Contents

Contributors, x
Foreword, xx
Preface, xxii
Abbreviations, xxiii

Section I Methodology of Evidence-Based Orthopedics

- 1 Principles of Evidence-Based Orthopedics, 3
Simrit Bains, Mohit Bhandari, and Paul Tornetta III
- 2 Understanding Hierarchies of Evidence and Grades of Recommendation, 7
Raman Mundi and Brad A. Petrisor
- 3 Critical Appraisal Tools for Surgeons 12
Farrah Hussain, Sheila Sprague, and Harry E. Rubash
- 4 Understanding Diagnosis, Therapy, and Prognosis, 17
Helena Viveiros, Sarah Resendes, Tania A. Ferguson, Mohit Bhandari, and Joel Matta
- 5 Systematic Reviews and Meta-Analysis, 25
Nasir Hussain, Farrah Hussain, Mohit Bhandari, and Saam Morshed
- 6 Economic Analysis, 30
Laura Quigley, Sheila Sprague, and Theodore Miclau III

Section II Orthopedic Medicine

- 7 Osteoporosis and Metabolic Disorders, 37
Celeste J. Hamilton, Sophie A. Jamal, and Earl R. Bogoch
- 8 Thromboprophylaxis in Orthopedic Practice, 56
Ernest Kwek and Richard E. Buckley
- 9 Blood Transfusion, 72
David W. Sanders and Jeffrey L. Carson
- 10 Wound Infections, 78
Wesley G. Lackey, Kyle J. Jeray, Atul F. Kamath, John G. Horneff III, and John L. Esterhai, Jr

- 11 Gouty Arthritis, 86
Jasvinder A. Singh
- 12 Perioperative Medical Management, 93
Daniel A. Mendelson, Susan M. Friedman, and Joseph A. Nicholas
- 13 Orthobiologics, 100
T. William Axelrad and Thomas A. Einhorn

Section III Joint Reconstruction

III.I Hip and Pelvic Reconstruction/Arthroplasty

- 14 The Role of Computer Navigation in Total Hip Arthroplasty, 119
Jonathan M. Loughead and Richard W. McCalden
- 15 Highly Crosslinked Polyethylene in Total Hip Arthroplasty, 131
Glen Richardson, Michael J. Dunbar, and Joseph P. Corkum
- 16 Hip Resurfacing vs. Metal-on-Metal Total Hip Arthroplasty, 137
Sanket R. Diwanji, Pascal-André Vendittoli, and Martin Lavigne
- 17 The Role of Ceramic in Total Hip Arthroplasty, 153
Peter M. Lewis and James P. Waddell
- 18 Minimally Invasive Techniques in Total Hip Arthroplasty, 164
Amre Hamdi and Paul E. Beaulé

III.II Hip Revision Surgery

- 19 Management of Femoral Periprosthetic Fractures After Hip Replacement, 171
Tamim Umran, Donald S. Garbuz, Bassam A. Masri, and Clive P. Duncan
- 20 Evaluation of the Painful Total Hip Replacement, 178
Matthew Oliver and James N. Powell

- 21 Revision of the Femoral Components: Role of Structural Bulk Allografts and Impaction Grafting, 186
Christopher R. Gooding, Bassam A. Masri, Donald S. Garbuz, and Clive P. Duncan
- 22 Revision of the Acetabular Components: Role of Structural Bulk Allografts and Porous Tantalum Implants, 205
John Antoniou, Alan J. Walsh, and Vassilios S. Nikolaou

III.III Knee Reconstruction/Arthroplasty

- 23 Antibiotic Cement in Total Knee Arthroplasty, 212
Philip A. O'Connor and Steven J. MacDonald
- 24 Cemented vs. Uncemented Fixation in Total Knee Arthroplasty, 220
Eric R. Bohm, Ili Slobodian, Thomas R. Turgeon, and Martin Petrak
- 25 High-Flexion Implants vs. Conventional Design Implants, 228
Nicholas Paterson, Robert J. Orec, and Douglas D.R. Naudie
- 26 The Neuropathic/Charcot Joint, 236
Rajrishi Sharma and Mitchell J. Winemaker

III.IV Knee Revision Surgery

- 27 Cemented vs. Uncemented Stems in Revision Knee Arthroplasty: Indications, Technique, and Outcomes, 242
Gerard M.J. March and Paul R. Kim
- 28 Management of Structural Defects in Revision Knee Arthroplasty: Femoral Side, 249
Sandor Gyomory, Paul T.H. Lee, and David J. Backstein
- 29 Patellar Options in Revision Knee Arthroplasty, 257
Hatem Al-Harbi and Paul Zalzal

III.V Shoulder Reconstruction/Arthroplasty

- 30 Total Shoulder Replacement vs. Hemiarthroplasty in the Treatment of Shoulder Osteoarthritis, 263
Olivia Y.Y. Cheng and Michael D. McKee
- 31 Cemented vs. Uncemented Fixation in Shoulder Arthroplasty, 270
Shahryar Ahmadi and Christian Veillette
- 32 Reverse Total Shoulder Arthroplasty, 278
Ryan T. Bicknell
- 33 Glenoid Fixation in Total Shoulder Arthroplasty: What Type of Glenoid Component Should We Use?, 284
Eric C. Benson, Kenneth J. Faber, and George S. Athwal

III.VI Foot and Ankle Reconstruction/Arthroplasty

- 34 Fusion vs. Arthroplasty in the Treatment of Ankle Arthritis, 294
Timothy R. Daniels, Mark Glazebrook, Terence Chin, and Roger A. Haene
- 35 Fusion vs. Arthroplasty in the Treatment of 1st MTP Arthritis, 307
Jeffrey G.M. Tan, Gilbert Yee, and Johnny T.C. Lau
- 36 Charcot-Marie-Tooth Disease and the Treatment of the Cavo-Varus Foot, 317
David N. Townshend and Alastair S.E. Younger

Section IV Trauma

IV.I Upper Extremity

IV.I.I Shoulder Girdle

- 37 Acromioclavicular Joint, 325
Bill Risteovski and Michael D. McKee
- 38 Clavicle, 332
Bill Risteovski and Michael D. McKee
- 39 Scapula, 341
Peter A. Cole and Lisa K. Schroder
- 40 Post-Traumatic Avascular Necrosis of the Proximal Humerus, 351
Ilia Elkinson and Darren S. Drosdoweck

IV.I.II Humerus

- 41 Proximal Humerus Fractures, 360
Job N. Doornberg and David Ring
- 42 Humeral Shaft Fractures, 366
Amy Hoang-Kim, Jörg Goldhahn, and David J. Hak
- 43 Distal Humerus Fractures, 374
Aaron Nauth and Emil H. Schemitsch

IV.I.III Elbow and Forearm

- 44 Fracture-Dislocations of the Elbow, 383
Reyhana A. Chaudhary, Maurice Tompack, and J. Whitcomb Pollock
- 45 Radial Head Fractures, 397
Andrea S. Bauer and David Ring
- 46 Monteggia Fracture-Dislocations, 403
Bryce T. Gillespie and Jesse B. Jupiter
- 47 Olecranon Fractures, 409
Bryce T. Gillespie and Jesse B. Jupiter
- 48 Forearm Fractures, Including Galeazzi Fractures, 416
S. John Ham, Matthijs R. Krijnen, and Rudolf W. Poolman

IV.I.IV Wrist and Hand

- 49 Distal Radius Fractures, 425
Boris A. Zelle and Michael Zlowodzki
- 50 Perilunate Dislocations, 437
Geert A. Buijze, Job N. Doornberg, and David Ring
- 51 Carpal Fractures, 443
Bertrand H. Perey, Anne-Marie Bedard, and Fay Leung
- 52 Metacarpal Fractures, 462
Brent Graham

IV.II Lower Extremity**IV.II.I Hip**

- 53 Hip Dislocations, 468
Gregory J. Della Rocca, Brett D. Crist, and Yvonne M. Murtha
- 54 Femoral Head Fractures, 474
Chad P. Coles
- 55 Intracapsular Fractures, 480
Jennifer A. Klok, Marc Swiontkowski, and Mohit Bhandari
- 56 Intertrochanteric Fractures, 491
Ole Brink and Lars C. Borris

IV.II.II Femur

- 57 Subtrochanteric Fractures, 497
Steven Papp, Wade Gofton, and Allan S.L. Liew
- 58 Femoral Shaft Fractures, 504
Costas Papakostidis and Peter V. Giannoudis
- 59 Distal Femur Fractures, 522
Matthijs R. Krijnen, J. Carel Goslings, and Rudolf W. Poolman

IV.II.III Knee

- 60 Knee Dislocations, 527
James P. Stannard and Allan Hammond

IV.II.IV Tibia

- 61 Proximal Tibia, 534
Richard J. Jenkinson and Hans J. Kreder
- 62 Tibial Shaft, 541
Jennifer A. Klok
- 63 Distal Tibia/Plafond, 549
Hossein Pakzad and Peter J. O'Brien

IV.II.V Foot and Ankle

- 64 Malleolar Fractures, 561
David W. Sanders and Ajay Manjoo
- 65 Talus Fractures, 567
Gregory K. Berry
- 66 Calcaneus Fractures, 574
Stephen J. McChesney and Richard E. Buckley

- 67 Midfoot/Metatarsal Fractures, 583
Robin R. Elliot and Terence S. Saxby

IV.III Pelvis and Acetabulum

- 68 Pelvis, 593
G. Yves Laflamme, Stephane Leduc, and Dominique M. Rouleau
- 69 Acetabulum, 602
Kelly A. Lefaivre and Adam J. Starr

IV.IV General

- 70 Open Fractures, 617
Atul F. Kamath, John G. Horneff, John L. Esterhai, Jr., Wesley G. Lackey, Kyle J. Jeray, and J. Scott Broderick
- 71 Acute Compartment Syndrome, 627
Andrew H. Schmidt
- 72 Noninvasive Technologies for Fracture Repair, 636
Yoshinobu Watanabe, Makoto Kobayashi, and Takashi Matsushita
- 73 Calcium Phosphate Cements in Fracture Repair, 642
Ross K. Leighton, Kelly Trask, Thomas A. Russell, Mohit Bhandari, and Richard E. Buckley
- 74 Damage Control Orthopedics, 649
Philipp Kobbe and Hans-Christoph Pape
- 75 Mangled Extremity, 655
Ted V. Tufescu

Section V Adult Spine**V.I Cervical Spine**

- 76 Mechanical Neck Pain, 663
Gabrielle van der Velde
- 77 Whiplash, 669
Gabrielle van der Velde

V.II Mechanical Low Back Pain without Neuropathy

- 78 Mechanical Low Back Pain: Operative Treatment—Fusion, 675
Rahul Basha, Alex Gitelman, and Jeffrey C. Wang
- 79 Mechanical Low Back Pain: Nonoperative Management, 678
Andrea D. Furlan, Victoria Pennick, Jill A. Hayden, and Carlo Ammendolia

V.III Low Back Pain with Neuropathy

- 80 Neurogenic Claudication—Operative Management (Decompression and Fusion), 686
Hormuzdiyar H. Dasenbrock, Reza Yassari, and Timothy F. Witham

- 81 Neurogenic Claudication: Nonoperative Management, 694
Carlo Ammendolia
- 82 Adolescent Idiopathic Scoliosis—Nonoperative Management, 702
Calvin T. Hu and James O. Sanders
- 83 Adolescent Idiopathic Scoliosis—Operative Management, 710
Calvin T. Hu and James O. Sanders
- 84 Metastatic/Myeloma Disease—Operative Management, 721
Harsha Malempati, Erion Qamirani, and Albert J.M. Yee
- 85 Metastatic/Myeloma Disease—Nonoperative Management, 728
Harsha Malempati, Erion Qamirani, and Albert J.M. Yee

Section VI Sports Medicine

VI.I Shoulder

- 86 Treatment of the First Shoulder Dislocation, 737
Charles L. Cox, and John E. Kuhn
- 87 Chronic Shoulder Instability, 744
Joost I.P. Willems and W. Jaap Willems
- 88 Rotator Cuff Injury, 752
John E. Kuhn
- 89 Shoulder Impingement Syndrome, 763
Ron L. Diercks and Oscar Dorrestijn
- 90 Pathology of the Long Head of the Biceps, 772
Paul W.L. ten Berg, Luke S. Oh, and David Ring

VI.II Elbow

- 91 Ulnar Collateral Ligament Injury, 781
Denise Eygendaal and Laurens Kaas
- 92 Tennis Elbow, 787
Peter A.A. Struijs, Rachelle Buchbinder, and Sally E. Green

VI.III Knee

- 93 Initial Management of the Sports Injured Knee, 796
Jaskarndip Chahal, Christopher Peskun, and Daniel B. Whelan
- 94 Meniscal Tears (Meniscectomy, Meniscopexy, Meniscal Transplants/Scaffolds), 803
Nicola Maffulli, Umile Giuseppe Longo, Stefano Campi, and Vincenzo Denaro
- 95 Anterior Cruciate Ligament Injury, 812
Verena M. Schreiber, Kenneth D. Illingworth, Hector A. Mejia, and Freddie H. Fu

- 96 Posterior Cruciate Ligament Injury, 822
Rune Bruhn Jakobsen and Bent Wulff Jakobsen
- 97 Operative vs. Nonoperative Treatment of Combined Anterior Cruciate Ligament and Medial Collateral Ligament Injuries, 832
Rocco Papalia, Sebastiano Vasta, Vincenzo Denaro, and Nicola Maffulli
- 98 Posterolateral Corner Injury, 841
Pankaj Sharma and Daniel B. Whelan
- 99 Cartilage Injury, 847
Joris E.J. Bekkers, Anika I. Tsuchida, and Daniël B.F. Saris
- 100 Runner's Knee, 853
Ella W. Yeung and Simon S. Yeung

VI.IV Foot and Ankle

- 101 Ankle Ligament Injury, 862
Michel P.J. van den Bekerom, Rover Krips, and Gino M.M.J. Kerckhoffs
- 102 Achilles Tendinopathy, 872
Nicola Maffulli, Umile Giuseppe Longo, Stefano Campi, and Vincenzo Denaro

VI.V Hip

- 103 Labral Tears, 879
Sanaz Hariri, Henk Eijer, and Marc R. Safran
- 104 Hip Impingement, 892
Marc J. Philippon and Karen K. Briggs
- 105 Snapping Hip, 898
Bas van Ooij and Matthias U. Schafroth

VI.VI Other Injuries

- 106 Ergogenic Aids: Creatine Supplementation as a Popular Ergogenic Aid in Young Adults, 905
Michael J. O'Brien

Section VII Wrist and Hand Surgery

VII.I Wrist Surgery

- 107 Acute Management of Distal Radius Fractures, 913
Ruby Grewal
- 108 Prognosis: Pain and Disability After Distal Radius Fracture, 923
Joy C. MacDermid and Ruby Grewal
- 109 Reconstruction of Malunited Distal Radius Fracture, 930
James T. Monica and David Ring
- 110 Scaphoid Fractures, 938
Ruby Grewal

- 111 Nonunions of the Scaphoid, 946
Nina Suh and Ruby Grewal
- 112 Trapeziometacarpal Arthritis of the Thumb, 954
Anne Wajon, Emma Carr, Louise Ada, and Ian A. Edmunds
- 113 Salvage Procedures for the Treatment of Wrists with Scapholunate Advanced Collapse, 962
Jonathan Mulford, Paul K. Della Torre, and Stuart J.D. Myers
- 114 Wrist Arthroscopy, 969
Aaron M. Freilich, Bryan S. Dudoussat, Fiesky A. Nunez Jr, Thomas Sarlikiotis, and Ethan R. Wiesler
- 115 Rheumatoid Wrist Reconstruction (Arthrodesis and Arthroplasty), 979
Warren C. Hammert and Kevin C. Chung
- VII.II Hand Surgery**
- 116 Management of Finger Fractures, 987
Kristin B. de Haseth and David Ring
- 117 Prevention of Adhesion in Flexor Tendon Surgery, 993
Filippo Spiezia, Vincenzo Denaro, and Nicola Maffulli
- 118 Therapy: Flexor Tendon Rehabilitation, 998
B. Jane Freure and Mike Szekeres
- 119 Carpal Tunnel Syndrome—Conservative Management, 1012
Jean-Sébastien Roy and Jessica Collins
- 120 Carpal Tunnel Syndrome—Surgical Management, 1021
Jessica Collins, Jean-Sébastien Roy, Leslie L. McKnight, and Achilleas Thoma
- 121 Dupuytren’s Disease, 1029
Larisa Kristine Vartija, Leslie L. McKnight, and Achilleas Thoma
- 122 Extensor Tendon Surgery, 1039
Carolyn M. Levis and Monica Alderson
- 123 Rheumatoid Hand Reconstruction, 1046
Oluseyi Aliu and Kevin C. Chung
- 124 Flexor Tendon Surgery, 1057
Shima C. Sokol and Robert M. Szabo
- 125 Replantation, 1072
Stephanie Ma, Leslie L. McKnight, and Achilleas Thoma
-
- Section VIII Orthopedic Oncology**
- 126 Radiation in Soft Tissue Sarcoma: Pre- or Postoperative, 1083
Kurt R. Weiss, Rej Bhumbra, Peter C. Ferguson, Brian O’Sullivan, and Jay S. Wunder
- 127 Soft Tissue Sarcoma: Does the Evidence Support the Administration of Chemotherapy?, 1088
Jennifer L. Halpern, Jill Gilbert, Ginger E. Holt, Vicki L. Keedy, and Herbert S. Schwartz
- 128 Surgery in Bone Sarcoma: Allograft vs. Megaprosthesis, 1097
Kelly C. Homlar, Jennifer L. Halpern, Herbert S. Schwartz, and Ginger E. Holt
- 129 Biopsy of Soft Tissue Masses, 1108
Bruce T. Rougraff, Albert J. Aboulafla, J. Sybil Biermann, and John Healey
- 130 Surgical Margins in Soft Tissue Sarcoma: What Is a Negative Margin?, 1112
Bruce T. Rougraff
- Index, 1121

Evidence-Based Medicine Series

Updates and additional resources for the books in this series are available from:

www.evidencebasedseries.com

Contributors

Albert J. Abouafia MD FACS MBA

Director Sarcoma Services
Sinai Hospital and University of Maryland,
Baltimore, MD, USA

Louise Ada PhD

Associate Professor of Physiotherapy
University of Sydney, Sydney, NSW, Australia

Anthony Adili Peng MD FRCS

Associate Professor
McMaster University
Chief of Surgery, Chief of Orthopaedics
St. Joseph's Healthcare, Hamilton, ON,
Canada

Shahryar Ahmadi MD FRCS

Assistant Professor of Orthopaedics
Director
Shoulder and Elbow Surgery, Department of
Orthopaedics, University of Arkansas for
Medical Sciences, Fayetteville, AR, USA

Monica Alderson BSc(OT) OT Reg.(Ont.)

Clinical Leader and Manager
St. Joseph's Healthcare, Hamilton, ON, Canada

Hatem Al-Harbi MB ChB FRCS

Clinical Fellow in Adult Reconstruction
McMaster University, Hamilton, ON, Canada

Oluseyi Aliu MD

Surgical Resident
University of Michigan, Ann Arbor, MI, USA

Carlo Ammendolia DC PhD

Clinical Researcher
Mount Sinai Hospital
Assistant Professor
University of Toronto
Associate Scientist, Institute for Work &
Health, Toronto, ON, Canada

John Antoniou MD PhD FRCS

Associate Professor
McGill University, Montreal, QC, Canada

George S. Athwal MD FRCS

Associate Professor of Surgery
St. Joseph's Health Care, University of
Western Ontario, London, ON, Canada

T. William Axelrad MD PhD

Director
Orthopaedic Trauma and Limb
Reconstruction
Lake Charles Memorial Hospital, Lake
Charles, LA, USA

David J. Backstein MEd MD FRCS

Associate Professor
University of Toronto, Mount Sinai Hospital,
Toronto, ON, Canada

Simrit Bains HBSc, MA MD(Cand)

McMaster University, Hamilton and
University of Western Ontario, London,
ON, Canada

Rahul Basho MD

UCLA Spine Center Fellow
UCLA Medical Center, Santa Monica, CA,
USA

Andrea S. Bauer MD

Fellow in Hand Surgery
Massachusetts General Hospital, Boston,
MA, USA

Paul E. Beaulé MD FRCS

Associate Professor and Head, Adult
Reconstruction Service
University of Ottawa, Ottawa Hospital,
Ottawa, ON, Canada

Anne-Marie Bedard MD FRCS

Upper Extremity Fellow
Laval University, Centre Hospitalier
Universitaire de Quebec, Quebec, QC,
Canada

Joris E.J. Bekkers MD

PhD Student
University Medical Center Utrecht, Utrecht,
The Netherlands

Eric C. Benson MD

Assistant Professor
University of New Mexico, Albuquerque,
NM, USA

Gregory K. Berry MDCM FRCS

Staff Orthopaedic Surgeon and Associate
Director Surgical Services
McGill University, Montreal, QC, Canada

Mohit Bhandari MD PhD FRCS

Professor and Academic Chair
Canada Research Chair
Division of Orthopaedic Surgery
Department of Surgery
McMaster University, Hamilton, ON, Canada

Rej Bhumbra MBBS PhD (Orth), FRCS (Tr & Orth)

Senior Register
London Sarcoma Service
Royal National Orthopaedic Hospital
London, UK

Ryan T. Bicknell MSc MD FRCS

Assistant Professor of Orthopaedic Surgery
Queen's University, Kingston, ON, Canada

J. Sybil Biermann MD

Associate Professor Orthopaedic Surgery
University of Michigan Hospital and Health
Systems, Ann Arbor, MI, USA

Earl R. Bogoch MSc MD FRCS

Medical Director, Mobility Program, St.
Michael's Hospital
Professor, Department of Surgery, University
of Toronto, Toronto, ON, Canada

**Eric R. Bohm BEng MD MSc
FRCS**

Associate Professor
Director of Arthroplasty Research
University of Manitoba and Concordia Joint
Replacement Group, Winnipeg, MB, Canada

Lars C. Borris MD

Consultant Surgeon
Århus University Hospital, Århus, Denmark

Karen K. Briggs MPH

Director of Clinical Research
Steadman Philippon Research Institute, Vail,
CO, USA

Ole Brink MD PhD MPA

Associate Professor and Consultant Surgeon
Århus University Hospital, Århus, Denmark

J. Scott Broderick MD

Associate Professor
Director of Orthopaedic Trauma
Greenville Hospital System University
Medical Center
GHS-Associate Professor
University of South Carolina School of
Medicine-Greenville, Greenville, SC, USA

Dianne Bryant MSc PhD

Associate Professor
Division of Orthopaedic Surgery, University
of Western Ontario
Associate Professor
School of Physical Therapy and Schulich
School of Medicine & Dentistry
Associate Professor
Clinical Epidemiology & Biostatistics,
McMaster University, Hamilton, ON,
Canada

**Rachelle Buchbinder MB BS
(Hons) MSc PhD FRACP**

Director
Monash Department of Clinical
Epidemiology, Cabrini Institute, Malvern
Department of Epidemiology and
Preventive Medicine
School of Public Health and Preventive
Medicine, Monash University, Melbourne
Joint Coordinating Editor, Cochrane
Musculoskeletal Group, Malvern, VIC,
Australia

Richard E. Buckley MD FRCS

Professor and Head of Orthopaedic Trauma
Foothills Medical Centre, University of
Calgary, Calgary, AB, Canada

Geert A. Buijze MD

PhD Research Fellow
Orthopaedic Research Center Amsterdam,
Academic Medical Center, Amsterdam,
The Netherlands

Jason W. Busse DC PhD

Scientist
Institute for Work & Health, Toronto
Assistant Professor
Department of Clinical Epidemiology
& Biostatistics, McMaster University,
Hamilton, ON, Canada

Stefano Campi MD

Resident
Campus Bio-Medico University, Rome, Italy

Emma Carr PT MHS CHT

Senior Hand Therapist
Pacific Hand Therapy Services, Dee Why,
NSW, Australia

Jeffrey L. Carson MD

Professor and Chief, Division of General
Internal Medicine
University of Medicine and Dentistry of
New Jersey, New Brunswick, NJ, USA

Jaskarndip Chahal MD

Orthopaedic Sport Medicine and
Arthroscopy Fellow
University of Toronto, Toronto, ON, Canada

**Reyhan A. Chaudhary MBA
MD FRCS**

Shoulder and Elbow Clinical Fellow
University of Ottawa, Ottawa, ON, Canada

Olivia Y.Y. Cheng MD FRCS

Clinical Fellow
St. Michael's Hospital, University of
Toronto, Toronto, ON, Canada

Terence Chin MB BS FRACS

Fellow
Queen Elizabeth II Health Sciences Centre,
Halifax, NS, Canada

Kevin C. Chung MS MD

Professor of Surgery, Section of Plastic
Surgery, Department of Surgery
Assistant Dean for Faculty Affairs
University of Michigan Medical School, Ann
Arbor, MI, USA

Peter A. Cole MD

Chief, Regions Hospital
Professor, Department of Orthopaedic
Surgery, University of Minnesota, Saint
Paul, MN, USA

Chad P. Coles MD FRCS

Associate Professor
Dalhousie University, Halifax, NS, Canada

Jessica Collins MD

Plastic Surgery Resident
McMaster University, Hamilton, ON,
Canada

Joseph P. Corkum BEng

Orthopaedic Researcher
Dalhousie University, Halifax, NS, Canada

Charles L. Cox MD

Assistant Professor
Vanderbilt University School of Medicine,
Nashville, TN, USA

Brett D. Crist MD FACS

Assistant Professor and Co-director,
Orthopaedic Trauma Service
University of Missouri, Columbia, MO, USA

Timothy R. Daniels MD FRCS

Associate Professor
St. Michael's Hospital, University of
Toronto, Toronto, ON, Canada

Hormuzdiyar H. Dasenbrock BA

Medical Student
Johns Hopkins University School of
Medicine, Baltimore, MD, USA

Kristin B. de Haseth MD

Research Fellow
Massachusetts General Hospital, Boston,
MA, USA

**Gregory J. Della Rocca MD
PhD FACS**

Foreword

Evidence-based medicine (EBM)—or evidence-based surgery, or evidence-based orthopedics (EBO)—is about solving clinical problems. In particular, EBO provides tools for using the medical and surgical literature to determine the benefits and risks of alternative patient management strategies, and to weigh those benefits and risks in the context of an individual patient's experiences, values and preferences.

The term evidence-based medicine first appeared in the medical literature in 1991; it rapidly became something of a mantra. EBM is sometimes perceived as a blinkered adherence to randomized trials, or a health care managers' tool for controlling and constraining recalcitrant physicians. In fact, EBM and EBO involve informed and effective use of all types of evidence, but particularly evidence from the medical literature, in patient care.

EBM's evolution has included outward expansion—we now realize that optimal health care delivery must include evidence-based nursing, physiotherapy, occupational therapy, and podiatry—and specialization. We need evidence-based obstetrics, gynecology, internal medicine and surgery and, indeed, urology and neurosurgery. And of course, we need evidence-based orthopedics.

Applying EBO to management decisions in individual patients involves use of a hierarchy of study design, with high-quality randomized trials showing definitive results directly applicable to an individual patient at the apex, to relying on physiological rationale or previous experience with a small number of similar patients near the bottom rung. Ideally, systematic reviews and meta-analyses summarize the highest quality available evidence. The hallmark of evidence-based practitioners is that, for particular clinical decisions, they know the quality of the evidence, and therefore the degree of uncertainty.

What is required to practice EBO? Practitioners must know how to frame a clinical quandary to facilitate use of the literature in its resolution. Evidence-based orthopedic surgeons must know how to search the literature efficiently to obtain the best available evidence bearing on their question, to evaluate the strength of the methods of the studies

they find, extract the clinical message, apply it back to the patient, and store it for retrieval when faced with similar patients in the future.

Traditionally, neither medical schools nor postgraduate programs have taught these skills. Although this situation has changed dramatically in the last decade, the biggest influence on how trainees will practice is their clinical role models, few of whom are currently accomplished EBO practitioners. The situation is even more challenging for those looking to acquire the requisite skills after completing their clinical training.

This text primarily addresses the needs of both trainees and of this last group, practicing orthopedic surgeons. Appearing 20 years after the term EBM was coined, the text represents a landmark in a number of ways. It is the first comprehensive EBO text. The book represents a successful effort to comprehensively address the EBO-related learning needs of the orthopedic community, and summarize the key areas of orthopedic practice.

To achieve its goals of facilitating evidence-based orthopedic practice, the text begins with chapters that introduce the tools for evaluating the original orthopedic literature. Those interested in delving deeper into issues of how to evaluate the literature, and apply it to patient care, can consult a definitive text, the *Users' Guides to the Medical Literature*.

The bulk of the current text, however, provides evidence summaries to guide each of the key common problems of orthopedic practice. Thorough and up to date at the time of writing, they provide a definitive guide to evidence-based orthopedic practice today. That evidence will, of course, change—and in some areas change quickly. Clinicians must therefore use *Evidence-Based Orthopedics* not only as a text for the present, but as a guide for updating their knowledge in the future. That future will hopefully hold the advent of an evidence-based secondary journal similar to those that have been developed in other areas including *Evidence-Based Mental Health*, *Evidence-Based Nursing*, and the *ACP Journal Club*, which does the

job for internal medicine. These survey a large number of journals relevant to their area and choose individual studies and systematic reviews that meet both relevance and validity screening criteria. These journals present the results of these studies in structured abstracts that provide clinicians with the key information they need to judge their applicability to their own practices. Fame and fortune await the enterprising group that applies this methodology to produce *Evidence-Based Orthopedics*.

Whatever the future holds for the increasing efficiency of evidence-based practice, the current text provides an introduction to a system of clinical problem-solving that is becoming a prerequisite for modern orthopedic practice.

Preface

Evidence-based orthopedics, in principle, is simple. It aims to empower health care providers and patients with valid and reliable information on which to base important decisions about a therapy, a prognosis, or even a diagnostic test. But there is a fundamental requisite to finding the best evidence—finding the time to do it! Evidence-based practitioners begin with a clinical question, conduct a comprehensive search to identify high-quality publications, critically evaluate and appraise the content of the resultant publications, assimilate the findings across the literature, and use this new knowledge (or evidence) to plan their next action. The challenge in medicine is not the theory of the evidence cycle, but its practicality to busy clinicians, health care providers and students alike. The solution has come in the form of pre-appraised resources in medicine. These resources have been targeted to clinicians who need answers to clinically important questions but simply lack the expertise or time to feel confident acquiring and appraising orthopedic evidence. Resources for the surgical community, specifically our orthopedic surgical community, are deficient and often limited in scope.

A desire to create a practical, evidence-based compendium of orthopedic questions and answers fueled the conception and development of *Evidence-Based Orthopedics*. This book is a critical evidence resource in the field of orthopedics, spanning a wide spectrum of topics including orthopedic medicine, arthroplasty, trauma, spinal disorders, sports, upper extremity and hand, foot and ankle and oncology. Our approach is simple. Using the principle, “evidence cycle begins and ends with the patient,” we begin all our chapters with clinical cases and formulate a series of 5–10 top questions about the scenario. Each chapter follows the evidence cycle for each question towards an evidence-based recommendation for action. Transparency is the key to our recommendations. All chapters contain our key

search strategies, a summary of studies we identified and our appraisal of this evidence. A trusted resource for best evidence, readers can quickly review the recommendations sections in each chapter to gain the evidence-based summary of the topic.

The uniqueness of *Evidence-Based Orthopedics* has as much to do with our global family of expert contributors as our innovative, standardized format. With over 260 contributors, this book was an enormous undertaking of commitment and purpose. I personally thank each and every individual, from Associate Editors to Section Editors to Chapter Contributors for aligning their chapters into the most comprehensive summary of orthopedics in our field. A special thank you to our administrative staff, Ngan Pham, Teresa Chien, Kim Madden, and Ivanna Ramnath, for all of their diligent work. A heartfelt thanks to our publishing partners and friends. To Mary Banks, with whom this idea developed and flourished, this is a testament to the desire for evidence in the orthopedic community. And to Cathryn Gates, Jon Peacock, Simone Dudziak, Ruth Swan, and Brenda Sibbald for all your support in moving our written words to a beautiful resource for the orthopedic community at large.

Finally, this book is as much for me as I hope it is for you. I have learned from so many of our contributors about streamlining evidence into palatable segments, with the overriding goal of making evidence accessible and simply put, fun! While this book in its publication represents the best evidence in our field, evidence is not static—and we will provide online updates to ensure you are always armed with nothing else but the best evidence.

1

Principles of Evidence-Based Orthopedics

Simrit Bains¹, Mohit Bhandari¹, and Paul Tornetta III²

¹McMaster University, Hamilton, ON, Canada

²Boston University Medical Center, Boston, MA, USA

Introduction

The traditional approach to solving clinical problems involves a great emphasis on professional authority, with the approach being dictated almost exclusively by the experience and rationale of the clinician.¹ This approach was dictated largely by the opinions of practitioners, which is problematic because there are a wide variety of opinions and it is reasonable to suggest that not all of these opinions can be correct. Evidence-based orthopedics is a contrast to this paradigm and has arisen from a need of effectively solving clinical problems.¹ Evidence-based orthopedics is part of a broader movement known as evidence-based medicine, a term first used at McMaster University during an informal residency training program. Since that time, evidence-based medicine has entered the vocabulary of every medical field and has steadily gained prominence.² Although orthopedic surgeons have been generally slow to adopt this new approach, it is becoming increasingly accepted as a positive alternative in patient care.³ Evidence-based orthopedics does not accept the traditional paradigm as being adequate to address clinical problems, especially when considering the large quantity of valuable information available to clinicians to help them in their problem-solving process. Less emphasis is placed on the clinician's own professional authority.¹ His or her experiences, beliefs, and observations alone are not enough to make satisfactory decisions with respect to patient care. Evidence-based orthopedics promotes the need to evaluate the evidence available in the medical literature from published research and integrate it into clinical practice. As such, critical appraisal of studies is of paramount importance.³

The importance of evidence-based orthopedics

To fully appreciate the principles of evidence-based orthopedics, it is helpful to have an understanding of the importance and value of this approach. The ultimate goal of a clinician is to provide the best clinical care for his or her patient.⁴ To that end, the clinician's own experiences and training are important assets. However, there is a wealth of information available in the literature that can assist the clinician in numerous ways, from assessing the efficacy of a certain treatment to recommending lifestyle changes that may help prevent illness.⁵ As such, it is important for the clinician to evaluate and incorporate this evidence into his or her own reasoning and judgment when considering the best approach to patient care. A failure to consider such evidence while adopting a clinical approach may result in patients being denied the best possible care.⁴ There is a greater risk of applying an inappropriate treatment or not applying an appropriate treatment.

Top four questions

1. What are the most important principles of evidence-based orthopedics?
2. How do you apply these principles to a clinical approach?
3. What is an example of applying these principles to a clinical approach?
4. What are some common misconceptions about evidence-based orthopedics?

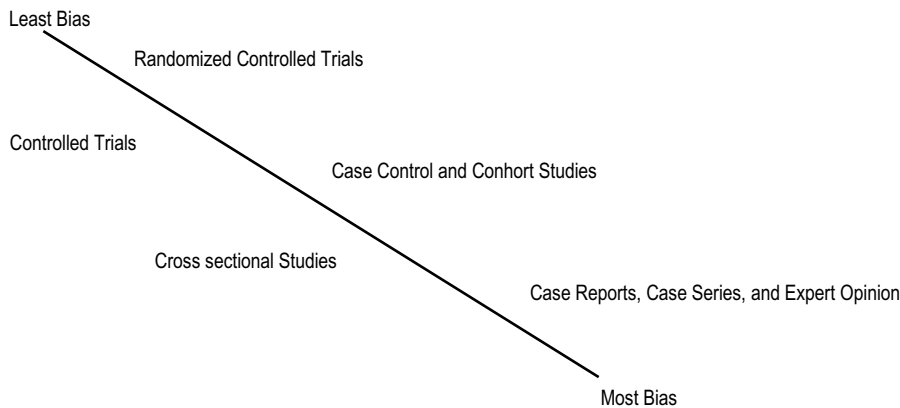

Figure 1.1 A general hierarchy of evidence, with the least bias present at the top of the hierarchy.¹

Question 1: What are the most important principles of evidence-based orthopedics?

Patient values

This principle is fundamental to any clinician. The key goal of good clinical practice is to deliver the highest quality care to patients, and this can only be done if there is a thorough understanding of the patient and his or her problem.¹ This includes knowledge of the patient's values, demographics, and circumstances. Consideration of the patient's desires based on their values or preferences is paramount in evidence-based orthopedics and it must be considered an important factor when a clinician decides which course to pursue in order to treat the patient.³ Evidence-based orthopedics therefore stresses patient involvement and understanding. This is positive for ethical reasons and also for improving patient satisfaction and care.

The need for evidence

Once the clinician has a thorough understanding of the problem, he or she can begin to seek evidence to supplement their judgment. The intuition, experience, and rationale of a trained clinician are all immensely valuable and essential to delivering high-quality care. However, evidence-based orthopedics seeks to supplement the skills and judgment of the clinician with the relevant information that has been gathered about the particular problem.⁶ Such evidence can assist a clinician with comparing the efficacy of different types of surgery, an operative vs. a nonoperative approach, and more. This is especially true now because of the sheer quantity of easily accessible evidence available to clinicians.⁵

The evidence is unequal

The large quantity of available data is of benefit to clinicians looking for the best clinical approach, but it is easy to be inundated with such large amounts of information.⁷

Integrating questionable evidence into a clinical approach may cause more harm than benefit to the patient.³ Therefore, evidence-based orthopedics is specific in its emphasis on evidence published in the literature and careful assessment of this evidence.⁷ Clinicians must therefore be adept at understanding study design and critically appraising the literature.⁵ The various study designs are typically represented in a hierarchy of evidence (Figure 1.1), where they are ranked according to the validity of their results. Expert opinion is at the bottom, being the most susceptible to bias and producing the most questionable evidence.⁸ At the top of the hierarchy are randomized controlled trials and meta-analyses, which are the least vulnerable to bias. Randomization is an important feature of a study because of the random allocation of patients to treatment and control groups, which balances known and unknown prognostic factors between the two groups.⁹ However, the clinician must still determine if the study is methodologically sound. A poorly designed randomized trial, for example, would no longer qualify as producing evidence of high validity.⁵

Integrating evidence and clinical expertise

The clinician must appropriately apply the relevant evaluated evidence to the clinical problem. This must be done with the full context of the situation taken into consideration, which is dependent upon the clinician's expertise and experience.³ He or she must consider the evidence in light of the patient's characteristics: values, preferences, demographics, medical history and more. The clinician also knows the specific details of a patient's condition and medical problem, which may differ slightly but importantly from what is discussed in the literature. It is therefore up to the clinician to use his or her best judgment and skill, in consultation with the patient, to pursue the best possible course of action. In other words, that which is indicated by the evidence as the best course of action will not always dictate the clinical approach.⁷

Question 2: How do you apply these principles to a clinical approach?

The evidence cycle

With the key principles of evidence-based orthopedics having been presented, a general clinical approach that employs these principles can be shown. This approach is called the *evidence cycle*.⁴

1. *Assess*: The first step for the clinician is to thoroughly understand the patient and his or her problem.
2. *Ask*: With the patient's problem in mind, the clinician must next formulate a research question that seeks a solution to the problem and lays the foundation for a search of the literature.
3. *Acquire*: This step involves obtaining evidence from databases.
4. *Appraise*: Next, the clinician must critically appraise the evidence. It must be determined where the study fits on the hierarchy of evidence, whether the methodology is sound, relevance of the results, and so on.
5. *Apply*: The evidence that the clinician has obtained and evaluated must now be applied to the patient, but only with the full context of the situation in mind. The patient's values and the circumstances of the problem must be considered when applying the evidence.

Question 3: What is an example of applying these principles to a clinical approach?

Case scenario

A patient presents in clinic with a vertebral fracture. He is compromised with respect to daily function and also experiences a high degree of pain from this fracture. The goal here is to relieve the patient's pain, allow him to at least partially return to his daily activities and heal the fracture. A typical procedure for a case like this is vertebroplasty, a stabilizing surgery that involves injection of a "cement" substance into the spine. It is widely believed that this surgery helps to heal such fractures, reduces pain, and improves daily functioning of the patient.¹⁰ However, the patient asks you if this surgery is absolutely necessary as it is a procedure that he is uncomfortable with. With knowledge of the patient and their condition established, you can now begin to search the literature with a specific question in mind: What is the evidence for the efficacy of vertebroplasty?

Vertebroplasty is a common procedure and therefore numerous studies have been published about this type of surgery. Many of the studies show dramatic positive effects of this surgery on patients. Healing was found to be accelerated, pain reduced, and daily function improved—all goals of the clinician. However, when it comes time to evaluate the evidence you have obtained, you notice significant flaws in these studies. Not only do they lack ran-

domization, but there is also no comparison to a placebo control group.¹¹ These studies rank quite low on the hierarchy of evidence.⁸

On the other hand, a randomized controlled trial from the Mayo Clinic compared two groups of compression fracture patients.¹⁰ One group had the vertebroplasty performed while the control group had a placebo surgery performed. The result was a lack of significant difference between the vertebroplasty and the placebo surgery with respect to pain relief and returning the patient to daily function.¹⁰ Another randomized trial from Australia reached the same conclusions.¹¹ The studies are methodologically sound, the results are highly relevant, and, as a randomized trial, it ranks high on the hierarchy of evidence. The evidence generated by this study is therefore of high validity.

At this point you can return to your patient and inform him with a high degree of confidence that if he is uncomfortable with the surgery, he may choose to forego it without risking detrimental effects to his recovery.

Question 4: What are some common misconceptions about evidence-based orthopedics?

There are many common misconceptions regarding evidence-based orthopedics.

Evidence-based orthopedics replaces the judgment of the clinician

As previously mentioned, the judgment of the clinician that arises from professional training and experience is highly valuable in clinical practice and is irreplaceable. Evidence-based orthopedics seeks to supplement rather than replace the authority of the clinician by expanding the tools he or she uses to achieve the best possible care for their patients.⁶

Only randomized controlled trials are acceptable evidence

Although randomized controlled trials may be of the highest quality, evidence-based orthopedics does not suggest that they are to be used as the exclusive source of information.⁷ Due to ethical and technical considerations, randomized controlled trials are not always a feasible way to generate the desired information, so the clinician must turn to the information provided from other studies.⁸ Alternatively, a randomized controlled trial available on the issue of interest may have serious design flaws that bring the validity of the evidence into question. To approach clinical problems with the most effectiveness and to improve patient outcomes, it is important to consider all types of evidence and apply it if appropriate.⁵

The clinician is bound to a certain course of action by the evidence

The evidence is to serve as a guide, not as a dictate. It is up to the clinician to use the evidence as he or she believes appropriate given the circumstances of the situation.³

Conclusion

A vast amount of information is available to clinicians to use in an effort to improve patient care. The paradigm of evidence-based orthopedics stresses the importance of using this evidence to achieve the best possible outcome for patients, but only by critically appraising the evidence and integrating it with the clinician's own judgment and knowledge of the specific circumstances of the patient's case. It is a practice growing in popularity but also continues to be hampered by misconceptions, so being familiar with the principles of evidence-based orthopedics is important to any clinician seeking to get the most out of this alternative approach to patient care.

Understanding Hierarchies of Evidence and Grades of Recommendation

Raman Mundi and Brad A. Petrisor

McMaster University, Hamilton, ON, Canada

Case scenario

As an attending orthopedic surgeon at a teaching hospital, you are approached by a medical resident new to the specialty and eager to learn. As a proponent of evidence-based medicine, you had asked this resident the day earlier to “search the literature for recent best evidence on the management of displaced femoral neck fractures in patients less than 60 years of age.”

Excited to present his findings, the young resident tells you, “According to this study I found on a series of 50 patients all treated with internal fixation, the best surgical management appears to be internal fixation.”

Slightly disappointed, but not surprised, you ask, “But is this the ‘best available’ evidence?”

Introduction

In making treatment decisions, the practice of evidence-based medicine mandates the integration of the best available evidence, patient preferences and values, and clinical expertise.¹ Although eliciting patient values and being mindful of the clinical setting (i.e., surgeon experience, funding, etc.) are reasonable requests for the busy clinician, routinely sifting through a myriad of literature, appraising all relevant articles, and synthesizing findings to ascertain the “best available evidence” can at times seem overwhelming.² Nevertheless, clinicians must be aware of the evidence that exists so as to provide their patients with optimal care.

Hierarchies of evidence have been established to assist clinicians in approaching the medical literature by providing a measure of quality.³ In general, such hierarchies rank-

order research studies from the most methodologically sound, to those with less methodological rigor and a higher propensity for biased results. In addition to providing readers with a direct grading system, these hierarchies also allow journals to monitor the quality of the orthopedic literature.³ Furthermore, it is from these hierarchies that conclusions can be drawn to set out grades of recommendation and clinical practice guidelines.⁴

This chapter begins with a discussion of study designs and examples of hierarchies of evidence for therapeutic trials. We conclude with a discussion of the grades of recommendation as put forward by the GRADE Working

Understanding hierarchies of evidence: therapeutic studies

As mentioned, hierarchies of evidence are important in helping readers discriminate higher-quality studies from lower-quality studies, tracking the overall quality of the orthopedic literature, and knowing the quality of evidence that is incorporated into reviews that inform clinical practice guidelines.^{2,3} Because of its importance, orthopedic journals such as the *Journal of Bone and Joint Surgery* and *Clinical Orthopaedics and Related Research* have started reporting the level of evidence of individual studies.^{3,5}

In the orthopedic literature, several classes of studies exist including studies of therapy, prognosis, diagnosis, and economic analysis. These different classes of studies all have their individual hierarchies of evidence.⁵ Given that most of the orthopedic literature consists of therapeutic studies, this section focuses on levels of evidence for this specific class.^{6,7}

Therapeutic studies are those that investigate the effect of a treatment or intervention.⁵ Several organizations and groups have developed systems of hierarchy for therapeutic studies, some of which are presented later in this section. Despite subtle differences, the general principles behind these hierarchies are the same. They all place those studies which best minimize bias and are more likely to yield an accurate estimate of the truth at the top or as highest quality. In order to understand these hierarchies then, it is important to discuss which factors favor and diminish bias. Specifically, this merits a discussion of both study design and study quality.

Top six questions

1. What are randomized controlled trials?
2. What are systematic reviews and meta-analyses?
3. What are observational studies?
4. What are case series and case reports?
5. What are systems of hierarchies?
6. What are grades of recommendation?

Question 1: What are randomized controlled trials?

Studies of an intervention can be either observational in nature or have a randomized experimental design.^{2,6} The randomized controlled trial (RCT), in which patients are randomly allocated to the different treatment arms of the study, is considered the highest level of evidence. By the power of randomization, these trials attempt to control for both known and unknown prognostic factors by distributing these prognostic variables among all treatment arms. In this way, the RCT strives to eliminate variation between treatment arms and in turn, a biased outcome which could either over- or under-represent the true treatment effect.⁸

However, the process of randomization in itself does not make RCTs immune to other methodological flaws that can compromise study quality and introduce bias into the trial. For instance, allocation concealment entails that the individuals responsible for recruiting and allocating patients into the trial are unaware of which group the next patient will be randomized to. Methods that fail to uphold allocation concealment include randomization using chart numbers, unsealed envelopes, and odd vs. even days.⁶ It has been shown that failure to uphold allocation concealment in an RCT can result in an overestimation of the treatment effect.⁹ Other methodological parameters that safeguard RCTs from bias include blinding, ensuring equivalent surgical experience and skill for all treatment groups, minimizing loss to follow-up, and using the intention-to-treat principle (assessing patients based on the

groups they were originally assigned to, regardless of which treatment was actually received).

Question 2: What are systematic reviews and meta-analyses?

Systematic reviews and meta-analyses of RCTs are also considered high-level evidence. Systematic reviews rank highly because they employ a systematic approach in collecting, appraising, and synthesizing data. Meta-analyses are an extension of systematic reviews, in that they pool the data across all studies to effectively increase the sample size and produce a single estimate of the treatment effect.¹⁰

As for RCTs, there are quality issues that, if unmet, can shift systematic reviews and meta-analyses lower in the hierarchy. These studies are only as good as their component parts. That is, their quality is directly contingent upon the quality of studies included in the review. First and foremost, systematic reviews and meta-analyses that exclusively include RCTs are of higher quality and provide more compelling evidence than those that include nonrandomized studies.^{11,12} Secondly, even among those meta-analyses that include only RCTs, the strength of the single estimate of the treatment effect is dependent on the homogeneity of the RCTs. If the included trials have precise and consistent results, the results of the meta-analyses are strong, whereas heterogeneous trials with inconsistent results and large confidence intervals make the statistical pooling less trustworthy.⁶

Question 3: What are observational studies?

Not all questions surrounding interventions can be answered with a randomized trial. Although lower in the hierarchy of evidence, observational studies remain important in answering questions surrounding interventions that RCTs cannot.

In *cohort studies*, patients who are exposed to a risk factor or treatment are compared to unexposed patients. The patients are followed to determine the rate of occurrence of the outcome of interest.¹³ This study design works well for issues of harm, in which randomizing patients to a harmful exposure or intervention would be unethical. For instance, an RCT investigating the effect of smoking on nonunion rates in patients with tibial shaft fractures would be inappropriate, as forcing a patient to smoke is unethical.⁶ Among the observational studies, the cohort study ranks highest on the levels of evidence. The primary reason is that these studies are often prospective, and thus ensure more rigorous data collection and more thorough patient follow-up.⁶ Furthermore, investigators can attempt to match patients in the different treatment arms for known prognostic variables, although unknown prognostic variables may still bias the trial outcome.

Below cohort studies in the hierarchy of evidence is the *case-control study* design. In effect, this study design is the reverse of the cohort design. A group of patients that have already developed the outcome of interest are compared to a similar group of patients who have not developed the outcome. These groups are then assessed retrospectively for differences in exposures to risk factors that may be associated with developing the outcome.¹³ Case-control studies are valuable when dealing with rare disease entities, or for those outcomes that develop over a long time (for instance, lung cancer due to smoking), and when multiple risk factors need to be assessed.¹³ In addition to the inability to control groups for unknown prognostic factors, the primary limitation of this study design is its retrospective nature which makes it more prone to bias.

Question 4: What are case series and case reports?

Lower in the hierarchy of evidence are case series and case reports, the former being a description of a series of patients and the latter being a description of individual patients. Because these studies have no control group, conclusions should not be made regarding cause-and-effect relationships.¹³ Often these studies are prone to bias due to their retrospective nature and have limited generalizability as they usually depict the experience of a single center or surgeon. These studies are valuable, however, for describing rare diseases or complications of interventions, and for generating hypotheses that can be investigated by higher-quality research methods.⁶ The young resident described in the scenario at the beginning of this chapter was indeed referring to a case series.

Question 5: What are systems of hierarchies?

As mentioned, several organizations and groups have developed systems for rank-ordering evidence into levels.² The hierarchy proposed by Guyatt and Rennie¹ is: (I) N of 1 randomized controlled trial; (II) systematic review of randomized trials; (III) single randomized trial, (IV) systematic review of observational studies addressing patient-important outcomes; (V) single observational study addressing patient-important outcomes, (VI) physiologic studies; and (VII) unsystematic clinical observation. There are two aspects of this system that merit discussion. First, at the top of the hierarchy is the “N of 1” randomized trial in which the patient alternates between a period of target treatment and control treatment. The order is randomized, both the patient and clinician are blind as to whether target treatment or control is being received, and the patient continues alternating until it is concluded that an effect exists or does not exist. This study ranks highly because the patient of interest is directly involved in the trial and the

results are definitive as no generalizations are being made from a separate population of patients. Secondly, the authors recognize that both RCTs and observational studies can upgrade or downgrade levels on this hierarchy, depending in part on the methodological quality of the trial. Large observational studies with consistent results can provide more compelling evidence than RCTs; however, it must be kept in mind that RCTs have also been shown to contradict the results of large observational studies with consistent results.¹

In the system used by the Centre for Evidence-Based Medicine at Oxford University,¹² not only are there five levels of evidence, but sublevels within them. Furthermore, the study design in itself does not determine level of evidence as study quality is also taken into consideration by this system. For instance, high-quality RCTs with precise estimates of treatment effect are considered level I evidence, whereas lower-quality RCTs with less methodological rigor are considered level II evidence.¹² The Oxford levels of evidence have also been developed for other classes of study, such as studies regarding prognosis, diagnosis, and economic analyses. These levels of evidence are easily accessible at the Oxford Centre for Evidence-Based Medicine website, www.cebm.net.¹² In a review of the orthopedic literature in 2003, it was demonstrated that only 11.3% of studies (therapy, prognostic, diagnostic, and economic) qualify as level I according to the Oxford levels of evidence.⁷

These evidence scales do have certain drawbacks: they are mostly developed by expert opinion and lack validation; studies are ranked inconsistently across the different systems making universal communication difficult; and agreement in which level to assign a study in a given system is sometimes low (i.e., low inter-rater reliability).^{2,4}

Question 6: What are grades of recommendation?

In order to establish a grade of recommendation for an intervention or treatment, a full systematic review of all similar studies in terms of the intervention, outcomes, and patient population, must be carried out.⁴ Furthermore, discussions with content experts also prove helpful in establishing grades of recommendation.⁶

The GRADE Working Group has proposed a grading system in which they outline four factors that need be considered when giving an intervention one of four possible grades of recommendation.

- *The overall quality of the evidence.* Each study included in the systematic review needs to be assessed for its quality. It is suggested that the “overall” quality of evidence should be based on the lowest quality of evidence for outcomes that are critical in making a decision. This includes both outcomes regarding benefits and harms associated with the

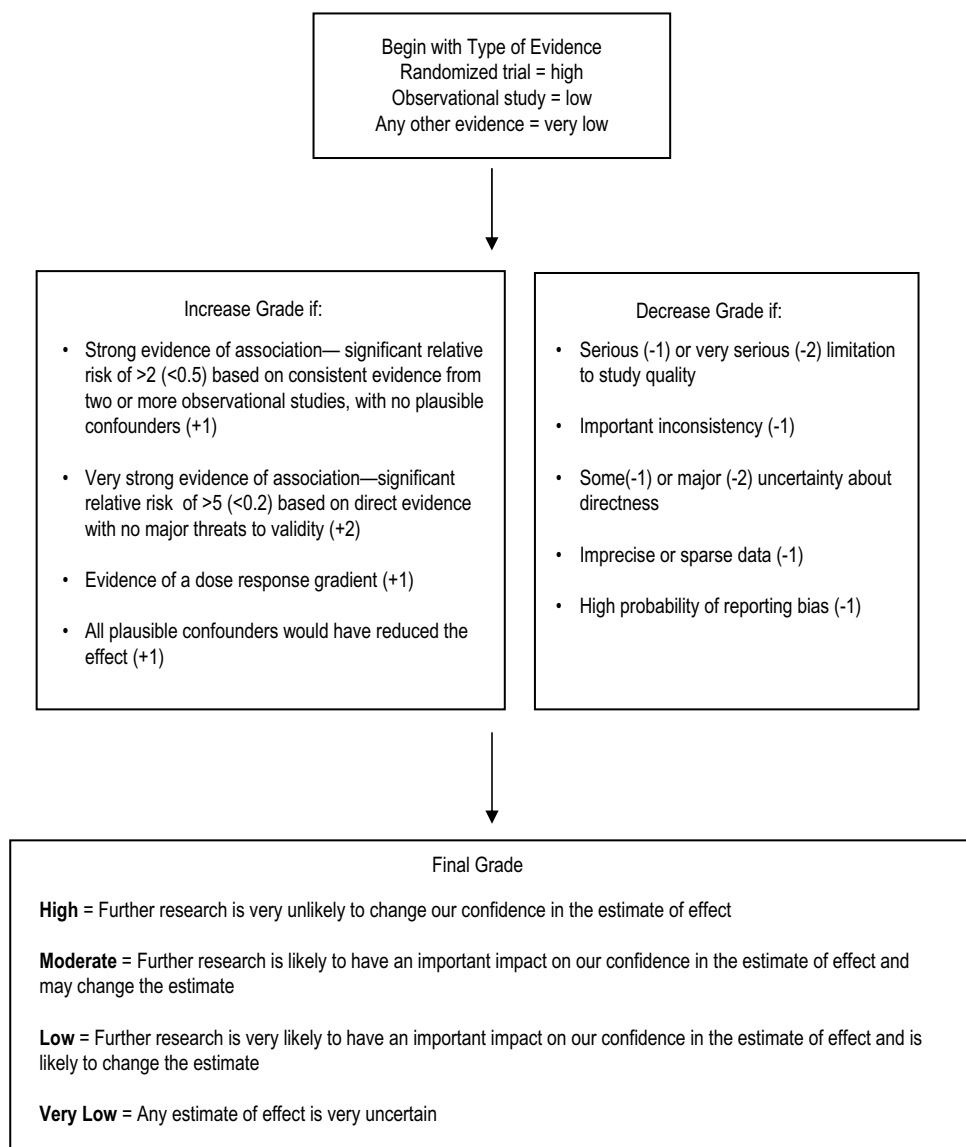

Figure 2.1 Assigning grades of evidence by GRADE Working Group. (Reproduced from Grading quality of evidence and strength of recommendations, Atkins D, Best D, Briss PA, et al, 328, 1490, 2004 with permission from BMJ Publishing Group Ltd.)

intervention.² In grading studies, this system combines four elements of the trial: study design, study quality, consistency, and directness. *Consistency* refers to similarity in results across other studies addressing the same issue. If an inconsistency is present—for example, differences in direction of treatment effect—than the grade of recommendation is considered lower quality as we are less confident about the results. *Directness* refers to how well the study can be generalized to the patients of interest. It takes into account how similar the study patients, interventions, and outcome measures are to those of interest to the clinician, patient, and clinical setting. In placing a study within this hierarchy, this system first assigns a grade of either “high,” “low,” or “very low”, based solely on study design. From

there, study quality, consistency, and directness influence the final grade of the study which will be either “high,” “moderate,” “low,” or “very low” (Figure 2.1).²

- *The benefits vs. harms (i.e. trade-offs)*. This necessitates placing a value judgment on each outcome. It is important to consider the setting and the values of the patient population of interest.²
- *Translating the evidence into a specific setting*. Practical issues that may influence the size of the treatment effect also need to be considered. For instance, if the success of an intervention depends on a surgeon’s level of training, then the availability of the necessary expertise must be considered.²
- *Baseline risk for population of interest*.

After considering these four factors, there are four categories of recommendation to place an intervention in: “do it,” “don’t do it,” “probably do it,” and “probably don’t do it.” The categories “do it” and “don’t do it” indicate a judgment that most well-informed people would make, whereas the categories “probably do it” and “probably don’t do it” indicate a judgment that a majority of well-informed people would make, but a substantial minority would not.²

A recommendation for an intervention does not always apply universally across all patients. It remains important to consider the individual patient, inform them of all options, and invite them into the decision-making process. Grades of recommendation facilitate and aid this decision-making process by taking into account the best available evidence and the general values of the population of interest. It is important to remember that it facilitates, but does not replace, the decision-making process.²

Conclusion

Various hierarchies of evidence have been developed for the different classes of studies (therapeutic, prognostic, diagnostic, economic) and, within the therapeutic class alone, several systems have emerged. The majority of these hierarchies take into account study design and study quality to place studies into levels. Those with a more sound study design (RCTs, meta-analyses) and methodological rigor (blinding, allocation concealment) are less vulnerable to biased results and rank highly in the hierarchy. Those studies that are more subject to biased results (observational studies) are less likely to provide an accurate estimation of the true treatment effect and thus rank lower in the hierarchy.

These hierarchies not only aid readers in gauging the validity of studies, but are crucial for establishing grades of recommendation. The overall quality of evidence surrounding an intervention, along with the benefits vs. harms, practical issues for the clinical setting, and baseline population risk, all govern how strongly an intervention will be recommended. Thus, the hierarchies of evidence and grades of recommendation together provide clinicians with a method for finding the “best available” evidence, and in turn, facilitate evidence-based decision making.

Critical Appraisal Tools for Surgeons

Farrah Hussain¹, Sheila Sprague¹, and Harry E. Rubash²

¹McMaster University, Hamilton, ON, Canada

²Massachusetts General Hospital, Boston, MA, USA

Introduction

Surgical innovation is the core of orthopedic surgical practice. However, many surgical procedures are innovations that are brought into practice with a degree of uncertainty. Therefore, critical appraisal skills are necessary to make informed decisions about patient care based on the evidence available.

