–tendon unit. Injury to these struc-

tures results in increased varus laxity, increased external rotation laxity, and increased posterior tibial translation. More recent surgical techniques aim to anatomically reconstruct these three structures.

Importance of the problem

Injuries to the PLC are rare but severely debilitating. Isolated PLC injuries are even rarer. DeLee³ found that only 12 (1.6%) out of 735 knee ligament injury patients had acute isolated posterolateral instability. LaPrade found a similar incidence of 2.1%; only 4 out of 331 consecutive patients with an acute knee injury resulting in hemarthrosis had an isolated PLC injury.⁴

Surgeons should be aware of potential PLC injury, as it has been established that unrecognized or untreated posterolateral instability is the commonest cause for failure of cruciate ligament reconstruction. Noyes and coworkers found 17 of 76 patients undergoing anterior cruciate ligament (ACL) revision surgery had unrecognized PLC injury.⁵

Google searches for “knee posterolateral corner injury” and “knee posterolateral corner reconstruction” generate respectively 38,000 and 58,800 results. As these links are often of uncertain quality, there is need for high-quality, evidence-based guides.

Top five questions

Diagnosis

1. How reliable is clinical examination in the diagnosis of PLC injury?
2. How accurate is MRI for the evaluation of PLC injury?

Therapy

3. What are the indications for nonoperative management for PLC injury?
4. Does acute surgical repair give better results than reconstruction for the management of PLC injury?
5. What is the best method of reconstruction for PLC injury?

Question 1: How reliable is clinical examination in the diagnosis of PLC injury?

Relevance

Accurate diagnosis of ligamentous injury of the knee allows an appropriate management plan to be formulated.

Current opinion

Several clinical tests have been described to evaluate PLC injury. However, limited data exists on the reliability of these tests and they rely on subjective assessment.

Finding the evidence

- Cochrane Database, with search term: “posterolateral corner injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “posterolateral knee instability and clinical tests”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “posterolateral corner injury” AND “clinical evaluation”
- Citations from relevant articles captured by the search

Quality of the evidence

Level IV

- 3 case series⁶⁻⁸

Findings

Hughston et al.⁶ found that 84% of 140 patients with chronic posterolateral rotatory instability of the knee had a positive external rotation recurvatum test, and 80% had a positive posterolateral drawer test. Overall, 72% of knees had a positive result for both tests.

In 71 patients, LaPrade et al.⁷ found a positive result for the posterolateral external rotation test performed at 90° of knee flexion and external rotation recurvatum test in 54 (76%) and 52 (73%) knees respectively. However, a positive result was not associated with injury to any specific PLC structure ($p > 0.05$). The posterolateral external rotation test performed at 90° of knee flexion is a variation of Hughston and Norwood’s posterolateral drawer test. Therefore, although these tests confirm injury to the PLC, they are unable to diagnose which structures are damaged.

More recently, LaPrade et al.⁸ reported that only 10 out of 134 patients with grade III PLC injury had a positive external rotation recurvatum test. All 10 patients had a combined PLC and ACL injury, which was confirmed at the time of

surgery. Overall the test was only positive in 30% of patients with a combined PLC and ACL injury ($n = 33$), and was not positive in any patients with isolated PLC injury or combined PLC and PCL injury. Therefore, in this study in which examination was performed in a clinical setting on conscious patients, the external rotation recurvatum test was shown to be very inaccurate in predicting a PLC injury.

Recommendations

- Clinical tests for assessing the PLC should be interpreted carefully as a significant number of patients with negative results may still have a PLC injury
- The overall evidence presented here is poor, as it is based on relatively small numbers of patients. In addition, there are also some conflicting findings from these studies

Question 2: How accurate is MRI for the evaluation of PLC injury?

Case clarification

Clinical examination reveals grade 3+ laxity on varus stress testing with the knee in 30° of flexion. In addition there is a positive external rotation recurvatum test. Plain radiographs of the knee demonstrate a small avulsion fracture of the fibular head. Ligament injury grading is based on the nomenclature described by DeLee et al.³ in 1983 (see box).

Ligament injury grading³

- 1+: 0–5 mm with definite endpoint to stress
- 2+: 5–10 mm with definite endpoint to stress
- 3+: >10 mm of joint opening with no or soft endpoint to stress

Relevance

Accurate diagnosis of ligamentous injury of the knee allows an appropriate management plan to be formulated.

Current opinion

Routine MRI scan is sought in the evaluation of almost all knee ligament injuries, as clinical examination cannot reliably determine which component of the PLC has been damaged. A fibular head fracture (arcuate fracture) is considered to be pathognomonic for PLC injury.

Finding the evidence

- Cochrane Database, with search term “posterolateral corner injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “knee posterolateral AND MRI” and “arcuate fracture AND MRI”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “posterolateral knee” AND “magnetic resonance imaging”
- Citations from relevant articles captured by the search

Quality of the evidence*Level IV*

- 5 case series⁹⁻¹³

Findings

Miller and coworkers⁹ found that 30 of 481 patients undergoing MRI for evaluation of internal derangement of the knee had injury to at least one PLC structure. Of these 30 patients the LCL was injured in 19 cases and popliteus in 16 cases. On the basis of clinical examination only 3 of these 30 patients were suspected to have a PLC injury.

Two studies (n = 20) have correlated MRI findings with examination under anesthesia or surgical findings. Ross et al.¹⁰ found that they were able to accurately diagnose PLC injuries in all of their six cases. Theodorou et al.¹¹ reported 100% accuracy for diagnosing LCL and gastrocnemius tendon tears 93% for biceps tendon tears and 86% for popliteus tendon tears.

Two studies report on the MRI evaluation of patients found to have an arcuate fracture. Juhng et al.¹² (n = 18) found that in 16 cases there was an injury to at least one cruciate ligament (13 ACL injuries and 12 PCL injuries), and in 9 cases both cruciate ligaments were injured. The popliteus musculotendinous unit was injured in 6 cases. Huang et al.¹³ (n = 13) found a popliteus injury in only 1 case, but a PCL injury was noted in all 13 cases; there were no cases of ACL injury. At surgery, 6 of 10 cases were found to have disruption of the arcuate complex. The arcuate complex was defined to consist of the arcuate, popliteofibular and fabellofibular ligaments; however, the authors were unable to assess the integrity of these structures on MRI scan.

Recommendations

- An MRI scan should be obtained in cases of suspected PLC injury, as clinical examination alone can miss injuries
- Clinicians should be aware that although an MRI scan can evaluate larger structures, the small ligaments cannot be confidently assessed
- In the presence of an arcuate fracture an MRI scan should be performed, as there is a high incidence of associated cruciate ligament injury
- The overall level of evidence presented here is low, as it is based on only a few studies with small numbers of patients

Question 3: What are the indications for nonoperative management for PLC injury?**Relevance**

If some types of PLC injury have a satisfactory outcome with nonoperative management, then surgery can be avoided for certain patients.

Current opinion

Surgery should be reserved for symptomatic patients with significant instability on clinical examination

Finding the evidence

- Cochrane Database, with search term “posterolateral corner injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “posterolateral corner injury AND non operative management”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “knee lateral ligament” AND “non operative management”
- Citations from relevant articles captured by the search

Quality of the evidence*Level IV*

- 2 case series^{14,15}

Findings

Kannus reported nonoperative management for 11 grade II and 12 grade III injuries of the lateral ligament compartment (Newcastle Ottawa Scale 3).¹⁴ Kannus describes the lateral ligament compartment to consist of the middle third of the lateral capsular ligament and the arcuate complex, which in turn comprised the LCL, arcuate ligament, popliteus muscle, and the lateral head of gastrocnemius. Patients were immobilized for a variable period of time (grade II 2–5 weeks, grade III 2–7 weeks), followed by early rehabilitation which continued for at least 6 months. At follow-up (average 8.3 years) the grade II patients were found to have approximately the same level of laxity as at the time of initial injury (Table 98.1). Patients with grade III injuries fared more poorly and at follow-up the knees were still laterally unstable; 2 patients changed occupation and 2 received a partial pension.

Krukhaug et al. reported on the nonoperative management of 7 patients with primary lateral instability of 1+ (Newcastle Ottawa Scale 5).¹⁵ Six patients were managed with early range of motion and 1 with a cylinder cast for 6 weeks. At follow-up (average 7.5 years), 6 patients had a completely stable knee on varus stressing, and 1 patient treated in cylinder cast had residual laxity of 1+. Median Lysholm score for the stable patients was excellent, at 95.

Recommendations

- In patients with isolated lateral laxity of 1+ or 2+, nonoperative management is likely to lead to a satisfactory result in terms of function and stability
- Patients with lateral laxity of 3+ or with evidence of other instability should be considered for surgery
- The overall level of evidence presented here is low, as it is based on only two studies with a small numbers of patients. Also there is no data on which structures of the PLC were damaged, as MRI scans were not performed

Table 98.1 Results reported by Kannus¹⁴

Injury grade	Lysholm score	Return to preinjury activity	Post-traumatic OA
Grade II (n = 11)	88 (good)	9	0
Grade III (n = 12)	65 (fair)	2	6

OA, osteoarthritis.

Question 4: Does acute surgical repair give better results than reconstruction for the management of PLC injury?

Relevance

Compelling data on acute repair vs. reconstruction will allow surgeons to perform the procedure which yields better results.

Current opinion

Acute repair is believed to lead to better results, although often a delay in patient presentation precludes repair in favor of surgical reconstruction.

Finding the evidence

- Cochrane Database, with search term “posterolateral corner injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “posterolateral corner reconstruction” and “posterolateral corner repair”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “posterolateral corner injury” AND “surgery”
- Citations from relevant articles captured by the search

Quality of the evidence

Level II 1 prospective cohort study¹⁶ (Newcastle Ottawa Scale 6)

Level III 1 retrospective cohort study¹⁷ (Newcastle Ottawa Scale 4)

Level IV 1 case series¹⁸ (Newcastle Ottawa Scale 5)

Findings

In 2005, Stannard et al. reported their prospective cohort study in which there were 57 cases of PLC injury.¹⁶ However, 44 of these patients had sustained high-energy trauma resulting in multiligament knee injury. A total of 13 patients had isolated PLC injury, with or without single cruciate ligament injury. Of these 13 patients, 7 underwent acute repair within 3 weeks of injury; the remaining 6 underwent

reconstruction. None of the 6 reconstructions failed, but 2 of the 7 repairs failed. Although knee scores were reported in this study, they were not broken down according to isolated PLC injury or multiligament injury.

In 2006, Tzurbakis et al. reported follow-up of 44 patients with multiligament injury.¹⁸ A subgroup in this study consisted of 11 patients with single cruciate ligament injury and total PLC rupture. Of these 11 patients 5 underwent acute repair, and 6 underwent reconstruction. Again in this study, results were reported as a composite for the whole group. In general acutely treated patients, scored better in a few areas of the International Knee Documentation Committee (IKDC) score, but this was not statistically significant.

Levy et al. have reported their results on patients with knee multiligament injuries who underwent either repair (n = 10) or reconstruction (n = 18) of the posterolateral structures.¹⁷ The repair group underwent staged surgery; therefore whilst initial surgical repair took place on average 19 days after injury, subsequent cruciate ligament reconstruction occurred on average 132 days after the repair. There were 4 failures in the repair group and only 1 failure in the reconstruction group; this difference was found to be significant (p = 0.04). No statistical difference was found between the two groups in terms of IKDC or Lysholm scores. Multivariate regression analysis found that patient demographics, time to surgery, interval between stages (for the repair group), number of ligaments involved, and location of FCL/PLC tears did not affect final outcome.

Recommendation

- Surgical reconstruction should be performed for PLC injuries, as acute repair results in a higher failure rate

Question 5: What is the best method of reconstruction for PLC injury?

Relevance

Strong evidence to establish the optimal form of reconstruction for PLC injury will allow that particular technique to be used in the management of these complex cases.

Current opinion

There is no clear consensus as to the optimal technique for PLC reconstruction.

Finding the evidence

- Cochrane Database, with search term “posterolateral corner injury”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “posterolateral corner reconstruction”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “posterolateral corner injury” AND “surgery”

- Citations from relevant articles captured by the search
- Studies with a minimum follow-up of 12 months and average follow-up of 24 months that employed validated knee scores for preoperative and postoperative analyses were included

Quality of the evidence

Level IV

- 9 case series¹⁹⁻²⁷

Findings

Our search yielded seven studies that reported on a variety of techniques employed for PLC reconstruction,^{19,20,22-24,26-27} summarized in Table 98.2. In four studies a limited reconstruction was performed, such as local augmentation, biceps tenodesis, or PFL reconstruction. In three studies a more extensive anatomic reconstruction was performed, whereby the LCL, PFL, and popliteus were reconstructed. In all studies the number of patients was small and the injuries sustained were varied. Therefore in three studies cases consisted of only PCL and PLC injury, but in three studies a variable combination of ligament injuries was included. All studies reported an improvement in knee specific scoring systems. In the most recent study on PLC reconstruction, LaPrade et al. employed an anatomic technique. They found an improvement in Cincinnati and IKDC scores.¹⁹ A significant improvement was noted in IKDC scores for varus opening at 20°, external rotation at 90°, reverse pivot shift, and single leg hop (p < 0.001). However it can be seen from Table 98.2 that no specific technique yielded a clearly superior improvement in knee scores.

Two studies have compared clinical outcomes for different types of reconstruction technique. Jung and coworkers reported a retrospective cohort study of patients with PCL and grade II PLC (increased external rotation of >10° combined with grade 0-2 varus instability) injury.²¹ In this study 19 patients underwent PLC reconstruction via a tran-

stibial sling procedure and 20 patients via a transfibular sling procedure. The fibular head tunnel technique led to a significantly better improvement in rotational stability (p = 0.007), although no significant difference was found for varus stability and clinical outcome scores. Yoon et al. retrospectively compared anatomic reconstruction (n = 21) with a PLC sling procedure (n = 25).²⁵ They found a significantly better improvement in external rotation laxity and varus laxity with anatomic reconstruction (p < 0.5). The Lysholm knee score improved significantly in both groups (p < 0.5) and no significant difference was found between the two groups.

Recommendations

- On the basis of available evidence no recommendation can be made
- The overall level of evidence presented here is low, as it is based on relatively small numbers of patients. In addition, there are also some conflicting findings from these studies

Summary of recommendations

- Clinical examination alone is inadequate to diagnose PLC injury
- A MRI scan should always be obtained in cases of suspected PLC injury, particularly in the presence of an arcuate fracture
- In patients with isolated lateral laxity of 1+ or 2+, non-operative management is likely to lead to a satisfactory result in terms of function and stability
- Surgical reconstruction should be performed for PLC injuries, as acute repair results in a higher failure rate
- There is insufficient evidence to make a recommendation regarding the best technique for surgical reconstruction

Table 98.2 Summary of studies on reconstruction procedures

Study	NOS	No. of patients	Type of reconstruction	Av. age	Av F/U	Time to surgery(months)	Lysholm		IKDC(% normal/near normal)		Tegner

F/U, follow-up; IKDC, International Knee Documentation Committee; NOS, Newcastle Ottawa Scale; NR, not recorded; PFL, popliteofibular ligament.

Conclusions

PLC injuries are both rare and complex; hence there is a shortage of high-quality evidence on which to base decision making. On the basis of available evidence, suspected PLC injuries should be investigated with an MRI scan. Isolated lateral laxity of grade 1+ or 2+ can be managed nonoperatively. However, more severe lateral laxity or combined posterolateral laxity should be managed with surgical reconstruction. The key PLC structures that require reconstruction are the LCL, the popliteofibular ligament, and the popliteus muscle–tendon unit. Various techniques have been described for PLC reconstruction, but at present there is insufficient evidence to recommend one specific technique.

Joris E.J. Bekkers, Anika I. Tsuchida, and Daniël B.F. Saris

University Medical Center Utrecht, Utrecht, The Netherlands

Case scenario

A 25 year old patient presents with a torsion trauma of the knee. He complains of persistent pain and occasional catching and locking which prevents him from returning to his preinjury sports level. A mild effusion of the left knee is present, the knee ligaments are intact, and meniscus tests indicate medial meniscus pathology. In addition, an articular cartilage defect is suspected.

Relevant anatomy

Articular cartilage is a zonal-oriented tissue that promotes smooth articulation and conducts high impact forces to the subchondral bone.¹ In a healthy joint, there is a stable equilibrium between the synovium and cartilage matrix.² After cartilage injury this joint homeostasis can be disturbed, resulting in a cascade of intra-articular factors which negatively influence cartilage healing.²

Importance of the problem

The prevalence of trauma-related cartilage lesions ranges from 23% to 54%.³ Most lesions are not detected at first evaluation and are likely to develop towards osteoarthritis (OA) at a young age, with subsequent decreased quality of life and increased medical costs. Adequate evaluation of cartilage injury, design of custom-made treatment plans, and identification of prognostic factors is essential to delay this progression and improve the functionality of patients after cartilage injury.

Top five questions

Diagnosis

1. How accurate is MRI in the diagnosis of focal cartilage lesions of the knee?

Therapy

2. What is the difference in clinical outcome between various surgical options to treat focal cartilage lesions of the knee?

3. What is the optimal rehabilitation protocol for patients after cartilage surgery?

Prognosis

4. Does a specific treatment perform better for specific patients?

5. What are prognostic factors that predict the outcome after articular cartilage surgery?

Question 1: What is the accuracy of MRI in the diagnosis of a focal cartilage lesion of the knee?

Case clarification

A meniscal tear is often accompanied by focal articular cartilage pathology. To evaluate the presence of a focal cartilage defect an additional MRI is obtained.

Relevance

Evaluation of cartilage pathology on MRI is important to inform the patient on possible treatment decisions during arthroscopy.

Current opinion

The clinical suspicion of an articular cartilage defect and related surgical strategy is mainly based on clinical examination and MRI.

Finding the evidence

- PubMed, with search term: “((MRI[TiAB]) OR (magnetic resonance imaging[TiAB])) AND Arthroscopy[TiAB]”
- Quality of the evidence was appraised using the Cochrane Handbook for Systematic Reviews of Diagnostic Test Accuracy⁴

Quality of the evidence

Level I

- 3 validating cohort studies with good reference standard⁵⁻⁷

Level III

- 1 diagnostic study of nonconsecutive patients⁸

Findings

All studies included had a prospective character and compared a prearthroscopic MRI to the findings during arthroscopy. Overall the sensitivity ranged from 33% to 100%, the specificity from 86% to 100%, the negative predictive value from 86% to 95%, and the positive predictive value from 39% to 85%.⁵⁻⁸ A pooled analysis, subcategorized to the defect grade (Figure 99.1), showed a good specificity (range 95–97%) and a sensitivity increasing with defect grade (Table 99.1).

Table 99.1 Specificity and sensitivity of MRI to detect articular cartilage lesions

Outerbridge grade	I	II	III	IV
Sensitivity	23%	22%	64%	70%
Specificity	95%	97%	97%	95%

Recommendation

- The MRI shows a moderate detection of clinically relevant (grade III and IV) articular cartilage defects (sensitivity 64–70%) [overall quality: moderate]

Question 2: What is the difference in clinical outcome between various surgical options to treat focal cartilage lesions of the knee?

Case clarification

The MRI showed a grade IV articular cartilage lesion at the medial femoral condyle. Several treatment options are available (see box).

Treatment options for focal articular cartilage lesions

- *Autologous chondrocyte implantation (ACI)*: Chondrocytes are taken by biopsy, expanded in vitro and re injected under a periosteal flap⁹ that covers the defect. Newer generations of ACI use collagen covers (2nd generation) or seed chondrocytes onto matrices (3rd generation)¹⁰

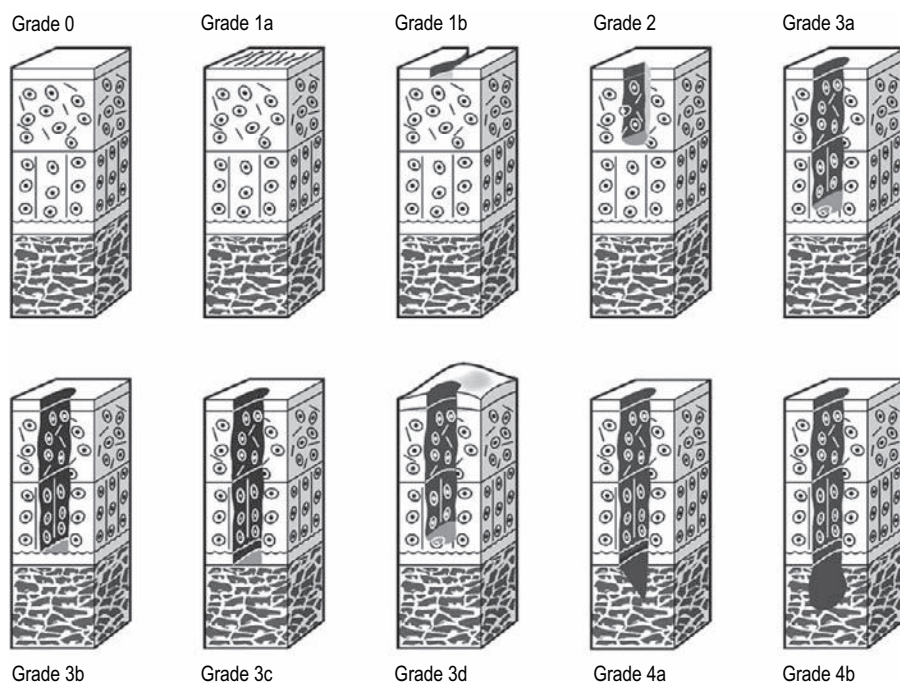

Figure 99.1 The International Cartilage Repair Society (ICRS) articular cartilage defect classification: Grade 0, macroscopically normal cartilage; Grade 1, nearly normal: superficial lesions, soft indentation (1a) and/or superficial fissures and cracks (1b); Grade 2, abnormal: lesions extending down to less than 50% of cartilage depth; Grade 3, severely abnormal: cartilage defects extending down to more than 50% of cartilage depth (3a), as well as down to the calcified layer (3b), and down to but not through the subchondral bone (3c) and cartilage defects with blisters (3d); Grade 4, severely abnormal: all cartilage defects into the subchondral bone. Permission to use this image was granted by the president of the ICRS, Professor Dr. D.B.F. Saris.

Treatment options for focal articular cartilage lesions (continued)

- *Osteochondral autologous transplantation (OAT)*: Osteochondral autografts are harvested from less-weightbearing areas of the knee and transferred to the defect¹¹
- *Microfracturing (MF)*: A 1–2mm diameter awl is used to penetrate the subchondral plate creating access to the bone marrow filling the cartilage lesion with a clot populated with bone-marrow-derived stem cells, growth factors, and platelets¹²

Relevance

Adequate treatment is important for patients presenting with focal cartilage lesions of the knee, who are generally young, to prevent progression towards OA in middle age.

Current opinion

MF is a good first line treatment, but ACI and OAT provide better long-term clinical results.

Finding the evidence

- PubMed: several synonyms of the treatment options. See detailed description in Bekkers et al.¹³
- Quality appraisal as explained in the Cochrane Handbook¹⁴

Quality of the evidence*Level I*

- 1 systematic review of randomized controlled trials (RCTs)¹³
- 6 randomized trials^{15–20}

Findings

All studies included were of high quality, with Coleman scores ranging from 74 to 94.¹³ The average defect size ranged from 2.4 to 5.1cm² and all defects were at least grade III (Figure 99.1). A pooled analysis of clinical outcome was not possible due to the heterogeneity of clinical outcome measures. After 1 year follow-up OAT showed clinical superior outcome compared to MF in both the Hospital for Special Surgery ($p < 0.05$) and International Cartilage Repair Society ($p < 0.03$) questionnaires.¹⁶ After 3 years follow-up MF shows inferior clinical results when compared to characterized chondrocyte implantation (CCI) ($p = 0.048$) or OAT ($p < 0.001$).^{16,20} After 19 months follow-up OAT and ACI did not differ ($p = 0.227$) on the modified Cincinnati score.¹⁵ A randomized study of chronic articular cartilage lesions did not show any difference in clinical outcome between ACI and MF at 5 year follow-up.¹⁸ An increase in clinical outcome after ACI or a decrease in MF is generally observed after 1 year follow-up, indicating a less stable regenerative product after MF.^{16,20}

Recommendations

- Treatment of focal articular cartilage lesions by ACI or OAT provides better mid-term clinical results than MF [overall quality: high]

- ACI and OAT are both good treatment options for grade III and IV focal articular cartilage lesions, with similar clinical results

Question 3: What is the optimal rehabilitation protocol for patients after cartilage surgery?**Case clarification**

Rehabilitation after cartilage surgery aims at resumption of previous function and activity levels.

Relevance

Rehabilitation is essential for optimal success after cartilage surgery.

Current opinion

Cartilage surgery requires extensive rehabilitation, which is currently primarily based on expert opinion.

Finding the evidence

- PubMed, with search term: “cartilage[TiAB] AND revalidation[TiAB]”

Quality of the evidence*Level I*

- 2 RCTs^{21,22}

Level II

- 1 cohort study²³

Level V

- 1 expert opinion²⁴

Findings

Time to weightbearing Two RCTs compared traditional weightbearing (full weightbearing after 8–10 or 11 weeks) vs. accelerated weightbearing (full weightbearing after respectively 6 or 8 weeks) after matrix-induced autologous chondrocyte implantation (MACI).^{21,22} The accelerated group reported less pain at 3 months ($p = 0.033$) compared to the traditional group²¹ and after 2 years both groups reported similar clinical outcome ($p = 0.910$) on the knee injury and osteoarthritis outcome (KOOS) score.²²

Low-load activities An RCT reported on the effect of low-load activities during rehabilitation on functional outcome after CCI or MF.²³ Lack of postoperative low-load activities resulted in a significantly worse functional outcome ($p < 0.05$) compared to high levels of postsurgery low-load activities.

Principles of rehabilitation Currently, the rehabilitation protocols after cartilage surgery are mainly based on expert opinion and the hypothesis of graft maturation, which divides the rehabilitation into several phases (Table 99.2).²⁴

Table 99.2 Phases of rehabilitation

Phase I	Recovery and protection (weeks 0–4) Protect graft from load and shear forces, weightbearing control Restore full passive knee extension, gradually increase pain-free knee flexion
Phase II	Inauguration (weeks 4–8) Increase pain-free ROM and weightbearing Gain quadriceps control in safe, multiangle CKC exercises
Phase III	Maturation (weeks 8–12) Full active pain-free ROM and gradual return to full weightbearing Regain optimal coordination for walking, stair climbing/ descending
Phase IV	Integration (weeks 12–26) Increase lower limb strength and gradually increase training load and volume Ensure safe static postures with balance exercises
Phase V	Functional adaptation (weeks 26–52+) Unrestricted ADL Prevent future damage/injury
Phase VI	Return to sports (weeks 26–78+) Restore symmetry, including lower limb strength and flexibility Aim for unrestricted sport (at same or lower level)

ADL, activities of daily living; CKC, closed kinetic chain; ROM, range of motion.

Recommendations

- Accelerated weightbearing is safe and does not lead to inferior clinical results.[overall quality: high]
- Low-load activities increase functional outcome after both MF and CCI [overall quality: moderate]
- Cartilage therapies require careful rehabilitation guided by trained professionals [overall quality: low]

Question 4: Do specific patients achieve a higher clinical outcome after a specific articular cartilage surgery?

Case clarification

The nature of regenerated tissue and the theoretical basis of different cartilage surgeries vary.

Relevance

Selecting the optimal treatment, based on specific patient characteristics, leads to a tailor-made treatment strategy

leading to superior outcomes after articular cartilage surgery.

Current opinion

Current opinion suggests that large articular cartilage lesions should preferably be treated by ACI or OAT. For small articular cartilage lesions or (multiple) chronic lesions, MF is the first treatment option.

Finding the evidence

- See Question 2

Quality of the evidence

Level I

- 3 randomized trials^{16,17,20}

Findings

Lesion size Lesions larger than 4cm^{2,17} or larger than 2cm^{2,16} perform clinically worse ($p < 0.05$) after MF treatment, while the influence of lesion size on clinical outcome was not present after ACI or OAT.^{16,17}

Symptom duration CCI resulted in a better clinical outcome than MF ($p < 0.04$) for patients with a symptom duration of less than 3 years.²⁰

Recommendations

- Large articular cartilage lesions (>4cm²) should be treated with ACI or OAT [overall quality: high]
- Patients with duration of symptoms less than 3 years should preferably be treated with CCI [overall quality: high]

Question 5: What are patient-specific, prognostic factors that predict the clinical outcome after articular cartilage surgery?

Case clarification

The overall benefit from cartilage surgery is 70–95%.

Relevance

Identification of prognostic factors for the clinical outcome after cartilage surgery will improve surgical timing leading to optimal benefit from the surgery.

Current opinion

Increasing age is expected to negatively influence the clinical outcome after cartilage surgery.

Finding the evidence

- See Question 2

Quality of the evidence

Level I

- 6 individual inception cohort studies validated in a single population^{25–29}

Level II

- 2 prospective cohort studies^{30,31}

Findings

Patient age Four studies showed a statistically significant influence ($p < 0.05$) of patient age on treatment outcome;^{26–28,32} increasing age is associated with inferior clinical results.

Duration of symptoms Treatment of articular cartilage lesions with a traumatic origin and symptoms for less than 1 year ($p < 0.05$) was more successful than those with symptoms for more than 1 year.²⁹ Similar results were shown for a symptom duration of 2 years ($p = 0.03$)²⁶ and patients with symptom duration less than 2 years are more likely to reach their age-matched healthy reference score.³²

Defect location Superior clinical results were described for defects located at the lateral femoral condyle ($p < 0.05$)^{26,28} while others report superiority ($p < 0.05$) of defects at the medial condyle.³² Additionally, other cohorts did not identify defect location as a prognostic factor for the outcome after ACI.^{25,27}

Recommendations

- Increasing age negatively influences the clinical outcome after cartilage surgery [overall quality: high]
- A shorter duration of symptoms favors the clinical outcome after cartilage surgery [overall quality: high]
- Location of the defect seems to influence the clinical outcome, however, results are conflicting [overall quality: low]

Summary of recommendations

- The MRI shows a moderate detection of clinically relevant (grade III and IV) articular cartilage defects (sensitivity 64–70%)
- The treatment of grade III and IV focal articular cartilage lesions by ACI or OAT provide better mid-term clinical results compared to MF
- ACI and OAT are both good treatment options for grade III and IV focal articular cartilage lesions with similar clinical results
- Accelerated weightbearing is safe and does not lead to inferior clinical results
- Low-load activities increase functional outcome after MF and CCI
- Cartilage therapies require careful rehabilitation guided by trained professionals
- Large grade III or IV articular cartilage lesions ($>4\text{cm}^2$) should be treated with ACI or OAT
- Patients with symptoms duration less than 2 years should preferably be treated with CCI

- Increasing age negatively influences the clinical outcome after cartilage surgery
- A shorter duration of symptoms favors the clinical outcome after cartilage surgery
- Location of the defect seems to influence the clinical outcome, however, results are conflicting

Conclusions

MRI is the best available noninvasive diagnostic tool to detect high-graded focal articular cartilage lesions. Several surgical treatment options for focal articular cartilage lesions are available. Mid-term clinical outcomes favor cell therapy over other cartilage surgeries. However, globally accepted outcome measures of cartilage surgery would enhance the comparison between studies. In addition, treatment selection and timing, based on patient profiling and prognostic factors respectively, will be essential to reach optimal results from articular cartilage surgery. The recent increase in scientific publications on rehabilitation after cartilage surgery initiates a shift from expert opinion towards a more evidence-based approach in rehabilitation after cartilage surgery.

Department of Rehabilitation Sciences, Hong Kong Polytechnic University, Kowloon, Hong Kong

Case scenario

A 30 year old woman presented to the physiotherapy clinic with bilateral anterior knee pain. She is a keen runner and she stated that the pain began 3 months ago when she increased her weekly mileage in preparation for running a marathon. She continued to run through the pain until it got so bad that it was impossible to ignore. Activities such as going up and down stairs also aggravated her pain. She stopped running to rest the knee but pain recurred as soon as she resumed training. She has had an MRI taken which showed no abnormality. Her doctor says she has runner's knee and advises her to stop running and start doing some quadriceps strengthening exercise.

Finding the evidence

To identify relevant trials, we searched the following electronic database systems:

- Cochrane Database of Systematic Reviews
- Cochrane Central Register of Controlled Trials (Cochrane Library Issue 3, 2009)
- Ovid MEDLINE (1966 to October 2009).

A combination of MeSH headings and keywords relevant to runner's knee was used. These include the following terms:

- "runner or jogg* OR sprint* OR racer," "athletic injuries," "knee injuries," "patella," "patellofemoral pain," "patellofemoral syndrome," "anterior knee pain," "chondromalacia patellae," "tendinitis," "physiotherapy," "physical therapy," "rehabilitation," "exercise," "strength," "stretch," "electrophysical," "orthoses," "orthotic," "brace,"

"splint," "strap," "taping," "massage," "manipulation," "mobilization"

Any systematic review, randomized controlled trial (RCT), or quasi-randomized trial of prevention or intervention for runners' knee in adolescent and adult subjects was considered.

Top seven questions

1. What is runner's knee and how commonly does it occur in runners?
2. What are the possible risk factors associated with patellofemoral pain syndrome (PFPS)?
3. What is the optimal training volume for a runner to remain injury free?
4. What are the best treatment options for patellofemoral pain, and is exercise therapy effective in alleviating or preventing it?
5. Is external support useful in preventing or alleviating patellofemoral pain?
6. Can other treatment modalities be used in the treatment of patellofemoral pain?
7. What is the prognosis for PFPS?

Question 1: What is runner's knee and how commonly does it occur in runners?

Case clarification

Runner's knee or PFPS is a common cause of anterior knee pain in young active individuals. Although it is common among runners, the condition is not unique to runners. In this chapter, we use the term PFPS to describe this condition.

Relevance

It has been reported that patellofemoral pain affects approximately 1 in 4 of the general population.¹ Both genders are affected but the incidence is reported to be higher in women.² Runners in particular are susceptible to PFPS, accounting for 20–25% of all new running injuries seen in sports medicine clinics.^{2–4} Recreational runners tend to have a higher incidence of PFPS than experienced runners.⁵ Besides runners, PFPS also occur in different athletes such as soccer, hockey and volleyball players and in military recruits.^{6,7}

If not managed properly, this condition can be both painful and debilitating. If pain becomes severe, it can adversely affect both training and performance. The symptoms have an insidious onset with no history of trauma. The clinical presentation is characterized by pain behind and around the patella and is aggravated by knee loading activities such as running, squatting, ascending and descending stairs, and prolonged sitting.

Current opinion

The pathogenesis of PFPS is unclear; several anatomical sources of pain including lateral and medial retinaculæ structures, subchondral bone and the synovium have been proposed.^{8,9} The etiology of PFPS is multifactorial; causative factors such as overuse, malalignment, and muscle imbalance have been suggested. Diagnostic radiological imaging often failed to detect specific pathology. Thus diagnosis of PFPS is based on symptoms and physical examination after excluding intra-articular and peripatellar pathology. Symptoms can often be reproduced with palpation of the patella facet and patella compression tests.^{10,11} Despite the uncertainty as to the underlying etiology, conservative management is generally accepted as the management approach in improving pain and function in the literature.

Question 2: What are the possible risk factors associated with PFPS?**Case clarification**

The symptoms of PFPS are often characterized by slow insidious onset. The causation of this condition is multifactorial, involving both intrinsic and extrinsic factors. In the case study presented here, the extrinsic factor relating to training error may contribute to the onset of symptoms.

Relevance

To prevent injury, there is a need to identify the potential risk factors associated with PFPS.

Current opinion

Literature suggests that the causes of PFPS are multifactorial.

Quality of the evidence*Level I*

- 1 systematic review¹²

Findings

Four categories of risk factors were identified that might predispose to the lower extremity running injuries:¹² systemic, lifestyle, health, and running/training related factors. The systemic, lifestyle, and health factors can broadly be grouped under intrinsic factors while running/training related factors are extrinsic causes.

It has frequently been suggested that excessive loading on the patellofemoral joint (PFJ) is the principal cause of PFPS.¹³ The intrinsic factors influence the magnitude and distribution of the PFJ load when a runner lands on his/her feet during running. For instance, Thijs et al.¹⁴ showed that runners who developed PFPS exerted a significantly higher vertical peak force underneath the lateral heel (2nd and 3rd metatarsal) during running. Distribution of the load at the knee joint is governed by how the patella moves into contact with the femoral trochlea during knee excursion. Structures around the knee joint that influence patella tracking include patella position, soft tissue tension, and control of the medial and lateral components of the vastus medialis obliquus (VMO) muscle.^{15,16} Given the interaction between the kinematics of the lower extremities in functional activities, it has been also been suggested that patellar tracking is influenced by back posture, femoral internal rotation, knee valgus, tibial rotation, subtalar pronation, and muscle flexibility.^{17–19}

For running/training related factors, several risk factors have been reported in the literature. These include weekly mileage, history of previous running injuries, number of years in running, training characteristics (running speed, frequency of training, training surface, weekly running mileage) and footwear.^{19–22} Amongst them, increase in weekly running mileage has frequently been suggested.^{19,22} These potential contributing factors have led to different treatment approaches. The efficacy of these treatment in relieving pain is addressed in the following sections.

Recommendation

- Intrinsic risk factors that influence the PFJ loading, including muscle imbalances and biomechanical alterations, are thought to contribute to the onset of pain. Extrinsic risk factors including training error and footwear are commonly reported [overall level: moderate]

Question 3: What is the optimal training volume for a runner to remain injury free?**Case clarification**

One of the most common factors implicated in running injuries is errors in training methods. Often injury results

because of increasing the training intensity too quickly and too soon without allowing the tissues to adapt to the stress.

Relevance

The training volume is a modifiable risk factor by which runners can prevent injury.

Current opinion

To avoid injuries, it has been suggested that total weekly running distance should not exceed 64km.¹² One popular strategy in preventing injuries is the use of the 10% rule; i.e., increasing mileage by no more than 10% a week.

Quality of the evidence

Level I

- 1 systematic review²³ and 1 RCT²⁷

Findings

A meta-analysis²³ revealed 20 RCTs related to the prevention of the running-related soft tissue lower limb injuries. Four studies^{24–27} reported training schedule modifications. Pollock et al.²⁵ showed that modification of training frequency (RR 0.19; 95% CI 0.06–0.66) and duration (RR 0.41; 95% CI 0.21–0.79) can reduce injury, while another study of army recruits showed that reducing running distance²⁶ could reduce injury (RR 0.70; 95% CI 0.54–0.91). Thus there is strong evidence for an association between training volume and running-related lower limb injuries. However, direct evidence for quantifying the optimal training load for a runner preparing for a 10km or marathon race is lacking.

Gradual increase in the volume of training over time has been a long-held belief in preventing overuse running injuries in novice runners. No significant reduction in injury was observed in a study that examined graduated running program in the prevention of shin splints.²⁴ The 10% running rule, which states that an athlete should not increase training volume (time or distance or intensity) by more than 10% per week, is a common practice among runners. However, an RCT²⁷ that examined novice runners training for a 4 mile (6.4km) run reported that a graded 13-week training program that adhered to the 10% rule did not reduce the number of running-related injuries compared with a standard 8-week training program that increased training volume by 50% (RR 1.02, 95% CI 0.72–1.45).

Recommendations

- There is high quality evidence indicating an association of running-related lower limb injuries with training volume. However there is lack of data to quantify optimal training load for a runner in preparation for a 10km or marathon race

Question 4: What are the best treatment options for patellofemoral pain, and how effective is exercise therapy in alleviating or preventing it?

Case clarification

Generalized quadriceps strengthening exercises may not be able to address patella maltracking caused by muscle imbalances.

Relevance

As discussed previously, weakness of the VMO relative to vastus lateralis muscle (VL) leading to patella maltracking has been suggested as a contributing risk factor to the development of PFPS.³⁰ A prospective cohort study³¹ tested the onset timing of VMO-VL in healthy subjects subjected to 6 weeks of strenuous training and showed that those individuals who developed PFPS during training had a significant delayed onset of VMO activity. Thus it may suggest that individuals with a delayed onset of VMO activation are susceptible to developing PFPS. Furthermore, in a systematic review³² of patients with PFPS, a delay in the activation of VMO relative to VL during functional activities (e.g., stair descent: pooled mean difference: 30.25ms; 95% CI 16.68–43.81) has been demonstrated. Our study also demonstrated a lengthening of electromechanical delay in the VMO during fatiguing condition, which would affect the stabilizing effect on the patella during knee extension.³³

Current opinion

Although the etiology of patellofemoral pain is uncertain, it is generally well accepted that nonoperative management is the treatment of choice. Long-term outcome results showed that up to 75% of the PFPS patients treated conservatively had good subjective and functional recovery and did develop patellofemoral osteoarthritis.^{28,29} It is, therefore, important that the treatment decision for PFPS is built on the best research evidence. In the literature, treatment options include exercise therapy, use of external support, pharmacological intervention and electrical modalities. VMO retraining addressing the imbalance in VMO and VL has often been recommended as an essential component for treatment. This is often performed in combination with other physiotherapeutic interventions.

Quality of the evidence

Level I

- 5 RCTs,^{40–44} 1 controlled clinical trial,⁴⁵ and a systematic review⁴⁶ were identified to compare the beneficial effects of open kinetic chain (OKC) vs. closed kinetic chain (CKC) quadriceps strengthening exercises
- 1 systematic review⁴⁹ was identified to assess whether VMO retraining is effective in the treatment of PFPS

Level II

- 1 systemic review,³⁴ 1 controlled clinical trial,³⁵ and 2 RCTs^{36,37} were identified to examine the efficacy of exercise therapy for PFPS

Level III

- 2 systematic reviews^{55,56} were identified to examine if hip musculature strengthening is beneficial in reducing symptoms associated with PFPS; the studies included in these reviews^{50-54,57-59} are of low quality

Findings

A systematic review³⁴ of studies published between 1966 and 2001 concluded that there was limited evidence to support that exercise therapy reduces anterior knee pain in patients with PFPS. There is conflicting evidence of functional improvement after exercise therapy. Three trials (2 RCTs and 1 controlled clinical trial) were included,³⁵⁻³⁷ with only one RCT³⁷ being assessed as high quality. In this study, the investigators³⁷ compared (6 treatments over 3 months) exercise therapy with a control group not receiving exercise therapy. The exercises consisted of eccentric quadriceps strengthening, stretching, and functional exercises. At the end of the intervention, improvements for pain (effect size = 0.10) and function (effect size = 0.11) were observed in both groups. At 12 month follow-up, patients in the exercise group showed significant improvements in pain compared to the nonexercise group. Although the large dropout rate (40%) at 12 months in this study³⁷ might have contributed to the significant difference, it has to be noted that more patients in the exercise group reported greater patient satisfaction and were discharged at 3 months ($p = 0.001$). An RCT conducted by Crossley et al.³⁸ compared physiotherapy intervention (6 treatments over 6 weeks; emphasizing VMO exercise retraining) in subjects with anterior knee pain with placebo treatment. Results indicated that the intervention group improved in pain (effect size = 0.80) and function (effect size = 0.91). A recent high-quality RCT³⁹ on 131 subjects provided further evidence to the positive effects of physiotherapy-supervised exercise therapy for improving pain and function in patients with PFPS at 3 (effect size = 0.47 for pain; 0.34 for function) and 12 months (effect size = 0.56 for pain) than usual care in general medical practice. The exercises included strengthening exercises for quadriceps, adductors and gluteal muscles, balance and stretching. Together, these three high-quality trials provide evidence that exercise therapy resulted in better clinical outcomes.

Quadriceps strengthening exercises can be either OKC or CKC. OKC exercises involve movement in which the distal segment is free to move in space, whereas CKC exercises are performed with the distal segment fixed (either on the ground or on a support surface). CKC exercises has been suggested to be more effective in the treatment of

anterior knee pain because of their close resemblance to daily activities and are also believe to produce less compressive stress to the PFJ. The benefits of both forms of exercises have been suggested in the literature. Five trials⁴⁰⁻⁴⁵ were included in a systematic review³⁴ which compared the effects of OKC and CKC exercises in the treatment of subjects with PFPS, and showed that both exercises are effective in the short term (6–12 weeks) for pain reduction or functional improvement. In one trial,⁴³ a 5 year follow-up was undertaken to examine the long-term effects of an OKC or CKC program in subject with PFPS. The results demonstrated that both groups maintained equally good subjective and functional outcomes.⁴⁴ Another systematic review⁴⁶ on training methods also concluded that quadriceps strength training is beneficial, but no single approach (CKC or OKC; isometric or eccentric training mode) is superior to another. Thus there is strong evidence to support that both OKC and CKC exercises are effective in the short- and long-term management of PFPS.

To address VMO:VL imbalance in patients with patellofemoral pain, it has been proposed that VMO must be specifically strengthened to restore abnormal patella tracking. Is there evidence to suggest a specific VMO retraining exercise to be more effective? In the study by Crossley et al.,³⁸ the authors reported that exercises emphasizing VMO retraining resulted in less pain and better outcome. This same group of investigators conducted two subgroup RCTs^{47,48} to show that VMO retraining significantly improved the timing of VMO activation onset, and this was not observed in the placebo group. However, it is important to note that in addition to specific VMO retraining, subjects were given other interventions (patella taping, stretching, and hip external rotator strengthening). The authors stated that these interventions were aimed at improving VMO function, but inevitably this claim is difficult to establish. Debate also arises as to whether VMO can be preferentially activated with limb position or cocontraction. A systematic review of studies (20 trials) published up to 2008 suggest that the evidence remain unclear.⁴⁹

Hip muscle weakness (specifically abductors and external rotators) has been suggested to contribute to the development of PFPS. These muscles act eccentrically to control or resist excessive femoral adduction and internal rotation during activities, and strength deficits may result in increased dynamic Q-angle and PFJ contact area. Based on five cross-sectional studies,⁵⁰⁻⁵⁴ Prins et al.⁵⁵ reported in their review that women with PFPS demonstrate a decrease in hip abduction, external rotation, and extension strength when compared with healthy controls. Is there any evidence to support the use of hip muscle strengthening for the treatment of PFPS? Based on a systematic review,⁵⁶ three studies (a case report, a cohort study, and a cross-

sectional study)⁵⁷⁻⁵⁹ published in 1998–2006 were identified. Currently there is limited evidence to suggest that hip musculature strengthening has any beneficial effect in reducing symptoms associated with PFPS.

Tightness of the iliotibial band,⁶⁰ hamstrings, and gastrocnemius muscles,^{15,51} and reduced patellar mobility⁶¹ have also been suggested to cause patella maltracking and are associated with subject with PFPS. Stretching has not been shown to be effective in preventing PFPS and running-related lower limb soft tissue injuries.²³ There is also no evidence to suggest that stretching these tight anatomical structures is beneficial to the treatment of PFPS.

Recommendations

- Moderate-quality evidence shows that physiotherapy-supervised exercise therapy is effective for PFPS
- High-quality evidence supports the use of OKC or CKC quadriceps strengthening in reducing pain and improving function in subjects with PFPS, both short- and long-term
- There is moderate quality evidence to suggest that VMO retraining is effective in the treatment of PFPS. However it is unclear if VMO can be preferentially activated
- There is low quality evidence to support hip muscle strengthening or stretching exercises in improving symptoms in individuals with PFPS

Question 5: Is external support useful in preventing or alleviating patellofemoral pain?

Relevance

Applying external supports such as patella tape, patellofemoral brace, or foot insoles/orthoses for prevention or reduction of PFPS has been suggested in the literature.

Current opinion

The rationale behind external support is to influence the intrinsic risk factors by (1) realigning the patella to improve tracking and to enhance the activation and/or timing of the VMO muscle; or (2) realigning the lower leg/foot alignment to reduce the PFJ contact pressure and improve shock impact.

Quality of the evidence

Level I

- 6 systematic reviews⁶²⁻⁶⁶ published between 2001 and 2008 were identified to examine whether subjects receiving patella taping show an improvement in pain and knee function
- 3 systematic reviews^{23,46,66} and 4 RCTs⁷⁴⁻⁷⁷ examined the use of a knee brace
- 1 systematic review²³ examined whether the use of insoles protects against knee injuries

Findings

Many of the same studies were included in the six systematic reviews.⁶²⁻⁶⁶ These studies assessed the effectiveness of patella taping for PFPS but have incorporated other interventions into the treatment program, making it difficult to ascertain treatment effectiveness. Four included RCT studies of high quality^{37,38,67,68} examined the outcomes of patients who received patella taping. Only one trial³⁷ compared patella taping vs. no taping, which showed no significant improvement in pain and knee function at 3 and 12 months follow-up. Although taping alone has not been demonstrated to have significant benefits, positive effects were observed with combined treatment. The other three RCTs^{38,67,68} incorporated different physical interventions (strengthening, stretching, biofeedback) with patella taping as a component. The results (n = 214, mean age 23 years) showed significant short-term (duration 4–6 weeks) improvement in pain and function compared to the control group. Although the effectiveness of taping alone cannot be determined, the findings nevertheless showed a clear advantage of a combined treatment approach addressing the multifactorial etiology of PFPS.

The effects of patella taping on patella position and in enhancing neuromuscular control (i.e., VMO activation pattern and/or timing) were also evaluated. Three controlled clinical trials⁶⁹⁻⁷¹ were identified in a systematic review⁵⁶ which examined the effect of taping on VMO activation. However, the results are conflicting and thus the evidence is inconclusive.

The use of a knee brace was examined in three systematic reviews,^{23,46,66} with two RCTs^{72,73} showing patellofemoral bracing to be an effective method in preventing the development of PFPS (n = 210; RR 0.33; 95% CI 0.17–0.65). Although the underlying mechanism of the positive effects is not known, it has to be noted that subjects (respectively athletes and army recruits) in these two trials had to participate in an unaccustomed strenuous training program with a minimal period of adaptation. The braces used in these trials purport to provide support or to correct the position of the patella. It may be possible that the brace facilitates quadriceps activity, which in turn helps stabilize the knee joint dynamically or decreases the loading to the PFJ.

Four RCTs⁷⁴⁻⁷⁷ examined the use of a knee brace for the treatment of pain in subjects with PFPS. Different types of braces, all aiming to improve patella alignment, were used. The evidence is conflicting, with two trials^{76,77} reporting improvement in pain and function while the other two^{74,75} reported no significance difference. In fact, Lun et al.'s study⁷⁷ which compared the effectiveness of four treatment approaches (exercise alone, patella bracing alone, patella bracing and exercise, exercise and knee sleeve) showed that all groups showed subjective and functional improvement over time.

Our meta-analysis²³ indicated significant protection of overall lower limb injuries with the use of insoles (RR 0.80; 95% CI 0.66–0.98). However, no such protection was observed when only the incidence of knee injuries was analyzed (RR 0.99; 95% CI 0.73–1.33).

Recommendations

- There is moderate quality evidence that patella taping alone has no beneficial effect in the management of PFPS
- Moderate-quality evidence suggests that taping combined with other physiotherapeutic treatment approaches can improve pain and function in individuals with PFPS. The challenge is to find the optimal combination of physical interventions
- There is a moderate-high level of evidence to suggest the use of patellofemoral brace in the prevention of PFPS in individuals undertaking strenuous and intensive exercises with short adaptation period
- There is a low level of evidence to support the use of knee brace in reducing pain in individuals with PFPS
- There is very low quality evidence to suggest that insoles is effective in preventing PFPS

Question 6: Can other treatment modalities be used in the treatment of patellofemoral pain?

Current opinion

Other treatment options such as pharmacological intervention and electrical modalities have been suggested in the literature for the treatment of PFPS.

Quality of the evidence

Level I

- 2 systematic reviews^{78,79}

Findings

The role of nonsteroidal anti-inflammatory drugs (NSAIDs) and glucocorticosteroids has been examined in a systematic review⁷⁸ which showed that there is limited evidence for short-term pain reduction in PFPS. Furthermore, the evidence for the effect of glucosamine polysulfate injection is contradictory. There is also insufficient evidence to show that therapeutic ultrasound therapy⁷⁹ is useful for pain relief in individuals with PFPS.

Recommendation

- There is very low quality evidence to suggest that pharmacological treatment or ultrasound therapy reduces pain in individuals with PFPS

Question 7: What is the prognosis for PFPS?

Relevance

The rehabilitation of PFPS can be slow, but understanding the natural history and prognosis of the condition can

increase the individual's compliance with treatment recommendations.

Current opinion

Different management approaches to the treatment of PFPS have been suggested in the literature. There is a need for long-term follow-up to examine if the treatment is able to change the natural course of the condition.

Quality of evidence

Level II

- 4 follow-up studies^{28,29,80,81} address the long-term outcome and prognosis for subjects with PFPS at different age groups; the duration of follow-up ranges from 7 to 20 years

Findings

In a cross-sectional study⁸¹ which examined the long-term outcome of anterior knee pain developed in childhood (n = 22; mean age 10.5 years at first diagnosis), 91% of the subjects at follow-up (4–18 years) still had complaints of knee pain which affected their daily activities. However, the diagnosis of PFPS had not been so clearly defined, except that the subjects had anterior knee pain. This is also reflected in the fact that a high percentage of subjects developed other medical conditions such as psoriasis, arthritis, and pain in other joints. As such, the result may not be a true reflection of the prognosis of PFPS. In a long-term study⁸⁰ which examined the outcome of adolescent girls (mean age 15.5 years at entry into the study) with PFPS showed that 50% of the subjects improved spontaneously at 3.8 years follow-up. This natural history of recovery may be related to the musculoskeletal development in adolescents. At 16 years follow-up, 27% of subjects continued to have pain and disability though there was no evidence of structural pathology. This incidence of pain is much lower than that previously reported.⁸¹ Prospective studies^{28,29} that examined the outcome in subjects with PFPS (mean age 27 years at entry to the study) showed that 75% of subjects who received a 6-week intensive quadriceps muscle training had good subjective and functional recovery at 6-month and 7-year follow-up. Furthermore, the results showed that good quadriceps strength significantly predicted good long-term outcome, whereas radiologic and MRI changes showed no association.

Recommendations

- PFPS developed during adolescence has a better prognosis and tends to resolve spontaneously [overall level: moderate]
- In adults with PFPS, if symptoms do not spontaneously resolve, an intensive quadriceps rehabilitation program is likely to produce a favorable outcome [overall level: moderate]

Summary of recommendations

- Intrinsic risk factors that influence the PFJ loading, including muscle imbalances and biomechanical alterations, are thought to contribute to the onset of pain. Extrinsic risk factors including training error and footwear are commonly reported
- There is strong evidence for an association between training volume and running-related lower limb injuries
- Direct evidence for quantifying the optimal training load for a runner preparing for a 10km or marathon race is lacking
- Physiotherapy-supervised exercise therapy is effective for PFPS
- Either OKC or CKC quadriceps strengthening has beneficial effects in reducing pain and improving function in subjects with PFPS, short- and long-term
- There is moderate-quality evidence to suggest that VMO retraining is effective in the treatment of PFPS, but it is unclear if VMO can be preferentially activated
- There is insufficient evidence to suggest that hip muscle strengthening or stretching to be effective in improving symptoms in subjects with PFPS
- The efficacy of patella taping alone in the management of PFPS is unclear, but taping combined with other physiotherapeutic treatment approaches can improve pain and function in subjects with PFPS
- There is moderate-high quality evidence to suggest the use of patellofemoral brace in the prevention of PFPS in individuals undertaking strenuous and intensive exercises with short adaptation period
- The evidence that knee brace is effective in improving pain in subjects with PFPS is conflicting
- There is limited evidence that the use of insoles is effective in preventing PFPS
- PFPS developed during adolescence has a better prognosis and tends to resolve spontaneously
- In adults with PFPS, if symptoms do not spontaneously resolve, an intensive quadriceps rehabilitation program is likely to produce a favorable outcome

¹Academic Medical Centre, Amsterdam, The Netherlands

²Diaconessenhuis, Leiden, The Netherlands

Case scenario

A female patient twisted her right ankle because she jumped while playing basketball and landed awkwardly on the foot of an opponent. Later that day she went to the Emergency Department because her ankle was painful and swollen. The Ottawa rules indicated a possible fracture, which was excluded with standard radiographs. Physical examination (range of motion and stability tests) was difficult to perform because of pain. There was no evidence of redness or heat. However, there was considerable swelling and pain on palpation over the lateral side of the injured ankle.

Relevant anatomy

The lateral ankle ligaments consist of three ligaments: the anterior talofibular ligament (ATFL), the calcaneofibular ligament (CFL), and the posterior talofibular ligament (PTFL).¹ The most common mechanism of injury is supination and adduction (i.e., inversion) of the plantar-flexed foot. It is known that the ATFL is almost always the first or only ligament to sustain injury. Broström² found that combined ruptures of the ATFL and the CFL occurred in 20% of cases and that isolated rupture of the CFL was very rare. The PTFL is usually not injured unless there is a frank dislocation of the ankle.

Most authors use the term “sprain” to describe a morphologic condition representing a diversity of pathology, ranging from overstretching of the ligament to complete rupture with instability of the joint. To classify the severity of ankle sprains and injury to the lateral ligaments, a grading system has been introduced (see box).^{3,4}

Grading system for ankle sprains and injury to lateral ligaments

- *Grade I:* mild stretching of the ligament with no instability
- *Grade II:* partial rupture with mild instability of the joint (e.g., isolated rupture of the ATFL)
- *Grade III:* complete rupture of the ligaments with instability of the joint

Importance of the problem

Acute ankle trauma is one of the most prevalent injuries of the musculoskeletal tract and it is the most frequently observed injury in the Emergency Department. It has been estimated that one ankle sprain occurs per 10,000 people each day.⁵ Each year, approximately 1 million patients with acute lateral ankle ligament injury are seen by primary care physicians in the United States.⁶ Inversion injuries are treated by emergency and primary healthcare physicians as well as by orthopedic and trauma surgeons.⁴

Inversion injuries involve about 25% of all injuries of the locomotor system, with over 20,000 patients in the US each day.⁷ About 50% of these injuries are sport related.^{2,8} Sports such as basketball, soccer, and volleyball have a particularly high incidence of ankle injuries.⁹ Inversion injuries of the ankle, if not treated properly, may lead to late symptoms in 30–40% of patients.^{7,10}

Although most physicians probably consider the clinical result as the most important outcome, the socioeconomic consequences of ankle sprains are impressive as well. The annual costs to society for ankle injuries have been estimated to be approximately US\$35 million per 1 million people.⁶ A Harvard study dating from 1983 estimated the annual costs for ankle ligament injuries in the US at approx-

imately US\$2 billion.¹¹ Apart from direct costs (materials, visits to Emergency Department and outpatient clinic, and consultant fees), these estimates include indirect costs, such as loss of income and incapacity to work during (part) of the rehabilitation period.

Care providers and patients are inundated with an ever-increasing and easily accessible body of information about lateral ankle ligament injuries. When the search term “ankle sprain” is entered into Google, over 5,000,000 hits appear. The variable quality and lack of filtering mandates the need for preappraised evidence-based guides.

Top ten questions

Diagnosis

1. How accurate is clinical examination in the diagnosis of acute lateral ankle ligament injuries?
2. When should the physical examination be performed?
3. Is there a role for additional examinations?

Therapy

4. Is rest, ice, compression, and elevation (RICE) therapy beneficial in the treatment of acute lateral ankle ligament injuries?
5. Is ultrasound beneficial in the treatment of acute lateral ankle ligament injuries?
6. Is functional treatment the optimal treatment compared with immobilization for acute lateral ankle ligament injuries?
7. What is the preferred type of functional treatment for acute lateral ankle ligament injuries?
8. Are the results of surgical treatment superior to conservative treatment for acute injuries of the lateral ligament complex of the ankle?

Prognosis

9. What are the long-term results of lateral ankle ligament injuries?

Prevention

10. What is the optimal prevention strategy to avoid acute lateral ankle ligament injuries?

Question 1: How accurate is clinical examination in the diagnosis of acute lateral ankle ligament injuries?

Case clarification

Our patient twisted her ankle while playing basketball. Which tests should be performed during physical examina-

tion to be sure that she sustained lateral ankle ligament injury? What is the sensitivity and specificity of these tests?

Relevance

Standard radiographs including AP, lateral, and mortise views are sufficient to rule out fractures, severe osteoarthritis, and significant osteochondral defects. The Ottawa ankle rules are helpful to save unnecessary radiographic investigation, using bony tenderness and ability to bear weight as indicator for radiography.¹²

Current opinion

The most important features of physical examination are swelling, hematoma, discoloration, localized pain on palpation, and positive anterior drawer test. The site of the pain on palpation is important. If there is no pain on palpation on the ATFL, there is no acute lateral ankle ligament rupture.¹³ Pain on palpation on the ALTL itself cannot differentiate a mild stretch from rupture.

Finding the evidence

- Cochrane Bone, Joint and Muscle Trauma Group Specialized Register
- Cochrane Controlled Trials Register
- Pubmed/MEDLINE
- Embase
- CINAHL
- PEDro—the Physiotherapy Evidence Database
- Reference lists of included articles

Quality of the evidence

Level III

- 2 studies^{13,14}

Findings

Localized pain on palpation in combination with hematoma discoloration gives a 90% chance that there is an acute lateral ligament rupture.¹⁵ A positive anterior drawer test by itself has a sensitivity of 73% and a specificity of 97%.¹⁴ A positive anterior drawer test in combination with pain on palpation on the ATFL and hematoma discoloration has a sensitivity of 100% and specificity of 77%.

Recommendation

- The anterior drawer test in combination with pain on palpation on the ATFL and hematoma discoloration is very reliable in diagnosing acute lateral ankle ligament injury [overall quality: low]

Question 2: When should the physical examination be performed?

Case clarification

We know which tests we have to perform during physical examination, but when is this examination most reliable?

Relevance

The inconsistent outcome of physical examination within 48 hours of trauma is caused by the diffuse character of the pain; the swelling itself, which gives no information as to whether it is due to hematoma or edema formation; and the unreliability of the anterior drawer test, due to pain and swelling.

Current opinion

By waiting a few days and performing a delayed physical examination, the pain and swelling can be expected to have decreased. First, this decrease in pain and swelling facilitates the palpation of the separate ligaments. The presence or absence of pain on palpation of the ligaments indicates a ligament rupture. Secondly, it allows clearer interpretation of a positive anterior drawer test as an indicator of ligament rupture. Thirdly, we will gain more insight into the contents of the swelling—hematoma indicates a rupture, while the absence of hematoma discoloration is likely to be associated with intact ligaments.

Finding the evidence

See Question 1

Quality of the evidence

Level III

- 2 studies^{13,14}

Findings

The specificity and sensitivity of delayed physical examination for the presence or absence of lateral ankle ligament rupture were 84% and 96% respectively.^{13,14}

Recommendation

- Delayed physical examination (4–5 days after trauma) provides a diagnostic modality of high quality and is more reliable than physical examination within 48 hours after trauma [overall quality: low]

Question 3: Is there a role for additional examinations?

Case clarification

We performed the physical examination 5 days after our patient twisted her ankle. Is there a role for additional examinations (stress radiography, CT, MRI, or ultrasound)?

Relevance

For most injuries, after the physical examination is performed additional investigations are necessary in order to make the definite diagnosis. Is the reliability of physical examination with additional radiographic examinations higher than that of physical examination alone? Should we

perform these investigations despite the costs, radiation exposure, and possible complications?

Current opinion

Today the golden standard in the diagnosis of acute lateral ligament injury is the delayed physical examination. Additional examinations could be useful in diagnosing and workup of chronic lateral ankle ligament instability.

Finding the evidence

See Question 1.

Quality of the evidence

Level III

- 12 studies^{3,13,14–22}

Findings

Stress radiography has proven helpful with concerns about lateral ankle ligament laxity. Both talar tilt and the anterior drawer test are useful in assessment of ligament laxity in patients with chronic instability complaints. In the acutely injured ankle, a stress test is quite painful; also, because of the wide variation of normal values, the interpretation of stress radiographs is often difficult. There is also the disadvantage of the use of radiography itself. Nowadays stress radiography is merely of scientific interest and has a limited role in making the definite diagnosis in clinical practice.

Ankle arthrography provides a relatively simple method for investigating acute ankle ligament ruptures.^{16,17} Since the ATFL is intimately associated with the joint capsule, a ligament tear will also result in a capsular tear, which can be demonstrated arthrographically. Capsular tears are rapidly sealed by clots and fibrin, so arthrography is only reliable within the first 24–48 hours after trauma. Arthrography has a high sensitivity with a lower specificity.^{21,22} The reliability of arthrography for quantification of the severity of ligament damage is quite poor;¹⁸ also, the test is invasive and thus a relative high burden for the patient.¹⁸

MRI is less suitable for differentiating between acute and chronic lateral ankle ligament injury. The primary use of MRI in the evaluation of acute ankle injuries therefore remains in the diagnosis and evaluation of tendon disorders and osteochondral lesions, although the latter can be diagnosed more reliably with a CT scan.¹⁵

Ultrasound investigation causes little discomfort to patients. The sensitivity and specificity of the ultrasound investigation are 92% and 64% respectively. The predictive value of a positive ultrasound investigation is 85% and of a negative ultrasound investigation 77%.^{3,13,14} Ultrasound investigation can be useful in diagnosing additional (cartilage) damage in patients with acute lateral ankle ligament injury.¹⁷

Recommendation

- The high costs, high burden for the patient, availability, possible complications, and lack of reliability of the most diagnostic modalities, as well as the lack of a simple test, motivated the improvements in reliability of the physical examination as a diagnostic tool [overall level: low]

Question 4: Is RICE therapy beneficial in the treatment of acute lateral ankle ligament injuries?**Case clarification**

Our patient is not yet diagnosed with an evident acute lateral ankle ligament injury, but we know she has a sprained ankle. Is RICE therapy beneficial for the first few days before making the definite diagnosis?

Relevance

The variation in treatment observed for the acutely injured lateral ankle ligament complex in the first week after the injury suggests a lack of evidence-based management strategies for this problem.

Current opinion

According to the Dutch Institute for Healthcare Improvement (CBO) consensus guidelines, RICE therapy is the treatment of choice for the first 4–5 days to reduce pain and swelling. After this period the physical examination provides a diagnostic modality of high quality.

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 1 systematic review¹⁵

Level II

- 11 randomized trials with methodological limitations

Findings

After removal of the overlaps between the different databases, evaluation of the abstracts, and contact with some authors, a final total of 24 potentially eligible trials remained. This resulted in the inclusion of 11 trials, involving 868 patients.

Pooling the results of the included studies was not realistic, mainly because of different outcome measures. Insufficient evidence is available from randomized controlled trials (RCTs) to determine the relative effectiveness of RICE therapy for acute ankle sprains in adults.²³

Recommendations

Treatment decisions concerning RICE therapy must be made on an individual basis, carefully weighing the relative benefits and risks of each option.

- Rest should be interpreted as relative rest and not as complete immobilization without weightbearing [overall level: very low]
- There is little evidence to support the use of ice in the treatment of acute ankle sprains [overall level: low]
- There is very little evidence to support the use of compression in the treatment of acute ankle sprains [overall level: very low]
- There is no evidence to support the use of elevation in the treatment of acute ankle sprains

Question 5: Is additional ultrasound beneficial for patients with acute lateral ankle ligament injuries?**Case clarification**

Our patient has an evident acute lateral ankle ligament injury and was treated with RICE for the first days. Thereafter treatment (operative or nonoperative) will be continued. Is additional ultrasound treatment beneficial for our patient?

Relevance

Ultrasound has been used in the treatment of musculoskeletal conditions for many years. Ultrasound equipment consists of a generator and transducer. The generator produces electromagnetic energy with a frequency of 0.5–3.5 MHz, which is converted by the transducer to mechanical energy with a similar frequency and intensity of up to 3 W/cm².²⁴ Laboratory research has demonstrated that the application of ultrasound results in the promotion of cellular metabolic rate and increased viscoelastic properties of collagen.²⁵ In animal studies, an exposure to 1 MHz ultrasound at 50 J/cm² is reported to be sufficient to increase tissue temperature.²⁶ This rise in temperature is assumed to be the mediating mechanism for tissue repair, the enhancement of soft tissue extensibility, promotion of muscle relaxation, augmentation of blood flow, and alleviation of inflammatory reactions of soft tissue.^{25,27–29}

Current opinion

Based on these experimental findings, ultrasound is used in physical therapy to relieve pain, reduce swelling, and improve joint immobility in a wide variety of musculoskeletal disorders including ankle sprains. Despite the theoretical benefits and widespread use, conclusive evidence on the effectiveness of ultrasound therapy in patient care is not yet available.

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 1 meta-analysis³⁰
- 4 randomized trials

Level II

- 2 randomized trials with methodologic limitations

Findings

Six trials were included, involving 572 participants. None of the four placebo-controlled trials (sham ultrasound) demonstrated statistically significant differences between true and sham ultrasound therapy for any outcome measure at 7–14 days of follow-up. The pooled relative risk for general improvement was 1.04 (random effects model, 95% CI 0.92–1.17) for active vs. sham ultrasound. The differences between intervention groups were generally small, 0–6% for most dichotomous outcomes. However, one trial reported relatively large differences for pain-free status (20%) and swelling (25%) in favor of ultrasound.

Recommendations

- The results of four placebo-controlled trials do not support the use of ultrasound in terms of symptom relief [overall level: high] and functional disability [overall level: moderate] in the treatment of ankle sprains
- Because of the limited amount of information on treatment parameters, no conclusions can be made regarding an optimal and adequate dosage schedule for ultrasound therapy, or whether such a schedule would improve on the reported effectiveness of ultrasound for ankle sprains

Question 6: Is functional treatment the optimal treatment compared with immobilization for acute lateral ankle ligament injuries?**Case clarification**

We have chosen to treat our patient nonoperatively after the initial RICE treatment. Do we have to treat her with a period of immobilization, or is a functional treatment more beneficial?

Relevance

Different nonoperative options are available for the treatment of an acute ankle sprain. The two main modalities of treatment are: (1) treatment with plaster cast immobilization and (2) functional treatment with tape, elastic bandage, or (lace-up) brace. The latter is an early mobilization program and involves the use of an external support combined with coordination training. Both types of treatment should have a minimal duration of 4 weeks and should be considered as a different treatment from short-term immobilization in the early inflammatory phase (first 4–5 days). The variation in treatment practice identified for lateral ankle ligament complex injuries suggests a lack of evidence-based management strategies for this problem.^{2,3}

Current opinion

Dehne first reported ankle injury treatment with immobilization below the knee.³¹ Many studies presenting results of

this type of immobilization have since been published.^{32,33} Freeman introduced a new concept in the conservative treatment of ruptures of the lateral ligaments of the ankle by suggesting that the use of proprioceptive training using coordination exercises could reduce the proprioceptive deficit and symptoms of the ankle “giving way”.^{10,34} Consequently, many patients were treated functionally with supportive elastic bandage combined with coordination training. Functional treatment with tape bandage or orthotic support has become more popular since the 1980s.^{35–39}

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 2 meta-analyses^{40,41}
- 9 randomized trials

Level II

- 16 randomized trials with methodological limitations

Findings

Twenty-five trials involving 2587 participants were included. For the primary outcomes, statistically significant differences in favor of functional treatment when compared with immobilization were found. More patients returned to sport in the long term (RR 1.89; 95% CI 1.24–2.89); more patients had returned to work at short-term follow-up (RR 5.17; 95% CI 2.36–11.34); the time taken to return to work was shorter (WMD 12.47 days; 95% CI 10.74–14.20); fewer patients complained about persistent pain at short-term follow-up (RR 1.90; CI 1.34–2.68) as well as at intermediate-term follow-up (RR 1.53; CI 1.13–2.06); and fewer patients complained of subjective instability at intermediate-term follow-up (RR 1.91, CI 1.36–2.61). In all analyses performed, no results were significantly in favor of immobilization. No significant differences between varying types of immobilization, immobilization and physiotherapy, or no treatment were found, apart from one trial where patients returned to work sooner after treatment with a soft cast.

Recommendation

- Functional treatment appears to be the favorable strategy for treating acute ankle sprains when compared with a period of more than 4 weeks of immobilization, with regard to symptom relief [overall level: low], return to work [overall level: moderate], return to sport [overall level: low], and joint stability [overall level: low]

Question 7: What is the preferred type of functional treatment for acute lateral ankle ligament injuries?

Case clarification

We have chosen to treat our patient with an acute lateral ligament injury nonoperatively, and we know that a functional treatment is superior to immobilization. What is the best functional treatment?

Relevance

Freeman introduced a new concept in the conservative treatment of ruptures of the lateral ligaments of the ankle by suggesting that the use of proprioceptive training using coordination exercises could reduce the proprioceptive deficit and symptoms of the ankle "giving way".^{10,34} Consequently, patients were treated with nonspecific elastic bandage combined with coordination training.

Current opinion

Functional treatment with tape bandage or orthotic support has become more popular since the 1980s.³⁵⁻³⁹ The preferable type of functional treatment was not known until the review by Kerkhoffs et al.⁴²

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 2 meta-analyses^{40,42}
- 8 randomized trials

Level II

- 3 randomized trials with methodologic limitations

Findings

Eleven trials and 1235 participants were included. Lace-up ankle support had significantly better results for persistent swelling at short-term follow-up when compared with semi-rigid ankle support (RR 4.19; 95% CI 1.26–13.98), elastic bandage (RR 5.48; 95% CI 1.69–17.76), or tape (RR 4.07; 95% CI 1.21–13.68). Use of a semi-rigid ankle support resulted in a significantly faster to return to work when compared to an elastic bandage (WMD 4.24 days; 95% CI 2.42–6.06). One trial found the use of a semi-rigid ankle support a significantly quicker return to sport compared with elastic bandage (RR 9.60; 95% CI 6.34–12.86); another trial found fewer patients reported instability at short-term follow-up when treated with a semi-rigid support than with an elastic bandage (RR 8.00; 95% CI 1.03–62.07). A fourth trial found a semi-rigid brace to be better than an elastic bandage with regard to swelling in the short term (WMD 5.90; 95% CI 0.59–11.21). A semi-rigid device was

also shown to be significantly better for pain in the intermediate (WMD 4.00; 95% CI 3.33–4.67) and long term (WMD 5.2; 95% CI 4.49; 5.91). Tape treatment resulted in significantly more complications, the majority being skin irritations, when compared to treatment with an elastic bandage (RR 0.11; 95% CI 0.01–0.86). No other comparisons showed statistically significant differences.

Recommendations

The most effective treatment, both clinically and in terms of cost, is unclear from currently available randomized trials. Definitive conclusions are hampered by the variety of treatments used, and the inconsistency of reported follow-up times.

- The use of an elastic bandage has fewer complications than taping [overall level: high] but appears to be associated with a slower return to work [overall level: high] and sport [overall level: high], and more reported instability than a semi-rigid ankle support [overall level: high]
- Lace-up ankle support appears to be effective in reducing swelling in the short-term compared with semi-rigid ankle support [overall level: high], elastic bandage [overall level: high] and tape [overall level: high]

Question 8: Are the results of surgical treatment superior to conservative treatment for acute injuries of the lateral ligament complex of the ankle?

Case clarification

Would surgical treatment be superior to nonoperative treatment for our patient?

Relevance

Ankle sprains are one of the most commonly treated musculoskeletal injuries. The three main treatment modalities for acute lateral ankle ligament injuries are (1) immobilization with plaster cast or splint, (2) functional treatment consisting of early mobilization and use of an external support (e.g., ankle brace), and (3) surgical repair or reconstruction.

Current opinion

Today, most patients with acute lateral ankle ligament injury are treated nonoperatively. Surgical repair is performed in patients with chronic lateral ankle ligament injury.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 2 meta-analyses^{43,44}
- 2 randomized trials

Openmirrors.com

Level II

- 18 randomized trials with methodologic limitations

Findings

Twenty trials were included. These involved a total of 2562 mostly young active adult males. Almost all trials had methodologic weaknesses. Specifically, concealment of allocation was confirmed in only one trial. Data for pooling individual outcomes were only available for a maximum of 12 trials and less than 60% of participants. The findings of statistically significant differences in favor of the surgical treatment group for the four primary outcomes (nonreturn to preinjury level of sports; ankle sprain recurrence; long-term pain; subjective or functional instability) when using the fixed-effect model were not robust when using the random effects model, or when one low-quality (quasi-randomized) trial that had more extreme results was removed. A corresponding drop in the I^2 statistics showed the remaining trials to be more homogeneous. The functional implications of the statistically significantly higher incidence of objective instability in conservatively treated trial participants are uncertain. There was some limited evidence for longer recovery times, and higher incidences of ankle stiffness, impaired ankle mobility, and complications in the surgical treatment group.

Recommendations

- Insufficient evidence is available from RCTs to determine the relative effectiveness of surgical and conservative treatment for acute injuries of the lateral ligament complex of the ankle in adults with emphasis on joint stability [overall level: very low], symptom relief [overall level: very low], recurrence [overall level: very low], and return to sport [overall level: low]
- Treatment decisions must be made on an individual basis, carefully weighing the relative benefits and risks of each option. Given the risk of operative complications, the higher costs (including those of hospital admission) associated with surgery, and the good results of secondary anatomic reconstructions of the lateral ankle ligaments, the best available option for most patients would be conservative treatment for acute injuries and close follow-up to identify patients who may remain symptomatic

Question 9: What are the long-term results or prognosis of lateral ankle ligament injuries?**Case clarification**

We have treated our patient according to the current evidence. What can we tell her to expect in the long term?

Relevance

In order to evaluate the effectiveness of therapeutic interventions and to guide management decisions, it is impor-

tant to have clear insight into the course of recovery after an acute lateral ankle injury and to evaluate potential factors for nonrecovery and resprains.

Current opinion

van Rijn et al.²² present a clear overview of the clinical course of acute lateral ankle sprains and an evaluation of prognostic factors for incomplete recovery and resprains.

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 1 meta-analysis⁴⁵

Level III

- 24 high-quality observational studies

Level IV

- 7 low-quality observational studies

Findings

In total, 31 studies were included, from which 24 studies were of high quality. There was a rapid decrease in pain reporting within the first 2 weeks. After 1 year 5–33% of patients still experienced pain, while 36–85% reported full recovery within a period of 3 years. The risk of resprains ranged from 3% to 34% of the patients, and resprain was registered in periods ranging from 2 weeks to 96 months after the initial injury. There was a wide variation in subjective instability, ranging from 0% to 33% in the high-quality studies and from 7% to 53% in the low-quality studies. One study described prognostic factors and indicated that training more than three times a week is a prognostic factor for residual symptoms.

Recommendation

- A high percentage of patients still experienced pain and subjective instability after 1 year of follow-up, and within a 3 year period, as many as 34% of the patients reported at least one resprain. From 36% to 85% of the patients reported full recovery within a period of 3 years.

Question 10: What is the optimal prevention strategy to avoid acute lateral ankle ligament injuries?**Case clarification**

We have treated our patient according to the current evidence and we have informed her about the long-term prognosis. How can she avoid recurrent lateral ankle ligament injuries?

Relevance

Prevention of ankle injuries has the potential to play an important role in maintaining health for people who engage in high-risk sports and those who have suffered a previous injury to the ankle ligament complex.

Current opinion

Methods of prevention of ankle ligament injuries include use of modified footwear and associated supports, ankle taping, adapted training regimens including ankle exercises, and injury awareness. Prevention of injury recurrence may include interventions such as ankle disk exercises aimed at enhancing coordination and retraining proprioception (sense of muscular position). Secondary prevention, the prevention of recurrence, is a common treatment goal for many studies of ankle sprain treatment.

Finding the evidence

See Question 1.

Quality of the evidence*Level I*

- 1 meta-analysis⁴⁶

Level III

- 4 high-quality observational studies

Level IV

- 10 low-quality observational studies

Findings

Fourteen randomized trials with data for 8,279 participants were included. Twelve trials involved active, predominantly young, adults participating in organized, generally high-risk, activities. The other two trials involved injured patients who had been active in sports before their injury. The prophylactic interventions under test included the application of an external ankle support in the form of a semi-rigid orthosis (three trials), air-cast brace (one trial), or high-top shoes (one trial); ankle disk training; taping; muscle stretching; boot inserts; a health education program, and controlled rehabilitation.

The main finding was a significant reduction in the number of ankle sprains in people allocated external ankle support (RR 0.53; 95% CI 0.40–0.69). This reduction was greater for those with a previous history of ankle sprain, but still possible for those without prior sprain. There was no apparent difference in the severity of ankle sprains or any change to the incidence of other leg injuries. The protective effect of high-top shoes remains to be established. There was limited evidence for reduction in ankle sprain for those with previous ankle sprains who did ankle disk training exercises. Various problems with data reporting limited the interpretation of the results for many of the other interventions.

Recommendation

- There is high-level evidence for the beneficial effect of ankle supports in the form of semi-rigid orthoses or air-cast braces to prevent ankle sprains during high-risk sporting activities (e.g., soccer, basketball) [overall level: high]. Participants with a history of previous sprain can be advised that wearing such supports may reduce the risk of incurring a future sprain. [overall level: high]. However, any potential prophylactic effect should be balanced against the baseline risk of the activity, the supply and cost of the particular device, and for some, the possible or perceived loss of performance

Summary of recommendations

- The anterior drawer test in combination with pain on palpation on the ATFL and hematoma discoloration is very reliable in diagnosing acute lateral ankle ligament injury. Delayed physical examination (4–5 days after trauma) provides a diagnostic modality of high quality and is more reliable than physical examination within 48 hours after trauma. The high costs, high burden for the patient, availability, possible complications and lack of reliability of the most diagnostic modalities as well as the lack of a simple test formed the motivation to examine how to improve the outcome of the physical examination as a diagnostic tool
- Rest should be interpreted as relative rest and not as complete immobilization without weightbearing. Mobilization and weightbearing as tolerated is the most optimal regime. There is little evidence to support the use of ice and compression in the treatment of acute ankle sprains, and no evidence to support the use of elevation
- The results of four placebo-controlled trials do not support the use of ultrasound in terms of symptoms relief and functional disability in the treatment of ankle sprains. Due to the limited amount of information on treatment parameters, no conclusions can be made regarding an optimal and adequate dosage schedule for ultrasound therapy or whether such a schedule would improve on the reported effectiveness of ultrasound for ankle sprains
- Functional treatment appears to be the favorable strategy (with regard to symptom relief, return to work, return to sport, and joint stability for treating acute ankle sprains when compared with a period of more than 4 weeks of immobilization
- The use of an elastic bandage has fewer complications than taping but appears to be associated with a slower return to work and sport, and more reported instability than a semi-rigid ankle support. Lace-up ankle support appears to be effective in reducing swelling in the short term compared with semi-rigid ankle support, elastic bandage, and tape

Openmirrors.com

- There is insufficient evidence available from RCTs to determine the relative effectiveness of surgical and conservative treatment for acute injuries of the lateral ligament complex of the ankle in adults with emphasis on joint stability, symptom relief, recurrence, and return to sport. Given the risk of operative complications, the higher costs (including those of hospital admission) associated with surgery and the good results of secondary anatomic reconstructions of the lateral ankle ligaments, the best available option for most patients would be conservative treatment for acute injuries and close follow-up to identify patients who may remain symptomatic and may require operative intervention

- After 1 year of follow-up, a high percentage of patients still experienced pain and subjective instability, and within a period of 3 years as many as 34% of the patients reported at least one resprain. From 36% to 85% of the patients reported full recovery within a period of 3 years

- There is high-level evidence for the beneficial effect of ankle supports in the form of semi-rigid orthoses or air-cast braces to prevent ankle sprains during high-risk sporting activities (e.g., soccer, basketball). Participants with a history of previous sprain can be advised that wearing such supports may reduce the risk of incurring a future sprain. However, any potential prophylactic effect should be balanced against the baseline risk of the activity, the supply and cost of the particular device, and for some, the possible or perceived loss of performance

Nicola Maffulli¹, Umile Giuseppe Longo², Stefano Campi²,
and Vincenzo Denaro²

¹Barts and The London School of Medicine and Dentistry, London, UK

²Campus Bio-Medico University, Rome, Italy

Case scenario

A 41 year old male runner presents with a swelling 2.5 cm in diameter, 4 cm proximal to the insertion of the Achilles tendon. For 3 months he has felt pain at the beginning and at the end of a training session, with diminished discomfort in between. There is tenderness of the Achilles tendon. He has no neurovascular deficits.