Evidence-based orthopedic surgery makes use of a clear definition of relevant clinical questions through a literature search pertaining to the questions, a critical appraisal of available evidence and its applicability to the clinical situation, and a balanced application of the evidence to the clinical problem. Critical appraisal involves a judgment on how much confidence can be placed in the evidence and recommendations provided by a study.¹ However, what is the “best available” evidence? Randomized controlled trials (RCTs) are considered to be the highest level of evidence, as randomization is the optimal method to balance known and unknown prognostic factors in treatment and control groups in therapeutic studies. However, RCTs cannot answer all clinical questions.² Randomized controlled trials compose 14% of published articles in the medical literature.³ In some cases, it is unethical to randomize patients to certain prognostic or risk factors. Moreover, due to sample size and follow-up requirements, RCTs may not always be feasible. Therefore, in orthopedic surgery, lower forms of evidence often provide valuable insights that RCTs cannot. The most important idea to keep in mind is that evidence-based orthopedic surgery makes effective use of all types of available evidence in clinical decision-making, whether it be an RCT or a case review.² The tools for critical appraisal discussed in this chapter will help

orthopedic surgeons successfully bring evidence into practice.

Top three questions

1. What are the criteria for determining level of evidence?
2. What are the steps involved in critical appraisal?
3. What are some other examples of tools for critical appraisal?

Question 1: What are the criteria for determining level of evidence?

Guidelines, or recommendations, have been developed systematically by panels of people with access to the available evidence and an understanding of the clinical problem and research methods. However, different organizations use a variety of systems to grade the quality of evidence and the strength of recommendations, thus creating confusion and hindering effective communication.¹ Recently, the GRADE (Grading of Recommendations Assessment, Development and Evaluation) working group, interested in the shortcomings of varied grading systems in health care, devised a new rating system to address such inadequacies (Table 3.1). The advantages of this system over others are that it makes clear what each of the grades indicates, as well as what to consider when assigning these grades. Furthermore, it ensures the proper consideration of the key components of quality of evidence (e.g., study design, quality, consistency, and directness of evidence), relative importance of outcomes, trade-offs between important benefits and harms, as well as other factors affecting the quality of evidence (e.g., imprecise or sparse data, reporting bias, strength of association, and confounding variables).^{1,4}

Table 3.1 GRADE criteria for assigning grade of evidence, which consists of a quality assessment and a summary of findings¹ (Reproduced from Grading quality of evidence and strength of recommendations, Atkins D, Best D, Briss PA et al, 328,1490–1497, 2004 with permission from BMJ Publishing Group Ltd.)

Type of evidence

Randomized trial = high quality

Quasi-randomized trial = moderate quality

Observational study = low quality

Any other evidence = very low quality

Decrease grade(s) if:

Serious (–1) or very serious (–2) limitation to study quality

Important inconsistency (–1)

Some (–1) or major (–2) uncertainty about directness

Imprecise or sparse data (–1)

High probability of reporting bias (–1)

Increase grade(s) if:

Strong evidence of association—significant relative risk of >2 (<0.5) based on consistent evidence from two or more observational studies, with no plausible confounders (+1)

Very strong evidence of association—significant relative risk of >5 (<0.2) based on direct evidence with no major threats to validity (+2)

Evidence of a dose response gradient (+1)

All plausible confounders would have reduced the effect (+1)

Question 2: What are the steps involved in critical appraisal?

Surgical interventions often have inherent benefits and associated risks. A three-step approach can be helpful in appraising surgical interventions:

1. *Are the results of the study valid?* The validity of a study concerns the credibility of the results. In this step, one should examine the degree to which the reported estimate of the treatment effect represents the underlying true effect, or whether the results represent an unbiased estimate of the treatment effect. *Systematic error* or *bias* is the first factor that can impact confidence in research results. Bias is directly linked to the design and execution of a study, and thus, the first step in critically appraising a study is to question its validity as well as the extent to which bias is present.⁵ Bias is particularly undesirable when the conclusions influence medical decisions.⁶ If the results are indeed valid, it may be feasible to examine the results further.⁵

2. *What are the results?* In this step, one should examine the size and precision of the treatment's effect, which may be superior in larger studies, such as multicenter trials.⁵

3. *How can these results be applied to practice?* This final step involves two parts: *generalizability* of the results and

the *net impact* of the treatment. Generalizability is concerned with how similar or dissimilar the patient in question is in comparison to those who participated in the trial. The net impact of the treatment is dependent on the benefits and risks of the treatment, as well as the consequences of withholding treatment.⁵

Although this chapter focuses on the evaluation of studies investigating therapy, it is also important to consider other study designs because of their inherent differences in bias. The hierarchy of evidence ranks literature on the basis of how accurately it provides an estimate of the truth, or how rigorous the study design is. There are three steps in classifying a clinical study.

- First, one must determine whether a study is investigating the results of a treatment, the outcome of a disease, or a diagnostic test, or developing a decision analysis.
- Then, one must place the study in the hierarchy between level I and level V evidence (see Chapter 2).
- Finally, the study needs to be subclassified within the level of evidence.⁷

Using this three-step approach, this chapter discusses how to critically appraise studies investigating therapy, diagnostic tests, and prognosis. For an in-depth look at selecting the appropriate diagnostic tests and therapies, and determining the most likely prognoses for patients, see Chapter 4.

Openmirrors.com: Studies investigating therapy

- Step 1: Are the results of the study valid?

When assessing the validity of a study investigating a therapeutic approach, one must ask if the patients were randomized. The goal of surgical treatment studies is to determine the impact of an intervention on the trial's target outcomes or events such as reoperations, infections, and death. Prognostic factors determine the frequency with which a trial's target outcome occurs. Bias can occur when prognostic factors are unbalanced between the treatment and control groups. The randomization of participants eliminates this bias by enabling an equal distribution of prognostic factors between the two groups.⁷ Randomization should also be concealed, as unconcealed randomization may cause surgeons to selectively enroll sicker or less sick patients to either treatment or control groups, leading to a biased result.⁷

One must also ask if patients were analyzed in the groups to which they were randomized. Analyzing patients to the group to which they were randomized is known as the "intention-to-treat" principle.⁷ For example, a patient may be assigned to receive a procedure, A, but due to a technical difficulty (e.g., bleeding), the surgeon may decide to carry out the alternative procedure, B. If this occurred with every patient with a poor prognosis, only those with a good prognosis would receive procedure A, resulting in an overestimation of its treatment effect.⁸

Patients in the treatment and control groups should also be similar with respect to known prognostic factors. If the treatment groups are not similar at baseline, statistical techniques can allow for the adjustment of the study result for baseline differences. A small sample size can result in an imbalance in prognostic factors and can also be statistically neutralized.⁷

The sources of blinding in the study must also be determined. By blinding patients, investigators are able to avoid the effects of patient awareness of allocation (placebo effects) and therefore add credibility to the results of their study. However, in some surgical trials, it may be unethical or impossible to blind patients, especially if the trial is comparing surgical with medical treatments. Those who are assessing outcome, such as those interpreting the data, the adjudication committee, and study personnel, should also be blinded to ensure that the outcome is assessed in a uniform manner in both experimental and control groups. Blinding becomes especially important when a judgment is necessary to determine whether a patient has suffered a target outcome, such as a nonunion.⁷

Finally, one must ask whether follow-up of patients was complete. Patients whose status is unknown or lost to follow-up can result from the patient not returning to the clinic for assessment, due to either suffering adverse outcomes or doing well.^{7,9} It is a threat to the validity of a study, because patients who are lost commonly have different prognoses from those who are not lost. A study's validity is not compromised if the inferences following a study's conclusions are not altered by assuming the worst-case scenario (i.e., all patients lost to follow-up had the worst outcome). The rule of thumb to use when assessing loss to follow-up is that a study that loses 20% of its patients to follow-up has poor follow-up procedures.⁷

- Step 2: What are the results?

Outcomes in RCTs can be continuous (e.g., blood pressure, points in a functional outcome measure) or dichotomous (e.g., reoperation, death, infection). Dichotomous measures are more frequently used in RCTs to monitor how often patients experience an adverse event or outcome.^{7,8} Results can be presented as the *absolute risk reduction*, *absolute risk difference*, or more simply, the difference between the proportion who suffered an adverse event in the control group and the proportion who suffered an adverse event in the treatment group. The impact of the treatment can also be presented as a *relative risk*, or the risk of an adverse event in patients in the treatment group relative to those in the control group. Dichotomous treatment effects are most commonly reported as the complement of the relative risk, or the *relative risk reduction*. The relative risk reduction is expressed as a percentage. A greater relative risk reduction indicates a more effective therapy. Therefore, a relative risk reduction of 70% means that the treatment under study reduced the risk of patients experi-

encing an adverse event by 70% relative to the risk among control patients. Investigators may also calculate the *hazard ratio* or the relative risk over a period of time in a *survival analysis*.^{7,8}

The precision of the estimate of treatment effect should also be discerned. Greater precision allows for greater confidence to be placed in the results. The precision can be determined in a rudimentary manner through the *p value*, which demonstrates how often an apparent estimate of a treatment effect will occur in a long run of identical trials if, in reality, no true effect exists. The *p value* does *not* assist clinicians in determining the range within which the treatment effect estimate resides. This job is reserved for the confidence interval.⁸

The *confidence interval* is a set of values in which one can be confident that the true value of the point of estimate resides. This is an arbitrarily chosen breadth; 95% is commonly used. A confidence interval of 95% means that if the study is repeated 100 times, the point of estimate will be found within the range of the confidence interval 95 times. The greater the sample size, generally, the narrower the confidence interval, and the greater the precision and confidence.⁸

- Step 3: How can these results be applied to practice?

The patients one sees in surgical practice frequently differ from those enrolled in the trial. If a patient meets all the inclusion criteria and does not violate any of the exclusion criteria, one can apply the results directly to that patient with substantial confidence.^{6,7} Treatments are not uniformly effective, however, and RCTs estimate an average treatment effect.⁷ This proves to be a limitation and applying these effects could mean that some patients benefit while others may not. An additional problem arises when a patient's characteristics fit within a subgroup of a study in which the investigators performed a subgroup analysis showing a benefit for that particular subgroup. It is common for investigators to test multiple subgroups, seeking any significant effect after the data becomes available.⁸ Since they are not planned ahead of time, subgroup analyses should be assessed rigorously and met with a degree of uncertainty.⁷

When asking how the results of a study could be applied to practice, one also needs to determine whether all clinically important outcomes were considered. Treatments should result in improved outcomes that are important to patients, such as preventing reoperations, improving function, or survival.⁷ Moreover, because conventional RCTs estimate *average* treatment effects, one must remember that few real patients will fit perfectly within a subgroup. Keep in mind that patients have their own values and beliefs, and often have other problems with their health. Therefore, all treatments are not uniformly effective; some patients may be exposed to the risks of treatment without achieving any benefit.⁷

Studies investigating diagnostic tests Most tests can separate healthy persons from those who have a severe condition. However, this is not indicative of the clinical utility of a test. The true value of diagnostic test studies lies in its resemblance to clinical practice and the ability of the tests to distinguish between conditions that might otherwise be confused. Therefore, when assessing the validity of a diagnostic test study, readers must ask if clinicians face diagnostic uncertainty. Readers must also ask whether an appropriate and independent reference standard (e.g., biopsy, surgery, autopsy, etc.) has been applied in a blind comparison of the accuracy of the diagnostic test in both treatment and control groups. The diagnostic test under study must not be part of the gold standard. Finally, when assessing the validity of such studies, one must ask whether the results of the diagnostic test influence the decision to perform the reference standard. This is also called *verification bias* or *workup bias*.¹⁰

When assessing the results of diagnostic test studies, readers need to ask what *likelihood ratios* were associated with the range of possible test results. A likelihood ratio indicates the degree to which a specific diagnostic test result will increase or decrease the pretest probability of the target disorder. In other words, it is a ratio of two likelihoods: (1) how likely is it that patients with the condition will have positive test results? and (2) how often is the same test result is found among people in which a condition was suspected but has been ruled out? In general, if the likelihood ratio is greater than 1, there is an increased probability that the target disorder is present, while likelihood ratios of less than 1 decrease this probability. Sensitivity and specificity can also be used to interpret the results of diagnostic test studies; however, the likelihood ratio approach is recommended because of its simplicity and efficiency.¹⁰

When seeking to apply the results of a diagnostic test study to patient care, one should ask if the reproducibility of the test result and its interpretation will be satisfactory in their clinical setting, whether the results are applicable to the patient in question, whether the results will change their management strategy, and finally, whether patients will be better off as a result of the test.¹⁰

Studies investigating prognosis Having an idea of a patient's prognosis is valuable in making the right diagnostic and treatment decisions. If a patient is at a low risk for adverse outcomes, high-risk, expensive, or toxic procedures are probably not the best idea. Similarly, a patient may be destined to experience adverse outcomes no matter the treatment offered. Aggressive therapy in such patients will prolong suffering and waste resources. Prognosis is also useful in the resolution of issues that are broader than the care of the patient in question, such as using outcomes to compare the quality of care across clinicians and institu-

tions. To assess the validity of such studies, readers should ask whether the sample of patients was representative, whether patients were sufficiently homogenous with respect to prognostic risk, whether follow-up was sufficiently complete, and whether objective and unbiased outcome criteria were used. To assess the results of studies investigating prognosis, one should ask how likely the outcomes are over time, and how precise are the estimates of likelihood. When applying the results to patient care, one should examine whether study participants are similar to those in their practice. One should also take into account the sufficiency of the length of follow-up and whether the results can be applied to manage patients in their practice.¹¹

Question 3: What are some other examples of tools for critical appraisal?

Although this chapter focuses on one tool for critical appraisal, others do exist and are commonly used. There has been much progress internationally in the development of guidelines for critical appraisal, and these guidelines may be the most suitable for the local circumstances in which they were developed. The National Guideline Clearinghouse is a publicly accessible resource for evidence-based clinical practice guidelines (<http://www.guideline.gov>) from institutions, professional societies, and government agencies worldwide.¹²

Many international groups have created guidelines to ensure that different types of studies contain all of the necessary information to ensure readers can adequately evaluate the study. Each of these guidelines has their own benefits and limitations.¹³ One of these guidelines includes the CONSORT (Consolidated Standards of Reporting Trials) statement for RCTs.¹⁴ This statement or set of guidelines provides a 25-item checklist pertaining to the content of the title, abstract, introduction, methods, results, discussion, trial registration, protocol, and funding. It also provides a flow diagram which depicts information from the enrolment, intervention allocation, follow-up, and analysis stages of an RCT. The statement is flexible and continuously evolving, as the checklist and flow diagram can be modified to incorporate new evidence required to properly evaluate a trial. In this way, the guideline is developed using an evidence-based approach. Limitations of the CONSORT statement include its specificity to two groups, parallel randomized controlled trials and meta-analyses, and the absence of recommendations for designing and conducting RCTs.^{14,15}

Not only are there guidelines to assess the quality of evidence provided by clinical research, there are also guidelines which have been developed to appraise the quality of other clinical guidelines. The AGREE (Appraisal of Guidelines, REsearch, and Evaluation) statement is

designed to evaluate the quality of clinical practice guideline development and how well the process of development is reported. The instrument is the first of its kind to be developed and tested internationally and consists of six quality domains: scope and purpose, stakeholder involvement, rigor of development, clarity and presentation, applicability, and editorial independence. The statement can be used by a wide range of professionals in European and non-European countries and provides standards for the planning, execution, and monitoring of guideline programs.¹⁶ Because it uses a numerical scoring scale, it also facilitates the comparison of different guidelines internationally.^{16,17} However, the instrument is not without its limitations. First, it is difficult to classify a clinical practice guideline as “good” or “bad” because it is impossible to set thresholds for the domain scores. In addition, the instrument does not address the clinical content or the quality of evidence supporting the recommendations of clinical practice guidelines. This is also a common problem with other existing tools for critical appraisal.¹⁷

Conclusion

There has been a shift in practice from an approach involving anecdotes, previous experiences, and expert opinions, to one that attempts to incorporate the best and most current available evidence into clinical practice.^{7,9} Orthopedic surgeons today are faced with the challenge of providing medical care that stems from valid and current evidence. As the credibility of clinical results varies from study to study, it is imperative that surgeons adopt an approach that selects only for valid results to be applied to practice.⁶ Critical appraisal of the orthopedic literature achieves this goal in an objective and structured manner.^{6,18}

Introduction

In order to make the best patient care decisions, advocates of evidence-based medicine (EBM) promote a methodological approach that integrates the best available evidence from the medical community, the surgeon's experience, and the patient's personal goals and values (Figure 4.1).^{1,2} Many branches of medicine have embraced the principles of EBM, and orthopedic surgeons are among its strongest advocates.^{3,4} Orthopedic surgeons help patients through three interrelated processes: first, by selecting the best diagnostic test for making a sound diagnosis (i.e., determining the disorder or disease from its signs and symptoms); second by administering appropriate therapy (i.e., a treatment that is intended to restore health); and third, by providing the most likely prognosis (i.e., indicating the likely outcomes for patients within the near future).

Hierarchies of evidence

Orthopedic surgeons wishing to integrate the best research evidence into their practice should understand what constitutes higher levels of evidence, as well as what constitutes higher quality evidence. A fundamental principle of EBM is the hierarchy of research study design with the randomized controlled trial (RCT) and systematic reviews at the apex.^{5,6} While many surgeons are aware that RCTs provide the best evidence for therapeutic studies, many do

not realize RCTs are not the best sources of evidence for either diagnostic or prognostic studies.

In this chapter we provide three tables listing the hierarchy of study design as it applies to studies relating to diagnosis, therapy, and prognosis.⁵ For each of these types of studies, systematic reviews are indicated at the pinnacle as level I evidence, but this space is not shared by RCTs in each case. For diagnostic studies the best evidence is retrieved from testing of previously developed diagnostic criteria in series of consecutive patients (Table 4.1). For therapeutic studies the best evidence is actually found in ideal RCTs with narrow confidence intervals (Table 4.2). For prognostic studies the best evidence is derived from high-quality prospective studies that enrolled all patients at the same point in their disease and maintained 80% or greater follow-up of enrolled patients (Table 4.3).

Critical appraisal for validity, results, and applicability

In this chapter we discuss the relevance of each of these processes within the context of EBM principles for critical appraisal of research studies. Five steps are involved in progressing from a clinical patient presentation to developing a plan towards a clinical resolution (Figure 4.2).² When presented with a problem we need to develop a structured question, and investigate this question by conducting a literature search for the available evidence. Knowing the hierarchies of evidence, as they apply to the three different

types of studies, helps us select the best available study articles. We can best progress to critical appraisal of these articles when guided by three overarching questions about validity (i.e., Are the results valid?), results (i.e., What are the study results?), and applicability (i.e., How are the results applicable to patient care?).² These three overarching questions lead us to eight to nine key subquestions for consideration for understanding diagnosis, therapy, and prognosis.

In this chapter we provide three tables to function as users' guides for navigating these three questions when assessing studies of diagnosis (Table 4.4), therapy (Table 4.5), and prognosis (Table 4.6). These tables are based on two EBM resources. The first is the seminal work, *Users' Guide to the Medical Literature*, first presented by the EBM Working Group in a series of articles and later compiled into a book.² The second is a related series of articles published in the *Journal of Bone and Joint Surgery*, developed by a group of orthopedic surgeons who have adopted the

III	Applicability: How can I apply the results to patient care? Q6: Were the study patients similar to my patient? Q7: Were all patient-important outcomes considered? Q8: Are the likely treatment benefits worth the potential harm and costs?

principles of EBM.⁶⁻⁹ The following overview is comprehensive but brief. For more detailed discussions, often accompanied by informative clinical case studies and examples of study articles, we recommend the *Journal of Bone and Joint Surgery* articles. Additionally, for a useful review of statistics in orthopedic papers we recommend the review article by Petrie.¹⁰

Diagnosis

For diagnostic studies the best evidence is retrieved from testing of previously developed diagnostic criteria in series of consecutive patients (Table 4.1).⁷ Surgeons make a diagnosis by assessing the signs and symptoms of disease or disorder presented by their patients. Diagnostic decisions are made by integrating the surgeon's experienced clinical judgment and using previously validated diagnostic tests. Diagnostic tests can be very useful, but only if the correct tests are used.^{11,12} Accurate tests can help the surgeon rule in, or rule out, a patient condition. This is the first step in helping us to best direct therapy and determine the most likely prognosis.

Investigators conducting a diagnostic test study hope to establish the test's power to differentiate between those patients who have the target condition and those who do not. In these studies the main issues to consider in determining the validity of a diagnostic test study are how the authors assembled their patients and whether or not they used an appropriate reference standard for each of these patients.⁷

Validity: are the study results valid?

Question 1: Did clinicians face diagnostic uncertainty?

Using tests to distinguish between severely affected and healthy patients is easy because there is minimal overlap between the two groups of patients. It is when test results for patients with the target condition are similar to results for those free of the condition that clinicians will want to apply diagnostic tests.⁷

Question 2: Was there an independent, blind comparison with a reference standard?

Readers should check that investigators applied independently the test under investigation and an appropriate reference standard (e.g., biopsy, surgery) to all patients. That is, the assessors of the test results should be blinded to the reference standard, and the assessor reference standard should remain blinded to the test results. When blinding is not used there is a significant danger of overestimating test performance.^{2,7,11}

Question 3: Did test results influence the decision to perform the reference standard?

If the results of a test influence the decision to carry out the reference standard, the properties of the diagnostic test will be distorted. This is called *verification bias* or *workup bias*. To avoid this bias, be wary of studies in which different reference standards were used for patients with and without the target condition.⁷

Question 4: Were methods for performing the test described in detail to permit replication?

The question to consider when assessing the validity of a study is whether or not sufficient detail was reported for performing the tests. Unless tests are applied in a homogeneous manner, there is too great a risk for variability in results.

Results: what are the results?

Question 5: Are test likelihood ratios, or data necessary for their calculation, provided?

The first step in the process of diagnosis starts with determining the probability that the target disease is present in a given patient group before the next test is performed—the *pretest probability*. This is determined by the integration of the evidence on disease presentation coupled with the surgeon's clinical experience and judgment. The second step in the process of diagnosis is to examine the characteristic of the test that indicates the direction magnitude of this change in probability, the *likelihood ratio* (LR). The LR represents the likelihood that a given test result will be expected in a patient with the target disorder compared with the

likelihood that the same test result would be expected in a patient without the target disorder. Many studies will present the properties of diagnostic tests in terms of sensitivity and specificity. Although less clinically useful than LRs, these terms can still be used for its calculation.^{2,7}

Applicability: how can I apply the results to my patient care?

Orthopedic surgeons rely heavily on radiographs for diagnosis, so it is important that some mention of the image acquisition protocol, or lack thereof, should be documented in well-reported studies. So much of orthopedic diagnosis is radiographic, and the way/orientation of the image beam changes the radiographic image so greatly that the acquisition protocol should be standardized and well described to the reader. If the images are not obtained in a precisely defined way, the study's repeatability and reproducibility will be compromised, as will the study findings.

Question 6: Will reproducibility and interpretation of the test result be satisfactory in my setting?

The value of a diagnostic test often depends on its reproducibility when applied within your own clinical setting. Highly reproducible tests are often simple and easily applied, or were conducted by highly skilled investigators.² If the latter is true, caution is warranted if you are in a setting in which only unskilled interpretation is available.

Question 7: Are the results applicable to my patient?

In general, if your patient meets the study eligibility criteria and your clinical practice setting is similar to that described in the study, you may be confident that the results are applicable to your own patient. Do take into consideration that test properties may be sensitive to the stages of disease severity and to different distributions of competing conditions.^{2,7}

Question 8: Will the results change my management of the patient?

When making management decisions, it is useful to link them explicitly with the probability of the target disorder. For most disorders we can speak of probabilities between the test threshold and the treatment threshold.^{2,7} It is when the probability of the target disorder lies between these two thresholds that you should adopt testing in the management of your patients.

Question 9: Will patients be better off as a result of the test?

The most important criterion for the usefulness of a diagnostic test is whether or not the benefits to patients outweigh the associated risks.^{2,7} In general, a test is particularly

valuable when the risks of test are minimal, the target disorder has major consequences if left untreated, or the disorder is readily treated once diagnosed.

Therapy

For therapeutic studies the best evidence is found in the research design known as the RCT, and ideally in ideal RCTs with narrow confidence intervals (Table 4.2). In RCTs patients are allocated by chance to an intervention or a control group. Often in therapeutic studies researchers compare the outcome of two or more types of interventions in order to determine which is more effective and so the treatment that surgeons should employ in their practice.⁸

Validity: are the results valid?

Question 1: Did the intervention and control groups start with the same prognosis?

When evaluating the literature, surgeons should value studies that employ random allocation by chance, a tactic that ensures no method has been used in order to allocate patients to experimental or control groups, therefore ensuring that each group has the same baseline prognoses and characteristics.¹³ Other important items that a surgeon should assess when evaluating the literature are whether or not blinding was used, i.e., whether allocation concealment was employed that help to eliminate bias.^{2,8} Patients in both groups should be similar with respect to known prognostic factors. Differences in prognosis between the two study groups will result in bias either for or against the treatment being investigated.

Question 2: Was prognostic balance maintained as the study progressed?

When possible, blinding is the optimal strategy for maintaining prognostic balance.^{2,8,10} In surgical trials it is not possible to keep surgeons blinded. Although patients may be blinded to what treatment group they were allocated, keeping them blinded after surgery is challenging and unlikely. At the very least outcome assessors can be kept blinded when adjudicating patient outcomes should and can remain blinded.⁸

Question 3: Were groups prognostically balanced at the study's completion?

Even with concealed randomization conducted at patient enrolment, with effective blinding maintained during monitoring, the quality of follow-up completion is essential for ensuring study groups remained prognostically balanced at study close-out. Ideally, at the study conclusion you should know the status of every patient enrolled with respect to target outcome, and the proportion of patients

lost within each group should be none to minimal. Additionally, all patients should be analyzed in the groups into which they were randomized, and the trial should not be stopped early but continue until planned follow-up.^{2,8}

Results: what are the results?

Question 4: How large was the treatment effect?

In surgical trials patients either do or do not have an event such as reoperation or deep infection. One way to report the proportion of patients who have such an event can be as the absolute difference (i.e., *absolute risk reduction* (ARR) or risk difference) between the proportions of those having the event in both treatment groups. Another way to express the treatment effect would be as *relative risk* (RR), the risk of the event among patient treatment groups. The most commonly reported measure of treatment effect is the complement of relative risk, *relative risk reduction* (RRR). A discussion of statistics is beyond the scope of this chapter, but a general rule is that the greater the RRR the more effective the therapy.^{2,8,10}

Question 5: How precise was the estimate of the treatment effect?

The range within which the true effect likely lies is calculated with *confidence intervals* (CI). The accepted general rule is to use the 95% CI. Assuming the study was well conducted and has minimal bias, we can consider the 95% CI as defining the range that includes the true RRR 95% of the time. The true RRR will generally lie beyond these extremes only 5% of the time, a property of the CI that relates closely to the statistical significance of $p < 0.05$. A further discussion of statistical significance is beyond this chapter, but another general rule is that the larger the sample size, the narrower the CI.¹⁰

When reviewing the results of a study, it is important to take the sample size of the study into consideration. The size of a sample needs to be large enough to ensure that the study has adequate *power*. Power refers to the likelihood that a difference between two interventions will be detected if one is present. For instance, a study with a sample size that is too small may result in no difference being found between two treatments when one truly exists (*beta error*) or a difference being found between two treatments when there is no difference in actuality (*alpha error*). A study by Bhandari and colleagues notes that the conventionally accepted standard for study power is 80%.¹⁴

Applicability: how can I apply the results to my patient care?

Question 6: Can the results be applied to my patient?

Lastly, we must consider if and how the results can be applied to patients in our own practice. We can determine

this by asking three questions about patient similarity, important outcomes, and overall benefits. First, consider whether your patient would be included in the study group. Given that the inclusion and exclusion criteria are clearly delineated, is there something about your own patient that would lead to his or her exclusion from the study? If so, the results may not apply to your patient. Second, consider whether your patient fits into a group whose benefit was demonstrated with a subgroup analysis. If the investigation benefits were identified from a post-hoc subgroup analysis, those findings are suspect due to poor design and caution should be taken if a therapeutic recommendation is made due to a subgroup analysis. Third, you must consider whether your surgical skills are comparable to the skills of the investigating surgeon(s).

Question 7: Were all clinically important outcomes considered?

One must also think about whether or not all outcomes of the treatment were reported (e.g., adverse events, etc.).² Surgical treatments are indicated if they provide benefits, but only if these benefits include outcomes that are important to your patient (i.e., are in line with their own goals and values).

Question 8: Are the likely treatment benefits worth the potential harm and costs?

For the safety and benefit of patients, it is critical that the potential benefits of the treatment outweigh any potential harm to the patient, or any unreasonable costs.^{2,8}

Prognosis

Although RCTs are the gold standard for evaluating new drugs and medical or surgical procedures, they are not commonly used for assessing prognostic factors. In practice it is not ethical to assign patients to potential risk factors. Generally, surgical studies investigating prognostic factors are observational studies, and the best such design is a cohort study. Ideally, the highest level of evidence for prognosis comes from high-quality prospective studies in which all subjects were enrolled at the same point in their disease or treatment and an 80% or greater follow-up rate was maintained (Table 4.3).^{5,9,15}

These cohort studies may be either prospective or retrospective. A *prospective cohort study* identifies potential prognostic factors and follows the study group forward in time to determine if any factors have a significant impact on outcomes. Unfortunately, these studies demand substantial planning in advance and require considerable time and resources to complete.^{2,9} Furthermore, new prognostic markers are continuously reported and may not have been identified at the inception of the data collection.

An alternative observational study is a *retrospective cohort study* or a *retrospective case-control study*. In case-control studies one starts with the outcome of interest and then looks backward to examine potential causal factors by comparing those who have the outcome (i.e., cases) with those who do not have the outcome (i.e., controls). The major drawback of retrospective studies is that the data quality is based mainly on patient records, and these records may not be sufficiently accurate. Another drawback of retrospective studies is that they are prone to *recall bias*, and this decreases the validity of results.^{2,9}

In studies of prognosis researchers examine prognostic variables to determine their relationship to possible outcomes, disease, therapeutic treatment, and predictions of the probability associated with their effect (i.e., the probability with which those outcomes can be expected to occur).^{2,9} It is possible to refine the prognosis by looking at subgroups defined by demographic variables (e.g., gender, age, comorbidity factors, socioeconomic status, disease stage). In the best-designed studies investigators will distinguish subgroups of patients based on prognostic variables.⁹ When variables or factors predict which patients do better or worse, we call them *prognostic factors*. Prognostic factors should not be confused with *risk factors* (i.e., those patient characteristics that are associated with disease in the first place).

Validity: are study results valid?**Question 1: Was the patient sample representative?**

In well-designed prognostic studies, the patient sample enrolled must match the target population under study.⁹ A patient sample is not representative when it differs systematically from the population of interest. Differences may result in a systematic over- or underestimation of the likelihood of adverse outcomes; i.e., the sample patients will have a worse or better prognosis respectively than the target population. A prognostic study is biased when it yields such differences from the truth about adverse outcomes.^{2,10}

Question 2: Were patients sufficiently homogeneous with respect to prognostic risk?

To estimate patient prognosis we examine outcomes in groups of patients with similar clinical presentation. The best-designed studies would have all enrolled patients similar enough for prognostic risk for the outcome of interest to be applicable to each and every one of them. Such similarity could include age, disease stage, smoking history, gender, and socioeconomic status. Ideally, prognostic factors should be validated in several studies to ensure that they are related to the outcome of interest. If patients enrolled were not sufficiently homogeneous, investigators should at least provide estimates for all clinically relevant subgroups in the study.⁹

Question 3: Was follow-up sufficiently complete?

We can only be confident in the validity of a cohort study of prognosis if the majority of the patients enrolled have completed follow-up. The proportion of loss to follow-up that threatens validity is related to the proportion of patients who had an adverse outcome. Generally, the larger the proportion of lost patients in relation to the proportion of patients with adverse outcomes, the less likely the study results are valid.^{2,9}

Question 4: Were outcome criteria objective and unbiased?

In well-designed studies investigators should define their target outcomes before study start-up, and they should base their criteria on the most clinically relevant measures. Furthermore, investigators should describe the type of patient monitoring and the frequency of follow-up. In orthopedic studies outcomes are objective when they are obvious to measure, such as reoperations or death. Some outcomes, such as fracture healing or nonunion, require more clinical judgment to assess. For the study to remain unbiased, it is very important that adjudicators remain blinded to all prognostic factors. Other outcomes, such as functional ability or quality of life, are subjective and challenging to measure. For these most difficult outcomes investigators should use previously validated and reliable measurement scales.¹⁵

Openmirrors.com
Swap patients.⁹

Results: what are the results?**Question 5: How likely are the outcomes over time?**

Quantitative results from studies of prognosis or risk are the number of events that occur over time. These events must be of a discrete nature and linked to a precise time. In orthopedic studies these events typically include reoperations, serious adverse events (SAEs), or death. A common and informative way to depict these quantitative results is as a *survival curve*. A survival curve may be understood as either the number of events over time, or conversely as the change of freedom from results over time.² For example, if the chance of outcome is much later after initial surgical treatment, this is typically represented by a curve that starts out flat and then becomes steep.

Question 6: How precise are the estimates of likelihood?

Investigators usually report risks of adverse outcomes with their associated 95% CI. If the study is valid, the 95% CI defines the range of risks within which it is likely that the true risk lies. The more precise the estimate of prognosis a study provides, the less uncertainty about the estimated prognosis and the more useful the study is for us. In most survival curves, results are derived from more patients during the early follow-up periods rather than the later

periods. This results from losses to follow-up and because study patients are rarely enrolled at the same time. This means that survival curves are more precise during the earlier periods of follow-up.

Applicability: how can I apply the results to my patient care?**Question 7: Were study patients and their management similar to those in my practice?**

In well-written articles, investigators describe the study sample in sufficient detail for readers to make a comparison with their own patients. This should include patient characteristics, and how these are defined. Oddly enough, while therapy is one factor that could strongly influence outcome it is rarely mentioned in prognostic studies. Therapeutic strategies can vary markedly among institutions, and change over time as new treatments become available or old treatments regain popularity. To the extent that treatments are beneficial or detrimental, overall patient outcome might improve or become worse. Studies that do not provide sufficient details about therapeutic strategies limit your ability to assess applicability. Given the rapid pace of evolving therapies in orthopedics, authors should detail the variety of implants, technologies, and surgical techniques used for long-term outcome studies in order for readers to assess the generalizability of the results to their

Question 8: Was follow-up sufficiently long?

Because the presence of illness often precedes the development of an outcome event by a long period of time, investigators should follow patients for long enough to detect the outcomes of interest. A prognostic study may provide an unbiased assessment of outcome during a short period of time, but only if it meets certain validity criteria. Such a study may be of little use for patients who are interested in their prognosis over a longer period of time.

Question 9: Can I use the results in the management of patients in my practice?

Prognostic data often provide the basis for practical decisions about surgical treatments. Knowing the expected clinical course of your patient's condition can help you judge whether or not a specific treatment is warranted. For example, for patients at very low risk of adverse outcomes even potentially beneficial therapies may not be justified. Specifically, for patients who are most likely to get well, clinicians should not recommend treatments that are potentially toxic or exorbitantly expensive. For those patients at high risk of poor outcomes, regardless of therapy course, aggressive therapy may only serve to prolong suffering and waste costly resources. Even in cases where the prognostic results do not help with selecting an effective

therapy, they may help you in counseling a concerned patient or relative about appropriate next steps in care.^{2,9}

Conclusion

Orthopedic surgeons wishing to apply the principles of EBM should learn to integrate the best available evidence from the medical community, and their own surgical experience, as well as their patients' own goals and values. In this chapter we provide users' guides for the best studies of diagnosis, therapy, and prognosis. Each of these guides is based on the three-step process of critical appraisal of study validity, results, and applicability to your own patients. By following these steps for critical appraisal, orthopedic surgeons can select the most appropriate tests to make a sound diagnosis, choose the most appropriate therapies available, and determine the most likely prognosis for their patients.

Systematic Reviews and Meta-Analysis

Nasir Hussain¹, Farrah Hussain¹, Mohit Bhandari¹, and Saam Morshed²

¹McMaster University, Hamilton, ON, Canada

²San Francisco General Hospital and the University of California, San Francisco, CA, USA

Introduction

Over 3 million new articles are published in scientific journals each year.^{1,2} Consequently, a researcher would be required to read close to 20 articles every day to keep current with research.¹ Obviously this is a daunting and impossible task for most healthcare professionals. To perform the accumulation of new evidence makes it easy to lose past findings and forget about them. The use of reviews has become an invaluable tool in orthopedic medicine to help keep up to date with the best available evidence. There are three types of reviews: narrative reviews, systematic reviews, and meta-analysis.^{1,2} Each of these is discussed in detail in this chapter.

Top six questions

1. What is a narrative review?
2. What is a systematic review?
3. What are the differences between a systematic review and a narrative review?
4. What is a meta-analysis?
5. Where do narrative reviews, systematic reviews, and meta-analyses rank on the hierarchy of evidence?
6. How are systematic reviews and meta-analyses critically appraised?

Question 1: What is a narrative review?

A narrative review summarizes different primary studies from which a broad perspective can be formulated. Interpretations contributed by the reviewers' own experience, and existing theories and models are often included in narrative reviews.^{3,4} For example, a narrative review summarizes the broad topic of femoral fractures.³

Current concepts are also a form of narrative review. They frequently describe the approach used by a group of surgeons to treat a situation, often discussing multiple treatment options.³ The literature used in the narrative review is summarized, but the methods used to locate and select the studies for inclusion are not systematic. In addition, the studies included are not formally critically appraised. For this reason, a narrative review may miss relevant studies, or the authors may have selected studies on the basis of their own preferences and opinions.^{3,4} Narrative reviews are also helpful in answering background questions, as these types of questions are broad in scope and are used to help understand the principle or problem. An example of a background question would be: "What are the epidemiology, prognosis, and screening approaches following a femoral fracture in adults?"

The strengths of this type of review lie in its ability to understand the diversity of ideologies surrounding scholarly research topics.³ As well, it provides the author of the

review with the opportunity to contribute their own knowledge and insight into this shared educational phenomenon.³ However, narrative reviews do not necessarily state the rules for inclusion of studies, nor do they state the rules used to determine to relevance and validity of included studies.^{3,4}

Example from literature: narrative review

Source

Doherty T, MacDermid JC. Clinical and electrodiagnostic testing of carpal tunnel syndrome: a narrative review. *Orthop Sports Phys Ther* 2004;34(10):565–88.

Abstract

Carpal tunnel syndrome (CTS) is a pressure-induced neuropathy that causes sensorimotor disturbances of the median nerve, which impair functional ability. A clear history that elicits relevant personal and work exposures and the nature of symptoms can lead to a high probability of a correct diagnosis. Hand diagrams and diagnostic questionnaires are available to provide structure to this process. A variety of provocative tests have been described and have variable accuracy. The Phalen's wrist flexion and the carpal compression tests have the highest overall accuracy, while Tinel's nerve percussion test is more specific to axonal damage that may occur as a result of moderate to severe CTS. Sensory evaluation of light touch, vibration, or current perception thresholds can detect early sensory changes, whereas 2-point discrimination changes and thenar atrophy indicate loss of nerve fibers occurring with more severe disease. Electrodiagnosis can encompass a variety of tests and is commonly used to assess the presence/severity of neuropathic changes and to preclude alternative diagnoses that overlap with CTS in presentation. The pathophysiologic changes occurring with different stages of nerve compression must be considered when interpreting diagnostic test results and predicting response to physical therapy management.

Question 2: What is a systematic review?

Unlike a narrative review, a systematic review addresses a specific question and uses a planned and systematic approach.⁴ This type of review is appropriate for answering foreground questions.^{4,5} An example of this type of question would be "In a patient with an acute rupture of the lateral ankle ligament, is cast immobilization or functional taping a better treatment option if the patient wants to return to work as soon as possible?"⁴ After this question has been asked, a systematic and rigorous literature search is performed followed by the critical analysis of the studies to be included.^{3,4} Lastly, the results are summarized and discussed.⁴

This type of review has various strengths, some of which include a narrow research question, a comprehensive and

exhaustive search for evidence, a criterion for assessing relevant literature for validity, the objective summary provided, and the implication for evidence-based medicine.³ However, the primary problem with systematic reviews is that the narrow focus may not allow for comprehensive coverage.³ The strict criteria used by systematic reviews may limit studies which are relevant, thus information may be lost.

Struijs PA, Smidt N, Arola H, Dijk CN, Buchbinder R, Assendelft WJ. Orthotic devices for the treatment of tennis elbow. *Cochrane Database Syst Rev* 2002;CD001821(1):1–18.

Abstract

Lateral epicondylitis (tennis elbow) is a frequently reported condition. A wide variety of treatment strategies has been described. As of yet, no optimal strategy has been identified. The objective of our study was to assess the effectiveness of orthotic devices for the treatment of tennis elbow. We searched Medline, Embase, CINAHL, the Cochrane Controlled Trial Register, Current Contents up to May 1999 and reference lists from all retrieved articles. Experts on the subjects were approached for additional trials. All randomized clinical trials (RCT) describing individuals with diagnosed lateral epicondylitis and comparing the use of an orthotic device as a treatment strategy were evaluated for inclusion. Two reviewers independently assessed the validity of the included trials and extracted data on relevant outcome measures. Dichotomous outcomes were expressed as Relative Risks (RRs) and continuous outcomes as Standardised Mean Differences (SMD), both with corresponding 95% confidence intervals (95% CI). Five RCTs (N per group 7–49) were included. Validity score ranged from 3–9 positive items out of 11. Subgroup analyses were not performed due to the small number of trials. The limited number of included trials present few outcome measures and limited longterm results. Pooling was not possible due to large heterogeneity amongst trials. No definitive conclusions can be drawn concerning effectiveness of orthotic devices for lateral epicondylitis. More well-designed and well-conducted RCTs of sufficient power are warranted.

Question 3: What is a meta-analysis?

Often confused with systematic reviews, meta-analyses are the statistical analysis of results from multiple separate studies.^{1,4} Usually this statistical analysis is included in systematic reviews that use quantitative methods, but this may not always be the case.¹ Like a systematic review, a meta-analysis typically answers a foreground question.⁴ A meta-analysis is conducted to determine the significance of the results from multiple research studies pertaining to the same research question.^{3,4} It can therefore increase the sta-

tistical power of the primary research by pooling the data and thus allows for the results to be more generalized.^{3,4}

Meta-analyses are performed using a concise, stepwise method. The steps include: (1) defining the research question, (2) performing the literature search, (3) selecting the studies, (4) extracting the data, (5) analyzing the data, and (6) reporting the results. Numerous protocols have been developed, such as the Quality of Reports of Meta-analysis (QUOROM), that provide detail on how to properly conduct each step.²

A meta-analysis is very beneficial in assessing effective treatment options. For example, a meta-analysis of clinical trials may help to increase the precision of estimates of treatment effects, thus decreasing the probability of false-negative results.² Therefore, by statistically pooling results from relevant studies, a meta-analysis allows for accurate and precise analysis, and increases the statistical power of the primary research by pooling the data and allowing the results to be more generalized.² However, the quality of a meta-analysis can be compromised if the included data is flawed due to poor methodological quality.² As well, various biases such as *publication bias* can be associated with a meta-analysis.²

Example from literature: meta-analysis

Kerkhoffs GM, Struijs PA, Marti RK, Blankevoort L, Assendelft WJ, van Dijk CN. Functional treatments for acute ruptures of the lateral ankle ligament: a systematic review. *Acta Orthop Scand* 2003;74(1):69–77.

Abstract

Our aim with this systematic review was to assess the effectiveness of various functional treatments for acute ruptures of the lateral ankle ligament in adults. We performed an electronic database search using MEDLINE, EMBASE, COCHRANE CONTROLLED TRIAL REGISTER and CURRENT CONTENTS. We evaluated randomized clinical trials describing skeletally mature subjects with an acute rupture of the lateral ankle ligament and compared functional treatments for inclusion in this study. 9 trials met our inclusion criteria. Two reviewers independently assessed the quality of these trials and extracted relevant data on treatment outcome. Where appropriate, results of comparable studies were pooled. Individual and pooled statistics are reported as relative risks (RR) for dichotomous outcome and (weighted) mean differences ((W)MD) for continuous outcome measures with 95% confidence intervals (95% CI). Heterogeneity between the trials was tested using a standard chi-square test. Persistent swelling at short-term follow-up was less with lace-up ankle support than with semi-rigid ankle support (RR 4.2; 95% CI 1.3–14), an elastic bandage (RR 5.5; 95% CI 1.7–18) and tape (RR 4.1; 95% CI 1.2–14). A semi-rigid ankle support required a shorter period for return to

work than an elastic bandage (WMD 4.2; 95% CI 2.4–6.1) ($p = 0.7$). One trial reported better results for subjective instability using the semi-rigid ankle support than the elastic bandage (RR 8.0; 95% CI 1.0–62). Treatment with tape resulted in more complications, mostly skin problems, than that with an elastic bandage (RR 0.1; 95% CI 0.0–0.8). We found no other statistically significant differences. We conclude that an elastic bandage is a less effective functional treatment. Lace-up supports seem better, but the data are insufficient as a basis for definite conclusions.

Question 4: Where do narrative reviews, systematic reviews, and meta-analyses rank on the hierarchy of evidence?

Systematic reviews and meta-analysis of randomized controlled trials are considered to be the highest quality of evidence and are commonly ranked as level I evidence.^{4,6} A meta-analysis pools the data from all relevant studies found for a specific research question. This pooling allows for the results to be generalized then they normally would be from the results of a single trial.^{3,4} As well, due to the systematic and rigorous approach used in conducting a systematic review or meta-analysis, the level of bias is greatly reduced.³

Ultimately, the quality of the systematic review and meta-analysis depends on the quality of the included studies.⁵ Poorly conducted trials compromise the quality of the meta-analysis.⁵ In essence, one should aim for homogeneity amongst the included studies. This occurs when similar studies are arriving at the same outcome, thus leading to a strong meta-analysis.⁴ On the contrary, heterogeneity occurs when studies analyzing the same outcome arrive at different results, which leads to a weak meta-analysis.⁴

Question 5: What are the differences between a systematic review, meta-analysis and a narrative review?

Various differences exist between a narrative review, systematic review, and a meta-analysis. The first major difference is at the level of the research question. Systematic reviews and meta-analyses pose a concise and specific research question which is called a *foreground question*.^{7,8} This allows for a greater insight into the research of interest and also helps make the search for relevant published literature much easier. A good example of a foreground question is, “In a patient with an acute rupture of the lateral ankle ligament, is cast immobilization or functional taping a better treatment option if the patient wants to return to work as soon as possible?”⁴ This foreground question should be answered in depth with many sources

of information, criteria-based selection of patients/trials, and critical appraisal and synthesis of all relevant studies.^{7,8} On the other hand, the question raised by a narrative review is often much more generalized and is known as a *background question*. An example of this type of question is, “How do bones heal after all treatments of humeral shaft fractures?”⁸ Since this question is very broad, large numbers of studies can be included in the analysis, some of which may now be relevant to the research question.

Another difference between these types of studies is the amount of *bias*. The studies which are commonly included in a narrative review are selectively chosen by the author, thus creating a *selection bias*.^{8,9} As well, narrative reviews often mix expert opinion with evidence, and this may cause inconsistencies in the reported findings.^{8,10} On the other hand, a systematic review and meta-analysis utilize an exclusive stepwise approach for the selection and methodological validity of the studies included.^{4,9} This in turn helps provide a safeguard against many common biases, such as publication bias and *citation bias*. The factors affecting the inclusion of studies are predefined by the researcher in order to ensure consistency.⁴ Some of these factors include study design, population characteristics, type of treatment/exposure, and outcome measures.¹¹

Differences between a narrative review and systematic review also exist in the quality of the literature search. A systematic review uses a comprehensive, specific search in order to obtain maximal results.⁷ In contrast, a narrative review uses a generalized search in which many different studies are found, some of which may not be relevant to the research question.^{7,11} After the search is completed, there are also differences in the inclusion and exclusion criteria. In a systematic review, studies are included on the basis of many different factors such as validity of the results, research methodology, type of treatments, and the outcome measures used.¹² Various tools such as the Jadad score, T.C. Chalmers score, and QUOROM checklist are regularly used to determine the quality of the study.¹² Thus, the inclusion criteria for a systematic review are specified and exhaustive whereas a narrative review adopts a more open-ended approach which incorporates the author’s opinion in the selection of included studies.¹² A summary on questions to consider when reviewing and evaluating included articles can be found in Chapter 3 on critical appraisal.

Question 6: What is a critical appraisal of systematic reviews and meta-analyses?

As already discussed in Chapter 3, it is important to carefully evaluate the studies included in a systematic review. Various characteristics of the studies are assessed such as the participants, outcome measures used, completeness of study, follow-up, and appropriateness of statistical meas-

Table 5.1 Oxman and Guyatt index

1. Were the search methods used to find evidence stated?
2. Was the search for evidence reasonable comprehensive?
3. Were the criteria for deciding which studies to include in the overview reported?
4. Was bias in the selection of studies avoided?
5. Were the criteria used for assessing the validity of the included studies reported?
6. Was the validity of all studies referred to in the text assessed using appropriate criteria?
7. Were the methods used to combine the findings of the relevant studies reported?
8. Were the findings of the relevant studies combined appropriately relative to the primary question the overview addresses?
9. Were the conclusions made by the author(s) supported by the data and/or analysis reported in the overview?

Question 10 summarized the previous ones, and, specifically, asks to rate the scientific quality of the review from 1 (being extensively flawed) to 3 (carrying major flaws) to 5 (carrying minor flaws) to 7 (minimally flawed). The developers of the index specify that if the “partially/can’t tell” answer is used one or more times in questions 2, 4, 6, or 8, a review is likely to have minor flaws at best and is difficult to rule out major flaws (i.e., a score ≤ 4). If the “no” option is used on question 2, 4, 6, or 8, the review is likely to have major flaws (i.e., a score ≤ 3).

Reprinted from Journal of Clinical Epidemiology, 44, Oxman AD, Guyatt GH, Validation of an index of the quality of review articles, 1271–1278, 1991, with permission from Elsevier.

ures.⁴ Tools such as the Oxman and Guyatt Index are used to critically evaluate the scientific quality of a systematic review (Table 5.1).⁴

One may also encounter overlapping systematic reviews which address the same clinical question but are conducted by different groups of authors.⁴ These conflicting studies can also have conflicting results. To help resolve this problem an algorithm was developed by Jaded et al. to help analyze and evaluate the conflicting systematic reviews to determine which is the most appropriate.⁴ In this algorithm aspects such as the methodological quality are assessed.⁴

Conclusion

Systematic reviews are becoming increasingly important in modern-day clinical research because of the vast amount of literature published every year. If they are conducted appropriately, they can effectively provide an accurate, descriptive, and concise summary of the available literature. Thus, when properly conducted using high quality

primary studies, systematic reviews can provide the highest level of current evidence to answer specific clinical questions.

Economic Analysis

Laura Quigley¹, Sheila Sprague², and Theodore Miclau III³

¹University of Toronto, Toronto, ON, Canada

²McMaster University, Hamilton, ON, Canada

³University of California, San Francisco, CA, USA

Importance of economic analyses

With rising healthcare costs, it is important for decision-makers to efficiently allocate resources. Between 1970 and 2008, the percentage of the United States gross domestic product (GDP) spent on health care has increased from 7.1% to 16%.¹ Economic evaluations are important because people, time, facilities, equipment, and knowledge are scarce resources, and choices need to be made in order to determine optimal utilization.^{2,3} Economic analyses identify, measure, value, and compare alternative courses of action in terms of costs and consequences.^{2,3} They provide standardized, quantitative estimates of the likely cost per unit of health benefit achieved by a given procedure, which help reach the primary goal of identifying procedures that produce the greatest health benefit for a given cost.¹ The breadth of outcomes considered varies according to the type of economic analysis performed. Furthermore, the costs and benefits considered vary depending on the viewpoint adopted in the analysis. Thus, economic analyses vary in scope, perspective, applicability, and complexity.⁴ Economic analyses in orthopedic surgery are particularly important, as this field has experienced tremendous growth and innovation over the past two decades.⁴

Top six questions

1. What are the different types of economic analyses?
2. Which costs are included in an economic analysis?
3. What perspective is adopted in an economic analysis and how does this affect the costs included?

4. What is the time horizon adopted in an economic analysis?
5. What are sensitivity analyses?
6. How are economic evaluations interpreted?

Question 1: What are the different types of economic analyses?

The four types of economic analyses most commonly reported in the literature are cost-minimization, cost-effectiveness analysis, cost-utility analysis, and cost-benefit analysis. Each of these analyses involves the systematic identification and valuation of the relevant costs and consequences of healthcare interventions.⁴

Cost-minimization analysis

A cost-minimization analysis (CMA) is used to compare cost differences among competing alternative procedures when these treatments produce equivalent outcomes.^{3,4} Only the costs of each alternative procedure, which are selected based on the chosen perspective, are considered and the least costly alternative is supported. While CMAs may provide useful information by identifying all of the costs associated with a particular treatment, they can be used to compare treatments only when there is strong clinical evidence that patient outcomes are the same or similar. Otherwise, inclusion of only costs can lead to misleading results.⁴

An example of an appropriate use for a CMA is a comparison of absorbable internal fixation devices (N = 994) and conventional metallic devices (N = 1173) in fracture patients.⁵ Several randomized controlled trials (RCTs) comparing these devices have shown no significant difference in outcomes, therefore a CMA is an appropriate analysis

to conduct. The costs included in the CMA resulted from the patients' medical care and their time lost from work. When the costs for an implant removal procedure after metallic fixation were included, the average cost saved per patient by using absorbable implants in fractures of the olecranon was \$410. Due to this cost saving, the authors concluded that absorbable implants should be the standard treatment.⁵

Cost-effectiveness analysis

In cost-effectiveness analysis (CEA), both the costs and consequences of health programs are examined.² A CEA compares procedures in terms of their monetary value per natural unit of health outcome (i.e., cost per life saved, cost per limb salvaged, etc.).⁶ When conducting a CEA, a perspective is selected to identify which costs are included, and the measure of effectiveness is established. It is important to provide a thorough description of the categories of costs included and how the effectiveness data are to be obtained. The medical literature is an important source of effectiveness data; however, an appraisal of the quality of the data is important. In situations where limited or no clinical evidence exists, the CEA may proceed by making assumptions about the clinical evidence, and then undertake *sensitivity analyses* of the economic results with differing assumptions. A sensitivity analysis is a statistical method used to account for uncertainty in an economic analysis.⁷ If such analyses reveal that the final results are not sensitive to the estimate used for a given variable, then the inferences made using these data are more robust.⁸

Cost-effectiveness is typically expressed as an *incremental cost-effectiveness ratio (ICER)*. An ICER is an estimate of the additional cost per additional unit of effectiveness of using one treatment in preference to another. In estimating an ICER, the numerator of the ICER is the difference of the mean cost of each procedure, and the denominator is the mean difference of the effectiveness.^{3,4,6} The equation for the ICER is:

$$\text{ICER} = \frac{[\text{Cost}_{(\text{Treatment A})} - \text{Cost}_{(\text{Treatment B})}]}{[\text{Effect}_{(\text{Treatment A})} - \text{Effect}_{(\text{Treatment B})}]}$$

Cost-effectiveness studies do not consider subjective factors such as patient preferences and the value of a particular treatment or health state to a patient. One advantage of this technique is that, with a common unit of outcome or effectiveness, different procedures can be compared and can be expressed in terms of cost per unit of outcome. However, CEAs are not helpful for choosing between treatments that have different outcomes or for which the outcomes were measured with different techniques.⁴ For example, a study which uses the outcome of life-years saved cannot be easily compared to a study where the outcome is disability days avoided, as these are not common units of effect.

An example of an appropriate cost-effectiveness study would be an evaluation of the cost per successful union in the treatment of open tibial fractures. The first treatment option of intramedullary nailing without reaming may cost \$25,000 per patient, whereas treatment by external fixation may cost \$20,000. Recent studies report that intramedullary nailing yielded a much lower rate of nonunion (15%) than did external fixation (42%). Thus, even though intramedullary nailing is more costly, it is more cost-effective for the treatment of open tibial fractures because of the lower cost per successful union.⁴

Cost-utility analysis

The cost-utility analysis (CUA) is a form of evaluation that focuses on the quality of the health outcome produced or forgone by health programs.² A CUA differs from a CEA because the incremental cost of a program from a particular perspective is compared to the incremental health improvement attributable to the program expressed in terms of a single *utility-based* unit of measurement and not natural units as in a CEA. Examples of utilities include *quality-adjusted life-years (QALYs)* gained and *disability-adjusted life-years (DALYs)* gained, thus the results are expressed as a cost per QALY or DALY gained.² An *incremental cost-utility ratio (ICUR)* can be calculated, which is similar to the ICER in a CEA.² To value health utility, or benefit, a variety of approaches are adopted, including the *standard gamble (SG)*, *time trade-off (TTO)*, and *visual analog scales (VAS)*. All are based on the value individuals place on not having a particular disease.⁵ The consideration of quality recognizes that individuals have different preferences for certain states of health.⁵

Definitions

- **QALY:** Quality-adjusted life-years is a measure of life expectancy weighted by the quality of life.³ A QALY is computed as a year of life gained, multiplied by the utility score during that year, which is expressed on a scale of 0 to 1.⁶
- **Standard gamble:** Respondents considering a particular health state find the balance between a chance of returning to perfect health and a risk of possibly dying in the process.⁶
- **Time trade-off:** Respondents find the point of balance between a shorter life in perfect health vs. a longer life in the health state under investigation.⁶
- **Utility:** A term used by health economists for the strength of preference for a state of health, attribute, or procedure.^{3,4,6} A higher value is placed on time spent in good health and a lower value is placed on time spent with impaired physical and emotional function.⁴ The values range from 0 to 1 (perfect health).^{3,7}
- **Visual analog scale:** Respondents indicate the desirability of a health state on a line with well-defined endpoints, usually from 0 to 1.21.⁶

By converting effectiveness data (i.e., Harris hip score) to a common unit of measure (i.e., QALYs gained) a CUA is able to incorporate simultaneously both the changes in the quantity of life (mortality) and the changes in the quality of life (morbidity).² Also, the measurement of utilities allows for valid comparisons among multiple treatment options, particularly when alternative treatments produce different outcomes or when longer survival is acquired at the expense of reduced quality of life.⁴

Haentjens et al. provide a practical example of a CUA in which they compare the costs and health outcomes of standard versus prolonged prophylaxis with low molecular weight heparin (LMWH), among patients undergoing elective total hip or knee replacement.⁶ The study adopted the perspective of a societal healthcare payer, in this case the Belgian Federal Ministry of Health. Costs were obtained from a panel of orthopedic surgeons and from the Federal Ministry of Health, while QALYs were based on utility scores found in the literature. The authors found that prolonged prophylaxis with LMWH was associated with a cost-utility ratio of €6,964/QALY after total hip replacement and €64,907/QALY after total knee replacement.⁹ According to European guidelines, an intervention costing less than €20,000/QALY exhibits strong evidence for adoption while one costing €20,000–100,000/QALY exhibits moderate evidence for adoption.⁹ The authors therefore concluded that there is strong evidence for adoption of prolonged enoxaparin prophylaxis among total hip replacement patients, but only moderate evidence for adoption among total knee replacement patients.⁹

Cost-benefit analysis

Cost-benefit analyses (CBA) provide an estimate of the monetary resources consumed by each procedure under study compared to the value of resources the procedure might save.⁸ In a CBA both the costs and health outcomes are valued in monetary units.^{2-4,6} One method of assigning values to health consequences is by determining a patient's willingness to pay.⁴ In practice, it is difficult to quantify health consequences in monetary terms, and ethical issues exist in assigning an amount of money to the value of human life, pain, and suffering.⁶ After the costs and consequences are quantified in monetary terms, a direct comparison can be made between the program's incremental costs and its incremental consequences in equal units of measurement.² To compare treatment options CBA commonly uses two comparators, the *net present value* and the *cost-benefit ratio*. The net present value is the value of health benefits minus costs, and the cost-benefit ratio is the ratio between the two.⁶ CBA has the advantage of allowing direct comparisons across programs. Also, the analysis of a single program can determine whether it is economically worthwhile.^{4,6}

Vasen et al. provide an example of a CBA.¹⁰ They compared the total cost of open vs. endoscopic technique for the surgical treatment of carpal tunnel syndrome, from a societal perspective. The costs included those incurred from medical procedures and complications as well as from lost wages. The authors hypothesized the two procedures could have different complication rates and different amounts of time off work. For this study design, outcomes were given a dollar value. Outcomes such as infection and nerve injury were translated as a cost in dollars. All complications except nerve laceration were assigned a cost of the operative correction of the complication plus 1 year's wages, because it is assumed that patients with complications would not return to work for 1 year. Patients with nerve lacerations were assigned the present value of their wage replacement throughout the remainder of their life expectancy in addition to cost of the operative procedure. In the base case, the cost (including surgery, complications, and wages) of the open technique was found to be \$6,315 and that of the endoscopic technique was found to be \$5,896, indicating that the endoscopic technique is the less costly alternative.¹⁰

Question 2: Which costs are included in an economic analysis?

The costs included in an economic analysis will vary on the basis of the time frame and perspective being considered in the study. Ideally, a thorough economic analysis measures direct, indirect, and intangible costs. Direct medical costs include all costs that are directly related to the procedure, including those for personnel, supplies, and the facility involved in the treatment. Direct nonmedical costs include costs borne by patients and their families in the course of treatment (i.e., transportation).⁴ Indirect costs include costs associated with lost productivity, usually valued as lost wages or a monetary value of time. For determination of intangible costs, an attempt is made to assign a dollar value to reductions in quality of life. Those costs are often included in the measurement of QALYs. It is also important to consider the downstream costs of resources that will be consumed in the future but are still attributable to the procedure.⁴ An allowance for the differential timing of costs and consequences due to time preference is also required. Thus, economic analyses should discount costs, and the rates of three and five percent are recommended.²

Question 3: Which perspective is adopted in an economic analysis and how does this affect the costs included?

Before beginning any economic analysis, the perspective of the analysis needs to be determined and explicitly stated.

Perspectives that can be adopted include that of the government, the hospital, the primary payer, or society.⁷ If the economic analysis is completed from a governmental perspective, an interest in identifying the employment costs may be apparent.⁸ The hospital perspective includes only costs that are incurred by the hospital, such as the costs of the surgery, costs of diagnostic tests, the cost of the medical device, the cost of the medications the patient takes during their hospital stay, and the cost of staying in the hospital ward. In contrast, the perspective of the primary payer includes all medical costs that are covered by the primary payer, in addition to those incurred in the hospital. For example, both in-hospital costs and costs after the patient has been discharged are included (e.g., home care and medications).⁷ The societal perspective includes all costs related to the treatments and is not limited to medical costs. Examples of additional costs include time lost from employment and all patient expenses.⁷ The societal perspective is generally recommended, especially if the analysis will otherwise overlook an important financial burden to the patient, their family, and society in general.⁷

Question 4: What is the time horizon adopted in an economic analysis?

The time horizon of a healthcare economic evaluation is the period of time for which the costs and outcomes are measured. The time horizon should be specified and justified as being appropriate for the clinical condition being studied. Other time-sensitive issues that should be considered include technological improvements and overall societal well-being that occur over time, as well as the learning curve effect that follows the introduction of a new technology.⁴

Question 5: What are sensitivity analyses?

Sensitivity analyses are a method of accounting for uncertainty in an economic analysis.⁷ Sensitivity analyses are utilized to assess the impacts of various model parameters or assumptions on the study results.^{2,4} There are three key elements to consider when conducting a sensitivity analysis: (1) how the uncertain parameters are identified; (2) how the plausible ranges for the variables are specified; and (3) whether an appropriate form of sensitivity analysis is used.²

There are five different forms of sensitivity analyses. The simplest is the *one-way analysis*. Estimates for each parameter are varied one at a time in order to investigate the impact on study results.² A *multi-way analysis* recognizes that more than one parameter is uncertain and that each could vary within its specified range.² In a *scenario analysis*, a series of scenarios is constructed to represent a subset of the potential multi-way analyses. The scenarios typically

include the most realistic (best guess), optimistic (best case), and pessimistic (worst case). The analyst may also include scenarios that they feel are applicable.² A *threshold analysis* identifies the critical value(s) of a parameter or parameters central to the decision. The analyst can then assess which combinations of parameter estimates could cause the threshold to be exceeded.² Alternatively, the threshold values for key parameters that would cause the program to be too costly or not cost-effective could be identified.² The fifth form of sensitivity analysis is the *probabilistic sensitivity analysis*. In this type of analysis, probability distributions are applied to the specified ranges for the key parameters. Samples are then drawn randomly from these distributions to generate an empirical distribution of the cost-effectiveness ratio.² If the sensitivity analysis for an economic evaluation reveals that the final result is not sensitive to the estimate of a given variable, then the inference made using these data are stronger.⁸

Question 6: How are economic evaluations interpreted?

The goal of an economic evaluation is generally to compare two treatment options in order to select the one that provides the maximum health benefit for a given increment of cost. There are nine possible outcomes when comparing one procedure to another in a CEA (Figure 6.1).² In particular, cell 1 in Figure 6.1 shows that the new procedure is less expensive and more effective than the standard treatment, and should be adopted. In cell 2, the new procedure costs more and is less effective than the standard treatment, and should not be adopted. The most common case is when a new procedure is both more effective and more costly (cell 7). In this case, the hospital administration, surgeon, and patient need to determine if the increased effectiveness is worth the additional cost.² When the result falls into a nondominance cell (cells 7–9) it may be useful to calculate the ICER or ICUR of the new procedure.⁴ Additionally, guidelines exist to recommend whether to adopt or reject a new procedure. For example, in North America US\$50,000/QALY is often recommended as a threshold for a cost-effectiveness procedure. Procedures which have an incremental cost higher than this are likely to be rejected.⁷ For example, in the study by Haentjens et al. described previously,⁹ the European guidelines for CUAs indicate that a procedure costing less than €20,000/QALY exhibits strong evidence for adoption, whereas one costing €20,000–100,000/QALY exhibits moderate evidence for adoption. Thus, according to these standards, the authors found strong evidence for adoption of prolonged prophylaxis among total hip replacement patients, and moderate evidence for adoption among total knee replacement patients. Sensitivity analyses incorporating 20% changes from the base-case analysis showed this outcome to be robust.⁹

(Reproduced from *Methods for the Economic Evaluation of Health Care Programmes* (Third Edition) by Michael F. Drummond, Mark J. Sculpher, George W. Torrance, Bernie J. O'Brien and Greg L. Stoddart (2005), Figure: Box 2.2, p. 13. By permission of Oxford University Press.)

Lastly, it is important to assess whether the conclusions of another study are applicable to the clinician's own practice (i.e., in terms of patient population, practice patterns, level of resource consumption, and relative costs).⁴

Conclusions

In view of rising healthcare spending, it is becoming increasingly important to use the most cost-effective health program that fits within the available budget. The use of economic analyses can help determine which health program provides the greatest effect at lowest cost. It is important to carefully consider the perspective, time horizon, discount rate, and sensitivity analyses when interpreting economic analyses. High-quality economic analyses are important for orthopedic research.

¹Women's College Hospital, Toronto, ON, Canada

²University of Toronto, Toronto, ON, Canada

³St. Michael's Hospital, Toronto, ON, Canada

Case scenario

A 70 year old ambulatory white woman who is living independently is brought to the Emergency Department after slipping and falling in her bathtub. She is unable to weight bear and is complaining of pain in the right groin area. Radiography reveals a right femoral neck fracture and she is subsequently sent to surgery for fracture repair.

Relevant anatomy

Hip fractures are anatomically classified as *intracapsular* or *extracapsular* depending on the site of the fracture in relation to the insertion of the capsule of the hip joint on to the proximal femur. Femoral neck (*intracapsular*) and intertrochanteric (*extracapsular*) fractures are the most common types of hip fractures in patients with osteoporosis.¹ Biomechanically, osteoporotic fractures occur due to skeletal fragility (from decreased bone quantity or impaired bone quality) and/or from falling.² The greater trochanter is generally the point of impact in a fall, making the femoral neck particularly vulnerable to fractures.³

Importance of the problem

Osteoporosis is characterized by a reduction in bone mass and a disruption of skeletal microarchitecture leading to an increased susceptibility to fracture with minimal trauma.⁴ Over 200 million people worldwide suffer from osteoporosis⁵ and osteoporotic fractures account for 0.83% of the global burden of noncommunicable disease.⁶ In the year

2000, there were an estimated 9 million osteoporotic fractures worldwide, of which 1.6 million were hip fractures, 1.7 million were forearm fractures, and 1.4 million were vertebral fractures.⁶ The lifetime risk of any osteoporotic fracture is 40–50% in women and 13–22% in men.⁷

Hip fractures are the most severe type of osteoporotic fracture as they require hospital admission and are associated with significant morbidity and mortality.⁷ At 1 year post hip fracture, mortality (in part due to other comorbidities) ranges from 12% to 20%,⁷ with the majority of deaths occurring within the first few months after fracture. An excess risk of death may persist for at least 5 years afterwards.⁸ Globally, there are approximately 740,000 deaths per year due to hip fracture and resulting complications.⁹ Loss of function and independence among survivors is also profound, with 40% of patients unable to walk independently and 60% requiring assistance a year later.¹⁰ Hip fracture risk rises exponentially with age¹¹ and as populations age, annual numbers of hip fractures are expected to escalate. The long-term costs associated with hip fractures are also devastating. By the year 2041, annual economic implications of hip fracture are expected to reach \$9.8 billion in the United States and \$650 million in Canada.¹²

Top five questions

Diagnosis

1. Are hip fracture patients receiving appropriate evaluation and treatment for osteoporosis?
2. How do I decide which fragility fracture patients are at high risk for future fracture and which patients to treat pharmacologically?

Therapy

3. What medications reduce the risk of hip fracture?
4. Does starting bisphosphonate therapy interfere with fracture healing?

Harm

5. What are the side effects associated with long-term bisphosphonate therapy?

Question 1: Are hip fracture patients receiving appropriate evaluation and treatment for osteoporosis?

Case clarification

After fracture repair, the patient is sent for bone mineral density (BMD) testing by dual-energy X-ray absorptiometry (DXA) and has blood tests to rule out secondary causes of osteoporosis.

The diagnosis of osteoporosis is determined by measuring a patient's BMD [the average concentration of bone mineral (g) per unit of bone area (cm²)]. BMD is measured using DXA, the gold standard method of measurement.

Relevance

The presence of a hip or other fragility fracture is a major risk factor for osteoporosis, especially in patients aged 50 years or older, and is an important indicator for osteoporosis diagnosis and treatment.¹³ Orthopedic surgeons are in an ideal position either individually or collaboratively with colleagues to initiate and provide osteoporosis care for patients with fragility fractures, as they are the first physicians to make contact with the patient following fracture.

Current opinion

Current opinion suggests that many patients who sustain hip or other fragility fractures do not receive appropriate evaluation or treatment for osteoporosis.

Quality of the evidence

Level I

- 3 systematic reviews or meta-analyses
- 6 randomized controlled trials

Findings

A recent systematic review of 35 studies that evaluated practice patterns relating to osteoporosis management after fragility fracture found that recognition and treatment of osteoporosis in these patients remained inadequate,¹⁴ confirming the persistence of an earlier identified global osteoporosis care gap.¹⁵ In this review, a clinical diagnosis of osteoporosis was reported in less than 30% of patients in the majority of studies. Further, DXA scans were performed in less than 15% of patients in studies that reported on BMD testing. More than half of the studies reported that no more than 30% of fracture patients were taking calcium and vitamin D and less than 15% of patients were receiving bisphosphonate therapy.

Despite these alarming statistics, over the past decade international awareness has grown regarding the need for effective osteoporosis management in high-risk patient groups, such as those with hip and other fragility fractures. While there are evident barriers to osteoporosis care in the orthopedic environment,¹⁶ the initiation and development of various intervention programs has facilitated a consistent improvement in osteoporosis diagnosis and treatment rates. A summary of randomized controlled trials that have piloted various interventions to improve the diagnosis and treatment of osteoporosis in patients with hip fractures is outlined in Table 7.1. A total of six randomized controlled trials were identified,¹⁷⁻²² all of which demonstrated significant improvements in osteoporosis diagnosis and treatment rates among patients randomized to an intervention vs. those receiving usual care. Several different intervention models proved to be effective including: (1) direct evaluation and management of osteoporosis by an orthopedic surgeon within a specialized osteoporosis clinic;²² (2) use of a clinical coordinator to identify, educate, and refer patients for treatment with their primary care physician;^{18,20,21} and (3) mail-outs or e-mail notifications to patients or primary care physicians about guidelines and recommendations for osteoporosis management.^{17,19} The common thread among these models was the establishment of effective communication between the orthopedic surgeon, patient, and primary care physician.

The most successful model to date appears to be the *clinical coordinator model*. In addition to evidence from randomized trials, there is a substantial body of literature from nonrandomized data supporting this program type in reference to hip as well as other fragility fractures.²³⁻²⁵ In the

Table 7.1 Summary of randomized controlled trials to improve the diagnosis and treatment of osteoporosis in patients with hip fracture

Reference	Population	Fracture site and etiology	Intervention	Results
Miki et al. 2008 ²²	INT: n = 26 CON: n = 24 Mean age 79.2 yrs 71% female	Hip Low trauma	INT: In hospital OP evaluation including BMD scans of the hip and spine and blood work. Started 1500 mg calcium and 800 IU vitamin D daily and were booked for a follow-up appointment in the orthopaedic OP clinic up to 1 month post-operatively. At follow-up, clinic team reviewed results of the BMD scans and lab work and prescribed risedronate 35 mg. Follow-up visits and/or phone calls at 2 months and 6 months. Care transferred to primary physician at 6 months. CON: Started 1500 mg calcium and 800 IU vitamin D daily. Asked to approach family physician for an osteoporosis evaluation. Follow-up phone call at 6 months.	The percentage of patients (58%) who were on pharmacologic treatment for OP at 6 mo postfracture was significantly greater when the evaluation was initiated by the orthopaedic surgeon and was managed in a specialized orthopaedic OP clinic vs. treatment managed by a primary care physician (29%) (p = 0.04)
Gardener et al. 2005 ²⁰	INT: n = 36 CON: n = 36 Mean age 82 yrs 78% female	Hip Low trauma	INT: Prior to discharge received a 15 min discussion from clinical coordinator about the association between OP and hip fractures, the efficacy of DXA scans in the diagnosis of OP and bisphosphonates in its treatment, and the importance of medical follow-up for OP management. Received 5 questions regarding OP treatment to be given to their primary care physician. Follow-up call 6 weeks later to remind them about the questions and at 6 months to determine if OP had been addressed. CON: At discharge received a 2-page pamphlet on fall prevention. Follow-up phone call at 6 months to determine if OP had been addressed.	A greater percentage of patients in the intervention group (42% vs. 19%) had their OP assessed by their primary physician (p = 0.036)
Davis et al. 2007 ¹⁸	INT: n = 28 Mean age 80.4 yrs 75% female CON: n = 20 Mean age 82.6yrs 65% female	Hip Low trauma	INT (PEPA): (a) Usual care for the fracture including surgical treatment (b) OP information and a letter for the patients that encouraged them to return to their primary care physicians for further investigation (c) A request for patients to take a letter from the orthopedic surgeon to their primary care physician alerting that physician to the hip fracture and encouraging OP investigation (d) A telephone call at 3 months and 6 months to determine whether OP investigation and treatment had occurred. CON: (a) Usual care for the fracture including surgical treatment (b) A telephone call at 3 months (general health inquiry) and 6 months to determine whether OP investigation and treatment had occurred.	PEPA group 68% were offered one or more components of best practice care compared with 35% in the usual care group (p < 0.05) 54% PEPA prescribed bisphosphonate therapy vs. 0% CON (p < 0.01) 29% PEPA had a BMD scan vs. 0% CON (p < 0.01) 39% PEPA prescribed calcium and vitamin d vs. 30% CON (p = 0.32) 32% PEPA were prescribed exercise vs. 0% CON (p < 0.01)
Bliuc et al. 2006 ¹⁷	INT1: n = 75 47% <50 yrs; 53% ≥ 50 yrs 51% female INT2: n = 79 54% <50 yrs; 46% ≥50 yrs 59% female	Any site Minimal or moderate trauma	Intervention initiated 3 months postfracture if patients had not been investigated or treated for OP by their primary care physician. INT1: Patients sent a personalized letter that outlined their risk factors for OP and recommended follow-up with their primary care physician. Follow-up phone call at 6 months. INT2: Same personalized letter plus an offer of a free BMD assessment. Follow-up telephone call at 6 months.	Significant increase in the number of people investigated for OP in the group receiving the letter plus BMD offer: 38%(letter + BMD) vs 7% (letter only); p = 0.001 Rates of treatment in both groups were very low (6%)

(Continued)

Table 7.1 (Continued)

Reference	Population	Fracture site and etiology	Intervention	Results
Majumdar et al. 2007 ²¹	INT: n = 110 CON: n = 110 Median age 74 yrs 60% female	Hip Any etiology	INT: Case manager provided one-on-one counseling about importance of BMD testing and the ability of bisphosphonate therapy and other treatments to reduce the risk of future fractures and arranged for a BMD test. Based on BMD results, case manager discussed risks and benefits of bisphosphonate therapy and arranged treatment for appropriate patients. All results and treatment plans communicated to the patient's primary care physician. CON: Study personnel provided counseling on fall prevention and the need for additional intake of calcium and vitamin D. Patients given educational materials on OP and were asked to discuss the materials with their primary care physician. 6 month follow-up	At 6 months postfracture 51% of patients in INT were receiving bisphosphonate therapy compared with 22% in CON group (adjusted odds ratio, 4.7; 95% CI, 2.4–8.9; p < 0.001) BMD tests performed in 80% of patients in INT group vs 29% in CON (p < 0.001)
Feldstein et al. 2006 ¹⁹	INT1: n = 101 34.6% 50–69 yrs 65.4% 70–89 yrs INT2: n = 109 37.6% 50–69 yrs 62.4% 70–89 yrs CON: n = 101 36.6% 50–69 yrs 63.4% 70–89 yrs	Any site No open fractures	INT1: Primary care physician sent a patient-specific EMR providing clinical guideline advice on OP. 3 months later another EMR sent to physicians who had not ordered a BMD or prescribed pharmacological treatment for enrolled study patients. INT2: Same as INT1 plus patients received a single mailing of an advisory letter identifying their risk, discussing clinical guideline recommendations and requesting that they discuss OP management options with a primary care physician. Educational materials were also included. CON: Usual care 6 month follow-up	At 6 months, provider reminder resulted in 51.5% of patients receiving BMD measurement or OP meds, provider reminder plus patient education resulted in 43.1% and usual care resulted in 5.9% (p < 0.001) Effect of provider advice combined with patient education was not significantly different from provider advice alone (p = 0.88)

coordinator model, a staff member in the fracture clinic (termed the coordinator) is assigned the task of identifying patients with probable fragility fractures. The coordinator then works with the orthopedic surgeon and other health professionals to educate the patient and ensure appropriate treatment and follow-up with the family physician. The coordinator program has been shown to be both effective²³ and cost-effective,²⁶ and the challenge today is to allocate systems and resources to facilitate this kind of care. A similar model that has been effective in Glasgow (UK) is termed a fracture liaison service.²⁵

Recommendations

In patients aged 50 years or older who have sustained a hip or other fragility fracture, evidence suggests that:

- Many patients are not receiving appropriate evaluation and treatment for osteoporosis postfracture [overall quality: high]

- Significant progress has been made towards developing and implementing programs to address this care gap [overall quality: high]

Question 2: How do I decide which fragility fracture patients are at high risk for future fracture and which patients to treat pharmacologically?

Case clarification

The DXA scan reveals that the patient has a T-score of -2.0 at the lumbar spine (L1–L4), a T-score of -3.9 at the left femoral neck and a T-score of -4.1 at the left total hip. On further questioning, the patient discloses that she has had a prior wrist fracture at age 55 and that her mother had a hip fracture. She is not taking oral steroids, does not have rheumatoid arthritis, does not smoke, and drinks less than

one drink per month. Blood tests to identify secondary causes of osteoporosis were negative.

A T-score is the number of standard deviations (SD) above or below the mean value of BMD for young adults (20–30 years old). The World Health Organization (WHO) defines osteoporosis as a T-score of -2.5 or less at the hip or lumbar spine.

Relevance

Many patients who sustain a fragility fracture do not receive appropriate pharmacologic treatment for underlying osteoporosis.¹⁴ It is important to identify those at high risk for future fracture and those who would benefit from pharmacologic treatment in order to prevent future fractures.

Current opinion

Current opinion suggests that lack of education and training about osteoporosis is an important barrier to orthopedic postfracture care. Opinion is divergent among orthopedic surgeons on which patients should be considered for pharmacologic treatment.

Finding the evidence

- Cochrane Database with search terms: “osteoporosis and treatment guidelines”

 - 4 limit 3 to (English language and humans)
- A review of reference lists of relevant articles for additional published trials

Quality of the evidence

Level I

- 8 systematic reviews or meta-analyses
- 3 clinical practice guidelines

Findings

Until recently, decisions about osteoporosis therapy were made based on the presence or absence of fractures and on T-score values ≤ -2.5 SD from DXA measurements of BMD. Although low BMD is a strong and independent risk factor for fracture,^{27,28} it is not the only one. Indeed, most fractures occur in women with osteopenia (T-score between -1.0 and -2.5 SD) and not osteoporosis.²⁹ The main reason for this observation is that BMD measures bone quantity and does not take into account bone quality. Bone quality represents essentially all of the other characteristics of bone tissue

other than BMD that contribute to the strength of a bone such as geometry, microarchitecture, remodeling, mineralization and damage accumulation.³⁰ It is the interplay between both quantitative and qualitative factors that ultimately determines the fragility of a bone and its susceptibility to fracture.³¹ For this reason, recent treatment guidelines have focused on evaluating a patient’s absolute fracture risk, which considers BMD as well as other clinical risk factors for fracture that are thought to capture some aspects of bone quality.

The World Health Organization (WHO) has developed an international Fracture Risk Assessment Tool (FRAX®), that can be used to compute the 10-year probability of fractures in men and women based on clinical risk factors for fracture (which represent bone quality), with or without the measurement of femoral neck BMD.³² The algorithms used in the FRAX model are based on a series of meta-analyses using primary data from population-based cohorts that have identified several clinical risk factors for fracture.³³ The performance characteristics of the clinical risk factors have been validated in independent, population-based prospectively studied cohorts with over a million person years of observation.³³ The FRAX tool calculates the 10-year probability of a major osteoporotic fracture (clinical spine, hip, forearm, or proximal humerus) and hip fracture calibrated to the fracture and death hazard of several countries.³⁴

The FRAX calculation tool is available for public use online at <http://www.shef.ac.uk/FRAX/index.htm>. After selecting an appropriate country of origin, a patient’s 10-year fracture risk probability can be determined by answering a simple set of 12 questions pertaining to the patient’s clinical risk factors for fracture (Table 7.2). Current fracture risk cutoffs for the tool are based on cost effectiveness. For example, low bone mass (T-score between -1.0 and -2.5 at the femoral neck or spine) and a 10-year probability of a hip fracture $\geq 3\%$ or a 10-year probability of a major osteoporosis-related fracture $\geq 20\%$ was shown to be cost-effective in the USA.³⁵ In a study from the UK, the fracture risk in women with a history of osteoporotic fracture was selected as the treatment cutoff, corresponding to a risk level of 7.5%.³² It should be noted that cutoffs have not been established for all countries that can utilize the FRAX tool.

While the FRAX tool facilitates the determination of who is at high risk for fracture, by assessing quantity and indirectly quality, it does have several limitations. Although FRAX is an international tool, it is suitable for use only in those countries for which epidemiological data are available.³⁶ The set of clinical risk factors used in the FRAX tool also has limitations. For instance, several risk factors can be indicated only as present or absent (“yes” or “no”) in the question set, such as glucocorticoid therapy or previous fracture. However, there is evidence that the risk associated with the use of glucocorticoids is dose responsive.^{37,38} In

Table 7.2 List of clinical risk factors included in the WHO Fracture Risk Assessment Model (FRAX)

Clinical risk factor
Geographic region
Race
Sex
Weight
Height

Rheumatoid arthritis
Secondary osteoporosis
Current smoking
Alcohol intake (≥3 or more drinks/day)

WHO, World Health Organization.

addition, the risk of future fracture increases progressively with the number of prior fractures.³⁹ Further, only femoral neck BMD is taken into account by FRAX, as it was the only site for which BMD data was available for all of the study cohorts. BMD measurement by DXA at the femoral neck site is difficult as accurate measurements require correct rotation of the femur and positioning of the region of interest by the technician. As a result, considerable variability in femoral neck BMD may occur. However, it should be noted that a patient's fracture risk probability can be obtained without entering BMD data into the FRAX tool, emphasizing again the importance of factors other than BMD on future fracture risk. Additionally, the FRAX tool can only be used to assess previously untreated patients.

Although the FRAX tool is available for use internationally, it is not incorporated into all sets of treatment guidelines for osteoporosis worldwide. Treatment guidelines for osteoporosis vary by country, and only some countries recommend the use of the FRAX tool. A summary of North American and European guidelines for fracture risk assessment and treatment of osteoporosis is presented in Table 7.3. The US National Osteoporosis Foundation (NOF)⁴⁰ and the European Society for Clinical and Economic Aspects of Osteoporosis and Osteoarthritis (ESCEO)⁴¹ both recommend the use of the FRAX tool to calculate absolute fracture risk in their treatment guidelines for osteoporosis. The Osteoporosis Canada 2010 Guidelines⁴² suggest the use of one of two closely related tools for estimating 10-year risk of major osteoporotic fracture: the FRAX tool or the Canadian Association of Radiologists/Osteoporosis Canada (CAROC) tool. Both were calibrated using the same Canadian fracture data and were validated in Canadians.^{43–45} The CAROC tool stratifies men and women over age 50 into three 10-year major osteoporotic

fracture risk zones (low, moderate, and high). An initial risk category is obtained from age, sex, and T-score at the femoral neck. Clinical risk factors—the presence of a prior fragility fracture after age 40 or recent prolonged systemic glucocorticoid use—increase fracture risk independent of BMD.

Recommendations

In patients aged 50 years or older who have sustained a fragility fracture, and have not received prior pharmacologic treatment, evidence suggests that:

- The FRAX tool can be used to calculate the 10-year probability of a major osteoporotic fracture (clinical spine, hip, forearm, or proximal humerus) and hip fracture [overall quality: high]
- Alternative methods are also available to determine absolute fracture risk [overall quality: high]
- Treatment decisions should be patient specific and guidelines developed by the appropriate country of origin should be considered [overall quality: high]

Question 3: What medications reduce the risk of hip fracture?

Case clarification

A complete dietary history reveals that the patient consumes 1 glass of milk (350 mg dietary calcium), 1000 mg of elemental calcium in the form of supplements, and 800 IU of vitamin D per day. She is not currently taking any prescription medications.

Recommended daily calcium and vitamin D intakes for populations vary by country. The Institute of Medicine (IOM) recommends a daily calcium intake of 1000 mg for men 51–70 years and 1200 mg for women. For men and women 71 years of age and older the recommendation is 1200 mg per day. Vitamin D recommendations are 600 IUs a day for men and women 51–70 years of age and 800 IUs per day for men and women 71 years of age and older

Relevance

A number of different pharmacologic agents are available for the treatment of osteoporosis.⁴⁶ Opinion among orthopedic surgeons is divergent on which pharmacologic agents are best to reduce the relative risk of hip fractures in postmenopausal women who present with low BMD or a prior fragility fracture.

Current opinion

Current opinion suggests that orthopedic surgeons prescribe a variety of different pharmacologic agents for the treatment of fragility fractures.

Table 7.3 North American and European guidelines for fracture risk assessment and treatment of osteoporosis

Continent	Fracture risk assessment	Treatment guidelines

Quality of the evidence

Level I

- 8 systematic reviews or meta-analyses
- 18 randomized controlled trials

Findings

The majority of pharmacologic agents available for the treatment of osteoporosis are antiresorptive agents, which include bisphosphonates (oral or intravenous), hormone replacement therapy (HRT), raloxifene, denosumab, and calcitonin. Other available agents are parathyroid hormone (an anabolic agent) and strontium ranelate (a combination antiresorptive and anabolic agent).⁴⁶ A summary of the efficacy of pharmacologic agents on the relative risk reduction of hip fractures is presented in Table 7.4. As the majority of pivotal clinical trials were in postmenopausal women, data in men is limited and will not be reviewed.

A recent review article⁴⁷ summarized the efficacy results from pivotal clinical trials of four commonly prescribed bisphosphonates—alendronate, risedronate, ibandronate and zoledronic acid—for the treatment of postmenopausal osteoporosis. A total of 11 randomized placebo-controlled trials were identified (3 for alendronate,^{48–50} 4 for risedronate,^{51–54} 2 for ibandronate,^{55,56} and 2 for zoledronic acid^{57,58}). Compared with placebo controls, alendronate, risedronate, and zoledronic acid but not ibandronate (no available hip data) were found to reduce the relative risk of hip fractures in postmenopausal women with low BMD and/or prior vertebral fracture by 30% to 51%. Similarly, two randomized placebo-controlled trials looking at the fracture efficacy of HRT in postmenopausal women with⁵⁹ and without⁶⁰ hysterectomy demonstrated that HRT could reduce the relative risk of hip fracture by 39% and 30% respectively. The clinical trial of denosumab reported a relative risk reduction of hip fracture with denosumab of 40%.⁶¹ In contrast, randomized placebo-controlled trials with raloxifene⁶² and calcitonin⁶³ have failed to demonstrate successful relative risk reductions of hip fracture in postmenopausal women. Two pivotal trials^{64–71} have examined the effects of hPTH(1–34) and hPTH(1–84) on fracture risk reduction in postmenopausal women. hPTH(1–34) was

shown to reduce the relative risk of nonvertebral fractures;⁷¹ however, the number of women with hip fractures was too small to estimate the incidence of hip fracture, and thus the specific relative risk reduction at the hip site. Similarly, the hPTH(1–84) trial⁷² did not report on the specific relative risk reduction of hip fractures, but the difference in the number of reported nonvertebral fractures was not statistically significant between treated and untreated groups. Finally, four randomized placebo-controlled trials have evaluated the effects of strontium ranelate on fracture risk reduction in postmenopausal women.^{73–76} Only one of these trials specifically assessed the efficacy of the drug on the relative risk reduction of hip fractures,⁷⁶ and failed to show a significant relative risk reduction.

Recommendation

In patients aged 50 years or older with low BMD or prior fragility fractures, evidence suggests that:

- Alendronate, risedronate, zoledronic acid, denosumab, and HRT are all effective pharmacologic agents for reducing the relative risk of hip fracture [overall quality: high]

Question 4: Does starting bisphosphonate therapy interfere with fracture healing?

Case clarification

After 1 week in hospital for hip fracture repair, the patient is discharged to a long-term care facility. Before discharge, she is prescribed an oral bisphosphonate.

Relevance

Bisphosphonates are antiresorptive agents used to treat osteoporosis and other bone diseases characterized by increased osteoclast-mediated bone resorption. As bone formation and resorption are coupled,⁷⁶ and hard callus remodeling during fracture repair is osteoclast-mediated,⁷⁷ a common concern of orthopedic surgeons is whether or not bisphosphonates interfere with the fracture healing process.

Current opinion

Current opinion suggests that the majority of orthopedic surgeons do not feel that bisphosphonate therapy interferes with clinical fracture healing.

Findings

The majority of studies examining the effects of bisphosphonates on fracture healing have been in animal models. Very few studies have examined this relationship in humans.

Animal studies Fourteen animal studies have documented the effects of bisphosphonate therapy on fracture healing^{78–91}: 1 in sheep, 3 in dogs, 1 in rabbits and 9 in rats (Table 7.5). Several studies in both rat and dog models demonstrate

that long-term continuous administration of bisphosphonates can delay hard callus remodeling.^{81,82,85,86,89,90} However, the mechanical integrity of the callus is generally not compromised.^{85,86,90} In fact, further studies of continuous bisphosphonate administration in rat and sheep models suggest that treatment can improve the bone mineral content of the callus.^{81,82,87,91} The most promising results, however, have been seen with single-dosing regimens of bisphosphonates. When bisphosphonates such as zoledronate are given in a single dose, the delays in hard callus remodeling appear to be reduced⁸⁹ and improvements are seen in both tissue volume and strength,^{78,79,88,89} suggesting that bisphosphonates may even assist the healing process.⁹²

Human studies Despite the large number of patients treated annually with bisphosphonates, only two studies have examined the effects of these drugs on fracture healing in human models.^{93–95} One randomized placebo-controlled prospective trial examined BMD in the fracture callus of 32 postmenopausal women with a distal radial fracture treated with cast immobilization.⁹³ At 2 months postfracture, women treated with clodronate had a 20% increase in

Table 7.5 Summary of animal studies examining the effects of bisphosphonates on fracture healing

Reference	Model	Agent and mode of administration	Effects on fracture healing
Goodship et al. 1994 ⁸²	Sheep	Pamidronate; A	More prolific callus formation with an associated rise in the rate of BMC as well as improved torsional strength; Callus remodeling was reduced but not arrested
Bauss et al. 2004 ⁸⁰	Dog	Ibandronate; B and A	No impairment in BMD, bone structure, bone repair, coupling nor serum parameters for bone formation and turnover after long-term administration
Peter et al. 1996 ⁹⁰	Dog	Alendronate; B and A	Treatment before or during fracture healing or both increased fracture callus size and delayed callus remodeling but had no adverse effects on the union, strength or mineralization of bone
Lenehan et al. 1985 ⁸⁴	Dog	EHDP; A	Dose-dependent and reversible inhibitory effects on fracture healing
Matos et al. 2007 ⁸⁸	Rabbit	Zoledronate; A	Improved bone formation resulting in larger trabecular bone volume and little fibrosis volume
McDonald et al. 2008 ⁸⁹	Rat	Zoledronate; A	Weekly dosing delayed hard callus remodeling
Yang et al. 2007 ⁹¹	Rat	Pamidronate; B and A	Callus ultimate load to failure was decreased (NS)
Amanat et al. 2007 ⁷⁹	Rat	Zoledronate; A	Greater callus BMD, volume and strength; Delayed drug administration produced a larger and stronger callus
Amanat et al. 2005 ⁷⁸	Rat	Pamidronate; A	Greater callus BMC, volume and strength
Koivukangas et al. 2003 ⁸³	Rat	Clodronate; B and A	Increased size of the fracture callus but fracture healing process not prolonged even with administration of the drug on a long-term basis before fracture
Cao et al. 2002 ⁸¹	Rat	Alendronate; A	Suppressed remodeling of the callus leading to higher woven bone content, lower lamellar bone content and persistent visibility of the original fracture line
Li et al. 2001 ⁸⁵	Rat	Incadronate; B and A	Long-term continuous treatment delayed fracture healing particularly with high-dose treatment, but without impairing the mechanical integrity of the callus
Li et al. 1999 ⁸⁶	Rat	Incadronate; B and A	Pretreatment did not affect fracture healing; Continuous treatment led to a larger callus and delayed bone remodeling especially with high-dose treatment
Madsen et al. 1998 ⁸⁷	Rat	Clodronate; B and A	Increased BMC and BMD when drug given before and after fracture, but no adverse effects on fracture healing

A, after fracture; B, before fracture; BMC, bone mineral content; BMD, bone mineral density; NS, not statistically significant.

BMD at the fracture site compared with the placebo group; however, the difference between groups diminished over time. A double-blind randomized placebo-controlled trial in a comparable population also showed similar effects on BMD postfracture after the administration of alendronate.⁹⁵ Greater BMD was observed in the treated group compared with the placebo group up to 1 year postfracture. Finally, it is also noteworthy to mention that data from the pivotal clinical trials of bisphosphonates in patients with osteoporosis (see Question 3) have not indicated that fracture healing is impaired, nor has return of fractures been reported with long-term bisphosphonate therapy.⁹⁶

Recommendations

On the basis of evidence available from preclinical investigations, it is evident that:

- Continuous administration of a bisphosphonate in the presence of a fracture may modestly delay hard callus remodeling, but generally does not compromise the mechanical integrity of the fracture callus [overall quality: very low]
- Single-dosing of bisphosphonates in the presence of a fracture can reduce delays in hard callus remodeling and improve bone strength [overall quality: very low]

On the basis of evidence from clinical investigations, it is evident that:

- Administration of a bisphosphonate in the presence of a fracture can improve BMD in the short-term at the site of fracture [overall quality: moderate]

Question 5: What are the side effects associated with long-term bisphosphonate therapy?

Case clarification

The patient is scheduled to have dental implants next month.

Relevance

Bisphosphonates are the most frequently prescribed drugs for the treatment of osteoporosis.⁹⁷ Long-term safety information about these agents is therefore clinically important. A concern of many orthopedic surgeons is whether or not long-term treatment with bisphosphonate therapy is safe for patients aged 50 years or older who have sustained a hip or other fragility fracture.

Current opinion

Current opinion suggests that orthopedic surgeons are concerned about the potential adverse effects of long-term bisphosphonate use.

Findings

Atrial fibrillation In 2007, the US Food and Drug Administration (FDA) announced an ongoing safety review of a potential link between bisphosphonate use and "serious" atrial fibrillation⁹⁸ based on data from two randomized trials: the HORIZON Pivotal Fracture Trial and the FIT Trial (Table 7.4).^{50,57} In the HORIZON Pivotal Fracture Trial,⁵⁷ more patients in the zoledronic acid group developed arrhythmia (6.9% vs. 5.3%, $p < 0.003$) compared to the placebo group. The incidence of serious atrial fibrillation (defined as life-threatening or resulting in hospitalization or disability) was also significantly higher among those using zoledronic acid. In the FIT Trial,⁹⁹ a trend towards a higher incidence of serious atrial fibrillation was seen in the alendronate group (relative hazard 1.51; 95% CI 0.97–2.40; $p = 0.07$) compared to the placebo group, however, no increase in the overall occurrence of atrial fibrillation (relative hazard, 1.14; 95% CI, 0.83 to 1.57; $p = 0.42$) was observed.

A recent meta-analysis¹⁰⁰ evaluated the risk of atrial fibrillation with bisphosphonate therapy in all studies to date that have reported on atrial fibrillation events. Bisphosphonate exposure was found to be significantly associated with the risk of serious atrial fibrillation events (OR 1.47; 95% CI 1.01–2.14; $p = 0.04$; $I^2 = 46\%$) based on data from four pivotal randomized controlled trial data sets.^{50,57,58,99,101} However, meta-analysis of all atrial fibrillation events (serious and nonserious) from the same data sets yielded a pooled OR of 1.14; 95% CI 0.96–1.36; $p = 0.15$; $I^2 = 0\%$). The two case-controlled studies included in the meta-analysis showed different results. One found a significant association between any bisphosphonate exposure (ever users) and atrial fibrillation¹⁰² (adjusted OR 1.86; 95% CI 1.09–3.15), whereas the other study found no association¹⁰³ (adjusted OR 0.99; 95% CI 0.90–1.10). In both studies, however, the association was not statistically significant when restricted to current users. Another register-based restricted cohort study¹⁰⁴ comparing fracture patients beginning bisphosphonates ($n = 15,795$) with unexposed patients of the same age, sex and fracture type ($n = 31,590$), reported incidence rates of atrial fibrillation to be 16.5/1000 person years for untreated fracture patients and 20.6/1000 person years in bisphosphonate users, corresponding to an age- and sex-adjusted hazard ratio of 1.29 (1.17–1.41). The effect size was further reduced to 1.18 (1.08–1.29) by adjustment for comedications and comorbidity. The study also found that bisphosphonate users were at increased risk of hospital-treated atrial fibrillation (adjusted HR 1.13 (1.01–1.26)), but the risk among bisphosphonate users was inversely proportional to adherence. Based on the current evidence to date, the FDA has communicated that there is no clear association between bisphosphonate use and the

rate of serious or nonserious atrial fibrillation, regardless of dose or duration of bisphosphonate therapy. Further, the FDA maintains that the current indications for bisphosphonate use should remain unchanged.¹⁰⁵

Osteonecrosis of the jaw Since 2003, there have been several case reports of osteonecrosis of the jaw (ONJ) associated with the use of bisphosphonates, primarily in patients with cancer,^{106,107} although a consensus on diagnostic criteria for ONJ is vague. The American Society for Bone and Mineral Research (ASBMR) task force on ONJ,¹⁰⁸ a multidisciplinary expert group assembled to address key questions related to the disorder, developed the following definition of ONJ to help future investigations of the condition:

an area of exposed bone in the maxillofacial region that has not healed within 8 weeks after identification by a healthcare provider in a patient who is receiving or has been exposed to a bisphosphonate and has not had radiation therapy to the craniofacial region.

The clinical severity of ONJ has led to a number of investigations examining the incidence and prevalence of ONJ among bisphosphonate users.¹⁰⁹ Current evidence from case reports suggests that the risk for ONJ associated with oral bisphosphonate therapy for osteoporosis is very

low.^{108,110} The ASBMR task force on ONJ recently reviewed published and unpublished case reports of ONJ,¹⁰⁸ and identified 57 cases of ONJ in patients treated with bisphosphonates for osteoporosis, the majority of which were associated with alendronate. The review concluded that the risk for ONJ in this patient group was very low (between 1 in 10,000 and <1 in 100,000 patient-treatment years). The ASBMR task force on ONJ also developed a number of clinical management recommendations regarding ONJ for patients initiating or already receiving bisphosphonate therapy, which are outlined in Table 7.6. Woo et al.¹¹⁰ also conducted a systematic review of all potential cases of ONJ reported between 1966 and 2006 and came to a similar conclusion as the ASBMR task force on ONJ. Only 15 of 368 reported cases of ONJ were in patients using oral bisphosphonates for osteoporosis.

In data from randomized clinical trials of the bisphosphonates marketed in the US for the treatment of osteoporosis, no cases of ONJ have been reported, out of over 17,000 patients exposed to alendronate, more than 44 000 patient-years of exposure to risedronate and over 12,000 patients exposed to ibandronate.¹⁰⁹ However, none of these trials included the reporting of dental adverse events, nor was there an adjudication of suspicious dental findings. These findings were documented in a recent review paper

Table 7.6 ASBMR Task Force on ONJ recommendations and precautions for patients with osteoporosis or other nonmalignant bone disease initiating or already receiving bisphosphonate therapy¹⁰⁸

Patient Group	Recommendations and precautions
Initiating bisphosphonate therapy	<p>Patients should be informed that the risk of developing bisphosphonate-associated ONJ with routine oral therapy for osteoporosis or Paget's disease seems to be low, ranging between 1/10,000 and 1/100,000</p> <p>Patients who express concern about ONJ should be encouraged to seek additional information from a dentist or dental specialist</p> <p>Healthcare providers should encourage patients who are starting to take bisphosphonates to practice good oral hygiene and have regular dental visits</p> <p>Because the risk of developing bisphosphonate-associated ONJ seems to be related to longer duration of bisphosphonate exposure and the risk is low, it is not necessary to recommend a dental examination before beginning oral bisphosphonate therapy or to otherwise alter routine dental management</p>
Receiving bisphosphonate therapy	<p>Healthcare providers should encourage patients to practice good oral hygiene and have regular dental visits</p> <p>Patients with periodontal disease should receive appropriate nonsurgical therapy. If surgical treatment is necessary, it should be aimed primarily at reducing or eliminating periodontal disease. Modest bone recontouring may be considered when necessary</p> <p>Current information indicates that taking bisphosphonates for osteoporosis is not a contraindication for dental implant placement. However, if dental implants are considered, appropriate informed consent is recommended and should be documented</p> <p>Endodontic treatment is preferable to extraction or periapical surgery when possible</p> <p>If an invasive dental procedure is anticipated, some experts suggest stopping the bisphosphonate for a period before and after the procedure. There are no data to suggest stopping the bisphosphonate will improve dental outcomes, however, given the long retention of bisphosphonates in the skeleton, temporary discontinuation of bisphosphonate therapy is unlikely to have an adverse effect on the patient's skeletal condition</p>

Adapted from Khosla et al. Bisphosphonate-associated osteonecrosis of the jaw: Report of a Task Force of the American Society for Bone and Mineral Research. *J Bone Miner Res* 2007;22(10):1479–89.

by Silverman et al.¹⁰⁹ and were based on personal communications between the authors and the corresponding drug companies. In a recently completed trial entitled the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly (HORIZON) Pivotal Fracture Trial⁵⁷—a major randomized clinical trial that evaluated yearly zoledronic acid 5 mg for the treatment of postmenopausal osteoporosis in 7,736 postmenopausal women—an adverse event review process was established to assess maxillofacial adverse events objectively and independently. This is the largest trial to date in which ONJ has been examined in a systematic fashion with adjudication of all potential cases.¹¹¹ In the HORIZON Pivotal Fracture Trial there were no spontaneous reports of ONJ; however, after a thorough review of all maxillofacial adverse events, two potential cases of ONJ were found to meet predefined adjudication criteria (exposed bone in the oral cavity present >6 weeks): one case in the treatment group and one in the placebo group, making incidence rates similar between groups. In both patients, the condition resolved after antibiotic therapy and debridement.

Atypical fractures Several case reports^{94,112–115} have documented atypical fractures linked to long-term bisphosphonate use. Atypical fractures are those occurring at sites that are uncommon (but not absolutely unlikely) for osteoporosis such as the midshaft femur, pelvis, and tibia, as well as those that have exhibited impaired healing. Recently, a multidisciplinary expert group (task force), similar to the one discussed previously for the issue of ONJ, was established by the ASBMR to address key questions related to these fractures. A report put out by this task force¹¹⁶ developed a formal case definition for the condition, reviewed available published and unpublished data, and provided a set of recommendations for orthopedic and medical management (Table 7.7). The report reviewed 310 cases of atypical femoral fractures and found that 291 patients (94 %) with this condition had taken a bisphosphonate; however, a causal association was not established. The report concluded that the incidence of atypical femoral fractures associated with bisphosphonate therapy for osteoporosis is very low (~3–10 per 10,000 patients), particularly in comparison to the number of vertebral, hip and other fractures that are prevented by bisphosphonates. However, the findings suggested that the risk increases with increasing duration of exposure, thus there was concern that a lack of awareness and under-reporting may currently mask the true incidence of the problem. Given the rarity of atypical femoral fractures, the task force recommended that specific diagnostic and procedural codes be created and that an international registry be established to facilitate studies of the clinical and genetic risk factors and optimal surgical and medical management of these fractures. Physicians and patients will also be made aware of the possibility of

atypical femoral fractures through a change in labeling of bisphosphonates.

Recommendations

In patients aged 50 years or older who use long-term bisphosphonate therapy for osteoporosis, evidence suggests that:

- There is no clear association between bisphosphonate use and the rate of serious or nonserious atrial fibrillation, regardless of dose or duration of bisphosphonate therapy [overall quality: high]
- The risk of developing bisphosphonate-associated ONJ with routine oral therapy for osteoporosis is very low [overall quality: high]
- The benefits of bisphosphonates in preventing hip and other osteoporotic fractures outweigh the risk of developing atypical femoral fractures. [overall quality: low]

Summary of recommendations

- Many patients who have sustained a hip or other fragility fracture are not receiving appropriate evaluation and treatment for osteoporosis postfracture
- Significant progress has been made towards developing and implementing programs to address the osteoporosis care gap
- The FRAX tool can be used to calculate the 10-year probability of a major osteoporotic fracture (clinical spine, hip, forearm or proximal humerus) and hip fracture
- Alternative methods are also available to determine absolute fracture risk
- Treatment decisions should be patient specific and guidelines developed by the appropriate country of origin should be considered
- Alendronate, risedronate, zoledronic acid, denosumab and HRT are all effective pharmacologic agents for reducing the relative risk of hip fracture in patients with low BMD or prior fragility fractures
- Continuous administration of a bisphosphonate in the presence of a fracture may modestly delay hard callus remodeling in animals, but generally does not compromise the mechanical integrity of the fracture callus
- Single-dosing of bisphosphonates in the presence of a fracture can reduce delays in hard callus remodeling and improve bone strength in animals
- Administration of a bisphosphonate in the presence of a fracture can improve BMD in the short-term at the site of fracture
- There is no clear association between bisphosphonate use and the rate of serious or nonserious atrial fibrillation, regardless of dose or duration of bisphosphonate therapy
- The risk of developing bisphosphonate-associated ONJ with routine oral therapy for osteoporosis is very low

Table 7.7 ASBMR Task Force on Atypical Femoral Fractures recommendations for orthopedic and medical management of atypical femoral fractures¹¹⁶

Issue	Recommendations
Surgical management	
History of thigh or groin pain in a patient on bisphosphonate therapy	Rule out femoral fracture. AP and lateral plain radiographs of the hip, including the full diaphysis of the femur should be performed. If the radiograph is negative and the level of clinical suspicion is high, a technetium bone scan or MRI of the femur should be performed to detect a periosteal stress reaction
Complete subtrochanteric/diaphyseal femoral fracture	Orthopedic management includes stabilizing the fracture and addressing the medical management (below). Endochondral fracture repair is the preferred method of treatment since bisphosphonates inhibit osteoclast remodeling. Intramedullary reconstruction full-length nails accomplish this goal and protect the femur. Locking plates preclude endochondral repair, have a high failure rate, and are not recommended as the method of fixation. The medullary canal should be overreamed to compensate for the narrow intramedullary diameter, facilitate insertion of the reconstruction nail and prevent fracture of the remaining shaft. The proximal fragment may require additional reaming to permit passage of the nail and avoid malalignment. The contralateral femur must be evaluated radiographically whether or not symptoms are present
Incomplete subtrochanteric/femoral shaft fractures	Prophylactic reconstruction nail fixation is recommended if pain is present. If there is minimal pain, a trial of conservative therapy in which weight bearing is limited through the use of crutches or a walker may be considered. However, if there is no symptomatic and radiographic improvement after 2–3 months of conservative therapy, prophylactic nail fixation should be strongly considered because of the possibility of complete fracture. For patients with no pain, weight bearing may be continued but should be limited and vigorous activity avoided. Reduced activity should be continued until there is no bone edema on MRI
Medical management	
Prevention	Decisions to initiate pharmacologic treatment including bisphosphonates to manage patients with osteoporosis should be made based on an assessment of benefits and risks. Patients who are deemed to be a low risk of osteoporosis-related fractures should not be started on bisphosphonates. Complaints of thigh or groin pain in a patient on bisphosphonates require urgent radiographic evaluation of both femurs even if pain is unilateral
Treatment	For patients with a stress reaction, stress fracture, or incomplete or complete subtrochanteric femoral shaft fracture, potent antiresorptive agents should be discontinued. Dietary calcium and vitamin D status should be assessed and adequate supplementation should be prescribed. Teriparatide should be considered in patients who suffer these fractures, particularly if there is little evidence of healing by 4 to 6 weeks after surgical intervention

Adapted from Shane et al. Atypical subtrochanteric and diaphyseal femoral fractures: Report of a Task Force of the American Society for Bone and Mineral Research. *J Bone Miner Res* 2010; 25:2267–94.

- The benefits of bisphosphonates in preventing hip and other osteoporotic fractures outweigh the risk of developing atypical femoral fractures

Conclusion

This chapter reviewed orthopedic issues relating to osteoporosis including: (1) the identification of osteoporosis in patients with fractures, (2) treatment guidelines for patients with osteoporosis, (3) effective pharmacologic therapies for reducing fracture risk, (4) bisphosphonate therapy and fracture healing and (5) adverse effects associated with pharmacologic therapies for osteoporosis. Clinical evidence confirms that osteoporosis is an important ortho-

pedic concern and necessitates continued evaluation and attention.

Thromboprophylaxis in Orthopedic Practice

Ernest Kwek and Richard E. Buckley

Foothills Medical Center, University of Calgary, Calgary, AB, Canada

Case scenario

A 52 year old healthy man was involved in a low-energy ski collision. He sustained bilateral proximal humeral fractures and a right distal tibia fracture. He was initially assessed and treated in a local hospital before being sent to the regional trauma center 12 hours later. Due to resource constraints, surgery was delayed for a further 38 hours during which time the patient did not receive any thromboprophylaxis. Simultaneous successful fracture surgery was performed on the left shoulder and right ankle, but the patient desaturated acutely after the tourniquet on the right lower limb was released. He became hypotensive and required cardiac massage and inotropic support. A trans-esophageal echocardiogram was performed in the operating room and a large clot was found in the right atrium. The patient underwent immediate open cardiac surgery to remove the clot, but continued complications resulted in an intraoperative stroke and brain death. He eventually succumbed to complications 3 days later.

Relevant anatomy

Venous thromboembolism (VTE) is a significant complication of major orthopedic surgery, and can manifest as deep venous thrombosis (DVT) or pulmonary embolism (PE). DVT typically occurs in the lower extremities, with distal

DVT involving the deep calf veins, and proximal DVT defined as thrombosis at or above the popliteal vein. PE results when a piece of thrombus is detached from a vein wall and lodges within the pulmonary arteries. This is the most serious and life-threatening complication of DVT.

Importance of the problem

The global incidence of VTE is unknown, because of its silent nature in asymptomatic patients, as well as significant differences in incidence depending on race/ethnicity. However, in studies involving predominantly white populations, the incidence of first-time, symptomatic VTE, standardized for age and sex to the United States population, ranged from 71 to 117 cases per 100,000 population.¹⁻⁵ This incidence rate cannot be extrapolated to nonwhites because of the 2.5-4-fold lowered risk in Asians/Pacific Islanders and Hispanics, and the slightly higher risk in African-Americans.⁶⁻⁸ Clinical studies (that do not include autopsy data) report the incidence of clinically diagnosed DVT to be approximately twice that of PE.^{1,9} When autopsy data is included, studies generally report a higher proportion of PE (~55% PE, 45% DVT), possibly due to the detection of asymptomatic cases of PE at autopsy.^{2,10} Proximal extension of symptomatic calf vein thrombosis occurs in 40 to 50% of cases,¹¹ with an estimated 30% of these cases resulting in fatal PE.^{2,12}

Almost all hospitalized patients have at least one risk factor for VTE, with 40% having three or more risk factors.^{12–16} The incidence of hospital-acquired DVT is approximately 40–60% following major orthopedic surgery.¹⁷ In American acute care hospitals, VTE is the second most common medical complication, the second most common cause of prolonged length of stay, and the third most common cause of excess charges.¹⁸ PE is the most common preventable cause of hospital death.¹⁹ With an estimated 1 million individuals affected each year by symptomatic VTE, the management of VTE incurs a significant healthcare cost of approximately \$1.5 billion/year.²⁰ Moreover, the burden of VTE extends beyond the initial event to include long-term complications like recurrent VTE, post-thrombotic syndrome, and chronic pulmonary hypertension.

Top ten questions

Diagnosis

1. What is the diagnostic modality of choice to detect DVT?

Therapy

2. Which patients require thromboprophylaxis?
3. Which orthopedic procedures require thromboprophylaxis?
4. Are mechanical thromboprophylactic measures effective?
5. What is the role of inferior vena caval filters?
6. What is the ideal anticoagulant agent?
7. What about aspirin or warfarin?
8. When should anticoagulant treatment be initiated?
9. What should the duration of anticoagulant treatment be?

Harm

10. What is the risk of bleeding with anticoagulants?

Question 1: What is the diagnostic modality of choice to detect DVT?

Relevance

The basis of the diagnosis of DVT or PE has evolved from invasive to noninvasive tests over the past 15 years. Ultrasonography (US) has replaced venography for the diagnosis of deep vein thrombosis, and CT pulmonary angiography has replaced pulmonary angiography and ventilation/perfusion (V/Q) lung scans for detection of PE. Recent evidence also supports the use of clinical prediction rules and D-dimer assays for assessing pretest probability of DVT or PE before ordering more definitive tests.

Current opinion

Venography remains the gold standard for DVT diagnosis, whereas spiral CT angiography is now the diagnostic tool of choice for PE. The need for such definitive testing can be reduced by using clinical prediction rules and D-dimer assays.

Finding the evidence

- Cochrane Database, with keywords “diagnosis” and “venous thromboembolism,” “pulmonary embolism,” or “deep vein thrombosis”
- PubMed clinical queries search: “diagnosis” and “venous thromboembolism,” “pulmonary embolism,” or “deep vein thrombosis”
- PubMed sensitivity search using keywords “ultrasonography,” “D-dimer,” “clinical predictor rule,” “helical CT” with “deep vein thrombosis” and “pulmonary embolism”

Quality of the evidence

Level II

- 3 systematic reviews/meta-analyses of cohort studies
- 21 cohort studies

Findings

Clinical prediction rules combined with rapid D-dimer assays In a systematic review of 12 studies (N = 5431 patients),^{21–33} outpatients who had a low clinical probability of DVT using the Wells clinical prediction rule (Table 8.1)³⁴ and a normal D-dimer assay (using the less sensitive SimpliRED assay) had a 3 month VTE incidence of 0.5% (95% CI 0.07–1.1%). When a highly sensitive D-dimer assay was used, the 3 month incidence of VTE was 0.4% (95% CI 0.04–1.1%) among patients with low or moderate clinical probability and a normal D-dimer assay.

Ultrasonography for DVT A meta-analysis of 100 cohort studies (N = 10323 patients)³⁵ compared US to venography in patients with suspected DVT. Duplex US (combined compression and color Doppler US) had pooled sensitivity of 96.5% (95% CI 95.1–97.6) for proximal DVT and 71.2% (95% CI 64.6–77.2) for distal DVT, and specificity of 94.0% (95% CI 92.8–95.1). Compression US alone had pooled sensitivity of 93.8% (95% CI 92.0–95.3%) for proximal DVT, 56.8% (95% CI 49.0–66.4) for distal DVT and specificity of 97.8% (95% CI 97.0–98.4).

Spiral CT angiography for PE A meta-analysis of 9 studies (N = 520 patients)^{36–45} reported a pooled sensitivity for single- or double-row helical CT of 86.0% (95% CI 80.2–92.1%), and specificity of 93.7% (95% CI 91.1–96.3%). The reliability of multislice CT angiography may be enhanced by clinical assessment (pretest probability) and CT venography, but this has yet to be borne out in large prospective trials.

Table 8.1 Wells prediction rule for deep venous thrombosis: clinical evaluation table for predicting pretest probability of deep vein thrombosis

Clinical characteristic	Score
Active cancer (treatment ongoing, within previous 6 months or palliative)	1
Paralysis, paresis or recent plaster immobilization of the lower extremities	1
Recently bedridden >3 days, or major surgery within 12 weeks requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling 3 cm larger than asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Alternative diagnosis at least as likely as deep venous thrombosis	-2

Note: A score of 3 or higher indicates a high probability of deep vein thrombosis; 1 or 2, a moderate probability; and 0 or lower, a low probability. In patients with symptoms in both legs, the more symptomatic leg is used.

Recommendations

- The use of a D-dimer assay combined with a clinical prediction rule has a very high negative predictive value. Less sensitive D-dimer assays can be used to exclude VTE in patients with low clinical probability of VTE, while more sensitive assays can be applied to patients with low or moderate probability of VTE. D-dimer assays have no role in patients with high probability of VTE [overall quality: moderate]
- Ultrasonography has high sensitivity for proximal DVT, modest sensitivity for distal DVT and high specificity for all locations. Optimal sensitivity, particularly for distal DVT, is achieved by using duplex or triplex US, while compression US alone has optimal specificity for proximal DVT. Ultrasonography also has other benefits including wide availability, noninvasiveness and the ability to exclude alternative diagnoses. Despite this, venography has higher sensitivity for detecting distal DVT and remains the gold standard [overall quality: moderate]
- With modern, multidetector row CT scanners, the sensitivity and specificity of spiral CTs are approaching the gold standard set by the pulmonary angiogram, and many consider CT angiograms to be the new gold standard. Despite the apparent lack of sensitivity, it is safe to withhold anti-

Table 8.2 Risk factors for venous thromboembolism

Surgery
Trauma (major trauma or lower-extremity injury)
Immobility, lower-extremity paresis
Cancer (active or occult)

Acute medical illness
Inflammatory bowel disease
Nephrotic syndrome
Myeloproliferative disorders
Paroxysmal nocturnal hemoglobinuria
Obesity
Central venous catheterization
Inherited or acquired thrombophilia (activated protein C resistance, antithrombin III deficiency, protein C/S deficiency, heparin cofactor II deficiency, factor V Leiden mutation, prothrombin mutation 20210 ga, hyperhomocysteinemia, lupus anticoagulant, anticardiolipin antibodies)

coagulation after a negative good-quality CT scan [overall quality: moderate]

Question 2: Which patients require thromboprophylaxis?

Relevance

Every patient undergoing surgery should be stratified for VTE risk to assist in the surgeon's decision-making process. There are several approaches to doing this: one is to determine the VTE risk in each patient based on predisposing factors (Table 8.2).¹⁷ Risk assessment models for DVT have been devised for medical and surgical patients.⁴⁶ A second approach is to assign patients to one of four VTE risk levels based on several factors (Table 8.3).⁴⁶ A final approach involves group-specific thromboprophylaxis as recommended by the American College of Chest Physicians (Table 8.4).⁴⁷

Current opinion

Current risk assessment models are not comprehensive and have not been validated in orthopedic surgery. Controversy exists as to whether all the commonly cited risk factors are relevant for postoperative VTE.