Relevant anatomy

The confluence of the gastrocnemius and soleus muscles forms the Achilles tendon. The gastrocnemius is more superficial and originates from two heads above the knee. The soleus is anterior to the gastrocnemius and originates below the knee.¹ The Achilles tendon derives its sensory nerve supply from the nerves of the attaching muscles and cutaneous nerves, in particular the sural nerve.¹

Achilles tendinopathy (AT) is characterized by pain, impaired performance, and swelling in and around the tendon.² It can be categorized as insertional and noninsertional, two distinct disorders with different underlying pathophysiology and management options.³⁻⁵ Other terms used as synonymous of noninsertional tendinopathy include tendinopathy of the main body of the Achilles tendon and midportion AT.^{2,6}

Importance of the problem

Although scientifically sound epidemiological data are lacking, AT is common in athletes, accounting for 6–17% of all running injuries.^{7,8} However, it also presents in middle-

aged, overweight, nonathletic patients without history of increased physical activity.⁷ To date, the incidence and prevalence of AT in other populations has not been established, even though the condition has been correlated with seronegative arthropathies.⁹

Most studies include more men than women, although a definite greater prevalence in men has not been shown. Aging has not been shown to represent a risk factor for tendinopathy.⁸ AT is not, by itself, a predisposing factor to rupture. Most series reporting the results of conservative or surgical management of an Achilles tendon rupture report that up to 5% of patients had a diagnosis of AT before rupture. The vast majority of ruptures occurs in patients who were otherwise asymptomatic before the tear.¹⁰

A Google search for “Achilles tendinitis” or “Achilles tendinopathy” returns over 900,000 hits.

Top seven questions

Diagnosis

1. What is the accuracy of clinical examination in the diagnosis of AT?

Treatment

2. What is the efficacy of a program of eccentric exercises vs. control?

3. What is the efficacy of eccentric exercises with or without heel brace?

4. What is the efficacy of eccentric exercises vs. shockwave therapy?

5. What is the efficacy of eccentric exercises vs. topical glyceryl trinitrate?

6. What is the efficacy of low-level laser therapy vs. a programme of eccentric exercises?
7. What is the efficacy of eccentric exercises vs. platelet-rich plasma injections plus eccentric exercises?

Question 1: What is the accuracy of clinical examination in the diagnosis of AT?

Case clarification

At clinical examination, palpation of the tendon is present. The painful arc sign and the Royal London Hospital test are positive.

Relevance

A variety of clinical diagnostic tests are available for AT. Therefore, clinicians need to select diagnostic tests that are the most specific to confirm AT and the most sensitive to establish that AT is unlikely.

Current opinion

Current opinion suggests that the majority of health professionals use pain and tenderness following performance of palpation, the painful arc sign, and the Royal London Hospital test as clinical diagnostic tests for AT.

Finding the evidence

- Cochrane Database, with search term “Achilles,” “tendon,” “tendinopathy,” “Achilles clinical examination,” “palpation,” “arc sign,” and “Royal London Hospital”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “Achilles,” “tendon,” “tendinopathy,” “Achilles clinical examination,” “palpation,” “arc sign,” and “Royal London Hospital”
- MEDLINE search identifying the population (Achilles tendon) and the methodology (diagnosis), using keywords: “Achilles,” “tendon,” “tendinopathy,” “Achilles clinical examination,” “palpation,” “arc sign,” AND “Royal London Hospital”

Quality of the evidence

Level III

- 1 study¹¹

Findings

Sensitivity and specificity One study¹¹ (n = 24 patients) investigated the accuracy of clinical tests for assessing AT. The overall average sensitivity for AT is 0.583 (95% CI 0.393, 0.752) for palpation, 0.525 (95% CI 0.347, 0.697) for the arc sign, and 0.542 (95% CI 0.345, 0.726) for the Royal London test. The overall average specificity for AT is 0.845 (95% CI 0.745, 0.911) for palpation, 0.833 (95% CI 0.717, 0.908) for the arc sign, and 0.912 (95% CI 0.858, 0.952) for the Royal London test.

Recommendation

- If a patient presents with a tender area of intratendinous swelling that moves with the Achilles tendon and whose tenderness significantly decreases or disappears when the tendon is put under tension, a clinical diagnosis of tendinopathy can be formulated [overall quality: low]

Question 2: What is the efficacy of eccentric exercise vs. control?

Case clarification

The physician makes a diagnosis of AT. Eccentric exercise could represent an option for this patient. However, the patient would like to apply a wait-and-see policy or a program of concentric exercises.

Relevance

Several management options have been proposed to allow recovery of patients with AT. However, the long-term follow-up of the different options is not well defined.

Current opinion

Current opinion suggests that the majority of health professionals consider eccentric exercises as an appropriate management tool for AT.

Finding the evidence

- Cochrane Database, with search term “Achilles,” “tendon,” “tendinopathy,” “eccentric exercises,” “training,” “physiotherapy”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “Achilles,” “tendon,” “tendinopathy,” “eccentric exercises,” “training,” “physiotherapy”
- MEDLINE search identifying the population (Achilles tendinopathy), the intervention (diagnosis) and the methodology (MRI), using the keywords: “Achilles,” “tendon,” “tendinopathy,” “eccentric exercises,” “training,” “physiotherapy”

Quality of the evidence

Level I

- 3 randomized trials¹²⁻¹⁴

Level II

- 3 systematic reviews¹⁵⁻¹⁷

Findings

Comparison of eccentric exercise vs. wait-and-see strategy Rompe et al.¹² conducted a randomized controlled trial (RCT) comparing the effectiveness of eccentric loading vs. repetitive low-energy shockwave therapy (SWT) vs. wait-and-see. At 4 month follow-up, eccentric loading and

low-energy SWT showed comparable results. The wait-and-see strategy was ineffective for the management of AT.

Comparison of eccentric exercises vs. concentric exercises
Silbernagel et al.¹⁴ compared eccentric and concentric exercises in 32 patients with proximal achillodynia. They found an overall better result for the eccentric group with significant improvements in plantar flexion, and reduction in pain on palpation, number of patients having pain during walking, having periods when asymptomatic, and having swollen Achilles tendon. The controls did not show such changes.

Mafi et al.¹³ conducted a prospective randomized study to compare eccentric and concentric training regimen for 44 patients. After completion of the eccentric training regimen, 82% of the patients (18/22) were satisfied and had resumed their previous (preinjury) activity level, compared to 36% of the patients (8/22) who were treated with the concentric training regimen. The results after treatment with eccentric training were significantly better ($p < 0.002$) than after concentric training.

Recommendation

- Eccentric exercises are superior to wait-and-see treatment or concentric exercise [overall quality: good]

Question 3: What is the efficacy of eccentric exercises with or without heel brace?

Case clarification

The patient decides to go for a program of eccentric exercises, but he says that he would like to have a brace in addition to the exercises.

Relevance

Several braces have been proposed to optimize the healing of AT. However, the efficacy of these braces is not well defined.

Current opinion

Braces are an attractive option for patients with AT because they are associated with high compliance and do not require the patient to take medication. However, clinical results of the use of braces have not been clarified.

Finding the evidence

- Cochrane Database, with search term "Achilles," "tendon," "tendinopathy," "heel," "brace," "pad"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "Achilles," "tendon," "tendinopathy," "heel," "brace," "pad"
- MEDLINE search identifying the population (Achilles tendon) the intervention (Brace) and the methodology (clinical trial), using the keywords "Achilles," "tendon," "tendinopathy," "heel," "brace," "pad"

Quality of the evidence

Level I

- 7 randomized trials¹⁸⁻²⁴

Findings

Roos et al.²³ showed that a program of eccentric exercises resulted in significantly lower pain scores after 12 weeks when compared with night splints alone. They did not find any difference in pain score when comparing those who performed eccentric exercises and wore night splints to patients who received eccentric exercises alone. Similarly, Mayer et al.²⁴ demonstrated no difference in pain score when comparing eccentric exercises with custom-fit insoles,²⁴ although the insole group was noted to have significantly better pain scores than controls.

In an RCT, Knobloch et al.^{18,19} showed that the combination of eccentric training with the AirHeel brace can optimize tendon microcirculation, but these microcirculatory advantages do not translate into superior clinical performance when compared with eccentric training alone. On the other hand, Petersen et al.²⁰ found that the AirHeel brace was as effective as eccentric training in the treatment of chronic AT and that was no synergistic effect when both treatment strategies are combined.

De Vos et al.^{21,22} concluded that night splint is not beneficial in addition to eccentric exercises in the treatment of chronic midportion AT.

Recommendation

- There is currently no scientifically substantiated reason to believe that splinting would improve the outcome over a program of eccentric exercises [overall quality: low]

Question 4: What is the efficacy of eccentric exercises vs. SWT?

Case clarification

After failed management with eccentric exercises and brace, the physician proposes to the patient that he should undertake SWT.

Relevance

Unfortunately, not all patients with AT respond well to a program of eccentric exercises, and often other management modalities are required. SWT may be a good option in these patients

Current opinion

SWT offers a potential alternative to other more invasive management modalities

Finding the evidence

- Cochrane Database, with search term: "shockwave therapy"

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "Achilles tendon," "shockwave therapy"
- MEDLINE search identifying the population (Achilles tendon) the intervention (shockwave therapy) and the methodology (clinical trial), using the keywords: "Achilles tendon," AND "shockwave therapy"

Quality of the evidence

Level I

- 4 randomized trials^{12,25-27}

Findings

A prospective RCT showed comparable results of eccentric loading and low-energy SWT.¹² The same scientific team found in another RCT that, at 4-month follow-up, eccentric loading alone was less effective when compared with a combination of eccentric loading and repetitive low-energy SWT.²⁶ A prospective RCT on 48 patients comparing the effect of supplementing eccentric exercises with extracorporeal SWT or placebo showed similar results.²⁵

No advantage of SWT was found in another RCT on 49 patients.²⁷

Recommendations

- Comparable results can be obtained with eccentric loading or low-energy SWT [overall quality: good]
- Eccentric loading alone is less effective when compared with a combination of eccentric loading and repetitive low-energy SWT [overall quality: low]

Question 5: What is the efficacy of a program of eccentric exercises vs. topical glyceryl trinitrate?

Case clarification

After undergoing eccentric exercises, the patients asks for topical glyceryl trinitrate.

Relevance

A molecular link between the apparently disparate events of tendon degeneration and the subsequent orchestration of effective tendon healing may lie in the control of the production and persistence of reactive oxygen species within both the intra- and extracellular milieu of the tendon tissue.

Current opinion

Topical glyceryl trinitrate may enhance tendon healing.²⁸

Finding the evidence

- Cochrane Database, with search terms: "Achilles," "tendon," "tendinopathy," "topical glyceryl trinitrate," "oxygen free radicals," "nitric oxide"

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "Achilles," "tendon," "tendinopathy," "topical glyceryl trinitrate," "oxygen free radicals," "nitric oxide"
- MEDLINE search identifying the population (Achilles tendon) the intervention (topical glyceryl trinitrate) and the methodology (clinical trial), using the keywords: "Achilles," "tendon," "tendinopathy," "topical glyceryl trinitrate," "oxygen free radicals," "nitric oxide"

Quality of the evidence

Level I

- 3 RCTs²⁹⁻³¹

Findings

Paoloni et al. showed that topical glyceryl trinitrate significantly reduced pain with activity and at night, improved functional measures, and improved outcomes in patients with AT both in the short²⁹ and long term.³⁰ However, another RCT on 40 patients³¹ did not produce the same results, failing to support the clinical benefit of topical glyceryl trinitrate patches.

Recommendation

- In patients with tendinopathy of the main body of the Achilles tendon, there is some evidence to recommend topical glyceryl trinitrate for the management of AT [overall quality: low]

Question 6: What is the efficacy of low-level laser therapy and a program of eccentric exercises?

Case clarification

The patient is still not well. He asks for laser therapy.

Relevance

Laser therapy is a widely available and frequently used electrophysical agent in sports medicine.

Current opinion

There is insufficient evidence to support a beneficial effect of laser therapy for AT.

Finding the evidence

- Cochrane Database, with search terms: "Achilles tendon," "laser therapy"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "Achilles tendon," "laser therapy"
- MEDLINE search identifying the population (meniscal tears) the intervention (meniscectomy) and the methodology (clinical trial), using the keywords "Achilles tendon," "laser therapy"

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “Achilles tendon,” AND “laser therapy”

Quality of the evidence

Level I

- 3 randomized trials³²⁻³⁴

Findings

Stergioulas³² conducted an RCT on 52 recreational athletes with chronic AT randomized to either eccentric exercises plus low-level laser therapy (LLLT) or eccentric exercises plus placebo LLLT over 8 weeks in a blinded manner. The results of the intention-to-treat analysis for the primary outcome, pain intensity during physical activity on the 100mm visual analog scale, were significantly lower in the LLLT group than in the placebo group.

Tumilty et al.³³ performed a similar study on 20 patients randomized into an active laser or placebo group. No conclusions were made regarding effectiveness because of the low statistical power of this pilot study.

Chester et al.³⁴ in a prospective randomized single-blind pilot study investigated the potential effectiveness of eccentric exercise compared with therapeutic ultrasound in subjects with relatively sedentary lifestyles. There were no statistically significant differences between groups or clear trends over time.

Recommendation

- There is no definitive evidence whether LLLT may lead to better clinical outcome in patients undergoing a program of eccentric exercise [overall quality: low]

Question 7: What is the efficacy of eccentric exercises vs. platelet-rich plasma injections?

Case clarification

After searching the internet, the patient asks the doctor to give him an injection of platelet-rich plasma (PRP).

Relevance

PRP is a bioactive component of whole blood, which is now being widely tested in different fields of medicine for its possibilities in aiding the regeneration of tissue with poor healing potential.³⁵ The rationale for the use of PRP to promote tendon healing is the high content of cytokines and cells in hyperphysiologic doses of PRP.

Current opinion

PRP can be used for the management of AT.

Finding the evidence

- Cochrane Database, with search terms: “Achilles tendon,” “platelet-rich plasma,” “growth factors”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “Achilles tendon,” “platelet-rich plasma,” “growth factors”

- MEDLINE search identifying the population (complete meniscectomy) the intervention (meniscal substitution) and the methodology (clinical trial), using the keywords “Achilles tendon,” “platelet-rich plasma,” AND “growth factors”

Quality of the evidence

Level I

- 1 RCT³⁶

Findings

De Vos³⁶ performed an RCT at a single center of 54 randomized patients with chronic AT. Patients were randomized to eccentric exercises (usual care) with either a PRP injection (PRP group) or saline injection (placebo group). The mean VISA-A score improved significantly after 24 weeks in the PRP group by 21.7 points (95% CI 13.0–30.5) and in the placebo group by 20.5 points (95% CI 11.6–29.4). The increase was not significantly different between both groups (adjusted between-group difference from baseline to 24 weeks, -0.9; 95% CI, -12.4 to 10.6). This confidence interval did not include the predefined relevant difference of 12 points in favor of PRP treatment.

Recommendation

- There is no evidence to justify a PRP injection in patients with AT [overall quality: good]

Summary of recommendations

- If a patient presents with Achilles tendon with a tender area of intratendinous swelling that moves with the tendon and whose tenderness significantly decreases or disappears when the tendon is put under tension, a clinical diagnosis of tendinopathy can be formulated
- Eccentric exercises are superior to wait-and-see treatment and concentric exercise
- There is currently no scientifically substantiated reason to believe that splinting would improve the outcome over a program of eccentric exercises
- Comparable results can be obtained with eccentric loading or low-energy SWT
- Eccentric loading alone or low-energy SWT are each less effective than a combination of eccentric loading and repetitive low-energy SWT
- There is some evidence to recommend topical glyceryl trinitrate for the management of AT
- There is no definitive evidence whether LLLT may lead to better clinical outcome in patients undergoing a program of eccentric exercise

- There is no evidence to justify a PRP injection in patients with AT

Conclusion

Even though AT is frequent and results in high healthcare costs, the quality of the available studies on its management is generally low, and, because of methodologic limitations, pooling of data is almost always impossible. There is an urgent need for large well-conducted RCTs to improve the evidence basis on the management of AT.

Sanaz Hariri¹, Henk Eijer², and Marc R. Safran¹

¹Stanford University, Redwood City, CA, USA

²Regionalspital Emmental, Burgdorf, Switzerland

Case scenario

An athletic 38 year old woman presents with insidious-onset, moderately severe, groin pain that is activity related, especially when she is walking or pivoting on the right leg. Pain is worse going from sitting to standing. She also has night pain.¹

Relevant anatomy

The acetabular labrum is triangular in cross-section, is an incomplete ring composed primarily of type II collagen fibro-cartilage, attached to the acetabular rim peripherally (its base) with a free margin centrally (its apex).²

Importance of the problem

Magnetic resonance arthrography with intra-articular contrast (MRA) has recently greatly enhanced our ability to diagnosis labral tears. The relatively constrained anatomy of the hip joint (e.g., its shape, difficulty achieving sufficient distraction, relative depth, and surrounding thick soft tissue envelope) has only recently been addressed sufficiently to fuel the recent popularity of hip arthroscopy for treatment of labral tears.

One study reported a 22% prevalence of labral tear in young patients presenting with groin pain.³ Cadaveric studies show an increasing prevalence of labral tears with age: 52% in those over age 48 and 96% in those over age 61.^{4,5}

There is debate as to the predominant mechanism of injury resulting in labral tears. Ganz asserts that the labrum

and cartilage undergo a degenerative process due to impingement between the femur and the acetabulum, specifically in internal rotation.⁶⁻¹³ Alternatively, McCarthy theorizes that tears are largely caused by chronic repetitive stress by maneuvers such as twisting and pivoting which place high strains on the labrum even in positions not consistent with impingement.^{4,14-16}

Impingement

- *Femoroacetabular impingement* (FAI) occurs when an osseous abnormality of the proximal femur (cam) and/or acetabulum (pincer) traps soft tissue between the two bony structures, damaging the labrum and/or articular cartilage
- *Cam impingement* occurs when a nonspherical femoral head abuts against the anterior acetabulum (e.g., with hip flexion)
- *Pincer impingement* is the result of femoral overcoverage by the acetabulum (e.g., retroversion, coxa profunda, and/or protrusio)

Searching the Cochrane Database of systemic reviews using the term “labrum,” we found no studies of the hip acetabular labrum. A PubMed search for “shoulder labrum” yields 792 results while a search for “hip labrum” yields 316 results. We did not find a single randomized controlled trial (RCT) or meta-analysis investigating labral tears. The vast majority of studies are retrospective case series.

Because the focus of this chapter is sports medicine, we have primarily concentrated on arthroscopic treatment of hip pathology. However, it must be noted that FAI was originally treated with an open surgical dislocation and that the open approach is commonly used to address FAI anatomy, particularly in Europe.^{17,18}

Top ten questions

Background/diagnosis

1. What is the vascular supply of the labrum?
2. What is the function of the labrum?
3. How do patients with labral tears present clinically?
4. What is the sensitivity of MRI and MRA?

Therapy

5. What are the results of labral debridement (a.k.a. labrectomy)?
6. In patients with a labral tear in the presence of abnormal hip morphology, how are the results affected by surgically addressing the morphology?
7. What are the results of labral repair?

Prognosis

8. How does the presence of articular cartilage damage affect the prognosis of a patient with a labral tear?

Harm

9. What are the complications associated with labral debridement and repair?
10. What are the possible pitfalls of labral debridement in patients with acetabular dysplasia?

Question 1: What is the vascular supply of the labrum and how does that affect the choice of treatment options?

Case clarification

When inspecting a typical labral tear during surgery, it is found that the tear mostly involves the free edge of the labrum on its articular side.

Divisions of the labrum

The labrum is considered to consist of two portions:

- the *articular portion* is the layer adjacent to the femoral head
 - the *capsular portion* is the layer opposite to the articular side
- The labrum is also divided as:

- the *free edge* or *apex*
- the *bony attachment* adjacent to the acetabulum^{19,20}

Relevance

Since blood supply is important for a labral repair to heal, the location of the tear (and relative vascularity) are important in determining reparability

Current opinion

It has been shown that the periphery of the acetabular labrum is better vascularized than its more central (apex) portion.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) search, using keywords: “hip” AND “labrum” AND “vascularity” as well as “hip” AND “labrum” AND “vascularization”

Quality of the evidence

- 3 cadaver studies

Findings

The synovium surrounding the labrum is highly vascularized. The adjacent joint capsule supplies blood vessels to only the peripheral one third of the labrum. A group of small vessels travel circumferentially in the substance of the labrum at the labrum’s attachment site on the outer surface of the bony acetabular extension.^{2,19} The capsular portion is significantly better vascularized than the articular portion.²⁰

Recommendation

- Labral tears in central, avascular zones should be debrided because they have limited capacity to heal, whereas those in the peripheral, vascular regions should be considered for repair [cadaver studies]

Question 2: What is the function of the labrum and how might that affect the choice of treatment?

Case clarification

During surgery, 1 cm of the labrum is found to be detached from the acetabular rim. The surgeon must decide whether to perform a partial labrectomy or a labral repair.

Relevance

When deciding how much labrum to debride and whether to repair the labrum, one should consider the function of the intact labrum and therefore the possible consequences of a partial or complete labrectomy.

Current opinion

The biomechanical functions of the acetabular labrum are not yet well understood.

Finding the evidence

- PubMed search, using keywords: “hip” AND “labrum” AND “biomechanics”

Quality of the evidence

- 8 biomechanical studies

Findings

The labrum significantly increases the surface area and volume of the acetabulum.²¹ In the normal hip, the labrum does not have a significant load-sharing role in the single-leg stance phase.²² Disruption of the labrum creates subtle joint instability.²³ In the dysplastic hip, the labrum may assume a load-sharing role and hypertrophy, helping to stabilize the femoral head within the acetabulum.²⁴

The labrum acts as a seal against synovial fluid flow in and out of the hip central compartment. This seal may enhance joint lubrication and articular cartilage nutrition, maintain a protective fluid film between the articular surfaces, and unload the cartilage by limiting fluid expression from its matrix during loading.^{25–28}

Compartments of the hip joint

- The *central compartment* is limited by the confines of the acetabulum and labrum
- The *peripheral compartment* is the intra-articular region outside the confines of the acetabulum and labrum, i.e., the region along the femoral neck

Recommendation

- The labrum may play a significant role in articular cartilage health and hip stability. Therefore, the labrum should be conservatively debrided and/or repaired when possible [biomechanical studies]

Openmirrors.com

Question 3: How does a patient with a labral tear present clinically on history and physical examination?

Case clarification

The patient reports having had groin pain for about 1.5 years and has seen two other physicians about this pain. They had diagnosed her with muscle strains and early osteoarthritis (OA). She has gone to about 20 physical therapy sessions without any pain relief.

Relevance

Labral tear as part of the differential diagnosis of hip pain has only recently achieved prominence in the lexicon of orthopedics.

Current opinion

As evidenced by the frequent delay in diagnosis, the signs and symptoms of labral tears are not yet well appreciated and therefore inadequately investigated.

Finding the evidence

- PubMed search using keywords “hip” AND “labrum tear” AND “diagnosis” as well as “hip” AND “labral tear” AND “presentation”

Figure 103.1 The impingement test (hip flexion, adduction and internal rotation) typically produces pain or a clicking sensation in the presence of an anterior-superior labral tear.

Quality of the evidence

Level IV

- 8 case series

Level V

- 1 expert opinion

Findings

Patients are on average in their late 30s. The onset of symptoms can be insidious or traumatic with pain predominantly in the groin, both sharp and dull, activity related, present at night, and exacerbated by sitting. Most have a painful mechanical locking. The average period between onset of symptoms and diagnosis is 21–35 months; patients see an average of 3.3 healthcare providers before diagnosis.^{1,29}

Physical examination should include gait analysis, impingement test (Figure 103.1), Trendelenburg sign, flexion–abduction–external rotation test, flexion–internal rotation–adduction test, and palpation of the greater trochanter. Clinical examination maneuvers need improvement in accuracy, sensitivity, and interobserver reliability.^{30–33} Radiographs should be examined to detect abnormalities in hip morphology—i.e., FAI (e.g. coxa profunda, Figure 103.2) or dysplasia—that may guide treatment.^{34–38}

Recommendations

In patients presenting with nonarthritic hip pain:

- History should focus on location of pain, character of pain (sharp and/or dull), activities that induce pain, and whether they have pain at night [overall quality: low]
- Physical examination should include the impingement test [overall quality: low]

Figure 103.2 (a, b) AP pelvis radiograph reveals bilateral coxa profunda (i.e., the medial acetabular wall is medial to the ilioischial line).

Figure 103.3 Magnetic resonance arthrograms (MRA) showing a labral tear (arrows) on T2 weighted (a) coronal and (b) axial images.

- Radiographs should be studied for the anatomy of impingement and dysplasia to help guide treatment [overall quality: low]

Question 4: What is the sensitivity of MRI vs. MRA?

Case clarification

The patient has an MRI of the hip without contrast that does not show a labral tear, but history and examination are very suspicious for a labral tear.

Relevance

Intra-articular injection of contrast has associated cost and morbidity. When evaluating a patient with history and examination consistent with a labral tear, clinicians must decide whether to order an MRI or an MRA.

Current opinion

Physicians order an MRA if the history and examination are consistent with a labral tear (Figure 103.3) These gadolinium injections are often combined with an intra-articular anesthetic injection to discern whether the pain generator

Figure 103.4 Intraoperative picture of a torn labrum (a) before and (b) after debridement.

is actually within the joint. However, patients are often referred with just a noncontrast MRI.

Finding the evidence

- PubMed search, using keywords: “magnetic resonance” AND “labral tear” AND “hip”

Quality of the evidence

Level IV

- 6 case series

Findings

Hip MRIs have been found to have an 8–95% sensitivity (lowest for those of the pelvis, highest for those focusing on the hip), 67% specificity, and 92% interobserver reliability for labral tears.^{30,39,40} MRAs studies reported a 63–100% sensitivity and 71–96% specificity for detecting labral tears.^{30,40–42} An intra-articular anesthetic can help identify patients with intra-articular pathology and can possibly identify labral tears that are asymptomatic.^{30,32}

Recommendations

- Patients with history and physical examination suspicious for a labral tear should be sent for an MRA rather than a MRI [overall quality: moderate]
- Addition of an intra-articular anesthetic during contrast injection for the MRA is helpful in discerning whether the pain generator is intra-articular [overall quality: low]

Question 5: What are the results of labral debridement?

Case clarification

During arthroscopy, the anterolateral labrum is torn with evidence of mucoid degeneration.

Relevance

The labrum contains sensory nerve end organs, mostly in the superficial layer of the labrum, that presumably cause the hip pain associated labral tears.⁴³ With advances in hip arthroscopy, these tears are most commonly being debrided (partial limbectomy or partial labrectomy) (Figure 103.4).

Current opinion

Partial labrectomy is thought to alleviate the pain and mechanical symptoms associated with a labral tear.

Finding the evidence

- PubMed search, using keywords: “hip arthroscopy” AND “labral tear”

Quality of the evidence

Level IV

- 8 case series

Findings

Labral debridement studies report 46–100% satisfaction or good results, even at up to 10 years follow-up, with worse results in the context of OA.^{29,44–48} Those with secondary gain also appear to have a poorer prognosis.⁴⁹ For those patients with symptoms during athletic activities, results of labral debridement are also good, with 87% returning to their sport.⁵⁰

Recommendation

- Arthroscopic partial labrectomy for labral tears without bony work to address FAI anatomy, when present, yields an approximately 70% satisfaction rate overall [overall quality: low] (See Question 3, Chapter 104, Hip Impingement)

Figure 103.5 AP pelvis (a) before and (b) after a cheilectomy of cam-type impingement.

Question 6: In patients with the anatomy of FAI and a labral tear, how is prognosis affected by the addition of osteochondroplasty to the labral debridement/repair?

Case clarification

On preoperative radiographs it is apparent that the patient has a crossover sign (indicating relative cranial acetabular retroversion), coxa profunda, and loss of femoral offset anteriorly—consistent with mixed pincer and cam impingement.

Relevance

If indeed there is an anatomic predisposition to labral tears, addressing the symptoms (i.e., the tear) without the underlying pathology may doom the patient to recurrent tears or continued pain.

Current opinion

There is a growing sentiment that the anatomy of FAI can lead to labral and chondral lesions and that the underlying hip morphology should be addressed.

Finding the evidence

- PubMed search, using keywords: “hip arthroscopy” AND “femoroacetabular impingement” as well as “hip arthroscopy” AND “osteoplasty”

Quality of the evidence

Level IV

- 7 case series

Findings

Studies of FAI patients show better results when an arthroscopic osteochondroplasty supplements the labral/chondral debridement (Figure 103.5) In the context of cam impingement, osteochondroplasty patients improved more in their outcomes scores, were less likely to require a reoperation, and had a higher proportion of good/excellent results compared to those with labral debridement alone.^{51–53} In FAI patients with chondral damage, there was no significant improvement in pain scores when a labral debridement was performed without an osteoplasty.⁵⁴

Analyzing revision hip arthroscopies for persistent hip pain, 79–97% had FAI anatomy seen on radiographs at the time of revision.^{55,56} Addressing the associated bony pathology at revision improved patients’ pain and increased function and activity levels.⁵⁷

Recommendation

- In patients with a labral tear and radiographically evident FAI anatomy, the FAI anatomy should be addressed to optimize pain relief [overall quality: low]

Question 7: Can the labrum be repaired, and what are the outcomes of labral repair?

Case clarification

Preoperative radiographs were consistent with pincer impingement: a crossover sign (indicating cranial acetabular retroversion) and coxa profunda. The patient is consented for an acetabuloplasty and labral debridement vs. repair. During arthroscopy, the anterosuperior labrum is

not found to have any significant signs of intrasubstance degeneration, calcification, ossification, or tearing.

Relevance

When arthroscopically treating pincer type impingement with an intact labrum, the surgeon must decide whether to debride the overlying labrum or to detach it from the rim and reattach it after the acetabular rim trimming.

Current opinion

In general, one should preserve nonpathologic normal structures if possible. Therefore, repair or refixation of the labrum is being increasingly attempted if the labrum does not appear significantly degenerated or torn within its substance (Figure 103.6). A study on sheep demonstrated that labral repairs do heal.⁵⁸

Finding the evidence

- PubMed search, using keywords: “hip arthroscopy” AND “labral tear”; “hip arthroscopy” AND “labral repair”; as well as “labral refixation”

Quality of the evidence

Level IV

- 2 case series

Level V

- 3 expert opinions

Findings

There are a couple of arthroscopic labral repair technique papers with only nonspecific reports on outcomes, noting that “nearly all” patients had marked symptomatic improvement with clinically “positive results.”^{59–61}

Larson published a detailed outcomes report comparing labral debridement with labral refixation in patients with pincer impingement at a minimum of 1 year follow-up and found the outcomes and proportion of good/excellent results were significantly higher in the labrum refixation group.⁶²

Recommendation

- Labral repair should be attempted, if possible, when performing an acetabuloplasty or treating a torn labrum (particularly if the tissue is of good substance and tear occurs at the labral–chondral junction) [overall quality: low]

Question 8: How does the presence of articular cartilage damage affect the prognosis of a patient with a labral tear?

Case clarification

During arthroscopy, a 10 mm × 12 mm full thickness cartilage defect is found in the anterior-superior quadrant of the

Figure 103.6 A labral repair. (a) Chondro-labral separation. The acetabular rim is prepared for the suture anchors. (b) The suture anchor has been placed, and a bird beak pierces through the labrum to create a vertical mattress stitch. (c) The labrum has been reattached to the acetabular rim.

acetabulum. When the arthroscopic photographs are reviewed with the patient postoperatively, she asks how this chondral lesion affects her prognosis.

Relevance

McCarthy et al. reported that, of those with both a labral lesion and chondral damage, 80% had both lesions located in the same acetabular zone. They theorized that labral tears may destabilize the adjacent acetabular cartilage, creating a weak point where joint fluid, under pressure during loading conditions, can furrow under the cartilage and create a lesion via a delamination mechanism. Subchondral

cysts may eventually be formed when the fluid furrows under the subchondral bone.^{4,16,63} The biomechanics of FAI can also explain the concurrence of chondral lesions and labral tears in similar locations.^{53,64,65} The pattern of chondral and labral damage has been found to correlate with hip morphology (i.e., cam or pincer type FAI).⁶⁶

Current opinion

Patients with radiographically moderate to severe OA may have concomitant labral pathology, but it is widely believed that those patients are best served by hip arthroplasty (THA) as the results of hip arthroscopy in the face of OA are poor.⁴⁸ The treatment decision-making for those patients with radiographically mild OA and the prognosis for those with normal radiographs but arthroscopically diagnosed chondral on the femoral head or acetabulum is less clear.

Finding the evidence

- PubMed search, using keywords: "hip arthroscopy" AND "labral tear"

Quality of the evidence

Level IV

- 7 case series

Findings

The data analyzing the influence of chondral damage on prognosis following a labral debridement is mixed, but several studies indicate that the presence of chondral damage is a poor prognostic indicator.^{44,48,67}

Three other studies have not found a correlation between chondromalacia/OA and outcomes after labral debridement.^{45,47,49} Byrd reported that their FAI patients who had microfracture had a similar improved modified Harris hip score (MHHS) compared to the overall average improvement in FAI patients following labral debridement and femoroplasty (Figure 103.7).⁶⁸

Recommendation

- Patients with labral tears in the context of chondral damage should be cautioned that their prognosis is overall less favorable than those with intact articular cartilage [overall quality: low]

Question 9: What are the complications associated with labral debridement and repair?

Case clarification

Postoperatively, the patient has some numbness along her anterolateral thigh. She wonders how common this is and if it will resolve.

Relevance

Overall, the rate of complications for hip arthroscopy ranges from 0.5% to 6.4%.⁶⁹⁻⁷¹ The largest case series (1,054

Figure 103.7 (a) Full thickness chondral lesion of the acetabular rim. (b) An awl is used to penetrate the subchondral bone. (c) Microfracture is completed.

Figure 103.8 (a) A patient with a left hip labral tear presented to our clinic for a second opinion. (b) He had his left hip arthroscopy, partial labrectomy, acetabuloplasty, and cheilectomy elsewhere and returned to our clinic with persistent left hip pain. The radiograph shows a decreased center-edge angle now meeting the criteria for hip dysplasia.

arthroscopies) reported a 1.4% complication rate.⁷² An understanding of the possible complications can help the surgeon take steps to minimize the patients' risk and to properly inform the patient during the consent process.

Current opinion

To minimize the risk of the most common complication—i.e., traction injuries—traction time should be as brief as possible (<2 hours is optimal), and traction force should be the minimum needed to distract the joint sufficiently. Neuropraxias are regarded as transient and due to stretch and/or pressure rather than direct nerve trauma.

Finding the evidence

• PubMed search, using keywords: “hip arthroscopy” AND “labral tear” as well as “hip arthroscopy” AND “complications”

Quality of the evidence

Level IV

- 7 case series
- 5 case studies

Nonclinical

- 1 cadaver study

Findings

Though likely under-reported, perhaps the most common complication is iatrogenic chondral scuffing and labral perforation, though it has been suggested that it may not affect outcomes.⁷³ The most commonly reported complication is transient neuropraxia of the pudendal, sciatic, peroneal, lateral femoral cutaneous nerve (LFCN), and femoral

nerves due to traction.⁷⁴ Direct trauma to neurovascular structures may also occur, most commonly affecting the LFCN during establishment of the anterior portal (incidence of ~0.5%). Direct trauma to the sciatic nerve or femoral neurovascular structures can be catastrophic.⁷⁵

Instability and even dislocation can occur with extensive debridement of the labrum, acetabular osteoplasty, and/or anterior hip capsulotomy, particularly in dysplastic hips (Figure 103.8).^{71,76,77} Femoral neck fractures, though exceedingly rare, can occur after a cheilectomy.^{71,75,78} A rare but potentially fatal complication is fluid extravasation into the retroperitoneal and intraperitoneal cavities.^{79–81}

Other reported complications include inadequate access or observation, excessive portal bleeding and hematoma, instrument breakage, vaginal tear, trochanteric bursitis, and infection.⁷²

Recommendation

- Preoperatively, hip arthroscopy patients should be counseled regarding the most common complications, particularly neuropraxias that are almost all transient [overall quality: low]

Question 10: What are the possible pitfalls of labral debridement in patients with hip dysplasia?

Case clarification

The patient comes back for follow-up at 6 months and reports pain in her other groin, with catching. An MRA shows a labral tear. Radiograph shows a center-edge angle of 18° (i.e., she has a dysplastic hip).

Center–edge angle (CEA)

The CEA is the angle formed by (1) a line drawn from the center of the femoral head to the lateral edge of the acetabulum and (2) a line straight up from the center of the femoral head. The CEA is measured on the AP pelvis radiograph.

Relevance

In acetabular dysplasia, the acetabulum does not provide adequate bony containment of the femoral head. In response, the labrum hypertrophies to accommodate increased load-bearing and is therefore subject to increased weightbearing stress and chronic shear stress. A tear of the labrum may be a sign of decompensation of the dysplastic hip. There is a high incidence of labral tears in dysplasias (up to 46%).⁸² Tearing and/or debridement of the labrum may remove a barrier protecting the articular cartilage, instigating or accelerating the development of hip OA.

Current opinion

The labrum is debrided conservatively in patients with acetabular dysplasia and a labral tear. Overall, hip arthroscopy has a limited role in acetabular dysplasia.

Finding the evidence

• PubMed search, using keywords: “hip arthroscopy” AND “labral tear” as well as “hip arthroscopy” AND “dysplasia”

Quality of the evidence

Level IV

- 1 case study
- 3 case series

Findings

Addressing labral tears without regard to the underlying morphology (ranging from FAI to dysplasia) may predispose patients to failure.⁸³ Removing large pieces of the labrum in a patient with dysplasia can increase pain, accelerate OA, and result in lateral hip subluxation.⁷⁶ However, acetabular dysplasia is not necessarily a poor prognostic indicator in hip arthroscopy. In a series of patients with a CEA less than 25, patients with rupture of the ligamentum teres and loose bodies had the best results, those with labral and chondral issues had average results, and those with clinical evidence of arthritis had the poorest results.²⁴ Dysplasias can also develop symptomatic labral tears after pelvic osteotomies that can successfully be treated arthroscopically.⁸⁴

Recommendations

• Labral debridement in classic acetabular dysplasia should be approached with caution as there is a risk of

increased hip pain, chondral degeneration, and/or hip instability [overall quality: low]

• A labral tear may be the harbinger of accelerated OA in dysplastic patients [overall quality: low]

Summary of recommendations

• The central, articular portion of the labrum is the least vascular while the peripheral, capsular portion of the labrum is the most vascular region. Thus, those tears in avascular zones should be debrided due to the limited capacity to heal while those in the vascular regions should be considered for repair

• The labrum may play a significant role in articular cartilage health and hip stability. Therefore, the labrum should be conservatively debrided and/or repaired when possible

• In patients presenting with nonarthritic hip pain:

◦ History should focus on location of pain, character of pain (sharp and/or dull), activities that induce pain, and whether they have pain at night

◦ Physical examination should include the impingement test

◦ Radiographs should be studied for the anatomy of impingement and dysplasia to help guide treatment

• Patients with history and physical examination suspicious for a labral tear should be sent for an MRA rather than a MRI

• Addition of an intra-articular anesthetic during contrast injection for the MRA is helpful in discerning whether the pain generator is intra-articular

• Arthroscopic partial labrectomy for labral tears without bony work to address FAI anatomy, when present, yields an approximately 70% satisfaction rate overall

• In patients with a labral tear and radiographically evident FAI anatomy, the FAI anatomy should be addressed to optimize pain relief

• Labral repair should be attempted, if possible, when performing an acetabuloplasty or treating a torn labrum (particularly if the tissue is of good substance and tear occurs at the labral–chondral junction)

• Patients with labral tears in the context of chondral damage should be cautioned that their prognosis is overall less favorable than those with intact articular cartilage

• Preoperatively, hip arthroscopy patients should be counseled regarding the most common complications, particularly neuropraxias that are almost all transient

• Labral debridement in classic acetabular dysplasia should be approached with caution as there is a risk of increased hip pain, chondral degeneration, and/or hip instability

• A labral tear may be the harbinger of accelerated OA in dysplastic patients

Conclusion

Advances in imaging (i.e., MRA) and treatment (i.e., hip arthroscopy) have only recently brought labral tears to the forefront of orthopedics, so the literature on this topic is limited. Patients with labral tears classically present with insidious onset of moderate/severe activity-related groin pain that is both sharp and dull, painful mechanical locking, and a positive impingement sign. Given that the function of the labrum is not yet fully understood, surgeons should be conservative in debriding a torn labrum and should consider labral repair if possible, particularly in the dysplastic hips. Currently, there is low-level evidence that addressing FAI anatomy during arthroscopy for a torn labrum enhances the prognosis. Chondral lesions are considered a poor prognostic indicator for recovery after hip arthroscopy.

Openmirrors.com

Marc J. Philippon and Karen K. Briggs

Steadman Philippon Research Institute, Vail, CO, USA

Case scenario

A 19 year old man is the goaltender for his hockey team. He uses the butterfly stance and is complaining of significant right hip pain. The pain is worse when he is playing hockey. It also bothers him when he sits for a long period of time. He has tried conservative management with no resolution of symptoms.

Relevant anatomy

Recently, femoroacetabular impingement (FAI) has been documented as a common problem in the athletic population. FAI is thought to be the underlying cause of many tears and chondral injuries.¹⁻⁴ Anterosuperior labral and chondral injury has been described as a result of abnormal contact between the femoral head–neck junction and the anterior acetabulum during terminal hip flexion.² FAI has been classified into two distinct categories—cam impingement and pincer impingement—based upon the location of the deformity (femoral head–neck junction vs. acetabulum) and the patterns of labral and chondral injury.⁵

Cam impingement is the result of an abnormally shaped femoral head and neck that contacts a normal acetabulum. The femoral head–neck junction has an increased radius of curvature and is not spherical anteriorly. This bony abnormality contacts the anterior acetabulum as the hip flexes and internally rotates. Chondral injury and labral tears result from the shear forces produced by the contact.^{4,6,7}

Pincer impingement is the result of contact from an abnormal anterior acetabular “overcoverage.”⁵ Repetitive contact between the acetabular rim and the femoral head–neck

junction causes the labrum to become crushed, leading over time to degeneration. Additionally, the contact can also cause leverage of the femoral head out of the acetabulum posteriorly leading to a “contre-coup” injury to the posteroinferior labrum.⁵

Importance of the problem

As the emphasis on FAI is relatively new, few studies have documented the cost of the disease. In young patients with hip pain, the prevalence of FAI is very high. FAI may be a cause of early osteoarthritis in young patients.^{4,5,7} The bony abnormalities associated with FAI expose the hip joint to excessive forces leading to labral tears and cartilage damage. If FAI and its sequelae go untreated, there may be rapid progression of joint degeneration, which has a large impact on the individual and society. With improved understanding of FAI and its treatment, it is possible that the prevalence of early osteoarthritis of the hip in the young patient could be reduced.

Top four questions

Diagnosis

1. What physical examination tests are used in the diagnosis of FAI?

Treatment

2. Is open or arthroscopic treatment of FAI the most effective in the sports medicine population?
3. Should a torn labrum be debrided or repaired?

Prognosis

4. Can athletes return to sport in a timely manner following treatment of FAI?

Question 1: What physical examination tests are used in the diagnosis of FAI?

Case clarification

The young hockey player had a positive anterior impingement sign and he had an increased FABER distance test on the painful hip.

- **Anterior impingement:** To perform the anterior impingement test, the patient is placed supine on the examination table. The hip is passively flexed to 90°, followed by forced adduction and internal rotation. In this position, the anterior femoral neck approximated the anterosuperior acetabulum, the most frequent region of chondral and labral injury. Recreation of the patient's pain with this maneuver is considered to be a positive impingement sign.
- **FABER distance test:** It is performed in the supine position by placing the affected extremity in the figure-4 position of flexion, abduction, and external rotation. A gentle downward force is then applied to the leg while stabilizing the pelvis. The vertical distance from the lateral aspect of the knee to the examination table is recorded. If the distance is greater for the painful hip, this is considered a positive

Relevance

A thorough physical examination is critical in order to determine the source of the patient's symptoms. The findings of the physical examination should guide the clinician in the ordering of further diagnostic investigations.

Current opinion

Current opinion suggests that use of the anterior impingement test, measured deficits of range of motion, and a positive FABER distance may provide good evidence that FAI is present.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/), from 2005 to 2010, using the search terms: "(femoroacetabular impingement) AND (diagnosis OR physical examination OR tests) AND (radiographs)"

Quality of the evidence

Level II

- 4 studies developing diagnostic criteria with gold standard

Level III

- 4 nonconsecutive patient studies with no gold standard

Level IV

- 6 case control studies

Findings

Several studies have investigated the physical examination for diagnosis of hip pain.⁸⁻¹¹ Although surgeons do not use one specific battery of tests, there are a few tests that are commonly reported in the clinical presentation of FAI.¹²⁻¹⁴ One study showed the ability to detect FAI is not dependent on the type of impingement. The FABER test was shown to have fair diagnostic ability and the impingement test was shown to have low diagnostic ability.¹¹ In several papers reporting clinical presentation of patients with FAI, the FABER test and the anterior impingement test are usually positive. The FABER test is used in two ways, and it is unclear which FABER test is more specific. The anterior impingement test is very examiner specific. It has been shown to be more specific when performed by physicians compared to physical therapists. When used in combination, these tests can be helpful in identifying patients who are at high risk for chondrolabral dysfunction due to FAI.

Several types of radiographs are used for analysis of the cam lesion.^{4,15-18} However, one study showed a direct correlation between the alpha angle and chondrolabral damage in the hip. Reported reliability of the alpha angle varies widely.^{15,16,18} Using the alpha angle as a dichotomous indicator of FAI has not been tested. It has been our experience that patients with an alpha angle over 55° are at high risk of pathologies associated with FAI. We have also shown the alpha angle to be associated with the FABER distance test as well. With a combination of tests, a screening program can be developed to identify those individuals who are at risk of intra-articular hip pathologies associated with FAI.

Recommendations

- A thorough clinical examination is necessary as there is no evidence to support the use of specific tests for the diagnosis of FAI [overall quality: moderate]
- It is our experience that the FABER distance test and the anterior impingement test are relatively specific for the diagnosis of FAI [overall quality: high]
- The alpha angle measured on radiographs is a helpful adjunct to the clinical examination in the diagnosis of FAI [overall quality: moderate]

Question 2: Is open or arthroscopic treatment of FAI the most effective in the sports medicine population?

Case clarification

The patient underwent hip arthroscopy for treatment of a labral tear with associated chondral delamination as a result of FAI.

Relevance

Several techniques are described to treat FAI. These include surgical dislocation, mini-open, and arthroscopy. The goal of these procedures is to return the patient to normal activities of daily living. In the sports medicine population, return to activity is the desired outcome following surgical intervention for injury. For many, activity is part of their work environment. The extent of surgical trauma, hospitalization, and rehabilitation differs between open and arthroscopic procedures. If arthroscopic intervention has similar or superior outcomes to open intervention, then hip arthroscopy would be the procedure of choice and would reduce the overall costs of treating FAI.

Current opinion

Current opinion suggests that hip arthroscopy allows the patient to return to activity sooner and is less likely to cause the patient to reduce their activity level and change their lifestyle.

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/), from 2005 to 2010, using the search terms: “(femoroacetabular impingement) AND (open OR arthroscopy OR arthroscopic)”

Quality of the evidence

Level IV

- 14 case control studies
- 1 therapeutic study

Findings

A recent systematic review of the literature concluded that treatment of FAI results in improvement in pain and function.¹⁹ It further concluded that current literature is limited and there is no evidence to support one surgical technique over another.¹⁹ In a review of six papers on the open surgical approach for the treatment of FAI, the failure rate was 16%.^{20–25} This was based on each author’s individual definition of failure. In a review of eight studies that reported on hip arthroscopy for FAI, the failure rate was 5%.^{26–33} There was also a higher rate of major complications in the open studies. Comparison of two studies showed that longer rehabilitation is required after an open approach. Bizzini et al. reported on open treatment of FAI.²⁴ Their patients returned to hockey in 6.7 months. In another study, 29 hockey players were treated with arthroscopic decompression of FAI and returned to hockey at an average of 3.4 months.³² The arthroscopic technique allowed for shorter rehabilitation and quicker return to sport. It is difficult to compare outcome scores between open and arthroscopic approaches. Most studies on open treatment report the Merle d’Aubigné score while most arthroscopic treatment papers report the modified Harris hip score (MHHS).

Recommendation

- An arthroscopic approach is preferred because of its lower failure rate, fewer major complications, and shorter rehabilitation time [overall quality: low]

Question 3: Should the torn labrum be debrided or repaired?

Case clarification

At arthroscopy, a large tear in the anterior–superior labrum was identified. The labrum was detached at the articular–fibrocartilage interface, consistent with a cam type pathology, and there was some flattening of the labrum consistent with pincer impingement. The tear was repaired with suture anchors. Three anchors were used to refix the labrum to its anatomic position.

Relevance

FAI is commonly associated with labral tears.^{2,5,6,14,28} When the damaged labrum is debrided or resected, the goal is to eliminate the unstable labral flap which is causing pain and discomfort. However, removing the native labrum eradicates its functional role in the hip, which may lead to future degeneration.³⁴ A recent study showed increased cartilage strain after labral resection when compared to labral repair.³⁵ This increase in strain may lead to early development of osteoarthritis. Similar to the meniscus in the knee, efforts should be made to preserve healthy labral tissue to help protect the articular cartilage. Loss of labral tissue and labral function can also lead to hip instability.³⁴

Current opinion

Preservation of healthy labral tissue is important when addressing labral pathology. Treatment should be based on the type of tear, the quality of tissue and the quantity of labral tissue. When feasible, repair should be the treatment of choice. There are instances when the tear is small and debridement is an acceptable option.

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/), from 2005 to 2010, using the search terms: “(acetabular OR acetabulum) AND (labral OR labrum tears) AND (hip arthroscopy)”

Quality of the evidence

Level III

- 1 case control study

Level IV

- 11 case series

Findings

One level III study provides the strongest evidence regarding arthroscopic labral debridement compared to labral

repair.³⁶ A group of 36 patients with labral debridement was compared to a group of 39 patients with labral repair. The study showed that labral repair resulted in improved function, fewer poor results, and fewer degenerative changes.³⁶ The results of this study are supported by several level IV studies.^{28,30,32,37} In one study, the choice of labral repair over labral debridement was an independent predictor of improved function.²⁸

Recommendations

- If adequate tissue is available, a labral repair is the preferred treatment [overall quality: low]
- Labral debridement should be used judiciously and only when repair is not possible [overall quality: low]

Question 4: Can athletes return to sport in a timely manner following treatment of FAI?

Case clarification

Eight weeks following arthroscopy, this patient passed the hip sport test and was allowed to return to full activity. The patient returned to the ice at 8 weeks and completed full training sessions at 9 weeks.

The **hip sport test** was developed to evaluate the patient's rehabilitation progress and determine if the patient can safely to return sport specific training. Instead of isolated measures of range of motion and single plane strength, the sport test uses combined coordinated movements of the entire involved extremity assessing muscle power (strength over time), ability to maintain correct form during exercises and presence of pain in common training situations.

Relevance

In the sports medicine population, return to activity is what patients expect following surgery. Many patients undergo surgery not because of the severity of symptoms, but because of inability to participate in their sport. In other populations, keeping people active is not only critical for muscle strength and weight control and to decrease the risk of osteoarthritis, but it is also a key element in the prevention of other chronic diseases.

Current opinion

Return to sport is possible following treatment of FAI.²⁶ However, there is no consensus on how long it will take the patient to return to sport. The rehabilitation program that patients are prescribed is critical in preparing the patient to return to sport in a timely manner. The patient must comply with the program.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/), from 2005 to 2010, using the search terms: "(femoroacetabular

impingement) AND (activity OR athlete OR sport) AND (arthroscopy OR arthroscopic)"

Quality of the evidence

Level IV

- 6 case series

Findings

Information on return to sport was available in four studies including a total of 228 athletes.^{26,32,33,37,38} In these studies, 79% of the athletes returned to activities. However, in two studies involving professional athletes, there was a 96% return to sport in a total of 73 athletes.^{26,32} One study documented the average time from surgery to return to activity: it showed that following hip arthroscopy, professional hockey players returned to skating/hockey drills at an average of 3.8 months with a range of 1–5 months.³² As noted above, this is half the time that was required to return to hockey following open treatment of FAI.

Three studies reported on the symptoms and function of active patients.^{30,33,38} Most active patients had improved symptoms and high function scores. It is difficult to interpret these studies together, as multiple outcome scores were used and these scores have not been validated in an active sports medicine population.

Recommendations

The evidence here is limited.

- Patients can expect to return to prior levels of activity [overall quality: low]
- Professional athletes will return to their professional sports [overall quality: low]
- A functional test should be used to determine if patients are ready to start sport specific training [overall quality: low]
- A new validated hip outcome score and activity scale is needed for the active sports medicine population [overall quality: low]

Summary of recommendations

- A thorough clinical examination is necessary as there is no evidence to support the use of specific tests for the diagnosis of FAI
- It is our experience that the FABER distance test and the anterior impingement test are relatively specific for the diagnosis of FAI
- The alpha angle measured on radiographs is a helpful adjunct to the clinical examination in the diagnosis of FAI
- In the active, sports medicine population, an arthroscopic approach is preferred due to shorter rehabilitation, lower complication rate, and lower failure rate

- If adequate tissue is available, a labral repair is the preferred treatment
- Labral debridement should be used judiciously and only when repair is not possible
- Active patients can expect to return to activities following hip arthroscopy
- A test of overall function should be used to determine if patients are ready to start sport specific training
- A new validated hip outcome score and activity scale is needed for the active sports medicine population

Conclusion

FAI is being seen more often in the sports medicine population. Early diagnosis and treatment of FAI is essential in avoiding degenerative changes in the joint. Arthroscopic treatment of bony abnormalities and associated pathologies can result in improvement in symptoms and function in the active population. These patients can also return to activity following a structured rehabilitation program.

Openmirrors.com

Bas van Ooij and Matthias U. Schafroth

Academic Medical Center and Orthopedic Research Center Amsterdam, Amsterdam, The Netherlands

Case scenario

A 21 year old ballet dancer presented with an 18 month history of an audible and painful “snap” during particular hip movements. Initially, the “snap” was only audible, but after 8 months it became painful. Because of this pain, she could no longer fully participate in ballet dancing. As no specific event or trauma had occurred, she attributed her complaint to her training program. Six months of physiotherapy (strengthening exercises and general stretching) and avoidance of ballet activities did not result in pain reduction. She described the therapy as having little to no benefit.

Relevant anatomy

The snapping hip syndrome or coxa saltans represents several different pathologic processes of the hip. It is a symptom complex of an audible, palpable, or even visible “snap” during movement of the hip. The causes can be classified as external, internal, and intra-articular. Intra-articular snapping has different causes, including loose bodies, labral tears, or articular cartilage fragments. In this chapter, the external and internal types of snapping hip are discussed.

In the *external snapping hip*, structures over the trochanter major can cause snapping. Most often, the snapping is caused by thickening of the iliotibial band. Fibrosis of the posterior fibers of the gluteus maximus can also cause hip snapping.¹ This thickening is believed to be caused by microtrauma of these structures and could cause an inflamed trochanteric bursa.²

The *internal snapping hip* is caused by the iliopsoas tendon or underlying bursa. The iliopsoas muscle is the strongest

hip flexor. The exact mechanism that causes snapping, due to the iliopsoas tendon or bursa, is controversial. It has been shown that the iliopsoas tendon shifts laterally in relation to the center of the femoral head during flexion of the hip. The tendon slides medially across the femoral head during extension (Figure 105.1).^{3,4} The iliopsoas bursa lies between the tendon and the anterior hip capsule and therefore could be involved and inflamed in iliopsoas snapping.

It has also been noted that in iliopsoas snapping, the prominence of the iliopectineal eminence or an exostosis of the lesser trochanter could be involved.⁴ Recently, another mechanism has been described: sudden flipping of the iliopsoas tendon around the iliac muscle, allowing the tendon to contact the pubic bone.⁵

Importance of the problem

No exact numbers have been published concerning the prevalence of the snapping hip in the general population. It is often reported as an unusual condition, most common in people in the age range 15–40 years and more common in women.⁶ The external snapping hip is the type most frequently encountered.² Snapping of the iliopsoas tendon as an asymptomatic sign is estimated to occur in approximately 5% of the population.⁷

However, the condition is very common in ballet dancers and athletes.^{8–10} Winston et al. reported a snapping hip in 91% of elite ballet dancers, of whom 58% had significant pain associated with the snap. Only a small number of dancers had to take time off training because of their pain.¹⁰

As it is clear that the snapping hip is usually asymptomatic, treatment is rarely necessary. If treatment is necessary, most patients will respond to a conservative program. This includes resting the hip from activities that cause pain, taking nonsteroidal anti-inflammatory medication, and

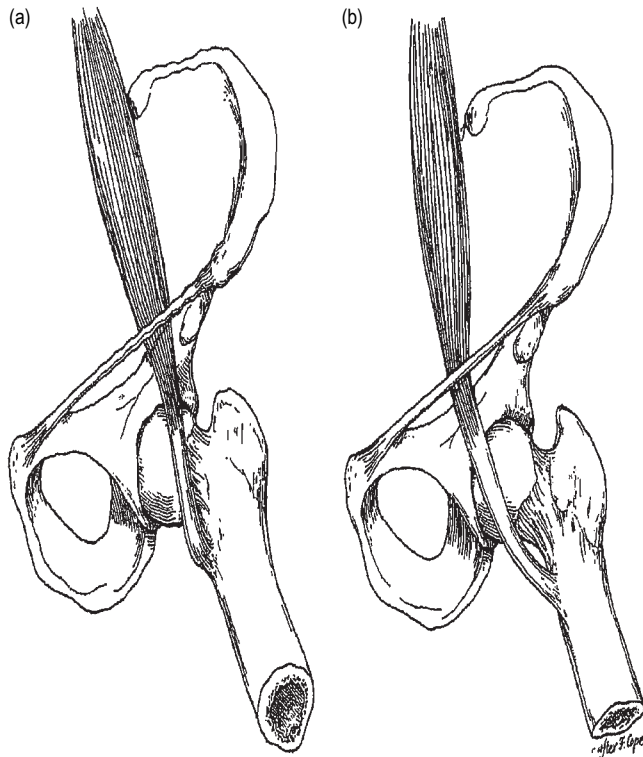

Figure 105.1 (a) With flexion of the hip, the iliopsoas tendon shifts laterally in relation to the center of the femoral head. (b) With extension of the hip, the iliopsoas tendon shifts medially in relation to the femoral head. (©1995 American Academy of Orthopaedic Surgeons. Reprinted from the Journal of the American Academy of Orthopaedic Surgeons, Volume 3(5), pp. 303–308, with permission.)

stretching and stimulating flexibility to reduce the tension on the tendinous structures.⁷ Complete resolution of symptoms may take up to 1 year.² If conservative treatment fails and pain with snapping remains or becomes worse, surgical treatment should be considered.

Top four questions

Diagnosis

1. Which radiographic study is the most useful to diagnose the snapping hip?

Therapy

2. What is the relative effect of open surgical treatment vs. endoscopic surgical treatment in the external snapping hip?
3. What is the relative effect of open surgical treatment vs. endoscopic surgical treatment in the internal snapping hip?
4. What is the optimal approach in endoscopic surgical treatment of the internal snapping hip?

Question 1: Which radiographic study is the most useful to diagnose the snapping hip?

An external snapping hip can be readily diagnosed by clinical examination alone, but if it is not clinically evident, ultrasound could be helpful.^{10,11}

Although no exact numbers of comparisons are published in literature concerning the internal snapping hip, a suitable question would be: What is the sensitivity and specificity of dynamic ultrasound compared to bursography in the internal snapping hip?

Case clarification

At clinical examination, the patient revealed pain along the inguinal crease and medial thigh. She reproduced the snap during active motion. In passive motion the snap occurred during adduction, internal rotation and extension, moved from an abducted, externally rotated, and flexed position. An internal snapping hip was suspected. Plain radiographs of the hip revealed no intra-articular loose bodies or bone spurs. To confirm the suspected diagnosis, we presented two options: a bursography or dynamic ultrasound of the iliopsoas bursa. Along with bursography or ultrasound examination, an injection of lidocaine and steroid would be administered.

Relevance

MRI with and without contrast is an excellent methodology for diagnosing intra-articular lesions or nondynamic iliopsoas diseases.^{12,13} In the internal snapping hip, it is not yet clear if bursography or dynamic ultrasound is the most accurate method.

Current opinion

Current opinion suggests that bursography is the most useful radiographic study to differentiate between intra-articular and internal causes, with or without therapeutic injections.^{4,14,15} Others consider ultrasound necessary to diagnose and confirm iliopsoas snapping.^{5,10,16,17} Ultrasound-guided injections are also considered useful to confirm and treat iliopsoas snapping.^{18,19}

Finding the evidence

- Cochrane Database, with search term: “snapping hip” OR “coxa saltans”
- PubMed clinical queries search/systematic reviews: “snapping hip” OR “coxa saltans”

Quality of the evidence*Level III*

- 1 cross-sectional study
- 5 studies of nonconsecutive patients

Findings

Bursography In 3 case series about bursography (n = 25), 18 patients (72%) revealed an abnormal motion of the iliopsoas musculotendinous unit during bursography.¹⁴⁻¹⁶ Because no gold standard is determined, sensitivity and specificity could not be calculated. Of these 25 patients, 10 received a therapeutic bursa injection, resulting in relief of symptoms in 8 patients for 2 weeks up to 2 years. Two of these 8 patients returned for another injection because of limited symptom relief. In 1 patient, the injection of cortisone did not alleviate symptoms.

In bursography of the iliopsoas bursa, the bursa is injected with contrast dye. After this injection, the hip is moved under fluoroscopy. In the case of an internal snapping hip, a sudden jerk of the iliopsoas muscle over the bursa is diagnostic.

Dynamic ultrasound In a cross-sectional study among elite ballet dancers, ultrasound was performed on 46 hips. In 27 (59%) of the hips, the iliopsoas tendon demonstrated an abnormal motion, but in this study, the snapping hips were also caused by the iliotibial band (in 2 hips, 4%) or by a possible intra-articular problem (in one-third of the hips, ultrasound did not identify the cause of the snap). It was concluded that ultrasound is helpful to diagnose an internal snapping hip.¹⁰

In two case series abnormal iliopsoas movement has been reported using dynamic ultrasound. One case series confirmed 100% of 10 patients,^{16,20} while the second reported 22 hips of 20 patients as having snapping hips.¹⁷ In contrast to these results, only 9 patients (23%) of 40 patients with a clinical confirmed internal snapping hip had documentation of an abnormal iliopsoas movement during ultrasound. These results possibly differed because the population could not reproduce the snap in a supine position. Sixteen of 18 patients (89%) had a good response to an iliopsoas bursa injection with steroids with an average of 4 months (range 2–10 months), so they concluded that even if the internal snapping hip was not visualized with ultrasound, a steroid injection could reduce symptoms.¹⁸

Recommendations

- Bursography and dynamic ultrasound are both useful to diagnose abnormal iliopsoas movement in the internal snapping hip with a higher sensitivity if the patient can reproduce the snap [overall quality: low]
- Both methods are useful to perform steroid injection in the iliopsoas bursa with variable results of the injection [overall quality: moderate]

Question 2: What is the relative effect of open surgical treatment vs. endoscopic surgical treatment in the external snapping hip?

Although no exact numbers of comparison are published in the literature, a suitable question would be: What is the relative effect of endoscopic iliotibial band release vs. open release in the external snapping hip?

Case clarification

At clinical examination, the patient revealed tenderness over the greater trochanter and a snap could be reproduced with repetitive flexion and extension. Ober's test was positive, indicative for a contracted iliotibial band. After two injections of corticosteroids with no improvement of symptoms, we presented two options for surgery: an open Z-plasty of the iliotibial band or an endoscopic release of the iliotibial band.

Relevance

Few surgical techniques have been described, often with disappointing results.²¹⁻²³ Different open approaches and endoscopic iliotibial band release have been introduced to improve the success rate in surgery of the external snapping hip.^{1,24-29}

Current opinion

Current opinion suggests that the majority of surgeons use Z-plasty for surgical release of the iliotibial band in surgery of the external snapping hip.

Finding the evidence

- Cochrane Database, with search term: "snapping hip" OR "coxa saltans"
- PubMed clinical queries search/systematic reviews: "snapping hip" OR "coxa saltans"
- PubMed and Embase sensitivity search using keywords: "external snapping hip" OR "external coxa saltans" OR "snapping iliotibial band"

Quality of the evidence*Level IV*

- 7 case series

Findings

Open release Four small case series described open Z-plasty of the iliotibial band in the external snapping hip.^{1,24,25,27} The total number of patients was 30 (34 hips). Success rates, based on both snapping and pain, were 100%,²⁴ 88%,¹ 89%,²⁷ and 72%.²⁵ Complications occurred in 6 patients. One patient needed a second Z-plasty with good results.

Two other recently described open techniques are the "step cut iliotibial tract over greater trochanter" and the

“multiple fibrous band release.”^{28,29} The first technique was performed in 16 patients (17 hips) with a success rate of 88% and patient satisfaction rate of 100%. Two patients needed a second release because of recurrent snapping; their symptoms resolved completely.²⁸

The second technique was performed in 44 patients with a success rate of 89%. Five patients had recurrence of snapping, but without the need for second surgery. Ten patients reported some limping or weakness, but it did not interfere with their work.²⁹

Endoscopic release Endoscopic iliotibial band release was performed in 11 patients (12 hips), with a success rate of 91%.²⁶ WOMAC scores were evaluated; the average preoperative score was 81 (range 78–87) and the average postoperative score at last follow-up was 94 points (range 89–96). One patient presented with recurrent snapping but without pain at the 2 year follow-up.

Recommendations

- Open release by use of Z-plasty, step cut iliotibial tract, and multiple fibrous band release has a reproducible high success rate, but attention has to be paid to recurrence and postoperative complications [overall quality: low]
- Endoscopic release of the iliotibial band is an effective and reproducible procedure in the external snapping hip [overall quality: low]

Question 3: What is the relative effect of open surgical treatment vs. endoscopic surgical treatment in the internal snapping hip?

Although no exact numbers for comparison are published in literature, a suitable question would be: What is the relative effect of endoscopic iliopsoas release vs. open iliopsoas release in the internal snapping hip?

Case clarification

The patient’s clinical examination revealed an internal snapping hip. After conservative therapy without improvement of symptoms, we presented two options for surgical treatment: open iliopsoas release or endoscopic iliopsoas release.

Relevance

Complications from open procedures in the internal snapping hip have been reported to occur in 43–50% of patients.^{2,3,30} Endoscopic treatment could reduce this complication rate.

Current opinion

Current opinion suggests that endoscopic release could reduce the complication rate of open procedures.

Finding the evidence

- Cochrane Database, with search term: “snapping hip” OR “coxa saltans”
- PubMed clinical queries search/systematic reviews: “snapping hip” OR “coxa saltans”
- PubMed and Embase sensitivity search using keywords: (“snapping hip” OR “coxa saltans”) AND (“iliopsoas tendon release” OR “psoas tenotomy”)

Quality of the evidence

Level IV

- 5 open release case series
- 6 endoscopic release case series

Findings

Open release In 5 case series, open release of the iliopsoas tendon was performed in a total number of 121 patients (139 hips). A retrospective review of 80 patients (92 hips) described “fractional” lengthening performed through an inguinal approach. In the overall results, 40 complications developed in 32 patients (43%). Recurrence of snapping occurred in 18 of the 80 patients (23%). However, overall satisfaction rate, determined by asking if the patient would undergo surgical treatment again, was 89%.³⁰ The same operation through a ilioinguinal approach was performed in 11 patients (12 hips). An overall success rate of 100% was published. Five out of 11 patients reported subjective hip flexor weakness.³¹ A modified intrapelvic and subperiosteal approach of this operation in 7 patients (8 hips) also resulted in a success rate of 100%, with slight subjective hip flexor weakness in 2 patients.³² Fractional lengthening through an iliofemoral approach in 9 adolescent patients (11 hips) resulted in a success rate of 91%, based on 1 recurrence.³³ A medial approach in 14 patients (16 hips) was described with a recurrence rate of 42%.³⁴

Endoscopic release The randomized trial described in question 4 is considered as a case series in this question because two different endoscopic techniques were compared.³⁷ Endoscopic release was performed in a total number of 65 patients. In all studies, a success rate of 100% regarding pain and “resnapping” was presented.^{7,19,35–38} No complications or revision surgery have been described. Four case series reported hip flexor weakness,^{19,35,36,38} but this improved at 6–12 weeks. In 2 case series, Harris hip scores were evaluated; evident improvement after surgery was seen with an adequate follow-up.^{19,35} In 2 studies, WOMAC scores were reported; evident improvement was presented after surgery with an adequate follow-up in these studies.^{36,37}

An important finding was shown in 4 studies: intra-articular pathology was found and treated in 29 of 40 patients (73%). Cam-type femoro-acetabular impingement, labral tears, cartilage delamination, ligamentum teres

Openmirrors.com

hypertrophy, and positive “wave sign” at the acetabulum were described.^{7,19,36–38}

Recommendations

- If iliopsoas tendon lengthening is performed by an endoscopic technique, it results in a better success rate than an open release, with minimal numbers of complications [overall quality: low]
- Because intra-articular pathology is frequently found in endoscopic iliopsoas release, hip arthroscopy should also be performed. [overall quality: moderate]

Question 4. What is the relative effect of endoscopic iliopsoas release at the insertion of the tendon on the lesser trochanter vs. endoscopic transcapsular psoas release from the peripheral compartment in the internal snapping hip?

Case clarification

The patient’s clinical examination revealed an internal snapping hip. After conservative therapy without improvement of symptoms, we presented two options for endoscopic surgery: an iliopsoas release at the insertion of the tendon on the lesser trochanter or a transcapsular psoas release.

Relevance

The main reason for endoscopic treatment of the internal snapping hip is to limit complication rate. It is not yet known which technique results in the lowest incidence of complications.

Current opinion

Current opinion suggests that the majority of surgeons use the iliopsoas release at the level of the lesser trochanter and that both techniques are good alternatives for the open procedures.

Finding the evidence

- Cochrane Database, with search term: “snapping hip” OR “coxa saltans”
- PubMed clinical queries search/systematic reviews: “snapping hip” OR “coxa saltans”
- PubMed and Embase sensitivity search, using keywords: (“internal snapping hip” OR “coxa saltans”) AND (“endoscopic release” OR “arthroscopic release”)

Quality of the evidence

Level I

- 1 randomized trial

Level IV

- 5 case series

Findings

Pain and function The randomized trial (n = 19 patients) evaluated postoperative WOMAC scores at a minimum of 1 year follow-up.³⁷ Preoperatively, group 1 (10 patients treated with release at the lesser trochanter) averaged 70.1 points (SD 10.7) and group 2 (9 patients treated with transcapsular release) averaged 67 points (SD 11.4). At the last follow-up, group 1 averaged 83.7 points (SD 7.1, 95% CI 78.63–88.77) and group 2 averaged 83.6 points (SD 5.9, 95% CI 79.16–88.04). Improvements in these scores were statistically significant in both groups (group 1, p = 0.0001; group 2, p = 0.001). There were no statistical differences preoperatively and after follow-up between the groups, but the small number of patients meant there was a type II error in the results. No measurements of hip flexor strength were performed.

Revision surgery and complications In the randomized trial, no revision surgery, “resnapping,” or other complications occurred in both groups.³⁷ The four case series of patients (n = 37) with release at the lesser trochanter and the case series of patients (n = 9) with transcapsular release also reported no complications.^{7,19,35,36,38} In these case series, hip flexor weakness was reported in both groups, but this improved within 3 months.

Recommendations

- Endoscopic iliopsoas tendon release at the lesser trochanter and endoscopic transcapsular psoas release from the peripheral compartment is both effective and reproducible [overall quality: moderate]
- There are no differences in complication rate, revision surgery, or pain and function recovery between both techniques [overall quality: low]

Summary of recommendations

- Bursography and dynamic ultrasound are both useful to diagnose abnormal iliopsoas movement in the internal snapping hip with a higher sensitivity if the patient can reproduce the snap
- Both methods are useful to perform steroid injection in the iliopsoas bursa with variable results of the injection
- Open release by use of Z-plasty, step cut iliotibial tract, and multiple fibrous band release has a reproducible high success rate, but attention has to be paid to recurrence and postoperative complications
- Endoscopic release of the iliotibial band is an effective and reproducible procedure in the external snapping hip
- If iliopsoas tendon lengthening is performed by an endoscopic technique, it results in a better success rate than an open release, with minimal numbers of complications

- Because intra-articular pathology is frequently found in endoscopic iliopsoas release, hip arthroscopy should also be performed
- Endoscopic iliopsoas tendon release at the lesser trochanter and endoscopic transcapsular psoas release from the peripheral compartment is both effective and reproducible
- There are no differences in complication rate, revision surgery, or pain and function recovery between both techniques

Conclusions

In the internal snapping hip, both bursography and dynamic ultrasound are useful in diagnosing abnormal movement of the iliopsoas tendon. In open surgical treatment of the internal and external snapping hip, success rate is quite high, but complications occur frequently. Complication rates in endoscopic surgery in snapping hips are promisingly low and success rate is promisingly high, but as yet no comparative data with open surgery has been published.

Ergogenic Aids: Creatine Supplementation as a Popular Ergogenic Aid in Young Adults

Michael J. O'Brien

Harvard Medical School, Children's Hospital Boston, Boston, MA, USA

Importance of the problem

Ergogenic aids have been described as any training techniques, mechanical devices, dietary nutritional supplements, pharmacological methods, or psychological techniques that can improve exercise performance capacity and/or enhance training adaptations.^{1,2}

Dietary nutritional supplements are a multibillion dollar industry worldwide. The most common legal performance-enhancing supplements used by athletes are creatine, protein powders, and caffeine. Creatine, however, is the most popular nutritional supplement used as an ergogenic aid at all levels of competition.³

Relevant physiology

Physiologically, creatine is synthesized from arginine, glycine, and methionine predominately in the kidneys but also in the liver and pancreas.³ A typical diet provides approximately 1–2g of creatine per day, with meat and fish being the main sources and supplying more than half of the daily requirement.³

Top two questions

1. Is creatine supplementation an effective ergogenic aid in healthy young adults?
2. Does creatine supplementation have any adverse side effects in healthy young adults?

Question 1: Is creatine supplementation an effective ergogenic aid in healthy young adults?

Relevance

Creatine is predominately stored in skeletal muscle (fast twitch, type II fibers) where it serves as the energy substrate for muscle contraction.³ In its phosphorylated form, creatine contributes to the resynthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) which occurs during short-duration and high-intensity exercises.⁴ This fact serves as the rationale for the use of creatine supplementation as an ergogenic aid.⁵

Current opinion

Creatine is typically used to gain weight and muscle mass, and enhance strength training. It is typically purchased in powder or capsule form and is taken as a post-workout drink or sometimes combined with weight gain and/or protein powders.

Creatine may be helpful with improving performance in short bursts of intense exercise, like bench press or sprint cycling. It seems to have no benefit with endurance in aerobic exercise. Several studies have demonstrated effectiveness in improving high-intensity exercise capacity and increasing muscle mass.

Finding the evidence

- PubMed, using "search terms": "creatine" OR [All Fields] AND "supplementation"[All Fields] AND "exercise" OR "exercise"[All Fields] AND "performance"[All Fields] with limits: "humans" AND English[lang] AND "adolescent" OR "young adult"

- Manual review of cited references from identified articles

Quality of the evidence

Level II

- 13 prospective studies of young adults in strength training and endurance training are discussed below. There is significant variability in the type of exercise used for testing, dosing schedules, and timing (in season vs. out of season training)

Findings

After 12 weeks of training with creatine supplementation, Volek et al. demonstrated increases in heavy resistance exercise in a double-blinded, placebo-controlled, randomized clinical trial (RCT). Treated subjects improved their one repetition maximum (1RM) bench press and squat exercises by 24% and 32%, respectively, vs. the placebo group (16% and 24%, respectively) subjects who had training but no supplementation.⁶ The gains in mass seemed to be a result of an improvement in the ability to recover faster from heavy workouts and train harder, resulting in greater muscle hypertrophy.^{7,8}

In another double-blinded placebo-controlled RCT, Stone et al.⁹ also observed the effect of creatine supplementation on anaerobic performance and body composition of American football players evaluating 1RM parallel squat, 1RM bench press, dynamic explosive strength test of vertical jump, and high-intensity endurance test of 15 5 second cycling rides with 1 minute rest period between rides. They found an 11.6% increase in squat, 10% increase in bench press, and 1.5% increase in vertical jump. However, they found no statistically significant change in cycle ergometer parameters. Both hydrostatic (7%) and skin-fold method (2.6%) indicated a substantial gain in lean body mass, and an increase in body mass of 1.4 % over 5 weeks.⁹

In another double-blinded, placebo-controlled RCT, 14 men ingested 25 g/day of creatine monohydrate for 7 days. Subjects performed five sets of bench press to failure and a jump squat (5 sets of 10 repetitions using 30% of each subject's 1RM). Creatine supplementation resulted in a significant improvement in peak power output during all five sets of jump squats and a significant improvement in repetitions during all five sets of bench presses. It was concluded that 1 week of creatine supplementation (25 g/day) enhances muscular performance during repeated sets of bench press and jump squat exercises.¹⁰

Kersick et al., in a double-blinded RCT, also studied 24 male resistance trainers taking 20 g/day of creatine for 5 days followed by 5 g/day for the remaining 23 days and then completed a resistance training program with 4 supervised workouts per week which targeted the major muscle groups. They concluded that the ingestion of creatine pro-

motes increases in lean mass, body composition, and 1RM bench press and leg press.¹¹

Okudan and Gokbel,¹² in a double-blinded, placebo-controlled trial, found similar results to the Birch et al. study (double-blinded, placebo-controlled RCT) utilizing the "Wingate tests" (30 seconds of maximal cycling effort).¹³ They found in the creatine group the total power output increased by 7.6%.

Ostojic also found a significant effect on short interval exercise. He concluded that creatine supplementation increases short-term bursts, such as dribble and power tests (vertical jumping) with young soccer players.¹⁴

Leenders et al. looked at the effect of creatine ingestion on swimming velocity. Fourteen female and 18 male collegiate swimmers took 6 days of 20 g creatine followed by 8 days of 10 g creatine. They found a 2% improvement in the performance of the creatine-supplemented male swimmers. However, this study was done at the start of the collegiate swim season, and the 2% increase was found after 14 days of training.¹⁵

Contrasting findings are documented by Javierre et al. This study observed 12 Spanish national-class sprinters taking 25 g of creatine for 3 days, and the testing consisted of two 150 m time trials 2 weeks apart. They found no statistically significant differences between the performance times of the first and second trials (mean difference -0.14 s, $p > 0.05$).¹⁶

Additionally, velocity performance was studied in ice hockey skaters. Seventeen male junior and collegiate ice hockey players took 0.3 g/body mass per day for 5 days. Players repeated 10 second sprints to exhaustion on a skating treadmill while blood lactate was simultaneously collected. No differences were found over time for blood lactate changes during repeat sprints on the treadmill. The authors concluded creatine was not effective for improving performance in these ice hockey players.¹⁷

Rico-Sanz and Mendez Marco also looked at the effect of creatine on endurance of cyclists. After 5 days of 20 g creatine supplementation, they tested maximal power output to exhaustion. They found that oxygen consumption was greater after creatine supplementation (10.40 ± 0.65 L vs. 11.82 ± 0.34 L).¹⁸

Reardon et al. looked at the potential effect of creatine supplementation on aerobic long-duration exercise. Their subjects completed 45 minute cycling sessions. They concluded that the ergogenic potential of creatine supplementation in endurance performance does not produce significant results.¹⁹

Engelhardt's findings agree with Reardon's; they also found creatine supplementation had no influence on endurance performance. After testing 12 regional-class triathletes for 5 days on a 6 g/day creatine dosing and cycling 30 minutes to exhaustion, they found endurance performance was not influenced.²⁰

Redondo et al. also produced similar findings in their sprint trials on collegiate athletes. They tested 14 female and 8 male collegiate athletes with 7 days of 25 g/day creatine supplementation. The protocol was three timed 60 meter sprint trials. The results showed creatine supplementation did not enhance speed during 60 meter sprints.²¹

Recommendations

- The suggestion from various sports and training regimens is that creatine supplementation may be effective as an ergogenic aid in short bursts of intense exercise, but does not seem to be beneficial in aerobic endurance exercises
- Although there are several well-designed prospective controlled studies, there are significant concerns about the variability in findings for creatine's effectiveness in strength training. In fact, there is inconsistency in the data with some studies demonstrating no statistically significant benefit from creatine.^{16,17} For young adult athletes involved in strength and endurance training, there does appear to be a good degree of relevance for these studies (directness). Relatively small sample sizes, variability in training protocols, and differences in dosing protocols create inconsistencies in the literature and confound data interpretation [overall quality: low]

Question 2: Does creatine supplementation have any adverse side effects in healthy young adults?

Relevance

Although creatine supplementation has been suggested to be effective in enhancing performance in short, high-intensity athletic-related situations, it is paramount to evaluate whether this supplement has any adverse effects or safety concerns. Creatine is a legal supplement, readily available over the counter. It is not a banned or regulated substance in any amateur or professional sport.

Current opinion

There are no universally agreed-upon dosing schedules. In general, a "loading" dose of approximately 20 g/day for 5 days followed by maintenance dosing of 3–5 g/day (or 0.03 g creatine per kg of body weight) has been suggested.^{3,11} Many athletes cycle creatine use, using it for 3 months at a time followed by a month without creatine use. The optimal time to take creatine is immediately after a workout, combined with a drink with a high glycemic index (i.e., a sports drink with sugar).²²

Short-term use of creatine has generally been considered safe but can still have potential side effects, which are usually mild. The most common side effects are bloating, cramping, and diarrhea.²³ These effects may be minimized by forgoing the loading dose and staying well hydrated.

Creatine does not seem to adversely affect kidney function, but special consideration should be given to athletes with pre-existing kidney disease. It has not been tested thoroughly for patients under age 18, but for adults it seems to be safe and possibly effective.^{24,25}

Finding the evidence

- PubMed, using the search terms: "creatine" AND "supplementation" AND "adverse effects"[Subheading] OR "adverse" AND "effects" OR "adverse effects"[All Fields] OR ("side"[All Fields] AND "effects"[All Fields]) OR "side effects"[All Fields]) with limits: "humans" AND English[lang] AND "adolescent" OR "young adult"
- Manual review of cited references from identified articles.

Quality of the evidence

Level III

- 1 prospective study²⁴
- 4 retrospective studies^{3,26,27,28}

Findings

Yoshizumi and Tsourounis concluded that, according to the existing literature, there appears to be no correlation between renal dysfunction and short-term creatine use in healthy individuals. However, they also caution that people with a history of renal disease may be associated with an increased risk of renal dysfunction as creatine supplementation may complicate the ability to detect progressive decreases in glomerular filtration.²⁶

Poortmans and Francaux investigated liver changes during medium-term (4 weeks) creatine supplementation in young athletes. They found no evidence of dysfunction on the basis of serum enzymes and urea production. However, they did find an increase in body mass during short-term creatine supplementation likely due to water retention, since they observed a 0.6L decline in urinary volume after ingestion of creatine 20 g/day for 6 days.²⁸

Greydanus and Patel reviewed various studies undertaken on the long-term effects of creatine supplementation. One such side effect observed is increased muscle mass, which may be the result of fluid (water) retention and not of increased protein synthesis. An increase of 0.7–3 kg in 1 month has been reported. They also found that weight gain can be maintained on 5 g/day of creatine during a 10 week period of detraining and maintained 4 weeks after it is stopped. Other adverse effects that are often cited but not proven include anecdotal reports of muscle cramps, strains, dehydration in hot humid weather, diarrhea, migraines, and nausea.³

A retrospective study by Schilling looked at the long terms safety of creatine supplementation. The study utilized questionnaires and blood samples on 26 athletes from various sports who had used creatine supplementation for

0.8–4 years. All groups fell within normal clinical ranges; no significant adverse health effects were found with long-term creatine supplementation. Some subjects reported short-term side effects of gastrointestinal distress, but in this study evidence was anecdotal and relied on athlete recollection.²⁷

Kreider examined the effects of long-term supplementation on a 69-item panel of serum, whole blood, and urinary markers of clinical health status in collegiate football players over 21 months of creatine supplementation. No significant differences were found in blood or urine markers between the groups that took creatine for 0–6 months and those who did not. His findings indicated that long-term creatine supplementation (up to 21 months) does not appear to adversely affect markers of health status in athletes undergoing intense training in comparison to athletes who do not take creatine.²⁴

Recommendations

- Creatine supplementation does not appear to have significant adverse side effects from either short- or long-term use in most young adult athletes. Shortcomings in the current studies available for review include a lack of well-designed RCTs. There is also a paucity of data for creatine use in athletes younger than 18 years old.
- Current consensus is to recommend against creatine use in athletes with existing renal disease. No evidence is available to suggest that athletes younger than age 18 should take creatine. Further research is very likely to have an important impact on the confidence in this estimate of effect and presumably will lead to modification of this estimate [overall quality: low]

Summary of recommendations

- Creatine supplementation may be effective as an ergogenic aid in short bursts of intense exercise, but does not seem to be beneficial in aerobic endurance exercises
- Current consensus is to recommend against creatine use in athletes with existing renal disease
- No evidence is available to suggest that athletes younger than age 18 should take creatine

Wrist and Hand Surgery

Openmirrors.com

Ruby Grewal

Hand and Upper Limb Centre, University of Western Ontario, London, ON, Canada

Case scenario

A 22 year old man sustained an isolated injury to his dominant arm after a fall on to his outstretched wrist. Radiographs confirm a displaced distal radius and ulnar styloid fracture.

Introduction

Distal radius fractures can be broadly classified as extra- or intra-articular depending on whether there is extension into the joint surface. Standard radiographic parameters are used to describe the degree of displacement (i.e., ulnar variance, dorsal tilt, radial inclination) (Figure 107.1).

Importance of the problem

Distal radius fractures represent the most common fracture of the upper extremity. The age and gender distribution is bimodal, with young adults (predominantly male) sustaining this injury following high-energy trauma and older adults (predominantly female) sustaining it after low-energy trauma such as a fall from standing height.

The incidence of distal radius fractures in women increases progressively with age from the perimenopausal period, whereas men have a relatively low incidence until later in life.¹ The age-adjusted incidence of distal radius fractures is 9/10,000 person years in men and 36.8/10,000 person years in women aged 35 years or over in the United Kingdom.¹ The lifetime risk of a radius or ulnar fracture at age 50 is estimated at 16.6% for women and only 2.9% for men.²

Top eight questions

1. What is the effectiveness of long-arm vs. short-arm cast for the immobilization of distal radius fractures?
2. What is the effectiveness of percutaneous pinning vs. cast immobilization?
3. What is the effectiveness of fracture fixation in elderly patients?
4. What is the effectiveness of associated ulnar styloid fixation in the setting of a concomitant distal radius fracture?
5. What is the effectiveness of bridging vs. nonbridging external fixation in the treatment of distal radius fractures?
6. Does an arthroscopic-assisted reduction improve outcomes in distal radius fractures?
7. Do volar locking plates offer the most effective form of fracture fixation?
8. What is the effectiveness of physical therapy following distal radius fracture?

Question 1: What is the effectiveness of long-arm vs. short-arm cast for the immobilization of distal radius fractures?

Case clarification

The patient has sustained an extra-articular distal radius fracture which requires cast immobilization. For patients with distal radius fractures amenable to cast immobilization, do long-arm or short-arm casts provide more effective fracture stabilization?

Relevance

Distal radius fractures can potentially be unstable, losing reduction despite acceptable initial alignment. Casts must

Figure 107.1 Standard radiographic parameters used to evaluate displacement of distal radius fractures: (a) dorsal tilt, (b) radial inclination, (c) ulnar variance.

securely immobilize the forearm to maintain fracture stability, but they must also be tolerated by patients. The ideal method of immobilizing distal radius fractures has been debated by many authors. Sarmiento³ and Bunker⁴ have both identified brachioradialis as a major deforming force and suggest a long-arm splint in supination is necessary to neutralize its action, whereas Wahlstrom⁵ has suggested that the pronator quadratus is the major deforming force and recommends a long-arm cast in pronation to prevent redisplacement. Others have shown that above-elbow immobilization is necessary and report that below-elbow casts provide adequate immobilization.⁶

Current opinion

Current opinion suggests that below-elbow casts are sufficient for immobilization of Colles' fractures.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, using search terms: "immobilization[Title/Abstract] AND distal[Title] AND radius[Title] AND Clinical Trial[ptyp] AND (Clinical Trial[ptyp] OR Randomized Controlled Trial[ptyp])"

Quality of the evidence

Level II

- 1 prognostic study⁷

Findings

A prospective randomized trial compared long-arm sugar-tong splints with short-arm radial gutter splints for their ability to maintain fracture reduction and patient satisfaction. In a study of 118 patients, Bong et al. found that both splints were equally able to maintain reduction in both stable and unstable distal radius fractures ($p = 0.78$). In addition, patients with short-arm casts had significantly better DASH scores than those with long-arm casts.⁷ Pool et al. also found that above-elbow casts offered no advantages over short-arm casts in the treatment of distal radius fractures in a prospective study.⁶

Recommendation

- Evidence suggests that short-arm and long-arm casts are equally effective at stabilizing distal radius fractures and short-arm casts are much better tolerated by patients [overall quality: moderate-high]

Question 2: What is the effectiveness of percutaneous pinning vs. cast immobilization?

Case clarification

Radiographic examination reveals that the patient's fracture is comminuted and there is concern regarding the ability of casting alone to maintain alignment. For patients with unstable distal radius fractures, does percutaneous pinning offer superior results to cast immobilization alone?

Relevance

Percutaneous pinning provides additional stability to distal radius fractures treated with cast immobilization, and is less invasive and less costly than open reduction and internal fixation (ORIF).

Current opinion

Percutaneous pinning of unstable distal radius fractures offers a viable option in treating unstable distal radius fractures but is less commonly used since the advent of volar locked plates.

Finding the evidence

- Cochrane review, "percutaneous pinning and distal radius"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search terms: "distal radius fracture" and "pinning AND (Clinical Trial[ptyp] OR Randomized Controlled Trial[ptyp])"

Quality of the evidence

Level II

- 1 systematic review of lower-quality randomized controlled trials (RCTs)⁸

Findings

Five published trials comparing the effectiveness of percutaneous pinning with plaster cast immobilization vs. closed reduction and casting alone were identified in a recent Cochrane review.⁸ Four of these trials utilized traditional Kirschner wiring techniques (with one or two K-wires)⁹⁻¹² and one trial evaluated Kapandji pinning¹³. A combination of both extra-articular^{9,10,13} and intra-articular^{11,12} fractures was included in the literature. All five studies included a predominance of female patients (range 73–98% female) with a mean age between 56 and 71.5 years.

In four of the five studies, the final anatomic results were better in the percutaneous pinning group when compared to casting.⁹⁻¹² There were significantly higher rates of deformity, malunion, and articular incongruity in the group receiving closed reduction and casting alone. This difference did not achieve statistical significance in the trial by Stoffelen evaluating Kapandji pinning.¹³

Azzopardi et al. did not identify any significant differences with respect to pain, range of motion, grip strength, activities of daily living, or SF-36 scores between groups in their trial evaluating low-demand patients over the age of 60. They identified greater ulnar deviation in the surgical group, but the functional significance of this is uncertain. Although Stoffelen did not limit his study group to low-demand elderly patients, he too did not identify any significant differences between the two groups. He reported a majority of good and excellent results in both the Kapandji pinning group (75%) and the cast group (74%).¹³ The other three trials evaluating percutaneous pinning vs. cast immobilization identified better range of motion¹⁰ and better overall anatomic and functional results (range of motion and grip strength) in the percutaneous pinning group.^{11,12} These trials included younger patients and unstable fractures (both extra-articular¹⁰ and intra-articular^{11,12}).

The overall reported complications were low in both groups. There were some pin-related complications in the surgical groups that were minor in nature, requiring pin removal and antibiotic treatment,⁹ and one report of K-wire migration.¹⁰ There was one case of a persistent superficial radial nerve injury in the operative group, likely related to pin placement.¹³ Redisplacement was the most common complication in the cast group. There were similar incidences of reflex sympathetic dystrophy in both groups.

Recommendations

- Percutaneous pinning results in fewer distal radius malunions and less deformity compared to casting alone [overall quality: moderate]
- There are no differences in clinical outcomes when comparing percutaneous pinning to casting in low-demand patients over the age of 60 [overall quality: moderate]
- There are better overall results with percutaneous pinning versus casting in trials which included younger patients and unstable fractures [overall quality: moderate]
- There are only few, minor complications associated with percutaneous pinning of distal radius fractures [overall quality: moderate]

Question 3: What is the effectiveness of fracture fixation in elderly patients?

Case clarification

A displaced distal radius fracture was treated with a closed reduction and short-arm cast in a 65 year old woman. Upon reassessment at 1 week, the fracture had lost reduction. Radiographs revealed that the distal radius was shortened and dorsally angulated. Does operative fixation of a displaced distal radius fracture result in better outcomes than cast immobilization in elderly patients?

Relevance

It is difficult to maintain alignment of distal radius fractures in older adults with closed reduction and casting alone. This may be a result of poor underlying bone quality or fracture comminution.

Current opinion

Older patients tolerate residual deformity and malunion much better than younger patients with distal radius fractures. It has been well documented that frail, low-demand, elderly patients tolerate residual deformity very well.¹⁴⁻¹⁶ However, older active patients may place greater functional demands on their wrist and may benefit from more aggressive intervention.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search terms: “(distal radius fractures[Title] OR colles[Title]) AND (elderly[Title] OR older[Title])”

Quality of the evidence*Level I*

- 1 high-quality prospective study¹⁷

Level II

- prognostic study¹⁸
- diagnostic study¹⁹
- 2 lower-quality RCTs^{20,21}

Level III

- 1 retrospective comparative study²²

Findings

Several studies demonstrate that traditional radiographic parameters for defining adequacy of reduction are not related to function in older patients. Anzarut et al. demonstrated that patients over the age of 49, whose distal radius fractures healed with more than 10° of dorsal tilt did not have higher reported pain and disability (DASH, SF-12) when compared to those whose fractures healed in an acceptable position.¹⁷ This was also corroborated by Grewal and MacDermid who found that patients 65 years of age or older demonstrated no statistically significant relationship between distal radius fracture malalignment (considering dorsal angulation, radial shortening, and radial inclination) and PRWE or DASH scores at 1 year.¹⁸ Kelly et al. randomized elderly patients (mean age 75) to acceptance of deformity (10–30° of dorsal tilt) vs. remanipulation and found no differences between the two groups in any of the measured outcomes. They concluded that regardless of remanipulation, most reduction is lost by the time of union in these patients.²⁰

There have been a few randomized trials evaluating the effects of accepting a misaligned fracture vs. surgical fixa-

tion in an elderly population. Roumen et al. randomized patients over the age of 55 with more than 10° of dorsal angulation or more than 5mm of radial shortening to acceptance of the deformity or remanipulation and external fixation.²¹ Although they found the external fixation group had a better anatomic result, their function was no better than the control group. Synn et al. also demonstrated that surgically treated fractures were better aligned anatomically, but there was no relationship between radiographic outcomes and subjective or objective functional outcomes in patients over the age of 55.¹⁹ Arora et al. compared patients over 70 years of age with volar locked plating and cast immobilization. They found that 89% of the casted patients had some degree of malunion and 77% had an obvious clinical deformity.²² Although the ORIF group did not have any patients with malalignment, there were no significant differences in range of motion (ROM), grip strength, DASH, or PRWE between the two groups.²²

Although it has been demonstrated that outcomes are not directly correlated to anatomical alignment following a distal radius fracture, there has been evidence to suggest that the relative risk of a poor outcome does increase with malalignment in this age group. Patients aged 65 or older demonstrated a higher relative risk of a poor outcome with fracture malalignment when compared to fractures with acceptable alignment, but this relative risk was much lower than that seen in patients younger than age 65 [RR of poor outcome with malalignment based on PRWE 2.9 (<65) vs. 1.6 (≥65) and DASH 5.2 (<65) vs. 1.5 (≥65)].¹⁸ Further studies are needed to assess the role of surgical intervention in an active elderly population.

Recommendation

- No significant correlation has been found between final anatomical and functional outcome in elderly patients [overall quality: moderate]

Question 4: What is the effectiveness of associated ulnar styloid fixation in the setting of a concomitant distal radius fracture?**Case clarification**

Further radiographic examination reveals that an associated ulnar styloid fracture is present. For patients with both distal radius and ulnar styloid fractures, what is the effectiveness of fixation of the ulnar styloid?

Relevance

The ulnar styloid is an attachment point for several ligamentous and soft tissue restraints around the wrist. Ulnar styloid fractures are commonly associated with distal radius fractures and the indications for fixation of these fractures and their influence on final outcomes is unclear.

Figure 107.2 Ulnar styloid fracture: (a) tip, (b) base.

Current opinion

Small ulnar styloid tip fractures (Figure 107.2a) are typically left untreated, while larger fractures through the base of the ulnar styloid (Figure 107.2b) cause greater concern and are sometimes fixed surgically.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search term: “ulnar styloid [Title/Abstract]”

Quality of the evidence

Level I

- 1 prospective study²³

Level II

- 1 lower-quality RCT²⁴

Level III

- 1 retrospective case series²⁵

Findings

In a prospective trial, Zenke et al. compared outcomes in patients with no ulnar fracture ($n = 50$), basal ulnar styloid fractures ($n = 41$), and ulnar styloid tip fractures ($n = 27$). All patients had a distal radius fracture that was treated with a volar locked plate, and none of the ulnar styloid fractures was treated surgically. Their results demonstrated that although union rates were higher in the ulnar tip fractures (40.7% tip vs. 26.8% basal, $p < 0.05$) there was no significant difference in ROM, grip strength, or DASH scores between the three groups. There was also no significant relationship between ulnar styloid fracture location, union, and persistent ulnar-sided wrist pain.²³

Ekenstam et al. conducted a randomized trial evaluating the effect of triangular fibrocartilage complex (TFCC) repair and ulnar styloid fixation in a group of patients treated with closed reduction of their distal radius fracture. There

were no differences in ulnar styloid union rates, subjective complaints of pain, or wrist arthrogram results between patients with TFCC repair and ulnar styloid fixation and those who were treated with closed reduction of the distal radius fracture alone.²⁴

In a retrospective analysis of 76 matched patients with and without an ulnar base fracture, Souer et al. found no significant difference in overall outcomes between patients with an unrepaired fracture of the ulnar styloid base and those with no ulnar fracture at any of the follow-up intervals. There was a trend toward less grip strength at 6 months, and less wrist flexion and ulnar deviation at 24 months for patients with untreated basal ulnar styloid fractures, but this did not reach statistical significance. They concluded that an unrepaired basal ulnar styloid fracture does not influence function or outcome after treatment of a distal radial fracture with plate-and-screw fixation.²⁵

Recommendations

- For distal radius fractures treated with volar locked plating, there are no significant differences in outcomes between those with ulnar styloid tip fractures, base fractures or those without ulnar styloid fractures [overall quality: high]
- Repair of the TFCC or ulnar styloid fixation does not improve outcomes in distal radius fractures treated with closed reduction [overall quality: moderate]
- The presence of a fracture of the ulnar styloid base does not influence function or final outcomes in distal radius fractures treated with ORIF [overall quality: low]

Question 5: What is the effectiveness of bridging vs. nonbridging external fixation in the treatment of distal radius fractures?

Case clarification

Nonbridging external fixators allow early range of motion at the wrist while bridging external fixators span across the

wrist joint and only allow ROM of the digits. Do nonbridging external fixators result in better long-term clinical outcomes when compared to bridging external fixators in the treatment of distal radius fractures?

Relevance

Nonbridging external fixators allow early ROM which may be an advantage when treating distal radius fractures with external fixation.

Current opinion

Static external fixators are widely used in North America. Publications from Europe report good results with nonbridging fixators.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search terms: "distal radius[Title] AND (external[Title] OR fixator[Title]) AND Randomized Controlled Trial[ptyp]"

Quality of the evidence

Level II

- lower-quality RCTs²⁶⁻³⁰

Findings

There have been five RCTs comparing bridging to nonbridging external fixators. McQueen et al. demonstrated better overall results for unstable distal radius fractures treated with a nonbridging external fixator. They found patients treated with a nonbridging fixator had statistically better grip strength, wrist flexion, and overall maintenance of fracture alignment when compared to bridging fixators in a prospective randomized trial of 60 patients.²⁹

The other four RCTs failed to show any significant advantage to fixation with a nonbridging external fixator. Krukhaug et al. compared the dynawrist bridging external fixator to the Hoffman nonbridging fixator and found that there were no statistically significant differences between the groups with respect to visual analog pain scales and DASH scores.²⁸ Atroschi et al. also compared bridging to nonbridging external fixation in a population of elderly patients with severely displaced distal radius fractures. They found no differences in DASH scores, satisfaction, ROM, or grip strength between groups.²⁶ Krishnan et al. reproduced these findings in a similar study which included a diverse age range of patients (mean 56 years, range 18-83 years).²⁷

Sommerkamp et al. also evaluated dynamic and static external fixators in an RCT and confirmed that there were no advantages in final ROM between groups and also found the dynamic external fixators had a higher frequency of complications and fewer patients who scored good to excellent on the Gartland and Werley scores (76% vs. 92%).³⁰

Recommendation

- There are no significant advantages to fixation with a nonbridging external fixator over a static, bridging external fixator in the treatment of distal radius fractures [overall quality: moderate]

Question 6: Does an arthroscopic-assisted reduction improve outcomes in distal radius fractures?

Case clarification

An active 25 year old man sustained an intra-articular distal radius fracture after a fall from his motorcycle. Radiographs show significant intra-articular involvement and incongruity. Does arthroscopic assistance improve the quality of the intra-articular reduction in the treatment of intra-articular distal radius fractures? Does this lead to better clinical outcomes?

Relevance

The addition of arthroscopy during the treatment of intra-articular distal radius fractures allows a more accurate reduction of the articular surface and allows identification of associated ligamentous, chondral, or TFCC injuries. An improved articular reduction could help reduce the risk of developing long-term post-traumatic arthritis following intra-articular distal radius fractures.

Current opinion

Fluoroscopy is widely used to determine the accuracy of fracture reduction intraoperatively and it is generally felt that arthroscopy is not necessary to obtain an adequate reduction.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search terms: ("arthroscopy"[MeSH Terms] OR "arthroscopy"[All Fields]) AND distal[All Fields] AND ("radius fractures"[MeSH Terms] OR ("radius"[All Fields] AND "fractures"[All Fields]) OR "radius fractures"[All Fields]) AND (Randomized Controlled Trial[ptyp]) AND English[lang])

Quality of the evidence

Level II

- 1 prospective cohort study³¹
- 1 lower-quality RCT³²

Findings

Ruch et al. performed a nonrandomized matched prospective cohort study comparing arthroscopic-assisted and fluoroscopic-assisted treatment for intra-articular distal radius fractures. Their study of 30 patients demonstrated no significant differences in final DASH score or radiographic results between the two groups.³¹

Another randomized trial comparing fluoroscopic-assisted (FA) reduction to arthroscopic and fluoroscopic-assisted (AFA) reduction in intra-articular distal radius fractures was conducted by Varitimidis et al. (n = 40).³² They found that the AFA group had less pain, an earlier return to work, and significantly better DASH and modified Mayo wrist scores ($p < 0.001$) at 3 months. There were no long-term differences in DASH scores at 1 and 2 years; however, the AFA group continued to demonstrate superior outcomes based on the modified Mayo wrist score at both 1 year (90.9 ± 2.5 vs. 85.3 ± 4.1 , $p < 0.01$) and 2 years (91.2 ± 2.2 vs. 86.7 ± 3.0 , $p < 0.01$) post fracture.³²

Recommendations

- There may be some evidence to suggest improved long-term outcomes (based on modified Mayo wrist score) for articular fractures treated with arthroscopic-assisted reductions compared to fluoroscopy alone [overall quality: moderate]
- There are no long-term differences in DASH scores between AFA reduction of intra-articular distal radius fractures [overall quality: moderate]

Question 7: Do volar locking plates offer the most effective form of fracture fixation?

Case clarification

A young, active patient has sustained an unstable, displaced distal radius fracture. Closed reduction and casting was not sufficient to maintain alignment. The patient is eager to receive definitive treatment and return quickly to full activity. The treating surgeon feels that the fracture is best treated with a volar locking plate. Is volar locked plating the most effective method of fixation for distal radius fractures?

Relevance

The popularity of volar locked plating for the treatment of distal radius fractures has grown exponentially over the past several years. Koval et al. report that the proportion of distal radius fractures that were stabilized with plating increased from 42% in 1999 to 81% in 2007 ($p < 0.001$).³³ This represents a shift away from percutaneous fixation with K-wires towards volar locked plating. A cost analysis study by Shyamalan et al. reported a calculated difference of £1,549 (about \$2,500) per case between percutaneous fixation with K-wires and volar locked plating.³⁴ Whether this shift in practice and additional expense is supported by the literature is not clear.

Current opinion

Volar locked plating is the most common method of stabilizing displaced distal radius fractures. It offers stable fixation and is an excellent option for osteoporotic bone (Figure 107.3).

Figure 107.3 Example of a volar locking plate.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search terms: (distal[All Fields] AND ("radius"[MeSH Terms] OR "radius"[All Fields]) AND volar[All Fields]) AND (Randomized Controlled Trial[ptyp] AND English[lang])

Quality of the evidence

Level I

- prospective randomized trials³⁵⁻³⁷

Findings

The push behind the exponential growth of volar locked plating is not evidence based. While there are several case series reporting good to excellent results with volar locked plates,³⁸ there are few prospective randomized trials comparing volar locked plating to other methods of fixation.

Three RCTs were identified through a PubMed search. One trial compared volar locked plating to closed reduction and casting (n = 45),³⁶ and two others compared volar locked plates to external fixation (n = 46)³⁷ and K-wire fixation (n = 77).³⁵ Patients treated with volar locked plates had superior DASH scores in early follow-up (≤ 3 months)^{36,37} but these advantages were not evident at 1 year.³⁵⁻³⁷ Volar locked plating showed an advantage in early ROM assessments (6–9 weeks,³⁶ <12 weeks^{35,37}) but not at final follow-up. Grip strength was not found to be statistically higher with volar plating.³⁷

Recommendations

- There is evidence to suggest that volar locked plating of distal radius fractures improves ROM and outcome scores in the short term (<3 months) [overall quality: moderate–high]

- There are no long-term differences in DASH scores between volar locking plates and either percutaneous or external fixation [overall quality: moderate–high]

Question 8: What is the effectiveness of physical therapy in distal radius fractures?

Case clarification

The aforementioned distal radius fracture was treated with ORIF using a volar locking plate. The fixation is deemed stable. Does immediate postoperative ROM improve long-term outcomes in distal radius fractures? Do patients receiving formal therapy sessions have better outcomes than those performing their exercises at home, in an unsupervised setting?

Relevance

The goal of therapy is to improve ROM, strength, and overall function. Regular structured therapy sessions for all patients with distal radius fractures may be associated with significant time and financial implications, which can sometimes be prohibitory for both patients and therapists.

Current opinion

Long-term immobilization leads to stiffness and difficulty regaining full ROM. Initiating early ROM, when possible, is usually felt to lead to optimal results. In uncomplicated cases, patients can often do their exercises independently, after formal instruction by a therapist.

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries, with search terms: (distal[All Fields] AND ("radius"[MeSH Terms] OR "radius"[All Fields]) AND ("range of motion, articular"[MeSH Terms] OR ("range"[All Fields] AND "motion"[All Fields] AND "articular"[All Fields]) OR "articular range of motion"[All Fields] OR ("range"[All Fields] AND "motion"[All Fields]) OR "range of motion"[All Fields])) AND ((Clinical Trial[ptyp] OR Randomized Controlled Trial[ptyp]) AND English[lang])

Quality of the evidence

Level I

- high-quality RCT³⁹

Level II

- lower-quality RCTs^{40–43}

Findings

The role of early ROM and physiotherapy has been investigated in a few RCTs. An RCT comparing patients treated with early motion (at 2 weeks after surgery) to late motion (6 weeks) after volar plating of distal radius fractures found

no significant differences in outcomes (flexion/extension arc, grip strength, Mayo pain or DASH scores) at 3 or 6 months.³⁹

Kay et al. compared patients receiving a single session of advice from a physiotherapist to patients receiving no advice and found no differences in ROM or grip strength between groups. However, patients receiving instruction in home exercises from a therapist had better QuickDASH scores at 3 weeks and better PRWE scores at both 3 and 6 weeks.⁴⁰

Three randomized trials were identified comparing outcomes following a program of independent home exercises (initial instructions given by a physical therapist) to a conventional structured physiotherapy program. At 6 weeks, Krischak et al. identified a greater recovery of grip strength (54% vs. 32%, $p = 0.003$) and ROM (70% vs. 59%, $p < 0.013$) in the group receiving home exercises (reported as a percentage compared to the normal contralateral limb).⁴¹ Maciel et al. evaluated patients at 6 and 24 weeks and did not find any significant differences between grip strength, ROM, pain intensity, or PRWE scores between groups.⁴³ At 6 months, Wakefield et al. also report no significant differences in grip strength or hand function between groups, although the physiotherapy group had a better arc of flexion and extension ($p = 0.044$).⁴²

Recommendations

- While there appear to be some early advantages to a structured therapy program, in patients with uncomplicated distal radius fractures there are no significant long-term differences between patients receiving instruction in home exercises and formal physiotherapy [overall quality: moderate]
- Early range of motion (2 weeks) does not offer any long-term advantage compared to ROM initiated at 6 weeks following volar plating of distal radius fractures [overall quality: high]

Summary of recommendations

- Short-arm and long-arm casts are equally effective at stabilizing distal radius fractures, and short-arm casts are much better tolerated by patients
- Percutaneous pinning results in fewer distal radius malunions and less deformity compared to casting alone
- There are no differences in clinical outcomes when comparing percutaneous pinning to casting in low-demand patients over the age of 60
- There are better overall results with percutaneous pinning vs. casting in trials which included younger patients and unstable fractures
- There are only few, minor complications associated with percutaneous pinning of distal radius fractures

- No significant correlation has been found between final anatomic and functional outcome in elderly patients
- For distal radius fractures treated with volar locked plating, there are no significant differences in outcomes between those with ulnar styloid tip fractures, base fractures or those without ulnar styloid fractures
- Repair of the TFCC or ulnar styloid fixation does not improve outcomes in distal radius fractures treated with closed reduction
- The presence of a fracture of the ulnar styloid base does not influence function or final outcomes in distal radius fractures treated with ORIF
- There are no significant advantages to fixation with a nonbridging external fixator over a static, bridging external fixator in the treatment of distal radius fractures
- There may be some evidence to suggest improved long-term outcomes (based on modified Mayo wrist score) for articular fractures treated with arthroscopic-assisted reductions compared to fluoroscopy alone
- There are no long-term differences in DASH scores between AFA reduction of intra-articular distal radius fractures
- There is evidence to suggest that volar locked plating of distal radius fractures improves ROM and outcome scores in the short term (<3 months)
- There are no long-term differences in DASH scores between volar locking plates and either percutaneous or external fixation
- While there appear to be some early advantages to a structured therapy program, in patients with uncomplicated distal radius fractures, there are no significant long-term differences between patients receiving instruction in home exercises and formal physiotherapy
- Early ROM (2 weeks) does not offer any long-term advantage compared to range of motion initiated at 6 weeks following volar plating of distal radius fractures

Conclusions

There are several unsolved questions regarding the effectiveness of the different available treatment methods for distal radius fractures. The current literature has several weaknesses including a paucity of large RCTs. Further research is needed before any high-quality treatment recommendations can be made.

Case scenario

A 52 year-old woman is seen in the Emergency Department of your hospital and is referred to your clinic with a diagnosis of distal radius fracture (DRF). The fracture has been reduced and she was placed in a cast. In your initial patient interview, she asks “What can I expect from my fracture healing and recovery?”

Relevant anatomy

The anatomy of the distal radius is reviewed in Chapter 107. Detailed information is available online in free open access resources including *Grey's Anatomy* (<http://www.bartleby.com/107/53.html>).

Importance of the problem

This chapter addresses how to respond to patients' questions using evidence about prognosis in patient-friendly terminology. Clinicians usually answer those questions based on their personal experience, which we know is biased.

Prognosis, or the ability to predict outcomes, is one of the most important functions performed by clinicians. Early accurate prognosis is critical for patients, their families, and other stakeholders to develop plans for managing the injury. Prognosis is integral to treatment planning, since treatment choices may be modified on the basis of prognosis and patient reactions and behaviors can be mediated by prognostic messages from care providers.

Prognostic factors are features or variables that are associated with an increased probability of having a specified outcome. Factors that are associated with a higher probability of a good outcome are considered *protective factors*, while those that are associated with a higher probability of an adverse outcome are considered *risk factors*. Prognostic factors can be associated with an outcome through a causal mechanism or confounded by relationship with another factor that is the actual mechanism for the relationship. For example, in DRF, malunion is a risk factor for adverse pain and disability outcomes;¹ older age (>65) is associated with a lessening of this risk,¹ which we assume is partially related to the “confounder” physical demands.

Case clarification

Two common subgroups of DRF are older people who fall from standing position (most common) or young individuals with higher-impact trauma or sports injury. There can be seasonal variation, with winter months having higher rates of slips on ice and snowboarding injuries and summer months having more sporting injuries, e.g., rollerblading. Most patients will be concerned about their recovery. Younger patients are concerned about return to work/sport, whereas older patients may be concerned about future fracture/health risks.

Current opinion

Most clinicians continue to believe that anatomic restoration is the key factor in restoring function after a wrist fracture. Many general and emergency physicians tend to assume that DRF is a minor injury. Clinical practice guidelines do not currently describe how to modify treatment based on prognostic factors.

Finding the evidence

We adopted the strategy of using Clinical Queries within PubMed using the prognosis filter to identify appropriate studies.

- PubMed Clinical Queries (<http://www.ncbi.nlm.nih.gov/sites/pubmedutils/clinical>) search using keywords: (Distal Radius and Fracture) and the prognosis (narrow) filter. Using this filter optimizes the search strategy using previously validated informatics methods (actual search performed using the strategy is “(distal[All Fields] AND (“radius”[MeSH Terms] OR “radius”[All Fields])) AND (“fractures, bone”[MeSH Terms] OR (“fractures”[All Fields] AND “bone”[All Fields]) OR “bone fractures”[All Fields] OR “fracture”[All Fields])) AND Prognosis/Narrow[filter]”

- This approach retrieved 181 studies, many of which were not appropriate to the topic. Additional searches for DRF and specific queries such as smoking were used to answer the specific questions

Quality of the evidence

A level I prognostic study is a large cohort study with pre-identified potential predictors and minimum of 80% follow-up (<http://www.cebm.net/index.aspx?o=1025>). A level II study is a retrospective cohort design, e.g., from a previously established clinical database or clinical trial. Prognosis tends to be addressed in level IV (case series and poor-quality cohort studies) as a secondary analysis. We focused on the higher-quality studies attained.

Top thirteen questions**Questions from patients**

1. Will my fracture heal?
2. Do you think my fracture will heal in the right position without further treatment?
3. What happens if my fracture does not heal in the correct position?
4. How long until my pain goes away?
5. Will I have permanent disability?
6. How much time should I take off work?
7. Will this happen to me again?
8. Does this mean I have osteoporosis?
9. Does it matter how active I am?
10. Does it matter if I smoke?
11. If I wear wrist guards, can I prevent this from happening again?

Questions from family

12. Mom seems afraid of falling. Is that normal? Should we worry about it?
13. Will this affect mom’s longevity?

Question 1: Will my fracture heal?

No studies were identified that specifically address the risk of nonunion. Rates of nonunion are so low that only small numbers are reported as unusual findings.² Level IV evidence suggests that late treatment of these with bone grafting can result in union, but persistent disability.²

Recommended response

- There are no good studies on this topic, but nonunion is rarely reported in the literature; it is an unexpected finding and is usually associated with an unusual incident or medical issue.

Question 2: Do you think my fracture will heal in the right position without further treatment?

In a level II study of 80 patients with DRF treated conservatively, a variety of radiological parameters were evaluated as potential predictors in loss of reduction at 1 or 6 weeks.³ Acceptable reduction was defined as dorsal tilt more than 15°, volar tilt more than 20°, radial shortening less than 4mm, and radial inclination less than 10°. Secondary shortening of 4mm or more was seen in 18% of fractures with no initial shortening, in 41% with moderate shortening (1–4mm), and in 52% with severe initial shortening (>4mm). Severity of initial preradiation radial shortening predicted unacceptable reduction at 6 weeks. There was a progressive collapse in 54% of fractures with radial shortening and 60% of fractures with dorsal angulation. Initial dorsal angulation was predictive of late failure, but not early failure, whereas radial shortening reliably predicted both.³

Leone et al.,⁴ studying a cohort of 71 patients with extra-articular DRF (50 dorsally displaced, 21 undisplaced), also found that the degree of initial radial shortening and volar tilt ($p < 0.05$) were predictive of early instability with dorsal comminution also playing a role ($p = 0.06$). Radial shortening, dorsal tilt, radial inclination, and age played a role in predicting late failure, with one third of undisplaced fractures in patients over 65 years of age progressing to malalignment.

Recommended response

- The reason we need to do repeated imaging of your wrist is to determine if your bone fragments slip from their current acceptable position. We know that about half of the fractures that show early signs of slippage will continue to slip up to 6 weeks, and if this occurs we may reconsider whether a cast is sufficient treatment for you. We measure something called shortening to help us determine this. Even if you have no signs of shortening now there is about a 20% possibility of it occurring later. For people with shortening, about half will lose the alignment of their bone fragments.

Question 3: What happens if my fracture does not heal in the correct position?

The importance of anatomic restoration is controversial. An increasing trend to use open reduction and internal fixation (ORIF),⁵ in particular volar plating, is based on the premise that better reduction results in better outcomes.

A level I cohort study of 216 patients with extra-articular DRF investigated whether unacceptable reduction (dorsal angulation >10°, radial inclination <15°, radial shortening >3 mm of ulnar positive variance) found that patients with unacceptable radial shortening or inclination had more pain and disability (29 vs. 16/100; 46 vs. 16/100, respectively) in patients under 65 years of age. The relative risk (RR) of a poor functional outcome with unacceptable reduction varied across age cutoffs: 10 for patients aged 45 or less, 11 at age 50 or less, and decreasing thereafter to RR = 2 for patients over 75 years of age.¹

A level I study of 79 consecutive DRF treated in a hand center found that after controlling for other variables, incongruity of at least 1 mm was associated with poorer outcomes.⁶ In another hand center cohort of 120 DRF patients (60% AO type C), no postreduction variables were associated with pain and disability reported at 6 months (prereduction radial shortening was a contributor).⁷

In a consecutive cohort of 74 patients over the age of 50 managed nonoperatively, 71% had at least one unacceptable radiographic deformity. No radiographic index, alone or in combination, significantly correlated to any of the patient self-report outcomes.⁸

In a level III study of 106 adults who had sustained a DRF before the age of 40, a long-term follow-up study was conducted at a mean follow-up of 38 years. There was evidence of post-traumatic osteoarthritis in 68% of patients with intra-articular fractures and a significant relationship between joint narrowing and extra-articular malunion (dorsal angulation and radial shortening). There was no relationship between patient-reported function and indices of malunion.⁹

Recommended response

- If you have what we consider unacceptable alignment of your bones after your fracture heals, then you are at higher risk of having problems with pain or difficulty using your hand. For some types of fractures, people who are less than 50 years of age are 10 times more likely to have problems if their fracture heals in an unacceptable position. However, if you are older and the fracture heals in an unacceptable position, the risk of functional problems is less—only twice instead of 10 times as likely. There is weak evidence suggesting that many people have post-traumatic arthritis on their radiograph when evaluated more than 20 years after their fracture. However, having problems on your radiograph either immediately after your fracture or in the long term has not been shown to predict long-term functional problems.

Question 4: How long until my pain goes away?

Two cohort studies were identified that assessed pain repeatedly over time intervals to address the recovery pattern. An inception cohort of 129 patients with DRF¹⁰ evaluated self-reported function, and physical impairments (range of motion, grip strength and dexterity) at baseline, 2, 3, 6, and 12 months following DRF. This study reported that at a baseline fracture clinic visit (3–7 days postfracture), median pain at rest was 3/10 and 9/10 at its worst. At 2 months following fracture, patients reported their worst pain was 5/10; and by 3 months, the median response was no pain at rest and 3/10 at its worst.

Recommended response

- It is normal to have some pain while your fracture heals. Once the initial treatment of your fracture is complete, the most common amount of pain reported by patients is about 3/10 at rest. Patients find this increases to 9/10 with activity. Three months after the fracture, most patients have no pain at rest and rate their pain as 3/10 at worst.

Question 5: Will I have permanent disability?

In a cohort study of mixed DRF evaluated longitudinally until 12 months postfracture, 1% of patients reported very severe pain and disability, 4% severe, 3% moderate severe, 14% mild, 53% minimal, and 26% none based on classifications of their total pain and disability score (median total score 12/100).¹⁰ In a level IV study, 16% of subjects reported moderate to very severe disability,¹¹ but there was potential for response bias because of a low response rate.

In a level I prognostic study of 120 consecutive DRF patients, the most influential predictor of pain and disability at 6 months was injury compensation. Patient education level and prereduction radial shortening also contributed to a total predictive ability of 25%. Wrist impairment was moderately correlated with patient-reported pain and disability ($r = 0.50$).⁷ A level I prognostic study of 222 extra-articular fractures found that comorbidity, injury compensation, and education predicted 16% of pain and disability scores at 1 year.¹² A smaller level II study of patients with surgically managed volar plating found that at 1 year after surgery, age and income were significant predictors after controlling for fracture type.⁶ Significant associations were found between pain medication usage for the wrist fracture and moderate to very severe residual pain (OR = 11). Moderate to very severe disability was associated with older age (OR = 6.5) and pain medication usage for the wrist fracture (OR = 4.8). Working was protective for disability (OR = 0.14).¹¹

Recommended response

- Our best evidence suggests that the chances of you having severe residual problems are about 5%. About 80% of people have no or mild residual deficits. Your overall health and personal circumstances will affect this

Question 6: How much time will I need to take off work?

A level I prognostic study addressed time off work following a DRF in 227 patients who were working at the time of injury.¹³ The median time off work was 8 weeks (interquartile range 1–14 weeks); 2.5% were off work more than 36 weeks; 21% lost no time from work. Time off work was related to the occupational requirements for hand use.

Recommended response

- It is possible that you do not need to take any time off work—on average, about 20% of people do not. If you are unable to do your job, the amount of time you take off depends on what you do at work. Half of people will take between 1 to 14 weeks off, the most common being about 8 weeks

Question 7: Will this happen to me again?

In a level I study of 2245 community-dwelling women and 1760 men aged 60 years or older followed for 16 years after their first fracture, RR of subsequent fracture in women was 2, and in men was 3.5. Within 10 years, 40–60% of surviving women and men experienced a subsequent fracture. In multivariate analyses, femoral neck bone mineral density, age, and smoking were predictors of subsequent fracture in women and femoral neck bone mineral density, physical activity, and calcium intake were predictors in men.¹⁴

Recommended response

- If you are over 60, then the answer is yes. The fact that you have had a wrist fracture doubles your chance if you are a woman and triples it if you are a man. There are number of factors other than this injury that also contribute to your risk of fracture. The strength of your bones, age, whether you smoke, diet and physical activity affect your risk

Question 8: Does this mean I have osteoporosis?

In a cohort study of 1800 DRF patients with a low-energy DRF,¹⁵ the prevalence of patients in need of osteoporosis treatment according to existing guidelines (using T-score ≤ -2.0 or ≤ -2.5 SD) whose 10-year fracture risk using the WHO fracture risk assessment tool (FRAX®), the risk of

hip fracture was 6% for men and 9% for women. Every second to third fracture patient met the present bone mineral density (BMD) criteria for osteoporosis treatment. Thus, all DRF patients 50 years of age or more should be referred to bone densitometry, and if indicated, offered medical treatment.

Recommended response

- I do not know if you have osteoporosis, but you are at an elevated risk. Based on the best evidence, it is recommended that everyone over 50 with a DRF have a bone test to answer this question. The test exposes you to very small amount of radiation and the likelihood that you need treatment for osteoporosis is about 1 in 3, so the test is worthwhile

Question 9: Does it matter how active I am?

No studies were identified that investigated the effect of physical activity on short-term healing or postfracture disability.

A level I cohort study had 152 men and 206 women aged 50, 60, 70, and 80 who were followed for 10 years and were tested for distal radius BMD, grip strength, balance, gait velocity, occupational and leisure-time activity, and self-reported fractures. The annual rate of bone loss was 0.6% per year less in individuals classified as active as compared to those who were inactive at both time points. Balance loss was also better preserved in active individuals, but no other differences were found.¹⁶ In a cross-sectional population-based study, a subset of 407 women were analyzed demonstrating that four factors were independently associated with fractures: low lifetime habitual physical activity (OR = 4), diabetes (OR = 0.2), living alone (OR = 2), and calcaneum BUA (OR = 2).^{16,17}

In a level II study of 97 male young athletes who were evaluated and retested in 5 years, BMD was higher than age-matched controls both for still-active and for retired athletes, although retired athletes lost more bone than those who continued sports activities. The same study reported on a second, older group of 400 former athletes and 800 controls 60 years of age and above. Fewer former athletes had fragility fractures than controls (2% vs. 4%) and DRFs (0.75% vs. 2.5%).¹⁸

Recommended response

- We are very sure that, on average, people who are more physically active have stronger bones, and fewer DRFs and other fractures. Both young and older people who stop being active gradually lose the protective effect

Question 10: Does it matter if I smoke?

In a cohort of consecutive DRFs, smoking was not predictive of pain and disability outcomes.⁷ No studies that were

identified evaluated the risk of delayed primary healing of DRF fracture associated with smoking. In a level IV study of 107 patients with acute fractures with bone loss and atrophic nonunions treated with bone grafts harvested from the forearm, femur, and tibia, healing occurred in 38/56 smokers compared with 49/56 nonsmokers. Eight (73%) of the 11 patients with graft failure had a significant smoking history.¹⁹ Given the lack of evidence in DRF, a broader search was conducted including other primary. Four studies of mixed quality addressed the effect of smoking on tibial fractures or ulnar shortening; all concluded that smokers were at increased risk of nonunion and delayed union.²⁰⁻²⁴

Recommended response

- There is insufficient evidence to say how smoking will affect healing of a typical DRF. We do have consistent evidence from other types of fractures that smoking is associated with slower healing. If your fracture does not heal and you need a bone graft for your DRF, it is more likely to fail if you smoke

Question 11: If I wear wrist guards will this prevent me from getting another DRF in the future?

Rollerblading^{25,26} and snowboarding²⁷ are sports that have demonstrated increasing prevalence of injury in young people,²⁸ and the most common site of injury for both sports is the wrist.^{27,29} Wrist guards are suggested as a potential injury prevention.³⁰ Between 16 and 60% of rollerbladers wear wrist guards.³¹⁻³⁴ In a case-control study of 161 injured in-line skaters, failure to use wrist guards was associated with increased risk of wrist injury (OR = 10).²⁹

A systematic review was located on the effects of wrist guards on wrist injury in snowboarding.³⁵ Six studies were identified and synthesized. The risk of wrist injury (RR = 0.23), wrist fracture (RR = 0.29), or wrist sprain (RR = 0.17) was significantly reduced with the use of wrist guards.³⁵ In a matched case-control study of 1,066 injured Canadian snowboarders who reported upper-extremity injuries and 970 snowboarders with non-upper-extremity injuries, the prevalence of wrist guard use among snowboarders with hand, wrist, or forearm injuries was 1.6%. Wrist guard use reduced the risk of hand, wrist, or forearm injury by 85% (adjusted OR = 0.15). However, the adjusted OR for elbow, upper arm, or shoulder injury was 2.4.³⁰

Recommended response

- There is strong evidence that wrist guards reduce injuries from snowboarding and moderate evidence that wrist guards reduce injuries from in-line skating. Based on a number of studies, we know that for every 50 snowboarders who wear a wrist guard, one wrist injury will be

averted.³⁵ There is weak evidence that snowboarders who wear wrist guards have higher rates of elbow and shoulder injury. A wrist injury is the most common injury in both in-line skating and snowboarding, and all studies suggest the incidents could be reduced by the use wrist guards

Question 12: Mom seems afraid of falling. Is that normal? Should we worry about it?

In a prospective cohort study of 52 individuals with a DRF (and 52 proximal humerus fracture), there was a large increase in fear of falling in the DRF patients; 6% had to give up housekeeping and 24% experienced at least two falls within the next 4 months.³⁶ In a population-based study of these fractures in Germany, including over 2,000 forearm fractures, patients reported no changes in living circumstances due to their fracture, but there was a trend for hip fractures to occur on average 10 years after a DRF.

Recommended response

- Limited studies on this topic indicate that in the short term, older men and women who have a DRF have a substantially increased fear of falling. Most people do not change their living circumstances because of a DRF. About a quarter of older patients who have had a DRF will experience two or more falls within 4 months. There is a higher rate of hip fractures that occurs about 10 years after DRF. Your mom may be afraid of falling and it is a legitimate concern. You may wish to have a fall risk assessment performed if she is concerned, or you notice that she seems unsteady or falls

Question 13: Will this affect mom's longevity?

In a case-control study of mortality as compared to the age-gender matched US norms in elderly patients (250 women, 65 men) with DRF, the cumulative estimated survival in the cohort at 7 years after DRF was 57% compared with an expected value of 71% for the US population.³⁷ Men had twice the mortality risk of women, and patients with comorbidity five times the risk.³⁷ In a population-based study of more than 15,000 fractures, DRF preceded hip fracture by approximately 10 years and was suggested as a signal event for risk reduction.³⁸

Recommended response

- There is weak evidence that people who experience a DRF do not live as long as the average population expectancy for their age. The exact reasons for this are not clear, but we know that physical activity, falls, osteoporosis, future fractures, and other comorbid health conditions are contributing factors. Management of osteoporosis, other health problems, and fall prevention strategies can be used to reduce health risks

Openmirrors.com

James T. Monica and David Ring

Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA

Case scenario

A 45 year old man sustained a distal radius fracture 3 months ago. He complains of visible deformity, stiffness, ulnar-sided pain that is worse with activity, and weakness. On exam there is a dorsal prominence deformity of the distal radius. Active and passive supination and flexion are limited to 30° and 45° respectively. Radiographs show an extra-articular malunion with 30° dorsal tilt of the articular surface on the lateral view and 5mm ulnar positive variance.

Relevant anatomy

The articular surface of the distal radius forms a platform that supports the carpus. The radiocarpal articular surface is divided into separate facets for the scaphoid and the lunate separated by a sagittal ridge. The sigmoid notch has a larger radius of curvature than the ulnar head, and motion at this joint consists of translation in addition to rotation. The triangular fibrocartilage complex spans from the distal end of the radius to the base of the ulnar styloid and functions to cushion the ulnar–carpal joint and stabilize the distal radioulnar joint (DRUJ).

The distal radius articular surface angles ulnarward an average of 23° as measured on a posteroanterior radiograph.¹ The average volar inclination of the distal radius articular surface on the lateral view is 11°. Ulnar variance is defined as the length between the distal limit of the head of the ulna and the radial articular surface at the lunate facet, as measured on a posteroanterior film with the forearm in neutral rotation.

The most common deformity following a dorsal bending fracture includes loss of the volar tilt of the articular surface

in the sagittal plane, loss of ulnar inclination in the frontal plane, ulnar positive variance, and supination of the distal fragment with respect to the proximal diaphysis.²

Importance of the problem

On the basis of actuarial risk calculations from Medicare data, the risk of a white woman in the United States sustaining a distal forearm fracture was estimated to be 6% by the age of 80 years and 9% by the age of 90 years.³ Fractures of the distal radius often heal with malalignment, but symptoms vary substantially. Deformity of the distal radius can hinder wrist and forearm motion and can contribute to posttraumatic arthritis, carpal malalignment, ulnocarpal impaction, and instability or incongruity of the DRUJ.^{4–10} On the other hand, the relationship between distal radius deformity and stiffness or pain is unpredictable and incompletely understood.

Top ten questions

Diagnosis

1. What are the most common complaints referable to malalignment of the distal radius?
2. What amount of radiographic malalignment correlates with dysfunction?

Therapy

3. What can be done besides surgery?
4. Is there a consequence to leaving malalignment untreated?
5. Early vs. delayed surgery?
6. Structural vs. nonstructural bone graft?
7. Volar vs. dorsal approach?

8. How is management of intra-articular malunions different from that of extra-articular malunions?

Prognosis

9. What are the outcomes of malunion?
10. What are the complications of surgical correction of distal radius malunions?

Question 1: What are the most common complaints referable to malalignment of the distal radius?

Question 2: What amount of radiographic malalignment correlates with dysfunction?

Case clarification

The patient complains of ulnar-sided wrist pain. Physical examination reveals dorsal wrist deformity, decreased flexion, and supination with no instability. Radiographs reveal an extra-articular, 30° dorsally angulated distal radius malunion with 6mm of radial shortening.

Relevance

The diagnosis of malunion implies that a patient's symptoms can be directly related to malalignment of the distal radius. Operative treatment is based on the ability to reduce the symptoms by improving alignment.

There have been several recommendations regarding acceptable alignments of distal radius fractures but these seem relatively arbitrary.

Current opinion

Correlation of symptoms with malalignment is not always straightforward. Many patients, particularly low-demand elderly individuals, function very well with malalignment of the distal radius. Symptoms such as ulnar-sided wrist pain can improve for more than a year after fracture of the distal radius. Ongoing pain can be unsettling, and patient and surgeon might overinterpret the correlation between malalignment and symptoms.

Finding the evidence

Question 1

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: "distal radius malunion" AND "pain" AND "symptoms"

Question 2

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: "distal radius" AND "radiographic parameters" AND "disability"

Quality of the evidence

Question 1

- Level IV: 7 studies

Question 2

- Level II: 2 studies
- Level IV: 5 studies

Findings

The evidence regarding symptoms ascribed to malalignment of the distal radius are mostly level IV. Patients may present with complaints of pain, stiffness, instability, weakness, numbness and tingling, or aesthetic concerns.^{11,12} Dorsal angulation of greater than 15° and shortening of 2mm are felt to affect forearm motion and cause pain.^{13,14} Leung and others reviewed 111 patients with intra-articular distal radius fractures and reported that those patients with axial compression (>2mm) and dorsal angulation (>15°) had worse functional outcome as measured by the modified Green and O'Brien scoring systems, and diminished range of motion (ROM).¹³

Incongruity of the DRUJ¹⁵ and positive ulnar variance¹⁶ have been associated with ulnar-sided wrist pain. The extent of fracture comminution and articular involvement correlates with loss of motion.¹⁷

At an average of 4 years following nonoperative management of distal radius fractures, McQueen and Caspers noted 17 patients with a good radiological result and 13 who were considered to have malunion.¹⁸ The displaced group had dorsal angulation of 12–34° and more than 2mm of radial shift. Functionally the displaced group performed significantly worse than the undisplaced group. Functional tests included grip strength, grip endurance, Jebsen test,¹⁹ ROM, activities of daily living, pain assessment, and cosmetic assessment. They concluded that malunion of a Colles' fracture results in a weak, deformed, stiff, and probably painful wrist.

Grewal and MacDermid²⁰ defined malunion as dorsal angulation greater than 10°, radial inclination less than 15°, or more than 2mm of ulnar positive variance. Malunion did not affect the Patient-Rated Wrist Evaluation (PRWE) ($p = 0.22$) or the Disabilities of Arm, Shoulder and Hand (DASH) questionnaire ($p = 0.39$) 1 year after fracture in patients aged 65 or older. In contrast, both PRWE ($p = 0.001$) and DASH ($p = 0.001$) were significantly higher (i.e., more pain and disability) in patients with malunion who were younger than 65.

Mackenney and associates identified predictors of distal radius fracture instability that were prognostic of radiographic outcome.²¹ Radiographic displacement was defined as a dorsal (apex volar) tilt of more than 10° (normal is 15° apex dorsal; therefore, 15° of dorsal angulation) and/or ulnar variance of more than 3mm. By this definition, 744 of 1,296 displaced fractures (60%) became malunited. Most

of these radiographic malunions were acceptable to patients, and only a small percentage of patients with radiographic malunion were considered for osteotomy.

Kelly et al. reported no detectable difference in radiologic or functional outcomes 3 months after distal radius fracture between elderly patients who received a closed reduction and those who did not. They concluded that up to 30° of dorsal angulation and 5 mm of radial shortening can be accepted without requiring further manipulation.²²

Recommendations

- Acceptable parameters for distal radius displacement are age dependent [overall quality: low]
- Patients under 65 years of age are more likely to have pain or stiffness or diminished grip strength with dorsal angulation 10° or more, radial inclination 15° or less, or ulnar positive variance 3 mm or more [overall quality: low]
- Dorsal angulation of the distal radius can reduce wrist flexion and supination [overall quality: low]

Question 3: What can be done besides surgery?

Case clarification

Our patient wants to try everything possible before considering surgery.

Relevance

The role of surgery can be better defined by an understanding of the value of nonoperative treatments.

Current opinion

Pain diminishes with time for over a year after injury, and motion can improve with exercises.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “distal radius malunion”

Quality of the evidence

- Level V

Findings

There is no data on nonoperative treatment for distal radius malunited fractures. When the radiographic deformity is less than 20° dorsal angulation of the articular surface on the lateral radiograph and less than 3 mm of shortening by ulnar variance, most authorities recommended a period of observation and adaptation before considering an osteotomy.²³ Comfort, motion and strength can improve for over a year. Exercises for motion and strength may help.

Recommendation

- It may be worthwhile doing stretching exercises and being patient for pain to resolve when malalignment is less

than 20° dorsal angulation or 3 mm ulnar positive variance [overall quality: low]

Question 4: Is there a consequence to leaving malalignment untreated?

Case clarification

The patient states that his pain and stiffness are not interfering with his daily activities and asks if his wrist will deteriorate without surgery.

Relevance

Is there ever a situation where surgeons should encourage patients with malalignment to have surgery?

Current opinion

Surgeon opinion on this seems quite variable.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: “distal radius malunion” AND “indications”

Quality of the evidence

- Level IV and V

Findings

Level IV studies have reported radiographic indications for operative intervention that include an articular step-off greater than 2 mm, carpal instability, more than 20–30° of dorsal angulation, and an incongruent DRUJ.²⁴ Dysfunction may result from symptomatic ulnocarpal impaction syndrome, DRUJ arthrosis, grip weakness, and articular incongruity. Malalignment does not always result in dysfunction.

While anatomic reduction is the principal aim of treatment, imperfect reduction of these fractures may not result in symptomatic arthritis in the long term. Forward and others reviewed 106 adults who had sustained a fracture of the distal radius between 1960 and 1968 and who were below the age of 40 years at the time of injury. They carried out a clinical and radiological assessment at a mean follow-up of 38 years (range 33–42). No patient had required a salvage procedure. While there was radiological evidence of post-traumatic osteoarthritis after an intra-articular fracture in 68% of patients (27 of 40), the disabilities of the DASH scores were not different from population norms, and function, as assessed by the Patient Evaluation Measure, was impaired by less than 10%.²⁵

A study by Cooney and others analyzed 565 Colles' fractures and found that radioulnar arthrosis (4.8%) was more common than radiocarpal arthrosis (1.8%).²⁶

Extra-articular deformity of the distal radius results in a compensatory midcarpal malalignment.⁸ There are no data

regarding the symptoms or consequences (e.g., midcarpal arthritis) of this malalignment. Midcarpal arthrosis is rarely observed in association with distal radius malunion. The midcarpal malalignment usually corrects after osteotomy of the distal radius.^{8,27,28}

Recommendation

- For a 45 year old patient with minimal symptoms and a dorsally displaced distal radius malunion, the following radiographic features warrant consideration of osteotomy: dorsal angulation greater than 20°, displaced fractures with carpal malalignment (>15° of dorsal angulation of the lunate on the lateral view), incongruity of the DRUJ, greater than 5 mm ulnar positive variance, or unacceptable cosmetic deformity²⁹ [overall quality: low]

Question 5: Early vs. delayed surgery?

Case clarification

The patient asks if it better to intervene as soon as malalignment is diagnosed.

Relevance

Surgery to correct malalignment may be easier when the original fracture line can be identified.

Current opinion

The traditional approach was to wait and operate on a mature nonunion, but young, active individuals with substantial malalignment are increasingly offered early surgery.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: "distal radius," "malunited," "early," "late"

Quality of the evidence

Level IV

- 2 studies

Findings

Jupiter and Ring³⁰ compared 10 early (average 8 weeks after injury) and 10 late (average 40 weeks after injury) osteotomies in patients with a dorsal tilt of more than 20°, articular incongruity of more than 2 mm, increased lunate dorsal tilt of greater than 15° on the lateral view compared to the contralateral wrist, subluxation of the radiocarpal joint, or complete incongruity of the DRUJ and found few differences. Their preference for early surgery was based primarily on speculative advantages and technical facility.

Recommendation

- Early surgery is technically easier and the rationale that a short time with malalignment would create fewer prob-

lems is appealing, but there is insufficient evidence to prove an advantage for early surgery [overall quality: low]

Question 6: Structural vs. nonstructural bone graft?

Relevance

Before the advent of plates with locking screws, structural corticocancellous bone graft from the iliac crest was felt to be necessary to help carry mechanical loads. Structural grafts were difficult to handle and often did not fit ideally even with careful preoperative planning.

Current opinion

When a locking plate is used, a nonstructural bone graft can be used.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: "distal radius," "malunited," "structural bone graft"

Quality of the evidence

Level III

- 1 study

Findings

Ring and others compared two matched cohorts of patients with dorsal malunions treated with opening wedge osteotomy, dorsal locking plate stabilization, and either structural or nonstructural cancellous graft. They reported comparable functional and radiographic results between the two groups.³¹

A case series by Nagy and others investigated the ability of precise preoperative planning of the size and shape of the corticocancellous bone graft to restore alignment of the radius to within 5° angular deformity and 2 mm ulnar variance as compared with the opposite, uninjured wrist. Only 6 of 15 patients (40%) satisfied these criteria. They concluded that distal radius osteotomy using a precisely planned and measured interpositional corticocancellous graft does not restore distal radius alignment in most patients, and that failure to restore length is associated with continued pain and stiffness.³²

Several different graft substitutes have been used in opening wedge osteotomies. Carbonated hydroxyapatite and calcium phosphate have been reported as substitutes for corrective distal radius osteotomy with good results.^{33,34} Abramo and colleagues used Norian SRS as a bone substitute with plate fixation in 25 consecutive patients after osteotomy of a dorsal distal radius malunion. At 1 year all but one osteotomy healed and radiographic correction achieved postoperatively was consistent over 1 year. Patients demonstrated increased grip strength and ROM and the procedure was performed on an outpatient basis.³⁵

Recommendation

• Use of a nonstructural, cancellous only bone graft is appealing in its relative simplicity and seems safe and effective when used in conjunction with locking plates, but this is based on very limited data. Other types of graft substitutes might be suitable, but more data is needed [overall quality: low]

Question 7: Volar vs. dorsal approach?

Relevance

Locking plates and the extended FCR exposure have made it possible to address dorsally angulated malunions via a volar approach.

Current opinion

The dorsal approach is more familiar and intuitive, but the volar approach may have some technical advantages.

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “distal radius,” “malunion,” “approach”

Quality of the evidence

Level IV

- 18 studies

Level V

- 6 studies

Findings

There are 16 case series of various techniques and no comparative studies. No advantages of one technique over another can be gleaned from the current literature.

Recommendation

• Either approach is acceptable in the 45 year old patient with a dorsally displaced distal radius malunion. No study has been performed comparing results from the dorsal vs. volar approach [overall quality: low]

Question 8: How does management of intra-articular malunions differ from that of extra-articular malunions?

Case clarification

CT scan reveals an intra-articular step-off of more than 2mm in the lunate facet. How does the intra-articular involvement affect management?

Relevance

There may be greater consequences of intra-articular malunion, but osteotomy can be more technically difficult and is sometimes impossible.

Current opinion

A subset of straightforward articular malunions may be amenable to osteotomy.

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “intra-articular,” “distal radius,” “malunion”

Quality of the evidence

Level IV

- 4 studies

Level V

- 3 studies

Findings

Despite various reports stating that articular incongruity is consistently identified as an important predictor of an adverse functional outcome in distal radius fractures,³⁶⁻³⁸ there have been relatively few articles describing intra-articular osteotomy.^{30,39-41} The relative reluctance to address intra-articular malunion may be due to several factors, including limited surgical access, difficulty achieving secure fixation of small articular fracture fragments, concern regarding the ability to recreate the articular fracture without causing additional articular damage, and concern about compromising the blood supply to the osteotomized fragment, which can lead to osteonecrosis with resultant collapse, failure to heal, and arthrosis.³⁹ The role of osteotomy of an intra-articular distal radius malunion is limited by the type of fracture and the timing of presentation. Intra-articular malunions must have relatively simple geometric patterns to permit reconstruction via intra-articular osteotomy.²³ Intra-articular osteotomy should be performed as early as possible to facilitate fracture plane recognition and preserve the articular surface.³⁹

In one study, 23 patients were followed for an average of 38 months following intra-articular osteotomy.³⁹ The indication for the osteotomy included dorsal or volar subluxation of the radiocarpal joint in 14 patients and articular incongruity of 2 mm or more as measured on a posteroanterior radiograph in 17 patients. All osteotomies healed without evidence of osteonecrosis and there was significant improvement in ROM, grip strength, articular congruity, and ulnar variance. There were 19 excellent/good results according to the systems of Fernandez⁴² and Gartland and Werley.⁴³ According to the Mayo modification of the Green and O'Brien system,⁴⁴ there were only 10 excellent/good results. The Green and O'Brien modification is very strict and consistently produces poorer results than the other scoring systems. The authors interpret this difference as indicating that intra-articular osteotomy restores useful function, but rarely restores normal function of the wrist.³⁹

Recommendations

- Early presentation of simple intra-articular malunion of the distal radius with more than 2 mm articular incongruity can be treated with osteotomy [overall quality: low]
- Osteotomy may restore useful function, but rarely restores normal wrist function [overall quality: low]

Question 9: What are the outcomes?**Case clarification**

Our 45 year old patient with the distal radius malunion is interested in knowing the outcome following surgical correction of his distal radius malunion.

Relevance

Knowledge of the outcomes of surgical correction of malunited distal radius fractures will help in treatment decision-making.

Current opinion

Several different methods of surgical correction exist, each with reported good outcomes. Surgeon preference along with malunion type and patient characteristics dictate which method is utilized.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “distal radius malunion,” “outcome”

Quality of the evidence

Level IV

- 7 studies

Findings

Uncontrolled series and retrospective unmatched cohort studies consistently show improvements following correction of malunited distal radius fractures, although most do not address disability or outcomes from the patient’s perspective.⁴⁵⁻⁵⁶

Flinkkilä and others reported good or satisfactory results in 33 of 45 patients with symptomatic distal radius malunion treated with corrective osteotomy.¹² It was found that osteotomy of the distal radius alone did not completely restore normal anatomy and relieve symptoms, and in several cases a second operation was needed. Osteoarthritic changes in the radiocarpal and radioulnar joints were common, and they correlated with restriction in ROM, but not with pain. ROM and grip power were reduced compared to the unaffected hand, but only loss of supination and ulnar deviation correlated with an unsatisfactory subjective result. They concluded that reconstructive procedures in patients with distal radius malunion may not completely restore normal function.¹²

Recommendations

- Several different methods of surgical correction exist to treat distal radius malunions with good outcomes in case series, but no comparative data [overall quality: low]
- Osteoarthritic changes in the radiocarpal and radioulnar joints are common following surgical correction of distal radius malunions and they may correlate with restriction in ROM, but not with pain [overall quality: low]

Question 10: What are the complications of surgical correction of distal radius malunions?**Relevance**

The complications of distal radius osteotomy factor into decision-making.

Current opinion

Serious complications such as nonunion, infection, and tendon rupture can lead to greater impairment than the malunion.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “distal radius malunion,” “complications”

Quality of the evidence

Level IV

- 6 studies

Findings

Postoperative edema, finger stiffness, hematoma, tendinitis, tendon rupture, infection, loss of fixation, malunion, nonunion, neurovascular injury, residual ulnar-sided pain, complex regional pain syndrome, arthritis, and problems with the bone graft harvest site have all been reported.^{40,45,51,57,58} The plates and screws used to secure the osteotomy can irritate and damage the extrinsic flexor and extensor tendons.⁵⁹⁻⁶²

Extensor pollicis longus (EPL) rupture and minor pin-track infections were noted when external fixation was used.⁶³

Recommendation

- The benefit anticipated by osteotomy must outweigh the risk of these potential complications [overall quality: low]

Summary of recommendations

- Acceptable parameters for distal radius displacement are age dependent
- Patients under 65 years of age are more likely to have pain or stiffness or diminished grip strength with dorsal

angulation 10° or more, radial inclination 15° or less, or ulnar positive variance 3 mm or more

- Dorsal angulation of the distal radius can reduce wrist flexion and supination
- It may be worthwhile doing stretching exercises and being patient for pain to resolve when malalignment is less than 20° dorsal angulation or 3 mm ulnar positive variance
- The following radiographic features warrant consideration of osteotomy: dorsal angulation greater than 20°, displaced fractures with carpal malalignment (>15° of dorsal angulation of the lunate on the lateral view), incongruity of the DRUJ, greater than 5 mm ulnar positive variance, or unacceptable cosmetic deformity
- There is insufficient evidence to prove an advantage for early surgery [overall quality: low]
- Use of a nonstructural, cancellous only bone graft is relatively simple and seems safe and effective when used in conjunction with locking plates
- Either dorsal or volar surgical approach is acceptable
- Early presentation of simple intra-articular malunion of the distal radius with more than 2 mm articular incongruity can be treated with osteotomy
- Osteotomy may restore useful function, but rarely restores normal wrist function
- Several different methods of surgical correction exist to treat distal radius malunions
- Osteoarthritic changes in the radiocarpal and radioulnar joints are common following surgical correction of distal radius malunions and they may correlate with restriction in ROM, but not with pain
- The benefit anticipated by osteotomy must outweigh the risk of these potential complications

Ruby Grewal

Hand and Upper Limb Centre, University of Western Ontario, London, ON, Canada

Case scenario

A healthy 25 year old man sustained an isolated wrist injury to his dominant arm after sustaining a fall. Physical examination revealed isolated pain in the area of the anatomical snuff box. Given the area of tenderness and mechanism of injury, the attending Emergency Department physician was concerned about a possible underlying scaphoid fracture.

Relevant anatomy

The scaphoid plays a key role in carpal motion and wrist stability. It is the most frequently fractured carpal bone.^{1,2} Because of its retrograde blood supply, nonunion rates can be high, resulting in deformity, arthritis, and significant lifelong impairment. Scaphoid fractures are most commonly described based on their anatomic location: proximal pole, waist, and distal pole (Figure 110.1). Accurate diagnosis and management is essential to ensure optimal results. This chapter focuses on diagnosis, management options, clinical outcomes and complications.

Importance of the problem

The annual incidence of scaphoid fractures was reported as 43/100,000 in Norway.³ A Danish study reported an incidence of 38 scaphoid fractures per 100,000 men,⁴ and a US study reported an incidence of 1.21/1,000 person years (unadjusted) in a US military population.⁵ The highest incidence of scaphoid fractures is seen in young males. A population-based Norwegian study reported the median age of affected patients to be 25 years, with a significantly

higher incidence in males compared to females (82% vs. 18%).³ An American study also reported that males were more likely to sustain a scaphoid fracture, with an adjusted rate ratio of 1.55 compared to females.⁵ They also reported that the highest incidence was seen in the 20–24 year old age group. Disability and impairment in this young population leads to a loss of productivity and potentially high opportunity costs for both the individual and society.

Top five questions

1. What is the best way to diagnose an occult scaphoid fracture?
2. Once a fracture is identified, what is the best method of immobilization?
3. Will the fracture heal faster and more predictably if treated with an ORIF?
4. Can patients expect better functional outcomes if treated with an ORIF?
5. What complications can be expected? Both with ORIF and with casting?

Question 1: What is the best way to diagnose an occult scaphoid fracture?

Case clarification

A 25 year old male construction worker who fell on to his dominant hand has isolated pain in the anatomical snuff box. Radiographs were obtained and no fracture was identified. The attending physician was concerned about the possibility of an occult scaphoid fracture, given the examination findings.

For patients presenting with pain in the anatomical snuff box, but normal radiographs, what is the best way of con-

Figure 110.1 Scaphoid fractures: (a) proximal pole, (b) waist, (c) distal pole.

firming the diagnosis: repeat clinical and radiographic assessment in 2 weeks? Bone scan? CT scan? MRI?

Relevance of the question

For many patients, 2 weeks of unnecessary immobilization can result in significant impairment and economic losses due to their inability to work. A prompt, accurate diagnosis will eliminate the need for unnecessary immobilization and ensure all fractures are identified and treated in a timely manner.

Current opinion

The majority of orthopedic surgeons will obtain further imaging to confirm a suspected scaphoid fracture. The imaging modality used varies, depending on available resources.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “scaphoid fracture” AND “diagnosis”

Quality of the evidence

Level II

- 1 randomized trial with methodologic limitations⁶
- 3 diagnostic studies with methodologic limitations⁷⁻⁹

Level III

- 1 diagnostic study with greater methodologic limitations¹⁰

Findings

Clinical suspicion of a scaphoid fracture is the first step in establishing a diagnosis. The diagnostic sensitivity is high for clinical examination, but the specificity is low, reported at only 74–80%.¹¹ As such, we rely on other modalities to establish the diagnosis. Radiographs are traditionally used to identify bony injuries; however, scaphoid fractures can be difficult to identify with plain radiographs alone.

Jenkins has shown that the negative predictive value of radiography is low (84%) and up to 25% of all fractures will be missed if this modality is used in isolation.¹⁰ Some advocate repeating radiographs at 2 weeks to help identify an occult fracture if clinical suspicion is high and initial radiographs are normal; however, Dias et al. have shown that repeating radiographs at 2–3 weeks does not improve their diagnostic ability.⁷ This has been confirmed by other authors who also report that repeat radiographs do not reliably improve diagnostic accuracy.^{10,12}

Because the consequences of a missed scaphoid fracture are concerning (i.e., nonunion, malunion, or avascular necrosis) many patients with suspected fractures are immobilized despite normal initial radiographs. It has been reported that 75% of patients with clinical suspicion of a scaphoid fracture will be immobilized unnecessarily if traditional radiographs are used alone.¹³ Jenkins reports that for each patient subsequently shown to have a fracture, 5.25 patients are overtreated.¹⁰ Because scaphoid fractures typically affect young men, periods of unnecessary

immobilization can result in a loss of productivity and time away from work/sport which is often a significant concern for this population. In order to help improve diagnostic accuracy and reduce unnecessary overtreatment of scaphoid fractures, a variety of second-line imaging techniques have been used.¹⁰

Traditionally, bone scans were the second-line imaging modality of choice. The sensitivity of bone scans is high (reported as 92–95%), but the specificity is low (60–95%), potentially resulting in a high number of false positives.¹¹ MRI has been shown to have better interobserver agreement for scaphoid injury than bone scan, with fewer false-positive reports.⁹ The sensitivity for MRI is high (near 100%);^{8,11} however, the specificity is estimated at 90% since many false-positive results can occur when injuries such as bone bruises are misinterpreted as fractures.¹¹

Thorpe et al. have shown the cost of MRI is comparable with that of bone scan and that the reduced immobilization time in these patients results in lower overall healthcare costs.⁹ Brooks et al. demonstrated that suspected scaphoid fractures imaged with MRI had significantly fewer days of immobilization (3 vs. 10, $p = 0.006$) and the MRI group used fewer healthcare units compared to controls who received “usual clinical care” (3 vs. 5, $p = 0.03$).⁶ The cost of health care in the MRI group was slightly higher than in controls (\$594 AUD vs. \$428 AUD, $p = 0.19$), but when productivity losses are considered, MRI may be considered cost-effective when used in a select population.⁶

With its ability to detect associated soft tissue injuries, its high sensitivity and specificity, some authors advocate MRI as the imaging modality of choice in suspected scaphoid fractures.^{8,10} Although it may be cost-effective, MRI is still not readily available in many centers. CT scans have been suggested as an effective, cheaper alternative to MRI with high reported sensitivities (97–100%).¹⁰ A comparative study of MRI and CT by Memarsadeghi showed that CT had a 100% sensitivity and specificity in identifying cortical involvement and was significantly superior to MRI ($p = 0.03$).⁸ It is also thought that CT scans allow clearer visualization of fracture displacement than MRI.¹¹ CT scans are unable to detect purely trabecular fractures, unlike MRI; however, this was not statistically significant ($p = 0.25$).⁸ In addition, the clinical relevance of detecting a purely trabecular fractures without cortical involvement is unclear. These fractures may not require immobilization and are less likely to result in nonunion if undetected. Therefore, with the ease of availability, lower cost, and high accuracy of CT scans, this is an excellent tool to help make therapeutic decisions in patients with suspected scaphoid fractures.

Recommendations

In patients with clinically suspected scaphoid fractures but normal initial radiographs, evidence suggests that:

- Repeat radiographs do not reliably detect occult scaphoid fractures and result in overtreatment [overall quality: moderate]
- Bone scans have a high sensitivity but low specificity and therefore can only reliably be used to rule out scaphoid fractures [overall quality: moderate]
- Both MRI and CT have a high sensitivity and specificity and can be relied upon to confirm a suspected scaphoid fracture [overall quality: moderate]

Question 2: What is the best method for immobilization of an undisplaced scaphoid fracture?

Case clarification

The treating Emergency Department physician identified an undisplaced scaphoid waist fracture on the radiograph and this was then confirmed by subsequent CT scan. The fracture was immobilized and the patient referred to an orthopedic surgeon. What is the best method of cast immobilization for patients with scaphoid waist fractures? Is a thumb spica cast better than a Colles cast? Is it necessary to immobilize in an above-elbow cast?

Relevance of the question

Cast immobilization can be cumbersome for young, active patients. If a less restrictive cast can be used without compromising outcomes, this would be a more attractive choice for patients.

Current opinion

In North America, the trend is to use thumb spica casting, either above- or below-elbow, for scaphoid immobilization, while in Europe the tendency is to use a short-arm cast with the thumb free.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search “scaphoid fracture” AND “casting”

Quality of the evidence

Level II

- 3 randomized trials with methodologic limitations^{14–16}
- 1 prospective cohort study with methodologic limitations¹⁷

Level IV

- 1 lower quality randomized trial with methodologic limitations¹⁸

Level V

- 2 biomechanical studies^{19,20}
- 1 expert opinion²¹

Findings

Thumb spica vs. short-arm cast In a prospective randomized trial comparing thumb spica vs. Colles casts in a study of 292 scaphoid fractures, Clay et al. found that the incidence of nonunions was independent of the type of cast used.¹⁸ Bohler et al. also found comparable union rates between Colles casts and thumb spica casts in an observational study.¹⁷ In a biomechanical study, using a cadaveric model, Schramm found that wrist immobilization is crucial for immobilization, but short-arm casting was just as effective as thumb spica casting in preventing fracture displacement.²⁰

Short-arm vs. long-arm casting Gellman et al. conducted a prospective randomized trial comparing short-arm to long-arm thumb spica casting. They found that patients treated with a long-arm cast united significantly faster than those with short-arm casts (mean of 9.5 weeks vs. 12.7 weeks, $p < 0.05$). There were also fewer nonunions (0 vs. 2) and delayed unions (2 vs. 6) in the group treated with a long-arm thumb spica cast. They concluded that proximal pole and middle third fractures had a significantly shorter time to union when treated in a long-arm thumb spica cast. Fractures of the distal third healed well regardless of type of cast used.¹⁵

Although Gellman believes that the elimination of forearm rotation reduces the shear stresses across the fracture site, improving union rates, this has not been corroborated by other authors. Alho performed a prospective randomized study evaluating 100 scaphoid fractures treated with above- and below-elbow casts. In this study, there were no statistically significant differences between union rates or outcomes in the two groups.¹⁴ Other authors have also demonstrated that pronation and supination of the forearm does not cause significant motion in scaphoid fracture fragments.¹⁹ These results were corroborated in a clinical study by Cooney who demonstrated a union rate of 94% in 45 scaphoids treated with immobilization in a below-elbow cast.²¹

Immobilization in wrist flexion or extension Hambidge et al. evaluated the influence of wrist position on scaphoid fracture healing. They found that the position of wrist immobilization (either slight flexion or slight extension) did not influence nonunion rates, wrist flexion, grip strength, or pain, but those immobilized in flexion had more difficulty regaining wrist extension.¹⁶

Recommendations

- Colles casts offer similar results to short-arm thumb spica casts [overall quality: moderate]
- Long-arm casts result in a faster time to union in scaphoid waist or proximal pole fractures [overall quality: moderate]

- Other cohort studies and biomechanical studies state that forearm rotation does not cause significant motion in scaphoid fracture fragments [overall quality: low–moderate]
- Scaphoid fractures should be immobilized in slight wrist extension [overall quality: moderate]

Question 3: Will scaphoid fractures heal faster and more predictably if treated with an ORIF compared to casting alone?

Case clarification

This healthy 25 year old construction worker, recently casted for an undisplaced scaphoid fracture, is unable to return to work until his fracture is healed. He is eager to return to his recreational activities and full duties at work as soon as possible.

Among patients with undisplaced scaphoid waist fractures, does ORIF offer more predictable union rates and a faster time to union than cast immobilization?

Relevance of the question

Patients and their treating surgeons both want the safest, most reliable method of treatment.

Current opinion

The role of surgical fixation for undisplaced scaphoid waist fractures is controversial. Conservative treatment yields excellent results for undisplaced fractures, but proponents of operative fixation (Figure 110.2) cite a quicker return to activity (work/sport) and a reduced risk of nonunion compared with that for cast treatment and with minimal additional risk.

Figure 110.2 ORIF of scaphoid fracture with Acutrak screw.

Finding the evidence

- PubMed: “scaphoid fractures” AND “(randomized controlled trial[ptyp])”

Quality of the evidence*Level I*

- 6 high-quality randomized trials²²⁻²⁷

Level II

- 2 randomized trials with methodological limitations^{28,29}

Findings

Time to union Time to union was reported in three of the six randomized controlled trials.^{22,23,28} Both Bond and McQueen reported significantly faster healing times for patients treated with ORIF.^{23,28} Bond et al. compared undisplaced scaphoid waist fractures treated with percutaneous Acutrak screw fixation to cast immobilization (6 weeks in a long-arm thumb spica cast followed by a short-arm thumb spica cast until healing confirmed, n = 25) and found a significantly shorter healing time for the ORIF group (7 weeks vs. 12 weeks, p = 0.0003).²³ McQueen et al. evaluated both displaced and undisplaced fractures treated with percutaneous Acutrak screw fixation to Colles cast immobilization (n = 60) and also found the ORIF group healed faster (9 weeks vs. 14 weeks, p < 0.001).²⁸ Adolffson also compared healing times in undisplaced scaphoid fractures treated with ORIF (percutaneous Acutrak) vs. a below-elbow cast (n = 53) and did not find any significant difference in healing times between the two groups.²²

Successful union Union rates were high in both the operative and nonoperative groups in five of the six studies, with no statistically significant differences between treatment groups.^{22,23,26,28,29} Bond et al. did not identify any nonunions in either treatment group.²³ Saeden et al. had one nonunion in the ORIF group (1/30) and two nonunions in the cast group (2/30).²⁹ McQueen et al. identified one nonunion in the ORIF group (1/30) and four in the cast group (4/30).²⁸ Adolffson had one nonunion in the ORIF group (1/30) with none in the cast group (0/30).²² Vinnars had only one nonunion in the cast group (1/26 cast, 0/26 ORIF), and in the 2008 study, had no nonunions in either treatment group.²⁶

The only study to report a significant difference in union rate was that of Dias et al. They also reported the greatest number of nonunions (10 of 44 with a cast vs. 0 of 44 for operative treatment, p = 0.001). They defined nonunion as absence of radiographic signs of healing at 12 weeks and a gap on CT scan at 16 weeks; however, this definition may be flawed as one such nonunion healed without additional treatment and 4 of 10 patients did not have a visible fracture line or evidence of mobility at the time of surgery. If further CT scans were taken, these may have been better classified as fibrous unions or delayed unions.²⁵

Summary These six studies are all moderate to high-quality randomized controlled trials, and are the best evidence we have to date. However, there are a few flaws in these studies: none of the six published clinical trials used CT or arthroscopy to diagnose fracture displacement, and it is possible that some of the fractures included were displaced or unstable, thus biasing the results.³⁰

In addition, the determination of union was suboptimal. These studies used clinical and radiographic assessments to confirm union, a method which has been shown to be unreliable by several authors.³¹⁻³³

Recommendations

- There are high union rates for both operative and non-operative treatment of undisplaced scaphoid fractures [overall quality: high]
- Opinion is divided as to whether scaphoid union does or does not occur more quickly with ORIF compared with casting

Question 4: Can patients expect better functional outcomes if treated with ORIF?**Case clarification**

This young active patient wants to ensure he has the best possible outcome. He wants to regain full strength and range of motion, and minimize his time away from work. Does ORIF or casting produce superior clinical results for manual laborers with undisplaced scaphoid fractures?

Relevance of the question

As scaphoid fractures typically occur in young men, minimizing the length of disability is essential as a physical impairment can have a significant impact on overall productivity in this population.

Current opinion

While union rates or time to union may not be significantly different between ORIF and casting, proponents of ORIF claim that it allows a quicker return to activity (work/sport).

Finding the evidence

- PubMed: “scaphoid fractures” AND “(randomized controlled trial[ptyp])”

Quality of the evidence*Level I*

- 6 high-quality randomized trials²²⁻²⁷

Level II

- 2 randomized trials with methodological limitations^{28,29}

Findings

The studies reviewed generally report earlier recovery of grip strength and motion in the operatively treated

group^{22,25} but no significant differences at the time of final assessment.^{22,23,25,28,29} Two studies reported a faster return to sport in patients treated with an ORIF compared to those treated with cast immobilization.^{22,28}

Return to work times have been reported to be significantly earlier with surgery by some groups ($p < 0.0001$ ²³ and $p < 0.001$ ²⁸); however, this has not been corroborated by all authors. Dias did not report a faster return to work in patients treated with an ORIF.²⁵ Vinnars ($p = 0.03$)²⁶ and Saeden ($p < 0.01$)²⁹ both demonstrated that only those working as manual laborers had a significantly faster return to work with surgical treatment compared to cast immobilization.

A cost analysis of surgery vs. cast treatment (including the cost of work disability) was conducted by Vinnars who demonstrated that despite the faster return to work times, the cast group still had lower total costs than the surgically treated group for both manual laborers (cast €3,485 vs. surgery €4,529, $p > 0.05$) and nonmanual laborers (cast €770 vs. surgery €2,253, $p < 0.047$); however, these costs were only significantly lower in nonmanual laborers.²⁶

Recommendations

- There is no significant difference in range of motion, strength, or patient-reported pain and disability at final follow-up between patients treated surgically or those treated with cast immobilization [overall quality: high]
- Some studies report a faster return to work time with ORIF, but this only achieves statistical significance in manual laborers [overall quality: high]
- Cast treatment has a lower total cost (treatment cost + work disability costs) than surgical treatment in both manual and nonmanual laborers, but the cost savings are only significant in nonmanual workers [overall quality: high]

Question 5: What are the complications of surgical treatment?