Table 8.3 Stratification of venous thromboembolism risk level

Low	Moderate	High	Highest
Uncomplicated minor surgery in patients <40 years old	Surgery in patients 40–60 years old without risk factors	Major surgery in patients >60 years old without risk factors	Major surgery in patients >60 years old
No risk factors	Major surgery in patients <40 years old and no risk factors Minor surgery in any age group with risk factors	Major surgery in patients >40 years old with risk factors	<u>With:</u> Previous VTE Malignancy Orthopedic surgery Thrombophilia Stroke/spinal injury Hip fracture

Table 8.4 Group-specific stratification of thromboembolism risk level

Levels of risk	Approximate DVT risk without thromboprophylaxis (%)	Suggested thromboprophylaxis options
Low risk Minor surgery in mobile patients Medical patients who are fully mobile	<10	No specific thromboprophylaxis Early and aggressive ambulation
Moderate risk Most general, open gynaecologic or urologic surgery patients Medical patients, bed rest or sick Moderate VTE risk plus high bleeding risk	10–40 Openmirrors.com	LMWH (at recommended doses), LDUH bid or tid, fondaparinux Mechanical thromboprophylaxis
High risk Hip or knee arthroplasty Hip fracture surgery Major trauma, spinal cord injury High VTE risk plus high bleeding risk	40–80	LMWH (at recommended doses), fondaparinux, oral vitamin K antagonist (INR 2–3) Mechanical thromboprophylaxis

Finding the evidence

- Cochrane Database, with keywords “risk stratification,” “risk factors,” “risk assessment models” and “venous thromboembolism”
- PubMed sensitivity search using keywords “risk stratification,” “risk factors,” “risk assessment models” and “venous thromboembolism”

Quality of the evidence

Level II

- 1 systematic review/meta-analysis

Findings

Risk assessment models No validated risk assessment models that are specific to orthopedic surgery are currently available.

Validity of common risk factors A systematic review was performed to determine the evidence base behind com-

monly cited risk factors, and found good evidence associating postoperative DVT with increased age, obesity, previous thromboembolism, varicose veins, the oral contraceptive pill, malignancy, factor V Leiden gene mutation, general anesthesia and orthopedic surgery.⁴⁸ There is a paucity of strong evidence, however, with regards to the suggested risk factors of hormone replacement therapy, gender, ethnicity or race, chemotherapy, other thrombophilias, cardiovascular factors, smoking, and blood type.

Recommendation

- A group-specific approach as recommended by the ACCP (American College of Chest Physicians) is the best approach to VTE risk stratification in patients. Currently, there is very little evidence recommending individualized risk factor assessment or the relationship of such factors to postoperative VTE risk [overall quality: low]

Question 3: Which orthopedic patients require thromboprophylaxis?

Relevance

It is widely accepted that major orthopedic procedures including hip and knee arthroplasty and hip fracture surgery confer the highest risk for venous thromboembolic events. More controversial are the indications for thromboprophylaxis in spine patients, knee arthroscopy patients, pelvic and acetabular fractures, and isolated lower extremity fractures.

Current opinion

There is a lack of consensus regarding the need for prophylaxis in patients other than those undergoing hip/knee arthroplasty or hip fracture surgery, stemming from the scarcity of evidence currently available.

Finding the evidence

- Cochrane Database, with keywords “venous thromboembolism” and “spinal surgery,” “spinal cord injury,” “arthroscopy,” or “fractures”
- PubMed sensitivity search using keywords “venous thromboembolism” and “spinal surgery,” “spinal cord injury,” “arthroscopy,” or “fractures”

Quality of the evidence

Level I

- 3 systematic reviews/meta-analyses
- 6 randomized trials

Level II

- 1 systematic review of cohort studies
- 1 randomized trials with methodological limitations
- 2 cohort studies

Findings

Spine surgery In a systematic review of 25 cohort studies (N = 9991 patients),⁴⁹ the pooled DVT rate for patients undergoing elective spine surgery without prophylaxis was 2.7% and the PE rate was 0.2%. The DVT/PE rate was 2.7%/0.6% in patients who received prophylaxis with graduated compression stockings, 4.6%/1.1% with pneumatic compression devices, 1.3%/1% with compression devices and compression stockings, 0.6%/0.3% with chemical anticoagulation, and 22%/1% with inferior vena cava (IVC) filters or other methods of prophylaxis.

Spinal cord injury The incidence of DVT in patients with acute spinal cord injury has been reported to be more than 50%, with the incidence of fatal PE estimated to be as high as 5%. In a systematic review of 23 studies examining various interventions for VTE prevention,⁵⁰ the best evidence available (2 RCTs, N = 148 patients),^{51,52} suggests that

low molecular weight heparin (LMWH), in particular enoxaparin, is more effective than standard subcutaneous heparin at reducing venous thromboembolic events. Moreover, the incidence of bleeding complications appears to be less with LMWH.

Knee arthroscopy A meta-analysis of 4 studies (N = 527 patients) included predominantly male patients (age range 31–44 years) undergoing various knee arthroscopic interventions.^{53–57} The relative risk of thrombotic events was 0.16 (95% CI 0.05–0.52) comparing any type of LMWH vs. placebo. All thrombotic events but one (PE in the LMWH group) were distal venous thrombosis. The number needed to benefit was 17. Adverse events were most common in the intervention group than in the control group (relative risk = 2.04, 95% CI 1.21–3.44). The number needed to harm was 20 for any adverse events.

Pelvic/acetabular trauma A systematic review of 11 studies included 1760 patients with pelvic and acetabular fractures.⁵⁸ Most studies were observational designs with minimal control data and quantitative pooling was not possible based on significant study heterogeneity. In one prospective cohort study the proximal DVT rate was 10%, with a symptomatic PE incidence of 5%.⁵⁹ No practical guidelines could be made based on the lack of strong evidence.

Lower extremity trauma In a prospective cohort study examining patients with lower extremity fractures distal to the hip (N = 102 patients),⁶⁰ the overall incidence of DVT was 28% (95% CI 19.9–38.2%), of which only 12% were proximal DVT. Risk of embolization was low. Another randomized controlled trial (N = 238 patients) studied the effect of LMWH on patients with surgically fixed fractures below the knee.⁶¹ The incidence of venographically proven DVT between patients receiving LMWH and placebo was similar (8.7% vs. 12.6%, $p = 0.22$), suggesting that thromboprophylaxis is not necessary for patients with fractures below the knee.

Recommendations

- As the VTE rate after elective spinal surgery is low, anticoagulation as the primary method of prophylaxis cannot be recommended. A combination of graduated compression stockings and intermittent pneumatic compression should suffice [overall quality: moderate]
- Spinal cord injury patients have a high rate of VTE. The best available evidence suggests LMWH as the thromboprophylactic of choice [overall quality: low]
- There is no strong evidence to suggest the routine use of thromboprophylaxis for patients undergoing knee arthroscopy is beneficial or safe [overall quality: low]
- There is inadequate evidence to suggest that any particular thromboprophylaxis regime is superior for patients with pelvic and acetabular fractures. Existing guidelines

recommend the use of LMWH in these high-risk patients [overall quality: low]

- Current available evidence suggests that lower extremity fractures below the knee do not require chemical thromboprophylaxis [overall quality: low]
- Patients with more proximal lower extremity fractures (above the knee) are more likely to develop DVT, and thus prophylaxis is recommended [overall quality: low]

Question 4: Are mechanical thromboprophylactic measures effective?

Relevance

Mechanical compression methods, including graduated compression stockings, intermittent pneumatic compression and foot pumps, are widely available, inexpensive, and have very few contraindications. These measures can be employed as monotherapy in patients with contraindications to anticoagulant therapy, or in conjunction with anticoagulants in higher-risk patients. Evidence regarding the effectiveness of mechanical thromboprophylaxis has been contradictory.

Current opinion

Mechanical measures effectively reduce the risk of venous thromboembolism, and are a useful adjuvant to anticoagulation agents.

Finding the evidence

- Cochrane Database, with keywords “mechanical thromboprophylaxis”
- PubMed clinical queries search: “mechanical thromboprophylaxis”
- PubMed sensitivity search using keywords “mechanical thromboprophylaxis”

Quality of the evidence

Level I

- 3 systematic reviews/meta-analyses
- 12 randomized trials

Level II

- 2 randomized trials with methodological limitations

Findings

Graduated compression stockings Seven studies (N = 1027 patients) reported on the incidence of DVT in a mixed population of surgical and medical patients.⁶²⁻⁶⁹ Patients who were treated with compression stockings developed a lower rate of DVT compared to the control group (relative risk = 0.36, 95% CI 0.26–0.49, $p < 0.00001$).

Intermittent pneumatic compression Three studies (N = 302 patients) reported on the use of cyclical compression

devices in patients undergoing hip fracture surgery.⁷⁰⁻⁷⁴ These devices significantly reduced the incidence of DVT and PE when compared to the control group (relative risk = 0.27, $p = 0.00085$).

Foot pumps Two studies (N = 147 patients) reported on the use of arteriovenous foot impulse systems in patients undergoing hip fracture surgery.^{75,76} These devices significantly reduced the incidence of DVT and PE when compared to the control group (relative risk = 0.20, $p = 0.000068$).

Combined therapy Two studies (N = 1934 patients) reported on the incidence of DVT in high-risk patients.⁷⁷⁻⁷⁹ Patients who were treated with compression modalities and anticoagulants had a significantly lower incidence of DVT compared to patients who were given anticoagulants alone (relative risk = 0.13, 95% CI 0.05–0.35).

Recommendation

- All the various methods of mechanical thromboprophylaxis have been shown to significantly reduce the incidence of DVT, whether provided as monotherapy or in combination with anticoagulant therapy. Judicious use is recommended, especially in patients with contraindications to anticoagulant therapy [Overall Quality: Moderate]

Question 5: What is the role of IVC filters?

Openmirrors.com

Relevance

IVC filters were historically used for patients with proven VTE but developed complications on anticoagulation, had contraindications to systemic anticoagulation, or had recurrent VTE despite adequate anticoagulation. However, these indications have expanded in the last two decades despite the lack of evidence-based guidelines (Table 8.5).^{80,81}

Current opinion

There has been increasing use of IVC filters, particularly with the advent of retrievable filters. Relative indications other than those recommended are not based on any existing clinical evidence.

Finding the evidence

- Cochrane Database, with keywords “inferior vena caval filters”
- PubMed sensitivity search using keywords “inferior vena caval filters”

Quality of the evidence

Level I

- 1 systematic review

Level II

- 1 randomized trial with methodological limitations
- 1 cohort study

Table 8.5 Indications for IVC filter use**Recommended use according to evidence-based guidelines**

Proven VTE with contraindication for anticoagulation
 Proven VTE with complications of anticoagulation treatment
 Recurrent VTE despite anticoagulation treatment (failure of anticoagulation)

Expanded use (not guideline recommended)

Recurrent PE complicated by pulmonary hypertension
 Patients with DVT and limited cardiopulmonary reserve or chronic obstructive pulmonary disease
 Patients with large, free-floating iliofemoral thrombus
 Following thrombectomy, embolectomy, or thrombolysis of DVT
 High-risk trauma patients (head and spinal cord injury, pelvic or lower extremity fractures) with a contraindication for anticoagulation
 High-risk surgical patients with a contraindication for anticoagulation
 Patients with DVT who have cancer, burns, or are pregnant

Contraindications for filter placement

Chronically thrombosed IVC
 Anatomical abnormalities preventing access to the IVC for filter placement

Findings

Permanent IVC filters Only one randomized controlled trial has been published in the literature (n = 400 patients).^{82,83} This study was flawed because it excluded patients with contraindications to anticoagulation or who had failed anticoagulation. It compared patients with permanent filters to a control group without filters, although both groups received anticoagulation concurrently.⁸⁴ At 8 years, the rate of symptomatic PE in the filter group was significantly reduced (hazard ratio = 0.37, 95% CI 0.17–0.79, p = 0.008), although the risk of recurrent DVT was increased with prolonged filter use (hazard ratio = 1.52, 95% CI 1.02–2.27, p = 0.042).

Temporary/retrievable IVC filters One prospective study (n = 47 patients) evaluated the use of temporary or retrievable filters.⁸⁵ Some contraindications to anticoagulation listed in this study include major trauma with pelvic fracture, planned operation, and childbirth. Twelve patients also received filters as a prophylactic measure, without any evidence of VTE. Two patients developed PE during or after filter removal; two filters migrated, requiring repositioning or replacement; and two patients required surgical filter removal due to trapped thrombi.

Recommendation

- There is a distinct lack of clinical evidence guiding the current use of IVC filters. In the absence of evidence, the

current accepted indication for filters remains “the contraindication to anticoagulation.” Clinical judgment should be exercised for the use of temporary or retrievable filters, or use of filters in nonrecommended situations [overall quality: low]

Question 6: What is the ideal anticoagulant agent?**Relevance**

The 2008 ACCP guidelines recommend the use of several anticoagulants for orthopedic surgery.¹⁷ These include low-dose unfractionated heparin (LDUH), LMWH, subcutaneous pentasaccharide fondaparinux, and vitamin K antagonists (VKAs), exemplified by warfarin. The ideal anticoagulant should have high efficacy, safety, low levels of bleeding, rapid onset of action, fixed dosing, and no requirement for therapeutic monitoring. In this section, the evidence for the injectable anticoagulants is presented. Warfarin is discussed in the next section.

Current opinion

LDUH has largely been surpassed by LMWH. The factor Xa inhibitor fondaparinux has even greater thromboprophylactic efficacy, but this is balanced by a higher rate of bleeding events.

Finding the evidence

- Cochrane Database, with keywords “heparin” or “anticoagulant” and “venous thromboembolism”
- PubMed sensitivity search using keywords “heparin” or “anticoagulant” and “venous thromboembolism”
- Preference was given to orthopedically relevant studies

Quality of the evidence*Level I*

- 1 systematic review/meta-analyse
- 21 randomized trials

Level II

- 1 cohort study

Findings

Efficacy of injectable anticoagulants A retrospective cohort study analysed 144,806 patients undergoing major orthopedic surgery using dalteparin, enoxaparin, fondaparinux, and LDUH.⁸⁶ VTE was less frequent in the fondaparinux group (1.5%). Patients receiving LDUH were most likely to have a VTE (odds ratio = 1.98, 95% CI 1.67–2.34, p < 0.0001), while patients in the enoxaparin and dalteparin groups were 40% (odds ratio = 1.39, 95% CI 1.19–1.62, p < 0.0001) and 20% (odds ratio = 1.22, 95% CI 1.01–1.46, p = 0.0370) more likely to have VTE than the fondaparinux group.

Bleeding rates In a meta-analysis of 21 studies (N = 20,523 patients) comparing the use of warfarin, unfractionated heparin (UFH), LMWH, and fondaparinux in patients undergoing major orthopedic surgery, LMWH resulted in fewer major bleeding episodes than UFH (relative risk = 1.52, 95% CI 1.04–2.23) and fondaparinux (relative risk = 1.52, 95% CI 1.11–2.09) but more than warfarin (relative risk = 0.59, 95% CI 0.44–0.80).^{87–109}

Cost In the same large cohort study mentioned above, patients who received fondaparinux had significantly lower adjusted mean costs than patients on LMWH or LDUH ($p < 0.01$), compared to LDUH which had the highest adjusted mean cost per patient.⁸⁶ This takes into account that patients who had an episode of VTE or major bleeding would incur greater costs.

Recommendations

- LMWH remains the best anticoagulation agent currently available for thromboprophylaxis in orthopedic patients. It is effective, safe, and relatively inexpensive [overall quality: moderate]
- Fondaparinux has the strongest thromboprophylactic efficacy and overall costs for treatment per patient is lower. However, the significantly higher risk of bleeding compared to LMWH limits fondaparinux use in postoperative orthopedic patients [overall quality: high]

Question 7: What about aspirin or warfarin?

Relevance

As a VKA, warfarin has been the only oral anticoagulant available for the past 65 years, and has historically been used for thromboprophylaxis in total hip arthroplasty patients. However, warfarin has numerous limitations, including its narrow therapeutic window, slow onset of action, multiple food and drug interactions, and genetic metabolic variations.¹¹⁰ Newer oral anticoagulants are being developed that are free from warfarin's drawbacks.

There has also been much interest in aspirin as a prophylactic agent in VTE, especially in its potential for use as an oral agent in extended-duration, out-of-hospital prophylaxis. It is believed that aspirin's overwhelming benefit in arterial occlusive disease may similarly have an effect on venous thrombus formation.

Current opinion

Warfarin remains a viable alternative to heparin in VTE prophylaxis. Aspirin, although effective, does not have an established role in VTE prophylaxis and its routine use is not recommended.

Finding the evidence

- Cochrane Database, with keywords "warfarin" or "aspirin" and "thromboprophylaxis" or "venous thromboembolism"

- PubMed sensitivity search using keywords "warfarin" or "aspirin" and "thromboprophylaxis" or "venous thromboembolism"

Quality of the evidence

Level I

- 1 systematic review/meta-analysis
- 21 randomized trials

Findings

Warfarin A meta-analysis of 20 randomized controlled trials (N = 6,900 patients) assessed LMWH, UFH, and warfarin as prophylaxis in orthopedic surgery patients.¹¹¹ The relative risk of DVT for LMWH vs. warfarin was 0.78 (95% CI 0.69–0.87, $p < 0.05$). The relative risk of PE for LMWH vs. warfarin was 1.00 (95% CI 0.10–9.94). Significantly more minor bleeding was found with LMWH vs. warfarin (relative risk = 3.28, 95% CI 2.21–4.70, $p < 0.05$).

Aspirin In a large randomized controlled trial involving 13,356 patients undergoing hip fracture surgery, low-dose aspirin was administered preoperatively and continued for 35 days after surgery.¹¹² Aspirin produced proportional reductions in pulmonary embolism of 43% (95% CI 18–60, $p = 0.002$) and in symptomatic DVT of 29% (95% CI 3–48, $p = 0.03$). In the same study, similar reduced rates of VTE were seen in 4088 patients who underwent elective hip arthroplasty. However, excess episodes of postoperative transfused bleeding were noted with its use ($p = 0.04$).

Recommendations

- Warfarin is less effective than LMWH in the prevention of VTE. However, it remains a feasible option because of its cost-benefit ratio and relative ease of administration [overall quality: moderate]
- While there is good evidence that aspirin does effectively reduce VTE, its use as a monotherapy agent in VTE prophylaxis is not clearly defined. First-line agents like LMWH and warfarin have suggested superior efficacy and safety profiles [overall quality: moderate]
- Newer oral anticoagulants that target either thrombin or factor Xa have the potential to surpass warfarin as the oral anticoagulant of choice. Drugs like dabigatran etexilate, rivaroxaban, and apixaban are currently undergoing phase III clinical trials and/or seeking US Food and Drug Administration approval for use in the orthopedic population [overall quality: low]

Question 8: When should anticoagulant treatment be initiated?

Relevance

Much controversy exists regarding the optimal time to initiate thromboprophylaxis. On one hand, the belief that

venous thrombi are formed perioperatively¹¹³ has directed the European practice of providing antithrombotic therapy preoperatively to maximize antithrombotic effectiveness. On the other hand, the North American practice is to start anticoagulation postoperatively to allow hemostasis of the wound and reduce the risk of bleeding complications.¹¹⁴ In addition, the administration of preoperative anticoagulation may preclude the use of neuraxial anesthesia for fear of developing spinal hematomas with catastrophic consequences.

Current opinion

Current opinion suggests that there is no significant difference in VTE incidence whether thromboprophylaxis is initiated pre- or postoperatively.

Finding the evidence

- Cochrane Database, with keywords “timing” and “anticoagulation” or “thromboprophylaxis”
- PubMed sensitivity search using keywords “timing” and “anticoagulation” or “thromboprophylaxis”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses
- 7 randomized trials

Findings

No large-scale randomized controlled trials exist which address the relative efficacy and safety of preoperative vs. postoperative initiation of VTE prophylaxis

Antithrombotic efficacy Six studies (N = 987 patients) evaluated the use of enoxaparin in patients undergoing elective hip replacement.^{115–121} When comparing the preoperative regimen (initiated 10–12 hours before surgery) to the postoperative regimen (initiated within 24 hours after surgery), there was no significant difference in the incidence of all DVT (10% vs. 15.3%, $p = 0.02$, 95% CI -9.58 to -1.06) or proximal vein thrombosis ($p = 0.38$, 95% CI -1.67 to 4.71).

Bleeding risk Six studies (N = 1219) compared the incidence of major and minor bleeding episodes between the preoperative and postoperative regimens in patients undergoing hip arthroplasty using enoxaparin prophylaxis.^{115–121} The frequency of major bleeding was surprisingly less for the preoperative group than for the postoperative group (0.9% vs. 3.5%, $p = 0.01$, 95% CI -4.24 to -1.10).

Perioperative regimens One study (N = 1501 patients) randomized patients undergoing hip arthroplasty into three groups: dalteparin within 2 hours before surgery, dalteparin at least 4 hours postsurgery, and oral anticoagulation with warfarin.¹²² Both dalteparin regimens administered in this

“close proximity” or “just-in-time” fashion showed significant reduction in DVT rates compared to the warfarin group ($p < 0.001$, relative risk reduction = 50%). However, increased major bleeding was observed for the preoperative dalteparin group compared to the warfarin group ($p = 0.01$).

Recommendations

- Thromboprophylaxis started 12 hours before surgery has not been shown to be more effective than prophylaxis initiated 12–24 hours after surgery [overall quality: moderate]
- Close-proximity perioperative regimens may provide the optimal effectiveness in thromboprophylaxis, but this has to be balanced against a higher risk for bleeding complications [overall quality: moderate]

Question 9: What should the duration of anticoagulant treatment be?

Relevance

Thromboprophylaxis is commonly administered for the duration of the hospital stay, which can range from 4 to 14 days. However, recent evidence shows that patients are still at risk of developing symptomatic thromboembolism after discharge from hospital. New guidelines now recommend the use of extended, out-of-hospital prophylaxis but this has to be balanced against the cost-effectiveness and risk-benefit ratio of such regimens.

Current opinion

The optimal duration of prophylaxis after major orthopedic surgery is still controversial.

Finding the evidence

- Cochrane Database, with keywords “extended” and “thromboprophylaxis”
- PubMed sensitivity search using keywords “extended” or “out-of-hospital” and “thromboprophylaxis”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses
- 9 randomized trials

Findings

Efficacy of extended-duration prophylaxis In a meta-analysis of nine randomized controlled trials (N = 3999 patients), it was found that extended-duration prophylaxis for 30–42 days with LMWH or UFH reduced the rate of symptomatic VTE (1.3% vs. 3.3%, odds ratio = 0.38, 95% CI 0.24–0.61).^{123–132} Risk reduction was greater in patients undergoing hip arthroplasty (1.4% vs. 4.3%, odds ratio = 0.33, 95% CI 0.19–0.56) compared with knee arthroplasty (1.0% vs. 1.4%, odds ratio = 0.74, 95% CI 0.26–2.15).

Safety of extended-duration prophylaxis In the same meta-analysis, there was no increase in major bleeding but extended-duration prophylaxis was associated with excessive minor bleeding (3.7% vs. 2.5%, odds ratio 1.56, 95% CI 1.08–2.26, number needed to harm = 83).

Cost-effectiveness of extended-duration prophylaxis In a meta-analysis of eight studies using LMWH and warfarin prophylaxis for hip arthroplasty patients, primary economic analysis found that the cost-effectiveness of LMWH relative to no further prophylaxis (\$106,454 per quality-adjusted life year gained) was unattractive, with the primary cost driver being the proportion of patients who required home nursing services for drug injection.¹³³

Recommendations

- Extended-duration prophylaxis is an effective and safe means to reduce the rate of symptomatic out-of-hospital venous thromboembolic events in arthroplasty patients, although knee arthroplasty patients may benefit less from it [overall quality: moderate]
- Cost-effectiveness of routine out-of-hospital prophylaxis with LMWH remains an issue. Less costly alternatives should be considered and evaluated [overall quality: moderate]

Question 10: What is the risk of bleeding with anticoagulants?

Openmirrors.com Recommendation

Relevance

Many orthopedic surgeons are averse to thromboprophylaxis because of the perceived risk of postoperative bleeding when using anticoagulant agents. Bleeding, when it does occur, is more acute than VTE itself, and potentially compromises the result of the procedure. This misperception remains one of the major barriers to routine thromboprophylaxis within the orthopedic community.

Current opinion

There is no good evidence that anticoagulant agents produce significant postoperative bleeding, or that it compromises operative outcomes.

Finding the evidence

- Cochrane Database, with keywords “bleeding risk” or “postoperative bleeding” and “anticoagulation” or “thromboprophylaxis”
- PubMed sensitivity search using keywords “postoperative bleeding” and “anticoagulation” or “thromboprophylaxis”
- Preference was given to orthopedically relevant studies

Quality of the evidence

Level I

- 1 systematic review/meta-analysis
- 4 randomized trials

Level II

- 1 randomized trials with methodological limitations

Findings

Wound hematoma Two studies (N = 81 patients) reported on the postoperative development of wound hematomas.^{70–72,134} Patients who were given perioperative heparin (LDUH or LMWH) thromboprophylaxis for hip fracture surgery did not have a higher risk of developing wound hematomas when compared to a placebo group (relative risk = 1.10, p = 0.90).

Blood loss Two studies (N = 90 patients) reported on estimated blood loss after hip fracture surgery and did not find any significantly increased blood loss after perioperative heparin (LDUH or LMWH) thromboprophylaxis (weighted mean difference = 47.21 mL, p = 0.25).^{70,134,135}

Transfusion requirements One study (N = 31 patients)^{71,72} reported on postoperative transfusion amount, and three studies (N = 249)^{71,72,136,137} reported the number of patients receiving transfusion after hip fracture surgery. There was no difference in transfusion amount (weighted mean difference = 83.82 mL, p = 0.54), or number of patients requiring transfusions between the heparin group and the placebo group (relative risk = 0.90, p = 0.48)

- The use of anticoagulants for thromboprophylaxis does not increase the risk of blood loss, wound hematoma formation, or transfusion requirements. The surgeon should realize that postoperative bleeding is a multifactorial problem and careful hemostatic techniques should be observed [overall quality: moderate]

Summary of recommendations

- The use of a D-dimer assay combined with a clinical prediction rule has a very high negative predictive value. Less sensitive D-dimer assays can be used to exclude VTE in patients with low clinical probability of VTE, while more sensitive assays can be applied to patients with low or moderate probability of VTE. D-dimer assays have no role in patients with high probability of VTE
- Ultrasonography has high sensitivity for proximal DVT, modest sensitivity for distal DVT and high specificity for all locations. Optimal sensitivity, particularly for distal DVT, is achieved by using duplex or triplex US, while compression US alone has optimal specificity. Ultrasonography also has other benefits of wide availability, noninvasiveness and the ability to exclude alternative diagnoses. Despite this, venography has higher sensitivity for detecting distal DVT and remains the gold standard

- With modern, multidetector row CT scanners, the sensitivity and specificity of spiral CTs are approaching the gold standard set by the pulmonary angiogram, and many consider CT angiograms to be the new gold standard. Despite the apparent lack of sensitivity, it is safe to withhold anticoagulation after a negative good-quality CT scan
- A group-specific approach as recommended by the ACCP is the best approach to VTE risk stratification in patients. There is very little evidence behind individualized risk factor assessment or the relationship of such factors to postoperative VTE
- As the VTE rate after elective spinal surgery is low, anticoagulation as the primary method of prophylaxis cannot be recommended. A combination of graduated compression stockings and intermittent pneumatic compression should suffice
- Spinal cord injury patients are associated with a high rate of VTE. The best available evidence suggests LMWH as the thromboprophylactic of choice
- There is no strong evidence to suggest the routine use of thromboprophylaxis for patients undergoing knee arthroscopy is beneficial or safe
- There is inadequate evidence to suggest that any particular thromboprophylaxis regime is superior for patients with pelvic and acetabular fractures. Existing guidelines recommend the use of LMWH in these high-risk patients
- Current available evidence suggests that lower extremity fractures below the knee do not require chemical thromboprophylaxis
- Patients with more proximal lower extremity fractures (above the knee) are more likely to develop DVT, although this tends to be below the popliteal fossa, with less likelihood of embolization
- All the various methods of mechanical thromboprophylaxis have been shown to significantly reduce the incidence of DVT, whether provided as monotherapy or in combination with anticoagulant therapy. Judicious use is recommended, especially in patients with contraindications to anticoagulant therapy
- There is a distinct lack of clinical evidence guiding the current use of IVC filters. In the absence of evidence, the current accepted indications for filters remain as failure of, or contraindication to anticoagulation. Clinical judgment should be exercised for the use of temporary or retrievable filters, or use of filters in nonrecommended situations
- LMWH remains the best anticoagulation agent currently available for thromboprophylaxis in orthopedic patients. It is effective, safe, and relatively inexpensive
- Fondaparinux has the strongest thromboprophylactic efficacy and overall costs for treatment per patient is lower. However, the significantly higher risk of bleeding compared to LMWH limits fondaparinux use in postoperative orthopedic patients

- Warfarin is less effective than LMWH in the prevention of VTE. However it remains a feasible option because of its cost-benefit ratio and relative ease of administration
- While there is good evidence that aspirin does effectively reduce VTE, its use as a monotherapy agent in VTE prophylaxis is not recommended. First-line agents like LMWH and warfarin have suggested superior efficacy and safety profiles
- Newer oral anticoagulants that target either thrombin or factor Xa have the potential to surpass warfarin as the oral anticoagulant of choice. Drugs such as dabigatran etexilate, rivaroxaban, and apixaban are currently undergoing phase III clinical trials and/or seeking US Food and Drug Administration approval for use in the orthopedic population
- Thromboprophylaxis started 12 hours before surgery has not been shown to be more effective than prophylaxis initiated 12–24 hours after surgery
- Close-proximity perioperative regimens may provide the optimal effectiveness in thromboprophylaxis, but this has to be balanced against a higher risk for bleeding complications
- Extended-duration prophylaxis is an effective and safe means to reduce the rate of symptomatic out-of-hospital VTE events in arthroplasty patients, although knee arthroplasty patients may benefit less from it
- Cost-effectiveness of routine out-of-hospital prophylaxis with LMWH remains an issue. Less costly alternatives should be considered and evaluated
- The use of anticoagulants for thromboprophylaxis does not increase the risk of blood loss, wound hematoma formation, or transfusion requirements. The surgeon should realize that postoperative bleeding is a multifactorial problem and careful hemostatic techniques should be observed

Blood Transfusion

David W. Sanders¹ and Jeffrey L. Carson²

¹University of Western Ontario, London, ON, Canada

²University of Medicine and Dentistry of New Jersey, New Brunswick, NJ, USA

Case scenario

An 84 year old woman is admitted to hospital with an intertrochanteric hip fracture. Her medical history is significant for coronary artery disease, hypertension, and chronic renal failure. Surgery is performed using an intramedullary device for this independent, active community ambulator. On the second postoperative day, the patient is having difficulty ambulating due to fatigue. Vital signs are stable; Blood pressure is 115/75; ECG is unchanged. Postoperative blood work reveals a hemoglobin concentration of 8.2g/dL.

Relevant physiology

The hemoglobin molecule includes four globin components, each of which includes an oxygen-binding heme ring. As the partial pressure of oxygen increases, the oxygen-binding affinity of hemoglobin increases. This allows oxygen loading in the lung and unloading in the tissues. Hypoxia occurs when oxygen delivery is insufficient to meet metabolic needs.

The physiologic reserves of the healthy human body are substantial. Oxygen delivery is related to hemoglobin concentration, hemoglobin saturation, and cardiac output, all of which adapt to an increasing need for oxygen delivery. In health, a decrease in hemoglobin to 5g/dL decreases

oxygen delivery to the critical threshold, at which point oxygen delivery equals consumption.

Adaptive mechanisms that occur to protect tissue oxygenation in anemia include a shift in the oxyhemoglobin dissociation curve to increase oxygen delivery, due to 2,3-diphosphoglycerate or decreased pH; increases in cardiac output; increased sympathetic tone to protect the coronary and cerebral circulation; and reduced blood viscosity. In the microcirculation, capillary recruitment and flow increases and oxygen extraction is increased.

The ability of the body to adapt to anemia relies upon healthy adaptive mechanisms. Age, coincident heart, lung, and cerebrovascular disease, severe illness, and certain medications (beta-blockers) decrease the adaptive response. The heart is most prone to adverse events as the myocardium requires high oxygen extraction, and coronary perfusion is restricted during systole due to left ventricular pressures.

Importance of the problem

Seventy-five million units of blood are collected worldwide annually. Transfusion is one of the only therapeutic interventions available to increase oxygen delivery to tissues. However, transfusion is expensive and not without risk. The cost of a unit of allogeneic blood ranges from US\$185 to US\$250, plus costs related to storage and administration. Blood transfusion safety is continuously improving, but

adverse events including transfusion-related acute lung injury (TRALI), cardiac overload, hemolysis, and infection do occur.

Top five questions

Diagnosis

1. How common are anemia and blood transfusion in orthopedic surgery, and what strategies reduce transfusion rate?

Therapy

2. What is an appropriate hemoglobin level to act as a transfusion trigger?

Prognosis

3. What is the effect of anemia on morbidity and mortality?
4. What is the effect of anemia and blood transfusion on function?

Harm

5. What are the risks of blood transfusion?

Question 1: How common are anemia and blood transfusion in orthopedic surgery, and what strategies reduce transfusion rate?

Case clarification

The patient had a hemoglobin of 11.2 g/dL on presentation to the Emergency Department. A repeat blood count done in the recovery room indicated a hemoglobin level of 10.4. On the second postoperative day, the hemoglobin level has dropped to 8.4 g/dL. Her family is concerned.

Relevance

Anemia is common in perioperative and elderly patients. In some studies, anemia is associated with increased short-term mortality.

Current opinion

Perioperative anemia follows major orthopedic interventions such as spinal surgery, hip fracture repair, and total joint arthroplasty. Assessing for anemia is an essential part of good clinical care.

Finding the evidence

- Cochrane Database, with search term “perioperative anemia”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “blood transfusion incidence” AND “orthopedic surgery”

Quality of the evidence

Level I

- 3 systematic reviews/meta-analyses
- 4 randomized controlled trials

Level II

- 8 randomized trials with methodological limitations

Findings

Orthopedic procedures associated with a high rate of transfusion include major spinal surgery, total joint arthroplasty, and hip fracture surgery. Transfusion rates for these procedures exceed 80% of patients in some studies. Variables such as closed suction wound drainage devices, antifibrinolytic therapy, autologous blood donation, and use of erythropoietin may affect transfusion rates.

A recent Cochrane Database meta-analysis compared transfusion rates with and without closed suction wound drainage. For total hip replacement, transfusion was required in 168/417 (40.3%) patients with drains vs. 132/421 (31.4%) in patients without drains (RR 1.28, 95% CI 1.07–1.52). Similar results were reported for total knee replacement.¹

Antifibrinolytic therapy is still investigational, but may reduce transfusion rates. A systematic review of randomized trials describing perioperative tranexamic acid, epsilon-aminocaproic acid, or aprotinin administration reported that patients receiving antifibrinolytic agents had reduced transfusion need (RR 0.52; 95% CI 0.42–0.64; $p < 0.00001$).² However, aprotinin is associated with increased mortality in cardiac surgery, and some antifibrinolytics raise concerns related to risk of thromboembolic events.

Red blood cell salvage and autologous blood donation reduce rates of allogeneic blood transfusion. Meta-analysis of clinical trials confirm a 40% reduction of allogeneic blood transfusion using autologous blood.³ However, autologous predonation is associated with a 30% increased blood transfusion rate (allogeneic or autologous). In one randomized controlled trial of nonanemic patients (hemoglobin >12.0 g/dL), autologous blood donation was associated with an additional cost of \$758 per patient with no alteration in allogeneic transfusion rate.⁴

Preoperative erythropoietin administration may decrease the need for allogeneic transfusion in elective procedures. In a randomized controlled trial of 200 patients undergoing major orthopedic procedures, allogeneic transfusion rates were 54% in patients treated with placebo compared to 17% in patients treated with high dose erythropoietin ($p < 0.001$).⁵ Perioperative erythropoietin can minimize

Openmirrors.com

the need for allogeneic red blood cell transfusion but is very expensive.

Recommendations

- Closed suction drainage devices increase transfusion requirements after orthopedic surgery [overall quality: high]
- Antifibrinolytic drugs hold promise, but concerns surrounding adverse side effects limit routine use [overall quality: moderate]
- Autologous blood predonation and perioperative erythropoietin may both reduce the need for allogeneic transfusion, but cost concerns remain [overall quality: moderate]

Question 2. What is an appropriate hemoglobin level to act as a transfusion trigger?

Case clarification

The patient now has a hemoglobin level of 8.2 g/dL and has mild symptoms of anemia (fatigue). She has a history of coronary artery disease, hypertension, and renal failure, and may be at risk of complications such as myocardial infarction as a result of her anemia.

Relevance

The decision to transfuse is based upon clinical findings and hemoglobin level. The specific hemoglobin level that should be used to trigger transfusion is controversial.

Current opinion

Healthy patients can tolerate anemia. Older patients, and those with cardiac disease or risk factors, may be less tolerant. However, the hemoglobin level which determines a positive risk/benefit balance for transfusion is unknown.

Finding the evidence

- Cochrane Database, with search term “transfusion trigger”
- PubMed search for randomized trials/systematic reviews using terms “transfusion trigger”

Quality of the evidence

Level I

- 1 meta-analysis of randomized trials
- 10 randomized controlled trials

Findings

Ten randomized trials compares transfusion thresholds. Three trials included over 100 patients each. The Transfusion Requirements In Critical Care (TRICC) trial⁶ randomly assigned over 800 ICU patients to a restrictive transfusion threshold of 7 g/dL or a liberal transfusion threshold of 10 g/dL. The number of units transfused was lower in the restrictive group (2.6 vs 5.6 units). Overall 30 day mortality did not differ between the groups. However, mortality was lower in the restrictive group for patients under 55 years of age ($p < 0.02$) and less ill patients ($p < 0.02$). In another

trial, 127 knee arthroplasty patients were assigned to receive autologous blood immediately after surgery (liberal group) compared to receiving autologous blood only for a hemoglobin value less than 9 g/dL.⁷ Transfusion rates were 100% vs. 27%, with no differences in outcome. Eighty-four patients with hip fractures were randomized to a transfusion threshold of 10 g/dL, vs. transfusion for symptoms or hemoglobin of less than 8 g/dL.⁸ There were no differences in outcomes including functional recovery, morbidity, and mortality. In a meta-analysis of trials, use of a restrictive transfusion threshold decreased transfusion rate by 42% with no negative effects on mortality, cardiac events, or length of hospital stay.⁹

Nonrandomized trials offer additional evidence. A study of 1958 patients who refused blood transfusion suggested that anemia is substantially less well tolerated in the presence of cardiovascular disease.¹⁰ The FOCUS trial studied over 2000 patients with hip fracture, all of whom have coexistent cardiovascular disease or risk factors. Morbidity, mortality, and functional outcome were compared between patients treated with a liberal transfusion threshold (10 g/dL) or a restrictive threshold (symptoms of anemia or 8 g/dL). This study will provide the best current evidence related to transfusion threshold.¹¹

Recommendation

- Transfusion thresholds are controversial, and may vary dependent upon comorbidities such as cardiac disease. Current evidence supports a restrictive transfusion threshold of 7.0–8.0 g/dL for healthy patients [overall quality: high].

Question 3. What is the effect of anemia on morbidity and mortality?

Case clarification

The patient has cardiovascular disease. Moderate anemia could be a risk for cardiac events and even mortality.

Relevance

Patients with known cardiac disease may be the most likely to benefit from blood transfusion. Although controversial, a more liberal transfusion threshold may benefit these individuals.

Current opinion

This issue is highly controversial, with advocates for and against transfusion in this population.

Finding the evidence

- Cochrane Database, with search terms “transfusion and mortality”
- PubMed search of clinical trials, randomized trials, and systematic reviews using keywords “erythrocyte transfusion” and “mortality”

Quality of the evidence*Level I*

- 2 meta-analyses of controlled trials
- 1 systematic review
- 8 randomized trials (including subanalyses)

Findings

Data supporting the use of red blood cell transfusion in moderate anemia remains limited, even in the presence of cardiovascular disease. Meta-analyses of transfusion thresholds¹² note no improvement in mortality with transfusion. One randomized trial tested the rates of silent myocardial ischemia related to hemoglobin concentration in a population of patients undergoing arthroplasty. Holter monitoring was used to assess the rates of silent myocardial ischemia. A postoperative episode of ischemia was experienced by 19% of patients in the restrictive transfusion group, compared with 24% of patients in the liberal transfusion group (95% CI -15.5% to 6%).¹³ The TRICC trial included 257 patients with severe ischemic heart disease. The restrictive transfusion group had lower (but nonsignificant) survival rates compared to the patients in the liberal group.¹⁴ There is limited evidence related to morbidity and mortality surrounding transfusion in the setting of moderate anemia.

Recommendation

- Although anemia is a known risk factor for cardiac events, in the presence of pre-existing cardiovascular disease, current clinical evidence does not support a more aggressive transfusion protocol in this population [overall quality: moderate]

Question 4. What is the effect of anemia and blood transfusion on function?**Case clarification**

This patient is a previously vital community ambulator. Currently, she is having difficulty ambulating due to fatigue. Early ambulation, a primary goal of hip fracture surgery, is not being accomplished.

Relevance

Elderly patients following hip surgery are at risk of complications of sustained recumbency such as thromboembolic events and infection.

Current opinion

Transfusion is performed to increase oxygen carrying capacity of blood to tissues. Many patients appear to “perk up” with increased energy, vitality, and ambulatory capacity following transfusion. It is unclear whether this apparent benefit is in fact substantial and sustained.

Finding the evidence

- Cochrane Database, with search term “perioperative anemia”

- PubMed clinical queries search/ systematic reviews: “blood transfusion and function and orthopedic surgery”

Quality of the evidence*Level I*

- 2 randomized controlled trials

Level II

- 8 nonrandomized trials or trials with methodological limitations

Findings

Blood transfusion increases tissue oxygenation in the presence of anemia. Less evidence is available to confirm that the benefits of transfusion extend to function. Foss et al., in a randomized study of 120 patients with hip fracture, compared functional recovery in patients transfused at a restrictive (8.0g/dL) or liberal (10.0g/dL) transfusion threshold. There were no differences in a postoperative ambulation score.¹⁵ In an observational study of 551 hip fracture patients, Halm et al. suggested that overall mobility scores were improved with transfusion only when the transfusion threshold exceeded 10.0g/dL.¹⁶ These authors suggested that only patients in whom transfusion restored a normal hemoglobin level achieved the functional benefit. Carson et al. compared 84 patients with hip fracture randomly assigned to transfusion thresholds of 10.0g/dL or transfusion for symptoms. No differences in functional recovery were detected comparing the two groups.¹⁷ In cancer patients, quality of life might be closely tied to energy and mobility, and therefore potentially related to hemoglobin level. In a recent study comparing erythropoietin therapy with placebo, improved hemoglobin levels in the treatment group did not seem to achieve the desired improvements in quality of life.¹⁸

Recommendation

- Limited evidence suggests a higher transfusion threshold does not improve function after orthopedic surgery [overall quality: low-moderate]

Question 5. What are the risks of blood transfusion?**Case clarification**

Before considering a blood transfusion, the patient and family request information on the risks of blood transfusion.

Relevance

Transfusion risks are constantly evolving. Infection risk, for example, was substantial prior to routine high-quality screening and testing programs. Other risks, such as acute hemolytic reactions, require urgent intervention to reduce ill effects.

Finding the evidence

- PubMed clinical queries search/ systematic reviews: “red blood cell transfusion and risks and orthopedic surgery”

Quality of the evidence

Level II

- 2 randomized trials

Findings

Acute hemolytic reactions are the most immediate of the adverse events associated with red blood cell transfusion. Reaction rates are 1 per 18,000, and mortality approximately 1 per 1,000,000. Accidental transfusion of ABO-incompatible blood is the leading cause of fatal reactions. Delayed hemolytic reactions can occur secondary to red blood cell alloantibodies in 1 per 5,000 units. Febrile non-hemolytic reactions occur in about 3% of patients, but are usually self-limited. Leukoreduction reduces the incidence of febrile reaction. TRALI (transfusion-related acute lung injury) is a severe reaction to donor leukocyte antibodies. Estimated risk of this potentially serious reaction is 1 in 5,000 transfusions.¹⁹

Infection risk from transfused blood appears to be decreasing. Current estimates suggest the risk of HIV transmission of under 1 in 2,000,000; hepatitis B 1 in 100,000; and hepatitis C, 1 in 1,000,000. The risk of other pathogens such as Creutzfeldt–Jakob disease is unknown.²⁰

Perioperative blood transfusion may increase the risk of surgical-site infection or infection at remote sites such as pneumonia or urinary tract infection. Transfusion-mediated immune modulation may result in a reduced host response to pathologic organisms. In a meta-analysis of 20 studies relating transfusion and bacterial infection, the authors quote an increased risk of infection after transfusion of 3.45 (CI 1.43–15.15) and even higher in the trauma patient (RR 5.26, CI 5.03–5.43).²¹

Recommendation

- The risks of transfusion include hemolytic and non-hemolytic reactions, infection, and immune modulation [overall quality: high]

Summary of recommendations

- Closed suction drainage devices increase transfusion requirements after orthopedic surgery
- Antifibrinolytic drugs hold promise, but concerns surrounding adverse side effects limit routine use
- Autologous blood predonation and perioperative erythropoietin may both reduce the need for allogeneic transfusion, but cost concerns remain
- Transfusion thresholds are controversial, and may vary dependent upon comorbidities such as cardiac disease.

Current evidence supports a restrictive transfusion threshold of 7.0–8.0g/dL for healthy patients

- Although anemia is a known risk factor for cardiac events in the presence of pre-existing cardiovascular disease, current clinical evidence does not support a more aggressive transfusion protocol in this population
- Limited evidence suggests a higher transfusion threshold does not improve function after orthopedic surgery
- The risks of transfusion include hemolytic and non-hemolytic reactions, infection, and immune modulation

Wound Infections

Wesley G. Lackey¹, Kyle J. Jeray¹, Atul F. Kamath², John G. Horneff III², and John L. Esterhai, Jr^{2,3}

¹Greenville Hospital System University Medical Center, Greenville, SC, USA

²Hospital of the University of Pennsylvania, Philadelphia, PA, USA

³Veterans Affairs Hospital, Philadelphia, PA, USA

Case scenario

A 28-year-old man is brought to the Emergency Department after falling 8 feet (2.5 m) from a ladder. Examination and radiographs reveal a closed split-depression tibial plateau fracture. The soft tissue envelope allows primary open reduction and internal fixation of the fracture with a lateral buttress plate. At the 2 week follow-up, there is drainage from the wound with surrounding erythema.

Importance of the problem

Surgeons perform over 27 million operations yearly in the United States,¹ with almost 500,000 of these procedures resulting in a surgical site infection (SSI),² implying that infection complicates nearly 2% of all surgical wounds. Open fractures, which occur at a rate of 250,000 per year in the US,³ have an increased rate of infection; although the risk varies depending on the severity of injury, the rate of infection can be as great as 50% in contaminated fracture wounds.^{4,5} These wound infections may require multiple subsequent operative procedures and prolonged antibiotic treatment courses, and result in complications such as delayed fracture union and possible amputation.

Wound infections cost an estimated \$1.5 billion per year in the US, with an estimated \$3,000–\$30,000 spent per infectious event.⁶ According to epidemiologic hospital data, a patient who develops an SSI is five times more likely to be

readmitted to the hospital and has mortality rates twice that of a patient without an SSI.⁷ The National Surgical Infection Prevention Project was initiated in the US in August 2002 by Medicare and Medicaid to better characterize the nature of SSI and to formulate better strategies to prevent and combat these infections.⁸ Although access to care and advances in technology and sanitation have improved health-related outcomes, infections and wound complications are still major factors relating to morbidity and mortality.

The risk of infection has also been strongly correlated with medical comorbidities^{9,10} and other host factors.¹¹ The additional treatment required to treat infections, as well as wound and bone healing complications, leads to a significant increase in healthcare costs and significantly impacts the patient's quality of life.

Despite aggressive medical and surgical management and evolving diagnostic and treatment modalities, orthopedic infections remain a challenging problem for both patients and clinicians. Where possible, a summary of the best available literature has been provided; due to the lack of homogeneity, well-controlled human clinical trials (level I and level II evidence) and suitable meta-analyses do not exist for most topics.

Relevant anatomy

Wound infections may occur in any anatomic location, and multiple factors contribute to their occurrence. For example,

a contaminated open tibia fracture has a higher risk of infection than a clean, elective hand surgery case. Associated orthopedic hardware influences the risk of infection and hampers its treatment because of the persistent nature of bacterial biofilms. Efforts have been made to categorize infections in order to better guide treatment as well as improve surveillance and standardize reporting of SSIs.

The US Centers for Disease Control (CDC) has developed criteria for defining SSIs in an attempt to create a national standard for diagnosis,¹² as summarized in the box below.

Surgical site infection: definitions

- *Superficial incisional SSI*: Infection, within 30 days of operation, that involves only skin and subcutaneous tissue.
- *Deep incisional SSI*: Infection occurs within 30 days after the operation if no implant is left in place, or within 1 year if implant is in place and infection appears to be related to the operation. Infection involves deep soft tissues (within the fascia or muscle).
- *Organ/space SSI*: Infection occurs within 30 days after the operation if no implant is left in place, or within 1 year if implant is in place and infection appears to be related to the operation. Infection involves any part of the anatomy (e.g., organs or spaces), other than the incision, which was opened or manipulated during an operation.

In the case of orthopedic wound infections, the infected organ/space is most often bone. Osteomyelitis has been further categorized by Cierny et al. in a clinical staging system (Table 10.1), which combines 4 anatomic types of osteomyelitis with 3 physiologic classifications to define 12 clinical stages of osteomyelitis.¹³ The purpose is to define the influential variables associated with osteomyelitis in order to better study the efficacy of treatment methods and to guide treatment.

Top five questions

Prophylaxis

1. What are the current recommendations regarding prophylactic antibiotic administration in the prevention of wound infections in orthopedic surgery?
2. What are the current recommendations regarding screening for methicillin-resistant *Staphylococcus aureus* (MRSA), treatment of carriers, and antibiotic prophylaxis?

Diagnosis

3. What is the optimal diagnostic approach in a patient with a suspected wound infection?

Table 10.1 The UTMB staging system for adult osteomyelitis

Anatomic type	
Type I	Medullary osteomyelitis
Type II	Superficial osteomyelitis
Type III	Localized osteomyelitis
Type IV	Diffuse osteomyelitis
Physiologic class	
A-Host	Good immune system and delivery
B-Host	Compromised locally (BL) or systemically (BS)
C-Host	Requires suppressive or no treatment; minimal disability; treatment worse than disease; not a surgical candidate
Clinical stage	
Type + class = clinical stage	Example: Stage IVBS osteomyelitis = a diffuse lesion in a systemically compromised host

4. What is the role of wound culture in diagnosing and treating orthopedic infections?

Therapy

5. What is the management of infected hardware?

Openmirrors.com

Question 1: What are the current recommendations regarding prophylactic antibiotic administration in the prevention of wound infections in orthopedic surgery?

Case clarification

At the time of the initial surgery, the wound was “prepped and draped in the usual sterile fashion.” Cefazolin was given intravenously within 30 minutes of surgery and stopped at 24 hours postoperatively.

Relevance

Despite guidelines established for SSI prevention based on studies demonstrating decreased rates of perioperative infections with prophylactic antibiotics, studies show that antibiotic prophylaxis is not always correctly administered.^{14,15} A pay-for-performance study found that 13% of patients did not receive timely antibiotic prophylaxis.¹⁶ Furthermore, the inappropriate use of antibiotics contributes to antibiotic resistance, increased risk of adverse reactions, and increased healthcare costs.¹⁷

Current opinion

Factors determining appropriate antibiotic prophylaxis include wound location, type of procedure, initial level of contamination, and host immune status. A systematic and evidence-based approach must be taken, and adequate

preoperative checks must be used to ensure the effective and timely administration of prophylactic antibiotics.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): “prophylactic antibiotic orthopedic infection”
 - 9 results
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “prophylactic antibiotic orthopedic infection”
 - Limits: English
 - 62 results, 22 reviews
- Embase (www.embase.com; excluding Medline duplicates): “prophylactic antibiotic orthopedic infection”
 - Limits: English, Embase only
 - 55 results

Quality of the evidence (best available)

- Level I: 19
- Level II: 3
- Level III: 5
- Level IV: 7
- Level V: 13

Findings

In larger studies of infection epidemiology, *Staphylococcus aureus*, coagulase-negative *Staphylococci*, *Enterococcus* species, and *Escherichia coli* are the most frequently isolated pathogens.¹⁸ An increasing proportion of SSIs are caused by antimicrobial-resistant pathogens, such as MRSA or vancomycin-resistant enterococci (VRE).

The 1 hour window to administer preoperative antibiotics has its roots in studies by Burke in 1961 in a *Staphylococcus aureus* infection model in guinea-pigs.¹⁹ When antibiotics were given within 1 hour before bacterial inoculation, there was no inflammatory response. Guinea-pigs that received antibiotics 3 hours or more after inoculation received no more benefit than those animals not receiving antibiotics.

The shortest effective duration of antimicrobial administration for preventing postoperative infection is not known.^{14,20} Studies comparing single-dose prophylaxis with multiple-dose prophylaxis have shown conflicting benefits in terms of SSI rate with the additional doses.^{21,22} Continuing antibiotic prophylaxis longer than 24 hours after wound closure has not proven to be beneficial; indeed, it may contribute to the development of antimicrobial resistance.^{20,21} A Cochrane review from 2001 examined the rates of SSI associated with either the use of single- or multiple-dose antibiotic prophylaxis in proximal femur and closed long bone fractures. They demonstrated the need to redose antibiotics in order to maintain tissue levels above the minimum inhibitory concentration throughout the duration of the surgical procedure.²³ Antibiotics should be redosed at one to two times the half-life of the anti-

otic.^{22,24,25} or when there is significant intraoperative blood loss.^{26–28}

Slobogean et al. conducted a meta-analysis of antibiotic prophylaxis in 7 trials encompassing 3,808 patients with closed long bone fractures.²⁹ When compared to a regimen of multiple doses of prophylactic antibiotics, administration of a single preoperative dose has a risk ratio of 1.24 (95% CI 0.60–2.60) with no statistical significance. Pooled results failed to demonstrate superiority of multiple-dose prophylaxis over a single-dose strategy in the management of closed long bone fractures.²⁹

Recommendations

The proportion of antibiotic-resistant surgical wound pathogens in the subsequent decade will be an important factor in directing future recommendations for surgical antibiotic prophylaxis. Local bacterial flora and resistance profiles are important to tailoring hospital-specific protocols.³⁰

To maximize the beneficial effect of prophylactic antibiotics while minimizing adverse effects, recommendations include the following [overall quality: high]:

- Antibiotic administered prior to incision
- Perioperative antibiotic course should not exceed 24 hours
- Antibiotics should be redosed when the duration of the procedure exceeds one to two times the antibiotic half-life^{22,24,25} or with significant intraoperative blood loss^{26–28}
- Verification of prophylactic antibiotic administration at the time of the “Time-Out” protocol may increase compliance rate⁶

Question 2: What are the current recommendations regarding MRSA screening, treatment of carriers, and antibiotic prophylaxis?

Case clarification

This patient has no known history of MRSA infection, but his sister did have a peculiar “spider bite” on her hip 1 year ago that was culture-positive for MRSA.

Relevance

MRSA infections represent a particularly prevalent and challenging issue in wound infection, especially now that community-acquired MRSA often represents the predominant organism of skin and soft tissue infections in many communities.³¹ Although MRSA is prevalent, the institution of prophylactic vancomycin for all surgical cases could theoretically yield to increasing resistance. Therefore, there has been a movement to study MRSA screening and treatment prior to elective surgery or even hospital-wide, but general recommendations for MRSA screening and prophylaxis have been varied.

Current opinion

Cephalosporins remain the standard prophylactic antibiotic. MRSA screening and treatment of carriers is not universal. Vancomycin is not routinely used for surgical prophylaxis, but may be used in patients with known or suspected MRSA infection or carriage.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): “MRSA screening orthopedic surgery”
 - 1 relevant review
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “MRSA screening orthopedic surgery”
 - Limits: English
 - 56 results, 17 relevant, 3 reviews

Quality of the evidence

- Level I: 1
- Level II: 6
- Level III: 4
- Level IV: 3
- Level V: 1

Findings

Currently, many institutions screen for MRSA by using a polymerase chain reaction (PCR) test for gene sequencing and identification of the nasal carriage of MRSA. This testing is available in a point-of-care testing device (a small machine which runs a PCR test result at the bedside) that has proven its accuracy as well as its convenience.³² Of 2,473 patients studied by Shukla et al., 3.2% were MRSA carriers upon admission.³³ Those carrying MRSA at the time of admission were more likely to develop SSI with MRSA (8.8% vs. 2.2% infection rate; $p < 0.001$).³³

Some data exist regarding the use of mupirocin to reduce nasal carriage of *Staphylococcus aureus* and rates of SSI in elective orthopedic surgery.^{34–36} A prospective study of MRSA surveillance using PCR-based testing, including 5,094 patients undergoing Surgical Infection Prevention Project procedures, showed a reduction of MRSA SSI from 0.23% to 0.09% with preoperative treatment including mupirocin.³⁷

In 2007 and 2008, a Texas Veterans Affairs (VA) hospital implemented a “MRSA prevention bundle” including MRSA nasal screening of patients upon admission, transfer, and discharge; contact isolation of positive patients; standardized hand hygiene; a cultural transformation education campaign; and ongoing monitoring of process and outcome measures. They reported significant decreases in MRSA transmissions, SSIs, and overall MRSA nosocomial infections.³⁸ In contrast, a randomized, double-blind, placebo controlled trial in nonorthopedic surgical patients failed to show a decrease in the overall incidence of SSIs, but the

study did show a decrease in *Staphylococcus aureus* infections in treated carriers.³⁹

Despite the rise in bacterial strains resistant to common prophylactic antibiotics, such as cefazolin (not only MRSA but also strains of the ubiquitous *Staphylococcus epidermidis*),⁴⁰ recommendations for prophylactic vancomycin are conservative. The American Academy of Orthopaedic Surgeons (AAOS) recommends that vancomycin use be limited to patients with known colonization with MRSA or in facilities with recent MRSA outbreaks.^{25,41}

Recommendations

Current recommendations for MRSA screening include the following [overall quality: moderate]:

- Routine MRSA screening and treatment with mupirocin may reduce the prevalence of MRSA colonization and incidence of postoperative infections
- Point-of-care screening for MRSA using PCR is available and is as effective as the laboratory test
- No threshold exists for prevalence rates justifying routine vancomycin use in prophylaxis, though it is recommended for colonized patients and in institutions with perceived high rates or outbreaks of MRSA infection

Question 3: What is the optimal diagnostic approach in a patient with a suspected wound infection?**Case clarification**

The patient presents for routine follow-up and suture removal at 2 weeks. He complied with his nonweightbearing status. Purulent discharge is noted on the dressing. The wound is not healed. There is some dehiscence over the proximal 20% of the incision with surrounding erythema. The hardware is not exposed.

Relevance

Diagnosis of a wound infection, particularly the extent of the infection, is important for guiding treatment. Laboratory values can be used for diagnostic purposes as well as for following improvement. Radiographic changes are rarely present in acute infection.

Current opinion

The evaluation of a suspected wound infection is largely clinically based. Laboratory values such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) can be useful for diagnosis and for following treatment response.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): “ESR CRP orthopedic wound infection diagnosis”
 - 0 relevant reviews

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “ESR CRP wound infection”
 - Limits: English

Quality of the evidence (best available)

- Level I: 1
- Level II: 1
- Level III: 7
- Level IV: 1
- Level V: 1

Findings

New or persistent drainage, induration, or erythema around a wound, may signify a deep infection. However, the diagnosis of a deep wound infection is made in the operating room,⁴² as SSIs are defined by their anatomic depth as discussed in the relevant anatomy section above.

Leukocyte count and ESR were originally used together for laboratory evaluation of infection, but CRP has gained attention as a better barometer of a clinical process due to its more prompt elevation (6–8 hours) and faster resolution (50% decline per day).⁴² In any case, ESR and CRP are best used together, with a sensitivity of 98% in a study of 265 children with culture-positive osteoarticular infections.⁴³

Although neither value is routinely followed after elective surgery, CRP was shown to be more “applicable, predictable, and responsive in the early postoperative period compared with ESR,” in terms of monitoring for postoperative infection when drawn daily.⁴⁴ In this study, the CRP value demonstrated a half-life of 2.6 days, while the ESR showed no reproducible pattern. A similar study attempted to quantify the CRP levels with postoperative infections in elective fracture surgeries. The authors noted that CRP peaked 2 days postoperatively and began to decline thereafter. When the values remained above 96 mg/L after the fourth postoperative day, the authors noted a sensitivity and specificity for deep infection of 92% and 93%, respectively.⁴⁵

It is often appropriate to draw these labs around the time of irrigation and debridement, even in the case of an obvious infection, in order to establish peak reference value. While lab values are inconsistent between patients and diagnoses, falling values can help confirm effective treatment and be used for screening in suspected recurrent infections.