Case clarification

What complications can this patient expect if he decided to proceed with operative fixation? Among patients with undisplaced scaphoid waist fractures, are the complications associated with surgical treatment greater than with cast immobilization?

Relevance of the question

The possible risks of both interventions need to be assessed before recommendations can be made for either treatment.

Current opinion

Current opinion is that scaphoid ORIF is safe with only minor expected complications; however, the long-term complications are still largely unknown.

Finding the evidence

- PubMed: “scaphoid fractures” AND “(randomized controlled trial[ptyp])”

Quality of the evidence

Level I

- 6 high-quality randomized trials²²⁻²⁷

Level II

- 2 randomized trials with methodologic limitations^{28,29}

Findings

The complications associated with both cast treatment and ORIF were considered to be minor overall. Adolfsson et al. had only one complication in their trial, a patient who developed complex regional pain syndrome (CRPS) after ORIF.²² Bond et al. had one patient in the ORIF group with prominent hardware at the scapho-trapezium-trapezoid (STT) joint.²³ In Dias' reported short-term results there were 10 patients in the ORIF group with minor scar-related problems, one with a superficial wound infection, one with hypoesthesia in the palmar cutaneous branch of the median nerve, and one with mild early algodystrophy.²⁵

McQueen et al. reported complications in both the cast group and the ORIF group. Two of their casted patients developed avascular necrosis of the scaphoid, one developed CRPS and one patient had symptomatic radio-scaphoid osteoarthritis (OA). In the ORIF group there were two perioperative complications, both involving breakage of the cannulated screwdriver, and one patient with a prominent screw in the STT joint.²⁸

Vinnars et al. reported one complication in the cast group (delayed union) and eight complications in the ORIF group. There were five patients with malpositioned hardware (two identified intraoperatively and removed, three with malpositioned screws and reactive erosion into the joint), two soft tissue injuries (partial FCR injury and partial injury to volar scapholunate ligament), and one patient with CRPS.²⁶

Of the six randomized trials reported in the literature, three also published long-term results of their cohorts.^{24,27,29} Saeden published 12 year results on his cohort and identified a significant increase in the incidence of radiographic STT OA (18/39) in the ORIF group ($p = 0.049$).²⁹ Vinnars et al. also found significantly more patients in the ORIF group (11/40 vs. 1/35) had STT OA ($p < 0.005$). They also identified cystic changes of more than 3mm on plain radiographs of five scaphoids in the operatively treated group compared with none in the nonoperatively treated group ($p = 0.057$).²⁷ Dias et al. also identified STT abnormalities in long-term follow-up for both the ORIF (3/28, 11%) and cast group (5/31, 16%).²⁴ Unlike the other authors, they did not identify a statistically significant difference between casting

and ORIF; however, their assessment was made by plain radiographs rather than CT as in the other studies.^{27,29} In addition, the STT OA was identified on radiographs only. The findings did not correlate with clinical symptoms and further long-term studies are necessary to understand the clinical significance of this problem.

Recommendations

- The expected short-term complication rate is low with both ORIF and cast treatment [overall quality: high]
- The long-term complications of ORIF include radiographic STT OA [overall quality: high]

Summary of recommendations

- In patients with clinically suspected scaphoid fractures but normal initial radiographs, evidence suggests that repeat radiographs do not reliably detect occult scaphoid fractures and result in overtreatment
- Bone scans have a high sensitivity but low specificity and therefore can only reliably be used to rule out scaphoid fractures
- Both MRI and CT have a high sensitivity and specificity and can be relied upon to confirm a suspected scaphoid fracture
- Colles casts offer similar results to short-arm thumb spica casts
- Long-arm casts result in a faster time to union in scaphoid waist or proximal pole fractures compared to short-arm casts
- Forearm rotation does not cause significant motion in scaphoid fracture fragments
- Scaphoid fractures should be immobilized in slight wrist extension
- There are high union rates for both operative and non-operative treatment of undisplaced scaphoid fractures
- There is no significant difference in range of motion, strength or patient-reported pain and disability at final follow-up between patients treated surgically or those treated with cast immobilization
- Some studies report a faster return to work time with ORIF, but this only achieves statistical significance in manual laborers
- Cast treatment has a lower total cost (treatment cost + work disability costs) than surgical treatment in both manual laborers and nonmanual workers, but the cost savings are only significant in nonmanual workers
- The expected short-term complication rate is low with both ORIF and cast treatment
- The long-term complications of ORIF include radiographic STT OA, but the clinical significance of this is largely unknown

Conclusions

There is still no concrete evidence to support an evidence-based recommendation for ORIF vs. casting (or vice versa) in undisplaced scaphoid fractures. The reported complications with both interventions are minor, but the long-term complications are still largely unknown. Further high-quality randomized controlled trials are needed to definitively answer this question.

Nonunions of the Scaphoid

Nina Suh¹ and Ruby Grewal²

¹University of Western Ontario, London, ON, Canada

²Hand and Upper Limb Centre, University of Western Ontario, London, ON, Canada

Case scenario

A 30 year old farmer presents with complaints of activity related wrist pain. Pain has been persistent since a “wrist sprain” approximately 1 year ago for which he did not seek medical attention. Physical examination reveals tenderness in the anatomical snuffbox. Radiographs confirm an established proximal pole scaphoid nonunion.

Importance of the problem

The scaphoid’s propensity for nonunion is well documented in the literature. Its tenuous retrograde blood supply and requirement for primary bone healing contribute to difficulty achieving union.¹ A consensus on the definition of nonunion has not been established, but persistence of a fracture line on plain radiograph 6 months after injury has generally been accepted in the literature.¹ The incidence of delayed union is estimated at 15% and nonunion as 12% in acute scaphoid fractures.¹ Numerous case series document the natural history of scaphoid nonunions and report the development of a predictable pattern of carpal arthritis and collapse if untreated.² This chapter explores risk factors, treatment options, and reported outcomes of scaphoid nonunions.

Top five questions

1. What is the natural history of scaphoid nonunions?
2. What are the operative options for scaphoid nonunions?
3. What factors increase the risk of developing a scaphoid nonunion?

4. Are there any modalities that can improve union rates?
5. Which salvage procedures offer the best results for scaphoid nonunion advanced collapse?

Question 1: What is the natural history of scaphoid nonunions?

Case clarification

This patient has an established proximal pole scaphoid nonunion, likely a consequence of the fall he sustained 1 year ago. He asks what would happen if he does not seek medical attention at this time. What is the natural history for patients with established scaphoid nonunions?

Relevance of the question

It is important to understand the natural history of scaphoid nonunions, as persistence of the nonunion will lead to the development of a predictable pattern of arthritis in the wrist, which can be prevented if the nonunion is successfully treated.

Current opinion

Scaphoid nonunions follow a predictable pattern of arthritis and carpal collapse, generally within 10 years after fracture.^{3,4}

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “scaphoid” AND “natural history”

Quality of the evidence

Level IV

- 7 retrospective review with methodologic limitations
- 1 systematic review with methodologic limitations

Findings

One of the most frequently cited natural history studies of scaphoid nonunions was performed by Mack et al. in 1984 and later confirmed by multiple other authors.^{3,5-7} They observed three main radiographic patterns of progressive arthritis in patients with scaphoid nonunions. Initially, changes are isolated to the scaphoid with development of cysts, sclerosis, and resorption. Degenerative changes then progress to involve the radial styloid and the entire scaphoid fossa, and finally result in pancarpal arthritis of the scaphocapitate and capitolunate joints. These radiographic changes were found to occur over 8.2 years, 17 years, and 31.6 years, respectively. Furthermore, Ruby et al. found 97% of patients with scaphoid nonunions developed arthritis if the injury was 5 years old or more (Figure 111.1).⁶

Displacement of the nonunion, carpal instability (defined as lunate dorsiflexion of more than 10°), and patient symptoms correlate with earlier progression and increased severity of wrist arthritis.^{3,8} The incidence of scaphoid displacement (and consequently increased severity of osteoarthritis) also increases with greater time from fracture, and consequently many authors have advocated early surgical intervention to prevent this.³ Because progressive degeneration was also observed in asymptomatic patients examined by Lindstrom and Nystrom, early surgical intervention is recommended for this group as well.⁹

Kerluke et al. highlighted that many of the natural history studies may be biased towards greater degeneration.¹⁰ They report that the temporal course cannot yet be fully elucidated because of limitations in earlier study

methodology, but it can generally be concluded that a predictable pattern of degeneration is eventually seen in all patients with scaphoid nonunions. Displacement and instability accelerate the pattern of degeneration and are found with greater number of years from injury.

Recommendation

- All patients with scaphoid nonunions, regardless of symptoms, can expect to develop a predictable pattern of carpal degeneration within 10 years [overall quality: moderate]^{8,11}

Question 2: What operative options are available for scaphoid nonunions?

Case clarification

The patient decides to proceed with surgical intervention and asks which surgical intervention has the highest chance of success.

For patients with scaphoid nonunions, without associated carpal arthritis, does vascularized grafting have superior union rates than nonvascularized grafting? Is there a preferred method of fixation?

Relevance of the question

Understanding the available surgical options and their associated complications is instrumental to guiding the management of scaphoid nonunions.

Current opinion

Nonvascularized bone grafting is sufficient for the majority of scaphoid nonunions; however, proximal pole nonunions or those with associated avascular necrosis are usually treated with vascularized bone grafting.

Level IV

- 75 prospective and retrospective case series with methodologic limitations

Figure 111.1 Representative radiographic example of a scaphoid nonunion advanced collapse of the wrist.

Findings

Two broad categories of bone grafts are available for treating scaphoid nonunions—vascularized and nonvascularized. Nonvascularized bone grafts range from cancellous chips to structural iliac crest or distal radius grafts.^{11,12} Vascularized grafts are typically harvested from the pronator quadratus, distal radius, medial supracondylar femur, rib, base of the second metacarpal, or thumb metacarpal.^{13–18}

A recent prospective randomized study compared vascularized to nonvascularized distal radius bone grafting in sclerotic scaphoid nonunions with poorly vascularized proximal poles. They found that union was achieved in 89.1% of patients treated with vascularized grafting vs. 72.5% in those treated with nonvascularized bone graft ($p = 0.024$).¹⁹ These results were echoed by another study showing higher union rates with vascularized bone grafting (88%) vs. standard wedge grafting (47%) in patients with avascular necrosis of the proximal pole ($p < 0.0005$).²⁰

A systematic review encompassing 5,246 cases of scaphoid nonunions divided patients into three major groups: standard bone grafting without internal fixation, standard nonvascularized bone grafting with internal fixation, and vascularized bone grafting with or without internal fixation. These authors did not detect any difference in union rates when internal fixation was added to a nonvascularized bone graft but did find an increase in union rates when a vascularized bone graft was used (p value not reported).²¹

Although the sources of vascularized bone grafts are plentiful, no large prospective randomized controlled trial has been conducted to directly compare the various vascularized bone graft sources against each other. Recently, Jones et al. performed a retrospective study comparing distal radial pedicle vascularized grafts with vascularized medial femoral condyle grafts and found union rates of 40% in scaphoids managed with radial grafts and 100% in those treated with the femoral grafts ($p = 0.005$).^{22,23}

In addition to bone grafting, there are also many options available for internal fixation. Compression screws dominate as the preferred method of internal fixation, with results from a recent meta-analysis of 127 scaphoid nonunions showing union rates of 94% with screw fixation (Figure 111.2) vs. 77% with Kirschner wires (K-wires; Figure 111.3) ($p < 0.01$).²⁰ Other studies have shown union rates with screw fixation of 80–100%, while Kirschner wires had a greater range of results with union rates (56–100%).^{10,21} Biodegradable screw fixation has the theoretical advantage of transferring stress directly to bone as the screws dissolve, as well as not requiring later hardware removal. Akmaz et al. have shown 100% union rates with biodegradable screws, but more studies into their efficacy are required.²⁴ Concerns have been raised about possible graft vs. host reaction; however, the clinical significance of this is questionable.

Figure 111.2 Representative radiographic example of a scaphoid nonunion treated operatively with iliac crest bone grafting and compression screw fixation.

Figure 111.3 Representative radiographic example of a scaphoid nonunion treated operatively with bone grafting and Kirschner wire fixation.

Operative intervention is the treatment of choice for persistent scaphoid nonunions; however, we cannot advocate for one intervention over another (bone graft or fixation methods) as there are no high-quality comparative randomized controlled trials in the literature.

Recommendations

- Higher union rates are reported with the use of compression screws compared to K-wires (94% vs. 77%, $p < 0.01$) [overall quality: moderate]²⁰

- Vascularized bone grafting provides higher union rates than nonvascularized bone grafting in poorly vascularized or avascular scaphoid nonunions (88% vs. 47%, $p < 0.0005$) [overall quality: moderate]¹⁹

Question 3: Which factors increase the risk of developing a scaphoid nonunion?

Case clarification

The patient's radiographs demonstrate a proximal pole scaphoid nonunion with no evidence of osteoarthritis. He tells you that he has been a heavy smoker for several years. Do these and other factors influence his chance of union? What factors led to the initial development of the nonunion, and what are his chances of successful union following surgery?

Relevance of the question

Underlying patient and fracture characteristics may influence nonunion rates and help predict outcomes in select groups.

Current opinion

Proximal pole fractures and displaced fractures are widely accepted as risk factors for nonunion. Delay to intervention, associated carpal instability, and smoking are presumed risk factors.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: "scaphoid" AND "nonunion"

Quality of the evidence

Level IV

- 5 lower-quality retrospective reviews and case series with methodologic limitations

Findings

Fracture characteristics such as location and displacement are strongly correlated with union. Proximal pole fractures have been associated with nonunion rates as high as 75%, compared to 15% and 2% for waist and distal scaphoid fractures.^{2,20} Fracture displacement has been defined as a fracture gap of 1 mm or more on any radiographic projection, a scapholunate angle greater than 60°, a radiolunate angle greater than 15°, or an intrascaphoid angle greater than 35°.²⁵ These displaced fractures are deemed unstable, often leading to a humpback deformity, and are associated with nonunion rates of 50% and osteonecrosis rates of 55%.²⁶⁻²⁸ Generally, diagonal fractures of the middle third and vertical-diagonal fractures of the proximal third are unfavorable fracture patterns due to high shear forces and are thought to lead to higher nonunion rates, although this has not been quantified in the literature.²⁹

Delayed treatment has also been suggested to contribute to increased nonunion rates. A retrospective study of 285 scaphoid fractures found that delaying immobilization of acute scaphoid fractures by more than 4 weeks was a significant risk factor for progression to nonunion.³⁰ A meta-analysis of 1,046 patients with established nonunions found a marked decrease in union rates if time to surgery exceeded 1 year (90% vs. 80%, $p < 0.0001$) but found no difference thereafter.²⁰

Patient characteristics also influence union rates. In their study of 34 patients, Dinah and Vickers found smokers were three times more likely to have persistent nonunions after autologous bone grafting and internal fixation as compared to nonsmokers ($p < 0.01$).³¹ In a Mayo Clinic study involving 51 patients, factors such as female gender, proximal pole avascularity, K-wire fixation, carpal collapse, and prior surgery were associated with increased nonunion rates, in addition to smoking.³²

Recommendations

- Proximal pole fracture and displaced fractures are associated with an increased risk of progression to nonunion [overall quality: moderate]
- Delay to intervention, carpal instability, K-wire fixation, and smoking increase the risk of scaphoid nonunion [overall quality: low]

Openmirrors.com

Question 4: Are there any modalities that can improve union rates?

Case clarification

There are several underlying factors (i.e., proximal pole nonunion, smoking history) that do not favour union in this patient. Are there any adjunctive modalities which can be used to improve union rates? Does pulsed electromagnetic field therapy or ultrasound improve union rates for scaphoid nonunions?

Relevance of the question

Adjunctive modalities, such as ultrasound and pulsed electromagnetic field therapy, may improve union rates, offering an attractive, noninvasive option for patients with scaphoid nonunions.

Current opinion

The efficacy of pulsed electromagnetic field stimulation and/or ultrasound lacks sufficient evidence in the literature to support its widespread use.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: "scaphoid" AND "ultrasound," or "scaphoid" AND "electromagnetic"

Quality of the evidence*Level I*

- 1 randomized double-blind controlled study with methodologic limitations

Level IV

- 7 case series with methodologic limitations

Findings

Pulsed ultrasound therapy provides a mechanical stimulus to the nonunion site, activating numerous cell types and biological pathways, stimulating endochondral ossification and, theoretically, union.³³ Published success rates are as high as 90%.^{34,35} However, limited studies have evaluated its efficacy in scaphoid nonunions. A recent double-blind clinical trial evaluated the efficacy of ultrasound as an adjunct to surgical intervention.³⁵ Twenty-one scaphoid nonunions were treated with vascularized bone graft and randomized to either placebo or low-intensity ultrasound therapy. The authors found that healing was accelerated by 38 days in the group treated with ultrasound ($p < 0.0001$).

With respect to electromagnetic (EM) therapy, a retrospective, nonblinded study combining scaphoid, clavicle, metatarsal, metacarpal, and calcaneus fractures reported a union rate of 79% after EM stimulation in 29 patients.³⁶ Another case series evaluating EM with cast immobilization in 54 scaphoid nonunions reported an overall union rate of 69%,³⁷ with union rates of 50% for proximal pole fractures and 73% for scaphoids with underlying osteonecrosis.

Recommendations

- Pulsed electromagnetic field therapy may accelerate healing when used as an adjunct to cast immobilization for nonoperative management of scaphoid nonunions [overall quality: low]
- Ultrasound has been shown to accelerate time to union when used as an adjunct to surgery [overall quality: moderate]

Question 5: What salvage procedures are available for the treatment of scaphoid nonunion advanced collapse?**Case clarification**

Despite attempts at ORIF and bone grafting, the patient's scaphoid nonunion did not heal and his symptoms of pain and stiffness have worsened. Radiographs reveal arthritis in the radioscapoid joint and persistence of the nonunion. What is the best treatment option for this patient? Does a proximal row carpectomy (PRC) or four-corner fusion provide superior outcomes in patients with stage 2 scaphoid nonunion advanced collapse (SNAC)?

Figure 111.4 Representative radiographic example of a proximal row carpectomy for scaphoid nonunion advanced collapse.

Figure 111.5 Representative radiographic example of a scaphoid excision and four-corner fusion for scaphoid nonunion advanced collapse.

Relevance of the question

Patients with stage 2 SNAC changes can be treated with either a PRC (Figure 111.4) or a scaphoidectomy with four-corner fusion (Figure 111.5). An understanding of the advantages and disadvantages of each is essential.

Current opinion

Both procedures can successfully relieve pain, but PRC allows for a greater postoperative wrist range of motion while four-corner fusion allows greater recovery of grip strength.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “scaphoid” and “nonunion”

Quality of the evidence*Level III*

- 5 retrospective comparative study with methodologic limitations
- 1 systematic review with methodologic limitations

Level IV

- 44 retrospective reviews and case series with methodologic limitations
- 2 biomechanical studies with methodologic limitations

Findings

The literature suggests that stage 1 SNAC wrists can be treated with a scaphoid reconstruction with or without radial styloidectomy. Meanwhile, stage 3 SNAC wrists should have midcarpal arthrodesis or complete wrist arthrodesis performed.

The options for stage 2 wrists are more widely debated. Dacho et al. reported greater pain relief (77% vs. 54%, $p > 0.05$) with PRC compared to four-corner fusion but reduced grip strength (PRC 50% vs. four-corner 72%, $p < 0.05$).^{38,39} Consequently, they advocated midcarpal arthrodesis for heavy labourers and PRC for nonmanual workers. The literature is inconsistent, as a systematic review of 52 articles by Mulford et al. did not report a difference between PRC and four-corner fusion with respect to grip strength or pain relief (no p value given), whereas Wyrick et al. (1995) found that PRC had a significantly higher grip strength ($p < 0.05$) and range of motion ($p < 0.05$) vs. four-corner fusion in scapholunate advanced collapse wrists.^{40,41} Although Mulford et al. initially reported better range of motion with PRC, these patients had higher rates of osteoarthritis in the long term.⁴⁰ Conversely, DiDonna et al. reported persistently good results with respect to pain and function with a minimum of 10 years follow-up after PRC.⁴²

Fixation methods used to achieve arthrodesis have also been studied in the literature, with good fusion rates being achieved with multiple fixation strategies. The Quad memory staple, dorsal rectangular plate, dynamic compression plate, internal headless compression screws, K-wires, and circular plates were all found to achieve union.^{43–45} However, studies comparing two different fusion methods are sparse. One study by Rodgers et al.

compared K-wires to circular plate fixations for limited wrist fusions and found the two fixation methods equivalent.⁴⁴ Similarly, Bedford and Yang found 100% fusion rates and only one complication in their series of 15 patients with scapholunate advanced collapse wrists treated with circular plates.⁴⁶ However, a case series by Shindle et al. found circular plates to have a 25% nonunion rate and 56% complication rate.⁴⁷ The paucity of randomized controlled trials examining different fixation methods makes it difficult to ascertain which fixation method is most reliable.

Recommendations

- Stage 2 SNAC wrists may be effectively managed with scaphoid excision with PRC or four-corner fusion [overall quality: moderate]
- PRC may offer greater range of motion and pain relief when compared to four-corner fusion [overall quality: low]^{38,41}
- There are conflicting reports in the literature with respect to the difference in final grip strength with reports that PRC results in greater,⁴¹ equivalent⁴⁰ and reduced³⁸ grip strength in comparison to four-corner fusion. As such, no evidence-based recommendations can be made at this time [overall quality: low]

Summary of recommendations

- All patients with scaphoid nonunions, regardless of symptoms, can expect to develop a predictable pattern of carpal degeneration within 10 years
- Higher union rates are reported with the use of compression screws compared to K-wires
- Vascularized bone grafting provides higher union rates than nonvascularized bone grafting in poorly vascularized or avascular scaphoid nonunions
- Proximal pole fracture and displaced fractures are associated with an increased risk of progression to nonunion
- Delay to intervention, carpal instability, K-wire fixation, and smoking increase the risk of scaphoid nonunion
- Pulsed EM field therapy may accelerate healing when used as an adjunct to casting for nonoperative management of scaphoid nonunions
- Ultrasound has been shown to accelerate time to union when used as an adjunct to surgery
- Stage 2 SNAC wrists may be effectively managed with scaphoid excision with PRC or four-corner fusion
- PRC may offer greater range of motion and pain relief than four-corner fusion
- There are conflicting reports in the literature with respect to the difference in final grip strength between PRC and four-corner fusion. As such, no evidence-based recommendations can be made at this time

Conclusions

Currently there is insufficient evidence to make definitive evidence-based recommendations for the management of scaphoid nonunions. The indications for, or effectiveness of, specific operative interventions and grafting procedures in the management of scaphoid nonunions have not been clearly established. Additionally, the majority of the literature utilizes plain radiographs to assess union instead of more advanced imaging modalities such as CT or MRI. Dias highlighted the fact that the shape and size of the scaphoid may lead one to erroneously assume trabeculae are crossing the fracture site in plain radiographs.⁴⁸ The author states that these “trabeculae” may simply be a by-product of the proximal and distal fragments overlapping when the X-ray beam is not in line with the fracture.⁴⁸ Consequently, the fundamental measurement of union rates and time to union may be flawed in studies using solely plain radiographs. Future studies, including a large, long-term, multicenter randomized trial with the use of computed tomography as the gold standard to define fracture pattern and progression of union are required to address the general paucity of literature on this important topic and to clarify the most appropriate treatment for scaphoid nonunions.

Trapeziometacarpal Arthritis of the Thumb

Anne Wajon¹, Emma Carr², Louise Ada³, and Ian A. Edmunds⁴

¹Macquarie Hand Therapy, Macquarie University, Sydney, NSW, Australia

²Pacific Hand Therapy Services, Dee Why, NSW, Australia

³University of Sydney, Sydney, NSW, Australia

⁴Hornsby Ku-ring-gai Hospital and Hornsby Hand Centre, Hornsby, NSW, Australia

Case scenario

A 58 year old woman presents with pain at the base of her right thumb. She is right hand dominant and reports pain and weakness when opening jars, writing, gardening, turning keys, and pulling up tights. She describes the pain as sharp when performing these tasks, but a dull ache at other times throughout the day.

Relevant anatomy

Arthritis at the base of the thumb affects the trapeziometacarpal joint in varying degrees. The trapeziometacarpal joint is a saddle-shaped joint at the base of the thumb and it is this shape that permits flexion/extension and abduction/adduction to be coupled and result in conjoint rotation. The articular surfaces offer little intrinsic constraint, so the joint relies on the constraint provided by an array of ligaments between the trapezium and the first metacarpal base. In osteoarthritis (OA), these ligaments become lax, resulting in altered wear patterns with loss of articular cartilage thickness, joint space narrowing, osteophyte formation, and joint subluxation.¹

Importance of the problem

The major cause of pain and disability in Australians is arthritis,² affecting more than 3.85 million people. Similarly in the United States, arthritis is the most common cause of physical disability, affecting 46 million (22%) adults.³ Further, it is estimated that 25% of adults aged over 18

years will have “doctor-diagnosed arthritis by the year 2030”.³ Considering that more than half of these people are of working age, the personal and socioeconomic costs are enormous. Since the incidence of OA increases with age^{4,5} and the global population is rapidly aging, it is likely that the demand on health care and community resources for people with OA will increase dramatically over the coming decades.

OA at the base of the thumb is associated with pain, weakness, and difficulty with many activities of daily living. Radiological changes at the base of the thumb occur six times more commonly in women than men, and become more prevalent with increasing age affecting 34% of people aged 51–60, and 57% of those aged 61–70 who suffered a distal radius fracture.⁶ Although only 30% of those with radiological changes report clinical symptoms,⁴ the impact of arthritis on an aging population should not be underestimated.

Clinicians and patients are often confused by the vast amount of information about intervention for this common condition. There are over 5,000,00 hits on the Google website when the search term “thumb arthritis” is entered (May 2011). Further, with a rapidly aging population, the need to determine the most clinically and cost-effective intervention should be considered a priority.

Top five questions

Diagnosis

1. How do the radiological findings, history, and physical examination contribute to the diagnosis of trapeziometacarpal OA?

Outcomes

2. What outcomes are considered important in determining the success of intervention?

Treatment

3. What conservative interventions are effective in relieving symptoms?
 4. Which surgical interventions provide the best outcome?

Harm

5. Is any surgical procedure associated with less adverse effects than any other?

Question 1: How do the radiological findings, history and physical examination contribute to the diagnosis of trapeziometacarpal OA?

Case clarification

The radiograph demonstrates degenerative changes at the trapeziometacarpal joint, but the scapho-trapezio-trapezoidal joint is not affected. The physical examination reveals tenderness on palpation of joint margins, a positive grind test, and enlargement of the base of thumb.

Relevance

It is important to differentiate trapeziometacarpal OA from other common conditions affecting the radial side of the wrist and base of the thumb.

Current opinion

Current opinion suggests that the severity of trapeziometacarpal OA can be staged according to radiological changes. Considering that the correlation between the severity of symptoms and the extent of radiographic changes is not always clear, the history and physical examination are fundamental to confirming the diagnosis.

Finding the evidence

- Cochrane Database, CINAHL, MEDLINE, PubMed, using search terms: "carpometacarpal joint, trapeziometacarpal joint, arthritis, diagnosis"

Quality of the evidence

Level V

- 7 studies

Findings

The severity of radiological degeneration can be staged according to the staging system described by Eaton and Glickel (Table 112.1).⁷ The system has moderate intra-rater reliability (0.66) and inter-rater reliability (0.53).⁸ It is based

Table 112.1 Staging of trapeziometacarpal osteoarthritis⁷

Stage I	Articular contours normal Slight widening of the joint space
Stage II	Slight narrowing of the joint space Minimal sclerotic changes Joint debris <2 mm diameter
Stage III	Joint space markedly narrowed or obliterated Cystic changes, sclerotic bone, varying degrees of dorsal subluxation Joint debris >2 mm in diameter Scaphotrapezoidal joint appear normal
Stage IV	Complete deterioration of trapeziometacarpal joint, as in stage III Scaphotrapezoidal joint narrowed, with sclerotic and cystic changes apparent

on a true lateral radiograph and may be helpful in planning surgical treatment.

Historically, patients complain of pain which is aggravated by "sustained forceful use of the hand involving daily activities like brushing the teeth, sewing, turning a key or picking up a book."⁹ The pain is generally located at the base of the thumb, more often on the volar aspect, and frequently radiating to the thenar eminence.¹⁰

Physical examination should begin with gentle movements of the thumb and palpation of the joint margins. Range of thumb motion may not be affected in the early stages of disease, but with advancing arthritis, osteophytes may "result in a dorsally fixed and subluxated joint that is adducted, with limited palmar abduction."¹⁰ This commonly leads to compensatory hyperextension of the metacarpophalangeal joint, and the resulting "collapse" deformity¹¹ becomes fixed in advanced stages.

Provocative tests include the grind test,¹² which involves axial compression and rotation of the metacarpal on the trapezium in order to reproduce pain at the base of the thumb. The axial compression adduction test involves placing axial compression on the metacarpal as the subluxation is reduced.¹⁰

The history and physical examination will contribute to the process of differentiating the diagnosis of trapeziometacarpal OA from other causes,¹³ including DeQuervain's tendinitis, scapholunate instability, scaphoid fracture, flexor carpi radialis tendinitis, scaphotrapezotrapezoid arthritis, and trigger thumb, which are common conditions that can cause pain at the base of thumb and radial aspect of the wrist.

Recommendation

- Radiological findings, history, and physical examination are considered in the diagnosis of the severity of trapeziometacarpal OA [overall quality: moderate]

Question 2: What outcomes are considered important in determining the success of intervention?

Case clarification

Considering that the main complaint of our patient is pain, determining whether a particular intervention can achieve a reduction in pain will be of most importance. Further, she has a restriction of web space, weakness of pinch and grip strength, and difficulty with various activities of daily living.

Relevance

Identifying the outcomes of interest will assist when analyzing the evidence for various interventions.

Current opinion

Current opinion suggests that pain, range of motion, strength, and function are the outcomes of interest.

Finding the evidence

- Cochrane Database, CINAHL, MEDLINE, PubMed, using the search terms: “carpometacarpal joint, trapeziometacarpal joint, arthritis, outcome measures”

Quality of the evidence

Level Ia

- 1 study

Level IIc

- 3 studies

Findings

A report of the OMERACT (Outcome Measures in Rheumatoid Arthritis Clinical Trials) III conference¹⁴ proposed that the following four domains should be evaluated in trials of hand OA: pain, physical function, patient global assessment, and joint imaging (for studies of 1 year or longer).

One review of 112 patients who had undergone trapeziectomy with ligament reconstruction and tendon interposition attempted to determine the optimal set of instruments for evaluating patient outcome.¹⁵ This study identified that the SF-36, the Disabilities of the Arm, Shoulder and Hand Questionnaire (DASH) or Patient Rated Wrist Evaluation (PRWE), and a custom set of clinical parameters (including range of motion, strength, and assessment of deformity) were appropriate for assessment of basal thumb joint conditions. These findings are supported by an assess-

ment of the validity of self-report measures of pain and disability for people following trapeziometacarpal joint arthroplasty.¹⁶

Recommendation

- Outcome measures should be patient-oriented and clinically relevant.¹⁵ Evidence suggests they should include: pain, measured on a 10 cm visual analog scale (VAS); physical function, measured by the DASH or PRWE; Patient Global Assessment, measured by SF-36; range of motion of palmar abduction, measured in degrees; strength, both grip and lateral pinch, measured in kilograms; and adverse effects [overall quality: moderate]

Question 3: What conservative interventions are effective in relieving symptoms?

Case clarification

The patient complains of pain with a variety of activities of daily living. She also presents with tenderness and inflammation at the trapeziometacarpal joint. Clinical experience suggests various conservative interventions exist, but it is important to determine which interventions are effective for her from current evidence.

Relevance

Clinicians need to select an appropriate intervention, which is likely to reduce pain and improve function in people with trapeziometacarpal OA.

Current opinion

Current opinion suggests that people with arthritis at the base of the thumb will gain benefit from splinting, education regarding joint protection strategies, heat, and gentle exercise. However, there is confusion as to whether any additional benefit is likely to be gained from glucosamine therapy or corticosteroid injections.

Finding the evidence

- Cochrane Database, CINAHL, MEDLINE, PubMed, with search terms; “carpometacarpal joint, trapeziometacarpal joint, arthritis, splinting, glucosamine, intervention, injections, exercise, joint protection”

Quality of the evidence

Level I

- 6 studies

Level II

- 9 studies

Findings

Splinting One randomized trial compared the short opponens splint with no splint¹⁷ in patients with stage II-IV

Figure 112.1 Short opponens splint.

Figure 112.2 Thumb trapeziometacarpal immobilization splint.

Figure 112.3 Long opponens splint.

trapeziometacarpal OA. After 1 month, there was no difference between groups in pain or hand function. After wearing a short opponens splint (Figure 112.1) at night for a further 11 months, the splint group had 14 mm (95% CI 5–23 mm) less pain on the VAS and 6 points (out of 90) (95% CI 2–11) better hand function than the no-splint group.

One crossover trial¹⁸ compared the trapeziometacarpal immobilization splint (Figure 112.2)¹⁹ with a long opponens splint (Figure 112.3) in stage I–IV trapeziometacarpal OA. After 2 weeks, there was no difference between groups in pain or strength.

Figure 112.4 Neoprene thumb support.

Figure 112.5 Three-point thumb splint.

One crossover trial compared the trapeziometacarpal immobilization splint with a prefabricated neoprene splint (Figure 112.4) in stage I and II trapeziometacarpal OA.²⁰ After 1 week, the neoprene splint group had 1.3 mm less pain ($p = 0.02$) but no more strength than the immobilization splint.

One randomized trial compared the short opponens splint with a three-point thumb strap splint (Figure 112.5)²¹ in stage I–III trapeziometacarpal OA.²² After 6 weeks, there was no difference between groups in pain, strength or hand function.

Joint protection and exercise One randomized trial compared joint protection advice and a home exercise program to an information session for patients with trapeziometacarpal OA.²³ After 3 months, 45% more of the joint protection and home exercise group ($p < 0.05$) improved in hand function compared with the information session group.

Glucosamine One systematic review of 25 randomized trials with 4963 participants compared glucosamine with placebo intervention for the treatment of OA.²⁴ The glucosamine group had 22% reduction in pain (SMD -0.47 ;

95% CI -0.72 to -0.23) and 11% improvement in function (SMD -0.47 ; 95% CI -0.82 to -0.12) compared with no intervention. However, if analysis was restricted to trials with adequate allocation concealment, there was no difference in groups in pain or hand function.

Stinging nettle One crossover trial compared rubbing the leaf of a common stinging nettle over the base of the thumb²⁵ with a placebo. After 1 week, the stinging nettle group had 15 mm less pain ($p = 0.03$) and 0.2 points less disability on the Stanford Health Assessment Questionnaire for disability ($p < 0.01$).

Leech therapy One randomized trial compared the single application of 2–3 leeches²⁶ with a nonsteroidal anti-inflammatory drug (diclofenac) applied twice a day for 30 days in patients with trapeziometacarpal OA. After 2 months, the leech group had 34 mm (95% CI 20–48) less pain than the nonsteroidal group.

Corticosteroid injections One randomized trial compared corticosteroid injections with placebo intervention¹⁷ in patients with trapeziometacarpal OA. After 24 weeks, there was no difference between groups in pain or hand function.

Hyaluronate injections One randomized trial compared intra-articular Hylan injections with placebo²⁷ in patients with trapeziometacarpal OA. Two other randomized trials compared intra-articular Hylan injections with corticosteroid injections and placebo^{28,29} in patients with trapeziometacarpal OA. After 6 months, there was no difference between groups in pain or strength.

Recommendations

- Splinting the thumb in a short opponens splint at night for 12 months will reduce pain [overall quality: moderate]
- There is no difference in the improvement in pain, strength, or hand function with either a long opponens splint, a thumb trapeziometacarpal immobilization splint, a three-point splint, or a neoprene splint [overall quality: low]
- Joint protection and home hand exercises provide significant improvements in both grip strength and function in patients with hand OA [overall quality: moderate]
- There is no evidence for the use of glucosamine in the management of trapeziometacarpal OA [overall quality: moderate]
- Stinging nettle provides effective pain relief but can be associated with skin irritations including rash and itchiness [overall quality: moderate]
- Leech therapy is more effective than topical nonsteroidal anti-inflammatory drugs for reducing pain [overall quality: moderate]

- There is no evidence that intra-articular injection with hyaluronate or corticosteroids improves outcomes more than placebo [overall quality: moderate]

Question 4: Which surgical interventions provide the best outcome?

Case clarification

The patient achieved substantial symptomatic relief with conservative interventions for a period of 3 years, but now finds the symptoms unresponsive to splinting and joint protection strategies. She has been referred to a hand surgeon, who identifies that the grind test is positive and that she has Eaton III arthritis.⁷

Relevance

It is important to consider the patient's vocational demands, interests, and hobbies along with the severity of her arthritis when considering appropriate surgical options. Removing the arthritic trapezium is likely to relieve her pain, but current opinion about the necessary reconstructive approaches differs greatly amongst hand surgeons.

Current opinion

Current opinion regarding the best surgical intervention for this patient is widely diversified. The two most common procedures are simple trapeziectomy and trapeziectomy with ligament reconstruction and tendon interposition (LRTI).

Finding the evidence

- Cochrane Database, CINAHL, MEDLINE, PubMed, with search terms "carpometacarpal joint" OR "trapeziometacarpal joint" AND "arthritis" AND "surgery"

Quality of the evidence

Level I

- 11 studies

Level II

- 1 study

Findings

One systematic review of 18 comparative studies and 8 reviews³⁰ was unable to perform statistical pooling due to heterogeneity of population, intervention, and outcomes. However, it alerted hand surgeons that LRTI may not be the best option available. The review was unable to draw any conclusions about superiority of any one procedure over another.

One systematic review of 9 randomized trials with 477 participants³¹ compared 7 surgical procedures: trapeziectomy with LRTI was compared to trapeziectomy by Belcher,³² Davis,³³ De Smet,³⁴ and Field³⁵; to trapeziectomy

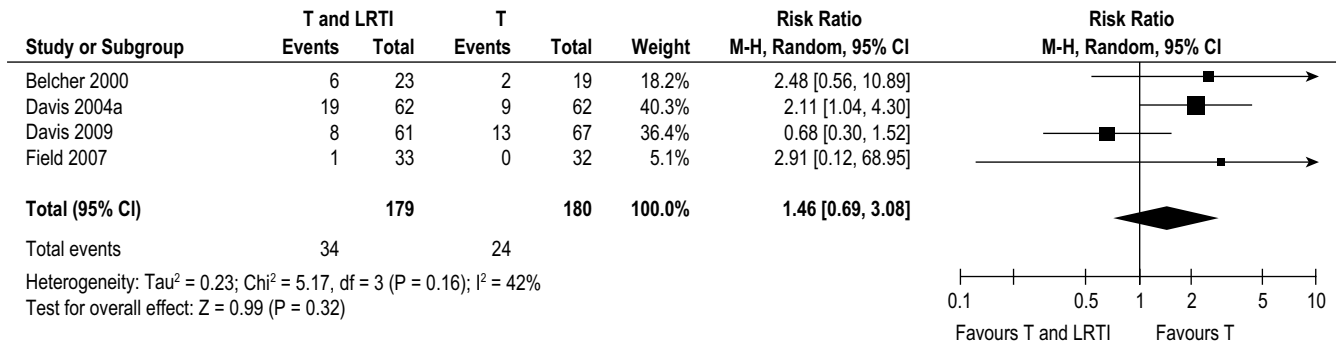

Figure 112.6 Comparison of adverse effects between trapeziectomy with LRTI and trapeziectomy.

with ligament reconstruction by Gerwin³⁶ and Kriegs-Au,³⁷ to trapeziectomy and interpositional arthroplasty by Davis 2004,³³ to Artelon joint resurfacing by Nilsson,³⁸ to arthrodesis by Hart,³⁹ and trapeziectomy with interpositional arthroplasty was compared to joint replacement (Swanson) surgery by Tagil⁴⁰ and to trapeziectomy by Davis.³³ The review failed to identify any additional benefit of one procedure over another in terms of pain, physical function, patient global assessment, range of motion, or strength.

One randomized trial compared trapeziectomy with LRTI (and K-wire fixation) vs. a simple trapeziectomy.⁴¹ After 12 months, there was no difference in outcomes of pain, hand function, range of motion, or strength.

Recommendation

- That there is no additional benefit of one surgical procedure over another in terms of pain, physical function, global assessment, range of motion, or strength [overall quality: high]

Question 5: Is any surgical procedure associated with fewer adverse effects than any other?

Case clarification

The patient intends to undergo trapeziectomy with LRTI for her stage III trapeziometacarpal OA. She is concerned about potential adverse effects.

Relevance

Various adverse effects have been reported in the literature following surgery for trapeziometacarpal OA, including persistent pain, weakness, scar tenderness and adhesion, and complex regional pain syndrome.

Current opinion

Current opinion suggests that there is no appreciable difference in the frequency or severity of adverse effects between the various procedures.

Finding the evidence

- See Question 4.

Quality of the evidence

Level I

- 1 study

Level II

- 1 study

Findings

One systematic review of 9 randomized trials with 477 participants³¹ compared 7 surgical procedures. There were significantly more adverse effects following trapeziectomy with LRTI than the simple trapeziectomy group (RR 2.20, 95% CI 1.17–4.12, random effects p = 0.01). However, when the recent study by Davis et al.⁴¹ is incorporated into the systematic review, the difference in adverse effects between trapeziectomy with LRTI and trapeziectomy is no longer significant (RR 1.46, 95% CI 0.69–3.08, random effects p = 0.32, Figure 112.6).

Recommendation

- There is no difference in the incidence of adverse effects between trapeziectomy with LRTI (19%) and a simple trapeziectomy (13%) [overall quality: moderate]

Summary of recommendations

- Radiological findings, history and physical examination are considered in the diagnosis of the severity of trapeziometacarpal OA
- Outcome measures should be patient-oriented and clinically relevant. Evidence suggests they should include pain, measured on a 10 cm VAS; physical function, measured by the DASH or PRWHE; Patient Global Assessment, measured by SF-36; range of motion of palmar abduction, measured in degrees; strength, both grip and lateral pinch, measured in kilograms; adverse effects
 - Splinting the thumb in a short opponens splint at night for 12 months will reduce pain
 - There is no difference in the improvement in pain, strength, or hand function with either a long opponens

splint, a thumb trapeziometacarpal immobilization splint, a three-point splint, or a neoprene splint

- Joint protection and home hand exercises provide significant improvements in both grip strength and function in patients with hand OA
- There is no evidence for glucosamine in the management of trapeziometacarpal OA
- Stinging nettle provides effective pain relief but can be associated with skin irritations including rash and itchiness
- Leech therapy is more effective than topical nonsteroidal anti-inflammatory drugs for reducing pain and improving strength
- There is no evidence that intra-articular injection with hyaluronate or corticosteroids improves outcomes more than placebo
- There is no additional benefit of one surgical procedure over another in terms of pain, physical function, global assessment, range of motion, or strength
- There is no difference in the incidence of adverse effects between trapeziectomy with LRTI and a simple trapeziectomy

Conclusions

Arthritis at the base of the thumb is common, and may be considered a normal part of the aging process.⁶ Symptoms include pain and inflammation at the base of the thumb, with loss of strength, motion and function developing with advancing disease.

There are many conservative intervention approaches, but those frequently used include splinting, joint protection advice, and exercise. Failure of conservative intervention, with persistent pain and disability, may lead patients to consider surgical options. Many surgical options exist, but there is currently no evidence to suggest superiority or inferiority of one over the other.

Salvage Procedures for the Treatment of Wrists with Scapholunate Advanced Collapse

Jonathan Mulford¹, Paul K. Della Torre², and Stuart J.D. Myers¹

¹Prince of Wales Hospital, Sydney, NSW, Australia

²Concord Hospital, Concord, NSW, Australia

Case scenario

A 45 year old manual worker presents with increasing dorso-radial wrist pain, loss of range of motion (ROM), intermittent swelling, and clicking of the wrist. He had sustained an injury to the wrist 15 years ago, after falling on to an outstretched hand while snowboarding. At the time of the injury he was told he had a wrist “sprain” and the radiographs were “normal”. His pain is now impacting on his ability to work. His radiographs show he has a scapholunate advanced collapse (SLAC) wrist (Figure 113.1).

Relevant anatomy

The scapholunate ligament (SL) is a C-shaped intrinsic ligament. The dorsal aspect is the most important for stability. The secondary stabilizers of the scapholunate joint include the dorsal radiocarpal ligament (DRC), the dorsal intercarpal ligament (DIC), and the volar capsule of the scapho-trapezium-trapezoid (STT) joint.¹

If the SL ligament is ruptured, the scaphoid tends to flex and the lunate extends. There is dorsoradial subluxation of the scaphoid which increases the stresses on the dorsal and lateral aspect of the scaphoid fossa of the radius. In time this results in wear of the articular surface and secondary osteoarthritis (OA).²

Importance of the problem

The true prevalence of scapholunate (SL) rupture is not known,³ as the diagnosis is commonly missed. The natural history is well documented. Not all patients become symptomatic enough to warrant surgical intervention.

The full impact of the rupture may not become apparent for years until the patient develops pain from secondary OA. The consequences can be profound for manual workers. A typical patient with SLAC wrist presents in the fourth decade and has expectations of being in the work force for a further 20 years.

Rupture of the SL ligament in combination with one of the secondary stabilizers gives rise to a gap (diastasis) of 3mm or more, between the scaphoid and lunate.^{4,5} In addition, the scaphoid flexes and may sublux dorsally. This alters the wrist biomechanics and eventually results in secondary OA. This pattern of arthritis is called a SLAC wrist. The wrist arthritis develops in a particular distribution. The radial styloid is affected first followed by the radioscaphoid joint and then the midcarpal joint (capitolunate joint).^{2,6} The radiolunate joint is last to be affected.

There are various salvage options for the treatment of a symptomatic SLAC wrist. These include motion-preserving procedures (proximal row carpectomy and four-corner fusion) or a complete wrist fusion (see box).

Figure 113.1 Radiographs of SLAC wrist: (a) AP and (b) lateral.

Definitions used in this chapter

- *SLAC wrist*: Arthritis of the wrist secondary to scapholunate dissociation
- *Salvage procedure*: A motion-preserving procedure performed when reconstructive procedure is contraindicated due to OA
- *Proximal row carpectomy (PRC)*: Surgical procedure to remove the scaphoid, lunate, and triquetrum
- *Four-corner fusion (4CF)*: Surgical procedure to remove the scaphoid and arthrodesis of the lunate, capitate, triquetrum, and hamate

Top nine questions

Diagnosis

1. What are the radiological findings that characterize SLAC?
2. What is the natural history of scapholunate rupture and SLAC?

Therapy

3. What are the motion-preserving salvage procedure options?

Prognosis

4. What is the grip strength that can be expected after a salvage procedure?
5. What is the ROM that can be expected from each procedure?
6. What pain relief can be expected after each procedure?
7. What are the subjective outcomes for each procedure?

Harm

8. What are the postoperative complications for each procedure?
9. How many patients have progression of OA after having a salvage procedure?

Finding the evidence

A systematic review was undertaken to clarify controversies regarding which procedure has the best outcome.

Articles were sourced from MEDLINE (1966–2009), Embase (1980–2009), CINAHL, and the Cochrane Controlled Trials Register electronic databases. The search was undertaken using the terms “proximal row carpectomy,” “PRC,” “midcarpal fusion,” “four-corner fusion,” “carpal instability,” “scapholunate advanced collapse,” “SLAC”. All languages were included in the search.

The title and abstract of papers identified in the search were screened. Definite and possible articles identified by both reviewers were then retrieved for possible inclusion in the study based on predetermined inclusion and exclusion criteria. Further search was also conducted (see below).

Inclusion criteria when reviewing articles

1. Original articles including patients with SLAC wrists treated with PRC or 4CF

2. Articles which reported on one or more of the primary outcomes: ROM, grip strength, pain score, physician or patient reported outcomes, and postoperative complication

Exclusion criteria when reviewing articles

1. Articles which did not document the underlying aetiology and/or minimum length of patient follow-up
2. Studies with less than 12 months of patient follow-up
3. Duplicate publication of any type, e.g., abstracts, comments, review or technique articles, duplicate reports, and articles based on preliminary data from larger series
4. Studies that included diagnoses other than SLAC, e.g., Kienbock's, Preiser's disease, scaphoid nonunion advanced collapse (SNAC), where SLAC data was not extractable. If this was not possible, studies were only included if SLAC patients comprised at least 70% of the patients in the series.

Additional search strategies

1. References from review articles found in the search, major orthopaedic/hand textbooks,⁷⁻⁹ and primary articles were checked to identify any additional articles not located in the original search
2. A manual search of the table of contents of the *Journal of Hand Surgery* (American, British and European) was performed, including reviewing published abstracts from European or North American hand meetings

Quality of the evidence

Caution is needed when interpreting the results in this evidence-based review. The level of evidence is low. All articles included in the systematic review were observational studies. The majority were retrospective case series. Three articles¹⁰⁻¹² compared data for PRC to 4CF in a retrospective case series. Six articles reported outcomes on 4CF¹⁰⁻¹⁵ and eight on PRC.^{10-12,16-20} One systematic review has looked at outcomes of PRC and 4CF for SLAC and SNAC wrists;²¹ however, no distinction was made between SLAC and SNAC.

In order to draw conclusions regarding outcomes for PRC and 4CF, weighted averages were calculated, which were based on the number of patients in each study. A meta-analysis to compare the procedure outcomes was not performed due to expected heterogeneity between studies, varying methodology, and lack of randomization and direct comparative results.

None of the studies has a randomization process to limit bias. Heterogeneity between studies, quality of studies, bias within studies, and publication bias are likely to affect the measured outcomes and thus any summarized outcome. Observational studies are likely to distort the magnitude

or direction of associations in outcomes. Few studies reported 95% confidence intervals (CI) or standard deviations (SD).

Question 1: What are the radiological findings that characterize SLAC?

Case clarification

This patient's radiographs show a diastasis of the SL interval. There is OA in the radiocarpal joint and no midcarpal OA.

Relevance

Imaging is important (1) to confirm there is a SL rupture, (2) to determine if OA is present, and (3) to stage the SLAC wrist, particularly if there is midcarpal involvement.

Current opinion

Signs of SL rupture on a radiograph are listed in the box.

Radiographic signs of SL rupture

- Scapholunate joint space (Terry-Thomas sign)²²⁻²⁴
- "Scaphoid ring" sign²⁵
- "Ring pole" sign²⁶
- Lack of parallelism^{27,28}
- Increased SL angle^{29,30}
- Taleisnik's "V" sign³¹

Signs of OA include osteophyte formation and joint space narrowing. The SLAC wrist can be classified radiographically depending on the areas of OA involved (see box).

Radiographic staging system for SLAC²

- *Stage 1:* Isolated radial styloid–scaphoid impingement
- *Stage 2:* Complete radial styloid OA
- *Stage 3:* Midcarpal arthritis

Quality of the evidence

The radiographic signs of a SLAC wrist are based on observational studies.

Recommendation

- Observational studies have provided the evidence for the radiological findings for a SLAC wrist [overall quality: low]

Question 2: What is the natural history of scapholunate rupture and SLAC?

Case clarification

This patient has a classical natural history of progression from SL rupture to SLAC over a 10–20 year period.

Table 113.1 Summary of demographics

	No. of articles	N wrists operated	Av. age	Male:female (%)	Av. follow-up (months)
4CF	6	91	49	85:15	36
PRC	8	134	45	74:26	56

4CF, four corner fusion; PRC, proximal row carpectomy.

Relevance

Although an untreated SL rupture classically progresses to secondary arthritis, not all patients become symptomatic and some may never present.^{2,6,32,33}

Current opinion

Surgery should be reserved for symptomatic patients.

Quality of the evidence

Evidence on the natural history of SL rupture is based on observational studies.^{32,33} Eight articles give outcomes on PRC and six for 4CF.

Findings

Table 113.1 summarizes the demographic features of patients in those articles that report outcomes of PRC and 4CF.

Recommendation

- Observational studies have provided the evidence for the natural history of scapholunate rupture and the most common patient is a 40 year old man [overall quality: low]

Question 3: What are the motion-preserving salvage procedure options?

Case clarification

Motion-preserving salvage procedures in this scenario include PRC and 4CF.

Relevance

Both PRC and 4CF can be used, as the midcarpal joint is maintained.

Current opinion

Advocates of 4CF claim that a better grip strength is achieved because the relative muscle length is preserved. There is a lower risk of progressive arthritis because the radiolunate joint is preserved and therefore the force per unit area is reduced.

Advocates of PRC claim the procedure is simple and lacks the complications associated with hardware and nonunion.

Quality of the evidence

There are no randomized trials. There are three comparative papers, eight papers reporting outcomes of PRC, and six for 4CF.

Findings

Both PRC and 4CF are management options. The evidence regarding the outcomes for each procedure is reviewed below.

Recommendations

- Salvage procedures for symptomatic SLAC wrists can give good outcomes. The choice between PRC and 4CF depends on patient and surgeon factors:
 - Patient factors include (a) general factors such as age, occupation, specific risks for nonunion, and expectations; (b) specific wrist factors such as the presence of midcarpal OA
 - Surgeon factors include familiarity with the technique
 - [Overall Quality: Low]

Question 4: What is the grip strength that can be expected after a salvage procedure?

Case clarification

The patient is a manual worker and would prefer a procedure that provides the best opportunity to maintain his strength.

Relevance

Patients want to maintain or improve their grip strength.

Current opinion

Advocates of 4CF argue this salvage procedure gives better grip strength as there is less skeletal shortening.

Quality of the evidence

There are eight articles giving grip strength outcomes for PRC and five for 4CF. Three articles give a comparison.

Findings

It is not appropriate to perform a meta-analysis on the data available. The weighted mean for grip strength was 73%

(56% preoperatively) for 4CF compared to 77% (60% preoperatively) for PRC.

A systematic review of PRC and 4CF for SLAC and SNAC wrists also showed comparable grip strength outcomes for both procedures.²¹

Recommendation

- The grip strength is comparable following either a PRC or 4CF. It has been shown to be approximately 75% of the contralateral side [overall quality: low]

Question 5: What is the ROM that can be expected from each procedure?

Case clarification

This patient would prefer to maximize his ROM.

Relevance

ROM, measured in flexion/extension (F-E) and radial/ulnar (R-U) axis, may be an important consideration depending on the patient’s individual circumstances.

Current opinion

PRC gives better ROM than 4CF.

Quality of the evidence

There were substantive ROM data sets in three articles for 4CF and six for PRC.

Findings

There is no major difference in the ROM between the two procedures (Table 113.2).

Recommendation

- The ROM achieved is similar after both procedures and usually slightly less than the preoperative measurement [overall quality: low]

Question 6: What pain relief can be expected after each procedure ?

Clinical clarification

Pain is one of the patient’s major complaints.

Table 113.2 Weighted mean ROM for PRC and 4CF

	DF (pre)	DF (post)	PF (pre)	PF (post)	RD (pre)	RD (post)	UD (pre)	UD (post)
4CF	39	35	40	34	11	17	23	22
PRC	35	36	36	34	13	10	20	21

4CF, four corner fusion; DF, dorsiflexion; PF, palmar flexion; PRC, proximal row carpectomy; RD, radial deviation; UD, ulnar deviation.

Relevance

Provision of ongoing improvement in pain is the main indication for performing a salvage procedure.

Current opinion

Both procedures give good pain relief.

Quality of the evidence

There are seven articles reporting pain outcomes for PRC and four for 4CF. Varying pain scores are utilized in different publications. Subjective scores were divided into “good pain outcome” (e.g., reported as excellent, good, satisfied) or “poor pain outcome” (e.g., reported as moderate, poor, severe).

Findings

With 4CF 48 of 61 patients (79%) had good pain relief. With PRC 79 of 104 (76%) patients had good pain relief.

Recommendation

- Both salvage procedures give good pain relief in approximately 75% of patients [overall quality: low]

Question 7: What are the subjective outcomes for each procedure?

Clinical clarification

Patients prefer to know the likelihood that they will perceive that surgery has been successful.

Relevance

Patient subjective outcomes are arguably the most important measures when examining the success of an operation.

Current opinion

Both procedures give good subjective improvements.

Quality of the evidence

There are five articles with subjective outcomes for PRC and three for 4CF. Subjective outcome are reported differently in different publications. Scores were divided into “good outcome” (e.g., reported as excellent, good, satisfied, would have surgery again) or “poor outcome” (e.g., reported as moderate, poor, severe).

Findings

For PRC, 62 of 72 patients (86%) reported a satisfactory outcome. For 4CF, 32 of 38 patients (84%) reported satisfactory outcomes.

Recommendation

- The subjective outcomes are good, and similar for both salvage procedures [overall quality: low]

4CF, four corner fusion; CTS, carpal tunnel syndrome; OA, osteoarthritis; PRC, proximal row carpectomy. RSD, reflex sympathetic dystrophy.

Question 8: What are the postoperative complications for each procedure?

Relevance

Patients may wish to undergo a procedure that has a lower risk of complication.

Current opinion

There are extra risks associated with 4CF, relating to the hardware.

Finding the evidence

The literature was reviewed for specific complications including nonunion, hardware failure, dorsal impingement, conversion to fusion, reflex sympathetic dystrophy, and sepsis.

Quality of the evidence

There were five articles reporting complications for PRC and four for 4CF.

Findings

Reported complications are summarized in Table 113.3.

Recommendation

- 4CF may have more complications than PRC due to hardware problems and nonunion [overall quality: low]

Question 9: How many patients have progression of OA after having a salvage procedure?

Case clarification

The patient is still young, with many years of manual work ahead of him.

Relevance

Further development of OA may not be ideal in this group of patients.

Current opinion and literature findings

PRC has a higher incidence of development of OA due to the mismatch in the shape of the lunate fossa and the head of the capitate.

Quality of evidence

Four articles specifically reported arthritis for PRC and four reported no evidence of arthritic change following a 4CF.

Findings

There were 18% of patients reported in the PRC group who developed secondary OA (25 of 134) (Table 113.3) and none from the 4CF group. However, the average follow-up time for PRC was 20 months longer than for the 4CF group.

A meta-analysis comparing PRC and 4CF for SLAC and SNAC wrists showed a significantly higher risk of developing OA after PRC than 4CF (RR 4.35, 95% CI 1.20–15.71).²¹

Recommendation

- PRC may have a higher incidence of progression of OA, but the clinical relevance of this finding is uncertain (usually reported as pain free despite radiological findings) [overall quality: low]

Summary of recommendations

- Observational studies have provided evidence to characterize the radiological findings for a SLAC wrist and the natural history of scapholunate rupture
- The motion-preserving salvage procedure options are PRC and 4CF. There are certain instances when PRC cannot be performed
- The grip strength is similar after PRC and 4CF. Postoperative strength is approximately 75% of the contralateral side
- The ROM achieved is similar after both procedures and usually slightly less than the preoperative measurement
- Both salvage procedures give good pain relief in approximately 3/4 of patients
- The subjective outcomes are good and similar for both salvage procedures
- 4CF may have more complications than PRC due to hardware impingement and nonunion
- PRC may have a higher incidence of progression of OA, but the clinical relevance of this finding is uncertain

Conclusions

This systematic review has shown the weak quality and quantity of studies. It is likely that both surgical options give good pain relief and improvements in subjective outcomes. PRC results in radiographic osteoarthritic changes, but the clinical implications of this are uncertain.

Case scenario

A 37 year old man presents to the Emergency Department with complaints of left wrist pain following a fall on his outstretched hand while rollerblading with his children. On examination, there is mild left wrist swelling and limited range of motion due to pain. The patient is neurovascularly intact.

Top eight questions

Distal radius fractures

Diagnosis

1. Is there a role for wrist arthroscopy in the evaluation of intra-articular distal radius fractures?

Therapy

2. What is the relative effect of arthroscopy vs. fluoroscopy alone on the anatomical and functional results of treatment of intra-articular distal radius fractures in adults?

Triangular fibrocartilage complex (TFCC) injuries

Diagnosis

3. What is the optimal method for diagnosis of TFCC tears: wrist arthroscopy or MR arthrography (MRA)?

Therapy

4. What is the optimal technique for fixation of peripheral TFCC tears: open or arthroscopic?

5. What is the relative effect of arthroscopic debridement combined with ulnar shortening osteotomy vs. debridement combined with arthroscopic wafer procedure on outcome in the management of degenerative tears of the TFCC associated with ulnar positive variance?

Scapholunate (SL) and lunotriquetral (LT) ligament injuries

Therapy

6. Do there a role for arthroscopy in the treatment of dynamic carpal instability associated with SL or LT ligament tears in adults?

Dorsal wrist ganglion cysts

Therapy

7. Is there an advantage of arthroscopic resection vs. open technique in terms of recurrence?

Harm

8. What are the complications associated with arthroscopic excision of a dorsal ganglion cyst of the wrist?

Distal radius fractures

Wrist arthroscopy has evolved into an important diagnostic and therapeutic tool. Since the first wrist arthroscopy was described by Chen in 1979, indications for wrist arthroscopy have increased due to the advent of improved equipment, new portals, and techniques.¹ The use of

arthroscopy has been expanded to manage distal radius fractures.

Importance of the problem

Fractures of the distal radius are common and have been the focus of numerous epidemiologic studies around the world. Population studies from cities such as Malmö, Sweden; Bergen, Norway; and Rochester, Minnesota, USA have shown incidence rates as high as 26 per 10,000 person years.² Many of these studies, including larger population studies from Dorset, England and Uppsala, Sweden, have also shown a significant increase in the occurrence of distal forearm fractures over the past two to three decades.²⁻⁴

In the United States, distal radius fractures account for approximately one sixth of all fractures seen in the Emergency Department.³ More recent studies have reported even higher rates; Bengner et al. reported that 125 per 10,000 Medicare beneficiaries will experience a fracture of the distal radius in their lifetime.⁴

Question 1: Is there a role for wrist arthroscopy in the evaluation of intra-articular distal radius fractures?

Case clarification

The patient's radiographs reveal a displaced, intra-articular distal radius fracture. In discussions with the patient, you explain the need for surgical intervention and suggest further evaluation of the cartilage and soft tissue structures either prior to or at the time of surgery.

Relevance

Diagnosis of cartilage and soft tissue injuries prior to definitive fixation can dictate the surgical plan and allow for better understanding of the position of the fracture fragment as well as facilitating early repair of torn SL or LT ligaments, and TFCC.

Current opinion

Wrist arthroscopy is the gold standard for the diagnosis of cartilage and soft tissue lesions accompanying distal radius fractures.

Finding the evidence

- Cochrane Database, with search terms: "arthroscopy" AND "MRI" OR "magnetic resonance imaging" and "arthroscopy" AND "radiographs"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: "wrist arthroscopy" AND "MRI" as well as "radius fracture" AND "arthroscopy"

Table 114.1 Prevalence of osteochondral lesions associated with intra-articular distal radius fractures

Study	Prevalence	Location	Treatment
Adolfsson and Jorgsholm ⁹	4 of 27 (15%)	N/A	Flap excision
Mehta et al. ¹⁰	5 of 25 (20%)	4 capitate, 1 hamate	Arthroscopic debridement
Shih et al. ⁸	6 of 33 (18%)	6 lunate	Reduction/K-wire fixation
Total	15 of 85 (18%)		

N/A, not available due to data deficiency

Quality of the evidence

Level II

- 2 randomized trials with methodologic limitations

Level IV

- 4 case series

Findings

Osteochondral lesions Fluoroscopy performed at the time of reduction of the distal radius fracture was unable to distinguish osteochondral lesions concomitant to this fracture type. However, these defects were easily identified on subsequent arthroscopic evaluation.⁵ MRI was reported to be 72% sensitive, 78% specific, and 74% accurate compared to wrist arthroscopy when diagnosing cartilage lesions in the setting of a distal radius fracture. CT arthrogram was reported to be 45% sensitive compared to arthroscopy when diagnosing cartilage lesions in the same setting.^{6,7} Three other studies provided data on the prevalence and location of concomitant osteochondral lesions (Table 114.1). These lesions often produce unstable fragments or loose bodies large enough to require reduction and Kirschner wire (K-wire) fixation.⁸⁻¹⁰

Intercarpal ligament and TFCC injury TFCC tears were the most commonly reported soft tissue injuries concomitant to distal radius fractures. Most of these injuries were treated with debridement at the time of arthroscopically assisted reduction and percutaneous fixation of the intra-articular fracture.^{9,10} However, in two studies, 25 out of 28 TFCC tears required suture repair.^{8,11} Partial or full tears of the SL and LT ligaments were also common. Two studies showed high rates of instability associated with these two injury types. K-wire stabilization was required in 29 out of 39 injuries in one study¹⁰ and 8 out of 10 injuries in another.⁸

Recommendations

In patients with distal radius fractures and suspected cartilage and soft tissue injuries, evidence suggests:

- Wrist arthroscopy is useful to identify cartilage lesions associated with distal radius fractures [overall quality: moderate]
- Wrist arthroscopy may facilitate diagnosis and treatment of soft tissue lesions associated with distal radius fractures [overall quality: low]

Question 2: What is the relative effect of arthroscopy vs. fluoroscopy alone on the anatomical and functional results of treatment of intra-articular distal radius fractures in adults?

Case clarification

A wrist radiograph reveals an intra-articular distal radius fracture with a “die punch” pattern. You present the possibility of using wrist arthroscopy to assist in reducing the articular surfaces of the fracture.

Relevance

Reduction of the articular surface in distal radius fractures, with less than 2mm step-off, directly affects outcome following fixation of these fractures.^{12,13} Wrist arthroscopy is proposed to improve the anatomic reduction of intra-articular distal radius fractures compared to fluoroscopic reduction alone.

Current opinion

Current opinion suggests that arthroscopically assisted reduction of certain types of intra-articular distal radius fractures may improve outcome following percutaneous fixation of these fractures.

Finding the evidence

- Cochrane Database, with search terms: “distal radius fracture” AND “arthroscopy”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: “distal radius fracture” AND “arthroscopy”
- MEDLINE search using keywords: “distal radius fracture” AND “arthroscopy”

Quality of the evidence

Level I

- 1 randomized controlled trial (RCT)

Level II

- 1 prospective cohort study

Findings

Articular surface reduction A prospective cohort study by Ruch et al. provided no significant difference in terms of

maximum step-off between fluoroscopically and arthroscopically assisted reduction groups at 12 months follow-up.¹⁴ However, in an RCT performed by Varitimidis et al., the arthroscopic technique resulted in significantly different reduction of the articular surface compared to fluoroscopy alone at 24 months follow-up. The mean articular step-off following arthroscopically assisted reduction of the fracture was 0.30mm vs. 0.8mm for the fluoroscopically assisted group ($p < 0.05$).¹⁵ In both studies the articular step-off was decreased to less than 1mm following either the fluoroscopic or the arthroscopic reduction technique.

Functional outcome Ruch et al. reported significant difference in improvement of flexion/extension of the wrist, and supination of the forearm for the arthroscopically assisted group compared to the fluoroscopically assisted group. There was no significant difference in DASH score between the two groups at 12 months follow-up.¹⁴ However, in an RCT by Varitimidis et al. patients reported significant difference in the MMWS at 3, 12, and 24 months follow-up as well as in DASH score at 3 months follow-up between the arthroscopically assisted and the fluoroscopically assisted group. Significant difference in improvement of flexion/extension of the wrist following arthroscopically assisted reduction of the fracture was also reported.¹⁵

Recommendations

In patients with intra-articular fractures of the distal radius, evidence suggests:

- The use of wrist arthroscopy may improve reduction of the articular surface of the radius compared to the use of fluoroscopy alone [overall quality: moderate]
- Functional outcomes may be improved by the use of arthroscopically assisted reduction compared to fluoroscopically assisted reduction alone [overall quality: moderate]

TFCC injuries

Relevant anatomy

The TFCC was described first by Palmer in 1981.¹⁶ Principally, it consists of an articular disc (fibrocartilage) surrounded by the volar and dorsal radioulnar ligaments. Each radioulnar ligament consists of a superficial and deep portion, with the deep one attaching to the fovea and the superficial one attaching to the ulnar styloid and joint capsule. The term “ligamentum subcruentum” represents the deep fibers of the TFCC inserting into the fovea. The TFCC shares the load across the wrist and provides stability to the distal radioulnar joint (DRUJ).¹⁷ Similarly to the meniscus in the knee, the outer 10–40% of the TFCC region

is well vascularized. There is also an inner avascular region.^{18,19} This anatomic pattern of vascularity allows for potential healing of tears and repairs in the vascular zone.

Importance of the problem

The use of arthroscopy in the treatment of wrist pathology has expanded. New techniques have been developed to provide a direct view of the TFCC. Arthroscopy has provided new methods for the treatment of ulnar-sided wrist pain, and specifically TFCC pathology.

Question 3: What is the optimal method for diagnosis of TFCC tears: wrist arthroscopy or MRI arthrography?

Case clarification

After being seen in the Emergency Department with negative radiographs, the patient was treated for a wrist sprain. Two months later he presented to the office with complaints of persistent ulnar-sided wrist pain that worsened with supination and pronation. MRI identified no TFCC pathology. Despite conservative treatment, the pain continued. Diagnostic arthroscopy was performed, and a peripheral TFCC tear was demonstrated and fixed.

Relevance

Early diagnosis and stratification of patients based on their extent of injury may improve recovery and allow patients to return to their normal daily activities.

Current opinion

Although the accuracy of MRI in the diagnosis and localization of tears is controversial, it remains a useful, if imperfect, screening tool in patients that fail conservative treatment. However, negative results should be viewed with some question.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords "MRI" and "TFCC"

Quality of the evidence

Level II

- 1 RCT with methodologic limitations

Level III

- 5 studies

Level IV

- 1 case series

Findings

Direct MRA Meier et al. studied 125 patients with direct injection MRI arthrography followed by wrist arthro-

scopy.²⁰ MRI sensitivity was 94%, specificity 89%, positive predictive value (PPV) 91%, and negative predictive value (NPV) 93%. In a study of 24 patients, Joshy et al. found a sensitivity of 74%, specificity 80%, PPV 95%, NPV 50%, and overall accuracy of 79% for direct MRA.²¹ This study used a conventional 1 T magnet and did not distinguish between central and peripheral tears. Another study (n = 41), using arthrography of the DRUJ, found a sensitivity of 85%, specificity of 76%, overall accuracy of 80%.²² They noted that 14 of 19 "noncommunicating tears" observed on MRI were confirmed as full tears at arthroscopy. All studies concluded that MRI is useful in examining the TFCC but cannot replace arthroscopy for definitive diagnosis.

Indirect MRA Haims et al. (n = 86) compared indirect MRA to arthroscopy and found sensitivity of 17%, specificity 79%, and overall accuracy of 64%.²³ If high signal was used as a criterion, sensitivity increased to 42%, specificity declined to 63%, and accuracy to 55%. They concluded that indirect MRA was inadequate and found no difference between standard MRI and indirect arthrography. A second study (n = 45) had a sensitivity of 100%, specificity of 77%, and accuracy of 93%.²⁴ In a case series, sensitivity was 61%, specificity 88%, PPV 85%, and NPV 68%.²⁵

High-resolution MRI Tanaka et al. in a small study (n = 11) examined the use of high-resolution MRI (1.5T) with a microscopy coil. They found 100% sensitivity and specificity that varied from 70% to 100% depending on which area of the TFCC was examined. They reported three false-positive results in their study.²⁶

Recommendation

- MRA is not superior to wrist arthroscopy to detect TFCC tears [overall quality: moderate]

Question 4: What is the optimal technique for fixation of peripheral TFCC tears: open or arthroscopic?

Case clarification

At the time of arthroscopy, probing of the TFCC demonstrated loss of the "trampoline" effect and obvious evidence of a tear of the peripheral ulnar attachment.

Relevance

As arthroscopy has become more prevalent, there has been a shift toward fixation or debridement of TFCC tears using this method.

Current opinion

The improved visualization of the TFCC with the arthroscope allows more accurate diagnosis and adequate fixation of tears.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords “arthroscopic” AND “triangular fibrocartilage complex”

Quality of the evidence

Level III

- 1 retrospective comparative study

Level IV

- 10 case series

Findings

In a retrospective comparative study, Anderson et al. reported on 75 patients undergoing either open (N = 39) or arthroscopic (N = 36) TFCC repair.²⁷ There was no significant difference in outcome between the two groups at 43 months follow-up. Patients showed a significant reduction in pain and improved function after surgery according to the MMWS system. Similar numbers (17%) in each treatment group required reoperation for instability. Osterman reported a case series of 52 consecutive patients who underwent arthroscopic treatment of TFCC tears;²⁸ 41 patients were followed between 13 and 42 months following surgery. Of these, 73% reported “complete” pain relief, and 88% considered surgery “worthwhile.” All remaining case series are summarized in Table 114.2.^{29–38} Evidence of DRUJ instability at the time of presentation or diagnosis was not addressed by any of available studies, therefore no conclusions can be drawn for this patient subset.

Recommendation

- Outcomes for arthroscopic repair or debridement of TFCC tears are equivalent to those of open treatment [overall quality: low]

Question 5: What is the relative effect of arthroscopic debridement combined with ulnar shortening osteotomy vs. debridement combined with arthroscopic wafer procedure on outcome in the management of degenerative tears of the TFCC associated with ulnar positive variance?

Case clarification

When the patient was further questioned at his initial presentation to the office, he said that ulnar-sided wrist pain had been present for over a year; however, the pain had become worse following the injury 2 months ago. An ulnar variance view on radiographs demonstrated 4 mm of ulnar positive variance. After failing conservative measures, an MRI showed a central perforation of the TFCC.

Relevance

Treatment of degenerative central TFCC tears with debridement alone on the ground of ulnar positive variance tends to result in recurrent or incomplete relief of symptoms.

Current opinion

Ulnar shortening osteotomy is the most frequently used method in addressing the length of the ulna in ulnocarpal impaction syndrome.

Finding the evidence

^bResults reported as good/satisfactory/poor.

Level IV

- 5 case series

Findings

In a retrospective comparative study, 16 patients treated with arthroscopic debridement of TFCC tear plus ulnar shortening osteotomy were compared in terms of outcome to 11 patients treated with debridement plus arthroscopic resection of the distal ulna (wafer procedure).³⁹ Nine out of 11 patients in the wafer procedure group and 11 out of 16 in the ulnar osteotomy group reported good or excellent results according to the MMWS system at 15 months follow-up. Pain relief also was similar in both groups. However, 1 patient in the wafer procedure group and 10 patients in the ulnar osteotomy group required secondary surgery (9 hardware removals). The remaining available studies are summarized in Table 114.3.^{40–44}

Recommendation

- An arthroscopic procedure to address ulnar variance in addition to TFCC pathology can provide similar pain relief compared to a combination of arthroscopic debridement with ulnar shortening osteotomy [overall quality: low]

SL and LT ligament injury

Relevant anatomy

Intrinsic ligaments of the wrist are directly attached to carpal bones and play an important role in the stability and coordination of the carpal construct. The SL and LT ligaments are the most important ones.⁴⁵ Dynamic instability was first described by Taleisnik in 1980.⁴⁶ Patients may present with findings on clinical examination; the static anteroposterior radiographs are normal. Stress views usually reveal a widening of the scapholunate interval.

Importance of the problem

Intercarpal ligament injuries remain an important clinical issue.⁴⁷ As arthroscopy continues to increase its role in both diagnosis and treatment of various wrist pathologies, strategies are needed to guide the treatment of intercarpal ligamentous disruptions, in order to achieve the desired outcomes.

Question 6: Is there a role for arthroscopy in the treatment of dynamic carpal instability associated with SL or LT ligament tears in adults?

Case clarification

After attempted conservative treatment, the patient's wrist pain continued; there is a 2.5 mm SL widening on stress views while static radiographs are normal. An MRI at this time was suggestive of a SL ligament tear.

Relevance

Available options for open treatment of dynamic carpal instability result in suboptimal outcomes with decreased range of motion (ROM). Arthroscopic debridement with or without pinning may help in achieving adequate results without the morbidity associated with an open procedure.

Current opinion

Arthroscopic debridement in the acute setting (<3 months) can provide adequate symptom relief.

Finding the evidence

- PubMed and MEDLINE searches for "arthroscopy," "wrist," "intercarpal," "ligament," "scapholunate," "lunotriquetral"

Quality of the evidence*Level IV*

- 3 case series

Findings

Results following arthroscopic debridement for either complete or incomplete intercarpal ligament tears were reported in a case series by Wiess et al.⁴⁸ A total of 27 SL ligament tears were treated. At 27 months follow-up, 21 patients reported improvement or complete resolution of symptoms according to the author's criteria (10 out of 15 complete tears and 11 out of 13 partial tears). Fifteen LT ligament tears were also treated. At follow-up, 13 had resolved/improved symptoms (7 out of 9 complete and 6 out of 6 partial tears). All 9 failures required additional surgery despite no evidence of static deformity at follow-up. No statistical difference in outcome was noted in patients with complete and partial tears treated in this manner. A third study evaluated patients (N = 11) treated for chronic dynamic scapholunate instability with arthroscopic debridement and closed pinning.⁴⁹ At 33 months follow-up, there were 3 failures requiring additional surgery; 6 patients had good/excellent results and 2 fair/poor according to the MMWS system. Ruch et al. examined arthroscopic debridement of partial SL and LT ligament tears in 14 patients who had failed 6 months of conservative treatment. 11 out of 14 patients reported complete pain relief and 2 more patients reported occasional residual pain but were able to return to work within 7 weeks.⁵⁰

Recommendation

- Arthroscopic treatment of chronic SL or LT ligament tears, in the setting of dynamic instability may provide adequate symptom relief in the short term [overall quality: low]

Dorsal wrist ganglion cysts**Relevant anatomy**

Ganglion cysts are masses filled with mucous fluid that is similar to synovial fluid, but thicker.⁵¹ A one-way valve system between the joint and the ganglion has been proposed to allow synovial fluid into the cyst.⁵² Commonly, dorsal ganglion cysts arise superficially between the second and fourth extensor tendon compartments.⁵³

Importance of the problem

Ganglion cysts account for 50–70% of all soft tissue tumors of the hand and wrist.^{53–55} Ganglion cysts may cause pain, weakness, joint stiffness, and deformity as their size increases.^{56,57}

Question 7: Is there an advantage of arthroscopic excision compared to open technique in terms of recurrence?**Case clarification**

The patient's pain and swelling gradually resolved. Eight months after initial presentation to the Emergency Department, he noted a swollen area on the dorsum of his wrist. The area enlarged progressively with activity-related discomfort, especially with wrist extension.

Current opinion

Excision is indicated for symptomatic ganglion cysts of the wrist that recur following previous aspiration. Numerous retrospective studies have reported various recurrence rates following either open or arthroscopic excision of dorsal ganglion cysts.^{58–63} However, in the single prospective randomized trial by Kang et al., similar recurrence rates following these two procedures were reported at 1 year postoperatively.⁶⁴

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/):sensitivity search using keywords: "prospective" AND "ganglia" AND "arthroscopic," "prospective randomized trial" AND "ganglia" AND "arthroscopic," "recurrence" AND "ganglia" AND "arthroscopic"

Quality of the evidence*Level I*

- 1 RCT

Findings

The recurrence rate following dorsal ganglion excision was reported to be equal between the open and arthroscopic technique groups in a prospective randomized trial.⁶⁴ A total of 72 patients were included and followed for a year. The recurrence rate was 1% in both groups.

Recommendation

- There is no significant difference in recurrence of dorsal ganglion cysts following resection with either the open or the arthroscopic technique [overall quality: high]

Question 8: What are the complications associated with arthroscopic excision of a dorsal ganglion cyst of the wrist?

SL ligament injury is reported to complicate open excision of a dorsal ganglion cyst. However, arthroscopic resection has not been associated with this type of injury.^{65–67} Better visual approach to the ligament through the scope is a possible explanation.⁶⁸

Complications such as postsurgical hematomas or injury of contiguous nerves have been reported after arthroscopic

resection, but in numbers similar to those found after open surgical resection.⁶⁹

The arthroscopic technique has been reported to minimize side effects of a painful scar, and wrist stiffness commonly associated with open excision of the ganglion cyst.⁶⁶

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: "complications" AND "ganglia" AND "arthroscopy," "nerve" AND "ganglia" AND "arthroscopic," "grip strength" AND "ganglia" AND "arthroscopic"

Quality of the evidence

Level IV

- 5 case series

Findings

From 2000 to 2009 three different authors reported a total of 111 dorsal wrist ganglia treated with arthroscopic excision with at least 24 months of follow-up.^{58,62,63} At 2 years follow-up, only five patients experienced minor complications.

Two other case series reported results from 96 patients treated with arthroscopic resection of dorsal wrist ganglia. Postoperatively, only four patients experienced mild complications (extensor tendon irritation).^{66,69}

Recommendation

- Arthroscopic resection for dorsal wrist ganglia is a safe procedure with minor complications [Overall Quality: Low]

Summary of recommendations

- Wrist arthroscopy is useful to identify cartilage lesions associated with distal radius fractures
- Wrist arthroscopy may facilitate early diagnosis and treatment of soft tissue lesions associated with distal radius fractures
- The use of wrist arthroscopy may improve reduction of the articular surface of the radius compared to the use of fluoroscopy alone
- Functional outcomes may be improved by the use of arthroscopically assisted reduction compared to fluoroscopically assisted reduction alone
- MRA is not superior to wrist arthroscopy to detect TFCC tears
- Outcomes for arthroscopic repair or debridement of TFCC tears are equivalent to those of open treatment
- An arthroscopic procedure to address ulnar variance in addition to TFCC pathology can provide similar pain relief compared to a combination of arthroscopic debridement with ulnar shortening osteotomy

- Arthroscopic treatment of chronic SL or LT ligament tears, in the setting of dynamic instability may provide adequate symptom relief in the short term
- There is no significant difference in recurrence of the dorsal ganglion cyst following resection with either the open or the arthroscopic technique
- Arthroscopic resection for dorsal wrist ganglia is a safe procedure with minor complications

Conclusions

The judicious use of wrist arthroscopy in the management of distal radius fractures may facilitate the diagnosis of associated cartilage lesions, enable early diagnosis and treatment of concomitant soft tissue injuries, and enhance anatomic reduction of the articular surface leading to improved functional outcomes. MRA to diagnose TFCC tears is not superior to wrist arthroscopy. Wrist arthroscopy may facilitate treatment of peripheral TFCC tears with equal results compared to open repairs. An arthroscopic wafer procedure to address a central TFCC tear with ulnar positive variance may provide similar outcomes compared to a combination of arthroscopic debridement with ulnar shortening osteotomy. Debridement of SL or LT tears in patients with dynamic instability and chronic wrist pain, may improve symptoms in the short term. Arthroscopic excision for dorsal wrist ganglion cysts is a safe procedure, with no difference in terms of recurrence when compared to open technique.

Rheumatoid Wrist Reconstruction (Arthrodesis and Arthroplasty)

Warren C. Hammert¹ and Kevin C. Chung²

¹University of Rochester Medical Center, Rochester, NY, USA

²University of Michigan Medical School, Ann Arbor, MI, USA

Case scenario

A 45 year old woman with a history of rheumatoid arthritis (RA) is seen in the office for a consultation relating to her hands. She reports progressive difficulty using her hands over the last several months due to swelling and pain in her wrist, limited motion of her wrists and fingers, and progressive deformity of her fingers (Figures 115.1 and 115.2).

Relevant pathophysiology

The effect of RA on the ulnar wrist begins with the ulnocarpal joint. Synovitis stretches the ulnar carpal ligaments and the triangular fibrocartilage complex (TFCC), resulting in an unstable, dorsal dislocated distal ulna, so-called “caput ulna.”¹ This is accompanied by volar subluxation of the extensor carpi ulnaris (ECU) tendon, which leads to carpal supination because the ECU tendon now acts as more of a flexor rather than an extensor to stabilize the ulnar wrist. The incongruity of the distal radioulnar joint (DRUJ) results in pain with forearm rotation, and this is often the earliest presentation of a RA patient who seeks surgical consultation (Figure 115.3).

Involvement on the radial side of the wrist begins with proliferative synovitis in the region of the radioscaphocapitate ligament and attenuation of the volar radiocarpal ligaments.^{2,3} The weakening of the volar radial support ligament leads to flexion and rotatory subluxation of the scaphoid. When combined with the dorsal subluxation of the distal ulna and relative shortening of the radial wrist, the metacarpals will deviate radially, leading to ulnar deviation of the fingers.^{1,4}

Importance of the problem

RA is the second most common type of arthritis after osteoarthritis,⁵ affecting 0.8% of the adult population throughout the world.⁶ In the United States, RA afflicts 1.3 million adults, with a prevalence of 1.06% in women compared to 0.61% in men.⁷ RA is a progressive and debilitating condition with up to 70% of patients having hand and wrist impairment⁸ that may preclude many activities of daily living.^{9,10} In the United States, the cost associated with RA was estimated to be \$8.7 billion annually in 1996.¹¹

Openmirrors.com Although medical treatments have improved due to newer medications, not all patients have access to these medications and, for some, the disease progresses despite medical treatments. In addition, there is disagreement between rheumatologists and hand surgeons regarding the timing, indications, and outcomes for surgical treatment of rheumatoid hand and wrist conditions.¹²⁻¹⁴

This chapter will discuss the management of the osseous structures of the wrist—the radiocarpal and midcarpal joints and the DRUJ.

Top nine questions

Diagnosis

1. What are the presenting complaints for patients with RA affecting the wrist?
2. What modalities are used in the diagnostic process?

Treatment of the radiocarpal joint

3. What is the role of limited wrist arthrodesis?

Figure 115.1 PA picture of patient with RA affecting wrist.

Figure 115.2 Lateral picture of patient with RA affecting the wrist.

4. What is the role of total wrist arthrodesis?
5. What is the role of total wrist arthroplasty?

Treatment of the DRUJ

6. What is the role of the Darrach procedure?
7. What is the role of DRUJ arthrodesis (Suave–Kapandji procedure)?
8. What is the role of ulnar head arthroplasty?

Figure 115.3 Clinical example of patient with dorsally prominent ulna (caput ulna).

Outcomes/prognosis

9. What are the outcomes of rheumatoid wrist procedures?

Question 1: What are the presenting complaints for patients with RA affecting the wrist?

Case clarification

Some patients with RA will have complaints related to pain, swelling, appearance, or loss of motion of the affected wrist, whereas others will seek treatment for hand conditions and may not have any complaints regarding their wrists. The appearance of a destroyed wrist does not usually mean that the patient will complain of incapacitating wrist pain. Although some patients truly have isolated hand conditions, most will have conditions affecting the wrist that need to be treated prior to or simultaneously with the hand.

Recommendation

- It is important to listen carefully to the patient's concerns and address the issue that is most bothersome to the patient

Question 2: What modalities are used for diagnosis?

The criteria used to diagnose RA have been clearly defined and are not included in this chapter. Similar conditions, such as those of other inflammatory arthritides or conditions with similar clinical presentation, can be treated in the same manner as RA.

Recommendation

- Routine zero-rotation PA and lateral radiographs of the wrist are diagnostic and treatment recommendations can be made based on physical exams and radiographic findings. There is no evidence to suggest additional imaging or laboratory tests will enhance the RA hand assessment

Question 3: What is the role of limited wrist arthrodesis?**Case clarification**

The patient may be a candidate for limited wrist stabilizing procedures if the cartilage is intact.

Relevance

The midcarpal joint may be spared even with extensive involvement of the radiocarpal joint due to the paucity of ligaments in the region of the midcarpal joint.¹ Synovium is concentrated in areas with abundant ligaments and therefore, the midcarpal joint is not involved until late in the destructive process.

Radiocarpal changes begin with synovitis affecting the ligaments that stabilize the proximal row. The ligament laxity resulted in flexion of the scaphoid, rotatory changes of the lunate (either flexion or extension) and subsequent ulnar translocation of the lunate and in more severe cases, the entire carpus. Prior to midcarpal involvement, Openmirrors.com carpal fusion (either radiolunate or radioscapulolunate), along with synovectomy of the midcarpal joint, will stabilize the wrist and retain some wrist motion.

The advantage to including the scaphoid in the fusion mass is related to the greater surface area to provide a more predictable fusion. Because the scaphoid is a link between the proximal and distal rows, removal of the distal scaphoid when performing the radioscapulolunate fusion will unlock or separate the proximal from distal rows and allow better motion.^{15,16}

In the event that the articular cartilage of the scaphoid is free of disease, the fusion can be limited to the radiolunate joint. Although the fusion area is not as large, this procedure will prevent radial deviation and ulnar subluxation of the carpus, which can maintain alignment of the hand on the wrist and forearm.

Wrist motion following radiolunate or radioscapulolunate arthrodesis occurs through the midcarpal joint with a more oblique path of the capitate along the dart thrower's axis.¹⁷

Findings

Honkanen has shown maintenance of fusion with a functional arc of wrist motion (flexion 29°, 67% of preoperative value, and extension 34°, 92% of preoperative value) at over 5 years follow-up.¹⁸ Ishikawa has shown good long-

term results with decreased pain and increased grip strength at 10 years follow-up. Carpal collapse progressed, but this did not seem to affect the overall results.¹⁹

Recommendation

- Limited wrist arthrodesis can be considered when there is a need to stabilize the radiocarpal joint due to ulnar translocation of the carpus or when there is destruction of the radiocarpal joint and sparing of the midcarpal joint

Question 4: What is the role of total wrist arthrodesis?**Case clarification**

Patients with advanced radiographic involvement, or those with pain and minimal motion, are not likely candidates for limited wrist arthrodesis and should be treated with total arthrodesis (Figure 115.4) or wrist arthroplasty.

Current opinion

The position of arthrodesis has not been clearly delineated, with some authors recommending fusion in extension and ulnar deviation, whereas others prefer the neutral position to help maintain finger alignment.^{20,21} For those patients requiring bilateral wrist arthrodesis, one side should be fused in slight extension and the other in slight flexion, because the flexion posture will help in perineal care.²²

Recently, Cavaliere and Chung performed a systematic review of arthrodesis and arthroplasty for the rheumatoid wrist. Of 1750 citations, 18 arthroplasty and 20 arthrodesis studies revealed better outcomes and more reliable pain relief following arthrodesis. Satisfaction was high in both groups, with a higher complication and revision rate in the arthroplasty group. Interestingly, of the 14 studies reporting range of motion data in the arthroplasty group, only 3 showed an average wrist arc of motion within the functional range.²³

Recommendation

- Total wrist arthrodesis should be considered for patients with severe destruction of the wrist secondary to rheumatoid disease

Question 5: What is the role of total wrist arthroplasty?**Case clarification**

Patients often have both wrists affected and may require procedures on both sides. They would often prefer a motion-preserving procedure, at least on one side, if given the choice with similar outcomes regarding pain relief and surgical risks.

Figure 115.4 Preoperative and postoperative PA radiographs of total wrist arthrodesis.

Figure 115.5 Preoperative and postoperative PA radiograph of total wrist arthroplasty.

Current opinion

Wrist arthroplasty (Figure 115.5) is an option for patients desiring to retain some motion and may be most beneficial when patients require treatment of both wrists. Newer designs have minimized some of the problems with earlier implants, but loosening and revision procedures remain common.

Findings

Murphy et al. compared arthroplasty to arthrodesis in 51 wrists and reported similar complication rates between the two groups, but the arthroplasty group had an easier time with personal hygiene.²⁴

Divelbiss et al. reported early results of arthroplasty with the Universal wrist prosthesis in 19 patients (22 wrists). Eight patients had 2 year follow-up and 14 patients had 1 year follow-up. Total wrist arc of motion and DASH scores improved, with three prostheses that became unstable and required further treatment.²⁵

Cavaliere and Chung surveyed members of the American Society for Surgery of the Hand practicing in the United States to determine surgeons' attitudes and preferences toward wrist arthroplasty and arthrodesis. They reported both arthroplasty and arthrodesis are preferable to nonoperative management, and there is a slight increase in quality-adjusted life years (QALY) in the arthroplasty group, but not great enough to make arthroplasty the preferred treatment.²⁶

Recommendation

- Currently, there is no evidence to support arthroplasty being superior to arthrodesis, arthroplasty may be considered an acceptable option. The best indications appear to be for patients requiring bilateral procedures and for those patients with a strong preference to retain motion, with the understanding that additional procedures are likely for treating complications such as implant dislocation or loosening

Question 6: What is the role of the Darrach procedure when the DRUJ is involved?

Case clarification

In addition to pain and limited motion at the radiocarpal joints, patients will often present with limited or painful forearm rotation, synovitis, and arthritis at the DRUJ.

Figure 115.6 PA radiograph following Darrach resection of distal ulna.

Relevance

The DRUJ is often involved early in RA, initially with synovitis and subsequent progress to instability with associated carpal supination and volar and ulnar subluxation of the carpus. The ECU tendon displaces ulnar to the ECU groove and subsequently becomes a flexor, rather than an extensor, which further aggravates the deformity. This leads to DRUJ instability (caput ulna) and when untreated, can result in attritional ruptures of the extensor tendons.

Current opinion

In cases with synovitis without instability or arthritis of the DRUJ, synovectomy alone may be adequate, but more commonly, a procedure at the DRUJ is combined with synovectomy. The Darrach procedure involves resection of the ulnar head proximal to the sigmoid notch and often is stabilized with local tissue (Figure 115.6). A variety of techniques have been described to stabilize the ulna stump, including using the joint capsule, ECU, FCU, pronator quadratus and a combination of these tissues.^{27–30} These stabilization procedures help minimize instability on the dorsal/volar plane, but do not prevent radial/ulnar impingement when the wrist is loaded.³¹ The Darrach procedure is more suitable for lower-demand patients, such as RA patients.

Findings

There is limited data involving outcomes of the Darrach procedure for patients with RA. Fraser et al. reported outcomes for patients with Darrach resections for RA and

post-traumatic conditions. Although motion was better in the post-traumatic group (both preoperatively and postoperatively), pain relief was significantly better in the RA group (86% to 36%).³²

Recommendation

- The Darrach procedure is suitable for lower-demand patients, such as RA patients.

Question 7: What is the role of DRUJ arthrodesis (Suave–Kapandji procedure)?

Case clarification

When arthritis and instability are present at the DRUJ and sufficient bone is present in a younger patient, there may be a theoretical advantage to maintaining the distal ulna and the TFCC attachments to stabilize the ulnar carpal joint.

Relevance

The Suave–Kapandji (SK) procedure (Figure 115.7) fuses the ulnar head to the sigmoid notch of the radius and creates an osteotomy of the ulna proximal to the DRUJ with resection of approximately 1 cm of bone, thus allowing forearm rotation through the site of the osteotomy. The ulnar stump can be stabilized similar to the Darrach procedure and the potential for instability of the ulnar stump is similar for both procedures. The theoretical advantage of this procedure over the Darrach procedure is the maintenance of the ulnar head and TFCC, which may provide stability to the ulnar side of the carpus.

Findings

Vincent et al. reported on 21 wrists in 17 patients with an average follow-up of 39 months. There was good pain relief and subjective stability. One patient with a Darrach procedure on one side and SK procedure on the other preferred the SK side.³³

Recommendation

- There is no evidence to indicate whether the Darrach procedure or the SK procedure is better

Question 8: What is the role of implant arthroplasty at the DRUJ?

Case clarification

Younger, more active patients may desire a more anatomic reconstruction than a resection of the ulnar head. In addition patients may present with pain from instability of the ulnar stump in spite of attempted soft tissue reconstruction.

Relevance

Ulnar head implant arthroplasty has gained popularity with the advent of newer materials and techniques that

Figure 115.7 Preoperative and postoperative radiographs of DRUJ arthrodesis (Suave-Kapandjii procedure).

have been successfully used for the painful and unstable DRUJ in post-traumatic conditions. It has also been used as a salvage procedure for the failed Darrach when radial-ulnar impingement occurs.

The procedure involves resection of the ulnar head and replacement with an endoprosthesis. The newer generation implants approximate the normal anatomy, but rely to some degree on the soft tissue support around the implant to maintain stability.

Findings

Schecker has developed an ulnar prosthesis with an ulnar stem, constrained to the sigmoid notch through a link to the radius, which eliminates the need for soft tissue stabilization.^{34,35} Additional designs are available,³⁶ but the role of these implants in patients with RA has not been clearly delineated.

Recommendation

- So far, there are no prospective studies evaluating arthroplasty for the DRUJ, and case series and reports are from post-traumatic or degenerative cases rather than in patients with RA.

Question 9: What are the outcomes of rheumatoid wrist procedures?

Relevance

Prospective randomized studies for RA surgery are sparse, and high-level evidence studies for the rheumatoid wrist conditions are similarly deficient. Medical management is improving and thus the number of surgical procedures for the RA hand is declining.³⁷

Outcomes for procedures in the hand, specifically silicone MCP joint arthroplasty, have been published and hopefully meaningful data regarding outcomes of wrist procedures will be available in the near future.³⁸⁻⁴¹

Summary of recommendations

- It is important to listen carefully to the patient's concerns and address the issue that is most bothersome to the patient
- Routine zero-rotation PA and lateral radiographs of the wrist are diagnostic and treatment recommendations can be made based on physical exams and radiographic findings. There is no evidence to suggest additional imaging or laboratory tests will enhance the RA hand assessment
- Limited wrist arthrodesis can be considered when there is a need to stabilize the radiocarpal joint due to ulnar translocation of the carpus or when there is destruction of the radiocarpal joint and sparing of the midcarpal joint
- Total wrist arthrodesis should be considered for patients with severe destruction of the wrist secondary to rheumatoid disease
- Currently, there is no evidence to support arthroplasty being superior to arthrodesis, arthroplasty may be considered an acceptable option. The best indications appear to be for patients requiring bilateral procedures and for those patients with a strong preference to retain motion, with the understanding that additional procedures are likely for treating complications such as implant dislocation or loosening
- The Darrach procedure is suitable for lower-demand patients, such as RA patients
- There is no evidence to indicate whether the Darrach procedure or the SK procedure is better
- So far, there are no prospective studies evaluating arthroplasty for the DRUJ, and case series and reports are from post-traumatic or degenerative cases rather than in patients with RA.

Conclusions

Unfortunately, the evidence regarding surgical treatment of the rheumatoid wrist consists of level IV and V data, which are based on retrospective case reviews and surgical techniques. A review of the Cochrane Database revealed only two reports and neither involved surgical treatment—one reviewed intraarticular steroids and splints whereas the second reviewed the use of the TENS unit for the management of rheumatoid hand conditions. There are currently no level I, II, or III studies regarding rheumatoid wrist conditions or addressing the questions above. With improvements in the medical treatment of rheumatoid arthritis, it is unlikely that there will be any level I or II studies for these conditions. Future research efforts will likely be directed towards cost-effectiveness and outcomes for existing procedures.^{42–44}

Kristin B. de Haseth and David Ring

Massachusetts General Hospital, Boston, MA, USA

Case scenario

A 31 year old woman presents to the Emergency Department after an injury playing field hockey. A direct blow from another hockey stick caused immediate pain and swelling of her right small finger. She is a keen athlete, has no medical history and does not take any medication.

On examination, she has diminished range of motion (ROM) of her right dominant small finger and a normal neurovascular exam.

resulted in almost 32.5 million days of restricted activity and over 9.5 million days off work. The estimated cost of these injuries was approximately \$18.5 million.

Hand fractures may be complicated by deformity from no treatment, stiffness from overtreatment, and deformity and stiffness from poor treatment.⁵ It is becoming increasingly clear that success of a procedure is also determined by the psychological and economic impact of the disease and its treatment on the patient's life.

Relevant anatomy

The hand skeleton is made up of 5 metacarpals and 14 phalanges. The metacarpophalangeal joints (MCPJ) and interphalangeal joints (IPJ) are stabilized through the volar plate, the collateral ligaments and the interosseous ligaments. Shortening, angulation, and rotation are the principle elements of deformity and may be seen in individually or in combination.

Importance of the problem

Metacarpal and phalangeal fractures are the most common injuries of the upper extremity.¹⁻³ The incidence of finger fractures peaks between the ages of 10 and 40 years. They are more common in males and are common sports injuries.⁴

Fractures of the metacarpals and phalanges have significant economic consequences. Kelsey et al.² reported that that were over 17.6 million upper extremity injuries that

Top six questions

Openmirrors.com

Diagnosis

1. Can observers agree on radiological characterization and classification of hand fracture?

Treatment

2. When should patients with extra-articular metacarpal fractures start exercises?

3. Should open reduction and internal fixation (ORIF) or a dynamic external device be used for management of unstable proximal interphalangeal joint (PIP) fracture-dislocations?

4. Which is a better treatment for extra-articular metacarpal and phalanx fractures: pinning or ORIF?

5. What is the best treatment option for closed, either bony or tendinous, mallet finger injuries?

Prognosis

6. What are the predictors of motion and function after plate and screw fixation of a finger fracture?

Question 1: Can observers agree on radiological characterization and classification of finger fractures?

Relevance

Reliable characterization and classification of hand fractures might influence both research and patient care.

Current opinion

There is a high degree of variability in radiographic assessment in interobserver reliability and intraobserver reproducibility of hand fractures.⁶⁻⁸

Finding the evidence

- PubMed (<http://www.ncbi.nlm.nih.gov/pubmed>) sensitivity search using keywords: "finger fracture," "metacarpal fracture," "intra/interobserver reliability," "imaging," "diagnostic," "radiography," "computed tomography"
- Ovid MEDLINE with search term as above

Quality of the evidence

Observational studies do not have levels of evidence.

Findings

In one study three observers independently evaluated radiographs of 32 patients with small finger metacarpal neck fractures.⁹ Six weeks later the process was repeated to evaluate intraobserver variability. The overall average for the difference in angles measured between two surgeons was 10.9°, with a SD of 9.2°. The mean weighted kappa coefficient for was 0.18 for interobserver variability and 0.26 for intraobserver variability. The mean kappa coefficient of intraobserver agreement on treatment recommendations was 0.36.

Another study assessed the reliability of the AO classification using 100 radiographs of hand fractures classified by 9 observers.¹⁰ Using Cohen's kappa, the overall interobserver and intraobserver agreement was 0.93 and 0.94 respectively for fractured bone; 0.8 and 0.92 respectively for fractured bone segment; and 0.44 and 0.62 respectively for fracture type.

In another study there was no significant difference between cone beam CT (CBCT) and multislice CT (MSCT) for preoperative evaluation of 57 articular phalanx fractures.¹¹ All 57 fractures were correctly classified on the basis of articular involvement at CBCT compared to MSCT (100% sensitivity and specificity) with no statistically significant difference. CBCT identified 92 out of 103 fracture fragments (89.3%) compared to MSCT. The mean diameter of missed fragments was 0.9mm at MSCT. None of the bone fragments missed by CBCT was located within the joint, in no cases the choice of the correct treatment prevented. Agreement among three observers was very good (kappa = 0.89–0.96).

Recommendations

- Consistent with other fractures, radiographic classification has limited reliability, which might improve with more sophisticated imaging techniques [overall quality: very low]
- It is unclear whether observer variation affects recovery.

Question 2: When should a patient with an extra-articular metacarpal fracture start exercises?

Case clarification

The fracture involves the small finger metacarpal neck.

Relevance

Immediate initiation of exercise might result in better final full ROM and function of the hand, since bone healing and recovery of ROM should occur simultaneously.

Current opinion

Most fractures need some protection, but immobilization risks tendon and joint adhesions. The balance between mobilization and immobilization is a matter of clinical judgment.

Finding the evidence

- Pubmed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using keywords: "metacarpal fracture," "intra-articular metacarpal fracture," "extra-articular metacarpal fracture," "exercise," "rehabilitation," "mobilization"
- Cochrane Database, using the same search terms

Quality of the evidence

- Level I: 2^{12,13}
- Level II: 1¹⁴
- Level III: 3¹⁵⁻¹⁷

Findings

A Cochrane review¹⁸ including 1 level I,¹² 1 level II,¹⁴ and 1 level III study¹⁵ addressing treatment of small finger metacarpal fractures with immobilization or early motion identified no differences in final motion 3 months or greater after fracture, but some differences at earlier time points.

Another level I trial involving stable metacarpal shaft fractures found better motion with a compression glove than with plaster splint immobilization after 2 and 3 weeks (28° difference, $p < 0.01$; 23° difference, $p = 0.001$).¹³

Two level III trials comparing cast immobilization and a custom mold plaster fracture brace found significantly better wrist, MCP and PIP motion after 3 and 4 weeks respectively in the brace group, but no differences after 3 months.^{16,17}

Recommendation

- Early mobilization does not affect the final outcome of closed metacarpal fractures and can be utilized at the discretion of patient and surgeon when there is motivation to avoid immobilization [overall quality: high]

Question 3: Should ORIF or a dynamic external device be used for management of unstable PIP fracture-dislocations?**Case clarification**

There is a fracture-dislocation of the PIP joint.

Relevance

Unstable dorsal fracture-dislocations of the PIP joint are difficult to manage.

Current opinion

There is wide variation in the treatment of these injuries.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using keywords: "proximal interphalangeal joint dislocation fracture," "treatment," "open reduction and internal fixation," "dynamic external device"

Quality of evidence

- Level I: 1¹⁹
- Level IV: 10⁸⁻¹⁷

Findings

Ten level IV retrospective case series addressed a single treatment technique.²⁰⁻²⁹ The average arc of PIP joint motion was 88.7° with a range from 70° to 165°. Complication rates ranged from 8% to 63%. There was no clear advantage of one approach over another.

One level I randomized controlled trial (RCT) compared percutaneous Kirschner wire (K-wire) fixation vs. ORIF with cerclage wire or lag screw.¹⁹ The arc of motion of the PIP joint was significantly better in the percutaneous K-wire fixation group (average flexion contracture to average flexion 60–108°) than in the screw fixation group (24–90°) or the cerclage fixation group (45–60°; $p = 0.05$). According to the patient-rated outcome, K-wires were superior to ORIF treatment ($p = 0.02$).

Recommendation

- There is insufficient evidence to recommend a specific operative treatment technique for unstable dorsal fracture-dislocations of the PIP joint. The data from one randomized trial suggest that less invasive treatment has advantages, at least in the short term [overall quality: high-moderate]

Question 4: Which is a better treatment for extra-articular metacarpal and phalanx fractures: pinning or ORIF?**Case clarification**

Radiographs reveal a displaced extra-articular fracture of the proximal phalanx.

Relevance

Although ORIF with plates and screws provide excellent stability and allows early motion, it causes additional soft tissue trauma and can lead to extensor tendon adhesions and objectionable scarring. Pinning, on the contrary, may eliminate such complications; however, it is uncertain whether the results are as satisfactory.

Current opinion

The ideal treatment of extra-articular finger fractures remains controversial. Despite the conceptual advantages of ORIF in providing stability and alignment, pinning frequently offer a good alternative.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using keywords: "extra articular hand fracture," "extra articular phalanx fracture," "extra articular metacarpal fracture," "treatment," "pinning," "K-wire fixation," "open reduction and internal fixation"
- MeSH search, using search terms as above

Quality of evidence

- Level I: 1³⁰
- Level III: 2^{31,32}

Findings

A level I prospective randomized trial comparing percutaneous K-wire fixation with open reduction and lag screw fixation of long oblique proximal phalanx fractures found no significant differences in motion, strength, pain, or radiographic alignment.³⁰

One level III study compared retrospective cohorts of patients with metacarpal fractures treated with intramedullary nail fixation or extra-articular with plate and screw fixation and found no significant differences in total active motion (TAM) or DASH scores regardless of fracture location.³¹

A level III nonrandomized controlled comparison of percutaneous transverse K-wire fixation and IM K-wiring of small finger metacarpal neck fractures found no statistically significant difference in TAM, grip strength, and fracture union.³²

Recommendation

- There are insufficient data to recommend one fixation technique over another [overall quality: high-moderate]

Openmirrors.com

Question 5: What is the best treatment option for closed, either bony or tendinous, mallet finger injuries?

Case clarification

On examination, the distal interphalangeal joint (DIPJ) of the patient's index finger is flexed 60° and she is unable to extend this joint. There is an avulsion fracture of the dorsal distal phalanx (mallet fracture).

Relevance

Mallet fractures are common.

Current opinion

Most hand surgeons believe that nonoperative care is the best option for treatment of mallet injuries in the absence of subluxation or a large intra-articular fracture.³³

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using keywords: "mallet finger," "treatment"
- PubMed (www.ncbi.nlm.nih.gov/pubmed) clinical queries search/systematic reviews, using search terms as above
- Cochrane Database, using search terms as above

Quality of evidence

- Level II: 3³⁴⁻³⁶
- Level III: 2^{37,38}

Findings

A Cochrane review³⁹ included one level II study³⁴ which prospectively randomized patients with mallet finger injuries who received either closed pinning or splint treatment. No statistically significant difference was found between the participants (surgical vs. splint: 10.5% vs. 13.6% had complications)

A level II nonrandomized prospective cohort study compared conservative and operative treatment of intra-articular mallet fingers.³⁵ In the operated group an outcome of 10–20° extension deficit occurred in 38% and a 10–15° flexion deficit occurred in 19%. In the splinting group the numbers were 33% and 8% respectively, and in the group which not received treatment they were 100% and 20%. Bony union was seen in 95.3% of these patients.

A level III retrospective study noted a complication rate of 53% in the surgically treated patients (most long-term) and 45% in the splinting group (almost always transient).³⁸ In a similar level III study complications were found in 22% of the operative group and 28.6% of the splinting group (20% due to noncompliance).³⁷ Degenerative changes were comparable.

Geyman et al.³⁶ pooled literature regarding conservative vs. surgical treatment of closed mallet finger injuries; suc-

cessful outcome was found in 77% in the conservative group, whereas 85% in the surgical group.

Recommendation

- Nonsurgical splinting is a safe and reliable treatment for most mallet injuries, whether bony or tendinous [overall quality: moderate]

Question 6: What are the predictors of motion and function after plate fixation of a finger fracture?

Case clarification

The patient has a crush injury, with a comminuted metacarpal and proximal phalanx fracture and a wound. The surgeon used a plate and screws to repair the fracture.

Relevance

There is a need to balance the value of stable fixation with the soft tissue damage needed to apply internal fixation.

Current opinion

There is debate regarding operative strategies for many hand fractures.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using keywords: "screw and plate fixation," "internal fixation," "predictors outcome," "hand surgery," "finger fracture"

Quality of evidence

- Level III: 2^{40,41}
- Level IV: 4⁴²⁻⁴⁵

Findings

Studies (two at level III^{40,41} and two at level IV^{42,43}) assessing the results of plate fixation of metacarpal and phalangeal fractures found better motion among metacarpal fractures compared to phalangeal fractures,^{40,42} closed compared to open fractures;^{40,41} extra-articular compared to intra-articular fractures ($p < 0.05$);⁴² transverse metacarpal fractures compared to other metacarpal fracture patterns ($p = 0.04$);⁴³ fractures fixed with standard plates compared to those repaired with mini condylar plates ($p = 0.004$ respectively $p = 0.006$);⁴⁰ and younger compared to older patients.^{41,42} Comminution and fracture location did not affect results.^{40,44}

With regard to fracture union, in level IV studies healing problems were more common among transverse compared to nontransverse fractures,^{42,43} phalangeal compared to metacarpal;⁴⁴ and manual workers compared to nonmanual workers.^{42,45} Nonunion was not associated with soft tissue injury or plate type.^{42,45}

Recommendations

- Predictors of final motion after plate and screw fixation of a metacarpal and phalangeal fracture are the age of the patient, open fracture/soft tissue injury, plate type, intra-articular fracture, and phalangeal fractures [overall quality: moderate–low]
- Predictors of nonunion include fracture location (proximal phalanx), pattern (transverse fractures) and occupation (manual workers) [overall quality: moderate–low]

Summary of recommendations

- Consistent with other fractures, radiographic classification has limited reliability, which might improve with more sophisticated imaging techniques
- Early mobilization does not affect the final outcome of closed metacarpal fractures and can be utilized at the discretion of patient and surgeon when a faster recovery is desired
- There is insufficient evidence to recommend a specific operative treatment technique for unstable dorsal fracture-dislocations of the PIPJ. The data from one randomized trial suggest that less invasive treatment has advantages at least in the short term
- For extra-articular finger fractures there are insufficient data to recommend pinning fixation technique over K-wire fixation
- Nonsurgical splinting is a safe and reliable treatment for most mallet injuries, whether bony or tendinous
- Predictors of final motion after plate and screw fixation of a metacarpal and phalangeal fracture are the age of the patient, open fracture/soft tissue injury, plate type, intra-articular fracture, and phalangeal fractures
- Predictors of nonunion include fracture location and pattern and occupation

Conclusions

Data regarding management of finger fracture varies from RCTs to case series. For closed metacarpal fractures, immobilization does not improve outcomes. With regards to specific operative technique for PIP joint fracture-dislocations and extra-articular finger fractures there is insufficient evidence for superiority of any one technique.

Further investigations, specifically high-quality comparative studies, are needed for further elucidation regarding adequate management of finger fractures.

Prevention of Adhesion in Flexor Tendon Surgery

Filippo Spiezia¹, Vincenzo Denaro¹, and Nicola Maffulli²

¹Campus Bio-Medico University, Rome, Italy

²Barts and The London School of Medicine and Dentistry, London, UK

Case scenario

A 35 year old manual worker is brought to the Emergency Department with a laceration of his left hand after a slip in the factory where he works. The bleeding is arrested, repair of the flexor tendons of the left ring finger is performed by a local surgeon, and the patient is splinted. After 4 weeks of splinting, the patient is seen by a hand surgeon. The hand is stiff, and he is currently unable to hold objects. He is neurovascularly intact. Peritendinous adhesions of the digital flexor tendons are diagnosed.

Openmirrors.com Stegler et al. classified the degree and extent of adhesions (see box).⁵

Relevant anatomy and physiology

Tendons consist mainly of collagen. Water, proteoglycans, and cells constitute the matrix. The composition of proteoglycans produced by cells changes in the pressure-bearing areas compared to the tension-transmitting areas within tendons. For example, chondroitin sulfate is found predominantly in the pressure contact areas, whereas dermatan sulfate is dominant in the tension-transmitting areas. The differences in the type and proportion of proteoglycans in the tension and pressure-bearing segments of the tendon are related to the functional needs of the tissue, and this may play a role in the formation of adhesions following tendon injury and repair.¹ Tendon healing occurs through a combination of intrinsic and extrinsic processes. Intrinsic healing is the result of the activity of tenocytes within the tendon itself, and it is facilitated by appropriate nutrition to the tendon itself. Chemotaxis allows extrinsic healing through the migration of specialized fibroblasts into the defect from the ends of the tendon sheath.² Synovial fluid

diffusion also provides an additional nutritional source for the intrinsic healing process.³

The development of adhesions is not directly stimulated by tendon injuries. Damaged flexor tendons with the ends retracted and rounded which lie freely within the sheath have no adhesions. Immobilization also does not lead to an adhesive response from the digital sheath. On the contrary, excision of the synovial sheath followed by immobilization most frequently results in an adhesive reaction. It has been also found that high degrees of trauma to the synovial sheath and gaps of 3 mm or more correlate with an increased rate of adhesion formation.⁴

Classification of adhesions

- **Grade 0:** Complete absence of adhesions
- **Grade I:** Thin, avascular, filmy, and easily separable
- **Grade II:** Thick, avascular, and limited to the site of anastomosis
- **Grade III:** Thick, vascular, and extensive

Importance of the problem

One of the main problems in hand surgery is peritendinous adhesions after repair of an injury to the digital flexor tendons. Although adhesions are part of the healing process, they may produce functional disability following the biological response of the tendon to injury.⁶ The management of this condition is challenging, and has led to an intensive search for modified surgical therapies and various

adjuvant therapies to prevent adhesion formation without compromising digital function. Different options have been proposed, including physical, surgical, and pharmacological treatment. However, the scientific evidence behind these methods should be carefully evaluated, because they are not necessarily in routine clinical practice. This chapter reviews these options, and evaluates the scientific evidence behind them.

Top four questions

Questions from the patient

1. Will I be able to hold objects and to use the hand again?
 - Yes, you will be able to use your hand after proper management and rehabilitation, although a strength deficit of the hand may persist
2. Will I be able to take part in sport activities again?
 - Yes, but it may be 3–6 months before you can do
3. How long does it take to fully recover?
 - It may take 6 months

Questions from family

4. Will he be able to work again?
 - Yes, your relative will be able to work again after proper management and rehabilitation, although a strength and movement deficit of the hand may persist

Case clarification

The flexor tendons are repaired using sutures. After the operation, the patient's hand was put in a splint. After 4 weeks, the hand surgeon diagnosed hand flexor tendon adhesions.

Current opinion

Current opinion suggests that the majority of surgeons use options including physical, surgical, and pharmacological treatment.

Finding the evidence

- PubMed, MEDLINE, CINAHL, and Embase were searched using the keywords: "tendon adhesion prevention," "tendon healing," "adhesion prevention in tendons," "adjuvants for adhesion prevention"
- Studies detailing the use of surgical, pharmacological, and nonpharmacological agents for adhesion prevention in

digital flexor tendons were identified, and their bibliographies were thoroughly reviewed to identify further related articles. This search identified studies which investigated the use of various pharmacological agents in adhesion prevention in digital tendons

- We excluded studies in languages other than English, studies not dealing with digital tendons, studies not reporting on adhesion prevention, case reports and letters to the editor.

Quality of the evidence

Most studies have been performed in animals, with very few human trials. This could potentially affect the quality of the evidence, because poor methodological standards in animal studies makes difficult to translate the positive results to the clinical domain. We found only a few randomized controlled trials, and the quality of the remaining studies is to be considered inferior to these.

Findings

Different options to manage adhesions are now available. Changes in surgical and postoperative rehabilitation techniques, modulation of inflammatory response and growth factors which may promote scarring through pharmacological agents, mechanical barriers between the tendons and the proliferating tissue, use of ultrasound and electromagnetic therapy, and, recently, gene therapy have all been explored.

Surgical management

Modern knowledge of tendon structure, nutrition, and biomechanical properties, and studies of tendon healing and adhesion formation, have produced various modifications of surgical management of tendon injuries.

One of the surgical techniques used to promote tendon healing decreasing the rate of adhesions is multistrand repair. Commonly the tendon is repaired using a two-strand technique.⁷ As the strength of a tendon repair is proportional to the number of suture strands that cross the site of rupture, it is now common to perform repairs with four, six, or even eight strands, allowing early mobilization, which decreases rupture rate. A greater number of suture strands means a more technically demanding procedure, and consequently more surgical handling of the tendon and a larger amount of suture material on the surface of the tendon.⁸

The effect of increasing strand numbers on the healing or adhesion response in tendons is not clearly known. Even though no significant differences have been identified,⁹ it

is reasonable that suture techniques with high friction may cause more adhesion formation than lower-friction techniques.¹⁰ Most studies in this field have been performed in animal models, and there is still a lack of human trials.

Another dilemma is whether or not to repair the tendon sheath at the site of rupture. Sheath closure following flexor tendon repair is common.¹¹ It has been proposed that a lacerated tendon may heal through its intrinsic cellular processes without adhesion formation,¹² because flexor tendons are mainly nourished through synovial diffusion in the within the region of synovial sheaths.¹³ Repair of the sheath may preserve nutrition of the tendons, allowing a smooth gliding surface and decreasing peritendinous adhesions.¹⁴

Sheath closure does not seem to improve tendon gliding function.¹⁵ Postoperative mobilization has been shown to decrease adhesion formation and to improve function after flexor tendon repair.¹⁶ However, the best mobilization strategy has not yet been identified.

When a flexor tendon injury occurs in the area of the major pulleys, the outcome of the repair is often unpredictable. There is a controversy between surgeons about performing a pulley incision or pulley plasty.

Incision of the pulley may improve the excursion of the flexor digitorum profundus (FDP) tendon and decrease the work of digital flexion over pulley closure. However, Kapandji pulley plasty did not increase tendon excursion and decrease the work compared with a simple pulley incision. After the repair, adhesions have been shown to be more severe with pulley plasty or closure than with pulley incision.¹⁷

Recommendation

- For the problem of simultaneous repair in simultaneous ruptures of FDP and flexor digitorum superficialis (FDS), the literature suggests that it is better to repair only the FDP with regional excision of FDS when both tendons are injured in zone 2C [overall quality: moderate]

Pharmacological agents

Pharmacological adjuvants aim to increase the recovery and function in hand tendons after injury or surgery, and can be divided into two categories: drugs and barriers. Nonsteroidal anti-inflammatory drugs (NSAIDs) competitively inhibit cyclooxygenase, an enzyme essential for the metabolism of arachidonic acid (AA) to prostaglandins; all these are involved in the inflammatory process which leads to adhesion formation.¹⁸ Several studies have shown that NSAIDs are likely to inhibit the formation of significant postoperative adhesions in a dose-dependent fashion.

Hyaluronic acid (HA) is a physiologic component of the synovial fluid, and has been suggested to play a role in healing of a variety of connective tissues, including injured

tendons.¹⁹ However, some human studies did not show beneficial effects.²⁰

5-Fluorouracil (5-FU) also seems to play a role in reduction of adhesion formation, maybe affecting cell proliferation,²¹ or reducing extracellular matrix molecules and growth factor production.²² 5-FU may have a modulating effect on cellular activity without preventing cell proliferation. This could reduce adhesion formation without preventing wound healing. The proliferative and inflammatory responses can be significantly reduced in tendons treated with 5-FU, especially reducing cellular cytokine response and in the activity of the known pro-scarring agent, transforming growth factor beta (TGF- β).²³

Human amniotic fluid (HAF) contains hormones, cytokines, and polypeptide growth factors that may have an effect on cell proliferation and differentiation. The exact role of amniotic fluid in preventing adhesion is not clear, but it has been suggested to have an inhibitory effect on fibroblast proliferation. All the evidence comes from animal studies.²⁴

TGF- β is a cytokine involved in wound healing and in the pathogenesis of excessive scar formation.²⁵ TGF- β stimulates chemotaxis, promotes angiogenesis, and regulates a wide spectrum of matrix proteins. In animal models, TGF- β accelerates wound healing. However, this effect may result in pathologic fibrosis, with excessive disordered collagen deposition and tendon adhesions.²⁶ Inhibitors of TGF- β may reduce adhesion formation. TGF- β inhibition using a neutralizing antibody was effective in blocking TGF- β -induced collagen I production in cultured flexor tendons.²⁷

Combinations of different substances have been also tried to prevent adhesions. For example, amniotic membrane, dipalmitoyl phosphatidylcholine, carboxymethylcellulose, and NSAIDs have been tried in animal models.

Chemical adjuvants such as alginate solution, collagen synthesis inhibitor (CPHI-I), enriched collagen solution, plant alkaloid halofuginone, human-derived fibrin sealant, and topical beta-aminopropionitrile have been studied for their potential role in preventing adhesions.²⁸

Recommendation

- NSAIDs are likely to inhibit the formation of significant postoperative adhesions in a dose-dependent fashion, but the effects of other pharmacological agents are controversial [overall quality: moderate]

Mechanical barriers

The cellular activity of intrasynovial flexor tendons may be specially adapted to intrasynovial environments. Thus, reconstruction of damaged flexor tendon sheaths with a biocompatible, diffusible membrane may not interfere with the nutrition and healing of repaired flexor tendons. Furthermore, acting as a barrier between surrounding

tissues and the repaired tendon, an interposed membrane may be able to further reduce the formation of adhesions.²⁹ This concept has led to the development of several chemical barriers to reduce adhesion prevention in digital tendons.

Expanded polytetrafluoroethylene (e-PTFE) has been used for reconstruction of tendon sheath and pulleys with promising results, and to decrease the formation of adhesions.³⁰ Other materials tested in animal models³¹ are hydroxyapatite, HA membrane, polyvinyl alcohol hydrogel (PVA-H), and bovine pericardium.

Recommendation

- The use of e-PTFE for reconstruction of tendon sheath and pulleys is promising [overall quality: moderate]

Ultrasound and electromagnetic radiation

Ultrasound therapy and pulsed electromagnetic fields have also been investigated in animals, with controversial results. Ultrasound may interact with one or more components of inflammation, improving the time of resolution of inflammation. Other effects have been shown *in vitro*, such as accelerated fibrinolysis, stimulation of macrophage-derived fibroblast mitogenic factors, heightened fibroblast recruitment, accelerated angiogenesis, increased matrix synthesis, more dense collagen fibrils and increased tissue tensile strength.³¹

Ultrasound may also have nonthermal effects including cavitation and acoustic microstreaming, which may play a role in the management of soft tissue lesions and adhesion prevention than the thermal effects. These effects may stimulate tissue repair. Human studies suggest regression of peritendinous adhesion between the tendon and skin, an increased range of movement, advanced scar maturation and decreased amount of inflammatory infiltrate.³¹

Recommendation

- Ultrasound may improve the time needed to resolve inflammation [overall quality: moderate]

Gene therapy

In the near future, with the delivery of growth factor genes, gene therapy may improve the healing of injured digital tendons. Adenoviral, adeno-associated viral (AAV), and liposome-plasmid vectors have been used to deliver genes to tendons to improve its healing. Unfortunately, clinical evidence is still uncertain at present.³²

Summary of recommendations

- The need to develop and use in clinical practice an optimal method for the prevention of adhesions in the

flexor tendons of the hand is a major problem in hand surgery

- Although recent advances have been made in the study of prevention of adhesions in flexor tendons, it is still unclear which is the best strategy to manage the problem
- At present, early postoperative mobilization of digits after tendon injury and repair is the only clinically justifiable treatment, although the best method of mobilization remains controversial

Conclusions

New pharmacological and nonpharmacological modalities, and changes in surgical techniques proposed in recent years, need to be tested in more controlled human trials.

B. Jane Freure and Mike Szekeres

St Joseph's Health Care, London, ON, Canada

Case scenario

Steve was carving a pumpkin with his children 9 days ago when the knife slipped and he cut the flexor tendons at the level of the proximal phalanx on his second, third, and fourth fingers on his right dominant hand, as well as cutting off some of the skin on his right thumb. He immediately went to his local hospital where the treating physician achieved hemostasis of the superficial wound and sutured the skin. The tendons were not fixed initially.

The patient was then referred to a larger hand center and had a consultation with the plastic surgeon 2 days later. The patient was brought to the operating room 4 days ago and had flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) repairs for his index, long, and ring fingers. He was placed in a bulky dressing postoperatively and was reviewed in the clinic today. The bulky dressing was removed and light dressing applied. The sutures remain in situ.

The patient has been referred to therapy with the following instructions: POD 4—FDS/FDP repairs zone II, right D2, 3, 4. Orthosis/protected ROM.

Relevant anatomy

Flexor tendon zones

The FDS and FDP muscles are the primary flexors of the fingers. Anatomic description of these muscles is simplified by dividing the tendons that travel distally from the muscle

bellies into zones. Figure 118.1 shows the superficial landmarks for the flexor zones of the hand.

Zone V to zone III

In zone V, the FDS lies superficial to the FDP in the forearm and is the only muscle in the intermediate layer of the forearm flexor compartment. Innervated by the median nerve, the FDS originates from the medial epicondyle of the humerus and the proximal radius and ulna. In the distal forearm it forms four separate muscles and tendons that travel through the carpal tunnel. Approximately 21% of the population does not have a FDS tendon to the small finger.¹ The orientation of the FDS tendons in the carpal tunnel is such that the tendons leading towards the long and ring fingers are superficial to the tendons for the index and small fingers. The FDS tendons are all superficial to the FDP tendons in zone IV. In the palm, these tendons diverge and travel to each finger.

The FDP shares the deep flexor compartment of the forearm with the flexor pollicis longus (FPL). It originates from the proximal ulna, the interosseus membrane, and proximal radius. Moving distally through the forearm, the FDP has two distinct muscle bundles. The radial bundle becomes the tendon for the index finger and the ulnar bundle powers the tendons for the long, ring, and small fingers. The innervation is usually provided by the anterior interosseous nerve for the index and long finger FDP. In zone IV, the tendons form the floor of the carpal tunnel. As the four FDP tendons diverge into the palm, the lumbrical muscles originate from their radial aspect. The lumbrical

Figure 118.1 The flexor tendon zones of the hand.

muscles travel distally from this level insert into the radial side of the lateral band of the extensor tendon at the level of the proximal phalanx.

Zone II and zone I

Zone II is a notoriously difficult area for surgical intervention and rehabilitation. Both the FDS and FDP tendons are confined within the flexor retinacular sheath at this level and are very closely approximated. Injury at this level increases the technical difficulty of surgical repair. Rehabilitation can also be difficult due to the potential for increased adhesion formation between the tendons and also between the tendon and retinacular sheath or pulley system. The FDS enters zone II superficial to the FDP. Proceeding distally, the FDS bifurcates at the mid-shaft level of the proximal phalanx. Once bifurcated, the FDP becomes superficial. The FDS then comes back together deep to the FDP and inserts just distal to the proximal interphalangeal joint on the middle phalanx. The FDP then continues distally into zone I to insert into the base of the distal phalanx.

The FDS and FDP tendons are maintained in close proximity to the phalanges with a series of annular and cruciate pulleys. These pulleys increase the biomechanical advantage of the flexor tendons by preventing bowstringing of the tendons as they glide proximally. The pulleys situated over the proximal phalanx (A2) and middle phalanx (A4) are the primary pulleys responsible for maintaining the tendons in a biomechanically advantageous position.

Other important anatomical features within zone II are the proper digital nerves and arteries. The proper digital nerves for the thumb, index finger, long finger, and radial half of the ring finger are extensions of the median nerve. The proper digital nerves for the ulnar half of the ring finger and the small finger arise from the ulnar nerve. The digital arteries course with these nerves in the finger. They are located on the palmar side of radial and ulnar aspects of each finger, leaving them susceptible to injury when the flexor tendons are injured in zone II.

Importance of the problem

Injuries to the hand vary with respect to their frequency and type based on culture, climate, industry, and leisure activities across the earth's many geographical areas. In the United States, injuries to the hand comprise approximately one fifth of all visits to Emergency Departments.²⁻⁴ In a review of over 50,000 hand injuries, approximately 5% were found to have some form of tendon involvement.⁵ Approximately 1% of all hand injuries involve the flexor tendons. The primary mechanism of injury for flexor tendon lacerations is usually a cut from broken glass or a knife.⁶ Early diagnosis and direct primary repair, if possible, is essential for regaining functional use of the hand. The consequences of a missed diagnosis of a flexor tendon laceration are usually not life threatening but can lead to deformity, contracture, decreased digital range of motion (ROM), and significant loss of hand function.

The cost of flexor tendon injuries to the healthcare system is related to patient age, and the method of postoperative rehabilitation. In 2003, Rosberg et al.⁷ reviewed the cost to the Swedish healthcare system after 139 flexor tendon repairs. They found that costs to the health system were significantly increased (57%) when immobilization was implemented postoperatively compared to passive and early active motion protocols. This highlights the importance of initiating protected motion of the digits after flexor tendon injury.

Top five questions

Diagnosis

1. What is the best way to diagnose the extent and location of an acute laceration of the FDP and FDS tendons?

Therapy

2. What type of flexor tendon surgical repair was performed in this scenario and how does it affect rehabilitation?

3. What factors determine how aggressively and how early postoperatively the tendons should be mobilized?
4. What kind of splinting is best for this type of postoperative rehabilitation?

Prognosis

5. What mediates functional outcome for this type of injury?

Question 1: What is the best way to diagnose the extent and location of an acute laceration of the FDP and FDS tendons?

Case clarification

Our patient lacerated the tendons of FDP and FDS in zone II of the hand. Lacerations in zone II are the most frequent and have the most severe prognosis.⁸ While a complete laceration of a flexor tendon requires surgical repair, the treatment for partial tendon lacerations has traditionally been more controversial. However, it is now generally accepted that a laceration of less than 60% of the tendon may do as well or better with conservative treatment than surgical.⁹ It is, therefore, important to be able to accurately diagnose the extent and location of flexor tendon injury so that an appropriate treatment plan can be determined.

Current opinion

Clinical assessment, surgical exploration, and MRI are the main traditional methods of quantifying laceration of the flexor tendons. Currently, less expensive and more time-efficient methods than MRI such as ultrasound and dual-energy CT are being further investigated to confirm their utility in diagnostics of this area.¹⁰⁻¹²

Finding the evidence

Quality of the evidence

Level IV

- 4 case series^{11,13-15}

Level V

- 2 expert opinions^{8,10}
- 9 case reports^{12,16-24}

Because the level of evidence available in this area is of grade IV or V, key results should be considered cautiously.

Findings

Clinical diagnosis of the flexor tendons should include observation of the normal cascade of the fingers. In the case of complete laceration of the flexor tendons, this cascade will be lost and the fingers will likely rest in an extended position (Figure 118.2).

Clinical evaluation should also include examination of isolated active flexion of the proximal interphalangeal (PIP) joint while the all other digits are passively held in full extension, to determine if the FDS is intact.^{1,25} Evaluation of FDP function is done by active flexion of the isolated distal interphalangeal joint of the finger.²⁵ Squeezing the forearm musculature should evoke flexion of the fingers. If there is a lack of digit flexion or an absence of tenodesis effect with flexion and extension of the wrist, the clinician should consider the possibility of a flexor tendon injury. Patients with a partial laceration may experience pain at the site of injury with gentle resistance to flexion.²⁵

The clinical diagnosis of a partial laceration is challenging because of the nonspecificity of physical signs.⁸ The clinician must, therefore, rely on other investigative tools to determine the degree of injury. The gold standard for

Figure 118.2 The normal cascade of the fingers is lost in the injured index, long, and ring fingers. Note the normal cascade in the small, uninjured finger.

diagnosis of a partial flexor tendon laceration is surgical exploration.^{8,25}

Traditionally, many surgeons have used MRI to determine whether an injury to a flexor tendon warrants investigation/treatment by surgical intervention. MRI affords optimal assessment of tendons^{8,15,21,26-28} and has the advantage of being noninvasive. It allows evaluation of the presence of a tear, the number of affected tendons, the extent of tendon retraction, and the presence of associated lesions.

Recently, more cost- and time-effective means of diagnosis, such as ultrasound, have been investigated to better understand their utility as diagnostic tools in cases such as a flexor tendon laceration.¹⁰ Kubiak et al. include ultrasound with MRI as the current modalities best suited for confirming clinical assessment findings of injury to the flexor tendons.¹² One unique asset of ultrasound over MRI is that real-time ultrasound can evaluate tendon gliding. Ultrasound is usually not effective at diagnosing rupture of flexor tendons after surgical repair as the presence of suture material make visualization of the damaged tendon ends difficult. Deng et al. cite dual-energy CT as a new and effective method to visualize the FDP and FDS.¹¹

Recommendations

- Clinical examination of the flexor tendons (including a subjective history, observation of the cascade of fingers, and isolated examination of the FDS and FDP) is the starting point for assessment [overall quality: low to very low]
- MRI of the flexor tendons is used to quantify the extent of injury for partial lacerations including percentage of laceration and any retraction of the tendon ends [overall quality: low to very low]
- There is currently not enough evidence to support the use of diagnostic ultrasound on its own (or enough studies to support the use of dual-energy CT for flexor tendons) but these may be promising options for future investigations to quantify [overall quality: low to very low]
- Surgical exploration is recommended to confirm a diagnosis for those flexor tendon injuries suspected to be greater than 60% lacerated [overall quality: low to very low]

Question 2: What type of flexor tendon surgical repair was performed in this scenario and how does it affect rehabilitation?

Case clarification

Variables that can be altered in repair of flexor tendons include the suture caliber, the number of suture strands that cross the repair site, and the type of suture used to secure the tendon. The strength of the repair is based on these characteristics and they, along with the surgeon's preference, will dictate what type of rehabilitation approach is undertaken.

Relevance

Historically, zone II was termed “no man’s land” and surgical approaches favored grafting rather than direct repair of the flexor tendons in this zone of the hand. Primary repair of the flexor tendons in zone II has since been universally accepted as the treatment of choice.²⁹ It has also been determined that it is better to repair both the FDP and FDS rather than the profundus alone, as was once thought to be the better option.²⁹ The strength of the repair in large part dictates what rehabilitation approach will be possible. There are three traditional approaches to rehabilitation: immobilization (now rarely considered to be the treatment of choice), early controlled active ROM, and early controlled passive ROM. The advancement of surgical repair approaches has allowed for earlier motion to be tolerated in rehabilitation protocols. There is, however, no one standardized protocol that is thought to be the best approach. Studies are difficult to compare because of differences in surgical technique.

Current opinion

Surgical repair of a flexor tendon laceration is no longer a surgical emergency.²⁹⁻³³ Primary tendon repair is the treatment of choice, with the aim of a repair that will be strong and smooth with enough tensile strength to allow early controlled motion after surgery.^{34,35} A four-strand repair offers approximately double the strength of the two-strand core suture while being more technically feasible than a six- or eight-strand repair.

Finding the evidence

- Cochrane review of rehabilitation protocols⁹

Level II

- 1 study of surgical options for flexor tendon repairs³⁶
- 2 studies of rehabilitation protocols^{42,43}

Level III

- 5 studies using cadaver specimens³⁷⁻⁴¹
- 4 studies of rehabilitation protocols^{37,44-46}

Level IV and V

- Multiple studies

Findings

The Cochrane review identified three randomized controlled trials (RCTs) that had been published in full in the area of flexor tendon rehabilitation,^{42,43,47} however, the study by Percival and Sykes (1989) examined the FPL and, therefore, does not directly pertain to the case question regarding laceration of D2–D4. The review identified that no trial tested the same comparison/protocol or surgical technique which makes data pooling impossible. While the review suggests that early mobilization regimes are generally favored in orthopedic rehabilitation, it also stipulates that the optimal protocol is yet to be determined due to insufficient high quality evidence.

Strickland listed the characteristics of an ideal primary flexor tendon repair as follows: sutures easily placed in the tendon, secure suture knots, smooth juncture of tendon ends, minimal gapping at the repair site, minimal interference with tendon vascularity, and sufficient strength throughout healing to permit the application of early motion stress to the tendon.⁴⁸

It has been demonstrated in numerous studies that the strength of a flexor tendon repair is roughly proportional to the number of suture strands that cross the repair site.^{29,48-56} However, the more suture strands that cross the repair site, the more difficult the technique and the more likely the method is to damage the tendon excessively or compromise its nutrition or ability to heal.^{29,50,57-61} Therefore, while there has been a departure from the core suture techniques that traditionally have used two-strand approaches to a replacement of the stronger four-strand methods which are approximately twice as strong as two-strand techniques,^{29,48,53-55,62} the advantages of the increased strength with six- and eight-strand methods have to be weighed against the more difficult technique and potential for tendon damage. In zone II, the increased bulk associated with six- and eight-strand repairs may also impact the ability to achieve optimal tendon gliding during rehabilitation due to the intimate association between the FDS, FDP, and the retinacular sheath.

It is thought that the roughness of suture material as well as the roughness of the repair (the size of knots and suture loops on the tendon surface) will affect the tendon repair's smoothness.³⁴ Resorbable suture materials are now avail-

able as well as a variety of suture materials (monofilament, coated, etc.). While investigators have demonstrated that larger-caliber sutures significantly increase repair strength,^{22,29} there is some debate on the effectiveness of locking loops on ultimate tensile strength of repair.⁶³⁻⁶⁵

Tendons are susceptible to rupture at suture knots, so the fewer the suture knots located in the tendon junction site the better.⁶⁵⁻⁶⁷ There may also be strength and biomechanical advantages to dorsal rather than palmar placement of core sutures and a strong peripheral suture will improve gliding and increase suture strength.^{29,43,66,68-75}

Recommendations

- A multistrand repair using a larger-caliber suture material with grasping and locking sutures has superior holding ability^{38,62,65-67,73,76-89} [overall quality: low]
- A four-strand core suture plus a strong peripheral suture can withstand the stresses of gentle early active motion^{48,53,73} [overall quality: low]
- No postoperative rehabilitation protocol has been identified as being optimal [overall quality: low]

Question 3. What factors determine how aggressively and how early postoperatively the tendons should be mobilized?**Case clarification**

The physician's orders in this case are for "orthosis/protected ROM". In other words, the physician has left the choice of protocol to the discretion of the attending therapist. Based on the findings from the previous question, we will assume for the purposes of discussion that the repair was performed with a four-strand suture plus a strong peripheral suture that is capable of withstanding early active motion. We also note from the case that the patient is 4 days postoperative so is moving from the inflammatory phase into the fibroblastic or collagen-producing phase of healing.²⁹ We will also assume that the bulky dressing has been removed and the patient is now in therapy, ready to begin rehabilitation.

Relevance

The advancement of surgical repair techniques and materials has allowed earlier mobilization after flexor tendon repair. Rehabilitation of flexor tendon repairs in zone II aims to achieve a balance between protecting the healing site and preventing gap formation while stressing it enough to enhance healing and prevent the formation of adhesions. The optimal protocol is yet to be determined but approaches are generally one of three: active extension–passive flexion, controlled passive motion, or controlled active motion.⁹

Current opinion

Rehabilitation of repaired flexor tendons in zone II favors early mobilization.⁹

Finding the evidence

Quality of the evidence

Level I Cochrane review⁹

Level II

- 2 studies^{42,43}

Level III

- 4 studies^{37,44–46}

Level IV and V

- Multiple studies

Findings

According to the Cochrane review,⁹ there are three main categories which affect the success of treatment for flexor tendon injuries of the hand: the kind of injury (e.g., level of injury, how many fingers have been injured, which zone of the hand has been injured, whether it is a clean cut versus a jagged laceration, etc.); the type of operation and surgical techniques used; and the rehabilitation program implemented postoperatively.

There is not one universally accepted protocol that is thought to be optimum for rehabilitation of flexor tendon injuries.⁹ In addition to the kind of injury and type of surgery performed, the timing of the surgery must also be considered. Those patients whose surgery was delayed may present with a shortened flexor tendon postoperatively, or if the situation is more chronic, the patient may require a more complex operation such as a two-staged flexor tendon repair. Both of these situations are examples of cases that would require tailoring of the postoperative protocol to the individual's unique presentation. Additionally, patient factors such as age, perceived compliance, and treatment goals must be considered when selecting the most appropriate postoperative regime. What has

been agreed upon is that immobilization results in unacceptable motion due to adhesions, and unrestrained normal motion almost always results in tendon rupture.^{34,90–92}

For patients unable to comply with rehabilitation instructions, immobilization may be a superior intervention to risking tendon rupture with unprotected active ROM and activity.⁹³ However, for compliant capable patients, current rehabilitation protocols aim for balance and use positioning and mobilizing splints during the early post-tendon-repair period. It is essential to tailor the rehabilitation to each individual, taking into account not only the anatomy, and surgical technique but also the distinctive features of each individual patient's capabilities and psychological responses,⁹⁴ goals, social supports, and motivation for recovery.⁹⁵

It is motion, rather than loading, that is thought to enhance tendon healing and no benefit has been shown to loading above what is needed to initiate tendon gliding.³⁴ It should be noted that breaking strength is not the real measure of the quality of tendon repair; rather, it is the presence of gapping.³⁴ For most repairs, gaps begin to form at approximately two thirds of the ultimate failure strength and can lead to triggering and blocking of motion.^{34,52,96–98} The identification of gapping and its relationship to reduced tensile force and tendon rupture has led to the development of “safe zones” for rehabilitation—the range of applied tendon loads that are large enough to induce tendon motion but small enough to avoid gapping or tendon rupture.³⁴

In a survey of Canadian Certified Hand Therapists, it was determined that the current trend in therapy management of zone II tendon repairs is to select the most appropriate^{99,100} rehabilitation protocol based on the surgeon's preference (58%), center protocol (22%), the clinician's concept of best practice (17%), or patient factors (3%).¹⁰¹ A separate survey of 191 hand therapists showed that there is a perceived lack of autonomy in clinical decision-making.¹⁰² A third survey was also completed by 191 therapists and cited reasons for initiating active ROM (in descending order) as: established protocol, number of post-operative days, physician order, suture technique, compliance issues, ROM measurements, and “other” (suture, compliance, patient healing, and scar adhesion formation). It was additionally reported that protective splinting is discontinued at a mean of 5.2 weeks postoperatively and that resisted exercises were initiated at a mean of 6.4 weeks postoperatively. It was noted that slightly more of the respondents follow a Kleinert-type protocol vs. the Duran-type protocol and that there is an increasingly frequent use of active finger flexion exercise within the first postoperative week. It was found that custom splints are used widely with little variation from a wrist position of 20–30° of flexion and metacarpal phalangeal flexion of 50–70°. ¹⁰⁰ The authors note that their findings vary significantly from the

Openmirrors.com

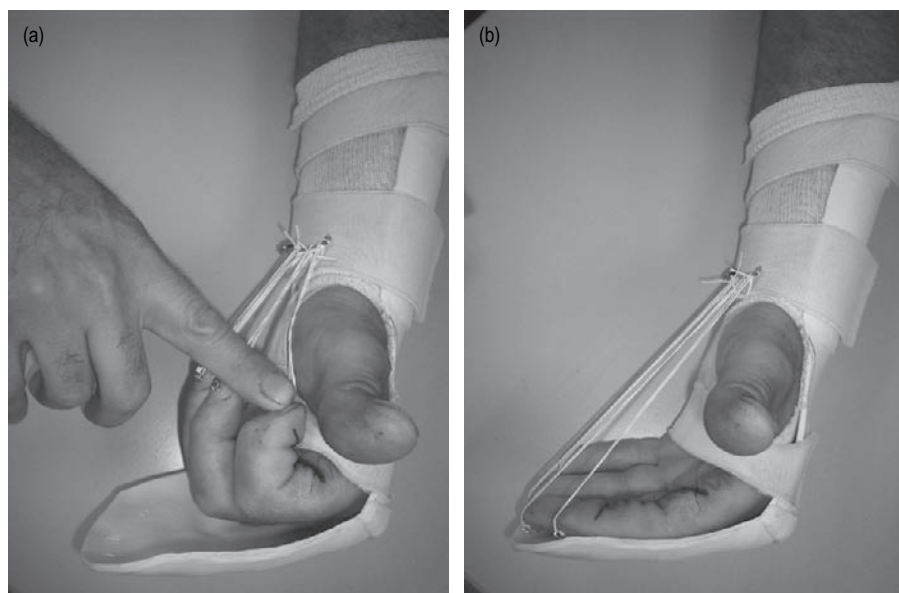

Figure 118.3 (a) Passive digital flexion of each finger, followed by (b) active extension within the limits of the splint using a modified Kleinert program.

literature. For example, the initiation of active flexion was reported as a mean of 18.6 postoperative days while the literature has traditionally recommended 28 days.^{99,100}

One very significant finding was that one third of the latter survey respondents report changing their postoperative regimen in the last 5 years which Groth¹⁰⁰ suggests may demonstrate a potential sensitivity to the advances in the scientific body of knowledge. This is in keeping with an observed shift towards increased emphasis of clinical reasoning in tailoring standardized protocols to meet individual patient needs and using “comparable signs” (objective repeatable measures) to monitor progress.

Sueoka and LaSayo proposed an algorithm to assist clinicians in using protocols more as guidelines.¹⁰³ The algorithm uses the concept of “tendon lag” as an indicator of how to proceed using an established protocol or modify the management approach by accelerating or decelerating the patient’s exposure to higher force exercises (p. 411). A “tendon lag” is the percentage difference in digital passive range of motion (PROM) and active range of motion (AROM) or a combination of both relative (%) and absolute (°) differences in PROM and AROM. Sueoka and LaSayo define the lag as a minimum 15° difference between PROM (greater) than AROM with the assumption that a tendon lag represents an adhered tendon that will impair normal gliding and thus reduce AROM.¹⁰³ The algorithm uses temporally based benchmarks to guide the rehabilitation approach. For example, in the scenario case, the patient is postoperative day 4 and thus is in the initial phase where the goal is to achieve full passive flexion of all digits and to reach the threshold level of extension as dictated by the passive protocols of Kleinert et al. or Duran et al.^{104–106} The goal is to achieve full passive flexion by 3 weeks at the

latest. Passive flexion and active extension with the limits of the dorsal blocking splint are the primary exercises for the modified Kleinert programs (Figure 118.3). The second stage (approximately weeks 3–8) introduces AROM, while resistance makes up the final phase.

Another approach which could both incorporate the algorithm by Sueoka and LaSayo¹⁰³ and be adapted within standardized protocols, is the “pyramid of progressive force exercises” that has been outlined by Groth.⁹⁴ This pyramid of progression starts with passive protected digital extension and moves through to place and hold finger flexion, followed by AROM and then isolated active tendon motion.⁹⁴ Wrist ROM is incorporated early in the pyramid through the concept of tenodesis—allowing the fingers to naturally drift into relaxed/unrestricted finger flexion while the wrist is in protected extension. This elicits less stress on the flexor tendon than composite extension, where both the wrist and digits are extended, and facilitates the desired differential tendon gliding between the FDS and FDP to prevent adhesions and promote organized tendon tissue healing. The protected wrist motion is progressed to unprotected wrist motion in accordance with the outlined pyramid levels and patient tolerance. The approach is based on tendon performance and moves from a high-frequency, low-load level of exercises to a low frequency with higher load levels as the patient ascends the pyramid.

Recommendations

- Choose an established protocol based on type and timing of surgery including the strength of repair and zone of injury as well as perceived patient compliance [overall quality: low]

- Implement the use of an algorithm such as the one proposed by Sueoka and LaSayo¹⁰³ which uses the presence/absence of a tendon lag sign to guide progression through rehabilitation and/or Groth's "pyramid of progressive force exercises"⁹⁴ to tailor protocols to individual presentations [overall quality: low]

Question 4: What kind of splinting is best for this type of postoperative rehabilitation?

Case clarification

In the case, the patient is postoperative day 4 and the physician has ordered "Orthosis/protected ROM". The type of splint used is dictated by the rehabilitation protocol selected, i.e., it will depend upon whether a controlled active or passive motion protocol is used.

Relevance

The splint will assist in protecting the tendon to allow for healing but also facilitate protected motion depending upon which protocol has been selected.

Finding the evidence

- Cochrane Database, with search term "flexor tendon rehabilitation"
- PubMed (www.ncbi.nlm.nih.gov/pubmed) clinical queries search/systematic reviews: "flexor tendon splints" or "postoperative wrist splints" (no results); clinical queries "flexor tendon splints"
- MEDLINE search identifying the population (Tendons/ or Tendon Injuries/ or Fingers/ or flexor tendons.mp. or Finger Injuries) and (adult) and (repair), the interventions (laceration.mp or lacerations/) and (rehabilitation.mp or Rehabilitation/) or (splints or splint.mp). We also used the keywords "zone II," "protocol," "Kleinert," "Duran," "Washington"
- PubMed (including ProQuest Nursing Journals) (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search with keywords "wrist splint" and "flexor tendons"; "rehabilitation" and "flexor tendons" and "laceration"

Quality of the evidence

- No studies higher than level IV or V were identified and no studies specifically answered the question as to an optimum splinting regimen.

Findings

A Cochrane review⁹ conducted in 2009 found no difference between dynamic vs. static orthoses and no conclusion could be formulated regarding active flexion vs. rubber band traction. The review also reported no significant difference found between controlled passive flexion with active extension (modified Kleinert) vs. controlled passive mobilization (modified Duran) nor any significant differ-

ence between grasping suture and early controlled active mobilization vs. modified Kessler technique with early controlled passive mobilization.¹⁰⁷

The quality of evidence to support one specific choice of orthosis is low as there are too many confounding factors such as surgical technique and protocol choice which will impact on splinting choices.

Recommendation

- The type of orthosis is based on the protocol chosen and should facilitate the achievement of benchmarks of movement by protecting the repair from excessive forces while allowing sufficient ROM to facilitate gliding and prevent adhesions [overall quality: low]

Question 5: What mediates functional outcome for this type of injury?

Case clarification

The patient in the case has undergone repair of the FDS/FDP on the second, third, and fourth digits of his dominant hand. In order to establish short- and long-term goals for the client, it is necessary to know what expected functional outcomes are realistic in this scenario.

Relevance

Many postoperative protocols aim not only to enhance function but to also to mitigate factors which may detract from the long-term functional outcome of the hand. Suboptimal outcomes are attributable to adverse events such as infection, tendon/scar adhesions, flexion contractures, stiffness of fingers, tendon bowstringing, gap formation, and rerupture of the flexor tendons. Quality of life for most people includes capacity for return to work and/or leisure activities, and many of these activities are thought to be closely linked to hand function. Therefore, it would be beneficial for both the patient and clinician to know how closely the function of a postoperative flexor tendon repair is expected to approximate preinjury status.

In order to quantify the patient's functional status, outcome measures must be implemented. Outcome measures can help to determine a patient's status at the time of assessment; to predict a subsequent event; and to detect change over time.¹⁰⁸ These characteristics assist in goal-setting and should help to determine the expected overall long-term functional outcome for the patient in the case scenario.

Current opinion

The ideal manner in which to assess health outcomes following tendon injury has yet to be determined. Defining "functional outcome" in the instance of flexor tendon rehabilitation is difficult because not only does the idea of what constitutes a "functional outcome" vary, but the variables

thought to contribute to overall function range widely, and the manner in which they are measured also varies greatly among studies. One must take into account measures of surgical technique and repair materials, and rehabilitation protocols, as well as the patient-specific variables which are thought to influence overall quality of life.

It has been noted that there is a marked difference in the selection of outcome measures by clinical researchers/epidemiologists and their clinical counterparts. While researchers have tended to choose outcome measures involving self-report measures, clinicians have relied on impairment measures to guide treatments.¹⁰⁹ A review of outcome measures following flexor tendon repair found that the majority of outcome measures used in the study methods were for digital ROM and muscle strength. In other words, the outcome measures could be classified in the World Health Organization's "International Classification of Functioning, Disability and Health" (ICF) model as body function and body structure, with a paucity of research reflected in the activity and participation categories of flexor tendon repair outcomes.^{110,111} Health outcomes can be measured using valuation methods (those that assess the value that an individual places on a given health state), health-status measurements (describe health), or classification methods (categorize health).¹¹² The ICF is increasingly being used as the conceptual framework for defining health attributes.^{109,113-117} The model acknowledges that there is a nonlinear and multidirectional relationship between physical impairments and resultant disability.¹¹²

Self-efficacy may be one determinant in the relationship between impairment and disability as it is highly related to a patient's ability to deal with their impairments or to participate in self-management programs.¹⁰⁹ "Comparable signs" are being identified, and then re-evaluated to guide advancement through the rehabilitation process. For example, a "lag sign" was described by Sueoka and LaStayo in their proposed algorithm to guide progression through accepted postoperative flexor tendon repair protocols.¹⁰³ Numerous rating systems for composite impairment measures for tendon injuries agree that motion is the primary physical impairment resulting from a tendon injury.¹¹²

It has been reported that for primary repair of zone II flexor tendon repairs, approximately 80% of normal motion can be restored with rehabilitation completed in 2-3 months.³⁴ While it is generally accepted that it is optimal to obtain AROM that approximates the PROM of finger flexion, what has not been established is the extent to which a loss of ROM will affect overall function.¹¹² The majority of flexor tendon repair studies have focused their outcomes on impairment measures, but it has not been determined to what extent these specific impairments will affect overall function.¹¹¹ The following scales have not been validated specifically to postoperative tendon repair but have been used across a wide spectrum of upper

extremity disorders: the Michigan Hand Questionnaire,¹¹⁸ the DASH,¹¹⁹ and the Patient Rated Wrist and Hand Evaluation.¹¹²

The risk of reinjury following a tendon repair is difficult to quantify due to a preponderance of surgical techniques, materials, patient characteristics, and differences in rehabilitation protocols. Tang suggests that repair ruptures are anywhere from 4% to 10% for zone II finger flexors, but this data is not specific to a four-strand repair.⁴¹

In consideration of the above factors, clinical experience dictates that the expected functional outcome for a four-strand surgical repair of FDS/FDP of the second to fourth digits on the dominant hand is variable and is closely associated with the patient's functional demands. For this reason, self-report measures are important for determining whether functional goals have been attained. With respect to measures of impairment, achievement of 90° of active MCP and PIP motion and 50° of DIP motion will usually be sufficient for functional use. Grip and pinch strength of 80% of a normal contralateral side will limit any functional impairment in most individuals.

- PubMed (www.ncbi.nlm.nih.gov/pubmed/)—sensitivity search with keywords "hand" AND "flexor tendons" AND "repair" AND "rehabilitation"; then combined with "four-strand" and with "outcome measures"; "rupture" AND "flexor tendons" AND "repair" AND "hand"

Quality of the evidence

Level II

- 1 systematic review that addressed the ICF components of corresponding outcome measures in flexor tendon rehabilitation;¹¹¹ however, it was not specific to a four-strand flexor tendon repair in zone II

Level V

- 2 review papers.^{41,110} The first reported outcomes with "excellent or good functional return" in more than three

fourths of primary tendon repairs following a variety of postoperative passive/active mobilization treatments with a 4–10% repair rupture in zone II finger flexors, while the second identified a lack of outcome measures in the activity and participation categories of the ICF model for flexor tendon repair outcomes

- No in vivo human study was identified to specifically identify *functional* outcome following a four-strand zone II repair or the risk of repair rupture with a four-strand repair in zone II

Findings

Physical impairments following a tendon laceration include a loss of motion and strength. Numerous rating systems for composite impairment measures for tendon injuries agree that motion is the primary physical impairment resulting from a tendon injury.¹¹² Outcome assessment following tendon repair and rehabilitation should include the total active motion of the affected joints.

Assessment of strength by manual muscle testing will allow determination of tendon integrity but is relatively insensitive to weakness in overall grip or individual digital strength.¹¹² The reliability of grip strength using a standardized test protocol for the Jamar dynamometer at the second handle position has been well established.^{120–122} While isolated loss of finger flexion force is common following flexor tendon repair, and has been correlated to elongation (gapping) in the tendon repair, there is limited availability of digital strength dynamometers clinically. Therefore, overall grip strength remains the common method of strength assessment. Pinch strength is also used to assess strength and protocols for measurement have been established by the American Society for Hand Therapists. The use of actual percentage (of the normal side) for assessment of motion and strength is an appropriate score.¹¹²

Other impairment measures include sensibility tests such as touch, temperature, and proprioception which may be evaluated by tests of threshold and innervation density. There is no consensus on what constitutes measures or standards of functional sensibility.¹¹² Cold sensitivity is common with peripheral nerve injuries which may accompany a tendon laceration, and is related to functional impairment and quality of life.^{99,123}

While there are a number of available questionnaires to assess activity and participation outcomes through self-report of function, none of these scales has been specifically validated for tendon injury.¹¹² However, the following scales have been used across a wide spectrum of upper extremity disorders: The Michigan Hand Questionnaire, the DASH, and the Patient Rated Wrist and Hand Evaluation.¹¹²

Recommendations

There is not enough quality research to specifically answer Question 5.

- Clinical experience dictates that the expected functional outcome of flexor tendon repair of D2/3/4 using a four-strand surgical approach is variable, which may explain the presence of several different management philosophies from both surgical and rehabilitation perspectives. From an impairment perspective, many studies have reported favorable results with early passive and controlled active protocols [overall quality: low]
- The risk of rerupture of a flexor tendon repair (not specific to a four-strand repair) has been reported as approximately 4–10% in zone II [overall quality: low]
- The relationship between specific impairment and function has not been established and data to determine the risk of rerupture of a four-strand zone II repair is inadequate.

Summary of recommendations

- Clinical examination of the flexor tendons (including a subjective history, observation of the cascade of fingers) is the starting point for assessment
- MRI of the flexor tendons is used to quantify the extent of injury including percentage of laceration and any retraction of the tendon ends
- There is currently not enough evidence to support the use of diagnostic ultrasound on its own (or enough studies to support the use of dual-energy CT for flexor tendons) but these may be promising options for future investigations to quantify
- Surgical exploration is recommended to confirm a diagnosis for those flexor tendon injuries suspected to be greater than 60% lacerated
- A multistrand repair using a larger-caliber suture material with grasping and locking sutures has superior holding ability
- A four-strand core suture plus a strong peripheral suture can withstand the stresses of gentle early active motion
- No postoperative rehabilitation protocol has been identified as being optimal
- Choose an established protocol based on type and timing of surgery including the strength of repair and zone of injury as well as perceived patient compliance
- Implement the use of an algorithm such as the one proposed by Sueoka and LaSayo¹⁰³ which uses the presence/absence of a tendon lag sign to guide progression through rehabilitation and/or the “pyramid of progressive force exercises”⁹⁴ to tailor protocols to individual presentations
- The type of orthosis used is based on the protocol chosen and should facilitate the achievement of benchmarks of movement by protecting the repair from excessive forces while allowing sufficient ROM to facilitate gliding and prevent adhesions
- Clinical experience dictates that the expected functional outcome of flexor tendon repair of D2/3/4 using a

four-strand surgical approach is variable, which may explain the presence of several different management philosophies from both surgical and rehabilitation perspectives. From an impairment perspective, many studies have reported favorable results with early passive and controlled active protocols

- The risk of rerupture of a flexor tendon repair (not specific to a four-strand repair) has been reported as approximately 4–10% in zone II

Conclusions

Diagnosis of flexor tendon repairs is usually done by clinical assessment. For patients who present with a normal cascade and a suspected partial tendon laceration, MRI or surgical exploration is warranted to ensure appropriate management.

The continued presence of several methods of rehabilitation for the management of flexor tendon injuries is a clear indicator that no single method has been shown, with good evidence, to be superior over another. Both early passive and early active motion protocols have shown to produce acceptable results. The choice of protocol depends on the quality of repair, zone of injury, experience of the clinician, and perceived patient compliance. The choice of orthosis is dependent upon the chosen protocols and positioning within the orthosis is variable in the literature. Regardless of the chosen protocol, the clinical decision-making as rehabilitation progresses through the various stages of healing is extremely important. Timely progression of stress to the repaired tendons is essential – not only for protecting the repairs – but also for achieving optimal tendon gliding and ultimately functional use of the hand.

Carpal Tunnel Syndrome— Conservative Management

Jean-Sébastien Roy¹ and Jessica Collins²

¹Laval University, Quebec, QC, Canada

²McMaster University, Hamilton, ON, Canada

Case scenario

A 52 year old woman who works on a production line consults a health professional because of pain and numbness in her right thumb and index and middle fingers. She also reports symptoms of tingling that awaken her from sleep and that are usually relieved by shaking her hands. Her symptoms have been developing for more than 4 months.

Relevant anatomy

Carpal tunnel syndrome (CTS) is a neurologic disorder involving gradual ischemia and mechanical deformation of the median nerve produced by elevated pressure within the carpal tunnel.¹ The compression of the median nerve under the flexor retinaculum leads to impaired nerve conduction and signs of nerve dysfunction. The clinical presentation of CTS usually involves symptoms of sensory (tingling, numbness and pain) and motor impairments (weakness, loss of hand dexterity and function) in the territory of the median nerve in the hand.

Importance of the problem

CTS is the most common peripheral nerve compression neuropathy. The prevalence of CTS in western European populations is estimated at 3.0–5.8% for women and 0.6–2.1% for men.^{2,3} In industrialized populations, the incidence of CTS is 99–105 per 100,000 person-years (52 for men, 149 for women)^{3,4} with the peak incidence between the ages of 50–59 years.⁵ The occurrence of CTS is associated with high

levels of hand–arm vibration, prolonged work with a flexed or extended wrist, high requirements for hand force and high repetitiveness.⁶ The average yearly claim rate for CTS is 27.3 per 10,000 full-time workers.⁷

When searching in databases, health professionals and patients are overwhelmed by the volume of information about CTS. In fact, over 3,000,000 hits appear on Google, and 6,700 on MEDLINE, when the search keywords “carpal tunnel syndrome” are entered. The variable quality and lack of filtering mandates need for pre-appraised evidence-based guides.

Top six questions

Diagnosis

1. How accurate are the clinical diagnostic tests for CTS?

Therapy

2. Is splinting beneficial for CTS?
3. Are ultrasound and laser therapy effective for CTS?
4. Are exercises and mobilization beneficial for CTS?
5. What is the effect of local corticosteroid injection for CTS?
6. What is the optimal approach of oral therapies for CTS?

Question 1: How accurate are the clinical diagnostic tests for CTS?

Case clarification

The information provided by this patient suggests that she has CTS. History alone can increase the likelihood of CTS.

For example, our patient reports waking at night and shaking her hand to relieve symptoms. This sign, known as the flick sign, is sensitive at 47% and specific at 62% for CTS.⁸ Clinical diagnostic tests are commonly used to help increase the confidence in the CTS diagnosis.

Relevance

A variety of clinical diagnostic tests are available for CTS. Therefore, clinicians need to select diagnostic tests that are the most specific to confirm CTS and the most sensitive to establish that CTS is unlikely.

Current opinion

Current opinion suggests that the majority of health professionals use the Tinel and the Phalen tests as clinical diagnostic tests for CTS.

Finding the evidence

- PubMed/systematic reviews: “CTS” AND “diagnosis”
- MEDLINE search identifying the population (CTS), the psychometric properties (sensitivity, specificity) and the methodology (diagnostic studies). We used the keywords “CTS” AND “diagnosis” AND (“sensitivity” OR “specificity”)

Quality of the evidence

Level I

- 2 systematic reviews
- 15 validating cohort studies with good reference standards

Level II

- 33 exploratory cohort studies with good reference standards

Findings

The two tests that were the most studied are the Phalen (31 trials; n = 3,218 cases, 1,637 controls) and Tinel tests (26 trials; n = 2,640 cases, 1,614 controls). According to a systematic review by MacDermid and Weissel,⁹ the overall average sensitivity for CTS is 68% for the Phalen test and 50% for the Tinel test (Table 119.1). These two clinical diagnostic tests are not the most sensitive for CTS. Carpal compression combined with wrist flexion (3 trials; n = 190 cases, 238 controls) and current perception threshold (2 trials; n = 46 cases, 63 controls) are the most sensitive at 80% (weighted average over all studies) (Table 119.1).⁹ Other sensitive tests included hand diagram (6 trials; n = 293 cases, 226 controls) at 75% and Semmes–Weinstein monofilament (11 studies; n = 811 cases, 567 controls) at 72%.⁹

Rates reported for overall average specificity differ according to the referent standard, i.e., between the studies that used asymptomatic controls vs. control with symptoms, but negative electrodiagnostic test.⁹ The average spe-

Table 119.1 Sensitivity and specificity of clinical diagnostic tests for carpal tunnel syndrome⁹

Diagnostic test	N ^a	Pooled sensitivity	Pooled specificity ^b
Phalen	3218/1637	68	65
Tinel	2640/1614	50	65
Current perception threshold	46/63	80	N/E
Carpal compression with wrist flexion	190/238	80	92
Static two-point discrimination	381/212	24	98
Abductor pollicis brevis atrophy	107/88	12	94

N = total sample size pooled.

^aNumber of cases/number of controls.

^bCalculated from subjects who had carpal tunnel syndrome-like symptoms but negative electrodiagnostic findings.

cificity of the Phalen and Tinel tests is, respectively, 73% and 77% for all the studies, and 65% for the studies with symptomatic controls (Table 119.1). Again, these two widely used tests are not the most specific. The most specific test is the static two-point (6 studies; n = 381 cases, 212 controls) at 98% (Table 119.1). Other specific tests for CTS include the abductor pollicis brevis atrophy at 94% (2 studies; n = 107 cases, 88 controls) and carpal compression combined to wrist flexion (3 trials; n = 190 cases, 238 controls) at 92% (Table 119.1). Note that the highly specific tests tend to have low sensitivity (Table 119.1). Combining tests can increase the resulting sensitivity and specificity. Fertl et al.¹⁰ combined the Phalen test with the median nerve compression test and found a sensitivity of 92% and a specificity of 92%.