Recommendations

Current recommendations for the diagnostic approach of wound infections include the following [overall quality: moderate]:

- The diagnosis of a wound infection is made in the operating room
- Increased pain, drainage, erythema, or dehiscence may suggest a wound infection

- CRP and ESR should be used together to support or help rule out a suspected wound infection

Question 4: What is the role of wound culture in diagnosing orthopedic infections?

Case clarification

The patient is admitted to the hospital for irrigation and debridement of the wound in the operating room. At the time of surgery, a wound culture is obtained in the operating room and submitted for microbiologic analysis.

Relevance

Isolating a culture of the causative bacteria is important for directed antibiotic therapy. An *intraoperative* wound infection specimen is the best chance to isolate an organism to facilitate directed antibiotic therapy.

Current opinion

Superficial wound culture in the outpatient setting is of limited value for diagnosis and treatment of a wound infection. Though routine intraoperative wound culture is not often used in clean or elective orthopedic surgery, deep culture at the time of surgical debridement of a wound infection is used to guide antibiotic therapy.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>) and PubMed (www.ncbi.nlm.nih.gov/pubmed/) were searched using combinations of keywords “wound culture, orthopedic infection”

Quality of the evidence (best available)

- Level I: 1
- Level II: 3
- Level III: 4
- Level IV: 2
- Level V: 2

Findings

Studies have shown that intraoperative cultures in a non-infected wound, whether surgical or traumatic, clean or contaminated, are not advisable. Lee et al. studied pre- and postdebridement cultures of open wounds.⁴⁶ Only 8% of organisms cultured eventually caused infection; conversely, 7% of patients with negative cultures eventually became infected. Postdebridement cultures had similar results: only 25% of organisms cultured caused ultimate infection; 12% of patients with negative cultures became infected.⁴⁶ The poor predictive value of initial wound cultures has been demonstrated in other reports.⁴⁷

In a study of wound infections after open fractures by Carsenti-Etesse et al., 92% of infections were caused by nosocomial (hospital-acquired) bacteria, rather than by the

initially cultured organism.⁴⁸ In one prospective trial with relatively small sample size, only 18% of infections in open fracture wounds were caused by initially cultured organism.⁴⁹

Bernard et al. examined 1,256 subfascial cultures in 1,102 patients undergoing elective/“clean” orthopedic surgery.⁵⁰ Wound cultures demonstrated 38% sensitivity, 92% specificity, 7% positive predictive value, and 99% negative predictive value.⁵⁰ The study’s literature review found only four of nine studies showing predictive benefit from intraoperative wound cultures in clean orthopedic surgery. The utility of wound cultures must be gauged against the timing, type of procedure, and clinical history of the patient.

Obtaining a specimen for culture is appropriate at the time of irrigation and debridement for a presumed wound infection in order to guide antibiotic therapy. A retrospective review of 800 image-guided bone biopsies for osteomyelitis showed that laboratory values, fever, and previous administration of antibiotics, could not be used to predict the success of growing positive cultures, but obtaining an aspirate of ≥ 2 ml of purulent fluid was significantly correlated (5 of 6 positive cultures, 83%).⁵¹ Increased sensitivity of wound cultures has been shown with the inoculation of blood culture bottles, because of the rich culture medium.⁵²

Recommendations

Recommendations for wound cultures in orthopedic surgery [overall quality: moderate]:

- Routine cultures of traumatic or clean surgical Openmirrors.com wounds are not recommended
- Superficial wound swab cultures of a suspected wound infection are of little value
- Intraoperative deep cultures if positive can help guide antibiotic therapy if an organism is isolated
- Sensitivity of cultures is increased if some of the specimen is placed in a blood culture bottle

Question 5: What is the management of infected internal fixation hardware?

Case clarification

The patient is 2 weeks from surgery and has a deep infection. His hardware is in good position but the fracture is clearly not healed.

Relevance

Infection rates are low in arthroscopy and hand surgery, while many SSIs occur in the presence of hardware, particularly when that hardware was introduced in the cases of open fractures. How to deal with this infected hardware may vary from case to case.

Current opinion

The surgeon must balance the goal of eradication of infection with the goal of fracture healing, which usually requires the hardware to remain in place.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): “infected hardware orthopedic fracture stability”
 - 0 relevant reviews
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “orthopedic infected hardware”
 - Limits: English

Quality of the evidence

- Level I: 1
- Level II: 2
- Level IV: 6

Findings

In 1998, Zimmerli et al. had success with eradication of infection with retained hardware, reporting 12/12 cure rate with a prolonged course of ciprofloxacin-rifampin in patients with acute infections after open reduction and internal fixation (ORIF).⁵³ On the contrary, Rightmire et al. found lower success rates in 2008 when they reviewed 69 cases of infected internal fixation hardware treated with irrigation and debridement, antibiotics, and hardware retention, and found a 32% failure rate, defined as hardware removal prior to healing.⁵⁴

Many authors contest that infected fractures will heal if the fracture is stable.⁵⁵ Simultaneously, it has long been accepted that an infection cannot be eradicated in the presence of infected hardware.⁵⁶ The principles of treatment should include adequate debridement, obliteration of dead space, and specific antimicrobial therapy.⁵⁷ It is reasonable to conclude that hardware should be retained until healing or at least relative fracture stability is achieved.

Recommendations

Current recommendations on managing infected hardware include the following [overall quality: low]:

- Prompt irrigation and debridement is recommended for deep infections, but hardware removal should be delayed until fracture stability is achieved
- Removal of infected hardware is probably necessary for complete eradication of infection

Summary of recommendations

- Prophylactic antibiotics should be administered prior to incision and should be continued for a maximum of 24 hours postoperatively. Antibiotics should be redosed at recommended intervals during surgery
- Screening and treatment for MRSA nasal carriage may reduce MRSA SSIs in MRSA carriers. Vancomycin should not be routinely used for prophylaxis, but is appropriate for patients who are MRSA carriers or in settings of MRSA outbreaks

- The diagnosis of a wound infection is made in the operating room
- Increased pain, drainage, erythema, or dehiscence may suggest a wound infection
- ESR and CRP should be used together as part of the workup for a wound infection and as a monitor of treatment effectiveness
- Superficial wound swab cultures of a suspected wound infection are of little value
- Wound culture should only be used at the initial irrigation and debridement of a wound infection. Increased sensitivity of deep wound cultures is associated with larger volumes of specimen in a blood culture bottle medium
- Infected hardware may prevent complete eradication of a wound infection, but the timing of hardware removal must be balanced with the need for fracture stability in treating a wound infection. Thus, in the majority of cases the hardware is retained in the acute infection period and removed after fracture stability/healing is achieved

Conclusion

Orthopedic wound infections represent a complex interplay among host factors and surgical interventions. Prevention will continue to be the best way to treat wound/surgical site infections in order to improve outcomes and reduce the economic burden of infection. Further well-designed clinical investigations are needed to guide the future of prevention and management of wound infections in the face of ever-changing bacterial resistance profiles in order to allow the surgeon to continue the practice of evidence-based orthopedics.

Gouty Arthritis

Jasvinder A. Singh

University of Alabama at Birmingham, Birmingham, AL, USA

Case scenario

A 75 year old man who is currently ambulatory and living independently came to the Emergency Department complaining of pain for 1 day in his left great toe. He has a history of coronary artery disease status post angioplasty, hypertension, diabetes, and peptic ulcer disease with major gastrointestinal bleeding 10 years ago. He has had increasing frequency of lower extremity joint pain and swelling involving the great toe, ankles, and knees in the last 2–3 years, now with acute attacks of arthritis occurring every 3–4 months, lasting 7–14 days. He is currently unable to step with his left foot. On examination, his left first metatarsophalangeal (MTP) joint is moderately swollen, erythematous, and very tender to palpation. Examination of the ankle, knees, opposite foot, and other joints is unremarkable. The patient is requesting some medication to relieve the excruciating pain.

Relevant anatomy and pathophysiology

Arthritis of the foot can be due to inflammatory causes (rheumatoid arthritis, spondyloarthritis or crystalline arthritis such as gout, pseudogout or calcium oxalate disease) or noninflammatory causes (osteoarthritis, metabolic/endocrine arthropathies). This chapter focuses

on management options for gout, a common type of inflammatory arthritis with a predilection for involvement of lower extremity joints. Gout is the commonest inflammatory arthritis in older men and can present either as acute intermittent monarticular or polyarticular arthritis. It is characterized by hyperuricemia (serum urate above the solubility level of 6.8mg/dl), which leads to formation of urate crystals in the joints and bursae leading to acute inflammation in one or multiple joints (acute gout). Untreated hyperuricemia in gout patients leads to chronic gouty arthritis characterized by chronic inflammation in the joints associated with chronic pain, swelling, joint destruction as well as formation of subcutaneous deposits of urate—the tophi.

Importance of the problem

It is estimated that approximately 5 million Americans have gout.¹ A recent study estimated that \$27 million are spent annually for care of new acute gout cases in the United States.² Gout accounted for 1.4 million outpatient visits in 2002.³ In two studies of large U.S. employer databases, compared to patients without gout, those with gout had \$3,000 higher annual medical costs.^{4–5} Over 31,400,000 hits appear on Google when the search term “gout” is entered. A PubMed search revealed 10,948 results for “gout.”

Top four questions

Diagnosis

1. How accurate is clinical examination for the diagnosis of acute gout and what role does joint aspiration for documentation of urate crystals have in the diagnosis of gout?

Therapy

2. What is the role of oral colchicine in treatment of acute gout?

3. How effective are other treatments including nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, and adrenocorticotrophic hormone (ACTH) in the management of acute gout as compared to placebo and each other?

4. What is the role for use of chronic anti-inflammatory therapy (colchicine, NSAIDs, etc.) in patients with gout?

Question 1: How accurate is clinical examination for the diagnosis of acute gout and what role does joint aspiration for documentation of urate crystals have in the diagnosis of gout?

Case clarification

The patient has had multiple attacks of lower extremity arthritis without any diagnosis. Radiography of the feet shows mild joint space narrowing of bilateral MTP joints. The patient is presented with two options—to undergo joint aspiration for a definitive diagnosis or have a presumptive diagnosis based on clinical features.

A typical X-ray finding in patients with gout is a “punched out erosion with overhanging margin”, but it may not be present in every patient with gout, many of whom may have no radiographic abnormality or joint space narrowing only.

Relevance

Making a definitive diagnosis of gout as the underlying cause of patient’s inflammatory arthritis is critical to institution of appropriate, effective treatment. Current opinion is divergent among practitioners on whether to aspirate the joint. However, joint aspiration is rarely done in emergent or outpatient settings for most patients, primarily due to lack of training (joint aspiration) among internists and family practitioners and/or lack of perceived value for a definitive diagnosis.

Current opinion

Current practice pattern suggests that the majority of practitioners use the clinical features based on preliminary

American Rheumatism Association (ARA) criteria to diagnose gout, rather than joint fluid aspiration.

Finding the evidence

- Cochrane Database, with search term “gout diagnostic criteria”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) clinical queries search/ systematic reviews: “gout AND diagnostic criteria”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) -sensitivity search using keywords “gout” AND “diagnostic criteria” as well as “gout” AND “classification criteria”

Quality of the evidence

Level III

- 2 observational studies

Findings

Two studies (n = 142 patients) provide data regarding the accuracy of clinical classification/diagnostic criteria and of radiographic features for gout. Malik et al. compared the clinical criteria with the gold standard of synovial fluid analysis for gout.⁶ In 82 patients with suspected gout who underwent joint fluid aspiration and examination for urate crystals (gold standard), the sensitivity of the ARA (now American College of Rheumatism (ACR)) preliminary classification criteria was 70%, specificity 79%, and positive predictive value, 66%. For two other clinical criteria for gout, the New York criteria and the Rome criteria, the sensitivity was 70% and 67% and specificity was 83% and 89%, respectively. Barthelemy et al. performed a prospective study of the radiographic features of 60 patients with gouty arthritis; the diagnosis was made based on crystal-documentation or satisfying 6 of the 12 ARA classification criteria. In this study 60% (36/60) patients had radiographic findings diagnostic of gouty arthritis in one or more joints; 32% (19/60) had features indistinguishable from osteoarthritis and 8% (5/60) had normal radiographs.⁷ In a literature synthesis of studies of quality control for examination of urate and other crystals in synovial fluid, moderate evidence for quality control was found.⁸

Recommendations

In patients with suspected gout, evidence suggests:

- Clinical criteria have moderate accuracy in the diagnosis of gouty arthritis [overall quality: low]
- Radiographic features typical of gout may be present in up to 60% of the patients with gout and assist in making the diagnosis of gout [overall quality: low]
- The gold standard for diagnosis of gout is documentation of urate crystals in joint fluid/material aspirated from joint, bursa, or tophaceous deposit using polarized microscopy [overall quality: low]

Question 2: What is the role of oral colchicine in treatment of acute gout?

Case clarification

The patient has a history of gastrointestinal bleeding, contraindicating the use of NSAIDs.

Relevance

Selecting the appropriate treatment for acute gout is important, since adverse events sometimes occur even with short-term medication use. The onset of pain relief may be rapid with NSAIDs or corticosteroids; however, one must be aware of potential adverse events and drug interactions of these medications. The pain relief achieved with colchicine may take longer to occur and one must be aware of associated gastrointestinal adverse events, including diarrhea, with this drug.

Current opinion

Current practice patterns suggest that the majority of practitioners avoid NSAIDs for treatment in such a patient and may use oral colchicine or oral or intra-articular corticosteroids.

Finding the evidence

- Cochrane Database, with search terms “gout,” “colchicine,” “randomized”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) clinical queries search/ systematic reviews: “gout colchicine randomized”

- PubMed (www.ncbi.nlm.nih.gov/PubMed/)—sensitivity search using keywords “gout,” “colchicine,” “randomized”

Quality of the evidence

Level I

- 1 systematic review/meta-analysis
- 2 randomized trials

Findings

A Cochrane systematic review found only one randomized study comparing colchicine to placebo for the treatment of acute gout.⁹ The single study included in this review by Ahern et al.¹⁰ is discussed in detail in the following paragraph. Since the publication of the review, another much larger randomized placebo-controlled trial has been published. Therefore, instead of presenting results from the Cochrane review, we provide updated forest plots (Figure 11.1 and Figure 11.2).

Two studies (n = 229 patients) provide data regarding the use of colchicine for treatment of acute gout. In a randomized study of 45 patients, 22 patients with gout were randomized to colchicine 1g followed by 0.5mg every 2 hours until complete response or toxicity occurred, and 21 patients received placebo;¹⁰ 2 patients were excluded because they were unable to understand the visual analog scale used for reporting pain. A significantly higher proportion of patients had at least a 50% reduction in pain score (73%) in the colchicine group compared to the placebo group (36%) (p < 0.01). Terkeltaub et al. compared low-dose (1.8mg total over 1 hour) and high-dose colchicine

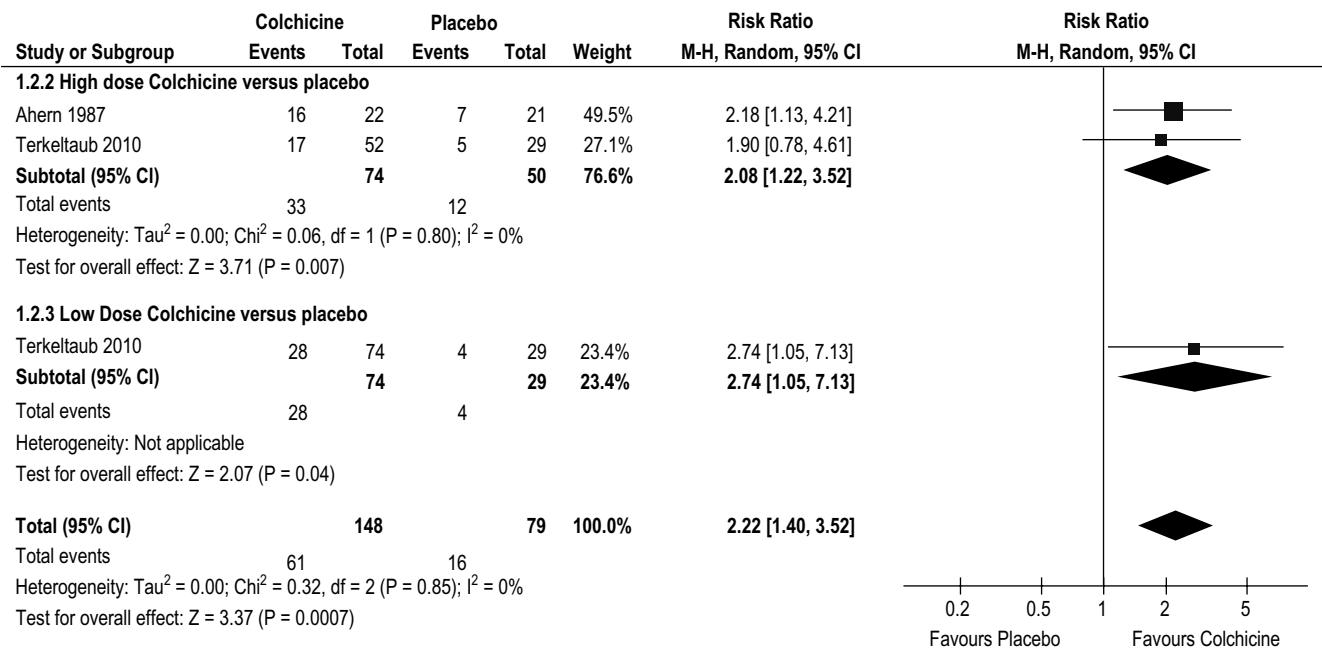

Figure 11.1 Efficacy of colchicine vs. placebo in 50% pain reduction.

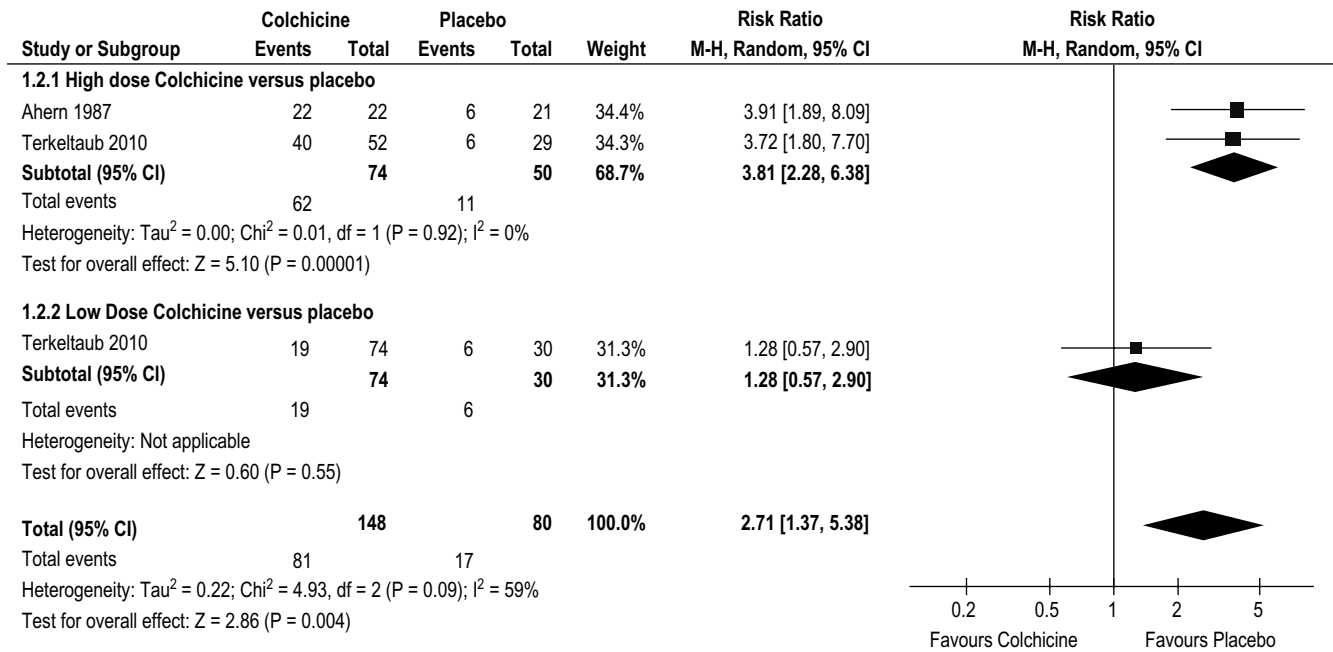

Figure 11.2 Gastrointestinal adverse events in colchicine vs. placebo.

(4.8 mg total over 6 hours) to placebo in 575 patients with acute gout.¹¹ Of these, 185 patients had a qualifying acute gout flare (52 in high-dose colchicine, 74 in low-dose colchicine, and 59 in placebo group), of whom 184 were included in the efficacy analyses (1 patient in placebo group did not provide data/flare confirmation) and all 185 were included in safety analyses. A 50% reduction in joint pain at 24 hours was noted in a significantly greater proportion of patients in the high-dose colchicine group (17/52, 32.7%) and the low-dose colchicine group (28/74, 37.8%) compared to the placebo group (9/58, 15.5%; $p = 0.034$ and 0.005 , respectively).

A combined analysis of the two randomized controlled trials showed that high-dose colchicine was significantly more likely than placebo to be associated with 50% pain relief at 24–36 hours with a relative risk of 2.08 favoring colchicine (95% CI 1.22–3.52). The absolute risk reduction was 25% (95% CI 2–28%), relative risk reduction was 108% (95% CI 22–252%) and number needed to treat to benefit (NNT-B) was 4 (95% CI 2–50). Low-dose colchicine was significantly more likely than placebo (RR 2.74; 95% CI 1.05–7.13) to provide 50% pain relief at 24–36 hours. The absolute risk reduction was 24% (95% CI 7–41%), relative risk reduction was and NNT-B was 4 (95% CI 2–14).

Two studies provided data for gastrointestinal toxicity of colchicine. Compared to placebo, gastrointestinal adverse events were significantly more common in high-dose colchicine with relative risk of 3.81 (95% CI 2.28–6.38). Low-

dose colchicine did not lead to more gastrointestinal adverse effects compared to placebo with relative risk of 1.28 (95% CI 0.57–2.90). The number needed to treat to harm (NNT-H) for gastrointestinal toxicity was 2 (95% CI 2–3) for high-dose colchicine and not applicable for low-dose colchicine (no significant differences compared to placebo). Any adverse event (RR 2.79; 95% CI, 1.52–5.12) and diarrhea (RR 5.58; 95% CI, 2.22–14.02) were reported by significantly more patients in the high-dose colchicine vs. placebo group. The low-dose colchicine group did not differ significantly compared to placebo for any adverse event (RR 1.37; 95% CI 0.70–2.66) or diarrhea (RR 1.72; 95% CI 0.63–4.70). For any adverse event, the NNT-H for high-dose colchicine was 3 (95% CI 2–4) and for diarrhea the NNT-H was 2 (95% CI 2–3).

Recommendations

In patients with acute gout, evidence suggests:

- Colchicine is better than placebo in improving pain in the first 24–48 hours [overall quality: high]
- Low-dose colchicine is as effective as high-dose colchicine for treatment of acute gout, which are both better than placebo [overall quality: moderate]
- Colchicine is associated with significantly more gastrointestinal adverse events than placebo; high-dose colchicine is associated with more gastrointestinal adverse events than placebo; and low-dose colchicine was not statistically significantly different than placebo [overall quality: moderate]

Question 3: How effective are other treatments including NSAIDs, corticosteroids, and ACTH in the management of acute gout as compared to placebo and each other?

The case clarification, relevance and current opinion relating to this question have already been presented in the context of Question 2.

Finding the evidence

- Cochrane Database, with search terms “gout,” “Nonsteroidal anti-inflammatory drugs,” “NSAID,” “steroid,” “randomized”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) clinical queries search/ systematic reviews: “gout,” “Nonsteroidal anti-inflammatory drugs,” “NSAID,” “steroid”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) -sensitivity search using keywords “gout,” “Nonsteroidal anti-inflammatory drugs,” “NSAID,” “steroid,” and “randomized”

Quality of the evidence

Level I

- 2 systematic reviews/meta-analyses
- 2 randomized trials

Findings

In a systematic review, use of NSAIDs, corticosteroids, and ACTH in acute gout was reviewed.¹² The systematic review identified one placebo-controlled trial comparing tenoxicam (an NSAID) to placebo,¹³ but no placebo-controlled trials of steroids or ACTH use in acute gout. One randomized controlled trial compared tenoxicam 30mg/day to placebo (n = 30). In this study 67% of tenoxicam-treated vs. 26% of placebo-treated patients had 50% or more reduction in pain at 24 hours, but no difference at the end of treatment at 4 days. A report in the Cochrane Database notes that there are no placebo-controlled trials of corticosteroids in gout.¹⁴ Of the nine studies that compared NSAIDs to each other, seven low-quality studies found no differences in efficacy of NSAIDs compared to each other. Only two were high-quality studies.^{15,16} A combined analysis showed that when comparing etoricoxib to indomethacin, there were significantly lower relative risks of any adverse event (0.77; 95% CI 0.63–0.95) and drug-related adverse events (0.47; 95% CI 0.33–0.66) in favor of etoricoxib. No differences were noted in the relative risk of serious adverse events (0.56; 95% CI, 0.03 to 9.40) or withdrawals due to adverse events (0.50; 95% CI 0.15–1.62).

One study compared ACTH to intramuscular triamcinolone (a corticosteroid) and found similar efficacy of the two with respect to the time required for complete resolution of acute gout.¹⁷ No placebo-controlled trials compared steroids or ACTH to placebo.

Two studies compared NSAIDs to prednisone in patients with acute gout, but there are no studies comparing colchicine or ACTH to NSAIDs or prednisone. In one study of 90 patients, an oral prednisolone/acetaminophen combination was found to be as effective as oral indomethacin/acetaminophen combination in relieving pain and was associated with fewer adverse effects.¹⁸ In an equivalence study of prednisolone and naproxen for acute gout, no significant differences were noted between treatment arms for pain reduction at 90 hours.¹⁹ Adverse events were similar between groups.

Recommendations

- NSAIDs may relieve symptoms of acute gout including pain and a variety of NSAIDs have similar efficacy in this regard [overall quality: low].
- Corticosteroids can also relieve pain during acute gouty arthritis [overall quality: low]

Question 4: What is the role of colchicine in prophylaxis during initial urate-lowering therapy?

The case clarification, relevance and current opinion relating to this question have already been presented in the context of Question 2.

Finding the evidence

- Cochrane Database, with search terms “gout” “colchicine” “randomized”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) clinical queries search/ systematic reviews: “gout colchicine randomized”
- PubMed (www.ncbi.nlm.nih.gov/PubMed/)—sensitivity search using keywords “gout colchicine randomized” AND as well as “gout colchicine randomized”.

Quality of the evidence

Level II

- 2 randomized trials with methodological limitations

Findings

There were no systematic reviews on this topic. Two randomized controlled studies with methodological limitations (n = 95 patients) provided data regarding the use of colchicine for prophylaxis of acute flares when initiating urate-lowering therapy. In a randomized double-blind study, 51 patients with crystal-proven gouty arthritis with high serum urate and frequent gout attacks/tophi were enrolled, 8 of whom were excluded since they did not participate beyond the initial enrollment and did not receive study drug. Of the 43 patients analyzed, 21 patients with gout were randomized to colchicine 0.6mg twice a day orally and 21 to placebo twice a day orally for 3 months beyond

attaining a serum urate of less than 6.5 mg/dL.²⁰ All patients received allopurinol starting at 100 mg orally and escalated by 100 mg increments (in renal failure, 50 mg increments) until the target serum urate was achieved. Patients treated with colchicine experienced fewer flares during the entire study (0.52 vs. 2.91, $p = 0.008$), and less severe flares as reported on a visual analog scale (3.64 vs. 5.08, $p = 0.018$). Overall, fewer patients in the colchicine (33%) vs. placebo (77%) group reported any gout flares ($p = 0.008$) or recurrent gout flares: 14% vs. 63%, respectively ($p = 0.004$). Comparing the safety profile of colchicine to placebo, similar proportions had overall withdrawals (14% vs. 18%) or any adverse event (43% vs. 38%, $p = 0.76$). A significantly higher proportion had diarrhea as an adverse event in colchicine (38%) vs. the placebo group (4.5%) ($p = 0.009$).

In a two-center randomized double-blind study, Paulus et al. compared two regimens in 52 patients with hyperuricemia and history of typical attacks of acute arthritis:²¹ 500 mg of probenecid tablet orally three times a day vs. 500 mg of probenecid + 0.5 mg of colchicine tablet three times a day. They analyzed 38 patients after excluding 18 as a result of noncompliance or loss to follow-up. Mean gout flares/month/patient were significantly less frequent in the colchicine vs. the placebo group, 0.19 vs. 0.48 ($p < 0.05$). Diarrhea was reported by 9/20 in colchicine and 6/18 in placebo group. Gastrointestinal adverse events were reported by 15/20 patients in the colchicine group and 8/18 in the placebo group.

The data from the two trials described above could be pooled for two outcomes: adverse event and diarrhea. Analyses showed that relative risk of any adverse effect (1.47 [0.94, 2.32]) or diarrhea (2.75 [0.41, 18.28]) was slightly higher in the colchicine vs. the placebo group, but the difference was not statistically significant.

Recommendations

- Prophylaxis with colchicine is effective in preventing acute gout flares during the initial urate-lowering therapy [overall quality: moderate]
- Adverse events with prophylactic colchicine during initial urate-lowering therapy are not significantly different from placebo [overall quality: low to moderate]

Summary of recommendations

- Clinical criteria have moderate accuracy in helping with the diagnosis of gouty arthritis
- Radiographic features typical of gout may be present in up to 60% of the patients with gout and assist in making diagnosis of gout
- The gold standard for diagnosis of gout is documentation of urate crystals in joint fluid/material aspirated

from joint, bursa or tophaceous deposit using polarized microscopy

- Colchicine is better than placebo in improving pain in the first 24–48 hours
- Low-dose colchicine is as effective as high-dose colchicine for treatment of acute gout, and both high and low dose colchicine are better than placebo
- Colchicine is associated with significantly more gastrointestinal adverse events than placebo; high-dose colchicine is associated with more gastrointestinal adverse events than placebo and low-dose colchicine was not statistically significantly different than placebo
- NSAIDs may relieve symptoms of acute gout including pain and variety of NSAIDs have similar efficacy in this regard
- Corticosteroids relieve pain during acute gouty arthritis
- Prophylaxis with colchicine is effective in preventing acute gout flares during the initial urate-lowering therapy
- Adverse events with prophylactic colchicine during initial urate-lowering therapy are not significantly different from placebo

Conclusions

The most common methods used in clinical practice to diagnose gout, including the clinical/classification criteria and radiographic criteria, do not have high specificity or sensitivity. Documentation of urate or other crystals in synovial fluid or tophaceous subcutaneous deposits is highly recommended to differentiate gout from pseudogout and osteoarthritis. Colchicine is effective in reducing pain associated with acute gouty arthritis, with low-dose (1.8 mg) being as effective as the high-dose hourly colchicine (4.8 mg) regimen. Other effective options for treatment of acute gouty arthritis include NSAIDs, corticosteroids (oral and intra-articular) and ACTH. Anti-inflammatory prophylaxis with colchicine or NSAID is indicated at initiation of urate-lowering therapy in patients with gout, to be continued for a few months to prevent acute flares. Colchicine seems to be well tolerated when used as prophylactic therapy at the time of urate-lowering therapy initiation.

Perioperative Medical Management

Daniel A. Mendelson, Susan M. Friedman, and Joseph A. Nicholas

Highland Hospital, University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

Case scenario

An 84 year old woman with heart failure, hypertension, hyperlipidemia, asthma, and diabetes trips on a rug at home. She is unable to bear weight, and is brought to the hospital. She is found to have a right intertrochanteric hip fracture.

Relevant anatomy

Hip fractures can be classified in relation to the hip capsule as intracapsular (femoral neck) fractures or extracapsular fractures, which includes both intertrochanteric and subtrochanteric fractures.

Importance of the problem

Since most patients who sustain hip fractures undergo surgery, optimizing the perioperative management of these patients is essential. Perioperative mortality is approximately 4%, with 1 year mortality ranging from 10% to 35%. Complications sustained during hospitalization may lead to a delay in rehabilitation, further functional decline, poor quality of life, and death.

Optimizing perioperative medical management has been shown to reduce complication rates, including cardiac complications, thromboembolism, infection, and delirium. Length of hospital stay is also reduced. This reduction in complications translates to a reduction in healthcare costs.

Top five questions

Diagnosis

1. Is preoperative echocardiography indicated for asymptomatic patients?

Therapy

2. Which approaches to delirium prevention work?
3. Does comanagement improve processes and outcomes?
4. Are beta-blockers useful in perioperative management?

Harm

5. What is the harm associated with delay to surgery?

Question 1: Is preoperative echocardiography indicated for asymptomatic patients?

Case clarification

Because the patient has a history of heart failure and cardiac risk factors, the anesthesiologist requests clarification of the patient's cardiac status. The patient has no new cardiac symptoms or findings.

Relevance

Echocardiography adds costs and often delays definitive care, which may result in worse outcomes. Recent studies suggest that proceeding to surgery quickly may result in lower hospital mortality, lower length of stay, and lower

30-day rehospitalization. Avoiding unnecessary echocardiography may produce better outcomes at lower cost.

Current opinion

There is no clear consensus upon obtaining preoperative echocardiograms for asymptomatic patients. There are wide practice variations.¹

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): with search terms: “hip fracture” and “echocardiogram”
 - Returned 1 results
- PubMed (www.ncbi.nlm.nih.gov/PubMed/): with search terms: “hip fracture” and “preoperative cardiac evaluation”
 - Returned 9 references
- MEDLINE (1990 to March 31, 2010) with search strategy:
 - 1 exp Hip Fractures
 - 2 exp Echocardiography
 - 3 1 and 2
 - Returned 16 references
- A review of reference lists of relevant articles for additional published trials

Quality of the evidence

- Level III: case series

Findings

Although physicians caring for hip fracture patients may feel more comfortable obtaining an echocardiogram prior to surgery, such evaluation rarely changes management when there are no new signs or symptoms of cardiac dysfunction. For the majority of patients, thoughtful fluid management, timely surgery, and appropriate medical management results in best outcomes without the cost or delay associated with obtaining additional cardiac testing.^{1,2}

Recommendation

- Echocardiography should not be obtained in patients without signs or symptoms of new cardiac conditions [overall quality: low]

Question 2: Which approaches to delirium prevention work?

Case clarification

At baseline, the patient is cognitively intact, pleasant, and interactive. On postoperative day 2, she screams at the nurse, accusing her of trying to poison her, and pulls out her intravenous line and urinary catheter. She is agitated, appears uncomfortable, and either does not answer questions at all, or responds inappropriately.

Relevance

Delirium is the most common postoperative complication following hip fracture surgery, with incidence estimates up

to 60%.^{3,4} Delirium occurs more commonly in this population than in other hospitalized older adults. The occurrence of delirium is associated with increased risk of complications, increased length of stay, decline in activities of daily living, decline in ambulation, admission to nursing home, and death.⁵⁻⁷ Furthermore, although delirium is considered to be an acute condition, about 40% of those who develop delirium still have symptoms on hospital discharge,⁶ which can in turn impact their ability to participate in rehabilitation.⁸ Patients who are admitted to rehabilitation with delirium are more likely to suffer further complications, more likely to be rehospitalized, and less than half as likely to be discharged to the community as those who are not delirious.⁹

Current opinion

Although delirium is extremely common following surgical repair of hip fractures, few centers have standardized, comprehensive approaches to delirium prevention. Optimizing medical and surgical treatment will help reduce the incidence and severity of delirium.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): with search terms: “hip fracture” and “delirium”
 - Returned 15 results
- PubMed (www.ncbi.nlm.nih.gov/PubMed/): with search terms: “hip fracture” and “delirium,” limited to clinical trial, meta-analysis, randomized controlled trial or review, AND English
 - Returned 18 references
- MEDLINE (1990 to December 14, 2009) with search strategy:
 - exp Hip Fractures
 - Delirium: prevention & control
 - Returned 22 references
- A review of reference lists of relevant articles for additional published trials

Quality of the evidence

Level I

- 2 systematic reviews or meta-analyses
- 4 randomized controlled trials

Level II

- 3 cohort studies

Findings

Interventions to reduce delirium have included comprehensive programs and specific medications.¹⁰ A randomized controlled trial of proactive geriatric assessment was completed on 126 hip fracture patients. The geriatrician visited daily and made recommendations based on a structured protocol. Recommendations focused on 10

topics, including fluid management, treatment of pain, medication management, bowel and bladder function, nutrition, and mobilization. Incidence of delirium was lower (32% vs. 50%, RR = 0.64, with 95% CI = 0.37–0.98). Severe delirium incidence was 12% vs. 29% (RR = 0.4, with 95% CI = 0.19–0.89). For those who developed delirium, there was no difference in number of hospital days with delirium.¹¹ An intervention of pre- and postoperative geriatric assessment, early surgery, oxygen, prevention of blood pressure falls, and treatment of complications led to a rate of delirium of 47.6% vs. 61.3% in historic controls.¹² Incidence of severe delirium and length of stay were also reduced. A pre-post study of nurse education, systematic cognitive screening, consultation, and a scheduled pain protocol showed a reduction in delirium severity and duration but not overall incidence.¹³

Haloperidol prophylaxis (0.5 mg three times daily) was studied in a randomized controlled trial of 430 hip fracture patients aged 70 and over. There was no difference in the primary endpoint of postoperative delirium incidence (15.1% vs. 16.5%, with RR = 0.91, 95% CI = 0.6–1.3). However, for those who developed delirium, severity was less ($p < 0.001$), duration was shorter (5.4 vs. 11.8 days, 95% CI for difference = 4.0–8.0, $p < 0.001$), and mean length of stay was lower (17.1 vs. 22.6 days, $p < 0.001$).¹⁴ Overall incidence of delirium in this population was low, which may be a result of all patients receiving proactive geriatric consultation. Randomized trials of donepezil¹⁵ and scopolamine¹⁶ did not affect delirium incidence.

There is observational evidence that delirium is associated with experiencing severe pain (RR = 9.0, 95% CI = 1.8–45.2), receiving less than 10 mg of parenteral morphine daily (RR = 5.4, 95% CI = 2.4–12.3), or receiving meperidine (RR = 2.4, 95% CI = 1.3–4.5).¹⁷

Recommendations

- Proactive, standardized geriatric assessment reduces delirium incidence and severity [overall quality: high]
- Low-dose haloperidol prophylaxis in a high-risk population may reduce delirium severity and duration [overall quality: moderate]
- Poorly treated pain may increase risk of delirium [overall quality: low]

Question 3: Does comanagement improve processes and outcomes?

Case clarification

The patient was admitted to the orthopedic surgery service and was comanaged by a geriatrics hospitalist. Medication, pain, and fluid management were primarily monitored by the geriatrician. The patient had surgery within 12 hours of admission and was discharged for rehabilitation at a skilled nursing facility on the third postoperative day.

Relevance

Patients admitted for fragility fractures frequently have comorbidities that warrant careful management by experts. The complexity of these patients is beyond what an orthopedic surgeon should be expected to manage on their own. Surgeons are busy in the operating room and often do not have the time to manage medical problems and coordinate care with the patient, family, and care team during regular working hours.¹⁸

Current opinion

There is a growing trend for geriatricians or hospitalists to specialize in the comanagement of geriatric fractures in order to improve outcomes including morbidity, mortality, length of stay, and costs.¹⁹

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): with search terms: “hip fracture” and “comanagement” or “co-management”
 - Returned 0 results
- PubMed (www.ncbi.nlm.nih.gov/PubMed/): with search terms: “hip fracture” and “comanagement” or “co-management”
 - Returned 4 references
- MEDLINE (1990 to March 31, 2010) with search terms:
 - 1 exp Hip Fractures
 - 2 comanagement.mp
 - 3 co-mangement.mp
 - 4 2 or 3
 - 5 1 and 4
 - Returned 4 references
- A review of reference lists of relevant articles for additional published trials

Quality of the evidence

- Level II: cohort studies, consensus

Findings

Comanagement of fragility fractures by geriatricians has been shown to improve in hospital mortality (1.5 vs. 3.2%), length of stay (4.6 vs. 5.2 days), and 30 day readmission rates (9.7 vs. 19.4%). Comanagement compared with usual care is associated with shorter time to surgery (24.1 vs. 37.4 hours), fewer postoperative infections (2.3 vs. 19.8%), less complications overall (30.6 vs. 46.3%), and less use of restraints (0 vs. 14.1%).^{20,21}

Recommendation

- Comanagement should be considered for fragility fractures [overall quality: moderate]

Question 4: Are beta-blockers useful in perioperative management?

Case clarification

The patient has a history of congestive heart failure, hypertension, hyperlipidemia, asthma, and diabetes mellitus. Her preoperative blood pressure is recorded as 108/62, with a pulse of 88 beats/minute.

Relevance

Despite an initial enthusiasm for the widespread use of beta-blockers in the perioperative setting, more recent studies have highlighted risks from beta-blocker therapy for some patients. Dose, timing and patient selection are likely important factors to consider.

Current opinion

Recommended practice has moved to limited beta-blocker use in patients with known coronary heart disease or who are already on a beta-blocker. Reduced risk for myocardial ischemia and infarction need to be weighed against risk for acute stroke. There is debate over the recommended dosing of beta-blockers, target population, target heart rate.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews/index.htm>): with search terms “beta-blocker” and “surgery”
 - No relevant reviews; 2 relevant protocols
- PubMed (www.ncbi.nlm.nih.gov/PubMed/): with search terms “beta-blocker” and “perioperative,” limited to clinical trial, meta-analysis, or randomized controlled trial, AND English
 - 91 references
- A review of reference lists of relevant articles for additional published trials.

Quality of the evidence

Level I

- 1 systemic review or meta-analysis
- 5 randomized controlled trials

Level II

- 1 cohort study

Findings

Since the initial publication of data galvanizing the widespread use of beta-blockers in the perioperative setting, a number of subsequent studies have suggested a more nuanced approach in patients undergoing noncardiac surgery, with many studies failing to confirm benefit.^{22–24}

The most recent published meta-analysis found reductions in nonfatal myocardial ischemia were offset by non-

fatal strokes and significant perioperative bradycardia and hypotension, with no effect on all-cause mortality.²⁵ The meta-analysis was dominated by the recently completed POISE trial,²⁶ which found increased mortality and strokes in patients started 2–4 hours preoperatively on a target dose of 200 mg/day extended-release metoprolol. More recently, the DECREASE-IV trial of bisoprolol 2.5 mg/day, started 30 days before surgery, did find a significant reduction 30-day cardiac death or infarction rates, without an associated increase in strokes, heart failure, bradycardia, or hypotension.²⁷ The protocols of these two major trials differed in many plausibly important ways, including study drug, dose, timing of drug initiation, and heart rate targets. DECREASE-IV enrolled a younger population than POISE and had a higher bradycardia threshold for holding the study drug.

There are no trials dedicated to studying the risk-benefit of perioperative beta-blockade in patients older than 75 years. There are no large, high-quality trials of lower-dose beta-blockade (less than metoprolol 50 mg/day) initiated just prior to surgery. In older patients with diminished physiologic reserve, requiring acute, noncardiac surgery, the risk-benefit of modest-dose beta-blockade remains unclear. Observational data suggests that a perioperative protocol for frail, elderly patients with hip fractures that includes low-dose metoprolol may be associated with significantly improved outcomes, including low myocardial ischemia and stroke rates.²⁰ After review of the POISE trial, the American College of Cardiology and American Heart Association have revised their guidelines, advising against perioperative initiation of high fixed-dose regimens in beta-blocker-naïve patients undergoing intermediate-risk procedures.²⁸ Less aggressive or slowly titrated beta-blockade, and continuing chronic beta-blockade, is likely less harmful, and may be associated with improved outcomes.

Recommendations

- For patients on chronic beta-blocker therapy undergoing nonvascular surgery, continue beta-blockers in the perioperative period [overall quality: low]
- Consider the initiation of low-dose beta-blocker (equivalent to metoprolol 25–50 mg/day) therapy in patients at increased risk for perioperative cardiac events; consider starting days to weeks in advance of surgery if possible [overall quality: moderate]
- Titrate beta-blockers carefully, to avoid hypotension and/or bradycardia [overall quality: high]
- Do not routinely use perioperative beta-blockade in patients at low risk for perioperative cardiac events [overall quality: moderate]
- Do not initiate high-dose beta-blockers in naïve patients in the immediate perioperative period [overall quality: high]

Question 5: What is the harm associated with delay to surgery?

Case clarification

The patient is admitted early Friday evening. Although she is medically stable, operating room time is limited over the weekend. On Monday, she is added to the surgical schedule at the end of the day, after more “urgent” cases are completed.

Relevance

Length of hospitalization for hip fracture repair varies tremendously depending on the healthcare system. The demand for urgent surgery often exceeds available resources. Guidance is needed to determine whether delays in surgery in medically stable patients will lead to poorer outcomes.

Current opinion

In many centers, surgical repair of a hip fracture is not viewed as urgent care.

Finding the evidence

- Cochrane Database (<http://www.cochrane.org/reviews>): with search terms: “hip fracture” AND “surgical delay” or “time to surgery” or “surgery timing”
 - Returned 21 results (0 related to topic)
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) search terms: “hip fracture” and “surgery timing,” limited to English
 - Returned 84 references (19 relevant)
- A review of reference lists of relevant articles for additional published trials

Quality of the evidence

Level I

- 1 systematic reviews or meta-analyses

Level II

- 18 cohort studies

Findings

Because of the ethical nature of this question, a randomized trial to address it is not feasible. In a recent systematic review of 52 studies involving 291,413 patients,²⁹ 3 studies involving 6,954 patients were prospective, excluded unfit patients, and adjusted for confounders. In one of these studies,³⁰ a delay of 4 or more days in medically stable patients increased mortality at 90 days (HR 2.25, 95% CI = 1.2–4.3, $p = 0.01$) and at 1 year (HR 2.4, 95% CI = 1.45–3.99, $p = 0.001$). Patients who were delayed due to acute medical comorbidities on admission had a higher mortality at 30 days (HR = 2.3, 95% CI = 1.62–3.33), 90 days (HR = 2.1, 95% CI = 1.6–2.7, $p < 0.001$), and 1 year (HR 1.72, 95%

CI = 1.38–2.15, $p < 0.001$), and there was no significant difference in mortality in this subgroup relating to surgical timing. In the second study, patients undergoing surgery within 24 hours had lower mean pain scores, fewer days of severe and very severe pain, shorter length of stay, and improved self-care at 6 months than those who had surgery after 24 hours, but did not have improved mortality.³¹ In a subanalysis restricted to individuals who did not have marked abnormal clinical findings on presentation and did not need further preoperative evaluation, early surgery was associated with a reduction in major postoperative complications (OR 0.26, 95% CI = 0.07–0.95). A third study showed no difference in discharge destination or mortality after adjusting for baseline characteristics, but did note an increase in length of stay.³²

Recommendations

- Delay in surgery more than 4 days in stable patients may increase mortality [overall quality: low]
- Surgery within 24 hours lowers overall pain and duration of severe pain [overall quality: moderate]
- Hip fracture patients who also have acute medical comorbidities are at increased risk of death due to those comorbidities, regardless of timing of surgery [overall quality: moderate]

Summary of recommendations

- Echocardiography should not be obtained in patients without signs or symptoms of new cardiac conditions
- Proactive, standardized geriatric assessment reduces delirium incidence and severity
- Low-dose haloperidol prophylaxis in a high-risk population may reduce delirium severity and duration
- Poorly treated pain may increase risk of delirium
- Comanagement should be considered for fragility fractures
- For patients on chronic beta-blocker therapy undergoing nonvascular surgery, continue beta-blockers in the perioperative period
- Consider the initiation of low-dose beta-blocker (equivalent to metoprolol 25–50 mg/day) therapy in patients at increased risk for perioperative cardiac events; consider starting days to weeks in advance of surgery if possible
- Titrate beta-blockers carefully, to avoid hypotension and/or bradycardia
- Do not routinely use perioperative beta-blockade in patients at low risk for perioperative cardiac events
- Do not initiate high-dose beta-blockers in naive patients in the immediate perioperative period
- Delay in surgery more than 4 days in stable patients may increase mortality

- Surgery within 24 hours lowers overall pain and duration of severe pain
- Hip fracture patients who also have acute medical comorbidities are at increased risk of death due to those comorbidities, regardless of timing of surgery

Orthobiologics

T. William Axelrad¹ and Thomas A. Einhorn²

¹Lake Charles Memorial Hospital, Lake Charles, LA, USA

²Boston University Medical Center, Boston, MA, USA

Case scenarios

Case 1

A 64 year old man presents 2 years after sustaining a Gustilo–Anderson type II distal-third tibia fracture treated with a statically locked intramedullary nail. He has type 1 diabetes and has smoked a pack of cigarettes a day for over 40 years. The patient had a small residual gap at the fracture site, and did not develop significant bridging callus. His fracture was treated with dynamization of the nail at 9 months with removal of the proximal interlocking screws, and then revision intramedullary nailing 6 months later for continued lack of healing. He continues to have pain at the fracture site and shows no evidence of cortical bridging on plain radiographs.

Case 2

A 55 year old woman is seen for debilitating low back and neck pain for over 8 months. She has failed 3 months of physical therapy as well as having had two epidural steroid injections approximately 2 months ago. MRI shows degenerative disc disease at L3–4 and L4–5 as well as C5–6.

Relevant anatomy

Fracture healing is affected by a variety of conditions as well as the anatomic location of the injury. Smoking, comor-

bidities such as diabetes, open fractures, and advanced age all have negative effects on the healing of fractures. Several anatomic regions have a higher rate of nonunion, such as the proximal metaphysis of the 5th metatarsal, the scaphoid, the femoral neck, and the subtrochanteric region of the femur.^{1–3} It is presumed that the tenuous nature of the local blood supply is largely responsible for the resistance to union at these sites.

Open tibia fractures have been the subject of intense research with regard to improving clinical outcomes related to bone healing and reducing the risk of infection. The blood supply to the tibia is predominately supplied by the posterior tibial artery.⁴ Fractures that have soft tissue stripping (which devitalizes the bone) or an associated vascular injury are at increased risk for delayed union and nonunion. Dickson et al. obtained angiograms in 114 patients treated for an open tibia fracture.⁵ They found that open fractures with documented arterial disruption had a rate of delayed and nonunion of 46% compared to a rate of 16% in similar injuries with a normal angiographic study. Others have achieved union in both distal femur and tibial nonunions after revascularization procedures alone.^{6,7} Anatomic studies of the vascular supply of the tibia have shown that the proximal tibia is richly vascularized, while the diaphysis contains few extraosseous vessels.⁸ Disruption of these vessels after fracture results in rapid revascularization. Delayed union and nonunion are characterized by an avascular area at the fracture site; in these cases restoration of stability and possibly bone grafting can result in healing.⁹

Several bones, when fractured, are resistant to union because their intraosseous vascular supply is provided by

a single vessel that is typically disrupted by the fracture. For example, fracture of the proximal 5th metatarsal diaphysis, also known as a Jones fracture, occurs in a vascular watershed, which likely contributes to the higher rate of nonunion in this region.¹⁰ The scaphoid is also prone to nonunion, as the proximal pole receives its blood supply proximally. Successful treatment has been accomplished with vascularized grafts,¹¹ further emphasizing the importance of the vascular supply in fracture healing.

Importance of the problem

In general, fractures heal, although the healing process can be impaired at specific anatomic sites, in fractures associated with soft tissue injuries, and in fractures occurring in patients with specific risk factors. With an aging population it is predicted by the World Health Organization that by 2050 there will be 6.3 million hip fractures worldwide, a significant increase from the estimated 1.66 million that occurred in 1990. Currently the highest rates of hip fractures are seen in North America and Europe, although by 2050 more than half of all hip fractures may occur in Asia.¹² A 2008 study on the incidence of all fracture types in England found that lifetime prevalence in middle-aged men was over 50% and it was 40% for women who lived past age 75.¹³ While some countries have reported a recent decline in the age-adjusted rate of hip fractures, studies from Finland, Canada, and Germany show that the absolute number of osteoporotic fractures continues to rise.¹⁵⁻¹⁹ Regardless of the change in rates, Kannus et al. note that the burden of osteoporotic fractures in Finland, for example, will continue to rise along with the rapidly aging population.²⁰ A separate review of perimenopausal and postmenopausal women from 2000 to 2005 found a significant increase in rates of distal radius, hip, and pelvic fractures.²¹ It is clear that with the increasing population worldwide, we will continue to experience the burden of both nonunions and delayed unions. Without appropriate interventions, this will likely result in significant increases in costs to both the patient and society. Not only will direct hospital and other medical costs increase, but the lost time from work by the patient and family members who become care givers will negatively impact society's productivity overall. Certain modalities, if used in targeted patients, may decrease the risk of nonunion or delayed union and thus decrease the overall cost of care for a given injury.

It appears that the incidence of clinically significant spine pathology is also increasing rapidly. From 1997 to 2006 the number of patients seeking medical attention for back complaints increased from 14.8 million to 21.9 million.²² This increase is consistent with the 77% increase in the number of spinal fusions that were performed during the five year period from 1996 to 2001.²³ Degenerative disk disease that

fails conservative management has been treated with decompression and fusion with or without instrumentation. The risk of pseudoarthrosis in patients undergoing spine fusion with iliac crest bone graft is estimated to be as high as 12%, with advancing age being a risk factor for this complication.²⁴ Chronic pain at the operative site is another complication that has been found to occur in nearly 40% of patients,²⁵ with both major and minor complications occurring in 10% and 39% respectively.²⁶

Top five questions

Risk factors

1. What patient and injury-related factors negatively affect bone healing?

Treatment

2. When should orthobiologics be used in the acute setting?
3. What orthobiologics are recommended for healing of recalcitrant nonunions?

Government regulations

4. What rules govern the use of orthobiologics?

Complications

5. What are the reported risk factors with the use of the various FDA (Food and Drug Administration)/EMEA approved orthobiologics?

Question 1: What factors negatively affect bone healing?

Case 1 clarification

Our patient has several perceived risk factors for impaired fracture healing. Smoking and diabetes are known risk factors for impaired bone healing. Aging might also be a risk factor for nonunion of a fracture, since the pool of available mesenchymal stem cells declines with age. Our patient is a candidate for revision intramedullary nailing with autograft or with an orthobiologic agent.

Relevance

There are a number of issues that can affect a patient's health and potentially affect bone healing after trauma or during elective procedures such as spinal fusion or correction of malunion. It is well established that diabetes and malnutrition can negatively affect wound healing and other factors, either in combination or alone, may help predict the likelihood of delayed union or nonunion following fracture.

Current opinion

It is a common belief that multiple factors affect bone healing negatively. This includes patient-specific factors such as age, diabetes, malnutrition, and immune compromise. Smoking and alcohol abuse are also thought to have a negative impact on bone remodeling. The need to use orthobiologics in patients considered to be at risk for impaired healing has not been validated with randomized clinical trials, but remains an available option for the treating surgeon, although in many cases such use is “off-label” and appropriate discussion with the patient is required preoperatively (see Question 4).

Finding the evidence: aging and bone healing

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “aging bone marrow stromal changes” and “aging osteogenic potential”

Quality of the evidence (best available)

- Basic science: 19 animal studies, 11 human studies

Findings

Bone healing occurs in part through the recruitment of osteoprogenitor cells. This occurs through the release of local and circulating growth factors that induce an inflammatory response under relatively hypoxic conditions, which in turn results in early recruitment of mesenchymal stem cells (MSCs) to the site of injury.²⁷ The higher rate of nonunion reported in elderly patients, such as those older than 75 years of age, has been postulated to be the result of various factors. Some have suggested that the increase in incidence in nonunion is the result of a delay or decrease in the initial angiogenic response at the fracture site. This has been confirmed in animal models in which there is an age-related decline in blood vessel formation after fracture.²⁸ Street et al. studied 32 patients undergoing emergent fracture repair.²⁹ They obtained samples of fracture hematoma at the time of surgery, as well as plasma samples from venipuncture at a distant site. The test subjects evenly divided into two groups: half of the patients were less than 40 years of age and the remaining group was older than 75 years of age. Circulating factors known to be involved in angiogenesis, including vascular endothelial growth factor (VEGF) and platelet derived growth factor (PDGF), were quantified using enzyme-linked immunosorbant assay (ELISA). The absolute amount of VEGF in the samples from the older cohort was significantly reduced when compared to the controls (31.4 vs. 68.4 pg/mL); however, the relative increase in the injured patients compared to age- and gender-matched uninjured control was nearly tenfold for the older group, while only a fivefold increase was seen in the controls. No significant differences were seen with regards to PDGF. In-vitro endothelial cell proliferation and

blood vessel tube formation on Matrigel was also increased comparably when treated with plasma from each group. Finally, fracture hematoma and plasma from both groups induced robust new blood vessel formation in a murine subcutaneous wound pocket assay. One issue with this study is that the cells studied were isolated from human umbilical veins, and others have shown that the response of the cells involved in new blood vessel formation, the endothelial precursor cells (EPCs), is attenuated in elderly individuals.³⁰ Overall, the available studies indicate that the inflammatory response is maintained in the elderly population, although the angiogenic response may be attenuated secondary to age-related changes in the cellular response.

Conflicting data has been published on the number and health of MSCs in elderly individuals, although this may be related to the methods used in harvesting and assaying the cells in culture.³¹ It is likely that aging results in a decrease in both the absolute numbers and health of MSCs. Most studies in animals have found changes in MSCs associated with aging.^{32–34} Several investigators have shown a decrease in the osteogenic potential and growth rate in MSCs taken from long bones in aged mice,^{35,36} while Bellows et al. found that cells isolated from the vertebral column responded similarly to treatments regardless of age.³⁷ Although the anatomic origin of the cells could be one reason for the differences seen in the various studies,³⁸ experiments in strains of mice that age at different rates suggest that variations in growth and differentiation may also be the result of differences in local growth factors and matrix composition of the donor.³⁹ D’Ippolito et al. studied the ability of MSCs from vertebral marrow aspirates to form colonies in vitro that expressed alkaline phosphatase, a marker of osteoblastic differentiation. Their results found that osteogenic potential declined with age up to approximately 40 years of age.⁴⁰ This same group isolated MSCs that they termed marrow-isolated adult multilineage inducible (MIAMI) cells, which also demonstrated an age-related decline from 0.01% of total marrow nucleated cells at 3 years of age, to 0.0018% by age 45.⁴¹ Similar to their previous study on MSCs, they found that the decline stabilized at this time and it appears that these cells are resistant to the effects of aging seen in other MSCs, with the exception of an increase in the doubling time by 30%.^{41,42} Stolzing et al. compared human MSCs from three age groups.⁴³ They found an age-related decline in the number of stem cells isolated from iliac crest bone marrow aspirates up to the age of 40. Cells isolated from patients over 40 years of age displayed an increase in the expression of the apoptosis markers p53 and, to a lesser extent, p21, with a significant increase in the rate of apoptosis. When the investigators assessed the ability of MSCs to differentiate into osteoblastic cells, the aged population showed a significant decline in alkaline phosphatase activity, and this

decline was evident in patients beginning after 18 years of age, with a 40% decline occurring in 19–40 year old group. Bidula et al. found a decline in relation to age in the number of marrow cells isolated from the anterior iliac crest.⁴⁴ However, they found no difference in the prevalence of alkaline phosphatase-positive cultures between subjects.

Recommendation

Although the debate continues, it appears that evidence favors an age-related change in MSC activity and health. However, what role this plays in bone repair as the population continues to age throughout the world remains to be determined with larger controlled trials.