Recommendations

- The most sensitive clinical diagnostic tests for CTS are the carpal compression combined to wrist flexion and current perception threshold at 80% [overall quality: moderate]
- The most specific clinical diagnostic test for CTS is the static two-point at 98% [overall quality: good]

Question 2: Is splinting beneficial for CTS?

Case clarification

Your evaluation suggests that your patient has mild to moderate CTS. You recommend trying conservative management first.

Relevance

Nonsurgical treatments are offered to those who have intermittent symptoms of mild to moderate CTS. The use

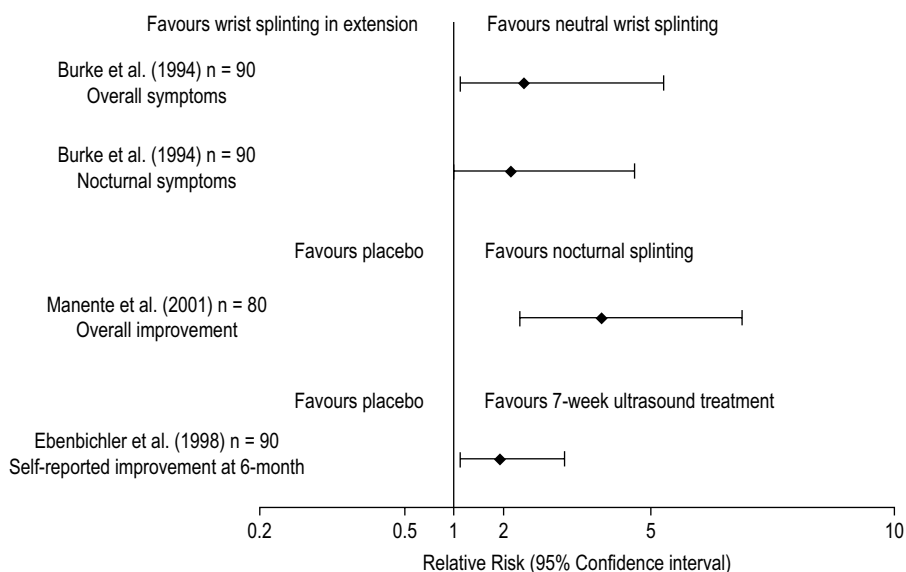

Figure 119.1 Effectiveness of ultrasound and wrist splint.

of conservative options could potentially result in resolution of symptoms without having to resort to surgery, which can result in complications and lost productivity.

Current opinion

Splinting is the usual first nonsurgical treatment used by the therapists for CTS.

Finding the evidence

- Cochrane Database, with search term “CTS”
- PubMed/systematic reviews: “CTS” AND “therapy” AND (“conservative treatment” OR “nonsurgical treatment” OR splint)
- MEDLINE search identifying the population (CTS) the intervention (splint OR splinting) and the methodology (clinical trial). We used the keywords “CTS” AND “(splint OR splinting)”

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses
- 6 randomized trials

Level II

- 13 randomized trials with methodologic limitations

Findings

Manente et al.¹¹ (n = 40 for each group) have compared the short-term effects of nocturnal hand splints for 4 weeks to a control group. They found a significant improvement of symptoms, hand function, and nerve conduction in the treated group at 2 weeks and 4 weeks. According to the Cochrane review by O'Connor et al.,¹² the relative rate (RR) of participants reporting overall improvement after four

weeks of splint use was 4.00 (95% CI 2.34–6.84) (Figure 119.1).

Burke et al.¹³ (n = 45 cases for each group) have shown a significant short-term effect in favor of the neutral position for wrist splinting in CTS compared with splinting in an extended wrist position (20°). According to the Cochrane review by O'Connor et al.,¹² the RR for improvement for neutral wrist splinting 2 weeks after the beginning of treatment was 2.43 (95% CI 1.12–5.28) for overall symptoms and 2.14 (95% CI 0.99–4.65) for nocturnal symptoms (Figure 119.1). Walker et al.¹⁴ (n = 11 cases for full-time use; n = 13 cases for night-time only use) have shown no significant difference in symptom/hand function improvement between night-time only use and full-time use of wrist splint over a 6 week period. Werner et al.¹⁵ (n = 63 cases for nocturnal splint; n = 49 cases for ergonomic education) compared nocturnal splint use with an ergonomic education programme. The group treated with splint showed greater improvement at 1 year follow-up. However, improvement was observed in both groups.

Recommendations

- Night splinting is effective for reducing symptom severity of CTS [overall quality: moderate]
- Full-time splinting does not reduce symptom severity or improve function more than night splinting alone [overall quality: low]

Question 3: Are ultrasound and laser therapy effective for CTS?

Case clarification

You are concerned that your typical conservative approach of 6 weeks of splinting may not be sufficient and wonder

if adding an adjunctive will enhance the benefit of a conservative treatment program.

Relevance

There is a plethora of conservative management modalities available for CTS. However, the optimal single or combination of modalities for symptom relief remains uncertain.

Current opinion

Even in the absence of complete relief, conservative management can be used for symptomatic benefit or to evaluate the likelihood of response.

Finding the evidence

- As for Question 2, but with “splint OR splinting” replaced by “laser therapy OR ultrasound OR ergonomic”

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses
- 10 randomized trials

Level II

- 13 randomized trials with methodologic limitations

Findings

Ultrasound Ultrasound therapy has been compared to placebo ultrasound therapy in two trials (n = 65 for ultrasound; n = 55 for placebo).^{16,17} The two trials demonstrated no short-term effects of ultrasound therapy for improvement in pain, symptoms, or nocturnal waking after 2 weeks of treatment. Furthermore, at 6 months, there was no group difference between ultrasound (7 weeks therapy) and placebo for peripheral nerve conduction, grip strength or pinch strength.^{16,17} After a 7-week therapy and at the 6 months follow-up, however, Ebenbichler et al.¹⁶ (n = 45 for each group) found a significant effect of ultrasound on symptom improvement (WMD -1.86 on 0–10 point VAS, 95% CI -2.67 to -1.05) and sensation (WMD -1.18 on 0–10 point VAS, 95% CI -2.02 to -0.34). The RR for self-reported improvement at 6 months was 1.91 (95% CI 1.13–3.23) favoring ultrasound over placebo (Figure 119.1). Oztas et al.¹⁷ (n = 10 for each group) did not find any significant effect of varying intensity of ultrasound (1.5W/cm² and 0.8W/cm²) for pain, symptoms, or nocturnal waking.

Laser therapy Low-level laser therapy has been compared to sham laser in two trials.^{18,19} The first trials (n = 7 for laser therapy; n = 8 for placebo) did not demonstrate any improvement in both groups.¹⁸ In the other trial, Naeser et al.¹⁹ combined low-level laser therapy to transcutaneous electrical nerve stimulation (TENS) and compared this combination to sham laser and TENS (n = 11). They found

that low-level laser and TENS led to a significant reduction of pain and symptoms.

Recommendation

- No recommendations can be given since there is conflicting evidence on whether ultrasound or low-level laser are effective

Question 4: Are exercises and mobilization beneficial for CTS?

Case clarification

Exercises and mobilization can also be used as conservative modalities for mild to moderate CTS.

Relevance

Exercises and mobilization include yoga, carpal bone mobilization, or nerve gliding. Therefore, clinicians need to know which ones are effective in the management of CTS.

Current opinion

Nerve gliding and mobilization are often used to reduce clinical symptoms of CTS. It is believed that the gliding may reduce adhesions that result in areas of traction along the nerve.

Finding the evidence

- As for Question 2, but with “splint OR splinting” replaced by “exercise OR nerve gliding OR mobilization”

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses
- 3 randomized trials

Level II

- 7 randomized trials with methodological limitations

Findings

Yoga The effects of yoga exercise on CTS symptoms have been compared to wrist splinting (n = 26 for yoga; n = 25 for wrist splint).²⁰ Yoga did not decrease pain or increase grip strength more than splinting. However, a significant effect of yoga on the Phalen sign was demonstrated. According to the Cochrane review by O’Connor et al.,¹² the RR for Phalen sign was 5.25 (95% CI 1.28–21.47) favoring yoga (Figure 119.2). There are different types of yoga and the specific type reported as effective is 11 yoga posture designed for strengthening, stretching, and balancing each joint in the upper body along with relaxation.

Nerve gliding exercises The effects of nerve gliding exercises or neurodynamic mobilization were evaluated in two trials.^{21,22} Tal-Akabi and Ruchton²² (n = 7 for each group) evaluated the short-term effect of nerve gliding exercises

Figure 119.2 Effectiveness of yoga.

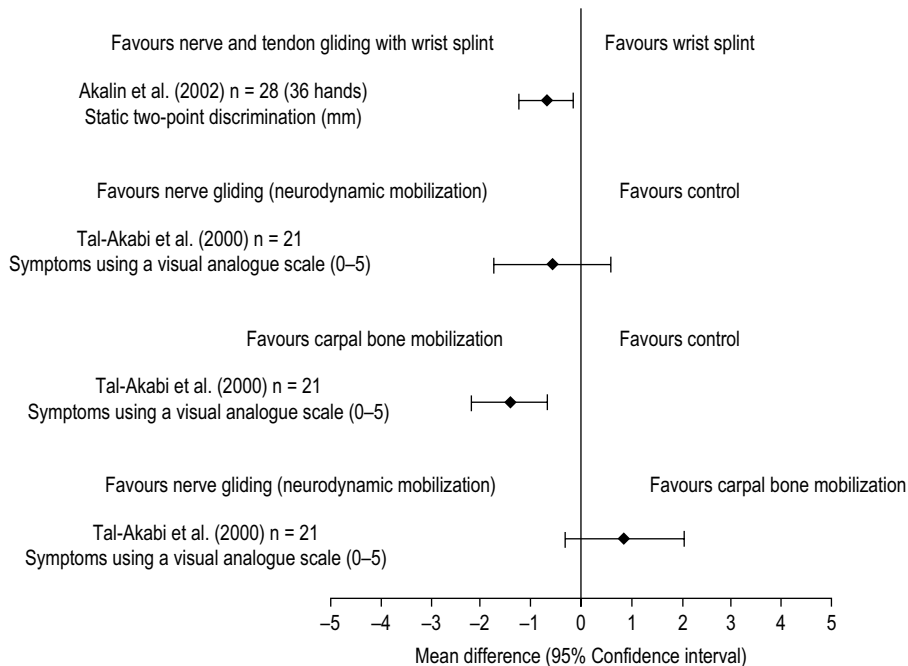

Figure 119.3 Effectiveness of nerve gliding and carpal bone mobilization.

on CTS symptoms when compared to no treatment. According to the post-hoc analyses performed in the systematic review by Muller et al.,²³ nerve gliding exercises relieve pain more than no treatment. In the same study, Tal-Akabi and Ruchton²² (n = 7 for each group) also evaluated the short-term effect of nerve gliding exercises as compared to carpal bone mobilization. The results show no significant benefit of nerve gliding exercises over carpal bone mobilization for improving short-term symptoms (Figure 119.3). In another trial, Akalin et al.²¹ (n = 18 for each group) evaluated the combined effects of nerve/tendon gliding exercises and wrist splint for 4 weeks on CTS symptoms when compared to wrist splinting alone. The addition of nerve/tendon gliding to wrist splint led to a significant effect on static two-point discrimination (WMD -0.70 mm, 95% CI -1.24 to -0.16) (Figure 119.3). However, nerve/tendon gliding exercises plus splinting did not reduce median nerve dysfunction, symptom severity, or improve function, grip strength more than splinting alone.

Carpal bone mobilization Tal-Akabi and Ruchton²² (n = 7 for each group) evaluated the effect of carpal bone mobiliza-

tion when compared to no treatment. Carpal bone mobilization significantly relieved symptoms more than no treatment (WMD -1.43 on 0-5 point scale, 95% CI -2.19 to -0.67) (Figure 119.3). However, it did not lead to a significant effect for improving pain, hand function, and active wrist motion.

Recommendations

- Yoga exercise improved outcome of the Phalen sign more than wrist splinting [overall quality: low]
- Nerve gliding exercises decrease pain in CTS [overall quality: low]
- Carpal bone mobilization improves symptoms of CTS [overall quality: low]

Question 5: What is the effect of local corticosteroid injection in the treatment of CTS?

Case clarification

Another commonly used treatment option for the conservative management of mild to moderate CTS is local steroid injections.

Relevance

The effectiveness of corticosteroid injections has to be determined since the recurrence rates of symptoms have varied from 8% to 100% following injection.

Current opinion

Current opinion suggests that the majority of health professionals use local steroid injection for short-term clinical improvement.

Finding the evidence

As for Question 2, but with “splint OR splinting” replaced by “injection OR steroid”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses
- 16 randomized trials

Level II

- 10 randomized trials with methodological limitations

Findings

Two studies (n = 73 for injection, n = 66 for placebo) have compared local corticosteroid injection to placebo injection. They demonstrated improvement with steroid injection after 2 weeks²⁴ and 1 month²⁵ with RR of 2.04 (95% CI 1.26–3.31) and RR of 3.83 (95% CI 1.82–8.05) respectively. According to the meta-analysis performed by Marshall et al.,²⁶ more participants improved after corticosteroid injection compared to placebo 1 month after the injection (RR 2.58; 95% CI 1.72–3.87) (Figure 119.4).

Two trials (n = 48 for injection, n = 47 for systemic corticosteroid)^{27,28} have compared local corticosteroid injection

to systemic corticosteroid. One trial²⁷ (daily oral corticosteroids vs. local injection) did not find any group differences at 2 weeks, but at 8 weeks and 12 weeks, local corticosteroid treatment was found to be significantly better (MD -7.10, 95% CI -11.68 to -2.52 at 12 months). The other trial²⁸ (local corticosteroid injection vs. single systemic corticosteroid injection) found that at 1 month there was a significant improvement in symptoms for the group undergoing local injection (RR 3.17, 95% CI 1.02–9.87) (Figure 119.4).

Two trials (n = 37 for each group)^{29,30} have compared low dose to high dose of corticosteroid injection into the carpal tunnel. According to the meta-analysis by Marshall et al.²⁶ there are no differences in clinical improvement between the two doses at six weeks (RR 1.00, 95% CI 0.76–1.31) (Figure 119.4). Another study showed no significant difference between groups treated with 20, 40, or 60 mg of methylprednisolone.³¹

One study has compared local corticosteroid injection to oral anti-inflammatory drugs combined to neutral angle wrist splint (n = 12 for injection, n = 11 for NSAID and splint).³² No significant difference for symptom and pain severity was found 2 weeks and 8 weeks after the start of the treatment. Finally, one trial (n = 20 for each group)³³ has compared a single local corticosteroid injection to two local corticosteroid injections. No significant difference was observed between the two groups at 8 weeks, 24 weeks and 50 weeks after the injection(s).

Recommendations

- Local corticosteroid injection leads to short-term clinical improvement [overall quality: good]
- Two injections do not lead to better clinical improvement than one local corticosteroid injection [overall quality: moderate]

Figure 119.4 Effectiveness of local corticosteroid injection.

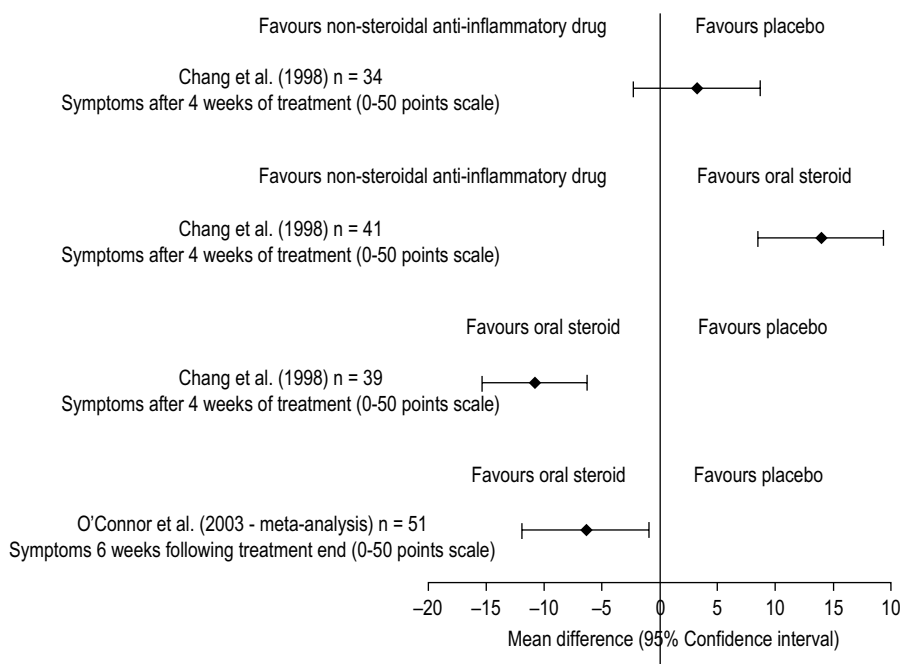

Figure 119.5 Effectiveness of nonsteroidal anti-inflammatory drug and oral steroid.

Question 6: What is the optimal approach of oral therapies for CTS?

Case clarification

Nonsteroidal anti-inflammatory (NSAID) medication and oral steroids can also be considered in early management of mild to moderate CTS.

Relevance

Oral therapy includes drugs, such as steroid, NSAID, diuretic, and vitamins. However, before using such modalities, clinicians must make sure of their effectiveness for CTS.

Current opinion

Oral therapy, mainly NSAID and steroid, are often the first treatment used for CTS.

Finding the evidence

Same as Question 2, but with “splint OR splinting” replaced by “oral therapy OR NSAID OR steroid”

Quality of the evidence

Level I

- 5 systematic reviews/meta-analyses
- 10 randomized trials

Level II

- 25 randomized trials with methodological limitations

Findings

Vitamin B₆ Two trials have evaluated the mid-term effects of vitamin B₆ therapy (n = 24 for vitamin B₆, n = 26 for

placebo/control).^{34,35} Vitamin B₆ therapy was found to be ineffective for improving symptoms, nocturnal discomfort, hand coordination, Phalen sign, or Tinel sign after 10–12 weeks of therapy.¹²

NSAIDs and diuretic treatment Chang et al.³⁶ have compared the short-term effects of NSAID to placebo and oral steroids (n = 18 for NSAID; n = 23 for oral steroid; n = 16 for placebo). Compared to placebo, no significant effect in favor of NSAID treatment was demonstrated for improving CTS symptoms. However, a significant effect in favor of oral steroids was demonstrated on symptom improvement with 4 weeks of treatment when compared to NSAID (WMD 14.00 on a 0–50 point scale; 95% CI 8.57–19.43) (Figure 119.5).¹² In the same study, Chang et al.³⁶ also compared the effects of diuretic (n = 16) treatment when compared to NSAID treatment and oral steroid. No significant difference between NSAID and diuretic was found following 2 and 4 weeks of treatment. Oral steroids proved to be more effective than diuretic to improve clinical symptoms after 4 weeks (WMD 11.60 on a 0–50 point scale; 95% CI 7.25–15.95).¹²

Oral steroids The use of oral steroid has been compared to placebo in three trials (n = 49 for oral steroid, n = 44 for placebo).^{36–38} According to the meta-analysis of O'Connor et al.,¹² a significant effect in favor of oral steroids was demonstrated on symptom improvement with 2 weeks and 4 weeks of treatment (pooled WMD after 2 weeks of treatment –7.23 points on a 0–50 point scale, 95% CI –10.31 to –4.14; after 4 weeks of treatment –10.8 points, 95% CI –15.26 to –6.34) (Figure 119.5). Herskovitz et al.³⁷ have

shown on a small sample ($n = 8$ for oral steroid; $n = 10$ for placebo) that 2 weeks and 6 weeks after the end of an oral steroid treatment, the benefits of the treatment are lost (WMD -6.19 on a 0–50 point scale, 95% CI -15.14 to 2.76)¹². In contrast, Hui et al. ($n = 18$ for each group) observed continued effects from oral steroid use 6 weeks after the end of treatment. According to the meta-analysis by O'Connor et al.,¹² the pooled WMD for improvement of CTS symptoms 6 weeks following the end of a 2 week oral steroid treatment was -6.46 points on a 0–50 point scale (95% CI -11.93 to -0.99).

Recommendations

- NSAID, diuretic therapy and vitamin B₆ are ineffective for reducing the clinical symptoms of CTS [overall quality: low]
- Oral steroid treatment improves the clinical symptoms of CTS in the short term [overall quality: moderate]
- There is equivocal evidence regarding the benefits of oral steroid 2–6 weeks after the end of the therapy, [overall quality: low]

Summary of recommendations

- The most sensitive clinical diagnostic tests for CTS are the carpal compression combined to wrist flexion and current perception threshold at 80%, while the most specific is the static two-point at 98%
- Night splinting is effective for reducing symptom severity of CTS, but full-time splinting does not reduce symptom severity or improve function more than night splinting alone
- Nerve gliding and carpal bone mobilization improves symptoms of CTS
- Local corticosteroid injection leads to short-term clinical improvement
- NSAID, diuretic therapy, and B₆ are ineffective for reducing the clinical symptoms of CTS, while oral steroid treatment improves the clinical symptoms of CTS in the short term [overall quality: moderate]

Conclusions

The results from the appraisal of the evidence related to treatment of CTS suggest that some conservative therapies for CTS, mainly local steroid injection, oral steroid, and splinting, lead to short- and mid-term clinical improvement. Therefore, the evidence strengthens the current opinion that conservative treatment should be attempted first in mild to moderate CTS. However, high-quality studies are needed to provide stronger evidence on the interventions currently supported by weak evidence, to develop decision rules based on responses to different

treatment options and to investigate optimal combinations and dosages.

Carpal Tunnel Syndrome—Surgical Management

Jessica Collins¹, Jean-Sébastien Roy², Leslie L. McKnight¹,
and Achilleas Thoma¹

¹McMaster University, Hamilton, ON, Canada

²Laval University, Quebec, QC, Canada

Case scenario

A 50 year old, healthy woman presents with complaints of hand weakness and numbness every night in her thumb and index and long fingers, which wakes her up at night.

Relevant anatomy

Carpal bones and the transverse carpal ligament form the carpal tunnel. It contains nine flexor tendons and the median nerve, which gives off its recurrent branch under or just distal to the ligament. Carpal tunnel syndrome (CTS) results from compression of the median nerve within the tunnel, which leads to motor and sensory abnormalities.

Importance of the problem

CTS is the most common peripheral compression neuropathy in the United States, with a prevalence of 3.7% and an annual incidence estimated at 0.4%.^{1,2} CTS has a significant socioeconomic impact due to workers' compensation claims³ and extended disability.⁴

Top four questions

Diagnosis

1. Are electromyogram (EMG) and nerve conduction studies (NCS) essential in the diagnosis of CTS?

2. Is there a role for imaging modalities (ultrasound, CT, MRI) in the diagnosis of CTS?

Therapy

- Is operative management superior to conservative management for relief of clinical symptoms?
- Which operative method provides the most improvement in clinical symptoms?

Question 1: Are EMG and NCS essential in the diagnosis of CTS?

Case clarification

You suspect the patient has CTS and send her for EMG and NCS for confirmation.

Relevance

There is divergent opinion on whether all patients require these investigations.

Current opinion

EMG and NCS should be considered on patients with severe symptoms for whom surgery is being contemplated. For mild to moderate symptoms, baseline data can be obtained, while others initiate conservative management and reserve investigation for patients who fail to respond.

Finding the evidence

- Cochrane Database, with search term: "carpal tunnel syndrome"
- PubMed and OVID MEDLINE search: "carpal tunnel syndrome," "electrodiagnosis," "electromyography/ or neural conduction," "diagnosis"

- American College of Physicians' Physicians' Information and Education Resource (ACP PIER), search term "carpal tunnel syndrome"
- American Academy of Orthopaedic Surgeons (AAOS) Clinical Guideline on Diagnosis of Carpal Tunnel Syndrome

Quality of the evidence

Level I

- 2 studies

Level II

- 2 studies

Level III

- 1 studies

Level IV

- 6 studies

Level V

- 2 studies

Findings

The AAOS guidelines⁵ recommend obtaining EMG and NCS when the diagnosis of CTS is uncertain, when patients fail to respond to conservative treatment, and when surgical treatment is being considered. EMG and NCS can confirm the diagnosis and severity of CTS, which can guide treatment.⁵ Patients who have obvious CTS signs can also benefit by obtaining baseline values to quantify post-treatment benefits.

Several studies mention that positive test results on both physical examination and EMG/NCS are related to positive surgical outcomes.^{6-9,10} NCS has a high sensitivity and specificity, over 85% and 95% respectively, in the diagnosis of CTS compared to control subjects.¹¹⁻¹⁵ NCS alone is associated with better surgical outcomes, although to a lesser extent than when combined with physical examination. False-negative electrodiagnostic test results occur in approximately 5% of cases.¹⁶ A recent study determined that the best predictor of symptom severity is the median nerve sensory distal latency, while the best predictor of functional status is the median nerve motor distal latency.¹⁷

Recommendations

- Combining physical examination and EMG/NCS provides the most accurate means of diagnosing CTS [overall quality: high]
- EMG/NCS should be considered in patients where the diagnosis is uncertain, there is failure to respond to conservative management, or when surgical treatment is being contemplated [overall quality: high]

- EMG/NCS can assess the severity of the nerve compression, which may assist with treatment selection [overall quality: moderate]

Question 2: Is there a role for imaging modalities in the diagnosis of CTS?

Case clarification

The patient's EMG/NCS studies show severe CTS. With no history of wrist trauma, you wonder if additional imaging would change your management.

Relevance

Imaging provides valuable information in musculoskeletal disorders. However, it is important to consider whether imaging for CTS will lead to changes in management.

Current opinion

Surgeons do not routinely use imaging for CTS.

Finding the evidence

- As for Question 1, except for keywords in PubMed and OVID: "carpal tunnel syndrome," "diagnosis," "magnetic resonance imaging or tomography, x-ray computed or ultrasonography"

Quality of the evidence

Level I

- 3 studies

Level II

- 5 studies

Level III

- 1 study

Level IV

- 7 studies

Level V

- 2 studies

Findings

Swelling or flattening of the nerve has been demonstrated on ultrasound.¹⁸⁻¹⁹ Measurements of the nerve's cross-sectional area to diagnose compression have shown a sensitivity of 83-94% and a specificity of 65-73%.²⁰⁻²⁶ However, EMG/NCS (sensitivity 78-82%, specificity 80-83%) proved to be superior at predicting symptom severity and functional status, and more accurate for diagnosis confirmation when compared to ultrasound (sensitivity 62%-72%, specificity 56-63%).^{17,27-29} Therefore, ultrasound may be the most useful in patients with symptoms and clinical findings in keeping with CTS with negative results on EMG/NCS.³⁰

The AAOS guidelines⁵ indicate that there is no role for routine use of CT or MRI for the diagnosis of CTS. However, these modalities may be useful when structural lesions are suspected,^{5,31} or when there is a history of previous wrist trauma, or bone or joint disease.⁴ MRI is most helpful when investigating lesions such as ganglions, soft tissue tumors, and muscle hypertrophy.^{32–34} Measuring the size of the tunnel has not shown definite benefits for making the diagnosis.^{34,35}

Recommendations

- Ultrasound is useful for nerve measurements and when EMG/NCS is inconclusive [overall quality: low]
- Selected patients may benefit from CT or MRI to diagnose structural CTS [overall quality: moderate]

Question 3: Is operative management superior to conservative management for relief of clinical symptoms?

Case clarification

Since this patient has severe CTS, you recommend surgical management. She asks whether conservative management could be of benefit instead of surgery.

Relevance

Conservative management can result in symptom resolution. However, the benefits of conservative modalities compared to surgery are uncertain.

Current opinion

Conservative management can be attempted in patients with mild to moderate CTS. If the patient does not improve, or originally has severe CTS, surgery is offered.

Finding the evidence

- Cochrane Database, with search term: “carpal tunnel syndrome”
- PubMed and OVID MEDLINE search: “carpal tunnel syndrome,” “steroids,” “glucocorticosteroids,” “injections, intra-articular,” “nonsurg or nonsurg or conservative treatment or therapy or manage,” “splints,” “treatment outcome”
- ACP PIER, search term “carpal tunnel syndrome”
- AAOS Clinical Guideline on the Treatment of Carpal Tunnel Syndrome

Quality of the evidence

Level I

- 4 studies

Findings

A Cochrane meta-analysis, including studies comparing splinting or steroid injections to surgery, indicated greater

recovery with surgical compared to conservative management with a pooled estimate of RR 1.23 (CI 1.04–1.46).^{36–39} Results at 6 months and 1 year also favored surgical management with a pooled estimate of RR 1.19 (95% CI 1.02–1.39) and RR 1.27 (95% CI 1.05–1.53) respectively.³⁹ In terms of improvements seen on electrodiagnostic tests, Hui et al.³⁸ reported that 92% of surgical patients vs. 64% of injected patients showed significant improvement in sensory potential amplitude (RR 1.44, 95% CI 1.05–1.97). Although these studies did not formally stratify patients into severity groups, many observed that patients with more severe CTS had the most improvement from baseline with surgical management. A meta-analysis demonstrated that a significant proportion of patients treated with splinting eventually required surgery, while the need for reoperation was low in patients originally treated with surgery (RR 0.04, 95% CI 0.01–0.17).³⁹ Finally, Gelberman stratified patients receiving steroid injections and splinting as mildly or severely symptomatic, and found that those with severe symptoms had the poorest response and experienced a higher rate of relapse (only 11%, vs. 40% of patients in the “mild” group, were still symptom free at 18 months).⁴⁰

Recommendations

- Patients with severe CTS should undergo surgery, regardless of whether conservative management has been attempted, since operative treatment will likely lead to more significant and long-lasting improvements [overall quality: high]
- For patients with mild to moderate CTS, a trial of conservative management can be attempted before surgical treatment [overall quality: moderate]

Question 4: In patients with CTS, which operative method provides the most improvement in clinical symptoms?

Case clarification

Since the patient’s CTS is severe, delaying surgery could be detrimental. The patient consents and you wish to review which technique would be most beneficial.

Relevance

Various surgical approaches to CTS have been proposed, but which results in the best outcomes is still controversial.

Current opinion

The decision to perform a specific release is largely based on surgeon preference.

Finding the evidence

- As for Question 3 except for keywords in PubMed and OVID: “carpal tunnel syndrome,” “endoscopy,”

“arthroscopy,” “decompression, surgical,” “open or endoscopic release or surg,” “treatment outcome”

Quality of the evidence

Level I

- 33 studies

Level II

- 8 studies

Level III

- 1 study

Findings

Options for surgical release that have been studied in the literature include open release, open release with a modified incision (short scar technique), endoscopic release, and KnifeLight® release, as well as additional procedures done at the time of release such as lengthening of the flexor retinaculum, internal neurolysis, epineurotomy, and tenosynovectomy.

Several randomized controlled studies have compared endoscopic to open release and found no differences in overall improvement at 3 months,^{41–48} although some studies showed a more significant reduction in pain in favor of endoscopic release^{49,50} and better satisfaction, functional status, and symptom improvement.⁵¹ With regard to long-term results, only Atroschi et al.⁴⁹ found continuation of more significant reduction in pain for endoscopic releases at 1 year follow-up. At 5 year follow-up, there were no significant differences in symptom severity and functional status scores between open and endoscopic groups.⁵² Three studies^{45,49,51} were included in a Cochrane meta-analysis⁵³ studying outcomes at 3 months. Both the symptom severity score and functional status score were lower for endoscopic release (mean difference [MD] –0.2; 95% CI –0.5 to 0.2 and MD –0.2, 95% CI –0.6 to 0.2 respectively), although these differences were very small and the studies had significant heterogeneity (I^2 approximately 90%). Data for scores at 1 year came from two of the three articles^{49,51} and found no significant differences (MD approaching zero on both scales). Several randomized controlled studies also investigated the time required to return to work after surgery: some found no significant differences,^{41,45,46,48,49,54–58} while others found that patients with endoscopic release returned sooner.^{42,44,47,50,51,59–62} Three of these studies^{47,49,57} were included in a meta-analysis⁵³ which determined that the weighted mean difference (WMD) in time to return to work was –6 days (95% CI –9 to –3) in favor of endoscopic release. In the randomized studies referenced above, no major complications were reported. There was a slight trend towards transient paresthesias with endoscopic release, and wound healing problems with open releases. The Cochrane review⁵³ assessed the need for repeated

carpal tunnel release by pooling the data from six studies,^{46,47,49,51,59,62} and found a higher likelihood of patients having undergone open release requiring repeat surgery (RR 1.2, 95% CI 0.5–3.1). Another meta-analysis and systematic review by Thoma et al.^{63,64} concluded that endoscopic release was favored in terms of reduction in scar tenderness, as well as increase in grip and pinch strength at a 12 week follow-up. This meta-analysis also found that it is three times more likely to suffer neuropraxia with the endoscopic than open technique. However, data was inconclusive with regards to symptom relief and return to work. A more recent evidence-based review agreed with these findings, except that it supports a slightly earlier return to work after endoscopic release and also mentions a higher risk of revision surgery with this type of release.⁶⁵

The short scar technique (1 cm incision) did not show significant benefits over standard open or endoscopic techniques.⁶⁶ A study which compared endoscopic release to open release with a modified incision found that wound pain was reduced more significantly in the endoscopic group at 2 weeks and 4 weeks but not after 8 weeks. All patients in both groups continued to have favorable outcomes at a 1 year follow-up.⁶⁷ Results were also found to be equivalent at 3 weeks and 1 year in two other studies.^{56,62} When compared to the standard open carpal tunnel release, no significant differences in symptom resolution were found in follow-ups ranging from 1.5 months to 2 years.^{62,68–72} Of these studies, two found no differences in how much time patients required to return to work^{68,69} while one found patients in the modified incision group returned earlier.⁷⁰ None of these studies reported any major complications; however, more scar tenderness with the standard incision was reported in some studies.^{70–72}

The use of KnifeLight was compared to standard open release, and both techniques were found to have similar findings in outcomes at 6 weeks.^{73,74} A study comparing KnifeLight to the modified incision open release found a more significant improvement in favor of the KnifeLight in terms of symptom severity and functional status scores at a mean follow-up time of 19 months, with both methods having similar outcomes at a mean follow-up of 30 months.⁷⁵ Two of these studies^{74,75} demonstrated that patients returned to work approximately 8 days earlier after a KnifeLight procedure but one⁷³ found no differences. One study reported less scar tenderness with KnifeLight.⁷³

Finally, additional procedures done concurrently with the carpal tunnel release did not show any significant benefits. This included lengthening the flexor retinaculum during open release at up to 26 week follow-up,⁷⁶ and internal neurolysis at 3 weeks to 4 year follow-ups.^{77–80} A meta-analysis demonstrated poorer global outcomes for patients who had undergone neurolysis or epineurotomy (odds ratio 0.54, 95% CI 0.32–0.90).⁸¹ As well, no significant

differences were seen in patients who had also undergone tenosynovectomy.⁸²

Recommendations

- Standard incision open carpal tunnel release has been shown to have equally favorable outcomes compared to other techniques [overall quality: high]
- Endoscopic carpal tunnel release was found to have a small benefit over open release in terms of scar tenderness and hand strength in the short term, but was not found to have any significant benefits in terms of symptom improvement and functional outcomes, while mixed findings were reported on a shorter time to return to work after endoscopic release. Neuropraxia is more likely to occur with the endoscopic technique [overall quality: high]
- No significant benefits were found for the short scar technique when compared to open or endoscopic release [overall quality: moderate]
- The use of KnifeLight showed mixed findings with regards to time to return to work, but otherwise showed no significant benefits over open release [overall quality: moderate]
- Additional procedures during release were not found to incur any benefits on final outcomes [overall quality: moderate]

Openmirrors.com

Summary of recommendations

- Combining physical examination and EMG/NCS provides the most accurate means of diagnosing CTS
- EMG/NCS should be considered in patients where the diagnosis is uncertain, there is failure to respond to conservative management, or when surgical treatment is being contemplated
- EMG/NCS can assess the severity of the nerve compression, which may assist with treatment selection
- Ultrasound is useful for nerve measurements and when EMG/NCS is inconclusive
- Selected patients may benefit from CT or MRI to diagnose structural CTS
- Patients with severe CTS should undergo surgery, regardless of whether conservative management has been attempted, since operative treatment will likely lead to more significant and long-lasting improvements
- For patients with mild to moderate CTS, a trial of conservative management can be attempted before surgical treatment
- Standard incision open carpal tunnel release has been shown to have equally favorable outcomes compared to other techniques
- Endoscopic carpal tunnel release was found to have a small benefit over open release in terms of scar tenderness

and hand strength in the short term, but was not found to have any significant benefits in terms of symptom improvement and functional outcomes, while mixed findings were reported on a shorter time to return to work after endoscopic release. Neuropraxia is more likely to occur with the endoscopic technique

- No significant benefits were found for the short scar technique when compared to open or endoscopic release
- The use of KnifeLight showed mixed findings with regards to time to return to work, but otherwise showed no significant benefits over open release
- Additional procedures during release were not found to incur any benefits on final outcomes

Conclusions

The accurate diagnosis of CTS and its severity is important for treatment planning. If this is uncertain after history-taking and physical examination, when a patient fails conservative management, or when surgical treatment is being contemplated, EMG and NCS should be considered. Further imaging studies are not routinely required. A trial of conservative management can be attempted for patients with mild to moderate CTS. Patients with severe CTS or who failed conservative management should be offered surgical treatment. Which method is used is largely based on surgeon and patient's preference since the literature has not shown significant benefits for one technique over another.

Larisa Kristine Vartija, Leslie L. McKnight, and Achilleas Thoma

McMaster University, Hamilton, ON, Canada

Case scenario

A 65 year old man is referred to you complaining of progressive loss of function in both hands. On examination, he is unable to fully extend his right ring and little fingers at the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints and his left long finger at the MCP joint. On his right hand, you palpate longitudinal cords which extend from the proximal palm to the middle phalanges of the affected digits. On his left hand, you palpate a longitudinal cord which extends from the proximal palm to the proximal phalanx of his long finger. He does not report pain. His digits are all neurovascularly intact.

Relevant anatomy

Dupuytren's disease (DD) is a benign fibroproliferative condition that primarily affects the palmar fascia. Fibroblast overgrowth distorts the fascia, creating nodules and cords (Figures 121.1–121.4). These nodules and cords are the affected bands of the palmar and digital fascia.¹ The pathological cords, their origins, contribution to joint contractures and neurovascular displacements are shown in Table 121.1.

Importance of the problem

The prevalence of DD is reported to be 12–46% depending on geographic location; the highest rates are reported in Scandinavian countries.² The presence of flexion contractures of the digits, often bilateral, causes functional impair-

ment of the hand that can limit productivity. Surgical management is often required and causes considerable financial burden.^{3,4}

Top six questions

Etiology

1. Is DD associated with frequent or repetitive manual work and/or hand vibration?

Therapy

2. Is the concomitant release of the PIP joint more effective than fasciectomy alone in correcting flexion contractures of the PIP joint and improving range of motion (ROM)?
3. How effective is percutaneous needle fasciotomy (PNF) compared to limited fasciectomy (LF)?
4. How effective is collagenase injection compared to placebo at reducing the degree of flexion contractures and improving ROM?
5. Does postoperative splinting help reduce finger extension deficits?

Prognosis

6. Can we predict who will develop disease recurrence?

Question 1: Is DD associated with frequent or repetitive manual work and/or hand vibration?

Case clarification

After examination, you diagnose the patient with DD. He asks you if it was caused by the repetitive manual labor he did for 20 years.

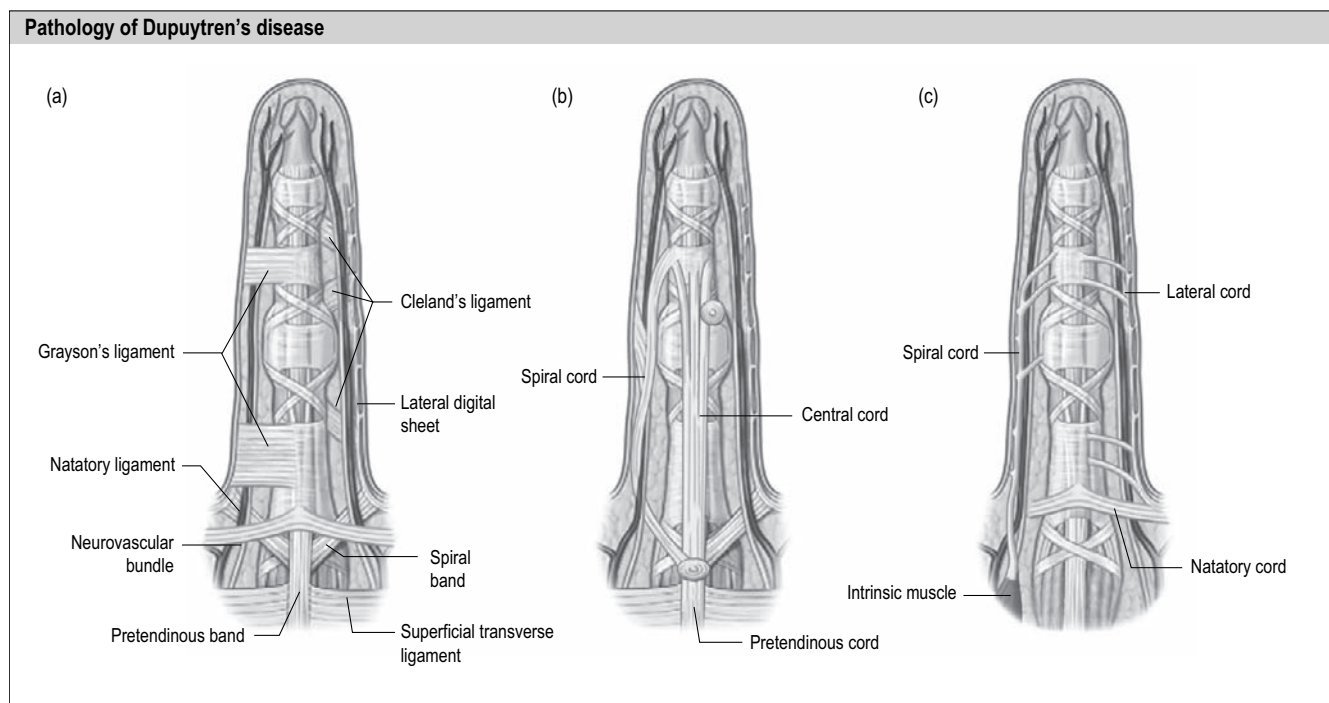

Figure 121.1 Pathology of Dupuytren's disease: (a) Parts of the palmar and digital fascia that become diseased in Dupuytren's contracture. (b) The diseased fascia associated with the pretendinous cord. (c) The diseased fascia not associated with the pretendinous cord. (Reproduced by permission of Wolters Kluwer, from McFarlane RM, Patterns of the diseased fascia in the fingers in Dupuytren's contracture. *Plast Reconstr Surg* 1974; 54(1):31-44.)

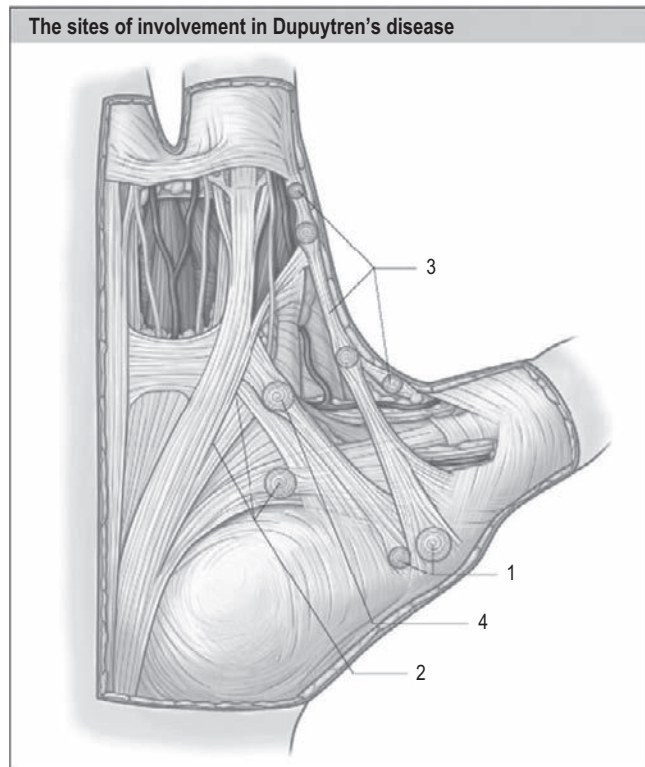

Figure 121.4 Sites of involvement in Dupuytren's disease. (Reproduced from Tubiana R. Location of Dupuytren's disease on the radial aspect of the hand. *Clin Orthop Relat Res* 1982; 168:222-229. With kind permission of Springer Science and Business Media.)

Relevance

For decades there has been controversy regarding whether cumulative mechanical work contributes to the development of DD. Patients often ask the hand surgeon if they should file a claim for workers' compensation.

Current opinion

Repetitive manual labor is not considered a strong risk factor for DD development and therefore does not warrant a workers' compensation claim. In some cases workers' compensation boards have allowed claims for DD, but in many cases it is considered a pre-existing condition. Nonetheless, the Ontario Workplace Safety and Insurance Board does not have a policy on DD specifically. Therefore, these claims are considered on a case-by-case basis.

Finding the evidence

- Cochrane Database, with search term: "Dupuytren's contracture"
- PubMed, using keywords "dupuytren*" AND "work," "occupation," "vibration," and "injury"

- MEDLINE and Embase, using "dupuytren's contracture" as a subject heading combined with "work," "vibration," and "injury" as keywords

Quality of the evidence

Level III

- 1 systematic review of controlled studies

Level IV

- 2 cross-sectional surveys

Findings

Four studies were included in the systematic review by Liss and Stock.⁵ In the only study of manual work, Bennett⁶ found the prevalence of DD to be 5.5 times higher in British workers doing repetitive hand work than those who did not, and twice the expected prevalence in a UK working population. The other three studies examined hand vibration (n = 1838) and showed consistent positive association between vibration and DD.⁷⁻⁹ DD was observed more frequently among vibration white finger claimants than controls.^{7,8} It was also found that a history of vibration exposure occurred more frequently among cases of DD than among controls.⁹ Two studies showed some evidence of a dose-response relationship.^{8,9}

Two cross-sectional surveys that were not designed specifically for the investigation of DD had conflicting results on the association between vibration and DD.^{10,11}

Recommendation

- Hand vibration is associated with DD [overall quality: low]

Question 2: Is concomitant release of the PIP joint more effective than fasciectomy alone in correcting flexion contractures of the PIP joint and improving ROM?

Case clarification

Intraoperatively, you find that after palmar and digital fasciectomy, the PIP joint contracture of the ring finger is only partially corrected. You consider performing concomitant PIP joint ligamentous release.

Relevance

The management of severe contracture of the PIP joint is difficult, as long-standing and severe contractures become more complicated to correct over time. Fasciectomy alone may not be sufficient to achieve good correction due to significant soft tissue contracture around the joint.

Current opinion

Two schools of thought exist: (1) At least partial division of the capsuloligamentous structures is needed to obtain

Table 121.1 The pathoanatomy of Dupuytren's disease

Cord	Origin	NVB displacement	Contracture	Other
Pretendinous cord (most frequent cord)	Pretendinous band	No	MPJ	Often extends distally to become continuous with digital cords
Vertical cord	Septa of Legueu and Juvara	No	No	Uncommon
Spiral cord	Pretendinous band, spiral band, lateral digital sheet, Grayson's ligament	Volar and medial	PIPJ	Most often in D5
Natatory cord	Natatory ligament	No	Web space	
Central cord	Extension of pretendinous cord in palm (no pre-existing central band)	No	PIPJ	Attaches into flexor tendon sheath near PIPJ or periosteum of middle phalanx on one side of digit
Lateral cord	Lateral digital sheet	Midline (due to its volume)	PIPJ and DIPJ	Attaches to skin or Grayson's ligament
ADM	ADM tendon	Sometimes	PIPJ	Can present as isolated digital cord; insertion varies
Distal commissural cord	Distal commissural ligament	No	Web space	Decreased radial and palmar thumb abduction
Proximal commissural cord	Proximal commissural ligament	No	Web space	Decreased thumb abduction
Thumb pretendinous cord	Thumb pretendinous band	No	MPJ	

ADM, abductor digiti minimi; DIPJ, distal interphalangeal joint; MPJ, metacarpophalangeal joint; NVB, neurovascular bundle; PIPJ, proximal interphalangeal joint.

additional release, as complete correction is not possible with fasciectomy alone. (2) One should use fasciectomy alone, as violating the PIP joint may result in permanent limitation of flexion or cause further scarring and contracture.

Finding the evidence

- Cochrane Database, using the search term: "dupuytren's contracture"
- PubMed, using keywords "dupuytren*" AND "proximal interphalangeal joint release" as well as "dupuytren*" AND "capsuloligament"
- MEDLINE and Embase, using "dupuytren contracture" as a subject heading combined with "proximal interphalangeal joint" as a keyword.

Quality of the evidence

Level II

- 2 prospective cohort studies

Level IV

- 1 retrospective cohort study
- 1 retrospective case-control study

Findings

In a prospective cohort study, Ritchie et al.¹² performed fasciectomies (n = 8) followed by sequential release of the accessory collateral ligaments and volar plates (n = 11) as necessary (intraoperative residual contracture >20°). No finger with a preoperative contracture of less than 45° required PIP joint release, whereas all fingers with initial contractures greater than 45° did require it. Mean flexion contracture immediately postoperative and residual contracture at 3 months was greater in those who underwent fasciectomy plus joint release, indicating that those who underwent fasciectomy alone achieved superior results (Table 121.2). However, these results are difficult to interpret, as the degree of preoperative contractures was much greater in this group compared to the fasciectomy alone group.

In a slightly larger prospective cohort study, Beyermann et al.¹³ performed fasciectomies (n = 32) followed by capsuloligamentous release (n = 11) as necessary (intraoperative residual contracture >20°). Preoperative PIP joint contracture was greater in those that underwent capsuloligamentous release. Flexion contracture was not different between groups immediately after surgery or at 6 months

Table 121.2 Results from study Ritchie et al.:¹² fasciectomy alone vs. fasciectomy plus joint release for the treatment of severe PIP joint contractures

	Fasciectomy alone	Fasciectomy and PIP release
Number of joints	8	11
Mean preoperative joint contracture	28° (20–45°)	70° (45–95°)
Mean flexion contracture immediately postoperatively	1° (0–5°)	7° (0–27°)
Residual contracture at 3 months	6° (0–13°)	26° (0–58°)
Residual contracture at 3 years	8° (0–15°)	29° (0–88°)
Range of motion—mean maximum flexion at 3 years	88° (84–95°)	83° (40–94°)

Table 121.3 Results from Beyermann et al.:¹³ fasciectomy alone vs. fasciectomy plus capsuloligamentous release for the treatment of severe PIP joint contractures

	Fasciectomy	Fasciectomy plus capsuloligamentous release
Number of joints	32	11
Mean preoperative joint contracture	78°	71°
Mean flexion contracture immediately postoperatively	2°	2°
Mean flexion contracture 6 months postoperatively	15°	16°
Number of joints that required dynamic extension postoperatively	21 (66%)	11 (100%)

(Table 121.3). However, 100% of the fasciectomy plus capsuloligamentous release group required dynamic extension splinting to help maintain PIP joint extension compared to 66% of the fasciectomy group. Thus, the magnitude of effect of capsuloligamentous release alone cannot be interpreted.

Level IV evidence suggests that residual flexion contracture is similar between fasciectomy and fasciectomy plus capsuloligamentous release groups.^{14,15}

Recommendation

- In patients with severe PIP joint flexion contractures, the effectiveness of fasciectomy vs. fasciectomy plus capsuloligamentous release in reducing residual flexion contracture is equivocal [overall quality: low-moderate]

Question 3: How effective is PNF compared to LF?

Case clarification

Although you recommend palmar and digital fasciectomy to reduce the degree of flexion contracture and prevent disease recurrence, your patient would prefer a less invasive treatment.

Relevance

PNF is desired by some patients because it is less invasive and has a shorter recovery time than LF.¹⁶

Current opinion

PNF is a reasonable treatment option for certain patients (i.e., elderly, nonsurgical candidates, those with nonsevere flexion contractures). However, it does not remove the pathological cords and is therefore believed to result in higher recurrence rates.

Finding the evidence

- Cochrane Database, with search term: “dupuytren’s contracture”
- PubMed, using keywords: “dupuytren*” AND “fasciotomy”
- PubMed (clinical queries: specific search): “dupuytren*” AND “fasciotomy”
- MEDLINE and Embase, using “dupuytren contracture” as a subject heading combined with “fasciotomy” as a keyword.

Quality of the evidence

Level I

- 1 randomized controlled trial (RCT)

Findings

One RCT was identified comparing PNF and LF (n = 166 rays, 88 PNF, 79 LF).¹⁶ All rays had pretreatment flexion contractures of at least 30° in the MCP, PIP, or distal interphalangeal (DIP) joints. Total passive extension deficit (TPED) was measured at 6 weeks. Outcomes at the PIP joints were worse than those at the MCP and DIP joints for both the PNF and LF groups. LF resulted in a greater reduction of TPED compared with PNF (p = 0.001). When results were analyzed using the Tubiana classification (Table 121.4), rays classified as Tubiana stage I or II before surgery had comparable outcomes with both treatments. For stage III and IV disease, LF was a superior treatment modality

Table 121.4 Tubiana classification

Grade	Total passive extension deficit
I	0–45°
II	45–90°
III	90–135°
IV	>135°

($p = 0.000$ and $p = 0.004$, respectively). There were no patients in the PNF group with flexion deficits compared with 19 patients in the LF group (mean deficit, 0.6 cm).

Because of the short length of follow-up, recurrence rates could not be determined. However, these patients are being followed over a period of 5 years; results have not yet been published.

Recommendations

- For Tubiana stage I and II, LF and PNF are equally effective at correcting flexion contractures [overall quality: low]
- For Tubiana stage III and IV, LF is more effective than PNF at correcting flexion contractures. [overall quality: low]

Question 4: How effective is collagenase injection compared to placebo at reducing the degree of flexion contractures and improving ROM?

Case clarification

You recommend palmar and digital fasciectomy, but your patient would prefer a less invasive treatment.

Relevance

Although many nonoperative treatments have been abandoned due to poor outcomes, the quest for nonoperative treatments continues. The two most popular approaches are PNF (discussed in Question 3) and collagenase injections.

Current opinion

Collagenase injection studies are showing promising results, but the treatment is not yet approved for widespread clinical use.

Finding the evidence

- Cochrane Database, using the search term: “dupuytren’s contracture”
- PubMed, using keywords: “dupuytren*” AND “collagenase”

- PubMed (clinical queries: specific search): “dupuytren*” AND “collagenase”
- MEDLINE and Embase, using “dupuytren contracture” as a subject heading combined with “collagenase” as a keyword

Quality of the evidence

Level I

- 2 RCTs

Level II

- 1 low-quality RCT

Findings

In a phase II trial, 10,000U of collagenase was established as the minimal safe and effective dose for the release of flexion contractures.¹⁷ The phase III trial¹⁸ showed positive results which were confirmed in the most recent study by Hurst et al.¹⁹ In this multicenter placebo controlled trial, patients ($n = 308$, joint contractures $>20^\circ$) received injections of collagenase or placebo at 30 day intervals (maximum 3 injections). The primary endpoint was a reduction in contracture to 0–5° of full extension 30 days after the last injection. More patients who were injected with collagenase than patients injected with placebo met the primary endpoint. Collagenase-injected joints also achieved a greater improvement in ROM (Table 121.5). The median time to reach the primary endpoint for collagenase-injected joints was 56 days.

Recommendation

- Collagenase injection is effective at reducing contractures to 0–5° of full extension and improving ROM compared to placebo [overall quality: high]

Question 5: Does postoperative splinting help reduce finger extension deficits?

Case clarification

One week after surgery, you observe a tendency for the finger to be kept in flexion at the PIP joint and wonder if your patient would benefit from a splint.

Relevance

A recent survey of orthopedic and plastic surgeons has highlighted the lack of consensus regarding splinting following surgery for DD.²⁰

Current opinion

Clinical experience and data extrapolated from other populations suggests the majority of surgeons splint the hand postoperatively for approximately 1 week, followed by a static night splint for up to 6 months.

Table 121.5 Treatment outcomes from study by Hurst et al.:¹⁹ collagenase vs. placebo injections for treatment of joint contractures >20°

	Collagenase	Placebo	p value
Number of joints	203	103	
All joints			
Primary endpoint ^a	64%	6.80%	<0.001
Mean change in ROM from baseline	36.7°	4.0°	<0.001
Metacarpophalangeal joints			
Primary endpoint ^a	76.70%	7.20%	<0.001
Primary endpoint ^a in joints with a baseline contracture of <50°	88.9%	NC	
Primary endpoint ^a in joints with a baseline contracture of >50°	57.70%	NC	
Mean change in ROM from baseline	40.6°	3.7°	<0.001
Proximal interphalangeal joints			
Primary endpoint ^a	40.0%	5.9%	<0.001
Primary endpoint ^a in joints with a baseline contracture of <40°	80.9%	NC	
Primary endpoint ^a in joints with a baseline contracture of >40°	22.40%	NC	
Mean change in ROM from baseline	29°	4.7°	<0.001

NC, not calculated; ROM, range of motion.

^aPrimary endpoint: percentage of patients who achieved reduction in contracture to 0–5° 30 days after last injection.

Finding the evidence

- Cochrane Database, with search term: “dupuytren’s contracture”
- PubMed, using keywords: “dupuytren*” AND “splint*”
- PubMed (clinical queries: systematic reviews): “dupuytren*” AND “splint”.
- MEDLINE and Embase, using “dupuytren contracture” as a subject heading combined with “splint” as a keyword.

Quality of the evidence

Level III

- 1 systematic review

Findings

Larson and Jerosch-Herold²¹ identified four studies (n = 349) that assessed postoperative splinting. Two studies evaluated static splints but no clear conclusions could be made. The two studies that evaluated dynamic splints had conflicting results. The authors were unable to pool results due to heterogeneity in splint types, duration of wear, outcomes and follow-up time. Although total active extension deficit improved in some patients wearing a splint, there were also deficits in finger flexion and hand function. The clinical significance could not be determined due to the lack of data on the magnitude of this effect.

Recommendation

- The effect of postoperative static and dynamic splints on final extension deficit is equivocal [overall quality: moderate]

Question 6: Can we predict who will develop disease recurrence?

Case clarification

Your patient asks you in follow-up if his disease will recur.

Relevance

Reported recurrence rates range from 0 to 78%, depending on the type of procedure done and length of follow-up.²² With each recurrence requiring reoperation, there is an increased risk of complications.^{23,24}

Current opinion

It is generally accepted that Dupuytren's diathesis (see box) is associated with a higher risk of disease recurrence. Some authors have suggested using histopathologic findings to determine who is at higher risk of recurrence.

Dupuytren's diathesis:

First described by Hueston in 1963,²⁵ it is a marker of aggressive Dupuytren's disease. Features include:

1. Bilateral hand involvement
2. Positive family history
3. Ectopic lesions
4. Ethnicity
5. Early age of onset (<50 years)^a
6. Male gender^a

^aAdded in 2006 by Hindocha et al.²⁶

Finding the evidence

- PubMed, using keywords “dupuytren*” AND “recurrence” and “prognosis”
- MEDLINE and Embase, using “dupuytren’s contracture” as a subject heading combined with “prognosis” as a subject heading

Table 121.6 Results from Abe et al.²⁷ Sensitivity, specificity and odds ratios for the six factors which were significantly associated with recurrence and/or extension

	Sensitivity	Specificity	Odds ratio (95% CI)	p value
Bilateral hand involvement	0.94	0.34	8.8 (1.0–72)	0.026
Little finger surgery	0.94	0.34	8.8 (1.0–72)	0.026
Early onset	0.28	0.94	5.6 (1.1–27)	0.032
Plantar fibrosis	0.67	0.85	11 (3.2–41)	<0.001
Knuckle pads	0.56	0.91	13 (3.3–54)	<0.001
Radial side involvement	0.56	0.89	11 (2.8–40)	<0.001

Table 121.7 Risk of recurrence and/or extension scoring system developed by Abe et al.²⁷ Scores >4 have high risk of recurrence and/or extension; scores <4 have little risk of recurrence and/or extension

Features of variables	Variables	Point(s)
High sensitivity and low specificity	(a) Bilateral hand involvement	1
	(b) Little finger surgery	1
	(c) Early onset of disease	1
Low sensitivity and high specificity	(d) Plantar fibrosis ^a	2
	(e) Knuckle pads ^a	2
	(f) Radial side involvement ^a	2

^aDemonstrated odds ratio values >2.0 for at the low 95% confidence limit.

Reproduced with permission from Abe Y, Rokkaku T, Ofuchi S, Tokunaga S, Takahashi K, Moriya H. (2004) An objective method to evaluate the risk of recurrence and extension of Dupuytren's disease. J Hand Surg [Br] 29B

Quality of the evidence

Level IV

- 4 retrospective case series

Findings

Dupuytren's diathesis Abe and colleagues (n = 65) found bilateral hand involvement, little finger surgery, early onset, plantar fibrosis, knuckle pads, and radial side involvement to be significantly associated with recurrence and disease extension (Table 121.6).²⁷ The authors also developed a scoring system to evaluate the risk of recurrence and extension (Table 121.7). However, this scale has not been validated.

In a larger retrospective review (n = 322 patients, 4 year follow-up), Hindocha et al.²⁶ calculated the statistical predictive value for Dupuytren's diathesis in relation to

Table 121.8 Adjusted odds ratios of developing recurrent Dupuytren's disease

Factor	Adjusted odds ratio	95% CI	p value
Men	2.15	1.07–4.32	0.03
Over 50 years of age at onset of DD	1.47	0.94–2.28	0.05
Garrod's pads	2.5	1.27–4.93	0.01
High alcohol consumption ^a	1.8	1.04–3.14	0.02
Bilateral DD	1.4	0.82–2.39	0.22
Ectopic lesions (any site)	1.54	0.90–2.64	0.07
Positive family history	1.32	0.85–2.05	0.14

^aDefined as men who drank >28 U/wk and women who drank >21 U/wk.

Reproduced with permission from Hindocha S, Stanley JK, Watson S, Bayat A. (2006) Dupuytren's diathesis revisited: Evaluation of prognostic indicators for risk of disease recurrence. J Hand Surg 31A, 1626–34.

disease recurrence (Table 121.8). A trend of an increased mean predictive risk with a greater number of diathesis factors present was found. Those with all five factors present (male gender, bilateral disease, Garrod's pads, age at onset <50 years, and a positive family history) had a predictive risk of 71% compared with 23% for patients with none of the factors present (baseline risk).

Histopathological findings Wilbrand et al.²² found no differences in the expression of anticollagen type IV, integrin 5 laminin, smooth muscle actin, procollagen type I, or desmin in patients with or without recurrence at four years (n = 103). They also failed to find any association between sex, age at onset, number of operations, heredity, diabetes mellitus, or drugs taken for cardiovascular disease, and the expression of any of the immunohistochemical markers.

Balaguer et al.²⁸ assessed the usefulness of the three-stage histological classification proposed by Rombouts et al.²⁹ in predicting recurrence (Table 121.9). At the time of surgery, the DD tissue was sent for histological examination and staging (n = 139 hands). After a mean of 5 years, type I, II, and III tissues had recurrence rates of 55%, 31%, and 11% respectively. Type I hands had a recurrence risk 2.5 times higher than type II hands (p = 0.04), and 10 times higher than type III hands (p = 0.05). Recurrence risk was three times higher in type II hands than in type III hands (p = 0.05). Histological staging was an independent risk factor for recurrence.

	Mitoses present
Type II (fibrocellular)	An intermediate stage with moderate cellularity Absence of mitoses
Type III (fibrotic)	Much less cellular, with increased amounts of collagen arranged in broad bundles

Reproduced with permission from Rombouts JJ, Noel H, Legrain Y, Munting E. (1989) Prediction of recurrence in the treatment of Dupuytren's disease: evaluation of a histologic classification. *J Hand Surg* 14, 644–52.

Recommendations

- There is an increased risk of recurrence associated with Dupuytren's diathesis [overall quality: low]
- There is an increased risk of recurrence associated with diseased fascia that is highly cellular [overall quality: very low]

Summary of recommendations

- Hand vibration is associated with DD
- In patients with severe PIP joint flexion contractures, the effectiveness of fasciectomy versus fasciectomy plus capsuloligamentous release in reducing residual flexion contracture is equivocal
- For Tubiana stage III and IV, LF is more effective than PNF at correcting flexion contractures
- For Tubiana stage I and II, LF and PNF are equally effective at correcting flexion contractures
- Collagenase injection is effective at reducing contractures to 0° to 5° of full extension and improving ROM compared to placebo
- The effect of postoperative static and dynamic splints on final extension deficit is equivocal
- There is an increased risk of recurrence associated with Dupuytren's diathesis
- There is an increased risk of recurrence associated with diseased fascia that is highly cellular

Conclusions

There is a paucity of high-quality evidence related to the etiology, therapy, and prognosis of DD. We found hand vibration to be associated with DD and LF to be more effective than PNF at correcting flexion contractures for Tubiana

stage III and IV. Phase III trials for collagenase injections are showing promising results. However, the evidence regarding fasciectomy vs. fasciectomy plus capsuloligamentous release for the treatment of severe PIP joint contractures as well as postoperative splinting was equivocal.

¹McMaster University, Hamilton, ON, Canada

²St. Joseph's Healthcare, Hamilton, ON, Canada

Case scenario

A 35 year old self-employed male contractor was cutting dry wall with a knife. The blade slipped causing a 4cm laceration to the dorsum of the nondominant hand, severing the extensor tendons to the four fingers between the metacarpophalangeal (MP) joints and the wrist. The patient is unable to extend his fingers.

Openmirrors.com

Relevant anatomy

The extensor tendons motor the finger extensors. They originate at the musculotendinous junction in the proximal forearm and insert distally to extend the fingers. The extensor tendons are classified in anatomic zones I–IX for the fingers and I–V for the thumb.¹

Importance of the problem

Hand injuries account for a significant number of Emergency Department visits and claims to workmen's compensation boards. The majority of injuries to the extensor tendons occur as a result of trauma to the dorsum of the digits, hand, and forearm with lacerations accounting for a significant percentage of the cases.

A careful history and the clinical evaluation will lead to an accurate diagnosis of extensor tendon injuries and is essential to planning operative management and therapy.

Top six questions

Therapy

1. What is the optimal technique to repair lacerated extensor tendons?
2. Can extensor tendons be effectively repaired under local anesthesia?
3. Does an early passive mobilization program yield better outcomes than an immobilization program?
4. What is the optimal early mobilization protocol following the repair of lacerated extensor tendons?

Prognosis

5. What factors predict functional outcomes after repair of lacerated extensor tendons?

Harm

6. What are the complications associated with repair of lacerated extensor tendons?

Question 1: What is the optimal technique to repair lacerated extensor tendons?

Case clarification

Examination of the patient reveals that the extensor tendons to the four fingers have been completely divided proximal to the MP joint. The surgeon's goal is to repair the tendons such that the hand therapist can begin an early motion

protocol and allow the patient to return to work as a self-employed contractor as soon as possible.

Relevance

An extensor tendon repair must be strong enough to withstand an early range of motion (ROM) rehabilitation protocol, which is believed to yield a more favorable outcome.

Current opinion

There is less controversy about the technique of repairing extensor tendons compared to flexor tendons. Most experts would agree that a strong repair that will withstand tension during early ROM protocols is advisable. A bulky repair that can be detrimental in flexor tendon repairs within the fibro-osseous tunnel is less problematic in extensor tendon repairs.

Finding the evidence

- Cochrane Database, PubMed/systematic reviews, with search term: (“extensor tendon repair” AND “techniques”)
- MEDLINE search, using keywords: (extensor tendon injuries), (surgery or repair) AND (clinical trial)

Quality of the evidence

Level VI: animal/laboratory research Compared to the literature concerning flexor tendon repair techniques, there are few studies on extensor tendons. Most of the research is on in-vitro animal or cadaveric models, making the results less generalizable to humans and a low level of evidence.

Findings

The studies compared different suture techniques and their biomechanical performance in tendon shortening, stiffness and final load to failure as measures of ultimate strength.

The results of Newport and William’s study indicated that the modified Bunnell repair was the strongest compared to mattress, figure-of-eight, and modified Kessler techniques.² In Howard et al.’s study, the augmented Becker repair had the highest strength (load to gap formation) compared with the modified Bunnell and the modified Krackow–Thomas methods.³ Woo et al. found that augmented Becker had the greatest load to failure and gap force compared to double figure-of-eight, double modified Kessler, and the six-strand double-loop.⁴ A recent cadaveric study by Lee et al. confirmed that the augmented Becker and modified Bunnell repairs had comparable strength but, because of the suture technique, led to a greater loss of tendon length than the running-interlocking horizontal mattress method. This technique had a similar strength profile but was faster to perform.⁵ The loss of tendon length can decrease the digital flexion and therefore overall grip strength.⁶

Recommendation

- The in-vitro studies may be used to establish the best technique to repair an extensor tendon. The limited studies suggest that a multistrand interlocking repair such as a Bunnell, augmented Becker or running-interlocking horizontal mattress, is stronger than other techniques. Although not specifically studied, the bulkiness of these repairs is not felt to be problematic in extensor tendon lacerations [overall quality: low]

Question 2: Can extensor tendons be effectively repaired under local anesthesia?

Case clarification

The patient in our scenario is healthy with isolated tendon injuries. He is a suitable patient for repair of the tendons under local anesthesia.

Relevance

The efficient use of limited hospital resources is becoming a major focus for surgeons and administrators. Furthermore, timely access to the operating room can be a challenge in some healthcare systems. As a result, some operative hand procedures such as the repair of extensor injuries are considered appropriate for the Emergency Department or minor procedure rooms using local anesthesia.

Current opinion

The location of extensor tendon repairs is another area of debate amongst surgeons with an increasing number advocating the use of local anesthesia and minor procedure room.

Finding the evidence

- As for Question 1, with search terms and keywords:
- “extensor tendon repair” AND “surgical suite,” “extensor tendon repair” AND “local anesthesia”
- extensor tendon injuries, surgery OR repair, AND clinical trial

Quality of the evidence

There are no trials comparing extensor tendon repairs in the main vs. minor procedure rooms or the type of anesthesia. The majority of reports are low level, including expert opinion.

Findings

Two papers advocate that repairs of simple extensor tendons⁷ and flexor tendons⁸ can be performed using local anesthesia in the Emergency Department or minor surgical suite provided adequate equipment and a skilled physician is available.

Recommendation

- In the absence of high-quality evidence, we turn to expert opinion when making recommendations about the repair of extensor tendon lacerations. There is support that local anesthesia is a safe and effective means of anesthesia for the surgical repair of these injuries in an appropriately equipped Emergency Department or minor procedure room, thereby reducing the financial burden to the payer [overall quality: low]

Question 3: Does an early passive mobilization program provide better outcomes than an immobilization program?

Case clarification

The scenario patient requires rehabilitation following repair of the tendons (zone VI). The hand therapist must understand which therapy protocol will yield a better outcome. Early controlled passive motion protocols are initiated immediately postoperatively to prevent loss of function.

Relevance

There is great debate in the literature and clinical community about the most effective postoperative management of primary extensor tendon repair in zones V–VIII (zone IX is less controversial as muscle-to-muscle repairs are usually treated with postoperative immobilization for 4–6 weeks). Traditional programs statically splint the injury for up to 4 weeks and then begin mobilization.⁹ The rationale for the development of early passive mobilization with dynamic splinting is that the extensor tendons are so superficial, are in close approximation to bony structures which makes them vulnerable to adhesions, and, depending on the chosen immobilization posture, can result in either joint capsule tightness or extensor lag.^{10–13} In a cadaveric study, Evans and Burkharter found with the wrist in 40–45° of extension and the MP joints limited in 30° of flexion, a required 5 mm tendon glide would occur in zones V–VII to prevent adhesions.¹⁴ Purcell et al. prospectively evaluated static protocols for all zones and found that injuries in zones VI and VII did not have good outcomes. They concluded that dynamic protocols for certain zones may be more efficacious.¹⁵

Current opinion

There is a range of opinions as to which approach is most cost-effective for the outcomes. Some clinicians believe that extensor tendon injuries are simple and do well regardless of the intervention provided.¹⁶ Others feel that the cost of early mobilization protocols outweigh the benefits.

Finding the evidence

- Cochrane, MEDLINE, and CINAHL, using search terms: “hand/wrist injuries” AND “rehabilitation/splinting” AND “extensor tendons”

- Reference lists from the articles found were reviewed for potential studies

Quality of the evidence

Level I

- 1 systematic reviews/meta-analysis
- 1 randomized controlled trial (RCT)
- 3 other designs

Findings

The meta-analysis by Talsma et al. reviewed another RCT in this category by Bulstrode but the protocol allowed early active and not passive motion.^{17,18} One RCT compared the results of early controlled motion with immobilization protocols. Mowlavi et al. designed an RCT for patients with simple injuries in zones V and IV.¹⁹ Patients were randomized into two groups. One group was in a static splint for 4 weeks (wrist 30° extension, MP joints 15–20° extension, distal joints straight). The dynamic splinting group was placed in a reverse Kleinert splint with MP joints allowed to flex to 30°, increased to 45° at 2 weeks. At 4 weeks, the dynamic splinting is discontinued and active range of motion (AROM) is initiated. A night, static splint is continued for 6 weeks. Results showed that patients in the early dynamic splinting protocol had better total AROM of injured digits at 4 weeks, 6 weeks, and 8 weeks but not at 6 months. Grip strength in the dynamic group was better compared to the immobilization group at 8 weeks but not at 6 months. When compared with uninjured hands, the dynamic splinting group had all achieved 80% of the grip strength at 6 months and only 73% of the static group had achieved the same level of grip strength as the uninjured hand. These results suggest that earlier recovery occurs with a dynamic mobilization program, which may be more important in complex injuries or with individuals who have underlying conditions (inflammatory arthritis).

A clinical trial by Chow et al. compared a dynamic protocol allowing progressive MP flexion (week 1 30°, week 2 45°, week 3 60°, and full motion at week 4) for a cohort of patients in a military hospital to a static protocol of immobilization for 3 weeks at another hospital. The outcome showed that the dynamic protocol is superior, with excellent results in all cases and excellent results in the immobilization program in only 40% of the cases. This study is flawed as there is no raw data for comparison and a military compared to civilian population is significantly biased.¹²

Russell et al. completed a retrospective evaluation of static vs. a dynamic protocol and found there was no difference between the two groups functionally, but this study is retrospective and draws conclusions about cost-effectiveness without data.²⁰

Recommendation

- Dynamic mobilization protocols would be the preferred protocol for more complex injuries, for individuals with underlying conditions, reliable patients, or where earlier recovery is essential. The limitation however, is the significant variability in the published protocols. The protocol should position the wrist in at least 21–45° of extension, the MP joints in neutral to prevent lags and a progressive increase in allowable MP flexion in the splint.²¹ [overall quality: high]

Question 4: What is the optimal early mobilization protocol following the repair of lacerated extensor tendons in our scenario?

Case clarification

The patient sustained simple, sharp tendon lacerations, which is favorable. Several tendons were divided and repaired in close proximity, directly under skin. These are both considered to be unfavorable factors. It is therefore important to apply the optimal therapy program following the repairs that will allow this self-employed patient to return to his work as soon as possible.

Relevance

Like flexor tendon protocols in the past, extensor tendon protocols are now progressing from passive controlled motion to early active motion. Cadaveric studies by Minamikawa et al. revealed that extensor tendon repairs can tolerate full finger excursion with the wrist in 25–30° extension for zones V–VI and the involved finger MP joint limited to 25–30°.²² The benefit of hyperextending the affected digit in relationship to the other digits in taking tension off the repair site was also observed.²³ These studies also found that very little tendon excursion occurred in the traditional passive protocol positioning with the wrist in 30° of extension. The evaluation found that to affect tendon excursion in zone VI, the wrist would need to be in 21° of extension with unrestricted finger motion.

Active movement is beneficial to promote healing, improve tendon gliding and tensile strength of repair, and reduce swelling. Early protected protocols allow the benefits of active mobility while avoiding tendon rupture.

Current opinion

Some clinicians feel that early mobilization protocols are time intensive for therapists and do not yield significantly better results than immobilization protocols.

Finding the evidence

- As for Question 4

Quality of the evidence

Level I

- 1 systematic review/meta-analysis
- 3 RCTs

Findings

There are three high-quality RCTs evaluating the benefits of early active mobilization compared to dynamic protocols. Bulstrode et al. randomized zone V and VI injuries to one of three groups: (1) immobilization with wrist 30° extension, MP and interphalangeal (IP) joints extended for 4 weeks; (2) immobilization with wrist 30° extension, MPs neutral, IPs free to move hourly; (3) splint positioning with wrist 45° extension, MP at 50° flexion and IPs straight for 4 weeks, every 4 hours extend digits off the pan and hook, splint at night/risk-prone activities until 8 weeks, no passive flexion or resisted flexion until 8 weeks. This study demonstrated that early active mobilization resulted in earlier recovery of motion and grip strength. They also evaluated the intensity of therapy requirements of the three groups and there was no difference in therapy requirements except that group 1 required intensive treatment when splint discontinued, whereas groups 2 and 3 had the intensive therapy at the onset.¹⁸

An RCT by Chester et al. studied patients with injuries in zones IV–VIII randomized to early active program using static splint with MP 30° flexion and wrist 30° extension between active exercises of digits (intrinsic plus and minus), wrist AROM at 2 weeks, concurrent fistng at 3 weeks, 4 weeks splint only at night or to a dynamic mobilization group with a dynamic outrigger with the wrist at 30° and the MP allowed to flex to 30°, at 2 weeks wrist AROM, splint only at night at 4 weeks. The authors found significantly better ROM in the early active motion group at 4 weeks but no difference at 6 months.²⁴

Khandwala et al. randomized patients with zone V and VI injuries to either a dynamic protocol as in Chow's study or an early active protocol where IP joints are free and MP joints are blocked from flexing beyond 45° and the wrist is in 30° of extension.^{16,12} At week 3, the splint is modified to allow 70° of MP flexion. This study also found no statistical difference between the two groups at the time points measured. The protocol in all RCTs included a static splint and specific progression of exercise within protected ranges.

Recommendation

- Early active protocols provide the same results as the passive protocols and may be easier for both the therapist and the patients to complete. The selection of the protocol should take into consideration the proximity to an experienced hand therapist and patient factors such as the self-employed status of the patient [overall quality: high]

Question 5: What factors predict functional outcomes after repair of lacerated extensor tendons?

Case clarification

A functional hand that allows the patient to return to the preinjury state should be the goal of management of extensor tendon injuries. In this scenario, the patient requires optimal hand function to be able to return to work as a contractor.

Relevance

Understanding the factors that predict a functional outcome after extensor tendon injury will assist the patient, surgeon, therapist, and employer in directing care and rehabilitation.

Current opinion

It is anticipated that a young, healthy individual with isolated lacerations to extensor tendons would regain normal function and a very good outcome following repair.

Finding the evidence

- As for Question 1, with search terms: “extensor tendon repair” AND “outcomes”
- extensor tendon injuries, surgery OR repair AND clinical trial Keywords “extensor tendon” AND “outcomes”

Quality of the evidence

Using “outcomes” as a keyword in the search strategy yielded reports that were in fact case series (level IV). The search strategy did not yield true outcome studies from prospective trials (level II); however, there were some individual cohort studies. One systematic review compiled several study types, although none of them were randomized trials.

Findings

Carl et al. (level IIb) in a prospective study of 203 tendon repairs concluded that recovery of finger function after repair was related to the complexity of injury and the zone of the laceration. In this group, static splinting for 6 weeks followed by ROM was an appropriate for zones I, II, IV, and V, and early ROM was more appropriate for injuries in zones III and IV, where more complex injury patterns seem to occur.²⁵ A review of the literature by Newport and Tucker in 2005 reported that immobilization as a postoperative treatment of extensor tendon lacerations yielded good or excellent results ranging between 54% and 95%. They concluded that clinical outcomes have consistently improved utilizing either dynamic or active motion with good or excellent results achieved in at least 90% of cases.²⁶

Recommendation

- Repair of simple extensor tendon lacerations followed by early ROM can be expected to have a good to excellent outcome compared to complex injuries and static splinting [overall quality: low]

Question 6: What are the complications associated with repair of lacerated extensor tendons?

Case clarification

The initiation of an early ROM protocol following extensor tendon repair in zone VI for our patient may lead to complications.

Relevance

The evolution of the management of extensor tendon injuries includes a shift from rigid immobilization for 6 weeks to involve early ROM following surgical repair. In recommending this protocol, the risk of complications compared to the associated benefits must be understood and accepted by the patient, surgeon, and therapist.

Current opinion

Most surgeons and therapists would agree that while the benefit of early motion allows for gliding of repaired tendons and avoidance of joint contractures, the potential for rupture does exist.

Finding the evidence

- As for Question 1, with search terms: “extensor tendon repair” AND “complication”
- extensor tendon injuries, surgery OR repair, AND clinical trial. Keywords “extensor tendon” AND “therapy” AND “complication”

Quality of the evidence

Numerous publications addressing complications associated with extensor tendon repairs are retrospective reviews of cohorts of patients, some dating back more than 50 years, and are therefore considered level IV evidence.

Findings

The reported complications associated with the surgical repair of the extensor tendons include general operative complications for hand surgery. The reports focus on those complications associated with early ROM vs. static splinting/immobilization. Numerous publications report decreased rates of complications such as loss of motion, extensor lag, loss of grip strength, and need for tenolysis^{9,12,16,27,28} without an increase in rupture rates^{9,28-30} for early motion protocols vs. static splinting.

Recommendation

- There is little question that lacerated extensor tendons should be repaired. The general and specific complications should be discussed with the patient including the potential benefit of early ROM over static splinting [overall quality: low]

Summary of recommendations

- The in-vitro studies may be used to establish the best technique to repair an extensor tendon. The limited studies suggest that a multistrand interlocking repair such as a Bunnell, augmented Becker or running-interlocking horizontal mattress, is stronger than other techniques. Although not specifically studied, the bulkiness of these repairs is not felt to be problematic in extensor tendon lacerations
- In the absence of high-quality evidence, we turn to expert opinion when making recommendations about the repair of extensor tendon lacerations. There is support that local anesthesia is a safe and effective means of anesthesia for the surgical repair of these injuries in an appropriately equipped Emergency Department or minor procedure room, thereby reducing the financial burden to the payer
- Dynamic mobilization protocols would be the preferred protocol for more complex injuries, for individuals with underlying conditions, reliable patients, or where earlier recovery is essential. The limitation however, is the significant variability in the published protocols. The protocol should position the wrist in at least 21–45° of extension, the MP joints in neutral to prevent lags and a progressive increase in allowable MP flexion in the splint
- Early active protocols provide the same results as the passive protocols and may be easier for both the therapist and the patients to complete. The selection of the protocol should take into consideration the proximity to an experienced hand therapist and patient factors such as the self-employed status of the patient
- Repair of simple extensor tendon lacerations followed by early ROM can be expected to have a good to excellent outcome compared to complex injuries and static splinting
- There is little question that lacerated extensor tendons should be repaired. The general and specific complications should be discussed with the patient including the potential benefit of early range of motion over static splinting

Conclusions

This review reveals a paucity of high-level (I–III) evidence regarding the management of extensor tendon injuries. Management includes the clinical evaluation to make an accurate diagnosis followed by tendon repair with a locking

modified Bunnell, augmented Becker, or running horizontal interlocking technique. The evidence that does exist supports the current opinion of experts that operative repair of extensor tendon lacerations can be adequately performed using local anesthesia in an Emergency Department or minor operating room suite and that early ROM protocols offer some benefit over immobilization in certain tendon zones in the first few months and may be appropriate particularly for patients who require rapid return to preinjury state. The review of the evidence also strengthens the opinion that improved functional outcomes following early motion outweighs the risk of complications associated with these protocols.

Openmirrors.com

Oluseyi Aliu and Kevin C. Chung

University of Michigan, Ann Arbor, MI, USA

Case scenario

A 58 year old white woman reports several months' history of generalized fatigue and "stiffness" of both hands that lasts through the morning. She has noticed painful swelling of the joints in her fingers. She describes throbbing pain that she rates as an 8 on a visual analog scale of 0 to 10.

Relevant anatomy

The inflammation that occurs in rheumatoid arthritis (RA) results in significant soft tissue and bone destruction. The supporting elements of small joints of the hand become attenuated, which causes laxity of collateral ligaments and joint capsules; this, coupled with contracture of the intrinsic muscles, causes the typical deformities such as metacarpophalangeal (MCP) joint subluxation and ulnar deviation seen in RA (Figures 123.1 and 123.2). Furthermore, hypertrophic synovial tissue infiltration creates bulges along the flexor tendon sheath that interfere with flexion of the digits. The dorsal wrist may also be the site of synovial disease leading to a high risk of extensor tendon ruptures. These anatomical derangements create esthetic and functional morbidity for RA patients.

Importance of RA

The worldwide prevalence of RA amongst adults ranges between 0.5% and 1.5%.¹ The disease has profound effects on the productivity and independence of patients because approximately one third of them are not able to work 5

years after disease onset and by 10 years, 50% of patients are not able to work at all.^{2,3} Permanent disability with loss of independence occurs in 20–30% of working-age RA patients within 2–3 years of diagnosis.⁴ In addition to the effect on patients, there is also a significant global financial burden associated with managing the disease including medical treatments, lost productivity, and support for patients who have lost the ability to attend to their activities of daily living. The overall cost of rheumatoid arthritis in the United States in 1996 was \$8.7 billion⁵ and a more recent analysis (2007) puts the cost at \$63 billion per annum in the United States and the equivalent of \$67 billion in Western Europe.⁶

Top seven questions

Diagnosis

1. Who has RA?

Treatment

2. What is the role of biologic disease-modifying antirheumatic drugs (DMARDs) in the management of RA?
3. Is there a role for small-joint synovectomy in the management of joint destruction in the rheumatoid hand?
4. What is the role of prophylactic extensor tenosynovectomy in the management of the rheumatoid hand?
5. What benefits are conferred by flexor tenosynovectomy in the management of the rheumatoid hand?
6. How effective are the surgical options for repairing tendon ruptures resulting from RA?
7. What is the role of MCP arthroplasty in management of the rheumatoid hand?

Figure 123.1 A patient with ulnar drift of fingers.

Figure 123.2 PA radiograph of MCP joint subluxation/dislocation.

Question 1: Who has RA?

Case clarification

The diagnosis of RA is primarily a clinical one. Specific criteria have been established by the American College of Rheumatology (ACR)⁷ to guide clinicians in making a diagnosis of RA that includes: (1) joint stiffness in the morning that lasts more than 1 hour; (2) arthritis of the wrist, metacarpophalangeal (MCP) joint, or proximal interphalangeal (PIP) joint; (3) arthritis of three or more of the following joints: right or left PIP, MCP, metatarsophalangeal (MTP), elbow, wrist, knee, or ankle; (4) symmetric joint involvement; (5) rheumatoid nodules; (6) serology showing the presence of rheumatoid factor (RF); and (7) radiographic evidence of joint erosions. A patient must have at least four of the seven criteria and the first four criteria must be present for a minimum of 6 weeks.⁷

Question 2: What is the role of biologic DMARDs in the management of RA?

Case clarification

The ACR⁸ has defined a core set of measures to characterize active RA after diagnosis has been made. These include: (1) a count of tender and swollen joints, (2) the patient's qualitative assessment of pain, (3) the patient's assessment of disease activity, (4) the patient's assessment of physical function, (5) the physician's assessment of disease activity, and (6) serum levels of inflammatory markers. Charting changes in these measures help to monitoring a patient's response to medical therapy.

Relevance

The objectives of treatment in RA are symptom relief, improvement in function, and arrest of disease progression. Biologic DMARDs may play a role in arresting joint and soft tissue damage by decreasing inflammation through modification of immunologic processes.

Current opinion

There is much emphasis on early control of rheumatoid disease activity, and using a combination of a biologic DMARD and methotrexate is widely advocated for refractory disease.

Finding the evidence

- Cochrane Database, using keywords: "adalimumab AND rheumatoid arthritis," "infliximab AND rheumatoid arthritis," "etanercept AND rheumatoid arthritis"
- PubMed systematic reviews, using keywords: "adalimumab AND rheumatoid arthritis," "infliximab AND rheumatoid arthritis," "etanercept AND rheumatoid arthritis"

Quality of evidence

Level I

- 6 systematic reviews/meta-analyses
- 20 randomized control trials (RCTs)

Findings

Clinical outcome The DMARDs are a group of medications used to slow the progression of rheumatoid disease through various mechanisms that influence the inflammatory process. Synthetic DMARDs—such as the chemotherapeutic agents methotrexate and sulfasalazine, among others—were the mainstay of treatment as monotherapy or in combinations for the management of active RA. The introduction in the past decade of a newer class of drugs known as biologic DMARDs has improved treatment for patients who are refractory to the traditional drugs. This newer class of drugs is made with recombinant DNA technology, and they modulate immune response by targeting specific elements of the immune system like tumor necrosis factor

(TNF)- α , CD20 receptors on B cells, and various interleukins. The superior effectiveness of the biologic DMARDs in improving radiographic and clinical outcomes in RA treatment is widely demonstrated, especially in managing disease refractory to the older synthetic DMARDs.

A meta-analysis of 13 RCTs (n = 6694) comparing biologic DMARD monotherapy to placebo clearly demonstrates the effectiveness of the biologic DMARD drugs studied including anakinra, etanercept, infliximab, and adalimumab.⁹ In all of these studies, the outcome measure was achievement of ACR20, which is a 20% improvement in the previously listed core measures of rheumatoid disease activity (see “Case clarification” section). Results of odds ratios (ORs) with 95% confidence intervals (CI) calculated for the achievement of ACR20 using biologic DMARD monotherapy were: anakinra 1.70 (0.9–3.19), etanercept 3.58 (2.09–6.91), infliximab 3.47 (1.66–7.14), and adalimumab 3.19 (1.97–5.48).⁹ The investigators also demonstrated the effect of combination treatment using a biologic DMARD and methotrexate, by calculating ORs for ACR20 achievement after the addition of methotrexate to an existing regimen of biologic DMARD mono-

therapy. Their results showed significantly increased effectiveness of the biologic DMARDs after the addition of methotrexate.⁹

Venkateshan et al.’s¹⁰ meta-analysis of 25 RCTs (n = 11252) provides further evidence of the effectiveness of combination therapy. They compared biologic DMARDs in combination with a synthetic DMARD (methotrexate) against placebo treatment (methotrexate only) in patients with active disease. Their reported OR (95% CI) for achievement of ACR20 measured at 24, 54, and 96 weeks after initiation of therapy were 3.69 (3.48–3.87), 3.31 (2.98–3.64), and 3.0 (2.64–3.35) respectively, demonstrating significantly superior effectiveness for the combination of biologic DMARDs and methotrexate compared to methotrexate only treatment with up to 96 weeks of follow-up.

In terms of radiographic outcomes, the Sharp score (TSS) is one of several methods used to measure the effectiveness of treatments for RA. This score comprises a tally of joint erosion and joint space narrowing (JSN) scores, and an increase over time indicates progressive joint destruction as a result of either erosion, joint space narrowing, or both (Table 123.1). One of the treatment goals for RA is to arrest

Table 123.1 Change in radiographic scores in comparisons of biological DMARDs (adalimumab, etanercept, and infliximab) to placebo

^bThese studies included more than one dosing regimen of the biological DMARDs; the most efficacious doses are represented.

joint destruction, and a wealth of evidence shows that patients who receive biologic DMARDs, either as monotherapy or in combination with methotrexate, have significantly less progression of joint erosions and JSN when compared with patients receiving placebo (Table 123.2).^{11–20} Furthermore, initiation of biologic DMARDs early in the course of treatment can aid in arresting joint destruction, and this was shown in a post-hoc analysis from a 3 year RCT. In this analysis a cohort with earlier addition of infliximab to a methotrexate-only regimen was compared to another cohort with a later initiation of infliximab. The investigators found that significantly fewer patients with earlier initiation of infliximab showed progressing joint destruction with majority of them achieving arrest of joint destruction.²¹

Recommendation

- Evidence suggests that treatment of early aggressive or refractory RA with combination of biologic DMARD and methotrexate improves clinical and radiographic outcomes [overall quality: high]

Question 3: Is there a role for small-joint synovectomy in management of joint destruction in RA?

Case clarification

Swelling of the patient's joints could be an indication of proliferative synovitis. Serial physical examinations show she has well-organized painful synovitis. Radiographs show no evidence of joint destruction.

Relevance

Active synovitis of joints in RA can result in destruction of joint structures and subsequent impairment of function.

Current opinion

Small-joint synovectomy can have a role in management of patients with persistent pain after up to 6 months of medical therapy, provided they show no joint cartilage and bone destruction.

Finding the evidence

• Cochrane Database, using keywords "tenosynovectomy AND rheumatoid arthritis," "synovectomy AND rheumatoid arthritis"

• PubMed, using keywords "tenosynovectomy AND rheumatoid arthritis," "synovectomy AND rheumatoid arthritis"

Quality of evidence

Level IV

- 3 observational cohort studies with inconsistency
- 3 case series

Findings

Synovial proliferation in the small joints of the hand causes joint tenderness, swelling, limited range of motion, and to a significant degree, the synovitis also propagates progressive joint destruction. Hand surgeons use open and arthroscopic techniques to remove the infiltrative synovium in order to ameliorate symptoms, improve function, and arrest destructive synovitis. Although outcome measures reported are variable across most studies, they do indicate that there is benefit to undergoing small-joint synovectomy.

In a study conducted by the Arthritis and Rheumatism Council and British Orthopaedic Association,²² 69 metacarpophalangeal (MCP) joints in 22 patients were randomized to synovectomy and nonsurgical management. The patients

were examined after 2 years and results demonstrated only improved joint swelling in the synovectomy group; however, assessment at 3 years showed these patients did not have significantly better outcomes overall. Additionally, the improved joint swelling seen at the 2 year follow-up period was not maintained, but all the patients who underwent synovectomy were satisfied with the procedure. McEwan et al.²³ reported similar results in their study of 20 patients with MCP joint synovitis; at 1 year after surgery, the patients had significant improvements in joint tenderness and swelling, but at 3 years after surgery, these favorable outcomes were not maintained.

Thompson et al.²⁴ randomized RA patients affected by synovitis who were undergoing pharmaceutical treatments into three groups—synovectomy, medications only, and splinting. Although the investigators did not specify the duration of follow-up, they showed that the synovectomy group demonstrated significantly better improvements in grip and palmar pinch strength, patient satisfaction, joint swelling, and sensitivity to pain compared to the other groups. However, as in McEwan et al.'s study,²³ the radiographs showed no difference in the degrees of joint degradation outcomes between patients who underwent synovectomy and their respective controls at follow-up.

In conclusion, some evidence suggests that most patients who underwent small-joint synovectomy reported significant pain relief and radiographic assessment showed that 37–45% of them achieved arrest of joint erosions (Table 123.3).^{25–27} Other studies demonstrate that the advantages obtained from small-joint synovectomy are temporary.^{23–24} The recurrence rates reported in the literature for small-joint synovitis vary between 6% and 30%, with up to 8 years of follow-up (Table 123.3).^{25–27}

Recommendation

- The evidence suggests that performing small-joint synovectomy, when there is persistent pain and functional limitation in the absence of joint destruction, can provide symptomatic relief for a limited period of time [overall quality: low]

Question 4: What is the role of prophylactic extensor tenosynovectomy in the management of the rheumatoid hand?

Case clarification

Patients with RA presenting with painful swelling of the wrist likely have proliferative synovitis affecting the wrist joint with associated extensor tendon synovitis.

Relevance

Rheumatoid arthritis patients with refractory wrist joint and extensor tendon synovitis are at high risk of extensor tendon ruptures,²⁸ which will cause debilitating functional problems and the morbidity associated with tendon reconstruction.

Current opinion

Prophylactic extensor tenosynovectomy is effective in preventing tendon ruptures.^{29–31}

Finding the evidence

- PubMed, using keywords “extensor tenosynovectomy AND rheumatoid arthritis,” “wrist synovectomy AND rheumatoid arthritis”

Quality of evidence

Level IV

- 8 case series

Findings

The wrist joint is commonly affected in RA,³² and the initial treatment of synovitis of the wrist as in the overall treatment of rheumatoid disease relies on drug therapy to prevent destruction of the joint. However, despite optimal medical treatment, patients may present with refractory disease by having proliferative synovitis involving the distal radioulnar joint (DRUJ) with or without extensor tendon involvement. If wrist synovitis is allowed to progress, the DRUJ is destroyed, causing dorsal displacement of the distal ulna and derangements of the carpus including axial collapse, ulnar translocation, and palmar

Table 123.3 Outcomes of small-joint synovectomy

Study	n	Follow up (yrs)	Joints involved	% of n with improved pain	% of n with no progression of erosions	% of n with recurrence	% of n with JSN progression
Ansell et al. ²⁷	56	1	PIP	91	37	19	NR
Nicolles et al. ²⁶	37	4–8	MCP	92	NR	6%	NR
Wilde ²⁵	39	1–3	PIP	88	45	30	40

JSN, joint space narrowing; MCP, metacarpophalangeal; NR, not reported; PIP, proximal interphalangeal.

subluxation.^{33–37} Ultimately, tendon ruptures occur from direct synovial infiltration of tendons and/or attritional damage from the tendons rubbing against the dorsally displaced distal ulna.²⁸

Dorsal tenosynovectomy is usually combined with distal ulna excision for refractory wrist joint involvement when there is DRUJ instability or destruction.³³ Several studies have demonstrated that prophylactic extensor tenosynovectomy, even when there is evidence of synovial invasion of extensor tendons at the time of surgery, significantly prevents tendon ruptures, with occurrence of subsequent ruptures in only 0–3% of patients.^{29–31} Excision of destructive synovium and removal of mechanical irritation from the displaced distal ulna contribute to the benefits of these procedures.³⁸

In addition to the prevention of extensor tendon rupture, dorsal synovectomy and distal ulna excision are reported to provide pain relief and improved pronation and supination of the wrist joint.^{30,34–37,39} However, ulnar translocation of the carpus progresses over time, regardless of whether patients undergo dorsal synovectomy and distal ulna excision.^{34–37} Ishikawa et al. suggest that ulnar translocation occurs significantly more in patients who undergo distal ulna excision because the support of the carpus provided by the distal ulna is lost.³⁶ Drawing inference from studies showing wrist stability in patients with spontaneous radiocarpal fusion and their results, they propose radiolunate arthrodesis to stabilize the wrist following distal ulna excision.³⁶

Recommendations

- Patients who present with refractory wrist joint and extensor tendon synovitis should undergo dorsal synovectomy. If there is DRUJ instability or destruction, distal ulna excision should be performed. Both procedures are effective in preventing extensor tendon rupture [overall quality: moderate]
- Distal ulna excision may result in accelerated ulnar translocation of the carpus, and limited radiocarpal fusion may be beneficial in stabilizing the wrist joint to prevent carpal translocation [overall quality: moderate]

Question 5: What benefits are conferred by flexor tenosynovectomy in the management of the rheumatoid hand?

Case clarification

When a patient with RA has difficulty with active digital flexion, it is important to distinguish whether the problem is in the joints or in the flexor tendons. For the flexor tendon problem, the patient will have full passive flexion or the joint, but the active flexion is limited because of swelling in the flexor tendons. On the other hand, a patient with an

isolated joint problem will have limited joint motion, both passive and active.

Relevance

The prevalence of flexor synovitis in RA has been reported to be between 40% and 55%.⁴⁰

Current opinion

Patients can achieve a significant improvement in functional ability with flexor tenosynovectomy

Finding the evidence

- Cochrane Database, using keywords “tenosynovectomy AND rheumatoid arthritis,” “synovectomy AND rheumatoid arthritis”
- PubMed, using keywords “tenosynovectomy AND rheumatoid arthritis,” “synovectomy AND rheumatoid arthritis”

Quality of evidence

Level IV

- 4 case series

Findings

Hypertrophic synovial infiltration within the flexor tendon sheath presents with bulges along the tendon sheath, and these bulges often occur at the weaker cruciform pulleys that are stretched.³³ A plain radiograph should be obtained to rule out concomitant PIP joint disease.

The available evidence suggests that between 50% and 75% of patients who undergo flexor tenosynovectomy achieve measurable improvements in extensor lag and flexion deficit, with less than 20% of them faring poorly (Table 123.4).^{40–42} Additionally patients have been shown to achieve a significant improvement in pain levels, in active and passive range of motion at the PIP joint and in overall satisfaction after the procedure with up to 12 years of

Table 123.4 Comparison of results of flexor tenosynovectomy with the Jackson and Paton scale

Study	n	% Excellent	% Good	% Fair	% Poor
Jackson and Paton ⁴¹	36	44	31	11	14

 Excellent: tip to palm 0cm, MCP/PIP extensor lag 0°
 Good: tip to palm ≤2cm, MCP/PIP extensor lag ≤30°
 Fair: tip to palm ≤2–4cm, MCP/PIP extensor lag ≤30°.
 Poor: tip to palm >4cm, MCP/PIP extensor lag >30°.

follow-up.^{40,43} Only one study reported the recurrence rate in their series of hypertrophic flexor tenosynovitis cases, which was 31% after up to 4 years of follow-up⁴².

Recommendation

- Flexor tenosynovectomy can provide functional benefit for patients with impairment of active flexion caused by synovitis [overall quality: low]

Question 6: How effective are surgical options for repairing tendon ruptures resulting from RA?

Case clarification

Both flexor and extensor tendons can rupture as a result of rheumatoid disease activity either due to attenuation directly from invasive synovitis or by attritional wear from eroded bones.

Relevance

If the underlying cause of tendon rupture is not identified and treated, further ruptures can occur, which can increase functional morbidity.

Current opinion

Prevention of tendon ruptures is most ideal and tenosynovectomy is effective in this regard.³¹ However, the functional impairment wrought by tendon ruptures should be a clear indication for tendon reconstruction.

Finding the evidence

- PubMed, using keywords "tendon transfer AND rheumatoid arthritis"

Quality of evidence

Level IV

- 4 case series

Findings

When a tendon rupture is suspected, the causative factor should be identified and addressed at the time of reconstruction. For instance, in the investigation of extensor tendon ruptures, radiographic studies often show a disrupted DRUJ with an eroded distal ulna. Physical examination demonstrates that the remaining intact tendons are rubbing over the surface of the eroded distal ulna and in a matter of time, additional ruptures are likely. In this case, dorsal synovectomy, distal ulna excision, or both should be performed at the same time as the tendon reconstruction to prevent rupture of the intact tendons. Ishikawa et al.³⁶ suggest that a radiolunate arthrodesis should be also considered early in addition to the above procedures to stabilize the wrist and prevent further wrist subluxation.

Surgical reconstruction for tendon ruptures may be achieved by either tendon transfers or free interposition grafting; however, there are no studies directly comparing the two methods. Mountney et al.⁴⁴ instead used a biomechanical model to show the advantage of interposition grafting compared to tendon transfers by demonstrating mathematically that a smaller angle between the line of force and the axis of its motor unit by using the native proximal tendon results in a greater percentage of maximum force generated. The inferred advantage to tendon grafts is that they are along the same axis as their motor units. Additionally, they reported an average MCP joint extension lag of 9° and flexion deficit of 10° after free interposition grafting with up to 45 months of follow-up.

Tendon rupture from RA tends to be progressive, and evidence suggests that prompt intervention is beneficial.⁴⁵ Although most patients in Shannon and Barton⁴⁶ and Moore et al.'s⁴⁷ series of tendon transfers achieve good outcomes in terms of extensor deficit and range of motion, those with reconstruction of isolated tendon ruptures, especially isolated extensor pollicis longus (EPL) ruptures, had the best outcomes. The worst outcomes were in patients with multiple tendon ruptures and tendon ruptures concomitant with untreated MCP joint disease.⁴⁵⁻⁴⁷

Recommendations

- Tendon reconstruction can be used to improve the impairment of hand function that results from extensor or flexor tendon ruptures [overall quality: moderate]
- Concomitant procedures like distal ulna excision and synovectomy may be required to achieve better outcomes and prevent further ruptures [overall quality: moderate]
- Interposition grafting may provide some benefit in force generation compared to tendon transfers [overall quality: low]

Question 7: What is the role of MCP arthroplasty in RA management?

Case clarification

Due to the progressive nature of RA, joint destruction can reach a stage in which a surgical salvage procedure such as MCP arthroplasty is necessary.

Relevance

The MCP joint is most commonly affected in RA and end-stage destruction of these joints can render patients functionally impaired, with unappealing appearance of their hands.

Current opinion

In a recent survey of hand surgeons, 84% had a favorable view of outcomes from MCP arthroplasty⁴⁸ citing improved

Figure 123.3 PA radiograph of a hand after MCP joint arthroplasty.

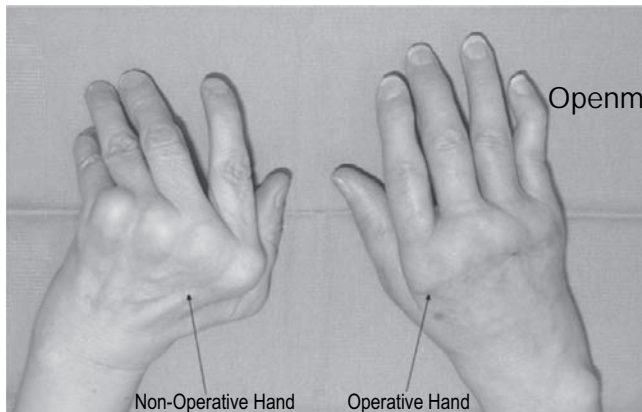

Figure 123.4 A hand after MCP arthroplasty with fingers in extension.

cosmetic appearance and function in daily activities (Figures 123.3–123.5).

Finding the evidence

- Cochrane Database, using keywords: “arthroplasty” AND “rheumatoid arthritis”
- PubMed, using keywords: “arthroplasty” AND “rheumatoid arthritis”

Quality of evidence

Level III

- 1 systemic review of cohort and case series studies
- 2 observational cohort studies

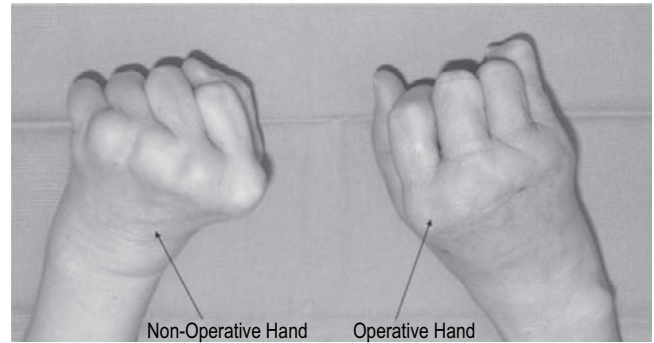

Figure 123.5 A hand after MCP arthroplasty with fingers flexed.

Level IV

- 1 case series

Findings

The course of MCP joint disease in RA results from synovial infiltration and subsequent attenuation of joint support structures. Radial and ulnar sagittal bands that stabilize the extensor tendon over the MCP joint are stretched by synovitis. The radial band is further weakened by the gripping motion involved in daily activities that causes progressive ulnar displacement of extensor tendons characteristic of rheumatoid hands. As a result, ulnar lateral bands contract to further accentuate the drift of the extensor tendons. Furthermore, the proximal phalanx itself may become volarly subluxed. These structural changes adversely affect the functional ability of the hand and are a significant cosmetic burden to patients. This degree of joint destruction is a clear indication for joint replacement.

The goals of MCP joint arthroplasty are to improve hand function and appearance. Although there is debate about the effectiveness and timing of surgical intervention in RA, the available evidence suggests that there are benefits in undergoing the procedure. In terms of physical outcome measures, several studies have demonstrated a significant improvement in range of motion after MCP arthroplasty.^{49–51} However, strength measures (grip and pinch) do not show the same favorable outcomes (Table 123.5).^{51–52} Additional favorable outcomes have been shown using the Michigan Hand Questionnaire (MHQ) that measures six domains important to the rheumatoid patient; (1) overall hand function, (2) activities of daily living, (3) pain, (4) work performance, (5) esthetics, and (6) patient satisfaction. The evidence demonstrates the short-term advantage of MCP arthroplasty in five of these domains, the exception being work performance.^{51–52}

In conclusion, subjective outcome measures demonstrate that patients perceive that they gain significant benefits from MCP arthroplasty in cosmetic improvement and the ability to perform daily tasks.

Table 123.5 Physical outcome measures after MCP arthroplasty

Study	MCP ROM (°)	Grip strength (kg)	Key pinch strength (kg)	Tip pinch strength (kg)	Palmar pinch strength (kg)

MCP, metacarpophalangeal; NR, not reported; ROM, range of motion
^aUnpooled results from a systemic review with 2 of 10 studies showing changes in grip strength represented in the split column.
^bStatistically significant change.

Recommendation

- MCP joint arthroplasty can deliver significantly improved hand function and appearance [overall quality: moderate]

Summary of recommendations

- Biological DMARDs in combination with a non-biological DMARD, especially methotrexate, have demonstrated efficacy in treatment of early aggressive RA and disease refractory to methotrexate monotherapy
- In patients with persistent pain and functional limitation from small-joint synovitis, synovectomy can provide symptomatic relief for up to 2 years
- Prophylactic extensor tendon and wrist joint synovectomy in combination with distal ulnar excision are effective in the prevention of tendon ruptures when indicated
- Flexor synovectomy can effectively improve flexion hampered by synovial proliferation along the tendon sheath
- Tendon transfers and tendon interposition grafting can reliably improve hand function after flexor or extensor tendon ruptures
- Prevention of tendon ruptures with such procedures as synovectomy and distal ulna excision is effective. These procedures may also be done at the same time as tendon reconstruction to stave off further ruptures
- MCP arthroplasty provides significant improvement in subjective outcomes and should be considered in endstage destruction of MCP joints

Conclusions

There is high-level evidence to support the use of biological DMARDs in the treatment of early aggressive arthritis and management of disease activity not responding optimally to monotherapy with methotrexate. Most surgical procedures to correct anatomic derangements are not as strongly supported by well-designed, high-quality studies. However, both objective and subjective components of outcome measures in the studies examined suggest that there is discernable benefit for patients undergoing rheumatoid hand reconstruction.

²University of California-Davis, Sacramento, CA, USA

Case scenario 1

A 35 year old male construction worker who is right-hand dominant presents with inability to bend his left ring and small fingers. Two weeks ago he sustained a laceration across the palmar aspect of his proximal phalanx of these two digits while cutting wire. On examination, his ring and small finger have increased resting extension posture. His wounds are healed. He cannot flex his proximal interphalangeal (PIP) or distal interphalangeal (DIP) joints to his ring finger. Flexion of his little finger PIP and DIP is weak and painful. His sensory examination is normal.

Relevant anatomy

The flexor tendons are enclosed in a synovial sheath in the distal palm and digits. The sheath provides a gliding surface for the tendons. Pulleys are thickenings of the tendon sheath which prevent bowstringing of the tendons and improve tendon excursion. in the finger. There are five annular (A) and three cruciform (C) pulleys; A2 and A4 are the most critical for complete finger flexion (Figure 124.1).¹

The nutritional supply of the flexor digitorum superficialis (FDS) and flexor digitorum profundus (FDP) arises from diffusion of nutrients within the synovial sheath, the surrounding paratenon, and arterial system in the volar finger. The blood supply enters the tendon dorsally and consists of vessels in the proximal synovial fold, the vincular system, and osseous insertion of the FDS and FDP.³ The vincula are dorsal folds of mesotenon through which small vessels travel to supply the tendon. The digital arteries in

the finger give off segmental branches, which supply the vincular vessels. Proximal to the sheath, the tendons are covered by an extensive vascular plexus.

Verdan classified flexor tendon injuries into five zones (Figure 124.2).^{4,5} Each zone has important anatomic considerations and prognostic implications. Zone II flexor tendon injuries are of particular interest to hand surgeons, as reflected in the large body of literature published on these injuries. Injuries in zone II, also known as “no man’s land,” include lacerations from the A1 pulley to the insertion of the FDS tendon. Zone II injuries are difficult to treat because of the small, unyielding space in which the two tendon slips of the FDS and the FDP tendon all pass. The other flexor tendon zones are illustrated in Figure 124.2.

Importance of the problem

Flexor tendon lacerations make up less than 1% of all hand injuries seen in the Emergency Department,⁶ but their the social and economic consequences are considerable because the injury is most common in young healthy adults, leading to lost work productivity. A 2003 multiple regression analysis of 97 flexor tendon lacerations treated in southern Sweden found the average costs of surgery and rehabilitation of zone II flexor tendon injuries to be over \$21,100.⁷ Healthcare costs averaged over \$7,000 and lost work productivity cost almost \$14,000. Setting hurdles for treatment decisions is the abundance of research literature and patient information available on the internet. PubMed searches for “flexor tendon injury” and “hand” yield over 1,200 published articles, whereas Google returns over 49,000 hits for “flexor tendon injuries.”

Figure 124.1 Flexor tendon pulley system: lateral (top) and palmar (bottom) views of a finger depict the components of the digital flexor sheath. The sturdy annular pulleys (A1, A2, A3, A4, and A5) are important biomechanically in keeping the tendons closely applied to the phalanges. The thin, pliable cruciate pulleys (C1, C2, and C3) collapse to allow full digital flexion. The palmar aponeurosis pulley (PA), adds to the biomechanical efficiency of the sheath system. (Reproduced with permission from Strickland JW. Development of flexor tendon surgery: twenty-five years of progress. *Hand Surg Am* 2000;25(2):214–235).²

Figure 124.2 Flexor zones of the hand. Zone V extends from the musculotendinous junction to the carpal tunnel. Zone IV injuries involve lacerations at the level of the carpal tunnel. Zone III injuries include injuries from the distal edge of the transverse carpal ligament to the proximal edge of the A1 pulley. The lumbricals originate in zone III. Zone II starts from the A1 pulley to the insertion of the FDS tendon (see text). Zone I injuries are distal to the FDS insertion and only involve the FDP tendon insertion. In the thumb (FPL lacerations), zones V and IV correspond to Verdan's zones V and IV for flexor tendon injuries to the other digits. FPL injuries at the level of the thumb metacarpal make up zone III. Zone II injuries include the A1 pulley to the metacarpalphalangeal joint. Zone I injuries extend from the interphalangeal joint to the FPL insertion.

Top seven questions

Surgical therapy

1. What suture configuration should be used to achieve the strongest repair in zone II flexor injuries?
2. What suture material should be used to repair flexor tendon lacerations?
3. Should a patient undergo surgical repair of the partial tendon laceration?
4. What is the optimal fixation for FDP avulsion injuries?

Prognosis

5. Does the use of botulinum toxin improve outcomes in flexor tendon repair?
6. Are there any medications or treatments to prevent adhesion formation after flexor tendon repair?

Diagnosis of failed tendon repair

7. What is the role of imaging in evaluating flexor tendon injuries and the status of flexor tendon repairs postoperatively?

Question 1: What suture configuration should be used to achieve the strongest repair in zone II flexor injuries?

Case clarification

Which core suture configuration is strong enough to allow the patient to start early active and passive range of motion (ROM) after flexor tendon repair?

Relevance

Biomechanical studies have shown the strength of the repair increases with the number of suture strands crossing the repair site. Suture techniques using more strands across the repair site are technically demanding, require increased manipulation of the tendon ends, and create a bulky repair, which may compromise tendon gliding.

Current opinion

Flexor tendon repairs should be performed with a core suture of at least four strands crossing the tendon repair site with equal strength across all strands. Repairs should be supplemented with an epitendinous suture.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: "core suture" AND "flexor tendon surgery" [also added: "NOT biomechanic*" and Limits to Humans]

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “suture technique(s)” AND “flexor tendon repair” AND “hand” OR “zone II flexor tendon repair”

Quality of the evidence

Level II

- 8 retrospective cohort studies

Level III

- 1 retrospective cohort study without adequate controls

Level IV

- More than 30 case series

Findings

Taking into account increased resistance from edema after surgery and a decrease in suture strength during the initial

weeks after flexor tendon repair, several authors have suggested that tendon repair strength should be at least 73.5N to withstand early active and passive finger motion.^{8,9} Numerous biomechanical studies have compared the strength of different repair techniques.¹⁰⁻¹⁶ These studies have shown that increasing the number of core sutures increases the strength of tendon repair (Table 124.1).

Epitendinous sutures increase the strength of core suture repairs by 10–50%, reduce gapping between tendon ends, and smooth the repair site.¹⁹ Stein and colleagues¹⁷ demonstrated increases in dorsal vs. volar grasping strength of Kessler and Robertson repairs (Figure 124.3) but had no effect on strength of locking Strickland and modified Becker repairs.^{17,20,21} Locking core sutures have also been shown to increase the strength of tendon repairs compared to grasping techniques. Increasing the number of suture locks or grasps further increases strength at the repair site.^{22,23}

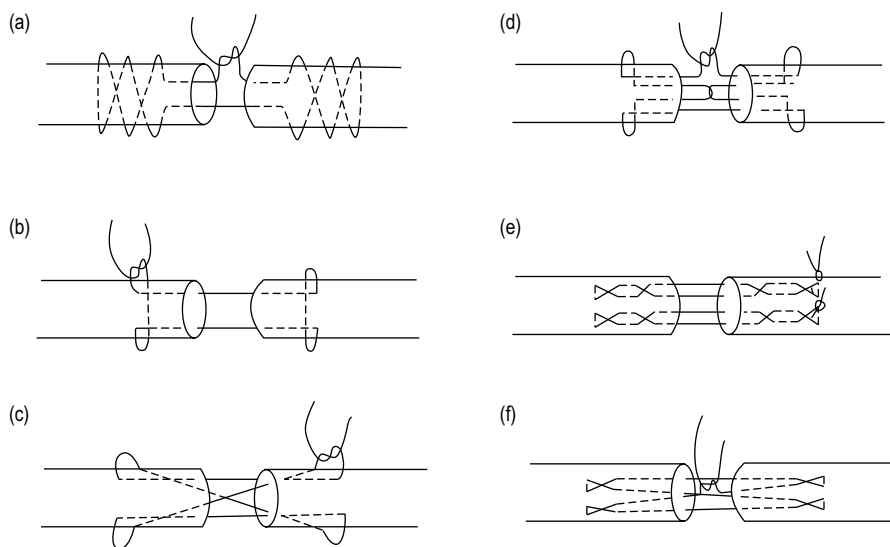

Figure 124.3 Various core suture techniques: (a) Bunnell, (b) Kessler, (c) cruciate, (d) interlock, (e) modified Becker, (f) modified Savage by Sandow.

Numerous clinical studies have reported results of flexor tendon repairs using various suture techniques. Results of various methods of flexor tendon repair evaluated using Strickland's criterion (see box) are summarized in Table 124.2. Several of these studies were focused on rehabilitation protocols and rarely involved more than one cohort within the same population, making comparison of the different techniques difficult. Other studies have many uncontrollable variables and different evaluation methods.

Strickland and Glogovac criterion^{26,38}

Originally developed to assess function after flexor tendon repair, it is calculated as a percentage of normal active PIP and DIP motion:

active PIP+DIP flexion-extension lag at the PIP and DIP/175° × 100

The percentage is then categorized as follows:

- Excellent: 85–100% of normal (100% = 175°)
- Good: 70–84%
- Fair: 50–69%
- Poor <50%

All ROM results in this chapter are based on this criterion unless otherwise stated.

There are only two clinical studies directly comparing different suture techniques. Hoffman et al.³² reviewed the clinical outcomes of 46 patients (51 digits) undergoing a six-strand Lim/Tsai repair to 25 patients (26 digits) treated with a two-strand modified Kessler stitch in zone II flexor tendon repairs. The complication rate was lower in the six-strand group (4%) than in the modified Kessler group (23%). The rupture rate was also lower in the six-strand

group (2% vs. 11% in the other group), but this was not statistically significant. The two groups followed different rehabilitation protocols, which confound the effects of the suture repair.

Osada and colleagues²⁴ compared clinical outcome of 22 patients (28 digits) with zone II flexor tendon lacerations repaired using two different six-strand suture techniques (Figure 124.4). The authors reported a 96% excellent result based on the original Strickland criterion, with no clinically significant difference in the outcomes of the two groups after average follow-up of 13 months (range 6–51 months). None of the repaired tendons ruptured.

Recommendations

Based on clinical and biomechanical studies:

- Four-strand or higher core suture technique supplemented by running epitendinous sutures are recommended to provide sufficient tensile strength to allow for postoperative passive and some active motion rehabilitation [overall quality: moderate]
- Dorsal placement of the suture and locking (vs. grasping) sutures increase the strength of repair. Increasing the number of grasps or locks also improves tensile strength. Whether or not the difference is seen clinically is unknown [overall quality: not applicable]

Question 2: What suture material should be used to repair flexor tendon lacerations?

Case clarification

The patient is taken to the operating room and found to have complete laceration of the ring finger FDS and FDP tendon in zone II. You must decide which suture material to use to repair his flexor tendon.

Table 124.2 Outcomes based on Strickland criteria for flexor tendon repairs using various core sutures^{24,25}

Study	Suture repair	Rehabilitation protocol	Number (digits)	Average follow-up (months)	G/E results (%)	Rupture rate (%)

^aResults included rerepair cases.

^bResults include injuries in other zones.

Rehabilitation protocols: Active, active flexion and extension; Kleinert, passive flexion and active extension; Duran Houser, passive flexion and extension; Immobilization, immobilization for 3 weeks, Modified active, active flexion after full passive flexion.

Relevance

Many types and sizes of suture material are available for flexor tendon repair. The need for a strong suture material must be balanced with the risk of excessive bulk and scar formation from foreign body reaction.

Current opinion

Most guidelines for suture repair include using a 3-0 or 4-0 nonabsorbable polyfilament material with at least four strands crossing the tendon repair site and equal strength across all strands. Most surgeons also use epitendinous sutures made of 5-0 or 6-0 monofilament nonabsorbable suture to smooth the repair site and improve tensile strength.¹⁹

Finding the evidence

• PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords: “core suture” OR “TenofixTM” OR

“suture material” and “flexor tendons” and “rupture” OR “flexor tendon repair”

Quality of the evidence

Level I

- 1 randomized controlled trial (RCT)

Level III

- 1 retrospective comparative study

Level IV

- 1 case series

Findings

There are many biomechanical and animal studies addressing the ideal core suture material for flexor tendon repairs to allow early postoperative motion (Table 124.1). Monofilament stainless steel sutures have been shown to

have the greatest tensile strength, but are difficult to use and may weaken with kinking.³⁹ Nonabsorbable 3-0 or 4-0 braided polyester sutures have better gliding properties with comparable tensile strength to stainless steel sutures.⁹ Monofilament nylon and polypropylene have better knotting capabilities than braided polyester but are not as strong.⁴⁰ They are most commonly used for epitendinous sutures. Larger-caliber sutures increase the strength of flexor tendon repairs.^{10,41,42} Larger sutures are bulky, however, leading to increased work of flexion and gliding resistance. Biomechanical studies have proven that repairs using 3-0 or 4-0 sutures provide sufficient tensile strength and adequate gliding efficiency to withstand early postoperative motion therapy.¹⁰

There are few clinical studies directly comparing the outcomes of flexor tendon repairs using different suture materials. Two studies have reported on the use of the Tenofix device for flexor tendon repairs. Tenofix is a knotless suture composed of two intratendinous stainless steel anchors joined by a single multifilament 2-0 stainless steel suture (Figure 124.5). It provides the strength of stainless steel

sutures without the difficulty of managing and tying it. Biomechanical studies have shown it has comparable repair strength to the standard 3-0 or 4-0 suture.^{37,43} Results from a manufacturer-sponsored, blinded, randomized clinical trial comparing Tenofix to a locked four-strand cruciate repair for the treatment of zone II flexor tendon lacerations showed superior results with the Tenofix repairs.¹⁸ None of the Tenofix repairs ruptured at 6 months compared to 18% (9 of 51) rupture rate for repairs using the cruciate technique. The 18% failure rate is higher than previous studies on four-strand repairs showing rupture rates of less than 10% (Table 124.2). Of note, Tenofix could not be used in a number of cases because of inadequate tendon exposure or an injury that was too distal in zone II for placement of both suture anchors.

Rocchi and colleagues²⁵ used Tenofix on 21 isolated zone II flexor tendon injuries in all digits (including the thumb). There were 86% excellent or good results and 14% (three) fair results. Two anchors required removal; one because of tendon rupture (failure rate 4%) and another because of infection. Patients in this study returned to work on average sooner than patients in previous reports on multistrand repairs (30 days vs. 60 days after surgery).^{31,44}

Absorbable suture has high tensile strength and is inextensible and easy to tie and use,⁴⁵ but is not widely used in flexor tendon repairs. In animal studies, these sutures maintain strength long enough to allow adequate tendon healing.^{46,47} Nonetheless, Mashadi and colleagues⁴⁶ concluded the absorbable suture they tested, polytrimethylene carbonate (MaxonTM), should not be used for tendon repairs because it stimulated a significant tissue reaction and subsequent adhesions in chickens.

One retrospective study³⁵ has shown comparable clinical results of flexor tendons repaired with absorbable sutures vs. nonabsorbable materials. In a series of 272 patients (566 tendon lacerations in 416 digits) repaired with a Strickland four-strand core suture repair supplemented with an epitendinous suture, absorbable suture (polytrimethylene/Maxon or PDSTM) in was used in 191 (73%) patients and nonabsorbable suture in 81 (27%). Rupture rate was 2% in both groups. There was no statistical difference in range of motion (ROM), outcomes, rate of infection, or need for tenolysis between the two groups. Among zone II injuries,

Figure 124.4 Six-strand suture techniques. (a) The Y1 technique: combination of Tsuge suture with a 4-0 looped thread and the modified Kessler suture using a 4-0 double strand with two needles. (b) The TL technique using three Tsuge sutures with 4-0 looped thread. (Reproduced with permission from Osada D, Fujita S, Tamai K, Yamaguchi T, Iwamoto A, Saotome K. Flexor tendon repair in zone II with 6-strand techniques and early active mobilization. *J Hand Surg Am* 2006;31(6):987–92.)

Figure 124.5 Tenofix device. Adapted from Su BW. The biomechanical analysis of a tendon fixation device for flexor tendon repair. (Reproduced with permission from Su BW. The biomechanical analysis of a tendon fixation device for flexor tendon repair. *J Hand Surg Am* 2005;30(2):237–245.)

151 were repaired using absorbable sutures and 41 using nonabsorbable sutures. Seven out of eight ruptures occurred in zone II: two ruptures occurred in the nonabsorbable group, and five occurred in repairs using absorbable suture.

Recommendations

For repairs of flexor tendon injuries:

- Biomechanical and clinical research has shown that 3-0 or 4-0 braided polyester sutures should be used to allow unrestricted finger flexion during rehabilitation without compromising work of flexion and gliding resistance [overall quality: moderate]
- Clinical research suggests Tenofix is safe and effective in the repair of flexor tendon lacerations. It may not be suitable in all cases; particularly those involving small tendons or poor soft tissue envelope [overall quality: moderate]
- There is insufficient evidence to support the use of absorbable sutures over nonabsorbable suture for repair of zone II flexor tendon injuries. Results of flexor tendon repair using absorbable sutures in all zones have shown comparable results compared to nonabsorbable sutures [overall quality: insufficient; very low]

Question 3: Should partial tendon lacerations be repaired?

Case clarification

During surgery for the patient, exploration of the small finger reveals a 65% laceration of the FDP in zone II. Should you repair the tendon?

Relevance

Flexor tendon repair is fraught with complications including adhesion formation, rerupture, and extensive postoperative rehabilitation. If the tendon could be treated nonoperatively without compromising function, the expense of surgery and a prolonged rehabilitation course could be avoided.

Current opinion

Current opinion suggests lacerations of more than 60% of the cross-sectional area should be repaired to prevent triggering and possible rupture.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: "partial flexor tendon laceration" AND "hand"

Quality of the evidence

Level III

- 1 retrospective comparative study

Level IV

- 2 case series
- 1 retrospective comparative study with small numbers

Findings

Complications of partial tendon lacerations treated nonoperatively include progression to complete rupture, triggering, and entrapment of the tendon.⁴⁸ Biomechanical studies have shown, however, that suturing a partial tendon laceration actually reduces the tensile strength of the tendon.^{49,50} Hariharan et al.⁵¹ showed even substantial lacerations could withstand the loads of active motion.

A prospective study⁵² showed 93% excellent and 7% good results with no complications in 17 partial zone II partial flexor tendon lacerations (15 patients) treated with tendon sheath repair only. The lacerations had not initial triggering and involved 55–90% of the tendon width. Similarly, Wray and Weeks⁵³ reported on partial tendon lacerations in all zones involving up to 95% (mean 60%) of the tendon treated with early mobilization. Twenty-three patients had excellent outcomes, one had good and one had fair. No tendons ruptured. One patient developed a transient trigger finger. McGeorge and coworkers⁵⁴ compared 9 patients (12 lacerations) treated nonoperatively to 4 patients (6 fingers) treated with repair of partial tendon lacerations up to 70% of the tendon cross-sectional area. The average cross-sectional area involved 54% (range 20–60%) in the no-repair group compared to an average 35% (range 20–70%) involvement in the repair group. All of the patients in the nonoperative group had excellent outcomes. Four of the six in the repair group had excellent outcomes, two had good outcomes. The no-repair group returned to work sooner and had better pinch grip strength than the repair group. The authors recommended that flexor tendon lacerations of less than 60% cross-sectional area should not be repaired.

In a retrospective review in children,⁵⁵ Stahl and coauthors compared repair vs. trimming of lacerated edges only for flexor tendon lacerations of less than 75% cross-sectional area. The mean cross-sectional area for the repair group was slightly higher than the nonrepaired tendons, 42% vs. 38%. A trend toward better outcome was found in the no-repair group although this difference was not significant. Tendon laceration of less than 40% undergoing surgical repair had worse outcomes than those treated without repair although the difference was not significant.

Recommendations

- Partial flexor tendon lacerations of less than 40–60% the cross-sectional area of the entire tendon (that do not trigger) are best treated with early ROM without tendon repair (Table 124.3) [overall quality: moderate]
- Partial tendon ruptures of up to 95% may be treated without tendon repair [overall quality: very low]

Table 124.3 Outcomes following treatment of partial flexor tendon lacerations

Study	Treatment	Patients	Tendons	Cross-sectional area	Excellent	Good	Fair	Complications
al Qattan et al. ⁵²	No repair	15	17	55–90%	14	1		0
Wray and Weeks ^{53,a}	No repair	26	34	25–95%	23	1	1	1 (resolved trigger)
McGeorge et al. ^{54,a}	No repair	12	12	54%	12			0
Stahl et al. ^{55,a}	No repair	12	19	38%	11	1		1 (infection)
Total (no repair)		65	82		92.3%	4.6%	1.5%	3%
McGeorge et al. ^{54,a}	Repair	6	8	35%	4	2		1 (joint contracture)
Stahl et al. ^{55,a}	Repair	11	17	42%	8	3		1 infection

^aIncluded children.

Case scenario 2

A 28 year old male surgery resident sustained a hyperextension injury to his right long finger while playing football 2 weeks ago. He is unable to flex his DIP and radiographs show a bony fragment in the proximal phalanx consistent with a type II FDP avulsion (see box).⁵⁶ The patient requires surgery to restore function to his finger.

Question 4: What is the optimal fixation for FDP avulsion injuries?

Case clarification

You consider methods to secure the FDP tendon to its insertion on the distal phalanx for your patient (scenario 2). What are your best options?

Relevance

Bunnell described the conventional suture repair technique using a pullout suture for repairs of zone I flexor tendon injuries. This surgery is difficult and carries the risk of infection, skin necrosis, and damage to nail bed. The button can get stuck on clothing and other things in the outside environment, causing failure. Good results have been reported with alternative techniques of FDP avulsion fixation.

Classification of FDP avulsions (modified Leddy and Packer classification)⁵⁶

- **Type I:** Tendon retracts into palm, vincula ruptured. Requires early repair
- **Type II:** Tendon retracts to PIP joint, vincula intact. Delayed repair allowed
- **Type III:** Tendon attached to large bony fragment with minimal proximal retraction.
- **Type IV:** Tendon separates from bony fragment and retracts into the palm (subtype I) or PIP (subtype II)

Current opinion

The pullout suture technique is a widely accepted method for treating acute FDP avulsions. Suture anchors, however, are commonly used for a number of orthopedic procedures requiring tendon-to-bone healing.^{57–59}

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords “zone I flexor tendon repair” or “flexor tendon” AND “button” OR “suture anchor” or “transverse intraosseous loop technique” OR “TILT”

Quality of the evidence

Level III

- 1 retrospective cohort study

Level IV

- 5 case series

Findings

Gerbino et al.⁶⁰ reported a 35% complication rate in his series of 20 zone I flexor tendon repairs. Kang and coworkers⁶¹ reviewed 23 cases of zone I injuries repaired using the pullout button technique. Fifteen of the 23 (65%) patients developed complications including abnormal nail growth, infection, hypersensitivity, and complex regional pain syndrome (CRPS). Moiemmen and Elliot reported on zone I flexor tendon injuries, including 23 patients with FDP bone or soft tissue avulsions repaired using the pullout suture method.⁶² They had over 50% poor results using their DIP motion criteria. Because of the significant complication rate of the pullout suture technique, alternative methods of fixation have been sought. Suture anchor repairs provide comparable failure loads to the standard pullout suture technique.^{63,64} A retrospective review⁶⁵ comparing suture pullout repairs to double suture anchor repairs of the FDP in 26 patients reported no failures in either group. The suture pullout group had two superficial infections. There

was no statistically significant difference in outcome except improved time to return to work for suture anchor group (9.77 weeks on average vs. 12.23 weeks).

Several authors have reported on various methods of transosseous fixation for FDP fixation. Suture anchor fixation can be complicated by infection, difficulty tensioning the repair, penetration of the dorsal cortex, dislodgement, and increased cost.^{63,66,67} There are two small case series on transosseous suture repair methods for FDP avulsions. In one study,⁶⁷ 10 out of 12 patients regained full functional ROM while 2 patients developed fixed flexion contractures. One flexion contracture occurred in a child with minimal functional deficit and another in an adult who underwent this procedure after multiple revisions. Teo et al.⁶⁶ reported on 18 patients (10 primary, 8 second-stage tendon grafting) using a transosseous suture technique. DIP ROM was good to excellent in 14 patients, fair in 2 and poor in 1 based on Moiemmen and Elliot criteria.⁶² Kang et al.⁶⁸ reported on five cases of FDP avulsion treated with a titanium miniplate. They had one rerupture 2 weeks after surgery. At 1 year, no patient had nail or scar issues or pain. Cost of the implant, hardware complications (failure, infection, prominence) and required extended incision were reported possible disadvantages of the miniplate.

Recommendations

For the treatment of FDP (zone I) avulsions, evidence suggests:

- Pullout suture repairs are still an accepted method of repair. Suture anchor fixation provides a safe alternative to the standard pullout suture technique [overall quality: low]
- Transosseous suture technique may be a cheaper alternative to suture anchors while avoiding complications associated with transcutaneous fixation [overall quality: low]
- There is insufficient data to recommend the use of a plate for fixation of this injury [overall quality: insufficient]

Question 5: What role does botulinum toxin have in the treatment of flexor tendon lacerations?

Case clarification

The patient in scenario 1 undergoes a successful zone II flexor tendon repair of the ring finger. You are concerned the patient will return to work before his tendon is completely healed, risking rupture of the tendon repair. Would injecting botulinum toxin into the muscle belly of the repaired tendon decrease the likelihood of repair failure?

Relevance

Patients must avoid forceful flexion of the finger after flexor tendon repair. Some patients, particularly children,

are unable to comply with these restrictions and risk rupturing their tendon repair. Casting these patients until the tendon heals is not ideal because of the risk of adhesion formation.

Current opinion

Patients who are unable comply with the strict rehabilitation protocol are routinely immobilized to protect the tendon repair. Immobilization, however, risks the development of tendon adhesions and decreasing the strength of the repair.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search or clinical queries search/prognosis using keywords: "Flexor tendon injury" AND "botulinum"

Quality of the evidence

Level IV

- 2 case series

Findings

Silva and coworkers found that a moderate amount of tendon excursion (2 mm) at a low level of tendon force (5 N) was sufficient to inhibit adhesion formation and promote healing.⁶⁹ Higher tendon forces increase risk of tendon rupture. Injecting botulinum toxin causes temporary (full muscle recovery in 12–16 weeks) partial denervation, during which the patient can generate enough force to allow early active mobilization but insufficient force to induce gapping or complete disruption of the tendon repair.⁷⁰ There are only two small case series on the use of botulinum toxin after flexor tendon repair. Tuzuner and coworkers⁷¹ reviewed seven children under the age of six with zone II flexor tendon repairs. There were 13 flexor tendon injuries (eight fingers) injected intraoperatively with botulinum injections and started on a passive motion rehabilitation protocol. They had five excellent and two good results. There were no infections, tendon ruptures, or adhesions. The botulinum toxin was well tolerated by all patients. Whether or not botulinum toxin necessarily improves outcomes in children under seven years old is unclear. Despite immobilization, primary repair of flexor tendon injuries in these children often have better results than in adults.^{72–74}

DeAguiar and associates⁷⁰ studied 18 adult patients with 65 repaired tendons. Botulinum was injected within 48 hours of surgery using electromyographic (EMG) guidance. According to the Kleinert and Verdan criteria (see box),⁷⁵ 94% of digits (32 of 34) in the botulinum-treated patients reviewed at 18 months had an excellent result and 6% (2 of 34) had a good result.

Kleinert and Verdan criteria⁷⁵

For evaluating outcomes after flexor tendon repair:

- *Excellent*: 85–100% of normal total active motion (TAM)
- *Good*: 70–84% of normal TAM
- *Fair*: 50–69% of normal TAM
- *Poor*: Fixed contracture or adhesions

These patients were compared to a retrospectively reviewed control group of 104 tendon repairs with 81% excellent results (84/104), 6% good, 8% fair, and 6% poor. The group treated with botulinum toxin had statistically better outcomes compared to the control group ($p < 0.021$).

Recommendation

- There is insufficient evidence to make recommendations on the use of botulinum toxin in flexor tendon repairs [overall quality: insufficient]

Question 6: Are there any pharmacologic or adjuvant therapies to prevent tendon adhesions after flexor tendon repair?

Case clarification

For the patient in scenario 1, you consider if any pharmacologic agent can be administered during the perioperative period to reduce postoperative adhesion formation.

Relevance

Adhesion formation after flexor tendon repair is a major concern. While mobilization after surgery decreases the risk of adhesion formation it may also place the repair at risk of rupture, particularly in patients who are unable to comply with rehabilitation protocols. Others, despite optimal management, still develop adhesions and have poor outcomes. Recent research efforts have focused on pharmacologic and mechanical barriers to prevent adhesions.

Current opinion

Postoperative mobilization is currently the mainstay of preventing adhesion formation after flexor tendon repair. There are several postoperative mobilization regimens that are discussed elsewhere in the literature. Pharmacologic agents are not routinely used in the prevention of adhesions following flexor tendon repair.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity or clinical queries search/therapy using keywords: “prevention of adhesions” AND “flexor tendon”

Quality of the evidence

Level I

- 1 systematic review
- 3 RCTs

Level I/II

- 1 RCT without mention of blinding

Findings

Khanna and coauthors⁷⁶ reviewed all data reported for pharmacologic agents used to prevent adhesion formation after flexor tendon surgery. These adjuvants are categorized as either medications or barriers. Barriers such as polytetrafluoroethylene (e-FTFE), hydroxyapatite, hyaluronic acid (HA) membrane, and fascia lata patch grafts have all been tested for prevention of adhesions but have not been tested in humans. Medications such as 5-fluorouracil, human amniotic fluid, and TGF- β have all shown beneficial results in animal models but have yet to be tested in vivo in humans.^{77–80} Similarly, several animal studies have shown positive results in the use of nonsteroidal anti-inflammatory drugs (NSAIDs) to prevent tendon adhesions after flexor tendon surgery.^{81–83} Animal studies and clinical trials on the effects of HA have shown inconsistent results.^{84–86} In a prospective double-blind RCT, sodium hyaluronate or physiological saline solution was injected into the tendon sheath after completion of tenorrhaphy or tendon grafting in 120 digits. Sodium hyaluronate had no significant effect on TAM at follow-up of at least 4 months.⁸⁷ Two studies (75 patients/80 fingers)^{88,89} showed no significant difference in total ROM between controls and patients treated with ADCON-T/N after tenorrhaphy. ADCON-T/N is a glycosaminoglycan-rich biore-sorbable gel similar to HA. Liew and coauthors⁹⁰ demonstrated patients treated with ADCON-T/N had significantly better PIP motion (87% vs. 68%, $p = 0.005$), whereas DIP motion, hand grip, and pinch strength showed no differences. The rate of rerupture after tendon repairs did not differ significantly in any of the three studies. Golash and others,^{88,89} however, observed a trend toward late rupture and inflammatory skin changes in patients treated with ADCON-T/N, raising concerns about its potential inhibitory effects on tendon healing.

Recommendation

- Hyaluronic acid and other pharmacologic agents have not been shown to provide significant benefit in preventing tendon adhesions after flexor tendon repair [overall quality: moderate]

Question 7: What is the role of imaging in evaluating flexor tendon injuries and the status of flexor tendon repairs postoperatively?

Case clarification

The patient in scenario 1 undergoes a zone II flexor tendon repair of the FDS and FDP of his ring finger. After six weeks, the patient feels better and returns to work. Three weeks later, he returns to the office complaining that he is

unable to actively flex his ring finger. After a complete physical examination, what is the best way to evaluate the status of his repair?

Relevance

Although the diagnosis of flexor tendon lacerations is often straightforward, in cases of nerve injury, fractures, or uncooperative patients, the diagnosis becomes more complicated. Following flexor tendon repairs, it may be difficult to determine if loss of active flexion is caused by adhesions or rupture. In case of rupture, prompt surgical treatment would be more suitable than continuing with physical therapy.

Current opinion

Current opinion suggests that ultrasound and MRI are important tools for determining the extent of partial flexor tendon injuries, the location of ruptured tendon ends and determining the status of a repaired flexor tendon laceration.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords: "ultrasound" OR "ultrasonography" OR AND "flexor tendon laceration" OR "flexor tendon injuries" OR "flexor tendon repair" AND "hand"

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/diagnosis: "flexor tendon injuries" AND "hand"

Quality of the evidence

Level III

- 1 case-control study

Level IV

- 3 case series
- 1 case-control study with small number of patients

Level V

- 1 study

Findings

Ultrasound Khaleghain and colleagues first showed that ultrasound could be used to determine the structure of normal and pathologic flexor tendons.⁹¹ Later, McGeorge and McGeorge⁹² described the normal appearance of flexor tendon repairs. Lee and coauthors⁹³ evaluated 13 injured

digits in 10 hands. Dynamic ultrasound accurately determined the status of 11 of 13 digits and 18 of 20 potentially injured flexor tendons. All patients had associated injuries requiring surgical exploration and repair, which allowed confirmation of ultrasound findings. The surgeon was blinded to the ultrasound results. There were two cases of false-positive findings. Ultrasound identified a 75% laceration in an intact index FDP and a complete FDP laceration in a 75% lacerated tendon. The finding of a 75% laceration in an intact tendon was attributed to air artifact in a newly closed wound and lack of active motion secondary to pain. A 50% partial tear in the same digit was also identified. It also correctly identified the location of the proximal tendon stump in five of six lacerations. They suggested that ultrasound might be useful in patients where examination is difficult, such as in children. Another study evaluated 30 patients with hand injuries using ultrasound.⁹⁴ Six patients who were unable to flex their digit underwent surgical intervention after ultrasound evaluated the status of the flexor tendon. In three cases, tendon rupture and location of tendon ends based on ultrasound was confirmed. Three other patients, who underwent surgery for other reason, had intact tendons by ultrasound that was confirmed intraoperatively. The authors warned image resolution is limited to tissue depth and therefore could only be used in the hand and finger, allowing for dynamic examination at less cost than an MRI scan.

Openmirrors.com
 O'Connell and colleagues⁹⁵ used dynamic ultrasound to assess TAM of the PIP and DIP after flexor tendon repair in 22 patients. Based on Strickland's criteria, 41% had excellent and 36% had good results. Only 5% had poor results. The assessment based on ultrasound showed only 27% had normal appearance while 32% had thickened, but well gliding, tendon. Two of three tendons that were ruptured on ultrasound were classified as good or fair according to Strickland's criterion. In addition, tendons found to have dense scar tissue had been graded as "good" or "fair." This study suggests ultrasound may be a more accurate measure of repair status than the Strickland method. This is however, the only study that compares clinical examination to ultrasound in the diagnosis of postoperative outcomes of flexor tendon repair.

MRI Several authors have reported on the value of MRI in evaluating flexor tendon pathology.^{96,97} Drape and authors⁹⁸ used MRI to evaluate the status of flexor tendon repairs in patients who had poor outcomes. MRI was performed on 51 patients (64 tendons) who had not regained active flexion after flexor tendon repair. The control group was seven patients (eight fingers) with good clinical outcomes following flexor tendon repair. Of the 64 fingers, 41 underwent reoperation. MRI diagnosis of tendon rupture was confirmed at the time of surgery in 10 cases. Eleven patients diagnosed with callus elongation underwent surgery.

Intraoperatively, two of these cases were noted to have adhesions without elongation (sensitivity 100%, specificity 94%). Isolated adhesions on MRI were confirmed at time of surgery in 20 patients (sensitivity 91%, specificity 100%). Focal bowstringing was found in 15 cases and confirmed intraoperatively in each. MRI failed to identify injured pulleys in nine cases.

Few studies have been performed on the role of MRI in diagnosing primary tendon ruptures. Kumar and coauthors⁹⁹ performed MRI on four patients with suspected zone I FDP rupture. MRI showed proximal retraction of the profundus tendon to the palm in two patients and limited retraction in the other two. Of these, two underwent hand exploration of the tendon and repair whereas two others had DIP fusion without confirmation of findings. According to the authors, MRI provided important preoperative information for surgical decision-making and planning in patients who present late with closed flexor tendon injuries of the hand. In a case series,¹⁰⁰ 10 patients with suspected closed tendon rupture underwent MRI imaging. Twelve flexor tendon ruptures were identified on MRI and confirmed at the time of surgery. MRI also accurately assessed the gap between tendon ends.

Recommendations

- Evidence suggests both MRI and ultrasound are able to accurately diagnose flexor tendon ruptures and causes for poor postoperative motion after flexor tendon repair. In cases of tendon retraction, MRI and ultrasound accurately locate tendon ends [overall quality: low]
- Whether or not imaging flexor tendon injuries and repairs is cost-effective or provides any decrease in morbidity (i.e., morbidity from increased incision and operative time trying to locating retracted tendon ends) has not been addressed [overall quality: insufficient]
- There is insufficient evidence to determine if MRI or ultrasound accurately evaluates partial tendon ruptures [overall quality: insufficient]
- There is limited data to support the use of imaging over physical exam in evaluating causes of poor outcome following flexor tendon repair [overall quality: insufficient].

Summary of recommendations

- For repair of zone II flexor tendon injuries a four-strand or higher core suture technique supplemented by running epitendinous sutures are recommended to provide sufficient tensile strength to allow for postoperative active or passive motion rehabilitation
- Dorsal placement of the suture and locking (vs. grasping) and increasing the number of grasps or locks improves results of repair

- Flexor tendon lacerations should be repaired with non-absorbable 3-0 or 4-0 braided polyester sutures
- Clinical research suggests Tenofix is safe and effective in the repair of flexor tendon lacerations but may not be suitable in all cases
- Partial flexor tendon lacerations of less than 40–60% the cross-sectional area of the entire tendon (that do not trigger) are best treated with early ROM without tendon repair
- For the treatment of FDP avulsions (zone I), evidence suggests suture anchor fixation provide a safe alternative to the standard pullout suture technique for repairs of FDP avulsions. Transosseous suture technique may be a cheaper alternative to suture anchors while avoiding complications associated with transcutaneous fixation
- Currently, there is insufficient evidence to make recommendations on the use of botulinum toxin in flexor tendon repairs
- HA and other pharmacologic agents have not been shown to provide significant benefit in preventing tendon adhesions after flexor tendon repair
- Evidence suggests both MRI and ultrasound are able to accurately diagnose flexor tendon ruptures, location of ruptured ends and causes for poor postoperative motion after flexor tendon repair
- Whether or not imaging flexor tendon injuries and repairs is cost-effective or provides any decrease in morbidity has not been addressed

Conclusions

Our improved understanding of flexor tendon healing has led to better outcomes following flexor tendon repairs. Recovery of good or excellent function is achieved in over 80% of cases with strong repair and early postoperative motion. Repair rupture, adhesions and joint stiffness remain frustrating complications. Future research will no doubt lead to better understanding of how to prevent and treat these difficult problems.

Stephanie Ma, Leslie L. McKnight, and Achilleas Thoma

McMaster University, Hamilton, ON, Canada

Case scenario

A 32-year-old carpenter is seen in the Emergency Department of your community hospital. He has suffered a clean amputation of the long finger of his dominant hand by a table saw at the level of the proximal phalanx. This injury occurred 5 hours earlier in a remote location and the digit was immediately placed on ice.

Relevant anatomy

Because digit replantation involves many structures, a definite sequence of procedures must be undertaken to ensure a timely and efficient repair. This sequence includes:

1. Copious irrigation and meticulous debridement
2. Identification and tagging of structures via a mid-lateral or other exposure (Figure 125.1)
3. Shortening of bone by 5–10 mm
4. Stabilization of bone (Figure 125.2)
5. Repair of extensor and flexor tendons
6. Nerve repair
7. Arterial anastomoses
8. Venous anastomoses
9. Skin closure

Importance of the problem

These injuries and their sequelae are potentially life-threatening and/or life-altering. Trauma is the second leading cause of amputation after vascular disease, accounting for 22% of amputations with 69% involving the upper

extremities. An estimated 30,673 persons suffer non-work-related digit amputations alone in the United States every year. Each digit replantation incurs an approximate hospital cost of \$18,000–\$27,000, an underestimate when one considers the substantial associated indirect costs.¹

Top five questions

1. Should digit replantation be performed only in tertiary hospitals?
2. Does single-digit replantation as compared to revision amputation lead to a better functional outcome?
3. Should two veins and one artery be anastomosed, or does one vein and artery suffice?
4. Should anticoagulant and/or antithrombotic agents be used postoperatively?
5. Does early range of motion (ROM) therapy following replantation improve outcome?

Question 1: Should digit replantation be performed only in tertiary hospitals?

Case clarification

As you prepare this patient for an emergency replantation, you consider transferring him to the closest tertiary hospital, knowing this will prolong ischemia time.

Relevance

Although amputations often present first to community hospitals, the published literature has focused almost exclusively on interventions performed and outcomes obtained in tertiary medical centers.

Current opinion

Many microsurgeons recommend the transfer of community patients to larger tertiary hospitals.

Finding the evidence

- Cochrane Database, with search term: “replantation”
- PubMed and Medline search using keywords: “replantation” AND “community hospital” OR “peripheral hospital” OR “academic hospital” OR “tertiary hospital” OR “centralized”

Quality of the evidence

Level IV

- 3 studies

Findings

Two studies examined the issue of microsurgery survival rates in community hospitals. Isenberg prospectively collected data on 41 replantations and 26 revascularizations (mean ischemic time 2h 50min), calculating an overall survival rate of 87%. All nine failures involved replantations of crushed-avulsed single digits, downgrading the actual success rate for replantations alone to 78%.² Pomerance et al. ascertained a similar overall survival rate of 88% in 151 cases of digit replantations and revascularizations, for a replantation-specific survival rate of 84% (n = 96/114).³

Braga-Silva conducted a trial of single-digit replantations in the ambulatory setting (n = 85 digit replantations) where patients were monitored for up to 8 hours postoperatively before same-day discharge home. Their achieved success rate of 86% (n = 73/85) compared to that of replantations performed in tertiary hospitals (86.2%) with the associated routine admission and inpatient monitoring.⁴ None of the failed replantations was due to a diagnostic delay secondary to patients omitting to contact the surgeon.⁵

Recommendation

- Survival rates for replantations performed in community hospitals with trained microsurgeons are comparable to those of tertiary hospitals [overall quality: low]

Image not available in the electronic edition

Question 2: Does single-digit replantation as compared to revision amputation lead to a better functional outcome?

Case clarification

You decide to manage the patient in your community hospital. He asks if replantation is the treatment option that will confer the best functional results.

Relevance

Traditionally, the success of digit replantation has been measured by survival rate. However, even a viable digit may impair the functional ability of the hand and delay or prevent return to previous occupation.

Current opinion

Many authors advocate that a single-digit amputation (excluding thumb and pediatric cases) warrants replantation under particular circumstances, whereas others claim that it represents an absolute-to-relative contraindication.

Finding the evidence

- As for Question 1, but using keywords: “replantation” AND “single digit” OR “single finger” AND “functional outcome” OR “hand function” OR “return to work” OR “manual labor”

Quality of the evidence

Level II

- 1 study

Level IV

- 6 studies

Findings

Three major indications for single-digit replantation were identified in the literature, although the level of evidence was low: (1) digits amputated at a level distal to the flexor digitorum superficialis (FDS) tendon insertion,⁶⁻¹² (2) digits amputated at the level of the distal phalynx,¹³⁻¹⁵ (3) type II and type IIIa ring avulsion injuries.^{13,16}

Contraindications for single-digit replantation include amputations at the level of the proximal phalanx or proximal interphalangeal (PIP) joint, especially if avulsed or crushed, massively contaminated wounds, and complete ring avulsion injuries.^{7,8,13} Relative contraindications encompass amputations proximal to the FDS insertion, single border digits (i.e., index and little fingers), and prolonged warm ischemia time.⁸

Goel et al. found that revision amputation led to a superior functional outcome, with 90.0% (9/10) of these patients rating their result as good to excellent as compared to only 44.4% (4/9) of replantation patients ($p < 0.05$).¹⁷ Hattori et al. (level IIb evidence) found replantation improved

Table 125.1 Summary of Hattori et al.'s results for fingertip amputations¹⁸

	Replantation (n = 23)	Revision amputation (n = 23)
Pain (n) ^a	2	14
Paresthesia (n)	7	7
Cold intolerance (n)	8	10
Flexion of PIP joint (°) ^a	94 ± 10	86 ± 15
DASH score ^a	2 ± 3	7 ± 5
Hospital stay (day) ^a	25 ± 6	3 ± 4
Time off work (months) ^a	4 ± 4	1 ± 1
Total direct hospital cost (\$)	14,379	2,808

^aThe authors found a statistically significant difference between groups.

hand function, ROM, and postoperative pain compared to revision amputation, but that revision amputation conferred shorter length of hospital stay and time lost from work, as well as lower direct costs (Table 125.1).¹⁸

Patient satisfaction In Waikakul et al.'s prospective study (n = 745 digit replantations), all 291 patients who had undergone single-digit replantation were satisfied regardless of suboptimal functional outcome. None required a revision amputation or would have retrospectively preferred a primary amputation. This finding was in contrast to that of Goel et al. (n = 19 patients; 9 replantations, 10 amputations), whereby 66.6% of patients who had undergone single-digit replantation would have retrospectively chosen to have a primary amputation. Moreover, only 44.4% of patients in the replantation group rated their function as good to excellent vs. the 90.0% of those in the amputation group, although they rated equally in terms of appearance.⁹

It is worth noting that certain patients give as much importance to physical appearance as they do to function, for various cultural or religious reasons. Thus, hand surgeons must be cognizant of the influences that these beliefs can play in the patient's decision to undergo digit replantation.

Return to work Time off work varied between 2.3 and 10.0 months,^{7,17,19} with a shorter return to work following revision amputation than replantation, at 6.64 vs. 40 weeks.¹⁷ Boeckx et al. (n = 34 digit replantations) found that 61.5% (n = 8/13) of patients who were employed before their injury were able to return to their original work, while 15.4% (n = 2/13) were still too disabled to work 4 years after replantation.²⁰ All 23 replantation and 23 amputation patients returned to original work in Hattori's review of fingertip injuries.¹⁸

Complications Although the reported incidence of post-replantation cold intolerance ranges from 35% and 82%, it did not correlate with DASH scores.¹⁷ Povlsen (n = 8 digit replantations) determined that patients who rated their cold-induced discomfort as moderate 2 years after replantation went on to experience long-term improvement upon reassessment one decade later, whereas the severely affected patients did not.²¹

Recommendations

- Single-digit revision amputation may confer a better functional outcome, lower hospital costs, and shorter length of therapy and time off work than replantation [overall quality: low]
- Replantation should be attempted for single fingertip injuries [overall quality: low]
- In general, patients having undergone single-digit replantation are capable of returning to previous work within 2.3–10.0 months [overall quality: moderate]

Question 3: Should two veins and one artery be anastomosed, or does one vein and artery suffice?

Case clarification

After successfully stabilizing the bone and repairing the tendons, you turn your attention to the microvascular anastomoses. You are presented with two options: Openmirrors.com
two veins vs. one vein for every artery repaired.

Relevance

Although Tamai et al.²² declared the appropriate ratio of vein to artery anastomosis to be 2:1, there remains a divergence of opinion. The optimal ratio of vessel repair is compounded by the fact that a balance must be achieved between maximizing survival rate while minimizing operative time for the purposes of cost-effectiveness and limiting ischemic time.

Current opinion

The majority of microsurgeons either repair as many vessels as possible, as dictated by the condition of the amputated digit, or two veins for every artery anastomosed.

Finding the evidence

- As for Question 1, but using keywords: “replantation” AND “artery” OR “vein” OR “ratio” OR “anastomosis”

Quality of the evidence

Level IV

- 7 studies

Findings

Two studies (n = 847 digit replantations) made recommendations with regard to the optimal ratio of vessel repair in

Figure 125.3 Tamai zones of digit amputation. Zone I is distal to the lunula; zone II is proximal to the lunula and distal to the DIP; zone III is proximal to the DIP and distal to the insertion of FDS; and zone IV is proximal to the insertion of FDS and distal to the MP joint. DIP, distal interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal. (From Lee B, Chung HY, Kim WK, et al. The effects of the number and ratio of repaired arteries and veins on the survival rate in digital replantation. *Ann Plast Surg* 2000;44:288–94. Reproduced with permission of Wolters Kluwer.)

relation to the associated Tamai zones of amputation (Figure 125.3)^{23,24}. Lee et al. analyzed 631 single-digit replantations and concluded that zone I replantations fared better with repair of one vein vs. none ($p = 0.008$). Also, the salvage external bleeding method resulted in a higher survival rate when employed in zone I than in other zones. Matsuda et al. (n = 216 digit replantations) found no significant difference between the success rate of zero-vein repair vs. one- or two-vein repair (Table 125.2).

For the remaining zones of digit amputation, the findings are inconsistent (Table 125.2). For zone II, Lee recommends repairing at least as many veins as arteries, whereas Matsuda recommends that at least one vein be repaired. For zone III, Lee counsels that if one artery is repaired, then one vein suffices ($p = 0.025$), whereas if two arteries are repaired, then it is necessary to repair two or more veins. Chaivanichsiri and Rattanasrithong (n = 61 middle phalynx replantations) found that although there was no statistically significant advantage to repairing more than one vein in this zone, it was important to repair at least one ($p = 0.018$).²⁵ On the other hand, Matsuda advocates repairing at least two veins in this zone. Finally, for zone IV amputations, Lee proposes repairing two arteries and two veins, while Matsuda supports the essential repair of only one vein.

Three studies (n = 980 digit replantations) conducted simple nonanatomic analyses and proposed repairing as many veins as possible, with a minimum of two.^{7,9,26} Two studies (n = 36 digit replantations) specifically addressed the topic of zone I fingertip replantations with anastomosis

Table 125.2 Number of anastomosed veins and associated survival rates(%)²³⁻²⁵

No. of veins repaired	None	One	Two or more
Zone I			
Lee et al.	73.2% (104/142)	90.0% (18/20)	N/A
Matsuda et al.	85.7% (12/14)	66.7% (4/6)	100.0% (1/1)
Zone II			
Lee et al.	49.0% (25/51)	80.8% (101/125)	92.6% (25/27)
Matsuda et al.	38.5% (5/13)	81.0% (17/21)	83.3% (10/12)
Zone III			
Lee et al.	47.6% (10/21)	76.5% (78/102)	88.1% (52/59)
Matsuda et al.	0.0% (0/1)	59.1% (13/22)	87.5% (35/40)
Chaivanichsiri and Rattanasrithong	40.0% (2/5)	84.4% (27/32)	91.7% (22/24)
Zone IV			
Lee et al.	N/A	74.5% (35/47)	100.0% (37/37)
Matsuda et al.	33.3% (1/3)	84.2% (16/19)	89.1% (57/64)

(), number of replanted digits.

of the digital artery alone and venous drainage, with very satisfactory survival rates of 87% and 76%.^{27,28}

Recommendations

- The essential number of veins to anastomose is: zone I, zero as long as immediate salvage via external bleeding method is performed; zone II, one, or at least as many as the number of arteries anastomosed; zone III, two, with ideally the same number of arteries; zone IV, one, but ideally two [overall quality: low]
- In general, repairing more veins confers a higher survival rate [overall quality: low]

Question 4: Should anticoagulant and/or antithrombotic agents be used postoperatively?

Case clarification

The amputated digit is successfully replanted without any complication. You consider starting the patient on prophylactic systemic anticoagulation.

Relevance

Venous insufficiency is the second most prevalent cause of replantation failure, with reported rates of up to 32%.²⁹ There is a lack of consensus with regard to the use prophylactic anticoagulation, as well as the optimal agent and regime.

Current opinion

Surveys have demonstrated that up to 96% of microsurgeons utilize some form of postoperative adjuvant anticoagulation following replantation.^{30,31}

Finding the evidence

- As for Question 1, but using keywords: “replantation” AND “anticoagulation” OR “antithrombotic” OR “heparin” OR “aspirin”.

Quality of the evidence

Level II

- 1 study

Level IV

- 5 studies

Level V

- 3 studies

Findings

In a survey involving 161 UK plastic surgeons, Ridha et al. demonstrated no correlation between the administration of dextran and replantation success rate. Still, 45% of the respondents routinely prescribed dextran after replantation and/or after free flap, while 29% employed an alternate form of thromboprophylaxis.³²

Khouri, in the largest prospective multicenter human study on 493 free-tissue transfers, found that the only anticoagulant to alter clinical outcome with a statistically significant difference ($p = 0.038$) was subcutaneous low molecular weight heparin. Indeed, its administration decreased the odds ratio for thrombosis by 27%.³³ Unfortunately, the transferability and hence, level of relevance, of this data for upper extremity replantation is unknown.

Two studies provided information on replantation without the use of any postoperative anticoagulation or antithrombotic agents. In one, the authors obtained a survival rate of 91%,³⁴ which approximates, if it does not surpass, the range of reported success rates for adult replantation of 86.2–93.0%.^{4,9} Similarly, a large-scale world survey (n = 1107 digit replantations) demonstrated a statistically significant superior survival rate of 89.0% (219/246) for replantations performed without anticoagulants compared to 76.5% (659/861) for those performed with anticoagulants ($p < 0.00001$).³⁵ When interpreting these findings, one must be aware of the biases associated with nonrandomized trials, as the patients' mechanism, level, and/or severity of injury could have influenced their baseline prognosis and the decision to prophylactically anticoagulate them.

Unfortunately, anticoagulation is not without risk. One retrospective study found that the incidence of blood loss requiring blood transfusion increased from 2% to 53% ($p < 0.0001$) when two or more anticoagulants were used in addition to aspirin compared to only one additional anticoagulant. This was without an associated advantage in survival rate (88% vs. 77%).³⁶

Recommendations

- Postoperative administration of dextran does not reduce the risk of venous thrombosis in microsurgical anastomoses and carries the risk of rare but potentially devastating side effects [overall quality: low]
- Not administering postoperative anticoagulation may improve survival rate for digit replantation [overall quality: moderate]

Question 5: Does early ROM therapy following replantation improve outcome?

Case clarification

As you prepare to discharge the patient, you wonder whether he would benefit from early ROM therapy.

Relevance

Replantation involves multiple anatomic structures, each of which warrants its own precautions and therapeutic approach. The therapeutic approach must mobilize the antagonistic flexor and extensor tendons while protecting the bony and microvascular repairs.

Current opinion

Most surgeons and hand therapists seem to advocate supervised controlled early mobilization therapy.

Finding the evidence

- As for Question 1, but using keywords “replantation” AND “range of motion” OR “rehabilitation” OR “therapy”

	principle of controlled tenodesis
Day 10–14	EPM II—passive and active phase
Week 3	Strategies to reduce edema, mobilize scar, improve graded desensitization If Kirschner wires are removed, single-digit static gutter splints may assist in supporting extensor tendon repair
Weeks 4–6	Wrist extension beyond neutral Full digit flexion and extension exercises with oscillating movements Composite motion Dynamic and/or intermittent static stretch splinting
Week 6–8, and beyond	Gross and fine strengthening exercises Rehearsal of functional activities

Quality of the evidence

Level IV

- 2 studies

Level V

- 3 studies

Findings

Two articles describe in detail the biomechanical implications of an early protective motion (EPM) program (Table 125.3).^{37,38} The goal of this program is reintegrating the patient to the work environment by 3–6 months.

Ross et al. (n = 103) found that when therapy was instituted within 14 days of injury, patients achieved significantly superior active range of motion (AROM) results ($p = 0.0001$). The average total active movement values were 165° for the “early therapy” group (n = 65 patients) versus 121° for the “late therapy” group (n = 38 patients). The only flexor tendon rupture observed occurred in the “late therapy” group.³⁹

Recommendation

- Early therapy (within 14 days of injury) may improve AROM results compared to later therapy [overall quality: low]

Summary of recommendations

- Survival rates for replantations performed in community hospitals with trained microsurgeons are comparable to that of tertiary hospitals

- Single-digit revision amputation may confer a better functional outcome, lower hospital costs, and shorter length of therapy and time off work than replantation
- Replantation should be attempted for single fingertip injuries
- In general, patients having undergone single-digit replantation are capable of returning to previous work within 2.3–10.0 months
- The essential number of veins to anastomose is: Zone I, zero as long as immediate salvage via external bleeding method is performed; Zone II, one, or at least as many as the number of arteries anastomosed; Zone III, two, with ideally the same number of arteries; Zone IV, one, but ideally two
- In general, repairing more veins confers a higher survival rate
- Postoperative administration of dextran does not reduce the risk of venous thrombosis in microsurgical anastomoses and carries the risk of rare but potentially devastating side effects
- Not administering postoperative anticoagulation may improve survival rate for digit replantation
- Early therapy (within 14 days of injury) may improve AROM results compared to later therapy

Conclusions

Since the first reported upper extremity replantation in 1962, a large body of literature on the topic has emerged, with subsequent increasing awareness from both the medical community and general population. Modern innovations now enable surgeons to successfully replant upper extremity traumatic amputations at almost any level of injury. As success rates continue to improve, the focus is gradually shifting from simply attaining digit and/or limb survival to achieving optimal function and hence, quality of life. The future prospects of microsurgical replantation are indeed inspiring, and will continue to mature as ongoing research studies aid in refining its indications and surgical techniques.