- The current evidence does not support treating elderly patients with fractures differently than any other group of patients with regards to the use of orthobiologics to stimulate fracture healing [overall quality: moderate-high]

Finding the evidence: diabetes

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “diabetes fracture healing,” “diabetic fracture”

Quality of the evidence (best available)

- Basic science: 2 animal studies, 1 human study
- Level III: 2
- Level IV: 1

Findings

Several medical conditions affect bone health and are related to an increase in fracture risk and possibly a higher rate of healing complications. Diabetes has many effects on cellular health and increased rates of fractures have been seen in both type 1 and type 2 diabetics. This increase in fracture risk may be multifactorial and includes a decreased bone strength as well as an increase in the rate of falls secondary to poor vision, peripheral neuropathy, and episodes of hypoglycemia.⁴⁵ Complications related to diabetes include delayed wound healing and difficulties with achieving bony union.^{46–48} Animal models of diabetic fracture healing indicate that in type 1 diabetes, the fracture callus is negatively affected by an upregulation of inflammatory markers, with an associated increase in osteoclast activity and cartilage breakdown.⁴⁹ There are, however, few clinical studies showing that diabetics have difficulties with fracture healing. Cozen reported on nine consecutive diabetic patients with delayed union or nonunion when compared to matched case controls.⁵⁰ Loder retrospectively reviewed 31 closed fractures in diabetic patients.⁵¹ These authors compared healing time, as measured by radiographic parameters and time to full weightbearing, with accepted healing times obtained from literature review. They determined that overall healing time was increased in the diabetic patients with an odds ratio of 1.63. Furthermore,

there was an increased incidence of delayed union in non-insulin-dependent diabetics, patients treated operatively, and those older than 50 years of age.⁴⁸ In a separate retrospective review of 84 patients with diabetes and operatively managed ankle fractures, Costigan et al. failed to show a difference in the rate of union.⁵² They did, however, note that 10 patients developed complications such as infection. These problems occurred in patients with absent pedal pulses and in those patients with peripheral neuropathy.

Two animal studies have been published examining the effect of approved orthobiologics on fracture healing in a diabetic model. Kidder et al. studied OP-1 (Stryker Biotech, Hopkinton, MA) in 54 streptozotocin-induced diabetic rats that were subjected to a traumatic femoral fracture.⁵³ The fractures were fixed acutely with an intramedullary pin and either 25 µg of OP-1 in a collagen carrier, carrier alone, or nothing. At both the 2 week and 4 week time points, the radiographic area of callus was significantly greater in the OP-1 treated animals. This increased callus did not result in a change in the torque to failure between any of the tested groups, including a nondiabetic control group. In a similar study, rhBMP-2 (Medtronic, Minneapolis, MN) was evaluated in diabetic Wistar rats.⁵⁴ The diabetic state in these rats was induced by an autoimmune reaction as opposed to chemical induction. Femoral fractures were created and stabilized in both diabetic and nondiabetic rats and either rhBMP-2 or vehicle alone was applied. There was no significant increase in new bone at the fracture site for the rhBMP-2 treated animals, however, there was an increase in the number of blood vessels in the diabetic animals. Interestingly, at both the 3 week and 6 week time points, no difference in the amount of new bone between the diabetic and nondiabetic animals was detected.

Recommendations

The available data are limited, although it appears that diabetic patients are at a higher risk for wound complications and infection. The results in the single animal study reviewed showed a positive effect of OP-1 on fracture callus mineralization, although it had no effect on the strength of the fracture callus. This study in isolation does not indicate a dramatic potential for OP-1 use in the acute fracture setting.

- Until larger and prospective human studies are available, diabetic patients deserve special attention with regards to management of lower extremity fractures, with particular attention to wound care, peripheral vascular disease, peripheral neuropathy, and renal disease [overall quality: moderate-low]

Finding the evidence: endocrine/nutritional deficits

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “endocrine nonunion,” “nutrition fracture healing”

Quality of the evidence (best available)

- Level I: 1
- Level IV: 1

Findings

Endocrine abnormalities other than diabetes may also play a role in fracture healing. Brinker et al. created an algorithm by which patients who suffered a nonunion that could not be explained by technical error, had sustained a previous low-energy fracture with at least one nonunion, or had a nonunion of a nondisplaced pubic rami or sacral ala fracture, were referred to an endocrinologist.⁵⁵ The investigators identified 37 patients out of a consecutive series of 683 nonunions, of which 31 were diagnosed with a new endocrine or metabolic abnormality. Medical management resulted in union in 30 of the 31 patients, with one patient treated with a hip arthroplasty for subtrochanteric nonunion. Eight of these 31 patients had no further operative treatment to achieve union. The most common abnormality identified was related to calcium homeostasis and vitamin D deficiency. Vitamin D deficiency is a significant health concern worldwide, with seasonal variations occurring in conjunction with variations in available sunlight. Studies in Australia found that the incidence of vitamin D insufficiency was as high as 74% in healthy middle-aged women during the winter months.⁵⁶ Similar differences were not seen in comparable male subjects,⁵⁷ although studies in Europe found rates of deficiency in 36% of elderly men and 47% of elderly women.⁵⁸ Doetsh et al. randomized 30 patients with proximal humerus fractures and a diagnosis of osteopenia or osteoporosis into two groups.⁵⁹ Each group was managed nonoperatively, with the treatment group receiving daily supplementation of 1g of calcium and 800 IU of vitamin D3. Over a 12 week period the investigators observed an increase in the bone mineral density (BMD) of both groups, with the greatest increase seen at 6 weeks. The treated patients showed significantly higher BMD when compared to placebo (0.623 vs. 0.570 g/cm², $p = 0.006$). Clinical differences were not reported, but the results suggest that fracture healing can be modulated by medical management.

Recommendation

- The prevalence of endocrine abnormalities, as well as the need to treat these conditions regardless of their effect on bone healing, should alert the treating physician to recognize patients at risk early in the treatment of fractures. In this way the appropriate tests can be administered and appropriate treatments can be implemented [overall quality: moderate-high]

Finding the evidence: HIV/AIDS

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): "HIV fracture healing"

Quality of the evidence (best available)

- Basic science: 1 human study
- Level I: 3

Findings

Increasing rates of infection with HIV and increased rates of AIDS worldwide, particularly in the aging population, has implications for both the incidence and treatment of fractures.⁶⁰⁻⁶³ It has been shown that HIV infection is associated with an increased risk for osteopenia and osteoporosis, as well as an increase in the serum levels of the inflammatory cytokine TNF- α .⁶⁴ Delayed wound healing and infection after fracture treatment may be increased in patients with HIV,^{65,66} specifically in relation to open fractures.^{67,68} Only one study has demonstrated an increased risk of fracture nonunion in individuals affected by HIV, but the difference in union rate only approached significance ($p = 0.059$) in this small cohort of patients with open fractures.⁶⁸

Recommendation

- With regard to HIV-infected patients, the available evidence suggests a trend that Gustilo-Anderson type II and III fractures are at an increased risk of infection and possibly nonunion, although larger randomized controlled trials are needed to better answer this question [overall quality: moderate]

Finding the evidence: obesity

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): "obesity fracture healing," "obesity fracture complications"

Quality of the evidence (best available)

- Level I: 1
- Level IV: 1

Findings

Obesity, and particularly morbid obesity, is a common problem that has reached epidemic rates in many parts of the world.^{69,70} Although obesity has not been shown to be a predictor of delayed fracture healing,⁷¹ obese patients are at a higher risk for wound and other perioperative complications.^{72,73} Nonunion is a difficult problem when it occurs, and complications, such as early hardware failure, have been shown.⁷⁴

Recommendation

In obese patients, methods that could promote faster healing could potentially reduce the rate of reoperation in this group that is at high risk of complications, although this hypothesis has not been adequately tested.

- Obesity alone is not an indication for the use of an orthobiologic agent [overall quality: moderate-low]

Finding the evidence: alcohol and tobacco abuse

• PubMed (www.ncbi.nlm.nih.gov/pubmed/): “alcohol fracture healing” “alcohol nonunion” “tobacco fracture healing” “nicotine fracture nonunion”

Quality of the evidence (best available)

- Basic science: 9 animal studies, 1 human study
- Level I: 3
- Level II: 6
- Level IV: 1

Findings

Addictive behaviors can have a major impact on the incidence and recovery of patients sustaining orthopedic injuries.⁷⁵⁻⁷⁷ Alcohol abuse can affect patient compliance and can be associated with tobacco use and malnutrition.⁷⁸ Animal studies suggest that alcohol abuse itself has a negative effect on bone remodeling,⁷⁹⁻⁸¹ and specifically osteoblast activity, although one study proposed that there was no effect on the healing of tibia fractures in rats.⁸² In this study, animals were fed increasing concentrations of ethanol for 8 days, at which time the tibial shafts were fractured and fixed with an intramedullary pin. The animals were killed at 6 weeks and both the injured and uninjured limbs were tested for mechanical strength. The results indicated that ethanol-fed animals had significantly lower total body BMD and bone calcium content when compared to control animals. Energy to refracture was also less in the animals treated with ethanol. Histologic or radiographic analysis was not done, and the conclusion that fracture healing was equivalent in the two groups was not supported by the reported findings. Studies on the effects of alcohol abuse on the rate of fracture healing in the clinical setting are scarce. Kristensson et al. reviewed the records of 107 chronic alcoholics and determined that the incidence of fracture in this group, when compared to age-matched controls, was increased by nearly fourfold.⁸³ They did not comment on the time to union or the incidence of complications related to the fracture treatment. Nyquist et al. reviewed tibial fractures in 49 alcoholics and compared rates of healing and complications with 150 patients who did not have a history of alcohol abuse.⁸⁴ Interestingly, there was no difference in complications or an increased incidence of nonunion. In the subset of patients who sustained a transverse tibial fracture, a statistical difference in the time to achieve union was present.

Smoking has long been regarded as a risk factor for wound healing and postoperative complications.^{85,86} Recent data from animal studies, however, suggest that nicotine may have positive effects on angiogenesis and wound healing but these effects may be countered by vasoconstriction resulting in decreased perfusion.^{87,88} Jacobi et al. found an endogenous cholinergic pathway that was involved in angiogenesis.⁸⁷ This pathway is activated by nicotine

through endothelial nicotine acetylcholine receptors. When the investigators treated wounds in diabetic mice with topical nicotine they noted healing rates that were similar to those treated with basic fibroblast growth factor. Fracture healing has also been extensively studied in animal models and, similar to the findings with regards to alcohol, not all studies have demonstrated a negative effect of tobacco use.⁸⁹⁻⁹² Skott et al. studied femoral fracture healing in rats treated with an intramedullary pin.⁹³ Animals were pretreated for 7 days with either subcutaneous nicotine, tobacco extract with or without nicotine, or placebo. Mechanical testing of the fracture at 21 days demonstrated a significant decrease in ultimate torque and torque at yield point for the tobacco extract group when compared to both groups. The addition of nicotine to the tobacco extract treated group did not have an effect on mechanical strength. Interestingly, no difference was seen in ultimate stiffness, energy absorption, or callus BMD within any of the groups.

Human studies on the effects of tobacco and nicotine have also had conflicting results. Analysis of marrow aspirates from the anterior iliac crest of 62 patients who were either nonsmokers, previous smokers, or current smokers, found no difference in the number of MSCs or the ability of these cells to undergo osteogenic differentiation.⁹⁴ Weresh et al. found no association between smoking and the need for multiple revision surgeries for femoral nonunions.⁹⁵ A review of 24,774 patients who had undergone spinal decompression and fusion found an overall infection rate of 3.04%, with tobacco use associated with an increased risk of infection (RR 1.19, $p = 0.09$), although the results only approached significance and the increased risk was relatively small.⁹⁶ A significant decrease in the time to union in tibial osteotomies was found in patients who used smokeless tobacco when compared to both smokers and nonsmokers.⁹⁷ The difference between union times in smokers and nonsmokers was only 1 week, and was reported as statistically significant ($p = 0.03$). With regard to the rate of nonunion and delayed union, no difference was seen between smokers and nonsmokers. The same group had previously reported an increase of 2 weeks to union in smokers when compared to nonsmokers, with smokers having a 2.5-fold increased risk for complications.⁹⁸ McKee et al. reviewed a series of patients treated with Ilizarov reconstruction for malunion, nonunion, and leg length discrepancy.⁹⁹ They found that the relative risk for nonunion in the smoking group was 5.8. Preoperatively, there was a trend towards significance ($p = 0.14$) in the rate of infections in the group of smokers. The authors also failed to mention the number of nonunions in each group preoperatively, a factor that could have preselected patients that had difficulty with achieving union and influenced the final outcome. Bhandari et al. found an association between smoking and secondary procedures after treatment of open tibial fractures with intramedullary nail with or without

rhBMP-2 supplementation.¹⁰⁰ They defined these outcomes as “all procedures with the potential of promoting fracture healing (or events such as inadvertent screw breakage associated with unlocking of the intramedullary nail, resulting in self-dynamization)” and the rate in smokers was 33% higher than in nonsmokers. The rate was significantly reduced for smokers who received 1.5 mg/mL rhBMP-2 (30% vs. 52%, $p = 0.0138$).

The most extensive research on the correlation between smoking and bone healing has occurred in spinal surgery. Hilibrand et al. evaluated the impact of smoking on the rate of pseudoarthrosis in anterior cervical spine fusion.¹⁰² The effect of smoking on fusion was variable in this series, with no differences seen in patients who had undergone corpectomy and strut graft with either fibular allograft or iliac crest autograft. In a larger series of patients who had multilevel interbody grafting, the rate of solid fusion at all levels was significantly less in smokers (62%) when compared to nonsmokers (76%). It should be noted that the rate of follow-up in this study was only 75%. In a retrospective review of 375 patients who underwent instrumented lumbar fusion, the rate of pseudoarthrosis in smokers was shown to be 26.5% compared to 14.2% for nonsmokers. In a third group that had quit smoking for at least 6 months, the rate of nonunion remained significantly higher.¹⁰² Finally, Mok et al. retrospectively reviewed 89 consecutive patients undergoing initial fusion of at least five levels.¹⁰³ While reoperation for any reason was high in smokers (RR 2.59), the investigators did not find a correlation with infection, implant failure, or rate of pseudoarthrosis. The higher rate of reoperation appears to result from the high incidence of pain in spinal segments adjacent to that of the index procedure in smokers when compared to nonsmokers (18.1% vs. 0%).

Recommendation

- The physician should counsel patients on smoking cessation and reducing or eliminating other risky behavior such as drug and alcohol abuse, as these interventions will promote the overall health of the patient and will likely decrease the risk of complications in those treated both operatively and nonoperatively [overall quality: moderate-high]

Question 2: When should orthobiologics be used in the acute setting?

Case 1 clarification

When examining our patient we noticed a small irregular scar approximately 3 cm in length over the site of the fracture. The patient informs us that at the time of the injury he had a bleeding wound at that site.

Case 2 clarification

Our patient decides to have anterior cervical discectomy and fusion at C5–6 with a staged fusion of L3–4 and L4–5

through either a combined anterior and posterior approach or through a posterior only approach.

Finding the evidence: fracture of the appendicular skeleton

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “fracture rhBMP-2,” “bone healing rhBMP-2,” “bone healing OP-1”

Quality of the evidence (best available)

- Basic science: 11 animal studies
- Level I: 4
- Level II: 1

Findings

Extensive research using rhBMP-2 in both rodents and larger mammals indicates that it stimulates faster and more robust fracture healing.^{104–106} However, there are only a couple of clinical trials of rhBMP-2 use in human fractures. Govender et al. conducted a large prospective randomized study using rhBMP-2 that include 450 patients who had sustained an open tibial shaft fracture.¹⁰⁷ Treatments were standardized in that each patient had their fracture managed with standard soft tissue management and the fractures were definitively treated with an intramedullary nail. Patients were then randomized to receive a type 1 collagen sponge containing either 0.75 mg/mL or 1.50 mg/mL of rhBMP-2 or nothing at the time of definitive wound closure. The primary outcome measure was return to the operating room for a subsequent procedure within 12 months of the operation. Patients treated with 1.5 mg/mL of rhBMP-2 had a significantly decreased need for reoperation. Secondary outcome measures of wound healing and infection rates were also significantly improved in this group. After the completion of this study, a subgroup analysis of Gustilo–Anderson type III open fractures, combined with results of a concurrent and similar randomized trial of 60 patients, found that initial treatment of an open tibia fracture with rhBMP-2 and either reamed or unreamed intramedullary nailing reduced the rate of secondary procedures, including bone grafting, and reduced the risk for infection by 48% (95% CI 8–70%).¹⁰⁸ There are several concerns with regard to the methods and outcomes in these studies. In the larger group, the randomization process was centralized, and resulted in heterogeneity between the control and treatment groups. Patients treated with 1.5 mg of rhBMP-2 were more likely to have reaming of the intramedullary canal prior to insertion of the nail (41% vs. 27%). This may have favored the treatment group, as recent randomized trial of reamed and unreamed nails in tibial fractures found that in the subgroup of open fractures there was a trend towards an increase in the use of dynamization and drainage of hematomas when reaming was used (RR 1.16, $p = 0.16$).¹⁰⁰ A more recent study has called into question some of the findings in the original. Aro et al. con-

ducted a randomized study of 277 patients treated with reamed intramedullary nailing with or without rhBMP-2.1.¹⁰⁹ The study had planned to enrol 300 patients but was suspended after a higher rate of deep infection was noted in the rhBMP-2 group (12 [9%] vs 3 [2%]). This increase in deep infections was particularly prevalent in Gustilo-Anderson type III injuries (7 [16%] vs 1 [2%]).

Jones et al. studied rhBMP-2 in combination with allograft as a substitute for autograft in the treatment of tibia fractures with critical-sized defects.¹¹⁰ They defined these defects as being 1–5 cm in length and at least 50% of the circumference of the diaphysis. Patients were initially stabilized with either an intramedullary nail or external fixation. They randomized 30 patients and followed them for 12 months and measured the rate of union and patient satisfaction using the Short Musculoskeletal Function Assessment (SMFA). They found no difference in the rate of union or satisfaction among the 24 patients (80%) who were available at the final follow-up.

OP-1 (Stryker Biotech, Hopkinton, MA) has been studied in both animal and human models and has been shown to positively affect the healing of nonunions.^{130–133} However, these positive findings were not confirmed in a randomized trial of the treatment of distal radius malunions.¹¹¹ In the study, 20 patients were randomized to treatment with either OP-1 or autograft after corrective osteotomy of the distal radius and dorsal plating. There was no difference in the clinical outcomes at the final follow-up, although the investigators did find that OP-1 use resulted in a significantly longer time to union (18 vs. 7 weeks) and a higher rate of partial union. In the autograft group, all 10 patients had complete osseous union, while only 4 patients in the OP-1 treated group had similar results. These findings highlight the risk of using orthobiologics for indications that have not yet been tested, as the response in different anatomic areas cannot be predicted based on previous studies.

Recommendation

The results of the available randomized controlled trials indicate that rhBMP-2 is effective at achieving bony union in human subjects. The significant cost associated with the use of bone morphogenetic protein (BMP) is a concern and should prohibit its use in routine, closed fractures at this time.

- On the basis of the existing literature, use of rhBMP-2 in open fractures can only be recommended in high-energy open tibia fractures treated with unreamed nails; there is no data in other long bones or with other modes of fracture stabilization [overall quality: high]

Finding the evidence: primary spinal fusion

- Level IV: 2

Findings

Pain and disability from degenerative spine disease, particularly low back pain, is a tremendous burden on both patients and society.¹¹² Treatment of this disorder is typically conservative, although fusion of the spine is an option for patients who have failed conservative management. This can be accomplished from an anterior, posterior, or combined approach, and stability and fusion can be accomplished with or without the use of instrumentation. The gold standard to enhance fusion is autograft in the form of iliac crest bone graft (ICBG), although there is reported morbidity associated with harvesting it, and the additional operative time, blood loss, and postoperative pain make an “off-the-shelf” bone-graft substitute product very attractive.¹¹³ In an effort to decrease the need for autologous graft, orthobiologics and allografts have been used with increasing frequency.

Animal studies have demonstrated the efficacy of rhBMP-2 in spinal fusion.^{114–119} Human studies have shown similar benefits. One of the earliest published studies was a pilot study for posterolateral spinal fusion. In this study 25 patients were randomized to either instrumented posterolateral fusion supplemented with either autograft or BMP-2 or BMP-2 alone without instrumentation.¹²⁰ The rate of fusion at 1 year follow-up was only 40% in the patients treated with autograft, while 100% of the patients who were treated with BMP-2 had achieved fusion. A larger randomized study compared rhBMP-2 in an absorbable collagen sponge carrier or ICBG in combination with a structural allograft dowel for anterior lumbar interbody fusion (ALIF).¹²¹ The patients were followed for 2 years, and at the final follow-up fusion was significantly greater in the rhBMP-2 treated patients (98.5 vs. 76.1, $p < 0.001$). Revision procedures were also more common in the control group, with eight patients returning to the operating room as compared to only two patients in the rhBMP-2 group.

Dawson et al. randomized 46 patients who underwent posterolateral spinal fusion with instrumentation to receive either rhBMP-2 on an absorbable collagen sponge with a ceramic granule bulking agent or autogenous ICBG. Their results showed a trend towards improvements in clinical outcomes and a higher rate of fusion in the rhBMP-2 group.¹²² A modification of the rhBMP-2 carrier to include a matrix that contained 15% hydroxyapatite and 85% beta-tricalcium phosphate particles was developed, with the evidence demonstrating that the new carrier would have improved properties with respect to bone remodeling.¹²³ Dimar et al. studied this new formulation in 463 patients who underwent posterolateral instrumented fusion who

were randomized to receive either autogenous ICBG or rhBMP-2.¹²⁴ With regard to the index procedure, patients in the ICBG group had longer operative times and greater blood loss, although the length of hospital stay was comparable with the BMP-treated group. Follow-up at 2 years was 89% and included both clinical and radiographic outcomes. The rates of fusion were higher for rhBMP-2 at all time points, with 96% achieving fusion by radiographic parameters compared to 89% at 2 years ($p = 0.014$).

A cost analysis was performed in conjunction with a randomized controlled trial of patients over 60 years of age who underwent posterolateral lumbar fusion.¹²⁵ The investigators found the final costs at 2 years were over \$2000 higher per patient for those treated with autogenous ICBG. It was suggested by the authors that the increased costs in the ICBG group may have been related to the insignificant increased rate of nonunion and subsequent revision operations. Other nonrandomized or retrospective studies have also found high rates of fusion with the use of rhBMP-2 in lumbar fusions that were comparable to autogenous ICBG.¹²⁶⁻¹²⁸

Initial studies in spinal fusion surgery using OP-1 were for posterolateral fusion in patients with degenerative spondylolisthesis. Results were comparable to historical controls and complications were minimal.^{129,130} These reports were followed by a randomized controlled trial that included 335 patients treated with posterolateral fusion for degenerative spondylolisthesis.¹³¹ The patients were randomized in a 2:1 fashion to receive either OP-1 putty or autogenous ICBG as the sole means of fusion. The use of OP-1 was associated with shorter operative times as well as less intraoperative blood loss. When the investigators analyzed patients with more than 36 months of follow-up they found that clinical and dynamic radiographic parameters were comparable. What was seen was a significant difference in the presence of new bone in the intertransverse process region as measured by CT scan, with only 56% of the OP-1 putty group showing bridging bone compared to 83% of the autograft group. This difference did not translate into a clinical difference, particularly in relation to revision procedures. The authors also noted a transient increase in OP-1 antibodies, although they reported no evidence of systemic toxicity from this.

Recommendations

The large numbers of randomized studies indicate that rhBMP-2 is effective in achieving fusion and this rate of fusion is superior, or at least equivalent to, that achieved with ICBG.

- While clinical outcomes appear equivalent, the cost analysis reported by Carreon et al. supports the use of rhBMP-2 as a potential cost-saving measure in lumbar fusion [overall quality: moderate-high]¹³²
- The trials have shown equivalent clinical outcomes when OP-1 is used as an adjunct to posterolateral fusion,

and although they did show shorter operative times and a decrease in blood loss in comparison to use of ICBG, the magnitude of these differences and the costs associated with the use of OP-1 do not warrant its use as a standard treatment at this time [overall quality: moderate-high]

Question 3: What orthobiologics are recommended for healing of recalcitrant nonunions?

Case 1 clarification

Our patient has persistent pain at the site of the fracture. Imaging shows an atrophic nonunion at the site of injury.

Case 2 clarification

Our patient returns for the 2 year follow-up with continued pain in the lumbar spine. Imaging confirms a pseudoarthrosis of both operative levels.

Finding the evidence: nonunion of long bones

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “nonunion OP-1,” “fracture nonunion rhBMP-2”

Quality of the evidence (best available)

- Basic science: 6 animal studies
- Level I: 1
- Level IV: 4

Findings

BMP-7, also known as osteogenic protein-1 (OP-1), is a member of the TGF- β superfamily that has been shown to be involved in fracture healing. This molecule shows an increase in expression during enchondral ossification, and has been shown to strongly induce osteoblastic differentiation.^{133,134} The strong association between fracture healing and OP-1 expression led to human clinical studies to rescue nonunions, potentially through the stimulation of local osteoprogenitor cells. The first randomized study using OP-1 was conducted by Friedlander et al. in which 124 patients were randomized to receive either autograft or a type 1 collagen sponge containing rhOP-1 (OP-1) at the site of nonunion.¹³⁵ During the initial 9 months, 81% of the OP-1 treated patients and 85% of the autograft treated patients were able to bear full weight, an indicator for clinical union. Giannoudis et al. retrospectively reviewed a prospectively collected database of 45 patients treated with a combination of autologous bone graft and OP-1.¹³⁶ This study included a mix of fracture locations, including 19 tibia fractures and 7 humeral and 19 femoral nonunions. Each of the patients had failed at least one previous attempt to achieve union. In this series of recalcitrant nonunions, all of the patients proceeded to unite at an average of 6.8 months (range 4–16). Pelvic pain from the donor site was the most common complication and was seen in six patients, followed by superficial wound infections in three patients

that resolved with a short course of antibiotic treatment. They also noted an absence of deep infections, which is usually high in revision fracture fixation.¹³⁵

There has been an increase in the published reports of patients treated with OP-1 for nonunions in areas other than the tibia. In an industry-sponsored study of 23 patients treated for humeral atrophic nonunion, Bong et al. found that supplementation with 3.5 mg of OP-1 resulted in union in all patients after revision surgery.¹³⁷ There were several problems with the design of this study, including the large variation in the type of bone graft used and the type of fixation employed. Pelvic nonunions and instability can be a source of significant pain. OP-1 was tested as a potential adjuvant in the treatment in these patients. A series of nine patients—four post traumatic nonunions, four patients with postpartum pelvic instability, and one patient with a significant bone defect after sacroiliitis—were treated surgically and supplemented with OP-1.¹³⁸ Overall, this group of patients had undergone an average of 1.6 procedures and had to have a preoperative bone defect of at least 2 cm. Three of the patients with postpartum instability had failed autogenous bone grafting. Union was achieved in eight cases at a minimum follow-up of 12 months.

Recommendation

The limited numbers of randomized studies showing a significant difference in the rate of union with the use of OP-1 make it difficult to recommend it for use on patients at risk for continued nonunion after revision, and when ICBG is not a reasonable option, then the use of either OP-1 or rhBMP-2 can be recommended, in light of the lack of other alternatives [overall quality: moderate-high]

- There is a need for more randomized studies, particularly in the upper extremity, to elucidate the safety and efficacy of OP-1 before expanded use can be recommended [overall quality: moderate-low]

Finding the evidence: spinal pseudoarthrosis

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “nonunion spine rhBMP-2,” “pseudoarthrosis spine rhBMP-2,” “nonunion spine OP-1,” “pseudoarthrosis spine OP-1”

Quality of the evidence (best available)

- Basic science: 1 animal study
- Level I: 1
- Level IV: 4

Findings

Fusion of the spine can result in pseudarthrosis, and when pain is present, revision fixation is usually indicated. Grauer et al. developed a spinal pseudoarthrosis model in New Zealand white rabbits.¹⁴¹ The investigators compared OP-1 to autograft in these animals and found an 82% rate of fusion for OP-1 compared to 42% for autograft. Furlan et al.¹⁴² prospectively enrolled 30 patients scheduled for posterior spinal fusion to evaluate OP-1 as an adjuvant to

autograft in patients who had a previous spinal pseudoarthrosis and/or were at high risk for nonunion. They were able to show an 80% rate of union at the 2 year follow-up. There were no significant events relating to OP-1 use, although they did note asymptomatic linear opacification in the soft tissues, resembling heterotopic ossification.

rhBMP-2 has also been tested in the spine as an alternative to autologous bone graft. It has been used in combination with MasterGraft™, a medical grade combination of 15% hydroxyapatite and 85% beta-tricalcium phosphate.¹⁴³ The graft must be used in combination with supplemental posterior fixation and can be used for two or more levels. Two studies^{144,145} as well as a pilot clinical trial¹⁴⁶ were the impetus for the approval of this product by the U.S. Food and Drug Administration (FDA). In the clinical trial, 25 patients received INFUSE/MasterGraft and 21 control patients receiving autograft. The rate of pseudoarthrosis was found to be 4% in the patients treated with INFUSE/MasterGraft while 9.5% of patients in the control groups suffered from this complication. Adverse events were similar between each group.

Recommendation

Spinal pseudoarthrosis is a difficult problem to address. The available evidence suggests that both OP-1 and rhBMP-2 may have benefits in patients at risk for continued nonunion after revision.

For patients at risk for continued nonunion after revision, and when ICBG is not a reasonable option, then the use of either OP-1 or rhBMP-2 can be recommended, in light of the lack of other alternatives [overall quality: moderate-high]

Question 4: What rules govern the use of orthobiologics?

Cases 1 and 2 clarification

Neither patient wants to have autograft taken from their “hip” as they have heard that the pain after this procedure can be permanent and debilitating.

Regulatory process

The approval process for new drugs and medical devices is an expensive proposition for pharmaceutical companies, estimated to cost \$0.8–1.7 billion.¹⁴⁷ Separate agencies regulate this process in each country. In the United States, the FDA is responsible for reviewing and approving new medical treatments. The European Medicines Agency (EMA) is the FDA equivalent in for the European Union (EU), while China regulates new drugs through the State Food and Drug Administration (SFDA). In the case of rhBMP-2, marketed as Infuse™ in the US and InductOs in Europe (Medtronic Sofamor Danek, Inc, Minneapolis, MN), it was first granted a community market authorization for use for open tibia fractures treated with an intramedullary nail in Europe after a centralized application was reviewed by the Committee

for Human Medicinal Products (CHMP). This committee is made up of delegates from each EU member state and a network of over 3,500 experts.¹⁴⁷ Two other processes, the mutual recognition procedure and the decentralized procedure, are available for achieving approval, although all biotechnology substances must use the centralized procedure. Once a drug or substance receives approval, a summary of product characteristics (SmPC) is published and includes such information as therapeutic indications, dosing, and any warnings. This information is updated as new information is published or new indications are granted.

In the US, the approval process proceeds in one of two ways, depending on the results of the clinical trial and the perceived and known risks and benefits, and results in the product receiving one of two designations. The different mechanisms for approval have important implications on how a drug can be used and marketed. Infuse was granted a pre-market approval (PMA) by the FDA shortly after its approval in Europe for a similar indication with regards to open tibia fractures. It has also received PMAs for anterior single-level lumbar spinal fusion and certain oral maxillofacial and dental regeneration procedures.¹⁴⁸⁻¹⁵⁰ The PMA allows the device to be used as the surgeon deems appropriate but sets regulations on how the company can market the product.

The other designation that a device or drug may receive is a Humanitarian Device Exemption (HDE). This is a much more complicated designation, and is used when safety has been established in clinical trials but efficacy remains in question. The FDA uses this as a way to approve products quickly for use in patients in whom there are few, if any, feasible alternatives. rhBMP-7 (OP-1™, Stryker Biotech, Hopkinton, MA) has received an HDE for two indications. These include “use as an alternative to autograft in recalcitrant long bone nonunions where use of autograft is unfeasible and alternative treatments have failed”¹⁵¹ and in spinal fusion surgery in patients who “have failed a previous spinal fusion surgery, and are not able to provide their own bone or bone marrow for grafting because of a condition such as osteoporosis, diabetes, or smoking.”¹⁵² The approval is further limiting in that the use of OP-1 is restricted to only 4,000 cases per year in the US.

Question 5: What are the reported risk factors with the use of the various FDA/EMA approved orthobiologics?

Case 1 clarification

The patient is treated with revision intramedullary nailing and OP-1 with allograft.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): “rhBMP-2 complications,” “OP-1 complications”

Quality of the evidence (best available)

- Level IV: 11

Findings

Complications have been reported with the use of both BMP-2 and OP-1. These have ranged from case reports of heterotopic ossification¹³⁹ to increased risk of postoperative swelling.¹⁵³ Some have suggested that the use of BMPs should be restricted to patients who are older than 18 years of age and who are not pregnant or expecting to be pregnant in 1 year, based on the supposition that its involvement in growth and development could negatively affect a developing child or fetus.¹⁵⁴ There is no clinical evidence to support the concern in younger patients, and in fact two groups have used BMP-2 in the repair of oral and maxillofacial surgery in a total of 53 patients less than 18 years of age (range 6–14) without short-term complications, other than transient increased swelling of the gums during the first postoperative week.^{155,156} With regard to the restrictions in women of childbearing age, there is evidence from in-vitro studies on both mice and humans that BMP-2 expression, through activation of a Wnt4 signaling pathway, is involved in the early development of the fetus and particularly the process of decidualization.¹⁵⁷ BMP-2 has also been shown to be involved in stimulating vascularization of tumors^{158,159} as well as preventing apoptosis in breast cancer cells¹⁶⁰ and thus there is a theoretical reason to avoid use in patients with active malignancy or in areas of resected tumor.

Each of the BMPs in clinical use has been associated with the formation of heterotopic bone. Wysocki and Cohen reported on a single case of triceps ossification after application of OP-1 for nonunion of a distal humerus fracture.¹⁶¹ A similar report of four cases in the upper extremity was reported by Axelrad et al.¹³⁹ OP-1 was used in three of the cases, while BMP-2 was involved in one case, and all cases involved the humerus. The radiographic appearance of the heterotopic ossification (HO) indicated that it was following the fascial planes, similar to the plane of surgical dissection. In a series of 23 humeral nonunions treated with OP-1, one patient suffered from development of HO around the shoulder that was reported as painful and restrictive.¹³⁷ Boraiah et al. retrospectively reviewed 40 patients treated for tibial plateau fractures.¹⁴⁰ Each patient underwent open reduction and internal fixation with metaphyseal defects treated with freeze-dried fibular allograft supplemented with BMP-2 in a collagen sponge carrier or bone void filler. The relative risk of developing HO was 14 ($p < 0.001$) in patients treated with BMP-2. Four patients treated with BMP-2 required surgical removal of the HO. Similar findings have been seen in spine surgery, although none of the reported cases have resulted in removal of the new bone or long-term sequelae.^{162,163}

The two approved BMPs are members of the TGF- β family, and part of the mechanism of action is through stimulation of the inflammatory process. Crawford et al. reviewed rhBMP-2 use in posterior cervical fusion procedures and found an increased rate of wound complications, although the number only approached significance ($p = 0.113$).¹⁶⁴ They proposed that this finding was related to a local inflammatory reaction induced by rhBMP-2. It is not surprising that there are several reports of postoperative swelling associated with its use.^{155,165–167} Shields et al. reported a 18.5% complication rate related to postoperative swelling after ACDF with INFUSE[®] graft.¹⁶⁵ This included 15 (8.6%) patients with hematoma, 8 of whom required a return to the operating room for evacuation. A similar review of 234 patients found a clinically significant increase in the rate of swelling, with only a 3.6% rate seen in the patients treated with autograft or allograft alone.¹⁶⁷

Summary of recommendations

- With regards to the use of orthobiologics to stimulate fracture healing, the current evidence does not support treating elderly patients with fractures differently than any other group of patients
- Diabetic patients deserve special attention with regards to management of lower extremity fractures, with particular attention to wound care, peripheral vascular disease, peripheral neuropathy, and renal disease
- The prevalence of endocrine abnormalities, as well as the need to treat these conditions regardless of their effect on bone healing, should alert the treating physician to recognize patients at risk early in the treatment of fractures
- For HIV-infected patients, the available evidence suggests a trend that Gustilo–Anderson type II and III fractures are at an increased risk of infection and possibly nonunion
- Obesity alone is not an indication for the use of an orthobiologic agent
- The physician should counsel patients on smoking cessation and reducing or eliminating other risky behavior such as drug and alcohol abuse, as these interventions will promote the overall health of the patient and will likely decrease the risk of complications in those treated both operatively and nonoperatively
- Use of rhBMP-2 in open fractures can only be recommended in high-energy open tibia fractures treated with nails; there is no data in other long bones or with other modes of fracture stabilization
- Cost analysis supports the use of rhBMP-2 as a potential cost-saving measure in lumbar fusion
- The use of OP-1 as a standard treatment is not warranted at this time

- There is a need for more randomized studies, particularly in the upper extremity, to elucidate the safety and efficacy of OP-1 before expanded use can be recommended.
- In patients at risk for continued nonunion after revision, and when ICBG is not a reasonable option, then the use of either OP-1 or rhBMP-2 can be recommended, in light of the lack of other alternatives

Conclusion

The evidence regarding the use of orthobiologics is slowly evolving. Currently, the expanding use of these products is reflected in an increasing number of case reports and series that evaluate the treatment of nonunions in areas of the body for which the product has not been tested. Long-term follow-up and larger-scale randomized trials will need to be conducted to confirm the safety and efficacy of these procedures, as well as the cost benefits when compared to current practice standards.

The Role of Computer Navigation in Total Hip Arthroplasty

Jonathan M. Loughead¹ and Richard W. McCalden²

¹Queen Elizabeth Hospital, Gateshead, UK

²London Health Sciences Centre, London, ON, Canada

Case scenario

A 54 year old woman, who works as an accountant and is normally active and independent, complains of increasing pain in her right groin. She can no longer play golf, and is having difficulty sleeping. Radiographs show significant loss of joint space as a result of osteoarthritis, and she has restricted flexion and internal rotation of her hip. She has made the decision, alongside her surgeon, to proceed with total hip arthroplasty.

Relevant anatomy

Alignment of total hip arthroplasty is important to reduce the risk of dislocation of the implant, and also to minimize edge loading and accelerated wear of the bearing surfaces. This chapter focuses on the role of navigated surgery to improve the alignment of hip arthroplasty or hip resurfacing. The orientation of the acetabulum is best described in operative terms as *inclination* in the coronal plane (rotation around the AP or sagittal axis), and *anteversion* (rotation around the transverse axis).

Importance of the problem

A large number of total hip replacements (THR) are performed annually in many developed countries. In Canada (2006–2007)¹ 24,000 were performed, and data in the from the UK joint registry recorded 71,000 THRs in 2008.² There is a trend towards increasing number of both primary and revision THRs. Extrapolation of data from the USA suggests that number of primary THRs will increase from

202,500 in 2003 to at least 572,000 by 2030.³ This increase in numbers of THRs is the result of a trend for operating on younger patients earlier in the disease, population expansion, and ageing of the population. In the UK the percentage of the population over the age of 65 years is increasing from 16% in 2008 to a projected 23% by 2033.⁴ In the USA in 2004 there were 36.3 million people aged over 65, and by 2050 this figure is projected to reach 86.7 million.⁵

Dislocation

Orientation of THR, in particular of the acetabular component, correlates with the risk of dislocation. Original work by Lewinnek et al.⁶ demonstrated a “safe zone” where the acetabular component could be inserted with a lower risk of dislocation. This zone was 40° abduction ±10° and 15° anteversion ±10°. Subsequent work supports a lower angle of abduction, resulting in a lower rate of dislocation.⁷ Dislocation following total hip replacement varies widely between publications but in most series is between 1–3%. Data from the New Zealand joint registry highlights dislocation as the most common reason for revision THR between 1999 and 2006.⁸

Wear

In addition to the increased risk of dislocation with poor acetabular component orientation, considerable evidence exists for an increase in wear of the joint surfaces and osteolysis. A number of studies have demonstrated lower polyethylene wear rates when the abduction angle is less than 45°.^{9–11} Additionally, a higher cup inclination angle has been associated with pelvic osteolysis.^{7,12} As we move towards alternative bearing surfaces the same trend for greater wear (as measured by metal ion concentration) has

Figure 14.1 Acetabular inclination and anteversion (operative).

been demonstrated with a higher abduction angle,^{13,14} and in one study by a higher anteversion angle.¹⁴ Since significant osteolysis may lead to revision, acetabular orientation can be correlated with a clinical outcome.

Defining acetabular component position

A multitude of terms are used to describe acetabular orientation, with inclination and anteversion being the most widely accepted (Figure 14.1). The orientation relates to the acetabular axis, which is perpendicular to the plane of the socket face. Most of the literature on acetabular orientation relates to measurements taken from a supine AP pelvic radiograph, but this measurement may differ to the position at the time of surgery when the pelvis may lie in a different plane, or the functional position when the patient is mobile.

When using navigation or CT, the orientation of the acetabulum is referenced to the anterior pelvic plane (the plane subtended by the pubic tubercles and the anterior superior iliac spines). It is important to note that this may not always be aligned with the coronal plane, and will therefore affect the measured anteversion of the cup.¹⁵ Additionally, if CT is used to measure component position then it may be based on the anatomic definition of anteversion and inclination as described by Murray,¹⁶ or it may use the radiographic definition. Using the anatomic definition of cup orientation will increase the measured inclination and anteversion.

As measured cup position on CT scan references off the anterior pelvic plane (APP), this correlates well with Lewineek's work as he attempted to standardize radiographs using a tripod level externally applied to the APP. Since conventional radiographs are normally aligned with

the coronal plane rather than the APP, any degree of pelvic tilt will affect the measurements taken on the AP radiograph. If the radiograph is centered on the pubic symphysis, rather than the hip, the anteversion is affected by divergence of the x-ray beam. Additionally, some investigators¹⁴ have used standing AP pelvic radiographs (which will alter pelvic tilt compared to supine films), arguing that this represents a more functional position. The vast difference in terminology and radiographic techniques in determining acetabular component position is problematic and certainly confounds comparison between studies.

An extremely large body of information on hip surgery and navigation is available to surgeons and the general public over the internet: a Google search returns more than 489,000 hits when the search terms "navigation" and "hip surgery" are entered. The variability in quality of the available information necessitates reference to good-quality, evidence-based literature.

Top five questions

1. Does navigation improve component alignment following hip arthroplasty?
2. Which type of navigation should be used and how should the patient be positioned?
3. When should navigation be used?
4. Does navigation improve alignment in hip resurfacing?
5. Does navigation improve clinical outcomes following THR?

Question 1: Does navigation improve component alignment following hip arthroplasty?

Case clarification

The patient and surgeon in question are anxious to avoid complications following elective THR irrespective of time or costs involved. Would the use of navigation reduce the likelihood of poor alignment?

Relevance

If the acetabular component is poorly aligned then the patient may be predisposed to a higher risk of dislocation or increased wear.

Current opinion

Hip navigation is likely to reduce the number of cups placed at the extremes of alignment compared to conventional surgery.

Finding the evidence

- Cochrane Database: under the search terms "hip AND navigation OR computer"

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: hip AND navigation OR computer
- MEDLINE search identifying the intervention (hip arthroplasty or hip replacement or hip resurfacing). We used the keywords “computer assisted” OR “navigation”
- The search was focused to exclude papers not directly related to alignment of hip replacement

Quality of the evidence

Level I

- 1 meta-analysis
- 3 randomized trials

Level II

- 1 randomized trials with methodologic limitations

Level III

- 4 case control studies

Level IV

- 3 case series

Findings

The articles from our search were narrowed down to those with the best quality of evidence. The main focus of concern is acetabular orientation, since this is technically the most error-prone step in THR. No Cochrane reviews were identified, but a single meta-analysis and three randomized con-

trolled trials (RCTs) exist. Additionally, there are four comparative series. The best evidence is summarized in Table 14.1. The remainder of the studies were either case series or based on model or cadaveric work and therefore represented a lower quality of evidence. We included all techniques of hip navigation (CT based, fluoroscopic, and imageless), and all hip approaches.

Evaluation of the final component position was performed using CT scan in the studies by Kalteiss et al.¹⁸ and Parratte et al.¹⁹ In contrast, the study by Leenders et al.²⁰ used standing AP pelvic radiographs centered on the pubic symphysis and only measured cup inclination, not cup anteversion. However, since cup inclination can be more reliably measured and the same technique was used in both groups, the results of their study are noteworthy. It should be remembered that measured cup anteversion on plain radiograph is affected by pelvic tilt and rotation and is more difficult to assess accurately. There is consistent reduction in outliers (as defined by Leewineek et al.⁶) using either CT or imageless navigation. Since we are interested in avoiding cups placed outside the “safe zone,” this would appear to be more valid than looking at the mean cup inclination and anteversion. All of the studies have analyzed either variance of the measured values from the safe zone or absolute numbers outside the safe zone. The study by Leenders et al.⁴ included three cohorts of patients, the first of which was performed freehand, while the subsequent two were randomized to either freehand

Table 14.1 Best evidence comparing hip navigation with free hand

Author	Type of study	Technique	N navigated	N control	Results	P value

Chapter 44: Imageless cup and stem navigation in dysplastic hips with the navitrack and vector vision systems.pp.344–51. Navigation and MIS in Orthopaedic Surgery: Springer Heidelberg 2007.)

	N cases	Outliers—inclination ^a	Outliers—anteversion	Dislocations	10° liner used
Freehand	37 (2 missing CT)	6	2	1	6
Navigated	37 (12 missing CT)	0	1	0	1

^a>10° from optimum position.

technique or navigation. There was a reduction in outliers comparing groups 2 and 3, which did not reach statistical significance, while both groups 2 and 3 were significantly better than the first cohort.

An additional clinical study is that by Babisch et al.²⁵ Although this was a randomized trial of imageless navigation vs. control, unfortunately its quality is significantly reduced by having follow-up CT data for only 60 of the 74 patients. The results of this study are summarized in Table 14.2.

Once again this study shows a reduction in outliers in the navigated group, and additionally a lower use of lipped liners. Numerous other studies have validated the use of other navigation systems by performing a series of cases followed by postoperative CT, while a number of laboratory-based studies compare cup position with navigation and freehand methods. Almost universally these studies demonstrate improved alignment with the navigation. It is worthwhile mentioning some of the earliest work performed by DiGioia et al.,²⁶ who demonstrated orientation outside the safe zone in 59 of 74 cups aligned using a conventional mechanical guide, using a CT-based navigation system as the control.

In summary, by reducing the number of outliers, navigation does appear to improve acetabular component position following THR. However, it is worth considering two further issues. First, although the studies demonstrate improved positioning of the cup (placed where the surgeon had planned), given our concerns about pelvic tilt and the change in orientation of the acetabulum in a functional position (standing, walking, etc.), we may be no further forward in placing the cup in the ideal position for each patient; secondly, radiographically measured alignment is a surrogate measure of success, but it remains unclear whether this leads to an improvement in clinical outcomes (discussed in Question 5).

Furthermore, since positioning the cup in a predetermined position may not be ideal for all patients, perhaps navigation should be used to assess the range of movement with cup and stem in situ, look for impingement, and confirm restoration of leg length and offset.^{21,27–29}

Recommendation

For patients undergoing THR, evidence suggests:

- Navigation reduces the number of acetabular components placed outside the “safe zone” [overall quality: moderate]

Question 2: Which type of navigation should be used and how should the patient be positioned?

Case clarification

Having decided to proceed with a navigated hip replacement, the surgeon wants to establish what is the best position to have the patient in to optimize the navigation, and which navigation technique to employ. The surgeon normally operates with the patient in the lateral decubitus position.

Relevance

Changing the technique which a surgeon normally employs for THR may increase complications in the learning curve. There are three different navigation techniques which are widely available.

Current opinion

Hip navigation must be performed with the patient supine and is most accurate using a CT-based system.

Finding the evidence

The best-quality studies identified for question 1 were re-evaluated. Additionally, further Level IV evidence was evaluated:

- 8 case series

Findings

Navigation concepts Hip navigation systems have evolved from the early systems which were based on a preoperative CT scan which is then mapped into the navigation software to create a virtual pelvis. During the surgery a solid reference array must be placed in the ilium, and then, using a pointer imaged with an infrared camera, key points on the

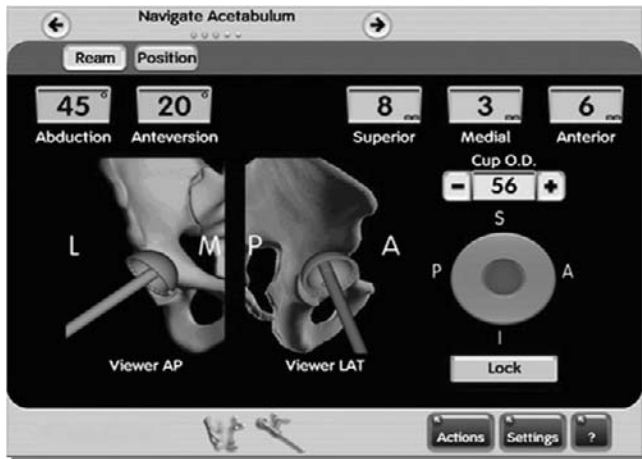

Figure 14.2 Use of navigation for component positioning.

pelvis are acquired. Eventually, through acquisition of sufficient points the navigation system software is able to correlate the pelvis mapped out on the surgery table with the virtual pelvis. The representation of the pelvis then appears animated on a screen, and with an array attached to the surgical instruments, the acetabular component can be reamed and seated (Figure 14.2). Greatest accuracy is obtained if the points acquired closely match the virtual pelvis and the points are obtained at maximum separation. Conventionally the frontal plane of the pelvis is acquired together with additional points around the acetabulum.

In contrast, imageless systems do not require the use of specialized preoperative imaging or the use of ionizing radiation during the surgery. This system uses the same technique of acquiring bony landmarks from the frontal plane of the pelvis and the acetabulum, but does not match this to the patient's previously imaged virtual pelvis. Instead, fluoroscopic systems utilize calibrated image intensifier images obtained at the time of surgery to digitize bony landmarks around the pelvis, and otherwise acquire points within the surgical field in a similar fashion to an imageless system.

Patient position Crucial to almost all of the systems in use is to accurately map out the frontal plane of the pelvis. This involves acquiring points from the contralateral side to the surgical site; in particular, the contralateral anterior superior iliac spine (ASIS) and pubic tubercle must be acquired. This is difficult to do with the patient in the lateral decubitus position. The most straightforward solution is to perform the surgery with the patient supine, and include the contralateral pelvis in the surgical field. The added advantage of the supine position is that it can control pelvic tilt and pelvic rotation to some extent, and may therefore facilitate acetabular positioning even without navigation.

With increasing frequency, however, THR is performed in the lateral decubitus position. In particular, the posterior approach cannot be performed with the patient supine, which arguably may preclude the use of navigation. In response a number of techniques have evolved to allow acquisition of the frontal plane of the pelvis while operating on the patient in the lateral position. The simplest of these involves setting the patient up in the lateral position, performing surgery in a conventional manner and using fluoroscopy to acquire the pubic tubercles and contralateral ASIS. This technique has been employed by a number of surgeons.³⁰⁻³⁴ Alternatively, the patient can be placed supine, have the reference array placed on the ipsilateral ilium percutaneously and remote to the surgical field, following which acquisition of the frontal plane is performed before final positioning and aseptic preparation of the patient. In future, it may be possible to use navigation without acquiring the frontal plane of the pelvis, and rather to utilize more points around the acetabulum and the transverse acetabular ligament.

Evidence for the techniques The best clinical studies identified (one meta-analysis, three randomized controlled trials, and four comparative series) have been stratified by the technique employed and the patient position (Table 14.3).

While all of the RCTs have positioned the patient supine and employed a lateral or anterolateral approach, there is supportive evidence for the CT-based and the imageless systems, although the imageless system in fact performs better. Two of the studies clearly specify the patient is positioned laterally and have used the posterior approach. Once again the findings are supportive of positioning the patient laterally and using either technique, although only the second cohort of patients having navigation in the series by Najarian et al. was significantly better than the historical controls.²⁴ Interestingly, Najarian et al. registered the contralateral ASIS having already positioned the patient in the lateral decubitus position, and it may be that this limits the accuracy of the system, particularly in obese patients. Additional support for the use of the lateral position with navigation is available from validated case series.³⁵⁻³⁷

None of the above studies used fluoroscopy, although this technique has been successfully employed by other authors,³⁰⁻³⁴ and lends itself to registration of the contralateral pelvis when the patient is in the lateral position.

Summary

Good-quality evidence exists for the use of either CT-based or imageless navigation systems. Although the quality of evidence supporting the use of fluoroscopy is poorer there are still a number of case series of its use, and validation with postoperative CT.

Table 14.3 Evidence for navigation by patient position and approach

Study	Number of cases	Technique	Patient position	Surgical approach	Results	P value
Kalteiss et al. ¹⁸	30 + 30	CT/imageless	Supine	Lateral	Outliers 53% vs. 17% (CT) vs. 7% (imageless) ^a	<0.001 vs. control
Leenders et al. ²⁰	50	CT	Supine	Anterolateral	Reduction in outliers/reduced SD	NS
Parratte et al. ¹⁹	30	Imageless	Supine	Anterolateral	57% outliers vs. 20%	<0.002
Lazovic et al. ²¹	127	Imageless	Supine	Lateral (Hardinge)	Outliers 2.7% vs. 0.8% (inclination) and 7.3% vs. 2.4% anteversion	Not given
Sugano et al. ²²	59	CT	Lateral decubitus	Posterior	Outliers 28% vs. 0%	<0.0001
Haaker et al. ²³	98	CT	Not specified	Anterolateral	Outliers (anteversion) 28% vs. 7%	<0.0001
Najarian et al. ²⁴	50 + 50	Imageless	Lateral	MIS posterior	NS difference between control and 1st cohort nav. P = 0.025 between control and 2nd cohort	= 0.025

^aP = 0.067 CT-based vs. imageless.

Clearly not all departments will readily have access to CT which can be transferred onto a navigation platform, and there is an issue about the use of ionizing radiation if it can be avoided. The imageless technique has the advantage that minimal additional equipment is required, and it is likely to appeal to those who are familiar with its use for knee replacement surgery. The system is most accurate if data is acquired with the patient supine or semilateral before final positioning. However, this will prolong surgery and for those who prefer to operate with the patient in the lateral position the option exists to utilize fluoroscopy to acquire the frontal plane of the pelvis.

Recommendation

For patients undergoing navigated THR, evidence suggests:

- CT based and imageless systems appear equally effective [overall quality: very low]

Question 3: When should navigation be used?

Case clarification

Having used the navigation system successfully for his first case, the surgeon is unsure whether he should incorporate navigation into all his cases or whether it should be used only in specific cases.

Relevance

Introducing navigation for THR will increase operative time and costs. As complication rates following THR

are low, introducing it for all cases may not be cost-effective.

Current opinion

Hip navigation is time consuming and the benefit in introducing it for all patients would be marginal.

Finding the evidence

- Cochrane Database: under the search terms “hip AND navigation OR computer”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: hip AND navigation OR computer
- MEDLINE search identifying the intervention (Hip arthroplasty OR hip replacement OR hip resurfacing. We used the keywords “computer assisted” OR “navigation”
- Search results were focused to evaluate clinical case series and clinical trials for length of surgery, and use of navigation in complex cases and minimally invasive surgery

Quality of the evidence

- 2 randomized trials

Level II

- 1 randomized trial with methodologic limitations

Level III

- 3 case control study

Level IV

- 4 case series

Level V

- 1 “bench” study
- 1 expert opinion

Findings

If navigation is to be used for all patients undergoing THR then one of the potential concerns is the surgical time. Studies that have compared surgery time with navigation and control are shown in Table 14.4. All studies demonstrate an increase in surgery time (ranging from 7 to 58 minutes per case), although one study comments on lengthy computing time which added to the length of the procedure.²² The study by Leenders et al.²⁰ comments on an additional preoperative CT planning time of 20 minutes. Three studies document blood loss in navigated and conventional THR with no difference seen.^{18,22,24}

Complex cases As a result of the increased surgical time with the use of hip navigation, it is arguably not a viable option for all cases; however, perhaps it has a role in more complex cases. The prospective randomized trial by Babisch et al.²⁵ employed navigation or control in a total of 74 patients with congenital hip dysplasia (CDH) (see Table 14.2). Although limited by not all patients having undergone postoperative CT to evaluate cup position, the study shows a considerable improvement in cup position, need for 10° lipped liner, and also more accurate restoration of planned leg length. There are other reports of the use of navigation in dysplasia by Jingushi³⁸ (imageless) and Ohashi³⁹ (CT-based). Where substantial deformity exists preoperatively, then logically a CT-based planning and subsequent navigation as described by Ohashi³⁹ would seem to have clinical merit.

Table 14.4 Operative time

Study	Study design	Increase in surgical time with navigation vs. control (mean)
Kalteiss et al. ¹⁸	RCT	Imageless 7 min CT 17 min
Parratte et al. ¹⁹	RCT	12 min
Lazovic et al. ²¹	Comparative series	11 min
Sugano et al. ²²	Comparative series	58 min ^a
Najararian et al. ²⁴	Comparative series	23 mins (19 min in 2nd cohort)

^a Authors comment on lengthy computing time.

In addition, navigation could also be considered for revision cases (where the anatomy of the acetabulum will be distorted) where reference could still be made to the anterior pelvic plane, perhaps leading to a decreased risk of dislocation, a problem more common in revision surgery.

Training Hip navigation could be used in the training of orthopedic residents. This may facilitate the transition from the resident relying on the consultant to make the decision about direction of reaming and final cup position, to learning to adjust the cup position independently with the use of the navigation feedback. From work done by Gofton et al.⁴⁰ there is evidence that hip navigation can improve accuracy of cup placement in early training and that this knowledge can be retained following delayed retesting without the navigation software.

Minimally invasive surgery Where a surgeon wishes to perform THR using a minimal approach and where the potential for incomplete visualization of the normal anatomic landmarks exists,⁴¹ then navigation may well have a role in aligning not only the acetabulum but also the femur. The study by Najarian et al.²⁴ employs a minimally invasive single-incision posterior approach in both groups, and navigation has been reported by other proponents of minimally invasive hip surgery.^{42–44}

Cost-effectiveness The main aim of using hip navigation is to reduce revision rates following surgery from recurrent dislocation or accelerated wear. Dislocation can result in considerable excess cost with multiple trips to the operating room for reduction of the hip, and then a subsequent revision surgical procedure.

Without good evidence clearly showing a reduction in the risk of dislocation with navigation, it is difficult to estimate the healthcare cost benefits. In order to be cost-effective, the additional equipment and running cost of the navigation, allied to the extended procedure time, would need to be counterbalanced by a saving in terms of revision surgery required. This calculation has been performed by Slover et al.⁴⁵ for the use of navigation in knee surgery. They have estimated that in larger centers, if a 2–2.5% reduction in annual revision rate was achieved with navigation, then over a 20 year period, computer navigation would be cost-effective. Unfortunately, even in total knee replacement (TKR), where navigation has been used for some time, sufficient data on relative risk of revision surgery for navigated and non-navigated TKR does not exist. Data from large joint registries may be necessary to demonstrate any true benefit to navigation.

Recommendations

For patients undergoing THR, evidence suggests:

- Operative surgical time is increased with the use of navigation [overall quality: moderate]

- Blood loss is equal with or without navigation [overall quality: very low]

Question 4: Does navigation improve alignment in hip resurfacing?

Case clarification

The patient and surgeon in question decide to proceed with hip resurfacing. This surgeon has performed limited numbers of this procedure and is anxious to reduce the error in placement of the femoral component. Would the use of navigation reduce the likelihood of misplacement of the femoral component?

Relevance

Both mechanical jigs and navigation are in use for guide wire placement in the femoral neck during hip resurfacing; there is no consensus amongst surgeons on the best technique.

Current opinion

Hip navigation could readily be applied to directing the guide wire for hip resurfacing, thus reducing the risk of notching, oversizing the femoral component, or malposition of the femoral component (excessive varus or valgus).

Finding the evidence

- Cochrane Database: under the search terms “hip AND navigation OR computer”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: hip AND navigation OR computer
- MEDLINE search identifying the intervention (hip arthroplasty OR hip replacement OR hip resurfacing.

We used the keywords “computer assisted” OR “navigation”

- The search focused to include only papers relating to the use of navigation in hip resurfacing

Quality of the evidence

Level III

- 5 case control studies

Level IV

- 3 case series

Level V

- 4 “bench” studies

Findings

Hip resurfacing is gaining increasing popularity as an alternative to THR, but it is a technically demanding procedure to learn. In particular, acetabular exposure can be difficult as a result of the femoral head being left in situ, and, additionally, it requires careful placement of the femoral component in slight valgus to reduce the risk of femoral neck fracture while avoiding notching of the superior tension cortex. Upsizing of the femoral component reduces the likelihood of the above complications but may result in removal of more acetabular bone. Since resurfacing of the femoral head is technically demanding, and is a newer technique, it lends itself to computer navigation. Studies which have compared the use of navigation and freehand placement of the femoral guide pin are summarized in Table 14.5.

The larger series published by Ganapathi et al.⁴⁸ and Resubal et al.⁴⁹ show a significant improvement in guide

Table 14.5 Use of navigation in femoral head resurfacing

Author	Type of study	N navigated	N control	Results	P value	Additional time with navigation
Schnurr et al. ⁴⁶	Retrospective comparison	30	30	NS neck shaft angle, 3 cases <130 in conventional group		15 min
Kruger et al. ⁴⁷	Retrospective comparison	9	9	NS diff		0
Ganapathi et al. ⁴⁸	Retrospective comparison	51	88	38% 5° off planned stem shaft angle in control vs. 0%. 4 notches in control vs. 0.	<0.0001	6 min
Resubal et al. ⁴⁹	Retrospective comparison	45	131	24% outliers for SSA vs. 0 3 notches vs. 0.	0.001	n/a
Seyler et al. ⁵⁰	Retrospective comparison	47	49	Outliers of SSA reduced using navigation, NS difference in notching	n/a	n/a

NS, not significant; SSA, stem–shaft angle.

pin placement with the use of imageless navigation. The work by Seyler et al.⁵⁰ is limited by the fact that the planned preoperative stem–shaft angle (SSA) for the mechanical jig group was not recorded, and they were therefore unable to analyze variability in planned and achieved SSA for the conventional group. Their results did, however, graphically show a reduction in spread of SSA with the use of navigation and additionally acceptable results achieved by residents in training.

A number of studies^{51–54} have performed comparison between mechanical techniques and navigated techniques (either imageless or CT-based), performed either on cadavers or CT-based models. They have universally shown an improvement in alignment with navigation compared to control. Additionally there are three good-quality case series in the literature demonstrating good results for imageless navigation in resurfacing: Olsen et al.⁵⁵ (100 cases), Bailey et al.⁵⁶ (37 cases), and Romanowski et al.⁵⁷ (71 cases).

Of note, there is no large prospective randomized trial to answer this question, although this seems highly justified as both conventional and computer-navigated techniques are currently being used. On the basis of the weaker evidence above, there appears to be an improvement in alignment in the coronal plane with the use of imageless navigation, associated with an increase in time for the procedure of between 0 and 15 minutes.

Recommendation

For patients undergoing hip resurfacing:

- Navigation improves the accuracy of femoral component position [overall quality: low]

Question 5: Does navigation improve clinical outcomes following THR?

Case clarification

The surgeon has been convinced of the evidence for improved alignment using hip navigation, but he wishes to know if there is any objective evidence of improved clinical outcomes with the use of navigation.

Relevance

Objectively reported improvements in clinical outcomes are the gold standard by which any new technique should be evaluated.

Current opinion

There is no clinical evidence of improved outcome with the use of navigation for total hip replacement.

Finding the evidence

- Cochrane Database: under the search terms “hip AND navigation OR computer”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: hip AND navigation OR computer

Level III

- 3 case control studies

Level V

- 1 “bench” study

Findings

Patient-reported clinical outcome measures are the current gold standard for assessing improvement with any new intervention. Although the radiographic analysis of a new procedure is important, it is arguably more critical that this adjacent technique results in either a reduction in complications for the patient or an objective improvement in function. This so called “improvement” is difficult to demonstrate in THR, which is highly successful with a very low complication rate.

Clinical outcome measures Babisch et al.²⁵ compared Harris hip score (HHS), Merle d’Aubigné and Postel score, SF-36, and WOMAC between navigation and control groups in dysplastic cases. No statistically significant difference was seen in SF-36 or WOMAC, while the HHS and Merle d’Aubigné and Postel score were both significantly better in the navigated group. This study also reported on the reproduction of the planned leg length at the end of the procedure; as this was significantly improved in the navigated group, it may account for the improvement in outcomes above.

Other studies by Sugano et al.²² (Merle d’Aubigné and Postel hip score), and by Kruger et al.⁴⁷ (WOMAC, satisfaction and HHS) both showed no significant difference between groups. It is not surprising that simply improving the alignment of the cup does not show a clear improvement in clinical outcomes. Patients who have either subluxation or frank dislocation of their THR may record a better score but, as clinical experience shows, even patients whose cup orientation is suboptimal frequently function well. One should recognize that restoration of leg length

Table 14.6 Dislocations

Authors	N dislocations (cases at risk)		
	Navigated	Control	
Babisch et al. ²⁵	0 (37)	1 (37)	
Kalteiss et al. ¹⁸	0 (60)	1 (30)	
Parratte et al. ¹⁹	0 (30)	0 (30)	
Lazovic et al. ²¹	4.7% (1st cohort) 0.3% (2nd cohort)	6.4%	
Sugano et al. ²²	0 (59)	7 (111)	P = 0.049

and offset, rather than improved cup orientation, may well improve patient satisfaction and perhaps represents the greatest chance of clinical improvement associated with the use of navigation.

Rate of dislocation As a marker for success in hip navigation, episodes of dislocation are a rigid endpoint which can be evaluated. Those comparative studies in which there were any dislocations are summarized in Table 14.6.

For most of the studies the dislocation rate is too low to draw any meaningful conclusion. The dislocation rate in the study by Lazovic et al.²¹ is high in both the navigated and control groups initially, but was considerably reduced in a subsequent second cohort of navigated patients. Sugano et al.²² with a 6 year follow-up for the patients had a significantly higher dislocation rate in the non-navigated group. However, analysis of the acetabular position of these cases showed that two of the cases were outside Lewineek's safe zone and five cases were inside, emphasizing how other factors such as head size and soft tissue repair may influence dislocation. Sugano also noted evidence of femoral neck impingement as demonstrated by wear on follow up radiographs in five of the non-navigated cases, and two further cases in the non-navigated group had evidence of impingement after retrieval at revision surgery.

Unfortunately, as the dislocation rate following THR is low, it would take a large comparative study to convincingly show a reduction in dislocation with the use of acetabular navigation.

Restoration of kinematics As discussed above, Babisch²⁵ shows more accurate restoration of leg length with the use of navigation, and similarly Sugano et al.²² quote correct restoration of leg length in 44 of the navigated cases and incorrect leg length in 11 of 83 non-navigated hips ($p = 0.01$). Unfortunately, Sugano does not explain the reason for

incomplete follow-up of all the patients and the method of assessment of leg length postoperatively. While the data may be lacking, if navigation is used to assess leg length and offset and to adjust it intraoperatively, one would expect it to be accurate, and relatively straightforward. It does not require insertion of a further array into the femur.

Petrella et al.⁵⁸ have published on computer prediction of impingement and range of movement based on digital acquisition of a patient's CT pelvis, and virtual planning of acetabular component position. By varying the orientation of the acetabulum, while keeping the center of rotation in the same place, they have predicted the point of impingement (either implant to implant or implant to bone) of inserting the cup in different orientations. They defined an acceptable range of movement (ROM) of the hip as: flexion 90°, external rotation 30°, extension 15°, abduction and adduction 30°. Using the variability in component position from previous published work,¹⁹ they calculated that non-navigated hips would impinge in 3–5% of cases before achieving this ROM, but all of the navigated hips would achieve this ROM.

Other complications Other problems have been reported with navigation including loosening of the reference array, breakage of the reference pin, and technical failure. Most of the reported series noted an inability to complete the navigated procedure in a small number of cases and felt that this was part of the normal learning curve.

Recommendation

None.

Summary of recommendations

- Navigation reduces the number of acetabular components placed outside the "safe zone"
- Operative surgical time is increased with the use of navigation
- Blood loss is equal with or without navigation
- CT based and imageless systems appear equally effective
- For patients undergoing hip resurfacing, navigation improves the accuracy of femoral component position

Conclusion

Computer navigation has evolved from the early days of slow, CT-based systems into more surgeon-friendly imageless systems. Although it does add additional complexity to the case, there is evidence that navigation can reduce outliers compared to conventional acetabular preparation and seating. Imageless systems appear to have good accu-

racy and have the benefit of not requiring preoperative CT scanning and planning, and the patient can be positioned either supine or in the lateral decubitus position. There are outstanding issues about the cost-effectiveness of navigation applied to all cases, and it is not yet possible to quantify any benefits beyond radiographic positioning. While navigation appears to be helpful in positioning the guide wire in femoral head resurfacing, a good-quality clinical randomized trial is needed to confirm the clear benefit of navigation. For the future, it will be interesting to see how hip navigation is incorporated into training of orthopedic residents, and whether acceptable accuracy is obtained simply by referencing from the ipsilateral pelvis. At present the routine use of navigation for THR is not the standard of care.

Highly Crosslinked Polyethylene in Total Hip Arthroplasty

Glen Richardson, Michael J. Dunbar, and Joseph P. Corkum

Dalhousie University, Halifax, NS, Canada

Case scenario

A 55 year old woman presents to an orthopedic surgeon with advanced osteoarthritis in her right hip. She is able to bear weight, but her gait is poor and overall activity is extremely limited due to the pain in her hip. Conservative treatment options are exhausted, but her pain persists so she is scheduled for a total hip arthroplasty (THA).

Relevant anatomy

Endstage arthritis of the hip joint is often managed with THA. In a THA the proximal femur of the hip is replaced with a prosthesis, and the acetabular liner is placed inside the acetabular cup. There are a number of options to choose for this bearing interface, including highly crosslinked polyethylene (HCLPE).

Importance of the problem

One of the main limitations of THA has been the longevity of the bearing surface (Figure 15.1). Much work has been invested in attempts at improving the bearing championed by Charnley. Any change to the bearing surface raises the potential for adverse unexpected outcomes. HCLPE has been taken up broadly by the orthopedic community, just as short-term results are becoming available. Joint replacement registries have illustrated the extent of crosslinked polyethylene in THA. The Canadian Joint Replacement Registry (CJRR) reported the use of crosslinked polyethylene increased from 45% of hip replacements in 2002–2003

to 76% of hip replacements in 2006–2007.¹ Furthermore, surgeons reporting to the CJRR are using more 32mm heads, up from 13% in 2003–2004 to 31% of THAs in 2006–2007. Coupling this trend with a greater number of younger patients undergoing THA and there certainly is a concern for accelerated wear of THA.

Top four questions

Prognosis

1. Is HCLPE more resistant to wear than ultra-high molecular weight polyethylene (UHMWPE)?
2. Does the improved wear rate of HCLPE allow for the use of larger femoral head sizes in THA?
3. Has the advent of HCLPE resulted in a decrease in the prevalence of osteolysis after THA?

Harm

4. Can the use of HCLPE compromise mechanical properties??

Question 1: Is HCLPE more resistant to wear than UHMWPE?

Case clarification

The patient enjoys outside activities that may put high levels of stress on the implant. Will she be better off in terms of wear by having a HCLPE acetabular liner?

Relevance

UHMWPE that wears more than 0.1mm per year is at higher risk of osteolysis and early implant failure.²

Figure 15.1 AP and lateral views of bilateral hip replacements with UHMWPE demonstrating advanced polyethylene wear and associated osteolysis 16 years postoperatively in a moderately active woman.

Current opinion

Both in-vivo and in-vitro studies have convincingly demonstrated a reduction in wear rates when comparing HCLPE with conventional polyethylene.

Nonclinical

- 7 basic science

Findings

All the manufacturers report significant decreases in wear rates, reporting 85–100% reductions in wear from hip simulator data.³ HCLPE was highly resistant to wear and performed better than conventional polyethylene (i.e., UHMWPE that is not crosslinked) in environments that are felt to increase wear such as the presence of third-body wear particles and roughened femoral heads.⁴⁻⁶

In order to interpret the substantial amount of reported data on HCLPE, a basic knowledge of the different methods of measuring in-vivo wear of polyethylene is necessary. There are manual techniques that rely on manual edge detection to calculate the migration of the femoral head.⁷ To improve accuracy and reproducibility, computer-aided techniques have been developed.^{8,9} The most accurate method of measuring wear is radiostereometry analysis (RSA).^{10,11} Studies looking at wear rates require follow-up

Table 15.1 Summary of evidence for highly cross-linked polyethylene

Study	Year	Methods	Wear analysis	Femoral head size	Liner	Follow-up (years)	Outcome
Ayers et al. ²⁹	2009	RCT	RSA	28mm	Longevity	2	Penetration rate 0.065 mm vs. 0.169 mm
Calvert et al. ²³	2009	RCT	Devane	28mm	Marathon	4	Volumetric wear rate 13.741 mm ³ vs. 60.24 mm ³
McCalden et al. ³⁰	2009	RCT	Martell	28mm	Longevity	6.8	Penetration rate 0.003 mm/yr vs. 0.051 mm/yr
Garcia-Rey et al. ²⁵	2008	RCT	Dorr with AutoCAD	28mm	Durasul	5	Mean wear was 6µm vs. 38µm
Glyn-Jones et al. ²⁶	2008	RCT	RSA	28mm	Longevity	2 yrs	Penetration rate 0.06 mm/yr vs. 0.1 mm/yr
Bragdon et al. ³⁴	2007	Prospective consecutive cases	RSA	28mm vs. 36mm	Longevity	2	No statistical difference in wear
Digas et al. ²¹	2007	Bilateral THA control	RSA	28mm	Longevity	5	Proximal head migration 0.08mm vs. 0.34 mm
Digas et al. ²¹	2007	RCT	RSA	28mm	Durasul	5	Proximal head migration 0.1 mm vs. 0.29mm
Rohrl et al. ³³	2007	Prospective cohort	RSA	28mm	Crossfire	6	Total penetration 0.23mm vs. 0.75mm including creep
Triclot et al. ²⁸	2007	RCT	Martell	28mm	Durasul	4.9	Penetration rate 0.025 mm/yr vs. 0.106 mm/yr
Engh Jr et al. ²⁴	2006	RCT	Martell	28mm	Marathon	5.7	Mean wear rate 0.01 mm/yr vs. 0.19 mm/yr
Geerdink et al. ³¹	2006	RCT	Martell	28mm	Durasul	5	Wear rate 0.083 mm/yr vs. 0.123 mm/yr
Martell et al. ²⁷	2003	RCT	Martell	28mm	Crossfire	2	2-and 3-dimensional linear wear rate reductions of 42% and 50%

RCT, randomized controlled trial; RSA, radiostereometry analysis.

of at least 2 years, in order to get a true estimate of steady-state wear rate because of the effect of plastic deformation (otherwise known as bedding-in or creep).¹²⁻¹⁴

There are seven papers reporting on randomized controlled trials (RCTs) using cobalt chrome femoral heads on HCLPE and using some form of computer-assisted technique to measure the polyethylene wear.¹⁵⁻²¹ Many of the major manufactures of HCLPE are represented in these articles. Marathon (5Mrads), Durasul (9.5Mrads), Longevity (10Mrads), and Crossfire (7.5Mrads) have all demonstrated significant reductions in steady-state wear rates compared to UHMWPE. The reduction in wear varies from 55% to 95% and is often is a function of the wear properties of the control group. Importantly, the follow-up was 4-5 years, but there are no long-term studies.

Five RSA studies on HCLPE have been reported in the literature^{14,22-25}. Durasul, Longevity, and Crossfire HCLPE have all been demonstrated to significantly decrease wear rates compared to UHMWPE. The length of follow-up varied from 2 to 6 years.

A summary of the evidence for HCLPE, regardless of measurement technique, is presented in Table 15.1.

Recommendation

- HCLPE has been demonstrated to decrease wear rates in vitro and in vivo compared to UHMWPE [overall quality: high]

Question 2: Does the improved wear rate of HCLPE allow for the use of larger femoral head sizes in THA?

Case clarification

The surgeon must choose an optimal head size for the femoral component.

Relevance

Larger femoral head components are felt to increase range of motion and decrease dislocation rates of THA.

Current opinion

With UHMWPE, the chosen head size was limited as a result of increased volumetric wear with increasing ball diameter.

Finding the evidence

 - Retrieved 16 articles with 10 potentially relevant

Quality of the evidence

Level III

- 2 retrospective studies

Level IV

- 6 case series

Level V

- 2 case reports and expert opinion

Findings

Muratoglu et al. demonstrated no significant increase in wear associated with head sizes from 22 to 46 mm³. This was also replicated with 32 mm and 38 mm heads articulating against HCLPE treated with 9.5 Mrad.²⁶ In a case series with a 5–8 year follow-up Lachiewicz et al. found no correlation between linear wear rate and head size, but did find an association with volumetric wear.²⁷ Bragdon et al. found similar results when they retrospectively compared 28 and 32 mm heads in a case series involving 200 hips with a minimum follow-up of 6 years.²⁸ RSA has been used to compare 28 and 36 mm heads in a cohort study and no significant difference was found at 3 years.²²

Recommendation

- The use of larger femoral head components with HCLPE does not appear to increase wear rates in short-term studies [overall quality: low]

Question 3: Has the advent of HCLPE resulted in a decrease in the prevalence of osteolysis after THA?

Case clarification

The 55 year old women receiving a THA can realistically expect to live another 20–25 years. Over this period of time the THA is more likely to fail due to osteolysis than any other failure mechanism.

Relevance

Periprosthetic osteolysis is the leading cause of long-term failure in THA.²⁹

Current opinion

The use of UHMWPE in active THA patients will lead to osteolysis and aseptic loosening.

- 3 expert opinion

Findings

In-vitro studies have demonstrated increased inflammatory response to HCLPE wear particles, but clinical studies utilizing CT scans to evaluating osteolysis demonstrate significant reductions in lytic lesions.^{30–33} Others have shown that HCLPE generates a similar macrophage response to conventional polyethylene, and have made the logical conclusion that their lower wear rates should reduce osteolysis.³⁴

Recommendation

- HCLPE reduces the risk of osteolysis at short-term follow up compared to UHMWPE [overall quality: moderate]

Question 4: Can the use of HCLPE compromise mechanical properties?

Case clarification

Should this active patient be concerned about the altered mechanical properties of HCLPE and the possibility of implant failure?

Relevance

In processing HCLPE the steps taken to increase the crosslinking worsen its mechanical properties and this could result in clinical failures.

Current opinion

Increasing the crosslinking in UHMWPE does have a measurable effect on mechanical properties; specifically, fatigue properties, crack propagation, and toughness are all decreased.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “crosslinked” OR “cross-linked” AND “polyethylene” AND “mechanical properties”
 - Found 10 articles
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) -sensitivity search using keywords “crosslinked” OR “cross-linked” AND “polyethylene” AND “mechanical properties”
 - Retrieved 91 articles with 28 potentially relevant

Quality of the evidence*Level III*

- 5 retrospective studies

Level IV

- 1 case series

Level V

- 4 case reports and expert opinion

Nonclinical

- 18 basic science

Findings

The creation of HCLPE results in unfavorable changes with ultimate tensile strength, ductility, modulus, toughness, and crack propagation resistance.^{35,36} Cases of liner failures are reported in the literature, but some of the failures were likely related to implant design.³⁷

Recommendations

- Mechanical properties of HCLPE are negatively affected by crosslinking [overall quality: high]
- Clinical reports of implant failure are rare [overall quality: moderate]

Summary of recommendations

- HCLPE has been demonstrated to decrease wear rates in vitro and in vivo compared to UHMWPE
- The use of larger femoral head components with HCLPE does not appear to increase wear rates in short-term studies
- HCLPE reduces the risk of osteolysis at short-term follow up compared to UHMWPE

- Mechanical properties of HCLPE are negatively affected by crosslinking
- Clinical reports of implant failure are rare

Conclusion

The exposure of UHMWPE to radiation creates a material that behaves differently both on the hip simulator and in the patient. In every study there has been a significant reduction in wear and—even more encouraging—there is a reduction in the number and size of osteolytic lesions. This is not the final story, as the longest follow-up in the best methodological studies is only 6 years. There remains the risk that wear rates could dramatically increase with longer follow-up. Despite the reported liner failures in case series,^{37,38} there have been no liner-associated complications in any of the studies presented in this chapter. Caution must be exerted when using larger head sizes, as there is one RSA RCT that shows there is no effect after only 2 years.²² At present, there is enough reported evidence to support the continued use of HCLPE in THA patients.

Hip Resurfacing vs. Metal-on-Metal Total Hip Arthroplasty

Sanket R. Diwanji, Pascal-André Vendittoli, and Martin Lavigne

Hospital Maisonneuve Rosemont, Montreal, QC, Canada

Case scenario

A 40 year old active man with no past medical history presents to your clinic complaining of right groin pain of 6 months' duration. He has restricted right hip motion and a mild limp. Radiography of the pelvis shows advanced osteoarthritis in the right hip with cystic changes in the femoral head.

Relevant anatomy

Precise knowledge of the vascular supply of the femoral head is important when considering surgical procedures around the femoral head and neck junction. The blood supply to the femoral head epiphysis has been studied in the past, with emphasis on the critical role of the deep branch of the medial femoral circumflex artery (traveling under the short rotators) and the lateral retinacular vessels (traveling along the posterolateral femoral neck).¹⁻⁵ Since the femoral component of hip resurfacing is supported in part by the femoral head epiphysis, it seems intuitive that damage to the blood supply could eventually jeopardize component fixation. None the less, clinical evidence has not confirmed this assumption as most surgeons use a posterior surgical approach without significant occurrence of femoral head collapse/failure.

Clarke described the femoral neck shape as being not circular but more of an ovoid shape with its larger diameter oriented from 2 o'clock to 8 o'clock.⁶ Thus, head-neck offset (distance between head equator and femoral neck surface) is not constant around the head/neck circumference. To replicate natural hip range of motion and avoid femoral neck impingement on the acetabular component, surgeons

performing hip resurfacing must make every effort to reproduce or restore the natural femoral head/neck offset all around the femoral neck.^{7,8} A detailed understanding of the relation between femoral neck diameter and femoral component diameter with the amount of acetabular bone resection and resultant range of motion is critical to optimize success of hip resurfacing.

Importance of the problem

Total hip arthroplasty (THA)* continues to be the gold standard for treatment of degenerative hip disorders. Although it has demonstrated satisfactory clinical outcome in elderly patients, concerns still exist regarding its longevity in young patients.⁹ Among male patients receiving a primary hip arthroplasty in the last decade, the group of patients between 45–54 years of age has grown rapidly, at a rate of 140% compared to the 36% rate seen in older (65–74 years) age group.¹⁰ The concern about the durability of hip arthroplasty in young adults, along with recent improvements in metal-on-metal bearing designs, has led to resurgence of metal-on-metal hip resurfacing (HR).

Since the introduction of metal-on-metal HR devices in the 1990s, over 300,000 procedures have been performed worldwide.¹¹ While HR is being performed with increasing frequency in the US, Canada and the UK,^{10,12,13} it is not quite as popular in Scandinavia¹⁴ and its use in Australia is on the decline.¹⁵ HR accounted for 7.6% of all primary total

*Throughout this chapter, THA means 28 or 32 mm THA (where the diameter of the prosthetic femoral head is 28 or 32mm). The term "LDH (large-diameter head)-THA" is specifically used for studies where diameter of the head is larger than 36mm.

hip replacements recorded by the Australian Joint Replacement Registry (AJRR) in 2008.¹⁵ Most patients were male around 50 years old, suffering from osteoarthritis of the hip. There has been a reduction in the number of female patients undergoing HR, from 27.7% in 2004 to 20.4% in 2008. HR accounted for 2.73% of all hip replacements in Canada in 2006–2007 and HR represented less than 0.5% of all hip arthroplasties in Nordik Hip Registry from 1995 to 2006.^{10,14}

The current surge in patient interest for HR is partly driven by direct-to-consumer advertising over the internet. The search term “hip resurfacing” yields 216,000 results on Google. Furthermore, surgeons are attracted by HR despite benefits that have not yet been validated. Some purported advantages of HR over THA are improved function, femoral bone preservation, better restoration of hip biomechanics, enhanced stability, and easier conversion to THA if need arises.^{16,17} On the other hand, femoral neck fracture, aseptic loosening of the femoral component, lack of long-term outcomes, and surgeon’s learning curve have prevented widespread adoption of procedure.^{18–20} In this scenario, it is imperative to define evidence-based guidelines for selection of the HR procedure over the gold standard THA.

Top ten questions

Perioperative parameters

1. What are the differences relating to surgical technique and hospitalization after HR and THA?
2. Is acetabular bone jeopardized in hip resurfacing?
3. How precise is biomechanical reconstruction of the hip joint after HR and THA?

Outcome of the procedures

4. Does HR provide better clinical outcomes and activity level than THA?
5. Does HR offer greater range of hip motion than THA?
6. Do patients have better gait and postural balance after HR?

Complications and survivorship

7. Is there any difference between procedures in the rate of complication?
8. What level of metal ion release is seen after HR and metal-on-metal THA?
9. Which procedure has higher failure rate: HR or THA?
10. Is HR revision surgery easier than revision of THA, and does it provide better outcomes?

Question 1: What are the differences relating to the surgical technique and hospitalization after HR and THA?

Case clarification

The patient’s BMI is 32 and his hemoglobin level is 13 g%. You explain the patient about operative time, length of incision, approximate blood loss, intraoperative complications, and duration of hospitalization for both procedures.

Relevance

Acetabular cavity exposure is more difficult due to conservation of the femoral head, and femoral component positioning is technically more challenging; HR usually requires more extensive exposure, length of incision and is longer in duration. On the other hand, the femoral canal is not violated in HR, which should lead to reduced blood loss and marrow damage.

Current opinion

Current opinion is conflicting regarding intraoperative outcomes and duration of hospitalization for both procedures.

Finding the evidence

- Cochrane Database with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- Embase with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”

Quality of the evidence

Level I

- 2 randomized trials

Level III

- 3 retrospective comparative studies

Findings

Two randomized controlled trials (RCTs) and three retrospective studies compared perioperative outcomes of HR and THA.^{12,21–25}

Vendittoli and coworkers found significantly longer surgical time in HR (mean 103 minutes) as compared to 85 minutes for THA ($p < 0.001$).^{21,22} The differences in incision length (17.2 cm in HR vs. 14.5 cm in THA, $p < 0.001$) and length of hospital stay (5.0 days in HR and 6.1 days in THA, $p = 0.01$) were statistically significant, whereas total blood

loss and transfusion rates were not. Regarding perioperative complications, two (1.94%) acetabular fissures were reported in the HR group and four (3.92%) intraoperative femoral fissures in THA, all without clinical consequences. The authors also reported that four (3.73%) patients randomized to the HR group were converted intraoperatively to THA for reasons such as extensive femoral head necrosis, severe femoral neck retroversion, acetabular component size not available for the particular system, and need for a supplementary screw fixation in a dysplastic acetabulum.

Three retrospective studies reported on perioperative outcome.^{12,23,24} Fowble and colleagues reported less estimated surgical blood loss ($p = 0.005$) and less postoperative drain output ($p = 0.05$) resulting in 252 mL less total blood loss ($p = 0.0005$) and fewer blood transfusions ($p < 0.0001$) after HR as compared to THA.¹² Vail and colleagues did not find substantial differences in the duration of hospital stay or estimated blood loss, and reported three (3.2%) intraoperative calcar cracks in the THA group.²³ Mont et al. found no difference in the duration of surgery and duration of hospitalization between 54 patients with HR and 54 patients with THA.²⁴

In an RCT comparing HR to large-diameter head THA (LDH-THA), Lavigne and colleagues reported three (12.5%) femoral calcar cracks in the LDH-THA group and one (4.16%) injury to the branch of the obturator artery in the HR group.²⁵

Recommendations

- Length of incision is longer for HR than THA [overall quality: moderate]
- There is conflicting evidence regarding duration of surgery, blood loss and duration of hospitalization after HR and THA [overall quality: low]
- The rate of perioperative complication is similar, but the types of complication are different for HR and THA

Question 2: Is acetabular bone stock jeopardized in hip resurfacing?

Case clarification

The patient's radiographic evaluation shows a remodeled femoral neck which seems larger than the contralateral normal side. The surgeon discusses the possibility of using a larger acetabular component to accommodate the femoral component of HR.

Relevance

Compared to THA, HR clearly preserves more proximal femoral bone stock. In HR, the size of the acetabular component (and thus the amount of acetabular bone resection) is determined by the femoral component diameter. The size of the femoral component may not match the native head

diameter because of a particular patient's neck anatomy, femoral neck enlargement by remodeling or osteophytes, or fear of femoral neck notching. Consequently, there is an ongoing debate on whether more acetabular bone is resected during HR.

Current opinion

Current opinion suggests that hip resurfacing may require a larger acetabular component and thus more acetabular bone removal than conventional THA.

Finding the evidence

- Cochrane Database with search term "hip resurfacing" AND "surface replacement arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: "hip resurfacing OR surface replacement arthroplasty" AND "acetabular bone"
- Embase with search term "hip resurfacing OR surface replacement arthroplasty" AND "acetabular bone"

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 prospective comparative study

- 3 retrospective comparative studies

Findings

Vendittoli et al. prospectively randomized 210 hips to compare conservation of acetabular bone after HR (Durom, Zimmer, Warsaw, USA) and THA (Allofit cup, Zimmer, Warsaw, USA).²⁶ The size of the last reamer used before cup implantation served as a surrogate of acetabular bone resection. They did not find any significant difference in the mean or median diameters of the last acetabular reamer used or the mean size of the acetabular component (54.9 mm for HR and 54.7 mm for THA, $p = 0.770$). However, in 6.8% of HR procedures the size of the acetabular component had to be increased by 2 mm to accommodate the selected femoral component.

In a prospective study, Brennan et al. compared weight of dehydrated, defatted acetabular bone reamed during HR and THA.²⁷ The mean weights of reamed bone were 13.8 g and 11.7 g and the mean external diameters of the acetabulum were 58 mm and 54 mm in the HR and THA groups, respectively. Because their study groups had significant differences in covariates of acetabular size they used nonparametric analysis of covariance (ANCOVA); regression curves displayed no significant difference in the mean weight of acetabular bone removed between the two groups.

Three retrospective studies compared resection of acetabular bone in HR (Birmingham Hip Resurfacing (BHR), Smith & Nephew, UK and Durom, Zimmer Warsaw, USA) and THA (various designs).²⁸⁻³⁰ Two of them reported increased acetabular bone resection for HR. Loughhead and colleagues found significantly larger acetabular component size in an HR group (56.6mm) as compared to a hybrid THA group (52.0mm) ($p < 0.001$).²⁸ Naal et al. also reported that HR required larger cups than conventional THAs in women (52.0mm vs. 49.9mm; $p = 0.00012$) and in men (57.3mm vs. 55.1mm; $p = 4.1E-14$).²⁹ Conversely, the third study found a mean outside diameter of the BHR acetabular components of 2.03mm less than that of the acetabular components in the uncemented THAs for the age-matched women, whereas in men no significant difference was found.³⁰

Recommendations

- Removal of acetabular bone during HR may be comparable to, or slightly greater than, that of conventional THA [overall quality: moderate]
- Implant design (femoral head size increment and acetabular component thickness) and surgical technique play a crucial role in acetabular bone removal.

Question 3: How precise is biomechanical reconstruction of the hip joint after HR and THA?

Case clarification

The patient's AP pelvic radiograph shows limb length shortening of 1.5cm and femoral offset of 34mm on the affected side vs. 44mm on the normal contralateral side. The patient expressed concerns about equalization of his leg lengths and resolution of his limp after HR.

Limb length is evaluated clinically by the spinomalleolar distance or the use of blocks under the affected limb, and radiographically by the perpendicular distance from the interteardrop line to the top of each lesser trochanter. The femoral offset is defined as the perpendicular distance from a line drawn in the center of the femoral canal to the center of rotation of the femoral head.

Relevance

Restoration of normal hip anatomy at hip arthroplasty is associated with improved outcome. Failure to restore the femoral offset is associated with a higher rate of impingement, dislocation, muscle weakness, limping, and bearing surfaces wear. Leg length discrepancy may lead to patient dissatisfaction, litigation, limp, and low back pain. HR should facilitate more precise biomechanical reconstruction of the hip.

Current opinion

Current opinion suggests that leg length equality and femoral offset restoration is more precise with HR.

Finding the evidence

- Cochrane Database with search term "hip resurfacing OR surface replacement arthroplasty" AND "total hip arthroplasty OR total hip replacement"
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: "hip resurfacing OR surface replacement arthroplasty" AND "biomechanical reconstruction OR femoral offset OR leg length"
- Embase with search term "hip resurfacing OR surface replacement arthroplasty" AND "biomechanical reconstruction OR femoral offset OR leg length"

Quality of the evidence

Level I

- 1 randomized trial

Level III

- 3 retrospective comparative studies

Findings

One RCT and two retrospective comparative studies described more precise biomechanical reconstruction after HR as compared to THA, whereas one retrospective study reported the opposite.³¹⁻³⁴

Girard and colleagues studied 120 patients randomized for unilateral HR or THA.³¹ When normal, the contralateral hip was used as a control. The postoperative femoral offset was restored within ± 4 mm in 57% of those with HR and 25% of those with THA ($p < 0.001$). Leg length inequality was restored within ± 4 mm in 86% of the HR and 60% of the THA patients ($p = 0.002$).

In a retrospective study comparing two groups of HR and hybrid THA, Ahmed and colleagues reported that HR restored the femoral offset more accurately and produced less change in leg length than THA.³² The mean difference in femoral offset was -1.3 mm in the HR group and 3.5mm in THA group ($t 2.025$, $p < 0.05$). The mean difference in leg length was 4.9mm (95% CI 3.3–6.4mm) in the HR group vs. 11.9mm (95% CI 8.2–15.6mm) in the THA group. ($t 3.597$, $p < 0.001$). Silva et al. compared 50 hips that had a HR with 40 THAs.³³ They concluded that restoration of leg length equality and femoral offset was more precise with HR provided that the preoperative difference was less than 1cm.

Loughhead and coworkers found significant reduction in femoral offset (from 49.4mm preoperatively to 44.9mm postoperatively) ($p = 0.0004$) and increase in length (3.7mm preoperatively to 6.8mm postoperatively) ($p = 0.001$) in 28 patients who had undergone HR, whereas femoral offset and overall hip length were accurately restored in 26 patients after hybrid THA.³⁴

Recommendations

- HR has the potential to preserve femoral offset and leg length better than THA [overall quality: moderate]
- HR has less potential than THA for restoring normal biomechanics in subjects with significant preoperative deformed anatomy [overall quality: low]

Question 4: Does HR provide better clinical outcomes and activity level than THA?**Case clarification**

The patient was told the choice of procedure was crucial as he would like to be able to perform martial arts and play competitive tennis after surgery.

Relevance

By preserving the proximal femoral anatomy (restoring precise hip biomechanics, using a large head diameter and providing more physiological mechanical loading), HR may potentially provide better clinical function than conventional THA.

Current opinion

Current opinion suggests that the level of activity after HR is higher than after THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- Embase with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”

Quality of the evidence*Level I*

- 3 randomized trials

Level II

- 1 prospective comparative studies

Level III

- 6 retrospective comparative studies

Findings

Vendittoli et al. randomized 210 hips to receive a hybrid HR (109 hips) or 28mm THA (100 hips).^{21,22} A preliminary report showed no significant difference on the WOMAC and Merle d'Aubigné scores at 6 months.^{35,36} In a recent

follow-up evaluation, patients with HR achieved greater WOMAC functional scores by 3.3 points at 2 years follow-up ($p = 0.007$). However, the authors do not believe this difference to be clinically relevant.

With the same group of patients as Vendittoli's study, Lavigne and colleagues compared a subgroup of 81 HRs with 71 THAs to assess type, intensity, and frequency of sports activities performed after each procedure.³⁷ They did not find significant difference in the overall activity score and UCLA score between the groups at 1 year after surgery.³⁸ The degree and intensity of postoperative sporting activities were greater in the HR group although the difference was not significant.

In a prospective comparative study, Fowble and coworkers found higher function score (Harris Hip Score (HHS) minus the pain, deformity, and range of motion components), SF-12 physical activity score, and UCLA scores in HR patients.¹² However, the authors believed that patients undergoing resurfacing were younger, in better general health, and had higher preoperative UCLA scores than patients who underwent THA.

We found six retrospective studies comparing clinical outcomes after HR and THA. Five studies described similar clinical scores,^{24,39-42} whereas one showed higher HHS in HR.²³ Four studies found higher activity levels after HR^{23,24,39,42} while the other two could not demonstrate a difference.^{40,41} (Table 16.1)

In a double-blind RCT of HR vs. LDH-THA, Lavigne and coworkers did not find any difference in the WOMAC and UCLA scores.²⁵ Similarly, Garbuz and colleagues prospectively randomized 104 patients to undergo either HR or LDH-THA.⁴³ At 1 year follow-up, they did not find any difference between two groups in the PAT-5D (Paper Adaptive Test in five domains of Quality of Life in Arthritis Questionnaire), WOMAC, and UCLA scores.

Recommendations

- Controversies persist regarding the clinical outcome and activity level after HR and conventional THA, although most studies favorable to HR included a bias in patient selection. The only RCT of HR and conventional THA found a difference in WOMAC score that was not clinically relevant and no difference in UCLA score [overall quality: low]
- Clinical outcomes and level of activity after HR and LDH-THA are similar [overall quality: moderate]

Question 5: Does HR offer greater range of hip motion than THA?**Case clarification**

On clinical examination, the patient has hip flexion of 100°, abduction 15°, adduction 5°, external rotation 15°, and internal rotation 5°. Since the patient would like to perform

Table 16.1 Summary of clinical outcomes

Study	Level of evidence	Procedure	No. of patients (hips)	Follow-up (months)	Mean clinical scores in points (range)	Conclusion
Pollard et al. 2006	III	HR	54(54)	61	OHS(15.9 (12–42) UCLA 8.4 (4–10)	Similar Oxford hip scores. Resurfacing associated with higher activity levels

martial arts after surgery, you explain him about expected improvement in range of motion (ROM) after HR vs. THA.

Relevance

ROM after hip arthroplasty is becoming an important issue, as patients present at a younger age and are willing to return to a high level of activity. The larger head diameter of HR is theoretically beneficial for improving hip ROM, although the larger neck diameter is unfavorable for the head to neck diameter ratio.

Current opinion

Current opinion suggests that the use of a larger head size in HR may provide greater clinical ROM compared to 28mm THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing” or “surface replacement arthroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing or surface replacement arthroplasty” AND “range of motion”
- Embase with search term “hip resurfacing or surface replacement arthroplasty” AND “range of motion”

Quality of the evidence

Level III

- 6 retrospective comparative studies

Findings

Six retrospective studies have compared ROM between HR and THA. LeDuff et al. reviewed 35 patients who had undergone bilateral surgery with HR on one side and THA on the other.⁴⁰ They found no difference in any of the ROM measurements even after separating the cohort into two groups based on femoral head size of the THA (<40mm

and ≥ 40 mm). Fowble et al. compared 50 HR with 44 THA procedures at a minimum follow-up of 2 years, and found no significant difference in the postoperative range of motion between the two groups.¹² However, the patients undergoing THA started with less ROM and had greater postoperative improvements in flexion, extension, and abduction.

Stulberg et al. compared Harris hip ROM score in 337 HR arthroplasties with 266 ceramic-on-ceramic THAs and found that although the THA group demonstrated greater flexion value, the resurfacing group showed slightly better results in abduction, adduction and internal rotation.⁴¹ Therefore, overall arc of motion at 24 months was similar between the two groups.

Li and colleagues measured ROM after HR and ceramic-on-ceramic THA in two groups of 21 patients, each with osteoarthritis secondary to hip dysplasia, and found significantly better ROM in the HR group ($p < 0.05$).⁴⁴

In another study comparing clinical outcome of HR vs. THA, the HR group exhibited significantly greater total ROM at 2 years (99° vs. 97°, $p < 0.001$).²³ The authors believed that since the examiners were not blinded they may have been more reluctant to force extreme ROM in the THA group for fear of causing dislocation. It is important to note that a difference of 2° in ROM is clinically insignificant.

Lavigne et al. performed hip ROM measurements in 165 patients (LDH-THA, $n = 55$; THA, $n = 50$; and HR, $n = 60$) at minimum 1 year follow-up with a novel standardized method of hip ROM assessment.⁴⁵ They found similar hip ROM in THA and HR. LDH-THA demonstrated a significant 20° increase in the total arc of hip ROM ($p = 0.001$).

Recommendations

- There is no difference in the postoperative ROM between HR and THA [overall quality: low]

- A greater hip ROM was observed with LDH-THA compared to 28mm THA or HR [overall quality: low]

Question 6: Do patients have better gait and postural balance after HR?

Case clarification

The patient now walks slowly with a mild lurch on the affected side. He inquires about improvement in gait after hip arthroplasty.

Relevance

Gait and postural balance analysis can detect subtle differences in functional outcome after hip arthroplasty.⁴⁶ By conserving parts of femoral head and neck, HR has been considered to better preserve hip anatomy. Whether or not this leads to better gait or postural balance parameters is a matter of debate.

Current opinion

Current opinion suggests that gait and postural balance after HR are better than after THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) search using key words: “hip resurfacing OR surface replacement arthroplasty” AND “gait OR posture”
- Embase with search term “hip resurfacing OR surface replacement arthroplasty” AND “gait OR posture”

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 prospective comparative study

Level III

- 1 systematic review of retrospective comparative studies
- 1 retrospective comparative study

Findings

Gait analysis In a prospective pilot study, Shrader et al. compared Lower Extremity Activity Scale (LEAS), gait parameters (maximum hip abduction, maximum hip abduction moment, step width, walking speed, and stride length) and HHS in 7 patients each with HR and THA (with 36mm head).⁴⁷ At 3 months postoperatively, the HR group had greater improvements in hip extension and abduction moment, indicating a more normalized loading of the hip.

In a systematic review comparing HR vs. conventional THA, Marker et al. included three gait studies.⁴⁸ The first one was a retrospective gender-matched study by Mont and colleagues. The study found at a mean 13-month follow-up that patients in the HR group walked faster than patients in either THA or control groups. However, there were no significant differences in hip abductor and extensor moments of patients in those two groups. Lavigne and coworkers examined the distribution of energy generation and absorption in three groups of patients: HR, THA with large-diameter heads and THA with small-diameter heads. They found that patients who received HR and LDH-THA returned to more normal gait patterns than patients who had small-diameter femoral heads. Shimmin and associates compared HR and THA patients who had HHS of 100 to age-matched asymptomatic control patients. They reported no significant difference in gait speed at either fast walking or jogging paces among any of the groups.

Lavigne et al. analysed gait speed and postural balance after HR and LDH-THA in a prospectively randomized double-blind study of 48 patients.²⁵ A third group of 14 healthy subjects served as control. During normal and fast walking and for postural evaluation, both study groups showed similar postoperative results at 12 months. The time period needed for both groups of patients to reach the normal control subject's value for each functional test was 3 months, except for the normal walking speed of the HR group, which reached the control value at 6 months postoperatively.

The postural balance study by Nantel and colleagues reported that THA had greater medial to lateral centers of pressure and mass displacement during dual stance when compared to HR ($p < 0.05$).⁴⁹ The authors attributed the difference to better anatomical preservation, absence of femoral stem, and the larger bearing component in HR.

Recommendations

- Gait speed is greater and postural balance seems better after HR than after THA [overall quality: low]
- There is no difference in gait pattern and postural balance after HR and LDH-THA [overall quality: low]

Question 7: Is there any difference between procedures in the rate of complication?

Case clarification

The patient is concerned about neck fracture of HR and risk of dislocation of THA when performing martial arts.

Relevance

Complications such as femoral neck fracture and avascular necrosis of femoral head are unique to HR. The types and

rate of complication seen after both procedures should be compared to assess the benefit of HR.

Current opinion

It is believed that HR has a higher rate of early complications than THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing” OR “surface replacement arthroplasty” AND “ total hip arthroplasty OR total hip replacement”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing” OR “surface replacement arthroplasty” AND “complications”
- Embase with search term “hip resurfacing” OR “surface replacement arthroplasty” AND “complications”

Quality of the evidence

Level I

- 2 randomized trials

Level III

- 5 retrospective comparative studies
- 1 cohort study

Findings

The findings are summarized in Table 16.2.

Postoperative femoral neck/shaft fracture Vendittoli et al. did not have any femoral neck fracture in an RCT comparing HR with THA.^{21,22}

Three retrospective comparative studies reported the incidence of femoral neck fracture after HR and femoral shaft fracture after THA.^{23,24,42} Pollard and colleagues described a 5.5% rate of femoral neck fracture after 54 HRs and no fracture after 54 THAs.⁴² Vail and colleagues reported femoral neck fracture rate of 1.92% after HR and femoral shaft fracture in two patients after THA (2.4%).²³ In a series of 54 HRs, Mont et al. described one (1.9%) traumatic femoral neck fracture while no fracture occurred in a comparative group of 54 THA patients.²⁴

A multisurgeon national audit of 3429 HRs performed in Australia over a 4 year period demonstrated a fracture rate of 1.46%.¹⁸ 1.91% for women and 0.98% for men. The relative risk of fracture for women vs. men was 1.94961 and this was statistically significant (p < 0.01).

Dislocation In an RCT, Vendittoli and colleagues reported 0% dislocation rate in their HR group compared to 3% in the THA group.^{21,22}

Three retrospective comparative studies compared dislocation rate after HR and THA. Pollard et al. reported a

dislocation rate of 7.4% amongst 54 patients post-THA while none occurred in 54 HR patients.⁴² Vail and coworkers described similar findings; four dislocations (4.3%) in the THA group and none in the HR group.²³ Fowble and colleagues had one posterior dislocation in each group (44 THAs, 50 HRs).¹²

No dislocation was observed in two randomized studies comparing LDH-THA with HR (Lavigne, HR 24 vs. THA 24; Garbuz, HR 48 vs. THA 56).^{25,43}

Heterotopic ossification One randomized study and three retrospective studies discussed heterotopic ossification (HO) after HR and THA. Vendittoli and colleagues evaluated incidence and severity of HO as part of an RCT.⁵⁰ The incidence of HO was 43.7% in the HR group compared to 30.9% in the THA group (p = 0.057). The HR group had a significantly higher rate of severe HO (Brooker grades 3–4) than THA (12.6% vs. 2.1%, p = 0.02).⁵¹ In a study by Fowble and colleagues, Brooker grade I or II HO occurred in 10 HR hips (20%) and four THAs (9.1%).¹² Two resurfaced hips had Grade III HO. There was no difference in the incidence of HO in two other retrospective studies of HR and THA.^{24,40}

Other complications Aseptic loosening of the femoral component of HR was reported by three studies, but no loosening of femoral component of THA was found in any of those studies.^{12,21,42} One randomized study and three retrospective studies reported incidence of infection after THA and HR. While three studies found no significant difference, Vendittoli observed five deep infections in THA and none in HR.^{21,23,24,42} Differences were found in the incidences of venous thromboembolic events and nerve palsy, but without statistical significance.^{12,21,23,42}

Recommendations

- The incidence of femoral neck fracture after HR is 0–5% with an average of 1.5% [overall quality: moderate]
- THA has a higher rate of dislocation than HR. The dislocation rates for HR and LDH-THA are similar [overall quality: moderate]
- The incidence of HO is higher after HR than after THA [overall quality: moderate]
- There seems to be no difference between HR and THA in the rate of infection, nerve injury, and thromboembolic events [overall quality: moderate]

Question 8: What level of metal ion release is seen after HR and metal-on-metal THA?

Case clarification

The patient wonders about possibility of metal ion release and its consequences after HR.

Table 16.2 Comparison of complications after HR and THA

Study	Procedure	No of patients (hips)	Follow-up (months)	Revision/awaiting revision	Intraoperative fracture	Postop. femoral neck /shaft fracture	Infection	HO	Aseptic loosening (femur)	Nerve palsy	Dislocation	DVT/ PE	Other

Relevance

Currently available metal-on-metal articulations are made of cobalt and chromium alloys. Metal ions are released as a result of combined effect of bearing surfaces wear and implant corrosion. Normal serum levels are 0.1–0.2 µg/L for chromium and less than 0.1 µg/L for cobalt.^{52,53}

Metal-on-metal bearing wear and implant corrosion generate insoluble metal particles and soluble metal ions, the later passing into the systemic circulation.⁵⁴ Concerns exist over metal hypersensitivity, osteolysis, chromosomal mutation, carcinogenicity, and fetal exposure to elevated ion levels.⁵⁵ This has prevented broader application of metal-on-metal arthroplasty to some extent.

Current opinion

Current opinion suggests the amount of metal ions released after HR is similar to THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing” AND “surface replacement arthroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing OR surface replacement arthroplasty” AND “metal ions” as well as “total hip replacement AND metal ions”
- Embase with search term “hip resurfacing OR surface replacement arthroplasty” AND “metal ions” as well as “total hip replacement AND metal ions”

Quality of the evidence

Level I

- 2 randomized trials

Level II

- 2(?) prospective comparative studies

Level III

- 5 retrospective comparative studies

Findings

Hip resurfacing vs. 28 mm head THA Vendittoli et al. compared postoperative chromium, cobalt, and titanium concentrations in 117 patients THA with metal-on-metal articulation and HR.⁵⁶ Significantly higher chromium and cobalt levels were found at 3 months in the HR group than in the THA group. No significant difference was found at 2 year postoperative follow-up: THA = 1.62 µg/L and HR = 1.58 µg/L for chromium ($p = 0.819$) and THA = 0.94 µg/L and HR = 0.67 µg/L for cobalt ($p = 0.207$).

Antoniu and coworkers compared metal ion levels among patients with a metal-on-metal THA with either a

28 mm (Metasul, Zimmer, Warsaw, USA) or 36 mm (Ultamet Depuy Orthopaedics, Warsaw, IN) femoral head diameter and patients with HR prosthesis (ASR, Depuy Orthopaedics, Warsaw, USA).⁵⁷ Neither the median (whole blood) cobalt level nor the median chromium levels were significantly different among the three groups at 1 year.

In retrospective studies using various implants, Clarke et al. and Witzleb et al. found significantly higher serum levels of cobalt and chromium in the HR group.^{58,59} Moroni et al. found no difference in ion levels between HR and THA patients.⁶⁰ Similarly, Daniel and colleagues found no significant difference in the values of cobalt and chromium in serum and urine of two groups.⁶¹

HR vs. LDH-THA Garbuz et al. measured chromium and cobalt ions in 26 of 107 patients randomized to a LDH-THA (Durom LDH system, Zimmer, Warsaw, IN) or HR (Durom system, Zimmer, Warsaw, IN).⁴³ At 1 year after surgery the median serum level for cobalt was 10-fold higher ($p = 0.000$) and median serum chromium level was 2.6 fold higher ($p = 0.023$) in the LDH-THA group than in the HR group.

Vendittoli et al. reported on chromium, cobalt, and titanium ion levels in whole blood in subjects with LDH-THA and HR (Durom LDH-THA and HR systems, Zimmer, Warsaw, IN).⁶² They found significantly higher cobalt levels in LDH-THA (2.2 µg/L vs. 0.7 µg/L, $p < 0.001$) at 1 year follow-up. They demonstrated that the addition of a sleeve with modular junctions and an open femoral head design of LDH-THA were significant sources of ion release.

Recommendations

Comparison of the data reported in the literature is complicated by differences in sampling (whole blood, serum, erythrocytes or urine), measurements with various technologies in different laboratories, type of data reported (mean or median, different units of measurement, compared or not to preoperative levels), and different types of implant combinations.

- Durom LDH-THA showed significantly higher cobalt ion release as compared to the Durom HR [overall quality: good]
- The cobalt and chromium ion release after HR and 28 mm THA has shown contradictory results depending on the type of implants studied [overall quality: good]

Question 9: Which procedure has higher failure rate: HR or THA?

Case clarification

The patient's radiograph shows a 1.5 cm cyst in the femoral head and this, combined with his activity level, produces a Surface Arthroplasty Risk Index (SARI) of 3.

The Surface Arthroplasty Risk Index (SARI) was developed by Beaulé and Antoniadis.⁶³ It is based on a 6-point scoring system:

- Femoral head cyst >1 cm = 2 points
 - Weight <82 kg = 2 points
 - Previous hip surgery = 1 point
 - University of California (UCLA) activity score >6 = 1 point
- A SARI score greater than 3 represents a 12-fold increase risk in early failure or adverse radiographic changes.

Relevance

With newer bearing surfaces and better fixation options, the results of modern cementless THA in young patients are quite encouraging.²⁰ At the same time, survival rates for HR are improving as surgeons have moved beyond their learning curves and refined their techniques.²⁴

Current opinion

Current opinion suggests that HR has higher early failure rate than THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- Embase with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”

Quality of the evidence

Level I

- 1 randomized trial

Level II

- Report of the AJRR (2009)

Level III

- 5 retrospective comparative studies
- 1 meta-analysis

Findings

Springers and colleagues performed a meta-analysis of modern cementless femoral components in young patients (mean age < 55 years) having HR or THA.²⁰ Fifteen studies on HR (n = 3002; hips = 3269) and 22 studies (n = 5907; hips = 6408) on THA were included. At a mean of 3.9 years of follow-up, the pooled mechanical failure rate of the femoral component for HR was 2.6% (95% CI 2.0–3.4%); it accounted for 70% of all failures of HR. The most common

reasons were femoral neck fracture and aseptic loosening of the femoral component. The pooled failure rate for THA using femoral revision for mechanical failure as an end-point was 1.3% (95% CI 1.0–1.7%) at a mean 8.4 years of follow-up. The pooled acetabular and overall failure rate (using failure for any reason as criteria) were respectively 2.8% (2.0–3.9%) and 4.6% (95% CI 3.7–5.6) for HR at a mean average follow-up of 3.9 years and 14.1% (95% CI 13.1–15.2%) and 16.1% (95% CI 14.9–17.3%) for THA at a mean average follow-up 8.5 years.

The annual report of the AJRR (2009) reported that HR had a significantly higher revision rate than THA (hazard ratio adjusted for age and sex) (adj HR) = 1.37; 95% CI (1.22, 1.55), *p* < 0.001.¹⁵ At 8 years the cumulative revision is 5.3% for HR compared to 4% for THA. The most common type of revision in HR group was a “femoral component only revision” and was most often undertaken for femoral neck fracture. There was no significant difference in the risk of revision for THA with respect to gender, whereas for HR women had a significantly higher rate of revision. The risk of revision also increased with increasing age in HR population. The registry reported an inverse relationship between the femoral component head size and the risk of revision.

In a randomized study, Vendittoli et al. reported similar rate of reoperations in HR group (four revisions for femoral aseptic loosening, one excision of HO, and one osteoplasty for femoro-acetabular impingement) and THA (one revision for chronic deep infection, one revision for recurrent dislocation, four debridement for early deep infection, and one distal femoral shortening osteotomy for symptomatic leg length discrepancy).²² Pollard et al. reported 4 revisions (out of 63 HR) for failure of femoral component and 4 in THA (3 for osteolysis and 1 for recurrent dislocation).⁴² Vail and colleagues described two reoperations in the HR group (one for fracture of femoral neck and one for deep infection) and two in the THA group (reasons not specified).²³ Fowble also reported one revision in the HR group for femoral neck fracture and none in the THA group.¹² Mont and colleagues reported two revisions in the HR group (one for neck fracture and one for displaced acetabular socket) and two in the THA group (one for acetabular loosening and one for infection).²⁴

Recommendations

- Aseptic loosening of femoral component and femoral neck fracture are the two common modes of failure of HR, which accounts for a higher failure rate of the femoral component of HR vs. THA [overall quality: high]
- Female gender and increasing age have higher risk of revision for HR as compared to males [overall quality: moderate]
- Rates of reoperation seem similar, but reasons for reoperation differ between HR and THA [overall quality: moderate]

Question 10: Is HR revision surgery easier than revision of THA, and does it provide better outcomes?

Case clarification

The patient is aware that revision surgery will likely occur eventually because he is relatively young. He wants to know how complicated the revision surgery will be after HR in comparison to THA.

Relevance

One likely advantage of HR is preservation of the proximal femur since failed femoral components can easily be revised with a primary femoral stem as the femoral canal is not violated during the index procedure.

Current opinion

Current opinion supports easier revisability of HR compared to THA.

Finding the evidence

- Cochrane Database with search term “hip resurfacing OR surface replacement arthroplasty” AND “total hip arthroplasty OR total hip replacement”
- PubMed (www.ncbi.nlm.nih.gov/pubmed) sensitivity search using key words: “hip resurfacing OR surface replacement arthroplasty” AND “revision”
- Embase with search term “hip resurfacing OR surface replacement arthroplasty” AND “revision”

Quality of the evidence

Level II

- Report of the AJRR (2009)

Level III

- 2 retrospective comparative studies

Findings

The Australian Joint Replacement Registry reported the risk of subsequent revision following the first revision of HR and primary conventional THA.¹⁵ They report that 3 years after the first revision for THA and 5 years after for HR, the cumulative percentage for a major total (both femoral and acetabular) revision is 5.3% for HR and 9.2% for THA.

Two studies have compared the outcomes of failed HR procedures converted to conventional THAs with patients who had primary conventional THA.^{64,65} Ball and colleagues compared revisions of 21 HR (in 20 patients) to a group of 58 hips (in 64 patients) who had undergone primary THA, all by the same surgeon.⁶⁴ They found no significant difference between the groups in terms of operative blood loss, operative time, or complication rate. At mean follow-up times of 46 months for the HR group and

57 months for the THA group, there were no significant differences in the HHS, UCLA pain, walking, or activity subscores, or the SF-12 scores.

McGrath and associates compared the perioperative factors, complications, and clinical and radiographic outcomes of 39 patients whose resurfacings were converted to THA to a group of THA patients matched by gender, age, BMI, and preoperative HHS, all performed by the same surgeon.⁶⁵ They found mean operative time for HR conversions were longer by 19 minutes, but all other perioperative measures were similar. At a mean follow-up of 45 months, the HHS of the two groups were similar.

Recommendations

- Clinical outcome of revision after a failed HR is comparable to that of a primary THA [overall quality: low]
- Re-revision rate after first revision seems lower for HR than for THA [overall quality: low]

Summary of recommendations

- HR requires more extensile exposure than THA but there is conflicting evidence regarding duration of surgery, blood loss, and duration of hospitalization after HR and THA
- The rate of perioperative complication is similar, but the types of complication are different for HR and THA
- Removal of acetabular bone during HR may be comparable, or slightly greater, to that of conventional THA
- Implant design (femoral head size increment and acetabular component thickness) and surgical technique play a crucial role in acetabular bone removal
- Hip resurfacing has the potential to better restore femoral offset and leg length as compared to THA, but has less capacity to correct severe deformities
- Controversy persists regarding clinical outcomes and level of activity after HR and THA, but was found to be similar after HR and LDH-THA
- No difference in hip ROM was found between HR and THA. A greater hip ROM has been observed with LDH-THA compared to HR or THA
- Gait speed is greater and postural balance seems better after HR when compared to THA; but is similar to LDH-THA
- Incidence of femoral neck fracture after HR is 0–5%; HR has higher rate of HO and lower rate of dislocation than conventional THA
- Durom LDH-THA showed significantly higher cobalt ion release as compared to the Durom HR
- The release of cobalt and chromium ion after HR and THA has shown contradictory results depending on the type of implants studied
- Higher rate of early femoral component failure has been found in HR as compared to THA

- Female gender and increasing age have higher risk of revision for HR as compared to males
- Rates of reoperation seem similar, but reasons for reoperation differ between HR and THA
- Clinical outcome of revision after a failed HR is comparable to that of a primary THA

Conclusions

The existing evidence does not clearly suggest that HR provide superior clinical outcomes to conventional THA. Preservation of proximal femoral bone can be a distinct advantage of HR, provided complications such as femoral neck fracture and avascular necrosis can be prevented. RCTs with long-term follow-up would be valuable to prove superiority of one procedure over the other.

The Role of Ceramic in Total Hip Arthroplasty

Peter M. Lewis¹ and James P. Waddell²

¹Prince Charles Hospital and Royal Glamorgan Hospital, South Wales, UK

²St Michael's Hospital and University of Toronto, Toronto, ON, Canada

Case scenario

An active 57 year old woman has progressively developed severe pain in her right hip. She has exhausted conservative treatments and is keen to remain active with hobbies including golf and badminton. At present she has mild rest pain and occasional sleep disturbance, but walking is limited to half a mile and she is unable to perform any sporting activities. She is otherwise fit and well.

Importance of the problem

Total hip replacement surgery is one of the commonest procedures performed in Western societies and is considered one of the most effective orthopedic procedures.¹ It is a safe and reliable procedure with an excellent long-term survival in the elderly population. Conventional metal-on-polyethylene (MP) replacements are the traditionally implanted bearings, used initially by Charnley in the 1960s, and still recommended by many today. The long-term survival of this bearing combination is, however, limited by the risk of polyethylene wear and wear-related osteolysis.² In the younger patient, with a longer life expectancy and increased activity demands, there is an up to tenfold increase in the tribological demands of any replacement bearing.³ Conventional MP may not therefore be the ideal option in this age group. In a long-term study of patients under the age of 51, a failure rate requiring revision arthroplasty of over 25% was identified at 20 years and almost 50% at 27 years.⁴ Revision procedures are challenging to both surgeon and patient and are of considerable cost to healthcare providers.⁵ Alternative bearings and joint replacements have therefore been developed. Options

include ceramic bearings, metal-on-metal (MM) resurfacings and replacements, and highly cross-linked polyethylene, all aimed to prolong a joint replacement's survival, and prevent the occurrence of osteolysis and its consequences.