Kurt R. Weiss¹, Rej Bhumbra², Peter C. Ferguson³, Brian O'Sullivan⁴, and Jay S. Wunder³

¹University of Pittsburg, Pittsburg, PA, USA

²London Sarcoma Service, Royal National Orthopaedic Hospital, London, UK

³Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada

⁴Princess Margaret Hospital, University of Toronto, Toronto, ON, Canada

Case scenario

A 25 year old woman presents with a growing mass in the medial thigh. On examination there is a firm 15 cm mass in the adductor compartment. MRI confirms a tumor with heterogeneous signal characteristics. The neurovascular bundle is displaced but not encased. A biopsy performed at the regional tumor unit is consistent with a high-grade undifferentiated sarcoma. Systemic staging is negative for metastasis.

Openmirrors.com

Importance of the problem

Soft tissue sarcomas (STS) constitute 1% of all cancer diagnoses and the incidence is estimated at 1 per 30,000. The mainstay of treatment is wide surgical excision. Radiotherapy (XRT) is used in the management of STS when wide margins cannot be obtained, with the goal of extending the "virtual margin" to the surrounding tissues.¹ Radiation-induced cell death is brought about by direct DNA damage and the production of free radicals. Tumors with varying DNA concentrations and local oxygen tensions respond differently to identical doses of radiation. The presence of prior surgery also affects tumor cell sensitivity.² The exact timing, sequence and dose of XRT remain controversial. A review of over 5,000 soft tissue tumors by Brennan et al.² documented the distribution of STS to be the lower extremity (30%), viscera (19%), retroperitoneum (15%), upper limb (13%), trunk (10%), and other sites (13%).

Top three questions

1. Is there evidence to use XRT in the management of STS?
2. What are the relative advantages and disadvantages of pre- versus postoperative XRT?
3. What are the short- and long-term effects of XRT?

Question 1: Is there evidence to use XRT in the management of STS?

Current opinion

Limb-sparing surgery plus XRT is as effective as amputation for the local control of STS.

Finding the evidence

- PubMed search using keywords: "radiation" AND "soft tissue sarcoma" AND "extremity"
- Ovid MEDLINE search using keywords: "radiation" AND "soft tissue sarcoma" AND "extremity"

Quality of the evidence

Sixteen articles were reviewed to answer this question.

Level I

- 2 systematic reviews/meta-analyses
- 3 randomized controlled trials (RCTs)

Level II

- 1 outcomes research

Level III

- 2 retrospective comparative studies

Level IV

- 8 retrospective reviews

Findings

STS are rare and there is a paucity of level I evidence upon which to base treatment decisions. There is agreement that local control is important, and some authors have correlated local recurrence with diminished overall survival.

Most studies are retrospective with small (average 182, range 41–517) numbers of patients. There are two systematic reviews that included 4,579 patients, and there is significant overlap between these reviews. There are 3 RCTs that evaluated 298 patients.

A systematic review concluded that XRT in addition to limb-sparing surgery improves local control for extremity STS over surgery alone, but does not affect overall survival.³ A review of RCTs in extremity STS found that limb-sparing surgery plus XRT is equivalent to amputation for local control.⁴ Furthermore, adding XRT to surgical resection significantly improves local control over surgery alone but does not improve overall survival.

The first RCT compared limb-sparing surgery plus postoperative XRT to amputation in 43 patients.⁵ At the time of this study, amputation was the standard of care for local control of STS. The authors found no significant differences in local recurrence ($p = 0.06$, OR = 6.32, 95% CI 0.32–125.52) or overall survival ($p = 0.99$, OR = 0.86, 95% CI 0.13–5.89) at 5 years. They concluded that limb-sparing surgery plus XRT is a reasonable alternative to amputation.

The next two RCTs compared limb-sparing surgery alone to limb-sparing surgery plus postoperative RT. Pisters et al. ($n = 164$ patients) reported a significant improvement ($p = 0.002$, OR = 0.23, 95% CI 0.08–0.66) in local control with surgery plus brachytherapy compared with the surgery alone in patients with high-grade tumors.⁶ Brachytherapy did not provide an advantage in patients with low-grade tumors. There were no differences between the two treatment groups in terms of metastatic disease ($p = 0.60$, OR = 0.74, 95% CI 0.35–1.56) or 5 year survival ($p = 0.65$, OR = 0.8, 95% CI 0.35–1.81). Yang stratified 141 patients into high- and low-grade tumors.⁷ All patients had surgery and were randomized to receive external beam XRT or not. XRT significantly improved local control in both high-grade ($p = 0.003$, OR = 0.05, 95% CI 0.00–0.81) and low-grade ($p = 0.02$, OR = 0.80, 95% CI 0.01–0.70) tumors. However, there were no differences in overall survival at 10 years ($p = 0.71$, OR = 0.93, 95% CI 0.40–2.15).

An outcomes study involving 8249 patients using the Florida Cancer Registry demonstrated that surgical resection ($p < 0.001$) and XRT ($p < 0.001$) were the only treatment variables to improve survival.⁸

The remaining studies support the systematic reviews and RCTs.^{9–16}

Recommendations

- XRT plus limb-sparing surgery is as effective as amputation for the local control of extremity STS [overall quality: high]
- XRT plus limb-sparing surgery is superior to surgery alone for the local control of high-grade extremity STS [overall quality: high]
- XRT does not impact overall survival [overall quality: high]

Question 2: What are the relative advantages and disadvantages of pre- vs. postoperative XRT?

Case clarification

The patient asks if she will receive XRT before or after surgery.

Relevance

Sarcomas are best treated by multidisciplinary teams and individualized treatment plans. The relative advantages and disadvantages of pre- vs. postoperative XRT must be related to each patient.

Current opinion

There are potential advantages and disadvantages to both pre- and postoperative XRT. Both strategies are successfully used to treat patients. Preoperative XRT is associated with a higher rate of wound complications, but better long-term functional outcomes.

Finding the evidence

- PubMed search using keywords “radiation” AND “soft tissue sarcoma” AND “extremity” AND “preoperative” AND “postoperative”.
- Ovid MEDLINE search using the keywords “radiation” AND “soft tissue sarcoma” AND “extremity” AND “preoperative” AND “postoperative”.

Quality of the evidence

Thirteen articles were reviewed to answer this question.

Level I

- 2 systematic reviews/meta-analyses
- 1 RCT

Level II

- 2 outcomes research

Level III

- 7 retrospective comparative studies

Level IV

- 1 retrospective review

Findings

Advantages and disadvantages Potential advantages of preoperative XRT include smaller radiation dose and treatment volume, greater sensitivity of the tumor to radiation, no delay in the initiation of XRT, less long-term tissue toxicity (joint contracture, fibrosis, edema, and fracture), and the ability to administer a postoperative radiation boost if desired. Reported advantages of postoperative XRT include immediate surgery, better quality tissue for pathologic evaluation, and fewer wound complications.

Level I, III, and IV data report statistically smaller treatment doses and fields with preoperative radiotherapy: preoperative radiotherapy is typically ~50Gy, whereas postoperative treatment is between 60 and 70Gy.

Recurrence and survival No studies have shown a significant difference in local recurrence or metastatic disease with either pre- or postoperative XRT. The Canadian RCT comparing pre- and postoperative XRT reported a slight survival advantage of preoperative XRT at 3 years ($p = 0.05$, OR = 0.47, 95% CI 0.23–0.97) which did not persist with longer-term follow-up.^{17,18}

Al-Absi et al. performed a meta-analysis comparing pre- and postoperative XRT for local recurrence and overall survival.¹⁹ Of 1098 patients, 526 had preoperative XRT. Although there were fewer local recurrences in the preoperative group, this finding was dependent on whether a random- or fixed-effect statistical model was used. The authors stressed that these findings should be interpreted cautiously due to heterogeneity within the meta-analysis (heterogeneity $p = 0.26$, variability = 25%). They concluded that the timing of XRT is unlikely to affect survival.

The decision to use preoperative or postoperative radiotherapy is based on the expected advantages of one treatment strategy vs. the other. Preoperative XRT might be chosen if the tumor is in close proximity to critical structures (e.g., spinal cord) and smaller radiation doses/volumes are required. Complex soft tissue reconstructions could make preoperative XRT desirable. Alternatively, patients unable to tolerate a wound complication might benefit from postoperative XRT.

Recommendations

- Preoperative XRT utilizes smaller treatment volumes and lower overall radiation dosages than postoperative XRT [overall quality: high]
- Pre- and postoperative XRT have equivalent efficacy in terms of overall survival [overall quality: high]

Question 3. What are the short- and long-term complications of radiotherapy?**Case clarification**

Apart from local recurrence, short- and long-term treatment morbidity remain important considerations for patients undergoing treatment with surgery and XRT.

Relevance

Pre- and postoperative XRT cause distinct complications. Immediately following preoperative XRT, wound complications are the most common problem, at least in the management of lower limb lesions. The longer-term effects of postoperative XRT on normal tissues increase the probability of developing limb and joint stiffness, fibrosis, edema, and long bone fracture.

Current opinion

Multiple studies have demonstrated that preoperative XRT increases the probability of wound complications compared with postoperative XRT, which can cause adverse long-term functional consequences. Wound complications are challenging but manageable problems. In contradistinction, once the long-term effects of radiotherapy have established themselves in the limb, they are difficult to manage.

PubMed search using keywords “radiation” AND “soft tissue sarcoma” AND “complication”

Quality of the evidence

Nine articles were reviewed to answer this question.

Level I

- 1 RCT

Level II

- 1 outcomes research

Level IV

- 7 retrospective reviews

Findings

Short-term complications Even without adjuvant treatment, wound complications are to be expected following STS excision. In a consecutive series of 98 patients managed with STS excision without adjuvant treatment, the wound complication rate was 40%.²⁰

The Canadian RCT demonstrated 35% (31 of 88 patients) vs. 17% (16 of 94 patients) wound complication rate in the pre- vs. postoperative XRT groups, respectively ($p = 0.01$, OR = 2.65, 95% CI 1.33–5.30) with the predominant effect almost entirely confined to the lower limb.¹⁷

The retrospective data of Cheng, Pollack, and Cannon independently reported that preoperative radiation leads to increased rates of wound complications in the lower limb compared to postoperative radiotherapy.²¹⁻²³ Specifically, Cheng et al.²¹ reported wound complications in 15 of 48 (31%) preoperative XRT patients compared with 5 of 64 (8%) postoperative XRT patients ($p = 0.001$, OR = 5.36, 95% CI 1.79–16.08). Pollack et al.²² reported wound complications in 32 of 128 (25%) preoperative XRT patients compared with 10 of 165 (6%) postoperative XRT patients ($p < 0.001$, OR = 5.17, 95% CI 2.43–10.99). Finally, Cannon et al.²³ reported complications in 90 of 269 (34%) preoperative XRT patients and 23 of 143 (16%) postoperative XRT patients ($p < 0.001$, OR = 2.63, CI 1.57–4.38).

Long-term complications Rimner et al. retrospectively reviewed 225 thigh tumors.²⁴ Overall complication rates at 5 years were edema (13%), joint stiffness (12%), wound reoperation (10%), nerve damage (8%), and bone fractures (7%). In this study 69% of these patients were treated with brachytherapy, while 31% received external beam XRT. Cannon et al. reported on 412 patients at 20 years following external beam XRT and found that chronic radiation-related complications were higher in patients with a tumor located in the groin or thigh.²³

Davis et al. analyzed 129 patients for late radiation morbidity in an RCT.²⁵ At 2 years there was a trend towards greater fibrosis following postoperative XRT ($p = 0.07$, OR = 0.49, 95% CI 0.24–1.02). Moderate degrees of fibrosis and stiffness correlated with significantly worse patient-reported outcomes (TESS scores) as well as objective assessments (MSTS scores). There was also increased edema (23% vs. 15%, $p = 0.26$, OR = 0.59, 95% CI 0.24–1.43), and joint stiffness (23% vs. 18%, $p = 0.51$, OR = 0.72, 95% CI 0.30–1.70) in the post- vs. preoperative XRT groups. Large field size is typically associated with postoperative XRT and was predictive of increased fibrosis ($p = 0.002$), joint stiffness ($p = 0.006$), and edema ($p = 0.06$) in logistic regression analysis. MSTS and TESS scores were not significantly different between both treatment arms but were adversely affected by radiation morbidity.

Stinson et al. retrospectively reviewed acute and chronic postradiation effects in 145 patients and identified tissue induration (57%), decreased range of motion (32%), decreased muscle power (20%), edema (19%), pain (7%), use of walking aids (7%), and fracture (6%).²⁶

Examining radiation-associated fractures, Holt et al. noted that patients undergoing thigh STS resection were more likely to sustain a fracture if they received either high-dose postoperative XRT or high-dose combined preoperative XRT and a postoperative boost (60 or 66 Gy) compared to low-dose (50 Gy) preoperative treatment.²⁷ In this study

24 of 27 fractures occurred in patients who had received high-dose XRT ($p = 0.007$, OR = 0.12, 95% CI 0.04–0.42).

Recommendations

- Preoperative XRT leads to an increased rate of wound complications relative to postoperative XRT in lower limb tumors [overall quality: high]
- Larger tumors treated with XRT have an increased risk of developing complications [overall quality: high]
- A moderate degree of fibrosis and stiffness leads to significantly poorer patient-reported outcomes [overall quality: high]
- Postoperative XRT leads to diminished long-term functional outcomes, when measured with MSTS and TESS scores, than preoperative radiotherapy [overall quality: moderate]

Summary of recommendations

- XRT plus limb-sparing surgery is as effective as amputation for the local control of extremity STS
- XRT plus limb-sparing surgery is superior to surgery alone for the local control of high-grade extremity STS
- XRT does not impact overall survival
- Preoperative XRT utilizes smaller treatment volumes and lower overall radiation dosages than postoperative XRT
- Pre- and postoperative XRT have equivalent efficacy in terms of overall survival
- Preoperative XRT leads to an increased rate of wound complications relative to postoperative XRT in lower limb tumors
- Larger tumors treated with XRT have an increased risk of developing complications
- A moderate degree of fibrosis and stiffness leads to significantly poorer patient-reported outcomes
- Postoperative XRT leads to diminished long-term functional outcomes, when measured with MSTS and TESS scores, than preoperative radiotherapy

Soft Tissue Sarcoma: Does the Evidence Support the Administration of Chemotherapy?

Jennifer L. Halpern, Jill Gilbert, Ginger E. Holt, Vicki L. Keedy, and Herbert S. Schwartz

Vanderbilt University Medical Center, Nashville, TN, USA

Case scenario

A 38 year old vending machine repairman presented for evaluation of left groin pain. Physical examination revealed asymmetric thigh girth (left 67 cm vs. right 55 cm). Imaging studies demonstrated a 12.5 × 15 × 20 cm mass within the adductor compartment of the left thigh. There was no evidence of lung parenchymal disease. Open biopsy of the mass was performed. Final pathology was reported as pleomorphic high-grade sarcoma (Figure 127.1).

Relevant anatomy

Soft tissue sarcomas (STS) are malignant neoplasms that arise in nonepithelial, extraskeletal tissues of the body. Despite this general classification, STS are extremely diverse, being variable in their gross and microscopic appearances and behavior. With the exception of low-grade liposarcoma, wide surgical resection is a critical component of successful treatment. Depending upon tumor grade (high or low), depth (superficial or deep), and size (>5 cm), neoadjuvant or adjuvant radiation can also be used to improve local control.

Importance of the problem

The World Sarcoma Network reports (based on U.S. data) that the incidence of STS globally is 30 cases per 1,000,000 people. In the United States, the incidence in 2007 was reported as 9,220 cases, with an overall mortality rate of

3,560 cases per year. Although the multimodal approach to treatment of resectable STS has resulted in excellent local control (10–15% local recurrence with limb salvage),¹ 50% of those diagnosed and treated for isolated disease will eventually die from metastatic disease,² most likely stemming from undetectable micrometastases at the time of diagnosis.

The two staging systems used to describe soft tissue sarcoma are the American Joint Committee on Cancer (AJCC) and the Enneking system (Surgical Staging System of the Musculoskeletal Tumor Society). The AJCC is based upon the tumor–node–metastasis (TNM) system, but also includes histologic grade as a measure. The Enneking system is based upon histopathologic grade, anatomic site and extent, and presence or absence of metastases.

Chemotherapy is currently offered to patients with metastatic STS at diagnosis or high-risk disease (AJCC ≥III or Enneking ≥IIB). However, there is little evidence to suggest that current chemotherapeutic regimens will prolong overall survival or disease-free survival. There is inherent difficulty in generating large, randomized controlled trials (RCTs) for the following key reasons: (1) STS are rare, which translates into a lack of statistical power in trials, and (2) with some exceptions, classifications based upon histologic descriptions result in unique tumor subtypes being grouped together. In fact, a PubMed search using the words “chemotherapy” and “soft tissue sarcoma” limited to the past 2 years generated only 17 studies involving chemotherapy and STS, and of these none were phase III trials. The implication is that despite improvements in surgical planning/techniques and administration of radiation,

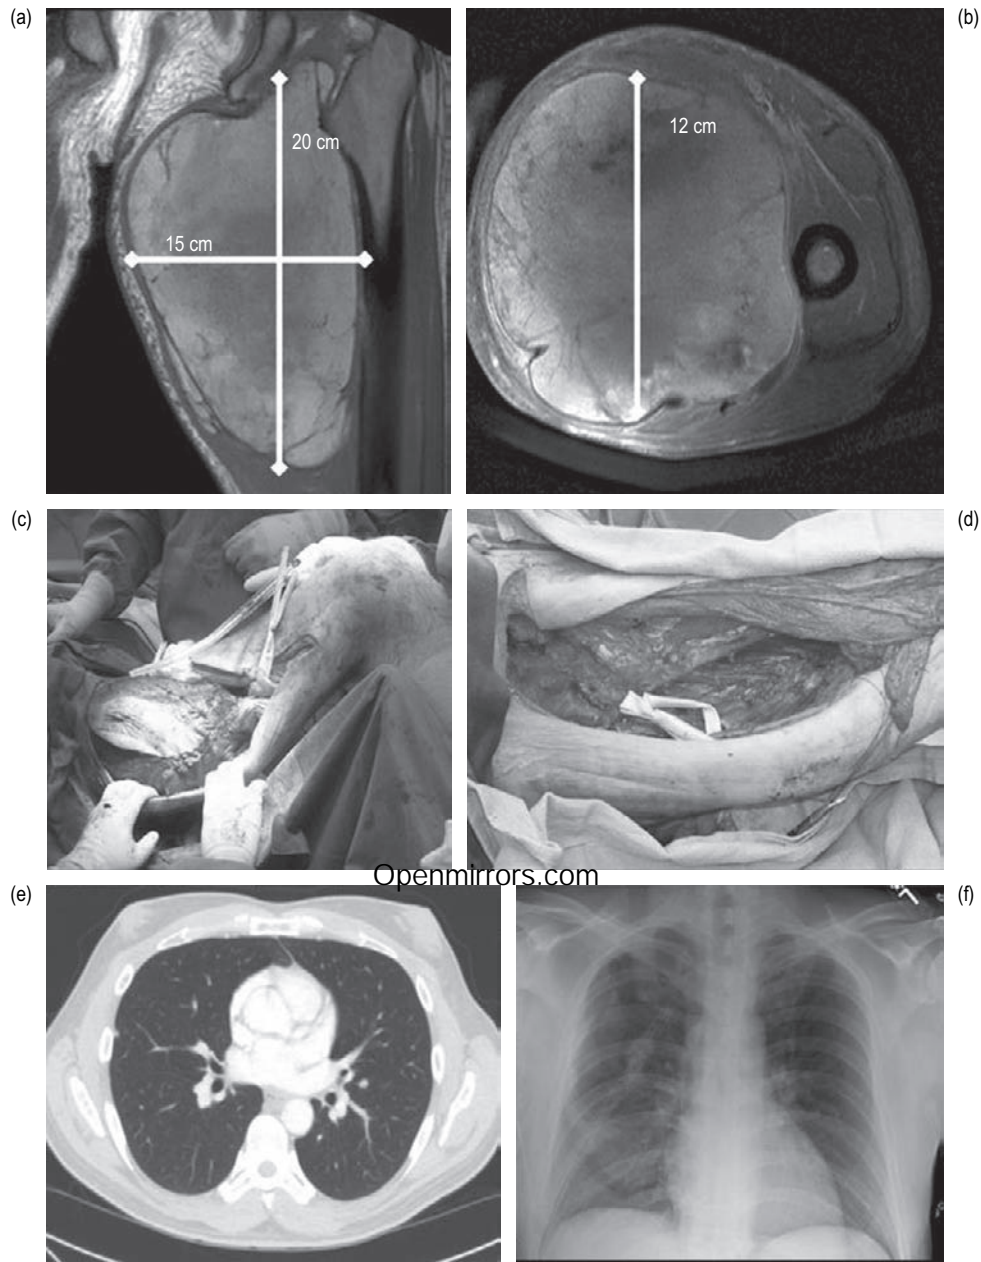

Figure 127.1 Clinical images of patient presented embody the inherent difficulty in treatment of high risk soft tissue sarcoma. Pretreatment MRI scans revealed a large 20×15×12 cm mass in the left medial thigh (a,b). Following neoadjuvant radiation therapy, the patient is taken to the operating room for a wide excision of the tumor (c). After resection, the sciatic nerve is skeletonized, tagged with a Vessel loop (d). Despite negative margins, no prior evidence of lung involvement on staging studies, and no evidence of local recurrence, the patient developed radiographically detectable lung metastases on CT scan 9 months after definitive resection (e). Following treatment with adjuvant chemotherapy (adriamycin and ifosfamide/mesna), the patient underwent pulmonary metastatectomies (f).

there has been a lack of promising systemic therapies in the setting of STS, and therefore overall survival has remained unchanged.

This chapter intends to offer an evidence-based approach to the administration of chemotherapy in patients with STS. It does not address future directions of ongoing research to find better systemic therapies. Unfortunately, the quality of evidence regarding the role chemotherapy of

in STS treatment is poor, and this chapter reflects the lack of good evidence that exists on this topic.

Top two questions

1. Is there a role for neoadjuvant chemotherapy in treatment of STS?

2. Is there a role for adjuvant chemotherapy in treatment of STS?

Question 1: Is there a role for neoadjuvant chemotherapy in treatment of STS?

Case clarification

Following diagnosis of isolated high-risk (large, deep, high-grade) pleomorphic sarcoma, treatment options are presented to the patient. One option is to administer neoadjuvant chemotherapy, with two goals: (1) to decrease the size of the tumor, thereby facilitating resection; and (2) to combat radiographically undetectable micrometastases.

Relevance

A multimodal approach using radiation and surgery achieves excellent local control. Using successful osteosarcoma treatment regimens as a model, the question raised was whether pretreatment of STS with chemotherapy would result in significant tumor necrosis, thereby facilitating wide resection, and would also decrease the incidence of distant disease.

Current opinion

Current opinion suggests that administration of neoadjuvant chemotherapy does not simplify tumor resection or improve overall survival, except in specific subtypes of soft tissue sarcoma known to be chemosensitive.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed) clinical queries/systematic reviews, using search term: "soft tissue sarcoma" AND "neoadjuvant chemotherapy."
- PubMed (www.ncbi.nlm.nih.gov/pubmed), using keywords: "soft tissue sarcoma" AND "neoadjuvant chemotherapy"; "synovial sarcoma" AND "neoadjuvant chemotherapy"

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 4 retrospective reviews

Findings

In general, level I evidence does not exist to justify administration of neoadjuvant chemotherapy in the setting of STS. In fact, retrospective reviews demonstrate dismal responses to neoadjuvant chemo. For example, Meric et al. showed that out of 105 patients treated with neoadjuvant

chemotherapy, only 12% responded enough to simplify their surgical procedure, and in addition 9% required a larger surgery because the tumor progressed while the patient was on chemotherapy.³ Despite that result, in the group that did demonstrate radiographic response, there were an increased number of margin-negative resections, fewer local failures, and improved overall survival when compared to patients with no radiographic response. Eilber et al., in a small group of patients, demonstrated that complete response to chemotherapy ($\geq 95\%$ necrosis), translated clinically into an improved 10 year local recurrence-free rate of 11% vs. 23% and 10 year overall survival of 71% vs. 55%.⁴

However, other studies report no difference in oncologic outcome in patients treated with neoadjuvant chemotherapy. This may or may not be because these studies were underpowered. Menendez et al. showed no statistical significance in recurrence-free or overall survival in patients who received three or four cycles of neoadjuvant doxorubicin, ifosfamide, and cisplatin.⁵ However, power analysis indicated that the necessary sample size to show an improvement in recurrence-free or overall survival would be 532 patients, and that study reviewed only 82 patients after exclusion criteria were considered. The European Organization for Research and Treatment of Cancer (EORTC) organized an RCT comparing neoadjuvant doxorubicin and ifosfamide in high-risk adult STS. No difference in overall or disease-free survival was noted and the study was closed early due to poor patient accrual.⁶ Finally, Pisters et al. reported a retrospective review of 76 patients with stage IIIB STS, treated with neoadjuvant chemotherapy with doxorubicin regimens.⁷ They found that there was no statistically significant difference in local recurrence-free survival, distant metastases-free survival, disease-free survival, or overall survival between responders and nonresponders (characterized radiographically). The implication was that even the purported advantage of neoadjuvant chemotherapy administration (decrease in tumor size and increase tumor kill), did not correlate with improved oncologic outcomes.

Therefore, the evidence does not overwhelmingly demonstrate a survival benefit in patients treated with neoadjuvant chemotherapy. As shown in Table 127.1, reported and calculated odds ratios show no statistical significance in a correlation between neo-adjuvant chemotherapy administration and overall survival.^{6,15} In addition, it is unclear whether there is even a survival benefit difference observed between chemotherapy responders and nonresponders.

Recommendation

- Administration of neoadjuvant chemotherapy is not beneficial in treatment of localized high-risk soft tissue

Table 127.1 Efficacy of chemotherapy in treatment of soft tissue sarcoma

Reference	Study design/ quality of evidence	No. of patients ^a	Results	Conclusions	Statistical significance: overall survival related to intervention
A. Efficacy of neoadjuvant chemotherapy in treatment of soft tissue sarcoma					
Meric et al. ³	Retrospective/ Low	65	Reviewed records of patients treated with NeoCT to determine radiographic response—34% partial, 9% minor, 31% stable, 26% progressive In 13%, NeoCT “downstaged” the operation, 78% had no change, and 9% progressed However, radiographic response was the most significant predictor of overall survival	Although only a few NeoCT patients had smaller surgery, radiographic response did correlate to improved survival	N/A—correlates radiographic response to survival
Eilber et al. ⁴	Retrospective/ Low	496	The percentage of patients who achieved ≥95% necrosis increased from 13% to 48% with the addition of IF to doxorubicin. 5 year survival in patients with >95% necrosis = 80% vs. 62% in patients with <95% necrosis	In patients who receive neoadjuvant therapy and have evidence of treatment-induced necrosis, patients with >95% necrosis demonstrate improved OS and LRFS	N/A—correlates % necrosis to overall survival
Menendez et al. ⁵	Retrospective/ Low	82	The overall five year survivorship for patients with <95% or ≥95% necrosis were 20% and 33% respectively	Tissue necrosis from NeoCT does not seem to predict outcome	N/A – correlates % necrosis to overall survival
Gortzak et al. ⁶	RCT/High	134	Chemotherapy did not interfere with planned surgery and did not affect post-operative wound healing. Trial closed after phase II because of poor patient accrual. Median follow-up of 7.3 years, 5 year disease-free survival was 52% for no neoadjuvant chemo and 56% for neoadjuvant chemo groups, and 64% and 65% respectively for overall survival	Although chemotherapy did not compromise surgical intervention, there was not a major survival benefit observed with administration of neoadjuvant chemotherapy	Calculated OR overall survival at mean of 7.3 years OR 0.68, 95%CI 0.34–1.38; p = 0.29
Pisters et al. ⁷	Retrospective/ Low	76	Responding patients had rates of LRFS, DMFS, DFS, OS similar to nonresponders	NeoCT associated with response, DFS, OS rates similar to reported adjuvant chemotherapy. Responding patients had rates of LRFS, DMFS, DFS, OS similar to nonresponders	N/A—correlates radiographic response to survival
Italiano et al. ¹⁵	Retrospective/ Low	237 (SS)	Median follow-up 58 months Neither neoadjuvant or adjuvant chemotherapy (IF containing regimen) had significant impact on DSS, LRFS, DRFS	Wide surgical excision of SS with adjuvant radiotherapy are accepted treatments. Chemotherapy shows no statistically significant benefit	Reported HR 0.91, 95% CI 0.56 – 1.49; p = 0.725

Reference	Study design/ quality of evidence	No. of patients ^a	Results	Conclusions	Statistical significance: overall survival related to intervention
B: Efficacy of adjuvant chemotherapy in treatment of soft tissue sarcoma					
Sarcoma Meta-analysis Group ⁸	Meta-analysis/ High	1568	HRs of 0.73 for LRFS, 0.70 for DRFS, 0.75 for DFS correspond to absolute benefits from adjuvant chemotherapy of 6%, 10%, and 10% respectively at ten years. For OS, the HR of 0.89 was not significant	Adjuvant doxorubicin-based chemotherapy (statistically) significantly improves time to local and distant recurrence and overall recurrence-free survival	Reported HR 0.89, 95% CI 0.76 – 1.03; p = 0.12
Frustaci et al. ⁹	RCT/High	104	Median follow-up of 59 months Median DFS 48 months in treatment group and 16 months in control group DSS was 75 months for treated group and 46 months for control Absolute benefit in OS was 13% at 2 years and 19% at 4 years	Intensified adjuvant chemotherapy had a positive impact on DFS and OS in patients with high-risk extremity STS	Calculated OR overall survival to 4 years: OR 0.54, 95% CI 0.25–1.18; p = 0.12
Frustaci et al. ¹⁰	RCT/High	104	Further follow-up of prior experimental group showed that DFS and OS differences in treatment arm vs. control group no longer statistically different	The previously observed overall survival benefit loses statistical significance at later time points. Therefore, time to recurrence may be lengthened, but overall survival at further follow-up is the same	Calculated OR overall survival to 89.6 months: OR 0.538, 95% CI 0.25–1.17; p = 0.12
Cormier et al. ¹¹	Retrospective/ Low	674	Median follow-up 6.1 years Use of chemotherapy is associated with time-varying clinical effects	Clinical benefits associated with doxorubicin-based chemotherapy are not sustained beyond 1 year	Reported HR DSS at 12 months: 0.37, 95% CI 0.20–0.69; p = 0.002 Reported HR after 12 months: HR 1.36 95% CI, 1.02–1.81; p = 0.04
Pervaiz et al. ¹²	Meta-analysis/ High	1953	OR for local recurrence was 0.73 in favor of chemotherapy For distant and overall recurrence, OR 0.67 in favor of chemotherapy Regarding survival, OR for doxorubicin with IF was 0.56 in favor of chemotherapy	Analysis confirms marginal efficacy of chemotherapy with respect to LRFS, DRFS, DSS	Reported OS doxo-alone based therapies OR 0.84, 95% CI 0.68–1.03; p = 0.09 OS doxo + ifos based therapies OR 0.56, 95% CI 0.36–0.85; p = 0.01
Cochrane Gynaecological Cancer Group ¹³	Cochrane systematic review/High	1568	LRFS HR with chemo was 0.73. DRFS was 0.70. Overall survival was 0.75. Those correspond to significant absolute benefits of 6–10% at 10 years. For OS, HR of 0.89 not statistically significant but does potentially represent absolute benefit of 4%	Doxorubicin-based chemo appears to significantly improve LRFS, DRFS, DFS, and trends towards improved OS	Reported HR 0.89, 95%CI 0.76–1.03; p = 0.12)

Table 127.1 (Continued)

Reference	Study design/ quality of evidence	No. of patients ^a	Results	Conclusions	Statistical significance: overall survival related to intervention
Eilber et al. ¹⁴	Prospective observation/ Low	101	4-year DSS of IF-treated patients was 88% compared to 67% in no treatment group. Treatment with IF associated with improved DRFS but not LRFS	IF-based chemotherapy associated with an improved DSS in adult patients with high risk extremity synovial sarcoma	Calculated OR overall survival to 48 months: OR 0.26 (95% CI 0.10–0.67); p = 0.005.
Italiano et al. ¹⁵	Retrospective/ Low	237 (SS)	Median follow-up 58 months. Neither neoadjuvant or adjuvant chemotherapy (IF containing regimen) had significant impact on DSS, LRFS, DRFS	Wide surgical excision of SS with adjuvant radiotherapy are accepted treatments. Chemotherapy shows no statistically significant benefit	Reported HR 1.62 (0.91–2.87); p = 0.099

Calculated, authors of this review have calculated OR/CI to improve statistical validity of analysis; DFS, disease-free survival; DRFS, distant recurrence-free survival; DSS, disease-specific survival; HR, hazard ratio; IF, ifosfamide; LRFS, local recurrence-free survival; N/A, does not address overall survival reported between control (no chemo) and experimental (chemo group); NeoCT, neoadjuvant chemotherapy; OR, odds ratio; OS, overall survival; Reported, authors report OR/CI in published sources; SS, synovial sarcoma.

^aNumber of patients pooled from 14 trials.

sarcoma, as there is no difference in overall survival or disease-free survival, and surgical resectability is not reliably improved by its administration [overall quality: very low]

Question 2: Is there a role for adjuvant chemotherapy in treatment of STS?

Case clarification

Another treatment option for the patient presented would be to initiate treatment with a combination of radiation and wide surgical resection, and then refer for adjuvant chemotherapy. The theoretic benefit of adjuvant chemotherapy would be to improve disease-free survival rates by eliminating micrometastases.

Relevance

A multimodal approach utilizing radiation and surgery achieves excellent local control. However despite local control, distant metastases are not controlled. Adjuvant chemotherapy potentially could address unrecognized micrometastases in high-risk patients.

Current opinion

Current opinion suggests that administration of adjuvant chemotherapy has marginal efficacy, and its benefits may be outweighed by the significant associated toxicities.

Finding the evidence

- EBM Reviews—Cochrane Central Register of Controlled Trials: “adjuvant chemotherapy” AND “soft tissue sarcoma”
- EBM Reviews—Cochrane Database of Systematic Reviews: “adjuvant chemotherapy” AND “soft tissue sarcoma”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) clinical queries/systematic reviews, using search terms: “soft tissue sarcoma” AND “adjuvant chemotherapy”; “synovial sarcoma” AND “adjuvant chemotherapy”
- PubMed (www.ncbi.nlm.nih.gov/pubmed), using keywords: “soft tissue sarcoma” AND “adjuvant chemotherapy”; “synovial sarcoma” AND “adjuvant chemotherapy”

Quality of the evidence

Level I

- 2 Cochrane systematic reviews
- 3 systematic reviews/meta-analyses
- 2 randomized trials

Level II

- 1 prospective case series
- 2 retrospective reviews

Findings

The best evidence, summarized in the Cochrane database review from 2009, suggests that doxorubicin-based adju-

vant chemotherapy improves time to local and distant recurrence and overall recurrence-free survival in adults with resectable sarcoma. A trend towards overall improved survival was also observed. Another recent meta-analysis suggests that there is a statistically significant marginal efficacy. However, as is indicated in this chapter, the evidence is problematic and historically confusing.

The Sarcoma Meta-analysis Collaboration formed and reported in 1997 on 1,568 with localized, resectable disease treated in a series of 14 doxorubicin-based trials. With a median follow-up of 9.4 years, they reported statistically significant treatment effects including decreased risk of local recurrence (27% decrease, absolute benefit of 6%), decreased risk of distant disease (30% reduction in risk, absolute benefit of 10%) at 10 years. There was a trend towards improved overall survival which was not statistically significant (hazard ratio (HR) 0.89, 95% CI 0.76–1.03; $p = 0.12$). However, in a specific subgroup (high-grade, large, extremity sarcomas) there was a clear survival advantage (7% at 10 years).⁸

Doxorubicin (adriamycin) is an anthracycline antibiotic used as a chemotherapeutic agent. It works by intercalating DNA. Toxicities can include nausea, vomiting, and heart arrhythmias. Cumulative doses can lead to cardiotoxicity including congestive heart failure and dilated cardiomyopathy.

Based on that meta-analysis, an RCT designed to assess the clinical efficacy of combined doxorubicin and high-dose ifosfamide therapy was initiated by the Italian Sarcoma Group.⁹ Initial results comparing outcomes of patients with extremity and pelvic sarcomas treated either with resection and adjuvant radiation, or with resection, radiation and adjuvant 4'-epidoxorubicin and ifosfamide demonstrated a statistically significant difference between the treatment and control groups. There were observed improvements in median disease-free survival (48 months vs. 16 months), median survival (75 months vs. 46 months), and an absolute survival benefit of 13% at 2 years and 19% at 4 years (*calculated OR overall survival to 4 years: OR 0.539 (95% CI 0.247–1.177); $p = 0.12$*)*. The study was stopped, based on the conclusion that chemotherapy afforded improved oncologic outcomes. However, the same 140 patients were subsequently evaluated in 2003.¹⁰ Now with longer follow-up (89.6 months), the previously observed survival benefit was no longer statistically significant (*calculated OR overall survival to 89.6 months: OR 0.538, 95% CI 0.247–1.172; $p = 0.11$*).

*In this chapter, the odds ratio (OR) reported in italics has been calculated by the authors and is not reported as part of the manuscripts referenced. Table 127.1 provides overall review of studies cited and includes either the reported or calculated HR or OR for overall survival as related to chemotherapy administration.

Ifosfamide (Ifex) is an alkylating agent whose mechanism of action includes the formation of covalent bonds with DNA, RNA, and proteins thereby impairing cell function. Dosing is limited by genitourinary and neurologic toxicity and is usually administered in conjunction with mesna to reduce the genitourinary toxicity.

Additional studies also failed to find a treatment benefit. A retrospective review of 674 patients out of Sloan Kettering and M.D. Anderson reported that positive treatment effects from adjuvant doxorubicin were not sustained for greater than one year (reported HR disease-specific survival at 12 months: HR 0.37, 95% CI 0.20–0.69); $p = 0.002$; reported HR after 12 months: HR 1.36, 95% CI 1.02–1.81; $p = 0.04$).¹¹

However, a more recent (2008) systemic meta-analysis of RCTs identified 4 new eligible trials, for a total of 18 trials (1,953 patients).¹² That meta-analysis revealed a marginal efficacy with regards to local recurrence, distant recurrence, overall recurrence and overall survival (OR 0.84, 95% CI, 0.68–1.03; $p = 0.09$) that is slightly enhanced with combination doxorubicin and ifosfamide therapy. This is considered strong evidence supporting the efficacy of ifosfamide, but the marginal improvement must be weighed against potential toxicity.

The most recent Cochrane reviews determined that adjuvant chemotherapy slightly improved the time to local and distant recurrence, and overall recurrence-free survival in adults with localized, resectable STS, with a trend towards improved overall survival (14 trials including 1,568 patients; reported HR 0.89 (95% CI 0.76–1.03); $p = 0.12$).¹³

The above analysis primarily focuses on adult STS without further delineating subtypes. Within the heading of "soft tissue sarcoma," there are specific tumors that have characteristic genetic translocations which potentiate more accurate classification. Improved classification translates into better evidence because of more homogeneous study populations. One example is synovial sarcoma.

Synovial sarcoma makes up 10–15% of adult STSs. Synovial sarcomas contain a characteristic translocation (X;18; p11;q11) representing the fusion of SYT (18q11) with either SSX1 or SSX2 (both at Xp11) resulting in the fusion genes SYT-SSX1 or SYT-SSX2.

In the case of synovial sarcoma, there is some evidence to suggest that adjuvant chemotherapy might improve oncologic outcomes, and therefore chemotherapy may be a reasonable intervention in those patients. In a recent prospective study of 101 patients, ifosfamide-based therapy was associated with an improved disease-specific survival (DSS) in adult patients with high-risk, primary, extremity

synovial sarcomas.¹⁴ In that study, 67 patients were treated with IF and 33% received no therapy (NoC). The 4-year DSS of the IF-treated patients was 88% compared with 67% for the NoC patients ($p = 0.01$) (calculated OR overall survival to 48 months: OR 0.262, 95% CI 0.102–0.674; $p = 0.005$). Smaller size (HR 0.3 per 5 cm decrease, $p < 0.0001$) and treatment with IF (HR 0.3 compared with NoC, $p = 0.007$) were independently associated with an improved DSS. Treatment with IF was independently associated with an improved distant recurrence-free survival (HR = 0.4, $p = 0.03$) but not associated with an improved local recurrence-free survival ($p = 0.39$).

However, even with synovial sarcoma there is conflicting evidence. A retrospective analysis of 237 patients with a median follow-up of 58 months, neither neoadjuvant or adjuvant chemotherapy has a significant impact on overall survival, local recurrence-free survival, or distant recurrence-free survival.¹⁵ Therefore, synovial sarcoma in adults is often treated like other STS, and chemotherapy is reserved for high-risk tumors or metastatic disease at presentation. If adjuvant chemotherapy is offered, combination doxorubicin and ifosfamide is prescribed in appropriate patients.

Recommendations

- Administration of adjuvant chemotherapy in the setting of high-grade, large extremity sarcomas may result in a longer time interval until local or distant recurrences. There is a trend, and perhaps statistically significant marginal improvement, in survival in those patients, and therefore in patients who can tolerate chemotherapy side effects, chemotherapy could be offered as an adjuvant [overall quality: high]
- There is not overwhelming evidence of a significant oncologic benefit in treating synovial sarcoma with adjuvant chemotherapy. There is evidence of increased tumor sensitivity to ifosfamide, and therefore, synovial sarcoma should be treated with meticulous surgical resection and neo-adjuvant or adjuvant radiation. Chemotherapy, utilizing doxorubicin and ifosfamide may be indicated in the treatment of high-risk patients or patients with metastatic disease at presentation [overall quality: low]

Summary of recommendations

- Administration of neoadjuvant chemotherapy is not beneficial in treatment of localized high-risk soft tissue sarcoma, as there is no difference in overall survival or disease-free survival, and surgical respectability is not reliably improved by its administration
- Administration of adjuvant chemotherapy in the setting of high-grade, large extremity sarcomas may result in a longer time interval until local or distant recurrences. There

is a trend, and perhaps statistically significant marginal improvement, in survival in those patients, and therefore in patients who can tolerate chemotherapy side effects, chemotherapy could be offered as an adjuvant

- There is not overwhelming evidence of a significant oncologic benefit in treating synovial sarcoma with adjuvant chemotherapy. There is evidence of increased tumor sensitivity to ifosfamide, and therefore, synovial sarcoma should be treated with meticulous surgical resection and neoadjuvant or adjuvant radiation. Chemotherapy, utilizing doxorubicin and ifosfamide may be indicated in the treatment of high-risk patients or patients with metastatic disease at presentation

Conclusion

Despite excellent strategies in STS local control, adjuvant chemotherapy offers only marginal efficacy in the treatment of STS. The evidence supporting this marginal efficacy is considered to be high quality (Table 127.1). Chemotherapy administered in the neoadjuvant setting does not result in easier resections. Adjuvant chemotherapy may result in improved survival in patients with large, high-grade isolated extremity sarcomas. The inherent difficult in good statistical analysis of these patients is the low number of patients that can be enrolled, resulting in studies not powered to determine the presence of true statistical significance. The future success of chemotherapy directed towards STS will depend upon genetic delineation of subtype and genetic/protein specific targets.

Surgery in Bone Sarcoma: Allograft vs. Megaprosthesis

Kelly C. Homlar, Jennifer L. Halpern, Herbert S. Schwartz, and Ginger E. Holt

Vanderbilt University Medical Center, Nashville, TN, USA

Importance of the problem

According to the American Cancer Society, an estimated 2,570 new primary bone cancers were diagnosed in the United States in 2009, causing 1,430 deaths.¹ With advances in chemotherapy and imaging, it is now possible to provide limb salvage surgery in 90–95% of patients.^{2–6} With longer patient survival, it is important that a durable reconstruction follow tumor resection.

In addition to primary bone sarcomas, orthopedic surgeons face the more common challenge of metastases to bone. It is estimated that around 350,000 people die each year in the United States with bone metastases,⁷ and the number of patients living with bone metastases is much higher. When present in periarticular areas, these metastases occasionally require tumor resection and reconstruction similar to that of primary bone sarcomas.

Three common means of reconstruction have been used after periarticular tumor resection: osteoarticular allograft, allograft–prosthetic composite (APC), and endoprosthesis. An osteoarticular allograft reconstruction utilizes a matched cadaver bone that is affixed to host bone via plate/screw construct or intramedullary nail fixation (Figure 128.1a). APCs combine an osteoarticular allograft that is skewered with a joint replacing prosthesis (Figure 128.1b). Endoprostheses replace resected bone with a metal implant cemented or press-fit into remaining host bone (Figure 128.1c).

Each method of reconstruction has many advantages and disadvantages. An important advantage of an osteoarticular allograft is the ability to repair host soft tissue to donor tendon/ligament attachments. Disadvantages of allografts include allograft fracture, host–allograft nonun-

ion, and secondary osteoarthritis. Advantages of endoprostheses include immediate use; disadvantages consist of aseptic loosening and wear. APCs provide donor soft tissue attachments for repair and prevent late osteoarthritis by resurfacing the joint, but carry the risk of allograft fracture and nonunion, transmission of infection, and the technical challenge of the reconstruction.

Although any anatomic location may be subject to tumor invasion requiring reconstruction, currently the most controversial sites of reconstruction are the proximal humerus and proximal tibia, as choices of reconstruction are largely based in individual surgeon experience and preference without universal agreement on optimal care. Thus, this chapter focuses on these two anatomic locations. The following questions will be addressed in each section:

1. What is the comparative risk of postoperative complications such as infection, recurrence, nonunion, aseptic loosening, fracture, and dislocation?
2. What is the comparative functional outcome between osteoarticular allografts, APCs, and endoprostheses via MSTs score or range of motion, if applicable?
3. What is the comparative success of limb salvage between osteoarticular allografts, APCs, and endoprostheses?
4. What is the comparative implant survival at 5, 10, and 20 years between osteoarticular allografts, APCs, and endoprostheses?

Finding the evidence

A literature search was performed by searching PubMed (www.ncbi.nlm.nih.gov/pubmed/) and OVID using a combination of terms including type of reconstruction and location (e.g., “allograft” and “proximal tibia”) for each

Figure 128.1 (a) Example of an osteoarticular allograft reconstruction. (b) Example of an allograft–prosthetic composite reconstruction. (c) Example of an endoprosthetic reconstruction.

area of the body discussed. All appropriate articles then underwent hand review to find any previously undetected articles in the reference section. All potential articles were then screened to see if they met the following criteria:

- Included 10 or more patients in the study
- A minimum of 2 year follow-up
- Data broken down by location, addressing at least three of the data points desired in each area of the body investigated (i.e., proximal humerus and proximal tibia)

Quality of the evidence

All studies identified were therapeutic, retrospective case series (level IV evidence).

Proximal humerus

Case scenario

A 13 year old female presents with a 3 month history of left shoulder pain that awakens her at night. Radiographs are shown in Figure 128.2. Open biopsy is consistent with Ewing’s sarcoma. Resection and reconstruction are planned.

Finding the evidence

Literature review found 7 articles meeting the criteria for osteoarticular allografts in the proximal humerus, 4 articles for APCs, and 14 articles for endoprostheses (Table 128.1).^{8–29}

Quality of the data

Pooled data can be found in Table 128.2 and relative risk calculations in Table 128.3.

Figure 128.2 Case example: proximal humerus.

Question 1: What is the comparative risk of postoperative complications such as infection, recurrence, nonunion, aseptic loosening, fracture, and dislocation?

Findings

Pooled data showed 1.4% deep infection in proximal humerus endoprostheses (11 papers, 7 of 517 patients, range 0–3.5%), 7.9% in osteoarticular allografts (7 papers, 10 of 126 patients, range 0–18.1%), and 5.1% in APCs (4

abd, abduction; FF, forward flexion; N/A, not applicable; NR, not reported.

papers, 4 of 78 patients, range 0–13.3%). The rate of deep infection is significantly lower in endoprostheses when compared to osteoarticular allografts (RR 0.17, 95% CI 0.07–0.44, $p = 0.00$).

Local recurrence occurred in 6.9% of endoprostheses (11 papers, 36 of 518 patients, range 0–15%), 8.7% in osteoarticular allografts (7 papers, 11 of 126 patients, range 0–18.1%), and 7.7% in APCs (4 papers, 6 of 78 patients, range 2.7–18.1%). These differences were not statistically significant.

Aseptic loosening occurred in 4.0% of endoprostheses (8 papers, 18 of 452 patients, range 0–7.8%) and in 4.7% of APCs (3 papers, 3 of 63 patients, range 0–8.3%).

Implant fractures occurred in 1.0% of endoprostheses (10 papers, 5 of 464 patients, range 0–5.5%). Periprosthetic fractures occurred in 0.24% of endoprostheses (10 papers, 1 of 416 patients, range 0–4.3%), 2.8% of osteoarticular studies (2 papers, 1 of 36 patients, at end of plate fixation), and in 0% of APCs in the only study commenting on periprosthetic fractures. Allograft fracture occurred in 35% of osteoarticular allografts (7 papers, 44 of 126 patients, range 25–53%) and only 1.9% of APCs (2 papers, 1 of 52 patients), reaching statistical significance (RR 0.06, 95% CI 0.01–0.39, $p = 0.00$).

Nonunion occurred in 11.1% of osteoarticular allografts (7 papers, 14 of 126 patients, range 0–25%) as well as 11.1% of APCs (3 papers, 7 of 63 patients, range 6.2–18%).

Dislocation occurred in 5.9% of endoprostheses (11 papers, 31 of 524 patients, range 0–56%), 21% of osteoarticular allografts (5 papers, 20 of 95 patients, range 5–69%), and 14.1% of APCs (4 papers, 11 of 78 patients, range 2.8–36%). Thus, endoprostheses had a significantly lower rate of dislocation than APCs (RR 0.42, 95% CI 0.22–0.88, $p = 0.0082$) and osteoarticular allografts (RR 0.28, 95% CI 0.17–0.47, $p = 0.00$).

Question 2: What is the comparative functional outcome via MSTS score and range of motion?

Findings

The mean 1993 revised MSTS score was 74% (22.3 out of 30) in the endoprosthesis group (8 studies, range 63–87%), 68% in the osteoarticular allograft group (5 studies, range 50–75%), and 77% in the APC group (3 studies, range 66–87%).

Range of motion (ROM) was reported in three studies using endoprostheses with an overall mean of 40° abduction and 47° forward flexion (range 34–45° abduction, 42–55° forward flexion). Mean ROM was only reported in one study using osteoarticular allografts with mean abduction 59° and forward flexion 47°. In APCs, a mean abduction of 55° (range 32–82°) was reported in three studies, and a mean forward flexion of 48° (range 40–56°) was reported in two studies.

Question 3: What is the comparative success of limb salvage?

Findings

Amputation for any reason was required in 4.8% of patients with endoprostheses (4 papers, 15 of 315 patients, range 0–8%), and in 10% of patients with osteoarticular allografts

Table 128.3 Proximal humerus: relative risk calculations. Statistically significant findings are in **bold**

Outcome	Comparison	N1/N2	RR	p value

(2 papers, 4 of 40 patients, both with 10%), and in 4% of APCs (2 papers, 1 of 47 patients, range 0–9%). These differences were not statistically significant.

Question 4: What is the comparative implant survival at 5, 10, and 20 years, if available?

Findings

Five year survival based on Kaplan–Meier survival analysis was reported in five studies evaluating endoprostheses with a range of 83–100%, four studies evaluating osteoarticular allografts with a range of 56–78%, and was 91% in the one study evaluating APCs. Mean 10 year survival rate was reported in four papers evaluating endoprostheses with a range of 42–85%, was not reported in osteoarticular allografts, and was 88% in APCs based on one paper. Only the endoprosthesis group had a 20 year survival rate reported as 66.7% in one paper.

Mean revision rate for any reason for the endoprosthesis group was 11.3% (8 papers, 47 of 417 patients, range 0–67%), 22% for osteoarticular allografts (3 papers, 13 of 59 patients, range 5.9–45%), and 5.1% for APCs (4 papers, 4 of 78 patients, range 0–8.3%). Endoprostheses and APCs had a significantly lower rate of revision than osteoarticular allografts (RR 0.53, 95% CI 0.3–0.91, p = 0.0253; RR 0.23, 95% CI 0.08–0.68, p = 0.0031 respectively).

Conclusions

The overall 5 year survival appears similar between endoprostheses and APCs, both of which have a trend toward improved survival when compared to osteoarticular allografts. Follow-up studies are needed to better predict the 10 and 20 year survival rates of these reconstructions.

Osteoarticular allograft reconstructions have a statistically significant higher rate of revision operations when compared to endoprostheses and APCs.

The rate of deep infection is significantly lower in endoprostheses when compared to osteoarticular allografts, but is not statistically different in comparison to APCs.

Allograft fracture occurred in a high percentage of osteoarticular allografts (35%). This, along with the higher rate of deep infections, may account for the significantly higher rate of revision operations.

Interestingly, despite the common belief that osteoarticular allografts offer improved stability due to the ability to repair donor tendon/ligament attachments back to what remains of host soft tissue, osteoarticular allografts had a significantly higher rate of dislocation without any apparent improvement in ROM or MSTS score. Endoprostheses had the lowest dislocation rate (6%) and APCs fell in between with 14%. The ROM was similar in all groups and overall poor, with no reconstruction obtaining a mean abduction greater than 60° or forward flexion greater than 50°.

Recommendations

- Though it is difficult to make strong recommendations as to the type of reconstruction that should be performed in the proximal humerus, it should be noted that osteoarticular allografts performed the worst in every outcome examined, with the exception of mean abduction. Endoprostheses and APCs performed quite similarly, with each appearing to be a viable reconstruction option

Proximal tibia

Case scenario

A 45 year old woman presents with a 6 week history of knee pain. Radiographs are seen in Figure 128.3. Open biopsy is consistent with high-grade dedifferentiated chondrosarcoma. Resection and reconstruction are planned.

Finding the evidence

Literature review found three articles meeting the criteria for osteoarticular allografts in the proximal tibia, three articles for APC, and 15 articles for endoprostheses (Table 128.4).^{8,10-12,30-45}

Quality of the evidence

Pooled data can be found in Table 128.5 and relative risk calculations in Table 128.6.

Figure 128.3 Case example: proximal tibia.

Question 1: What is the comparative risk of postoperative complications such as infection, recurrence, nonunion, aseptic loosening, fracture, dislocation/instability, and extensor mechanism failure?

Findings

Pooled data showed a deep infection rate of 15.6% in proximal tibia endoprostheses (134 of 861 patients, range 3.8–31% in 11 studies), 10.2% in osteoarticular allografts (9 of 88 patients, 2 studies), and 22% in APCs (22 of 100 patients, 3 studies, range 8.3–24%). These differences were not statistically significant.

Local recurrence occurred in 4.9% of endoprostheses (40 of 819 patients, 11 studies, range 0–10.5%), 3.7% of osteoarticular allografts (2 of 54 patients, 2 studies), and 12% of APCs (12 of 100 patients, 3 studies, range 4.8–27%). These differences were not statistically significant.

Aseptic loosening was similar between endoprostheses and APCs, occurring in 8% of endoprostheses (60 of 745 patients, 12 studies, range 0–25%) and 9% of APCs (9 of 100 patients, 3 studies, range 0–27%). Within the endoprosthesis group, independent analysis of fixed vs. rotating hinge designs could not be performed as studies including rotating hinges did not report separate aseptic loosening rates in this subgroup of their analysis. When comparing cemented vs. uncemented prostheses, there was significantly higher rate of aseptic loosening in cemented prostheses (RR 8.03, 95% CI 1.11–58.03, $p = 0.011$). Twenty-one percent of cemented endoprostheses had aseptic loosening (3 studies, 14 of 67 patients) versus 1.2% of uncemented endoprostheses (3 studies, 1 of 83 patients).

Bushing failures requiring reoperation occurred in 7.1% of endoprostheses.

Implant fractures occurred in 3% of endoprostheses (25 of 829 patients, 10 studies, range 0–14.3%) and 0% of APCs (0 of 100 patients, 3 studies). Periprosthetic fractures occurred in 2.9% of endoprostheses (19 of 653 patients, 9 studies, range 0–9%); no periprosthetic fractures were reported in APCs. Allograft fractures occurred in 35% of osteoarticular allografts (19/54 patients, 2 studies, range 31–37%) and in 7% of APCs (7 of 100 patients, 3 studies, range 0–27%).

One of the unique challenges of reconstruction after resection of proximal tibia tumors is reconstruction of the extensor mechanism. Of the papers that reported on extensor mechanism failures, they were reported in 11% of endoprostheses (13 of 120 patients, 3 studies, range 2.4–26%) and in 16% of APCs (16 of 100 patients, 3 studies, range 8.3–23%), not representing a statistically significant difference. Three studies on endoprostheses looked at mean extensor lag, with means of 6°, 18°, and 30° reported. 30% of patients with endoprostheses had an extensor lag more than 5° (24 of 79 patients, 2 studies, range 25–37%) as

Amputation	Endoprosthesis/allograft	10/2	0.96(0.5, 1.85)	0.9114
Amputation	APC1/allograft	2/2	0.5(0.18, 1.34)	0.1617
Extension mechanism failure	Endoprosthesis/APC1	3/3	0.68(0.34, 1.34)	0.2642

compared with 26% patients with APCs (10 of 38 patients, 2 studies, range 25–27%). Unfortunately, the three articles on osteoarticular allografts did not comment on extensor mechanism failure or extensor lags.

Question 2: What is the comparative functional outcome via MSTS score?

Findings

The mean 1993 revised MSTS score was 77% (23.1 out of 30) in the endoprosthesis group (6 studies, range 70–83%), 81% in the only study reporting in APCs, and was not reported in any study looking at osteoarticular allografts.

Question 3: What is the comparative success of limb salvage?

Findings

Amputation for any reason was required in 15.7% of patients with endoprostheses (10 papers, 123 of 782 patients, range 9.7–50%), in 8.1% of patients with APCs (2 papers, 6 of 74 patients, range 8–8.3%), and in 10.3% of patients with osteoarticular allografts (3 papers, 9 of 87 patients, range 2.6–18%). These differences were not statistically significant.

Question 4: What is the comparative implant survival at 5, 10, and 20 years, if available?

Findings

Mean 5 year survival rate based on Kaplan–Meier survival analysis was 65% in endoprostheses (8 papers, range 54–

84.5%), 78% based on one paper in osteoarticular allografts, and 70.5% based on two papers in APCs (survival rates of 68% and 73%). Mean 10 year survival rate was 45% in endoprostheses (6 papers, range 30–63%), 68% based on one paper in osteoarticular allografts, and 30% based on one paper in APCs. Only the endoprosthesis group had 20 year survival rates reported as 20.7 and 27% in two papers.

Mean revision rate for any reason for the endoprosthesis group was 36.5% (7 studies, 123 of 782 patients, range 15–63%), 35.2% in the osteoarticular allograft group (2 studies, 19 of 54 patients, range 31–44%) and 36.8% in the APC group (2 studies, 14 of 38 patients, range 0–54%). These differences were not statistically significant.

Conclusions

Overall, proximal tibia reconstructions have the highest rates of amputation, highest revision rates, and shortest overall survival when compared to reconstructions in any other part of the body.

Five year survival rates and revision rates were similar between the three methods of reconstruction; however, more data is needed to compare the long-term survival of these reconstructions.

Using the data obtained, there was no statistical difference between the groups in regards to deep infection, local recurrence, or amputation rates.

Extensor mechanism failure is a fairly common complication, seen in 11% of endoprostheses and 16% of APCs. Unfortunately this data is not available for osteoarticular allografts.

Openmirrors.com

SECTION VIII Orthopedic Oncology

Aseptic loosening is similar between endoprostheses and APCs (8% and 9% respectively). Allograft fracture is common, being seen in 35% of osteoarticular allografts, but only 7% of APCs.

Recommendations

- Based on the data points analyzed, it is not possible to recommend one type of reconstruction over the other in the proximal tibia except to note the higher risk for fracture in the osteoarticular allografts compared to endoprostheses and APCs

Case scenario

A 70 year old woman has an enlarging mass in the right axilla. Her primary care physician orders a needle biopsy to be done by a radiologist who carries out a fine needle aspiration (FNA) from 15 different sites around the 4cm mass in order to obtain adequate tissue. The result is nondiagnostic but suggestive of malignancy, possibly carcinoma with necrosis. The patient is referred to a breast oncologic surgeon who performs an extensive lymph node dissection and open biopsy of the axillary mass. The entire brachial plexus is carefully exposed and protected during the lymph node dissection. The pathologist finds that the lymph nodes are normal, but the axillary mass is diagnosed as a high-grade sarcoma. The woman is then referred to an orthopedic oncologist who discusses forequarter amputation for adequate local control.

The initial needle biopsy contaminated a large area of soft tissue around the sarcoma and was nondiagnostic. The next biopsy was definitive in making the diagnosis, but contaminated further tissue by exposing the brachial plexus at the time of the sarcoma biopsy. A carefully placed biopsy with adequate tissue for diagnosis could have allowed this woman a limb-sparing resection with an excellent chance of local control and probable cure.

Importance of the problem

There are three critical issues to address when determining how a biopsy of a soft tissue sarcoma should be performed. The first is to determine who is best suited to perform the biopsy—i.e., radiologist, primary care physician, general surgeon, general orthopedic surgeon, or orthopedic onco-

logic surgeon. The second is to identify the hazards of the various types of biopsies. Finally, the third is to identify the diagnostic accuracy of the soft tissue sarcoma biopsy types. Outcome measures are severely limited for procedure morbidity; however, the accuracy of the various techniques is a well-established and definable endpoint. The authors have brought together the following four questions to be addressed by the published literature.

Top four questions

1. When is a biopsy indicated?
2. How should the biopsy be placed?
3. How should the biopsy be performed (open incisional biopsy, core needle biopsy, FNA biopsy)?
4. Who should perform the biopsy (radiologist, sarcoma pathologist, general pathologist, general surgeon, general orthopedic surgeons, orthopedic oncologic surgeon)?

Finding the evidence

- PubMed search using keywords “biopsy” AND “soft tissue sarcoma”

Quality of the evidence

33 articles were reviewed.

Level II

- 3 outcomes research studies

Level III

- 2 retrospective comparative studies

Level IV

- 28 retrospective reviews

Question 1: When is a biopsy indicated?**Case clarification**

The patient reported an enlarging mass of uncertain etiology. This was felt clinically to require a biopsy.

Current opinion

In simple terms, a biopsy is indicated whenever a mass with biologic activity is clinically suspected and further surgical or medical treatment will be based on that result. Because many musculoskeletal lesions are inactive processes, not every lesion requires a biopsy or treatment.

Findings

No referenced article addressed the issue of when a biopsy of a soft tissue mass was indicated. In fact, a large variability of the incidence of neoplastic and non-neoplastic lesions was noted in these articles.¹ This variability resulted in confounding results of diagnostic accuracy of needle biopsy, particularly when larger inflammatory, infectious, and myxoid lesions were sampled.

Recommendations

- Soft tissue masses larger than 3 cm are more likely to require biopsy [overall quality: low]
- Masses that are actively growing or symptomatic are lesions that may require biopsy [overall quality: low]
- A soft tissue “hematoma” that is not associated with trauma, has no history of ecchymosis, and is increasing in size or symptoms may require biopsy [overall quality: low]
- Suspected hematomas that do not resolve over time may need a biopsy [overall quality: low]

Question 2: How should the biopsy be placed?**Findings**

None of the referenced articles addressed technical aspects of biopsy placement. The hazards of the biopsy have been studied when biopsy technique has wavered from the standard and the surgical morbidity is increased by 17%.² In the case of osteosarcoma, the local recurrence rate is increased as well as the systemic relapse for patients with inappropriate open tumor biopsy prior to referral to a cancer center.³ No study addressed whether needle biopsy placement affected local control or survival of patients with soft tissue sarcoma. Case reports of local recurrences in unresected needle biopsy tracts have been reported.

Recommendations

- Complete hemostasis during the biopsy is critical to prevent hematoma dissection outside of the tumor bed

which could potentially transport tumor cells into wider or newer areas [overall quality: low]

- The biopsy tract must be placed in a location that is resectable at the time of tumor excision (if the lesion is malignant) [overall quality: low]
- The biopsy should be placed longitudinally; in extremity, incisions should not expose critical neurovascular structures that could become contaminated with sarcoma [overall quality: low]

Question 3: How should the biopsy be performed?**Current opinion**

The first objective of a biopsy is to obtain diagnostic material. If the biopsy is done in conjunction with frozen section pathology, confirmation of diagnostic material can be done such that additional tissue may be obtained if necessary.

Findings

FNA has a lower diagnostic accuracy compared to core needle biopsy according to five studies that addressed this comparison.³⁻⁹ Incisional biopsy was associated with a 94% diagnostic accuracy and was more accurate than core biopsy (83%), but at a much higher expense in morbidity.¹⁰

Recommendations

The following are strong recommendations:

- Core needle biopsies are preferred over fine needle biopsies to improve diagnostic accuracy⁴ [overall quality: moderate]
- Core needle biopsies are preferred over open biopsies to reduce morbidity [overall quality: moderate]
- Excisional biopsy should be reserved for carefully selected clinical situations such as small subcutaneous tumors or lesions that have a diagnostic MRI appearance [overall quality: low]

Question 4: Who should perform the biopsy?**Findings**

Radiologists, pathologists, general surgeons, general orthopedic surgeons and sarcoma specialists were all represented in the available studies. Open biopsies performed by surgeons at a sarcoma center are associated with lower morbidity than those performed outside a sarcoma center.^{11,12} Needle biopsies performed by all physicians had equal rates of diagnostic accuracy whether or not they were at a sarcoma center.¹³ Needle biopsy performed with CT, ultrasound or MRI assistance can theoretically improve the quality of diagnostic material; however, no studies have directly compared the accuracy of radiologically guided to nonradiologically guided biopsies.^{2,4,7,14-21}

The results with highest diagnostic accuracy were reported by core needle biopsy performed by surgeons.^{3,10,22,23} However, this is probably explained by a selection bias whereby the most difficult diagnostic cases in the most challenging anatomic locations were referred to radiologists. The complication reported in four studies ranged from 0 to 2%.^{18,24-26} Frozen section done at the time of biopsy improved the diagnostic accuracy by 6–8% but may not be cost-effective.⁴

Recommendations

- Open biopsies should be performed in a sarcoma center by a sarcoma surgeon or radiologist [overall quality: moderate]
- Needle biopsies can be performed by a sarcoma surgeon or a radiologist with equal accuracy [overall quality: low]
- Frozen sections are not cost-effective for needle biopsies [overall quality: low]

Summary of recommendations

- Soft tissue masses larger than 3cm are more likely to require biopsy
- Masses that are actively growing or symptomatic are lesions that may require biopsy
- A soft tissue “hematoma” that is not associated with trauma, has no history of ecchymosis, and is increasing in size or symptoms may require biopsy
- Suspected hematomas that do not resolve over time may need a biopsy
- Complete hemostasis during the biopsy is critical to prevent hematoma dissection outside of the tumor bed which could potentially transport tumor cells into wider or newer areas
- The biopsy tract must be placed in a location that is resectable at the time of tumor excision (if the lesion is malignant)
- The biopsy should be placed longitudinally; in extremity, incisions should not expose critical neurovascular structures that could become contaminated with sarcoma
- Core needle biopsies are preferred over fine needle biopsies to improve diagnostic accuracy
- Core needle biopsies are preferred over open biopsies to reduce morbidity
- Excisional biopsy should be reserved for carefully selected clinical situations such as small subcutaneous tumors or lesions that have a diagnostic MRI appearance
- Open biopsies should be performed in a sarcoma center by a sarcoma surgeon or radiologist
- Needle biopsies can be performed by a sarcoma surgeon or a radiologist with equal accuracy
- Frozen sections are not cost-effective for needle biopsies

Surgical Margins in Soft Tissue Sarcoma: What Is a Negative Margin?

Bruce T. Rougraff

OrthoIndy, Indianapolis, IN, USA

Clinical scenario

A 57 year old male truck driver undergoes an excision of a 6 cm mass in his thigh that was found to be a high-grade soft tissue sarcoma (STS). The surgical margins are described in the pathology report as “close.” He is concerned that with loss of his quadriceps function he will lose his job and is worried about the side effects of radiation to his thigh. How close a margin is too close and should be treated with re-excision? How much further normal tissue would be resected? Is radiation needed and would it be enough? Would chemotherapy help his local control? Why not just wait until he develops a local recurrence before considering more surgical and radiation treatment?

Relevant anatomy

Over the last 30 years the surgical treatment for STS has transitioned from radical amputation to surgical resection. When a surgical resection is chosen as the local treatment for STS, the exact amount of tissue that needs to be resected around the soft tissue mass has remained confusing (see Further reading). Surgical margins for STS were first described in terms of anatomical setting by Enneking in 1981.¹ His margin classification was adapted from his experience with bone sarcomas which he had previously published. He described the margin as intralesional when the resection was carried out within the pseudo-capsule of the tumor. A marginal resection was when the tumor was shelled out with the surrounding reactive zone intact. A wide resection was described as a resection that passed through normal tissue in all planes around the anatomic

compartment with which the sarcoma was contained. In a radical resection, the entire compartment that contains the sarcoma is resected. He reported local recurrence of 50% after marginal resection 25% after wide resection 4% after radical resection. These data were based on 40 patients with STS that were treated before the advent of MRI.

The advantage to this anatomic approach was that it gave surgeons a common classification system to describe their attempted resection goals. It is still the method of describing surgical intervention. The problem with this anatomic approach to surgical margins is that it does not involve any absolute distance; it is unclear how wide is “wide enough.” Because large sarcomas frequently are close to neurovascular structures or periosteum and sometimes involve bone invasion, an intracompartmental sarcoma could be extremely close to other structures that were not resected and be within a cell layer of the margin, despite being technically a radical resection. Only one third of STS of the thigh are contained within a compartment and much fewer in the head, neck, and retroperitoneum. Likewise, subcutaneous sarcomas could never undergo a resection that was considered radical. Defining how “wide” is really wide enough has been very confusing in the literature.

In 1987 Rydholm² considered intact muscle to be a distinct anatomic compartment. He further subdivided wide margins as a wide subcutaneous margin when the tumor was resected from subcutaneous region with fascia and adequate subcutaneous tissue, and deep margin for deep tumors with adequate muscular envelope. Kawaguchi³ for the Japanese Orthopaedic Society ignored compartmental anatomy as a description for resection. This got rid of a contentious issue between what the pathologists saw with the specimen and what the surgeon was describing

anatomically. Kawaguchi described margins as curative, adequate, or inadequate depending on the width and the quality of tissue surrounding the entire resected specimen.

This lack of consensus has resulted in surgical margins being described in various ways. Some studies describe them as either positive, or negative. Other authors have described margins as inadequate if tumor was present at the inked surface. The International Union Against Cancer (IUAC) has promoted a system of R0, R1, and R2, where R0 denotes a complete resection (presumably without microscopic tumor present at any inked surface), R1 refers to microscopically positive margins, and R2 denotes incomplete resection or debulking procedure. Finally, other authors have described their margins as “adequate” if 2 cm of normal tissue is present around the mass. Still others use 1 cm or even 1 mm of normal cuff of tissue around the sarcoma as adequate margins.

To add to the confusion of surgical margins and STS, various adjuvant therapies have been used in reported studies in a nonrandomized fashion. External beam radiation, brachytherapy, intraoperative radiation therapy and chemotherapy have been described in the treatment STS. Their effect on local control and surgical margins has remained ambiguous and further confused by the lack of agreement of the adequacy of surgical margin. Finally, many studies have included surgical assessments reported by the surgical team which blurs the final pathologic assessment of surgical margins because of disagreement of what is “adequate” or not.

But there is still more to the issue of surgical margins and local control. The unique local biology of each sarcoma can dictate how adequate a margin is possible. A 2 cm sarcoma in the popliteal fossa at the vascular trifurcation is not going to have a large margin compared to the same tumor in the central quadriceps muscle. It can be easier to get “wider” margins for a very large intracompartmental tumor than for an extracompartmental sarcoma between the sciatic nerve and the posterior femur. Yet another consideration is whether the sarcoma is referred for definitive treatment before or after contamination by prior surgical manipulation or, even worse, after local recurrence. The final consideration is whether more (or less) intense attempts at local control impact patient survival.

Finding the evidence

A literature search of the English literature of surgical margins in STS that excluded studies with less than 50 patients, series with bone sarcomas, and studies limited to DFSP. This left a total of 91 studies that were adequate to assess their margin data and local control and patient survival.

Quality of the evidence

Level of evidence was assigned according to the criteria in Table 130.1.

Top ten questions

1. What is the reported range of local recurrence for patients with STS, and does that correlate/impact with reported survival rates?
2. How did prior studies report their surgical margins and did their system correlate with their local recurrences and survival?
3. What is an adequate surgical margin?
4. What should be done with an inadequate margin (margin at risk) and what is the expected outcome?
5. Does grade correlate with less quality margins or impact local control?
6. Does tumor size correlate to less quality margins or impact local control?
7. Does external beam radiation impact local control?
8. Does radiation impact survival?
9. Does chemotherapy impact local control?
10. Does prior local recurrence place the patient at increased risk for another local recurrence or worse survival?

Question 1: What is the reported range of local recurrence for patients with STS, and does that correlate/impact with reported survival rates?

Findings

Of the STS studies with margin and local control data, the range of local recurrence was from 4% to 60%, and the median of these studies was 19%. The highest local recurrence rates tended to be in series with higher percentage of head and neck cases or retroperitoneal tumors. The 5 year survival rate was between 39% and 91%. The lowest survival rates were in series limited to large, high-grade sarcomas and the highest survival rates were series limited to small superficial or low-grade sarcomas.

Three studies⁴⁻⁶ were limited to locally recurrent sarcomas and they reported 63–74% 5 year survival. Two of those three studies found that local recurrence was associated with decreased survival. Both studies were level II. No other study (89/91) was able to correlate local failure to survival. No study found improved survival with amputation compared to limb-sparing surgery.

Recommendation

- Local relapse after sarcoma resection and judicious adjuvant therapy occurs in about 20% of cases and is higher in

Table 130.1 Levels of evidence for primary research questions

Level	Types of studies			
	Therapeutic studies— investigating the results of treatment	Prognostic studies— investigating the effect of a patient characteristic on the outcome of disease	Diagnostic studies— investigating a diagnostic test	Economic and decision analyses—developing and economic or decision model
I	High quality randomized trial with statistically significant difference or no statistically significant difference but narrow confidence intervals Systematic review of level I RCTs (and study results were homogenous)	High quality prospective study (all patients were enrolled at the same point in their disease with $\geq 80\%$ follow-up of enrolled patients) Systematic review of level I studies	Testing of previously developed diagnostic criteria on consecutive patients (with universally applied reference gold standard) Systematic review of level I studies	Sensible costs and alternatives; values obtained from many studies; with multiway sensitivity analyses Systematic review of level I studies
II	Lesser quality RCT (e.g., $<80\%$ follow-up, no blinding, or improper randomization) Prospective comparative study Systematic review of level II studies or level I studies with inconsistent results	Retrospective study Untreated controls from an RCT Lesser quality prospective study (e.g., patients enrolled at different points in their disease or $<80\%$ follow-up) Systematic review of level II studies Case-control study	Development of diagnostic criteria on consecutive patients (with universally applied reference “gold” standard) Systematic review of level II studies	Sensible costs and alternatives; values obtained from limited studies; with multiway sensitivity analyses Systematic review of level II studies
III	Case-control study Retrospective comparative study Systematic review of level III studies	Case-control study	Study of nonconsecutive patients; without consistently applied reference “gold” standard Systematic review of level III studies	Analyses based on limited alternatives and costs; and poor estimates Systematic review of level III studies
IV	Case series	Case series	Case-control study Poor reference standard	Analyses with no sensitivity analyses

retroperitoneal and head and neck locations. There is some limited evidence that local recurrence impacts survival, particularly in the head and neck where locally recurrent disease can cause mortality without metastasis [overall quality: low]

Question 2: How did prior studies report their surgical margins and did their system correlate with their local recurrences and survival?

Findings

In these 91 studies, 10 different margin classification systems were reported. The most common system was the IUAC R0–2 system. 18/20 studies with LOE of II or III had strong correlation between margin R0 and local control. The second most common was the Enneking system, but only 5/20 studies had a correlation between margins and local control. Those five studies that showed a correlation tended to be the largest series, suggesting that there is a correlation but it takes a larger number of patients to show

it as compared to the IUAC system. All nine studies (9/9) that used ink present on the tumor as a positive margin showed strong correlation to margin quality and local control. Studies that called their margins microscopically positive or negative also had a strong correlation between margin quality and local control (11/17 studies). Unfortunately, these studies had a significant number of cases where the margin assessment was inadequate or incomplete and no comprehensive pathology review was done. These incomplete cases were typically included in the positive margin group in order to show significance to local failure. It appears that the worst margin assessment system in terms of predicting local failure is those that call a margin less than 1 or 2 cm as positive. Only one of eight studies found a correlation to local recurrence and this was a level III study. Eight studies used 1 mm as the cut-off for poor margin and six of these studies showed a correlation to local failure.

In terms of margin quality impacting survival, 15 studies found a correlation between surgical margin and 5 year

survival. Interestingly, these 15 studies tended to be the series with higher local failure rates. The average failure rate reported in these 15 studies was 32.3% vs. 18.8% in studies that did not show a correlation between margin quality and 5 year survival. In fact, no study with a local recurrence rate of less than 18% found that correlation.

Recommendation

- Pathologic analysis of the specimen looking microscopically for ink touching tumor cells anywhere on the resected specimen should be considered the most predictive of local relapse for STS. Other margin classification systems have merit but do not predict local failure as well and can be adapted to reporting whether ink touches tumor [overall quality: low]

Question 3: What is an adequate surgical margin?

Finding

As described in the previous section, it appears from these 91 studies that no ink touching tumor on the resected specimen or a system that uses R0–2 or 1 mm from the ink are most accurate in predicting local failure. This is supported by level II, III, and IV studies. Only two studies compared margin classification systems and both found microscopic evidence of ink on the tumor was a better predictor than Enneking margins for local failure.^{7,8} It is difficult to assess the need for radiation based on margin quality since the majority of these patients with “close” margins do receive radiation. Adequacy of margin becomes a distressing title since most cases treated by an experienced sarcoma surgeon that have a positive margin are in an anatomic location that is close to nonresectable tissues. In fact, commonly no further surgery other than amputation can be offered to the patient. No study reported a higher survival rate with amputation compared to resection and adjuvant therapy. A better term than “inadequate surgical margin” may be “margin at risk.”

Recommendation

- The microscopic finding of ink on tumor cells as found on the resected specimen represent a margin at risk or “inadequate margin.” This finding may be equivalent to R1 vs. R0 in many studies using the international margin system (CICC) [overall quality: moderate]

Question 4: What should be done with an inadequate margin (margin at risk) and what is the expected outcome?

Findings

Local recurrence after a resection with an inadequate or at risk margin ranges between 24% and 40%. The impact of

radiation to reduce this rate is ambiguous in the literature. Of the three studies that focused on positive margins and locally recurrent sarcomas and the value of radiation, two of the three found a definite improved local control with radiation.^{5,6,9} None of these studies explored results of chemotherapy.

Recommendation

- Patients who have margin at risk after an attempted wide resection should receive radiation therapy [overall quality: moderate]

Question 5: Does grade correlate with less quality margins or impact local control?

Of the 91 studies, only 3 showed a correlation between tumor grade and local control.^{10–12} None found a correlation with grade and quality of margin. The three studies were very large series, which suggests that there may be a very weak correlation if any at all.

Recommendation

- High-grade histology may be a weak predictor of increased local recurrence of STS [overall quality: moderate]

Question 6: Does tumor size correlate to less quality margins or impact local control

Four of the 91 studies showed a correlation between tumor size and margin quality.^{6,11,13,14} These were mid-sized series including only two that were level II. This may be a very weak association (if any at all), since 87/91 studies which included the largest patient series did not show this association.

However, tumor size was correlated to local control in seven of the largest series.^{5,6,11,15–18} This is probably a real association that can only be seen statistically with series with over 300 patients.

Recommendation

- Large tumor size is a weak predictor of local recurrence but probably not margin quality [level of evidence: moderate]

Question 7: Does external beam radiation impact local control?

Fourteen of the 91 studies found a correlation between radiation and better local control.^{5,9,10,15,19–28} Interestingly, 9/14 were European studies. Ten were level II, two were level III, and two were level IV. The local recurrence rate ranged from 13–60% with a median of 25%. Seventy-seven of the 91 studies found no improvement in local control

with radiation, but no studies were randomized and it is likely that a bias of more patients receiving radiation also had the highest-risk surgical margins.

Recommendation

- There is likely improved local control with radiation [overall quality: moderate]

Question 8: Does radiation impact survival?

Eighty-nine of the 91 studies (74 studies looked specifically at this issue) were unable to show improved survival with radiation. Two studies found an improved survival with the utilization of radiation.^{22,29} These included a study that was limited to patients with positive margins and no comparison group to radiation. It also included a high number of retroperitoneal sarcomas. The other was a level IV study that was poorly structured to look at this issue and had a very high number of patients with incomplete tumor resections. It also included a high number of head, neck, and retroperitoneal cases where local failure can cause death without metastases.

Recommendation

- There does not appear to be evidence that radiation prevents metastasis nor improves survival, particularly in patients with completely resected extremity sarcoma [overall quality: low]

Question 9: Does chemotherapy impact local control?

No study found improvement in local control with chemotherapy. No randomized studies have been published that address this.

Recommendation

- The use of chemotherapy to improve local control is not supported in the literature

Question 10: Does prior local recurrence place the patient at increased risk for another local recurrence or worse survival?

Fifteen of the 91 studies looked specifically at the issue of outcome after a local recurrence. Eleven of those 15 studies^{4,11,18,22,30-35} found strong evidence that local failure was a high risk factor for another local failure. Ten studies were level II, and one was level III. Four studies did not find this correlation (two were from the same institution), two were level II and two were level III.^{8,36-38} These were older studies and may have included more amputations, although that is not documented.

Recommendation

- There is good evidence that local recurrence of disease is at higher risk of recurring again locally if an amputation is not performed [overall quality: moderate]

Summary of recommendations

- Local relapse after sarcoma resection and judicious adjuvant therapy occurs in about 20% of cases and is higher in retroperitoneal and head and neck locations. There is some limited evidence that local recurrence impacts survival, particularly in the head and neck where locally recurrent disease can cause mortality without metastasis
- Pathologic analysis of the specimen looking microscopically for ink touching tumor cells anywhere on the resected specimen should be considered the most predictive of local relapse for STS. Other margin classification systems have merit but do not predict local failure as well and can be adapted to reporting whether ink touches tumor
- The microscopic finding of ink on tumor cells as found on the resected specimen represent a margin at risk or “inadequate margin.” This finding may be equivalent to R1 vs. R0 in many studies using the international margin system (CICC)
- Patients who have margin at risk after an attempted wide resection should receive radiation therapy
- High-grade histology may be a weak predictor of increased local recurrence of STS
- Large tumor size is a weak predictor of local recurrence but probably not margin quality
- There is likely improved local control with radiation
- There does not appear to be evidence that radiation prevents metastasis nor improves survival, particularly in patients with completely resected extremity sarcoma
- The use of chemotherapy to improve local control is not supported in the literature
- There is good evidence that local recurrence of disease is at higher risk of recurring again locally if an amputation is not performed

Conclusions

Surgical margins have been reported in the English literature at least 10 different ways. The most accurate predictor of local recurrence is the presence of ink on tumor. This may be equivalent to a “microscopically positive margin” in some studies or an R1 resection in others. Large tumor size and high sarcoma grade may be weak predictors of local failure. Surgical margins appear to only predict survival in the studies with the highest local failure rates. There is weak and indirect evidence that local recurrence rates above 18% may be associated with lower survival in patients with STS. Radiation appears to be effective in

decreasing local relapse but not metastasis. Chemotherapy has no published evidence of decreasing local failure. Patients who are referred for treatment after a local recurrence are much more likely to recur locally again without amputation. Amputation is not associated with survival benefit over limb salvage. Controlled, prospective, randomized studies with standardized margin classification to address the use of chemotherapy and radiation would be extremely helpful to clarify their indications.