Over 4.5 million alumina ceramic components have been implanted worldwide over the last 35 years.⁶ This chapter focuses on the efficacy of ceramic options available to the orthopedic hip surgeon.

Surgeons and patients are inundated with an ever-increasing easily accessible body of information about health, and specifically about total hip replacement surgery and its options. A Google search for "ceramic hip replacement" returns almost 600,000 hits. High-profile cases such as the article on squeaking ceramic hip replacements published on the front page of the *New York Times* in 1998,⁷ the variable quality, and lack of filtering mandates the need for preappraised evidence-based guides.

Top seven questions

Therapy

1. What are the orthopedic generations of ceramic?
2. What bearing options are available when using ceramics in total hip arthroplasty?
3. Are the clinical outcomes of ceramic total hip replacements equal to those of more conventional articulations?

Prognosis

4. Does a ceramic articulation truly reduce the amount of wear and wear-related osteolysis?
5. What is the risk of fracture?

6. What is the risk of squeaking for a patient considering a ceramic total hip replacement?

Harm

7. What is the risk of revision and what revision options are available if ceramic fails?

Question 1: What are the orthopedic generations of ceramic?

Case clarification

Your patient is intrigued to hear that a ceramic might provide her with an ideal orthopedic bearing. She is, however, interested to know that ceramics were initially related to a high level of failure. What improvements have been made to ceramics in order to limit failures?

Relevance

Optimizing a bearing surface at the expense of its safety is not a satisfactory solution to any initial presenting issue.

Current opinion

Modern ceramics are used with varying popularity around the world. The stigma of initial generations failing will remain of concern to the orthopedic community.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) search using keywords: "ceramic," "ceramic hip," and "ceramic bearings"
- MEDLINE search using keywords: "ceramic," "ceramic hip," and "ceramic bearings"

Quality of the evidence

- Historical review

Findings

Alumina has been continually improved over the years. First-generation alumina ceramics (1974–1988) were characterized by low density, high porosity, and a relatively large grain size. First-generation ceramics did not perform well. Early series reported high failure rates, although the majority of the failures were not due directly to the alumina itself. The main failures were due to aseptic loosening of the femoral stem^{8,9} or of the monoblock acetabular system.¹⁰ The alumina itself was, however, not ideal, with a reported fracture rate of 3–13%.¹¹ The aim with first-generation ceramics was to achieve full or nearly full density (no porosity), which required long sintering times.¹² This resulted in large grain or crystal sizes that translated into a reduction of strength and the high risk of fracture. Lessons were learned from these early series and became the driving force behind the development of second-generation ceramics in the 1980s.

Second- and third-generation alumina ceramics (1988–1994 and 1994–present respectively) are characterized by a reduction in grain size with increased alumina purity. Second-generation ceramics were developed with the addition of calcium oxide or magnesium oxide materials which would limit the increase in alumina grain size during the long sintering process,¹² resulting in a higher-strength product. With third-generation ceramics there have been further improvements with the introduction of processes of hot isostatic pressing, laser etching to avoid surface stress risers, and proof testing. The last of these has been described as the single most important development in improving the reliability of ceramics.¹¹ Before the advent of proof testing, ceramic components were subject to a finished product audit in which a certain number of components from each batch were subject to testing to destruction. If these tests showed values within an acceptable range then the batch was released for sale. Proof testing or "nondestructive stressing" involves subjecting each component to a substantial overload in a manner that ensures the part is not being damaged in any way yet eliminates the possibility of an internal flaw not being detected. One such method is to pressurize the taper portion of a ceramic head with fluid beyond the stresses expected from the metal trunnion. The problem with such techniques is that if an excessively low pressure is used not all flawed heads will be fractured, whereas if a pressure is too high, too many heads will fracture without reducing clinical failures or potentially damaging heads that were not defective.¹³

Advances during each generation resulted in grain size improvement from 4.2 μ m to 3.2 μ m to 1.8 μ m over first, second and third generations with a resultant burst strength improvement of 46 kN, 58 kN and 65 kN respectively.¹⁴

Despite these improvements there persisted a search for a ceramic material to satisfy increasingly more challenging patient demands such as smaller components and additional sizes along with even greater reliability and longevity. It is for this reason that alumina matrix composite was developed. Known as fourth-generation ceramic or by the trade name BIOLOX® (CeramTec AG, Plochingen, Germany) it is a combination of both the major subsets of ceramic, an alumina matrix with zirconia particles homogeneously dispersed and encapsulated. Using a principle that dates back to the early 1970s,⁸ when any crack touches the zirconium it triggers transformation with the resultant volume increase of the particle impeding crack propagation. This process increases the fracture toughness of the material. With the subsequent addition of chromium oxide this restrains the progress of cracking through the formation of platelet-like crystal or whiskers, resulting in further significant gains in mechanical properties.¹¹

Recommendation

With regard to ceramic used in orthopedic hip surgery, evidence suggests:

- There has been an improvement in the purity, production techniques and overall quality of ceramics between early-generation ceramics and current options [overall quality: moderate]

Question 2: What bearing options are available when using ceramics in total hip arthroplasty?**Case clarification**

The patient has been reassured by the explanation of ceramic and its history. Having done some research on total hip replacement, she assumed she would receive a polyethylene liner.

Relevance

The aim of using ceramic components is to optimize the bearing for a young active patient. Although ceramic may be used against a conventional polyethylene liner it may also be used with both ceramic and metal liners.

Current opinion

A recent review of practices in the UK showed there was no clear consensus as to component choice or even fixation method in the younger patient.¹⁵

Openmirrors.com

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) search using keywords: “ceramic,” “ceramic hip,” and “ceramic bearings”
- MEDLINE search using keywords “ceramic,” “ceramic hip,” and “ceramic bearings”

Quality of the evidence

- Historical/industry review

Findings

The proposed advantages of ceramic can be utilized in a number of different bearing options. It may be used as an alternative to a metal head in a conventional hard-on-soft bearing against polyethylene. With a lower R_a and improved wettability it has the potential to provide a low-wear alternative to either stainless steel or cobalt–chrome. It may also be used as a more modern hard-on-hard bearing against either a ceramic liner or, as more recently introduced, ceramic-on-metal (CM) bearing couple. An advantage with hard-on-hard bearings is the potential for fluid film lubrication, an exceptionally low wear rate, and avoidance of osteolytic polyethylene debris. Using hard-on-hard bearings also allows the use of large heads, which, if used with a conventional polyethylene option, would

create excessive volumetric wear. Ceramic-on-ceramic (CC) options also avoid the production of metal ions, which are released and may complicate MP and MM alternatives.¹⁶

No bearing option is perfect, however. A number of complications specific to ceramic, such as fracture and articular squeaking, are discussed in detail later in this chapter. A factor involved in all cases of CC hip replacement is the loss of head and liner option. Using a MP articulation a surgeon has access to multiple head sizes and modular neck lengths spanning 20mm. On the acetabular side, in addition to multiple inner diameter options, there is also the availability of lateralized liners; elevated rims; and anteverted, eccentric, and constrained liners. In contrast, most CC systems have only one head size per cup diameter, with three or four head lengths spanning 10mm or less. Ultimately this results in 20 times fewer options in the ceramic option compared with traditional MP. Equalizing leg lengths and maximizing stability are two crucial goals of total hip arthroplasty.¹³ The availability of numerous liners and head options is one of the ways of achieving this goal. The aforementioned complications of squeak and fracture associated with ceramic articulations are related to design and technique, and apply to a relatively low percentage of patients in clinical practice.¹³ Loss of all of these options may currently be the most substantial disadvantage of CC THA.

Recommendations

With regard to ceramic used in orthopedic hip surgery, evidence suggests:

- Ceramic may be used as a conventional hard-on-soft bearing with a ceramic femoral head articulating against polyethylene, or as a hard-on-hard CC or CM bearing.
- There is less modularity with ceramic bearings as compared to metal and polyethylene implants, limiting the available options to optimize leg lengths and stability.

Question 3: Are the clinical outcomes of ceramic total hip replacements equal to those of more conventional articulations?**Case clarification**

On offering the patient a ceramic total hip replacement you need to assure her that her outcome will be at least as good as with conventional bearings.

Relevance

Any proposed benefit of the longevity of a ceramic bearing would be limited if the clinical outcome for the patient was below the standard expected with a conventional hip replacement.

Current opinion

Most would assume the outcome scores for a patient receiving a ceramic total hip replacement would be equivalent to a conventional replacement.

Finding the evidence

- Cochrane Database, with search: “ceramic hip”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews/randomized control trials: “ceramic hip”
- MEDLINE search using keywords: “ceramic hip”

Quality of the evidence

- Level I: 7
- Level II: 1
- Level IV: 2

Findings

A randomized controlled trial (RCT) comparing 31 CC total hip replacements in 31 patients with 30 cobalt–chrome on highly cross-linked polyethylene in 30 patients revealed no difference in outcome scores between the two groups, looking at WOMAC and SF-36 scores at a follow-up of between 2 and 24 months.¹⁷ An RCT comparing 30 CC replacements with 26 ceramic-on-polyethylene replacements reports no significant difference in joint specific outcome scores at a mean follow-up of 8 years.¹⁸ With a mean follow-up of 35.2 months, an RCT comparing 346 alumina CC hip replacements with a 168 cobalt–chrome-on-polyethylene replacements reports equivalent Harris hip scores (HHS) and patient satisfaction.¹⁴ The results of a mean 5 year RCT comparing 213 CC hips with 101 cobalt–chrome on conventional polyethylene hips concludes that CC articulations are at least equivalent in performance to the MP design.¹⁹ The HHS was 96.6 in the ceramic group and 97 for the MP group. An extension of this series assessing a titanium-coated ceramic bearing again identified no difference in HHS with a mean of 96.6 with a mean of 4.2 years of follow-up.²⁰ Subsequent review of the same cohorts, now with mean follow-up of 8 years, again identified no difference in outcome scores.²¹ Finally, a minimum 2 year follow-up RCT comparing 250 CC articulations with 250 conventional ceramic-on-polyethylene hips showed no difference in clinical outcome and concludes that ceramic hips “reflected the typical results of primary total hip replacements.”²²

A retrospective observational study reports a mean HHS of 90.4 in 107 hips at a minimum follow-up of 7 years.²³ A further retrospective review of 999 CC hips reports an improvement in HHS from 66.5 to 91.2 points and, interestingly, reports an improvement of HHS from 60.1 to 91.3 in the 2.7% of squeaking ceramic hips without significant difference between the groups.²⁴

Recommendations

In terms of outcomes obtained by patients receiving a ceramic total hip replacement, evidence suggests:

- Patients obtain a significant improvement in disease-specific outcome and quality of life scores following a CC total hip replacement [overall quality: high]
- Patients can expect disease-specific and quality of life outcome score improvement at least equivalent to a conventional hard-on-soft total hip replacement at mid-term follow-up [overall quality: high]

Question 4: Does a ceramic articulation truly reduce the amount of wear and wear-related osteolysis?**Case clarification**

Your patient is understandably keen to know what complications she might be prone to with a CC articulation.

Relevance

The reason to consider a ceramic bearing within a total hip replacement is to limit the amount of wear and wear-related osteolysis. Any advantage in using a low-wear ceramic bearing aiming to optimizing the long-term survival will clearly be lost if there is an unacceptably high rate of complications.

Current opinion

Most would consider a ceramic articulation to be a low-wear articulation, but its use continues to cause concern to the orthopedic community with concerns of dislocation through a lack of modularity and lip liners and catastrophic complications such as fracture and requiring potentially complex revision procedures.

Finding the evidence

- Cochrane Database, with search: “ceramic hip”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews/randomized control trials: “ceramic hip” AND “revision”
- MEDLINE search using keywords: “wear” AND “ceramic hip”
- MEDLINE search using keywords: “ceramic hip” AND “osteolysis”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) search using keywords “ceramic hip” AND “osteolysis”

Quality of the evidence

- Level I: 7
- Level II: 1

Findings

In-vitro studies have shown very low wear rates for ceramic couples, with volumetric wear combinations from 2000 to 4000 times less than MP.^{14,25} A clinical review of in-vivo studies supports wear properties of ceramic in a hybrid articulation with wear rates reduced by 1.5–4-fold in comparison to MP.²⁶

An RCT comparing cobalt–chrome vs. zirconia femoral heads measured subsequent polyethylene wear with computer software at 51 months. It showed no difference in wear, with an annual head penetration of 0.06 mm/year in the cobalt–chrome articulation and 0.055 mm/year in the zirconia cohort.²⁷ This study was subsequently abandoned with concerns about the long-term stability of zirconia. A further RCT involving zirconia directly compared zirconia heads with cobalt–chrome heads in sequential randomized bilateral THAs in 52 patients. It revealed an annual wear rate of 0.17 mm/year in the cobalt–chrome group but a wear rate of 0.08 mm/year in the ceramic head.²⁸ Interestingly, two ceramic heads required revision as a result of aseptic femoral loosening. There had been little phase transformation of the surfaces, with R_a values of 15.87 and 17.35 nm. This compares to cobalt–chrome unimplanted heads with R_a values of up to 50 nm. Consistent with this zirconia ceramic wear rate, another RCT comparing alumina ceramic heads against two different conventional polyethylene liners reported polyethylene wear of 0.27 mm at 3 years.²⁹

An RCT comparing migration of CC vs. ceramic on highly cross-linked polyethylene confirmed two factors: there was no increase in migration of the hard-on-hard cup compared to the more conventional hard-on-soft, but mean wear in the cross-linked polyethylene was 0.016 mm between 2 and 24 months. In a longer-term RCT comparing 30 CC with 26 ceramic-on-polyethylene reports, an attempt was made to measure the amount of wear in a ceramic articulation.¹⁸ There was significantly greater wear in the polyethylene group, with a mean annual wear of 0.11 mm/year in that group but 0.02 mm in the ceramic group.

Ceramics are not immune to wear, however, and with hard-on-hard articulations component positioning is critical. Vertical cup positions increased wear with ceramic bearings—cups with angles greater than 60° had higher wear in vitro than cups at 45°. ³⁰ This was confirmed with retrieval studies confirming greater wear with acetabular angles greater than 55°.

An issue unique to ceramic bearings is that of *stripe wear*. This is the description given to a localized crescent-shaped area of surface alteration of a ceramic femoral head.¹³ Its cause is not fully understood, but proposed causes include microseparation, equatorial loading, abducted cup position, or loose bodies in the articulation causing eccentric stresses.¹³ The resultant damage to the surface is in the form

of grain fracture or pullout with resultant loose bodies and a roughened surface (R_a 0.21 μ m compared to 0.10 μ m for the conventionally worn areas of the head). This roughened area may be the precursor of more extensive excessive wear.¹³ With unknown etiology, stripe wear could be the occasional but random cause of severe wear in CC articulations.

With the resurgent interest in metal bearings with the success of second-generation MP hip replacements, there have been attempts to match an alumina head against a metal acetabulum. A limited number of studies are available, with only one identified RCT on the subject.³¹ That paper reports lower overall wear and incidence of stripe wear in adverse conditions in vitro. Within the current short follow-up of 6 months, the randomized trial of 31 patients only reports on reduced metal ions in the CM compared to those with a MP articulation. In contrast to this study, an in vitro study reported significantly greater wear in the CM group than the CC articulation after 5 million cycles.³²

A short-term RCT comparing CC and cobalt–chrome on cross-linked polyethylene reports no osteolysis at 24 months in either group.¹⁷ This is not unexpected, as even with conventional polyethylene hips wear-related osteolysis is not a short-term or even mid-term complication. In a longer-term study, with mean follow-up of 8 years, cortical erosions were reported in 4 of 287 (1.4%) alumina ceramic hips and in 25 of 82 (30.5%) control MP hips.²¹ Within this latter group, one patient required revision of cup and liner for osteolysis at 10.5 years and another had a liner exchange at 52 months for polyethylene wear and osteolysis at 8 years.²¹ This report followed an earlier 5 year mean publication of the cohorts with osteolysis recorded in 1.4% of 213 alumina hips and 14% of the 101 control cobalt–chrome on polyethylene hips.¹⁹ Linear wear was identified as higher in those hips with increased radiographic femoral scalloping, supporting the concept of wear-related osteolysis. A further mid- to long-term RCT (median 8 years), comparing 30 alumina CC with 26 ceramic-on-polyethylene articulations, reported significantly greater wear in the polyethylene group.¹⁸ One hip showed radiolucency around the acetabular component, but without accelerated wear and no osteolysis reported in any of the patients.¹⁸

A retrospective review of 103 total hip arthroplasties with ceramic implants reported a rate of osteolysis far higher than that found in these RCTs. At a mean follow-up of 92 months femoral osteolysis was found in 23 hips (22%) with 10 hips going on to require revision for loosening.³³ Tissue retrieved at revision confirmed abundant wear particles with conclusion that ceramic particles can stimulate foreign body response and periprosthetic osteolysis. This was the first published series of patients with a CC articulation demonstrating such a high level of osteolysis. It does,

however, report on a prosthesis that was subsequently withdrawn in the US due to high failure rates, and on a ceramic head that has a skirt leading to CC impingement.³⁴ In order to have an osteolytic environment appropriately sized particulate matter must be present in an adequate quantity, whether metal, plastic, or ceramic. This failure is felt by a number of authors to be a component design failure.³⁴ A further case study from 1997 reported a case of massive osteolysis with debris confirmed to be neither polyethylene nor cement.³⁵ Although this incited correspondence from other units,³⁶ the authors felt justified in concluding ceramic debris may not be bioinert and not a solution to osteolysis.³⁶

Reiterating the importance of avoidance of impingement, a further case report of two ceramic articulations revealed significant osteolysis.³⁷ Stripe wear of the ceramic head and neck impingement of the titanium shell was found, with periacetabular tissue revealing ceramic and titanium debris in both cases. It is unclear which caused the osteolysis, but this is a further demonstration of the risk that modern-generation alumina may be associated with osteolysis.

Numerous mid- and long-term retrospective studies and reviews have shown limited or no evidence of osteolysis in modern, well-functioning ceramic articulations.^{25,38-41}

Recommendations

With ceramic used in total hip arthroplasty, evidence suggests:

- Wear with CC articulations is significantly reduced in comparison to conventional hard-on-soft polyethylene replacements [overall quality: high]
- Wear with a ceramic head on polyethylene gives less wear than a similar articulation with a metal head [overall quality: moderate]
- Stripe wear is an occasional cause of severe wear in CC articulations [overall quality: low]
- Using CM articulations may reduce the overall amount of wear and the incidence of stripe wear [overall quality: very low]
- Any articulation, including a ceramic type, which produces excessive particulate wear, is likely to cause osteolysis [overall quality: moderate]
- A modern well-fixed CC bearing, without impingement, reduces the risk of mid- to long-term osteolysis compared to a comparable MP articulation [overall quality: high]

Question 5: What is the risk of fracture?

Case clarification

When you explained the risks and benefits of a ceramic hip replacement your patient was concerned to know that fracture is a risk of the procedure.

Relevance

Fracture is a catastrophic complication of a ceramic articulation requiring immediate revision. Benefits of low-wear articulations need to outweigh specific risks associated with the bearing.

Current opinion

With modern ceramics fracture is recognized to be a relatively rare, although catastrophic, complication.

Finding the evidence

- Cochrane Database, with search: "ceramic hip"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews/randomized control trials: "ceramic hip"
- MEDLINE search using keywords: "ceramic hip" AND "fracture"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) using keywords: "ceramic hip" AND "fracture"

Quality of the evidence

- Level I: 4
- Level II: 2
- Level III: 7
- Level IV: 1

Findings

Early in the production of ceramics, the fracture rate was as high as 13.4% for those manufactured before 1990, with catastrophic consequences.⁴² The same paper reports the survival of ceramic BIOLOX femoral heads as 0.026% for first-generation alumina and 0.014% for second-generation alumina and 0.004% for femoral heads manufactured after 1994, based on data collected from over 2 million femoral heads. Sedel's review of the 30-year history of alumina suggests the risk of fracture is 1 in 2000 for a 10-year period.³⁸ A further historical review reports 80% of ceramic head fractures occur within the first 2 years and 90% within the first 3 years.²² Barrack et al.'s "concerned" review of ceramic implants states that 1 in 10,000 ceramic revisions will be solely attributable to fracture¹³ despite proof testing and improved properties.

Reviewing the level I evidence, an RCT comparing MP with a number of full ceramic options confirmed 2 fractures, at 6.5 years and at 9 years, in a total cohort of 380 ceramic hips with overall mean follow-up of 8 years.²¹ There were also four ceramic chips on insertion of the liner, which were immediately changed to a new liner and shell, and none have required revision.²¹ In order to address the issue of fracture on insertion, a titanium-cased alumina ceramic component was introduced as a fourth group within this study. In a separate publication,²⁰ this group

showed no chips, fractures, or failures at a mean follow-up of 4.2 years in 209 hips. An RCT by Bierbaum et al. involving 514 hips in 458 patients compared cobalt–chrome–on–polyethylene articulations with alumina CC.¹⁴ It revealed no fractures in the 346 in the ceramic group with a mean follow-up of 35.2 months. There was, however, an insertional chip rate of 2.6% (9 of 346 hips) each identified and replaced at the time of surgery with as yet no sequelae. A minimum of 2 year RCT reports on 236 CC and 224 ceramic–on–polyethylene (CP) hips, with 1 rim chip in the study group.²² A large medium-term study involving 500 hips comparing an equal number of CC articulations with CP, at a minimum follow-up of 2 years, reports no ceramic fractures.²² One liner chipped on insertion, requiring exchange (0.4%). Finally, a review of 56 hips at a mean follow-up of 8 years reported no ceramic fracture or liner chips in 30 CC articulations and 26 CP hips.¹⁸

As important with regard to prevalence of an issue are observational studies. No fractures are reported at a mean of 50.4 months in 103 hips in 97 patients in a retrospective review.³⁹ A further retrospective observational study reports 3 fractures in 107 hips (2%) at a minimum follow-up of 7 years, although each was associated with an extra-long neck, an option that is now no longer used.²³ Numerous case reports of fracture have been published, one of which from 1995 reviews the available data from 10 previous published fracture reports. The authors concluded that, including their own case, common characteristics included young age at surgery, heavy, and active, and 8 of the 10 were male.⁴³ Torán et al. in 2006 published a case of fracture and similarly reported risk of failure to be increased in the heavy and active patient.⁴⁴

Recommendations

With regard to risk of fracture using ceramic bearings in total hip replacements, the evidence suggests:

- Care must be taken on insertion of ceramic liners to avoid the risk of insertional chips. This remains an issue even with modern materials and components [overall quality: high]
- Improvements in manufacturing and components have reduced the risk of fracture of ceramic components [overall quality: moderate]
- Risk of fracture may be increased in the young, heavier, active male [overall quality: very low]

Question 6: What is the risk of squeaking for a young active patient considering a ceramic total hip replacement?

Case clarification

Your patient recalls a newspaper article about a patient with a hip that squeaks. She asks if that was related to a

ceramic hip. You need to explain the risk of squeaking with a ceramic articulation.

Relevance

Any hip replacement must improve not only the patient's physical quality of life but also their mental quality of life. An articulation that causes audible noises with every step will be difficult for any patient to tolerate.

Current opinion

Squeaking remains a significant concern with hard-on-hard CC usage.

Finding the evidence

- Cochrane Database, with search: "ceramic hip"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews/ randomized control trials: "ceramic hip" AND "squeak"
- MEDLINE search using keywords: "ceramic hip"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) using keywords: "squeak" AND "ceramic"

Quality of the evidence

- Level I: 1
- Level III: 5
- Level IV: 3

Findings

Squeaking from the site of total hip arthroplasty is a phenomenon unique to hard-on-hard bearings, whether MP or CC.^{45–49} The cause is not fully understood, and a number of possible etiologies have been postulated including component mismatch and insufficient lubrication, stripe wear, and third-body metal debris.⁴⁵

Squeak is reported in 3 hips of 380 in an RCT comparing a CC articulation with polyethylene with a minimum follow-up of 5 years and a mean of 8 years.²¹ All were reported as transient in nature although one underwent revision for unexplained groin pain. A prospectively followed group of 159 arthroplasties in 143 patients with matched control group reported a 10.7% incidence of audible squeak during normal activities.⁴⁵ This was reproducible clinically in only four patients but, importantly, only one patient had complained of the squeak prior to direct questioning. This study showed no relationship between implant positioning and squeaking.

A recent retrospective review revealed 9 of 43 CC implants (20.9%) squeaking at a minimum 39.4 months (mean 47.3 months), and again suggests the incidence may in fact be under-reported.⁵⁰ No relationship was found with regard to cup inclination or anteversion, but shorter neck lengths were found to be associated with squeaking. No relationship was found with patient demographics. At a

mean of 50.4 months in 103 hips in 97 patients, a retrospective review identified squeaking in 5 patients (4.9%).³⁹ The squeak was intermittent in nature and found only in active patients. No radiological abnormality was identified within the squeaking hips with stable implantation and no obvious etiology. Again, in this series hip abduction angles were found not to vary from the controls. In contrast, a review of 17 squeaking hips against matched controls by Walter et al. suggested association with high cup abduction angles.⁵¹ In this series of ceramic hips 75% of 17 squeaking hips had an abduction angle outside 45±10°. The hips started squeaking after an average of 14 months, with patients with squeaking hips being younger, heavier, and taller than patients with silent hips.

A large retrospective review of 999 hips reports a squeak in 28 hips (2.7%).²⁴ A cohort was matched to analyze if cup position may be related to the onset of squeaking. No significant alteration was found in either cup inclination or version between the groups. In four hips that underwent revision, stripe wear was identified on the femoral heads and metal debris was found in the ceramic articulation.

Recommendations

In patients undergoing a CC total hip replacement, the evidence suggests:

- Squeaking is unique to hard-on-hard bearings [overall quality: high]
- The overall incidence squeaking may be under-reported [overall quality: moderate]
- Ideal component positioning may reduce the risk of squeaking [overall quality: very low]
- The risk of a squeaking articulation is increased in the younger, heavier, and taller patient [overall quality: very low]

Question 7: Is a CC articulation less likely to require revision than a conventional replacement? For any patient contemplating a ceramic hip replacement, what options are available should the bearings fail at any stage?

Case clarification

Because of her relatively young age, the patient has concerns about the need for further surgery in the future. She has read about squeaking and also fracture in ceramic hips. She asks what options are available to her should this occur.

Relevance

Although there are some undisputable advantages to ceramic bearings, consideration must be made of the potential for failure and need for revision within the lifetime of a younger patient.

Current opinion

The majority of surgeons would consider revision following a failed ceramic articulation to be one of the most challenging procedures in orthopedics, particularly if following ceramic fracture.

Finding the evidence

- Cochrane Database, with search: “ceramic hip”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews/ randomized control trials: “ceramic hip” AND “revision”
- MEDLINE search using keywords: “revision,” “fracture,” AND “ceramic hip”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) using keywords: “revision,” “fracture,” AND “ceramic hip”

Quality of the evidence

- Level I: 5
- Level III: 1
- Level IV: 4

Findings

Five trials^{14,17,18,21,22} (N = 1511) report postoperative revision rates in comparative randomized studies involving CC alumina articulations. Three further trials were excluded from analysis as they were previous publications of the same cohort.^{19,20,52} The results of pooled statistics are shown in Table 17.1. Two studies^{18,22} compare CC articulations with CP articulations, with a reduced risk of revision identified in the CC group (RR 0.309, 95% CI 0.063–1.502). Follow-up in these studies varied between a minimum of 2 years (N = 460) to a median of 8 years (N = 55). Two hips required revision in the ceramic group due to recurrent dislocations, while in the control group seven revisions were performed, one for pain of unknown etiology, one loose acetabulum, and five for recurrent dislocation. Within the remaining three studies^{14,17,19} comparison was made between CC and MP articulations in 1036 hips. Again a

Table 17.1 Revision surgery (values <1 favor ceramic-on-ceramic, >1 favor control)

	N	Events		RR	95% CI
		CC	Control		
CC vs. CP	475	2/226	7/249	0.309	0.063–1.502
CC vs. MP	1036	14/744	16/292	0.331	0.159–0.687
CC vs. all	1511	16/970	23/541	0.378	0.198–0.721

CC, ceramic-on-ceramic; CP, ceramic-on-polyethylene; MP, metal-on-polyethylene; RR, relative risk of revision with CC compared to alternatives.

reduced overall risk of revision was identified in the ceramic group (RR 0.331, 95% CI 0.159–0.687). Follow-up in these studies was 2 years (N = 61), mean 35.2 months (N = 500) and a mean of 8 years (N = 475). Taking all CC articulations and comparing with all of the controls reveals a relative risk of revision of 0.378 (N = 1511, 95% CI 0.198–0.721) for the CC option.

Revision of any hip replacement is a complex undertaking. Ideally the use of ceramic articulations during primary surgery would remove the need for a future revision hip replacement. If ultimately one is required, “the absence of osteolysis facilitates revision surgery”⁴¹ avoiding the need for bone graft.⁴⁰ Unfortunately, however, the use of any bearing will produce wear. Although the quantity is reduced with a ceramic bearing, what is produced is exceptionally hard and a potentially damaging third body for any subsequent articulation. Worse, if revision is required following fracture there will be extensive third-body debris within the effective joint space, damaging exposed femoral trunnions and acetabular shells. Any delay will cause further damage and soft tissue contamination and revision is therefore an urgent undertaking. The revision will likely require exchange of all components due to this damage with subsequent bearings likely exposed to macro- and microscopic particles of ceramic, limiting longevity.

Level I evidence reviewing this issue is difficult to obtain, but observational and retrospective evidence is available. Allain has published a case report and a study on a large series of head fractures.^{53,54} The case report was of a 54 year old patient who sustained a traumatic fracture of their femoral head 5 years after implantation.⁵³ This was revised to a stainless steel on polyethylene liner. Subsequently at 11 months the patient developed pain and then at 18 months required a second revision. Intraoperatively the stainless steel femoral head was deformed and severe metallosis was noted. Histologically, fragments of both stainless steel and alumina ceramic were noted in the soft tissue. A multicenter review by the same author⁵⁴ reviewed 105 revisions for ceramic head fractures: 31% went on to require at least one repeat revision with an overall 5 year survival rate of only 63%. This rate is worse than most revision series and in all likelihood due to retained ceramic particles.¹³ Allain’s review is the most extensive review available in the literature and makes a number of recommendations.⁵⁴ Factors influencing results included whether the cup was changed (57% required re-revision without, 21% with exchange), extent of synovectomy (re-revision in 67% with partial synovectomy, 19% with complete synovectomy) and patient age (54 years in those requiring revision and 63 in those who did not ($p = 0.02$)). Although definitive conclusions could not be made as to whether the femoral component required exchange, this paper does conclude that any revision following ceramic fracture should include cup exchange, total synovectomy, and a

cobalt–chrome or ceramic head. A revision following fracture is not therefore a simple undertaking, requiring an extensive revision and not simply a head and liner exchange.¹³ Even without previous fracture, revision of a previous ceramic articulation will be susceptible to retained ceramic wear particles, potentially limiting longevity.

Recommendations

With regard to revision for a failed ceramic hip replacement, evidence suggests:

- With maximum mean follow-up of 8 years CC hips have a lower risk of revision in comparison to alternatives in currently available level I studies [overall quality: high]
- Following ceramic fracture, revision total hip arthroplasty has a poorer survival than following conventional hip replacements [overall quality: low]
- Following ceramic fracture complete component revision is required due to damage to trunnions and cups by the exceptionally hard fragments [overall quality: low]
- Total synovectomy is required during any ceramic revision to reduce the amount of highly abrasive wear debris from the previous articulation [overall quality: low]
- Caution should be used before considering the use of any “soft” bearing such as polyethylene or stainless steel with risk of deformation, accelerated wear, and failure from retained abrasive third-body wear [overall quality: low]

Summary of recommendations

- Ceramics are exceptionally hard, wettable, and chemically inert, but they are brittle and, unlike metal components, prone to fracture
- Zirconia undergoes phase transformation, limiting its safety as an orthopedic device
- There has been an improvement in the purity, production techniques, and overall quality of ceramics between early-generation ceramics and current options
- Ceramic may be used as a conventional hard-on-soft bearing with a ceramic femoral head articulating against polyethylene, or as a hard-on-hard CC or CM bearing
- There is less modularity with ceramic bearings as compared to metal and polyethylene implants, limiting the available options for optimizing leg lengths and stability
- Patients can expect disease-specific and quality of life outcome score improvement at least equivalent to a conventional hard-on-soft total hip replacement at mid-term follow-up
- Wear with CC articulations is significantly reduced in comparison to conventional hard-on-soft polyethylene replacements

- Stripe wear is an occasional cause of severe wear in CC articulations
- With maximum mean follow-up of 8 years CC hips have a lower risk of revision in comparison to alternatives in currently available level I studies
- Using CM articulations may reduce the overall amount of wear and the incidence of stripe wear
- Any articulation, including a ceramic type, which produces excessive particulate wear, is likely to cause osteolysis
- A modern well-fixed CC bearing, without impingement, reduces the risk of mid to long-term osteolysis compared to a comparable MP articulation
- Improvements in manufacturing and components have reduced the risk of fracture of ceramic components
- Risk of fracture may be increased in the young, heavier, active male
- Care must be taken on insertion of ceramic liners to avoid the risk of insertional chips; this remains an issue even with modern materials and components
- Squeaking is unique to hard-on-hard bearings
- The overall incidence squeaking may be under-reported
- Ideal component positioning may reduce the risk of squeaking
- The risk of a squeaking articulation may be increased in the younger, heavier, and taller patient
- Following ceramic fracture, revision total hip arthroplasty has a poorer survival than following conventional hip replacements
- Following ceramic fracture, complete component revision is required due to damage to trunnions and cups by the exceptionally hard fragments
- Total synovectomy is required during any ceramic revision to reduce the amount of highly abrasive wear debris from the previous articulation
- Caution should be used before considering the use of any “soft” bearing such as polyethylene or stainless steel during a ceramic hip revision, with risk of deformation, accelerated wear and failure from retained abrasive third-body wear

Conclusions

The use of modern ceramic bearings has become significantly safer than when they were first introduced over 30 years ago. With improved manufacture and testing techniques, the risk of catastrophic failure through fracture has improved. A patient receiving a CC total hip arthroplasty can expect a low-wear articulation, outcome scores equivalent to a conventional hip replacement, and a low risk of long-term osteolysis. Fracture does, however, remain a risk, as does squeaking, which may be an under-reported issue. Revision procedures following failed ceramic hip replace-

ments are challenging. Exceptionally hard retained wear and fracture debris often necessitates complete component revision with the potential to compromise the long-term survival of the revised hip.

Minimally Invasive Techniques in Total Hip Arthroplasty

Amre Hamdi and Paul E. Beaulé

University of Ottawa, Ottawa, ON, Canada

Case scenario

A 53 year old woman who is otherwise healthy presents with left-sided groin pain that was first noticed 2 years ago and has been getting progressively worse over the last 3 months. Currently, she cannot walk for more than 30 minutes but does not use any walking aids. She has tried various anti-inflammatories and physiotherapy with no improvement. On clinical examination, she walks with an antalgic gait. Range of motion shows flexion of 100° with no internal and external rotation respectively in 90° of hip flexion. She has 5° of fixed flexion contracture, and leg lengths are equal. Motor power is 5/5 in flexion, abduction and extension. Her radiographs show a severely arthritic hip joint.

Importance

Total hip arthroplasty (THA) is one the most successful surgeries in modern era because of the overall marked improvement of the patient's function and quality of life.¹ Once a surgical intervention has achieved a certain standard of efficacy and reproducibility, further developments can be placed on minimizing the morbidity of the intervention. Less invasive surgical techniques as well as multimodal pain management have also evolved over the last decade in the field of joint replacements, especially THA, enabling patients to potentially recover faster as well as optimize their overall function by avoiding excessive muscle dissection.² As with any new surgical technique, initial enthusiasm was based on high patient expectations³ as well as surgeon enthusiasm but, as is all too common in

surgery, over enthusiasm lead to some serious complications.⁴ In this chapter we review the current techniques as well as clinical results and future of minimally invasive (MIS) hip replacement surgery.

One of the reasons total hip replacement (THR) surgery has been so successful is the standardization as well as reproducibility of the surgical approaches. As one would expect, different areas of the world will favor certain approaches because of history as well as available instrumentation, with the classic approaches in the literature for primary THR being posterior, lateral, anterolateral, and anterior (Table 18.1). To discuss how each of them evolved as well and became part of daily practice is not the purpose of this chapter; however, certain basic principles are common to those approaches for performing a successful THR:

- proper visualization and access to bony interfaces
- low risk of neurovascular injury
- minimal to no significant compromise on patient function.

The two-incision technique is probably the approach that brought the new MIS THR surgical technique to the forefront, with its optimization of pain management protocols as well as a rapid discharge program.² This also led to decreasing the length of the skin incision (6–10 cm) compared to standard surgical approaches such as the posterior and lateral approaches.⁵

Anatomy and surgical approaches

With respect to surgical approaches, we now briefly discuss the different techniques based on patient positioning and identified in the literature as MIS.

	Preserving the abductors	Internervous plane	Less risk of dislocation	
Disadvantages	Release of short external rotators Increase risk of dislocation	Difficult exposure to femur Neuropraxia of lateral femoral cutaneous nerve	Violating the abductors Chronic limp	Difficult exposure Damage to abductors

Lateral decubitus position

For both posterior and lateral approaches the patient is placed in the lateral decubitus position with the hip flexed 45–60° and adducted 10°. For the posterior approach an oblique incision is placed near the tip of the trochanter. The deep dissection splits the fascia over the gluteus maximus muscle and proceeds posterior to the gluteus medius and minimus muscle into the hip joint. The posterior approach generally requires transection of the piriformis tendon and at least a portion of the short external rotators down to the quadratus femoris muscle.⁶ Penenberg et al.⁷ recently reported on a technique which uses percutaneous portals for acetabular preparation and component insertion permitting only release of the piriformis tendon.

For the lateral approach, the skin incision is similar to that described for the posterior approach, with the incision placed obliquely over the greater trochanter, generally starting 1–2 cm above the tip of the trochanter and proceeding distally. For the anterolateral approach (Roetinger/Watson-Jones)^{8,9} the superficial dissection is between the tensor and gluteus medius and deep dissection between gluteus minimus and rectus femoris. An alternative is the standard lateral approach is splitting the anterior portion of the gluteus medius tendon in a continuous sleeve with the vastus lateralis and gluteus minimus in one layer with the hip capsule.^{8–10} The main downside to these approaches is that they are not truly internervous and damage to the gluteus minimus is common either during the exposure or femoral preparation.

Supine position

The direct anterior approach or Hueter approach represents the only truly internervous approach to the hip passing through the sheath of the tensor fascia lata muscle (superior gluteal nerve) with the sartorius muscle medially (femoral nerve).¹¹ The deeper plane is between rectus femoris and gluteus minimus.^{12,13} In order to facilitate access to the femur the leg can be placed in a “figure 4” position or by using an orthopedic positioning table permitting extension of the leg without the need for an assist-

ant to hold it.¹⁴ Recent multicenter data has shown this approach to be safe and reproducible.¹⁵

The two-incision approach for THA uses a small direct anterior approach for acetabular exposure and component placement, and a small posterior approach for femoral preparation and femoral implant insertion.² This approach is less and less used because of a high initial complication rate¹⁶ as well as significant damage to the gluteus minimus muscle.¹⁷

Finding the evidence

Since the evidence in the literature is lacking, it is difficult to critically analyze and formulate well-founded answers to the key clinical questions. We therefore present all the available evidence within MIS THR first, followed by attempts to answer the clinical questions.

- Cochrane Database, with search term “minimally invasive total hip replacement,” “minimally invasive total hip arthroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews, “minimally invasive total hip replacement,” “minimally invasive total hip arthroplasty”
 - 8208 hits
- MEDLINE search identifying the population (“hip” AND “minimally invasive total hip replacement”
 - 10,230 hits
- PubMed (www.ncbi.nlm.nih.gov/pubmed/), sensitivity search using keywords “minimally invasive total hip replacement”
 - 10,300 hits and, after review, 230 potentially relevant articles

Quality of the evidence

- Level I: 30
- Level II: 50
- Level III: 34 retrospective studies
- Level V: 19 case reports and expert opinion

Top four questions

- Does a MIS technique lead to quicker recovery?
- Does a MIS technique lead to less blood loss?
- Does a MIS technique lead to better patient function?
- Does MIS THR have similar complication rates to standard approaches?

Question 1: Does a MIS technique lead to quicker recovery?

Findings

The main premise for the introduction of these less invasive approaches was that patients would experience less pain and less blood loss, leading to a shorter hospital stay as well as overall quicker recovery to normal activities. The proponents of these techniques felt that these new procedures represented a dramatic evolution in hip arthroplasty by minimizing injury to tissues while maintaining the efficacy and safety of the classic surgical approaches. However, because of the advent of new anesthetic techniques during the same time it remained unclear what was mainly responsible for this quicker recovery: the smaller incision or the anesthetic protocol. In the vast majority of the clinical series on MIS THR, the anesthetic protocol involved premedication with anti-inflammatory several days before surgery, an oral narcotic on the day of surgery, and regional anesthesia and multimodal pain protocol postoperatively which included oral narcotics and anti-inflammatories.¹⁸

In a detailed review of the literature, Chen and associates¹⁹ illustrate well the difficulty in evaluating new surgical techniques in the field of orthopedics with no validated endpoint to establish the efficacy of the surgical technique, making it difficult to compare the different approaches and to interpret the conclusions. In terms of level I evidence, Ogonda et al.²⁰ compared 219 THR patients who were either randomized to a MIS posterior approach (≤ 10 cm) or standard incision (16 cm) posterior approach with a single surgeon performing all procedures with the same anesthetic protocol as well as postoperative physiotherapy regimen with all the allied health professionals blinded to the incision. They found no significant difference between the two groups in terms of hospital stay, blood loss, and complications as well as functional outcome at 6 weeks. In another randomized controlled trial (RCT) comparing the mini-posterior to the two-incision technique in 21 patients, Pagnano and associates²¹ found that patients in the two-incision group tended to have a slower rate of recovery at 6 weeks based on gait parameters and muscle strength evaluations. These findings are consistent with the anatomical studies comparing these two approaches which showed greater damage to the glutei muscles in the two-incision group compared to the mini-posterior.¹⁷ In nonran-

domized trials, four studies²²⁻²⁵ comparing small-incision THR to standard incision posterior approach THR in which the comparison groups were similar in demographic parameters, especially body mass index, found no significant difference. Similarly, deBeer and associates²² also found no beneficial effect to the smaller incision when used with the lateral approach to the hip.

Recommendation

- With similar anesthetic protocols, the length of the incision had little impact on patient recovery and length of stay. More importantly, the two-incision technique was actually inferior to the mini-posterior approach. Similarly, the use of narcotics postoperatively was not impacted by the length of the incision but dependent on multimodal analgesia [overall quality: strong]

Question 2: Does a MIS technique lead to less blood loss?

Findings

Ogonda et al.²⁶ found no significant difference in blood loss between THR patients that were either randomized to a MIS posterior approach (≤ 10 cm) or standard incision (16 cm) posterior approach. Similarly, in their meta-analysis of randomized trials on MIS THR Cheng et al.²⁷ found that the only significant improvements with MIS techniques were in the short term, i.e., less intraoperative blood loss and shortened hospital stay (Table 18.2) but because of the significant heterogeneity they could not reach firm conclusions regarding efficacy of the various MIS techniques. Two studies^{22,28} reported lower average intraoperative blood losses of 43 and 67 mL in patients undergoing the mini-incision THRs; however, there was no difference in the transfusion rates in these patient groups.

Recommendation

- MIS hip surgery showed no difference in blood loss [overall quality: strong]

Question 3: Does a MIS technique lead to better patient function?

Findings

Bennett and associates²⁹ found no difference in regards to velocity, step length of the affected or unaffected leg, stride length, or stance phase duration between the two groups.

Dorr et al.³⁰ concluded that compared with conventional THR performed through a posterior incision, posterior MIS THR resulted in better early pain control, earlier discharge to home, and less use of assistive devices. Subsequent evaluations at 6 weeks and 3 months showed equivalency between the clinical results in the two groups. In another review looking specifically at matched cohort studies of

Table 18.2 Summary of clinical studies on MIS THR

Study	Methods	Participants	Interventions	Outcome
Zhang et al. (China)	RCT; FU = 11 weeks	FNF = 60 MI vs. 60 SI; similar DC; unilateral THA	MI anterolateral 8.2 cm vs. SI posterior 14 cm; similar DC; unilateral THA Versys cementless prosthesis	Operative time; blood loss; HHS; complications
Wright et al. (USA)	qRCT; presence of assistant; FU = 5 years	OA, ON, RA = 42 MI vs. 42 SI; similar DC; unilateral THA	MI posterolateral 8.8 ± 1.5 cm vs. SI posterolateral 23.0 ± 2.1 cm press-fit cup and cemented stem; a senior surgeon	Operative time; blood loss; HHS; complications; radiographic evaluation
Chung et al. (Australia)	qRCT; observer blinded; alternation; FU = 14 months	OA = 60 MI vs. 60 SI; similar DC; unilateral THA	MI postetolateral 9.2 cm vs. SI posterolateral 20.0 cm; porous-coated cup and uncemented stem	Operative time; blood loss; length of hospital stay; HHS; complications
Hart et al. (Czech Republic)	RCT; observer blinded; FU = 39 months	OA = 60 MI vs. 60 SI; similar DC; unilateral THA	MI posterolateral 9–10 cm vs. SI posterolateral 20 cm; cemented prosthesis; two experienced surgeons	Operative time; blood loss; complications; radiographic evaluation
Chimento et al. (USA)	RCT draw card observer blinded; FU = 2 years	OA = 28 MIS vs. 32 SIS; similar DC; unilateral THA	MI posterolateral 8 cm vs. SI posterolateral 15 cm; press-fit cup cemented, or press-fit stem; a senior surgeon	Operative time; blood loss; complications; radiographic evaluation
Yan et al. (China)	RCT; FU = 6 months	OA, ON, FNF = 15 MI vs. 15 SI; similar DC; unilateral THA	MI anterior two incisions 3.6 cm; 5.7 cm vs. SI posterolateral 12 cm; Versys cementless prosthesis; a senior surgeon	Operative time; blood loss; complications; radiographic evaluation
Ogonda et al. (UK)	RCT sealed envelope patient and observer blinded; FU = 6 weeks	OA, ON, RA = 109 MI vs. 110 SI; similar DC; unilateral THA	MI posterolateral 9.5 ± 0.95 cm vs. SI posterolateral 15.81 ± 0.93 cm cementless cup cemented stem; an experienced surgeon	Operative time; blood loss; HHS; complications; a radiographic evaluation
Zhang et al. (China)	RCT sealed envelope; FU = 20 months	OA, RA = 60 MIS vs. 60 SIS; similar DC; unilateral THA	MI anterior 6.9 cm vs. SI posterolateral 16.3 cm Versys hip prosthesis	Operative time; blood loss; HHS; complications; radiographic evaluation
Kim et al. (Korea)	RCT randomized number table observer blinded; FU = 26.4 months	ON, OA, AS = 70 MIS vs. 70 SIS; similar DC;	MI posterolateral 8.8 ± 1.5 cm vs. SI posterolateral 23.0 ± 2.1 cm; bilateral THA cementless cup and cementless stem; a senior surgeon	Operative time; blood loss; HHS; length of hospital stay; complications; radiographic evaluation
Dorr et al. (USA)	RCT patient and observer blinded; FU = 3 months	OA, PA, HD, ON = 30 MIS vs. 30 SIS; similar DC; unilateral THA	MI posterior 10 ± 2 cm vs. SI posterior 20 ± 2 cm; cementless cup noncemented stem; two experienced surgeons	Operative time; blood loss; HHS; complications; radiographic evaluation
Dutka et al. (Poland)	qRCT odd or even day observer blinded; FU = 9.5 months	OA, HD, ON = 60 MIS vs. 60 SIS; similar DC; unilateral THA	MI lateral 6–8 cm vs. SI direct lateral 20–25 cm	Operative time; blood loss; HHS; length of hospital stay; complications
Speranza et al. (Italy)	RCT draw; FU = 6 months	OA, ON, FNF = 50 MIS vs. 50 SIS; similar DC; unilateral THA	MI direct lateral 7.1 ± 1.1 cm vs. SI posterior 12.8 ± 2.3 cm; cementless cup cementless stem; a senior surgeon	Operative time; blood loss; HHS; length of hospital stay; complications

DC, demographic characteristics; FNF, femoral neck fracture; FU, follow-up; HD, hip dysplasia; HHS, Harris hip score; MI, mini-incision; OA, osteoarthritis; ON, osteonecrosis; PA, post-traumatic arthritis; RA, rheumatoid arthritis; SI, standard incision.

A, change; AC, acetabular component; BMI, body mass index; CC : case controlled; CS, consecutive series; EBL, estimated blood loss; FC, femoral component; HHS, Harris hip score; IO, intraoperative; LOS, length of hospital stay; M :matched; NS, not statistically significant; RP, randomized prospective; ST, surgical time; TBL, total blood loss.

Reproduced from Vail and Callaghan.⁶

mini-incision THRs, Vail and Callaghan⁶ concluded that although these could be done safely in patients who are not obese there were no real differences in clinical outcome (Table 18.3). Having said that, Howell et al.³¹ gave significant importance to the psychological impact of improved cosmesis on patient attitude, satisfaction, and motivation for recovery. They cautioned that this appeal should not be underestimated when evaluating less invasive THR surgeries, with most studies reporting improved cosmesis and patient satisfaction with these smaller-incision approaches.^{32,33}

Recommendation

- No significant difference was found with regards to patient function, but the evidence is moderate as current tools to evaluate patient function may not be sufficiently sensitive. The positive impact on patient cosmesis is strong

Question 4: Does MIS THR have similar complication rates to standard approaches?

Findings

Finally, when assessing the overall clinical value of MIS THR it is critical to look at the overall incidence of complications as well as their severity. Mow et al. have shown evidence of more subcutaneous tissue necrosis and/or poor wound healing after the mini-incision procedures³⁴. All two-incision cohort studies report relatively long surgical times compared with those of open techniques, thus confirming the high degree of difficulty of this procedure. Although Berger³³ reported a low risk of femoral fracture (1%), others reported fracture rates of 7–9%.^{35,36} One author reported a 4% early revision rate for treatment of postoperative fractures that were assumed to have occurred intraoperatively but were not detected by fluoroscopy or by

immediate postoperative radiographs.³⁷ Another report showed a high 10% early revision rate for fracture, dislocation, and infection in patients who had THR with the two-incision procedure.³⁸ Two other studies also showed a relatively high incidence of nerve injury at 2.5–3.2%^{36,39} with the two-incision technique. Other less invasive approaches such as the mini-posterior as well as the anterior Hueter approach have not reported higher rates of complications. In a multicenter study of 9 surgeons and 1277 THRs examining the introduction of the anterior Hueter approach,¹⁵ the overall rate of revision was 2.7% with an incidence of proximal fracture of 1.8% including calcar splits. Obviously, the higher rate of complications associated with the two-incision technique reflects the difficulty in surgical exposure as well as the lack of familiarity for the surgeon in terms of patient positioning and instrumentation.

Recommendation

- The integration of new surgical techniques and approaches such as MIS may have a higher initial complication rate [overall quality: strong.]
- In regards to reproducibility, if the surgical technique is sound then it can be safely reproducible [overall quality: moderate]

Summary of recommendations

Openmirrors.com

- With similar anesthetic protocols the length of the incision had little impact on patient recovery and length of stay. More importantly, the two-incision technique was actually inferior to the mini-posterior approach. Similarly, the use of narcotics postoperatively was not affected by the length of the incision but dependent on multimodal analgesia
- MIS hip surgery showed no difference in blood loss
- No significant difference was found with regard to patient function, whereas the positive impact on cosmesis is strong
- The integration of new surgical techniques and approaches such as MIS may have a higher initial complication rate
- With regard to reproducibility, if the surgical technique is sound then it can be safely reproducible

Management of Femoral Periprosthetic Fractures After Hip Replacement

Tamim Umran, Donald S. Garbuz, Bassam A. Masri, and Clive P. Duncan

University of British Columbia, Vancouver, BC, Canada

Case scenario

An 81 year old woman presents with severe thigh pain and inability to weight bear after a simple slip and fall. She had a previous total hip arthroplasty (THA). Examination reveals external rotation deformity of the leg, bony crepitus, and tenderness around the proximal and mid thigh. Neurovascular exam is normal. Radiographs demonstrate a displaced periprosthetic femur fracture.

Relevant anatomy and pathomechanics

It is useful, when considering treatment, to divide the femur into three regions with reference to the stem: trochanteric (A); around or just below the stem (B); and distal to that (C). Furthermore, to integrate this with treatment, it is useful to subdivide the B type into those with a well-fixed stem (B1), a loose stem (B2), and a loose stem with poor bone stock (B3).

Importance of the problem

The prevalence of periprosthetic fractures ranges between 0.4 and 3.9% for all arthroplasties depending on whether it occurs in the primary or the revision setting.¹⁻³ These numbers have been steadily increasing over time as a function of the advancing age of the population and the increasing use of total hip arthroplasty (THR). This chapter discusses risk factors, diagnosis, management options, and outcomes of postoperative periprosthetic femur fractures, as supported by current available literature.

Top five questions

Etiology

1. Are there patient factors that may be predictive of a periprosthetic femur fracture?

Diagnosis

2. What classification system is effective in guiding treatment?

Therapy

3. What is the optimal management and outcome of Vancouver type A fractures?

4. What is the optimal management and outcome of Vancouver type B fractures?

5. What is the optimal management of Vancouver type C fractures (intraoperative and postoperative)?

Difficulty arises when comparing the results in these studies due to variability in length of follow-up, patient demographics, number of revision arthroplasties, types of implants used, technical methods employed to treat the fractures, and variable outcome measures used to assess patients.

Question 1: Are there patient factors that may be predictive of a periprosthetic femur fracture?

Case clarification

An 80 year old patient had a cemented THR 18 years ago. Recent follow-up visits have demonstrated progressive

osteolysis and loosening of the femoral component. While on the waiting list for revision surgery, she falls and sustains a periprosthetic femur fracture.

Relevance

Recognition of features associated with periprosthetic fractures could allow for prophylactic measures to preclude a fracture in the at-risk patient.

Current opinion

Current opinion suggests that patients with poor bone stock, loose components, and advanced age may have increased risk of periprosthetic fracture.

Finding the evidence

- PubMed (Clinical queries) (etiology): “periprosthetic hip fracture”
- PubMed: “periprosthetic hip fracture” AND (“risk factor” OR “epidemiology”)
- MEDLINE: “periprosthetic hip fracture” AND “risk factors” OR “epidemiology”

Quality of the evidence

Level IV

- Retrospective cohort studies

Findings

Gender There are 11 studies providing epidemiologic data regarding periprosthetic fracture and gender. In most case series the majority of fracture patients are female.^{1,4-7} This was questioned by the report of Lindahl et al. in 2005, whose results from the Swedish Hip Registry described a nearly equal rate of periprosthetic fractures in men and women.³ In agreement with this is a recent retrospective survivorship analysis by Cook et al.⁸ that found no relationship with gender looking at 124 periprosthetic fractures. Although some studies are suggestive that female gender appears to be a risk factor, it is likely that a multitude of other features contribute to this complication.

Patient age and length of time from index procedure It is clear that increasing age results in progressive weakening of bone because of osteoporosis. This is aggravated by osteolysis, if it develops. Epidemiologic data from a subset of series demonstrates an average age of 73.5 years (1220 fractures).³⁻⁵ In their survivorship analysis, Cook et al.⁸ found that patients older than 70 years had a relative risk of 2.9 for sustaining a fracture. He also reports a 0.8% incidence of periprosthetic fracture at 5 years, and 3.5% incidence at 10 years following primary THA.⁸

The literature also shows that the incidence of late post-operative periprosthetic fracture is increasing.^{1,9-13} The average time post-procedure for a fracture to occur is reported in a number of studies. Holley et al. report an

average of 112 months in a series of 99 patients.⁵ Lindahl et al. report an average of 7.4 years post primary THA (688 fractures), and 3.9 years post revision hip arthroplasty (361 fractures).³ Notably, Lindahl et al. looked retrospectively at the mean age at the time of the index operation and found a statistically significant higher fracture rate in those patients who were younger when they had their original surgery ($p < 0.001$). They postulated that younger and more active patients have a higher risk for sustaining an implant-related fracture in the future than those receiving arthroplasty later in life.³ This observation, that the younger the patient at the time of the primary arthroplasty the greater the risk for subsequent fracture, was confirmed in later studies.¹⁴

Rheumatoid arthritis Several authors have demonstrated a relationship between increased fracture risk and rheumatoid arthritis (RA).^{3,9,15} In the Swedish National Register of 191,351 hip replacements, only 6% of these entire group were patients with RA. Rheumatoid patients, however, had an increased representation in the periprosthetic fracture group, with an incidence of 11% and 10% in the primary and revision population respectively ($p < 0.001$).³

Osteoporosis and prior fragility fracture The presence of osteoporosis is a risk factor for intraoperative periprosthetic fracture. Taylor reports a series where 80% of the patients with periprosthetic fractures had osteoporosis.¹⁶ Wu et al. found that preoperative osteoporosis (according to the Singh index) was a significant predictor for fracture.¹⁷ Using fracture as a hallmark for osteoporosis, Beals and Tower observed that 38% of patients in their study had prior fragility fractures, and therefore osteoporosis.¹⁸ In a small case-control study, Sarvilanna reported a risk ratio of 4.4 for periprosthetic fracture if the primary diagnosis for arthroplasty was fracture, with confidence intervals of 1.4–14.¹⁹ Thus, osteoporotic patients, or those patients who have already sustained a fracture are at increased risk of having a periprosthetic fracture, a finding supported by several studies.

Component loosening Loose femoral components appear to be at risk for periprosthetic fracture. In an in-vitro study, Harris et al. found that femoral component loosening was a risk factor for periprosthetic fracture in cemented hips.²⁰ Several authors have reported that 50–75% of patients demonstrated evidence of loosening prior to fracture.^{21,22} This is in keeping with the Swedish Hip Registry findings indicating that 70% of the implants were loose prior to periprosthetic fracture.³

Recommendations

- Older female patients (>70 years) who have a history of RA, osteoporosis, or previous fragility fracture are at increased risk of periprosthetic hip fracture

- Patients exhibiting loosening of the femoral component on plain radiographs are at increased risk of periprosthetic fracture. Surgical intervention prior to fracture should be considered

Question 2: What classification system is effective in guiding treatment?

Case clarification

An 82 year old patient sustains a periprosthetic femur fracture. The fracture extends from the mid-stem region to the mid-diaphysis. The implant appears to be loose, and the bone stock is poor. The surgeon begins therapeutic planning based on an understanding of the classification of this fracture.

Relevance

Orthopedic surgery has classification systems intended to facilitate management. The variability of pathology seen in periprosthetic fractures of the femur necessitates an effective classification system to aid in the communication of diagnoses among surgical colleagues, and develop management plans. The ability to classify these fractures properly will assist in their management.

Current opinion

The classification method most commonly used is the Vancouver system, because of its relevance to the principles of management and to the measurement of outcomes.

Finding the evidence

- PubMed: “periprosthetic” AND “classification” AND “validation” OR “kappa”

Quality of the evidence

Level IV

- Retrospective cohort studies

Findings

A useful classification system incorporates clinical and radiographic information to guide management, allowing for appropriate treatment and comparison of similar fractures.

Early classification systems focused on the location of the fracture,²³ but became more sophisticated with time as surgeons recognized the implications of fracture pattern and implant stability on treatment.^{21,24-26}

A formal inclusion of implant stability into periprosthetic classification scheme was presented by Beals and Tower. In their retrospective review of 102 periprosthetic fracture treatments, they increased the level of sophistication by considering both anatomic fracture location and stability of the implant (inferred by implant/cement or implant/bone interface disruption).¹⁸

In 1995 Duncan and Masri published the Vancouver classification in order to emphasize the significance in the therapeutic decision-making process not only of the quality of the prosthetic–bone interface (stability), but also of the host bone stock.^{27,28} The Vancouver classification system has been subject to reliability and validity testing in both North America and Europe.²⁹⁻³¹ Brady demonstrated the reliability of the system when evaluated by experts and nonexperts alike, with intraobserver agreement ranging from 0.73 to 0.83, and interobserver agreement of 0.61–0.64 by kappa analysis, indicating substantial agreement between observers. Validity was also evaluated revealing substantial agreement (kappa value of 0.78).²⁹ Rayan revalidated the classification system in Europe, demonstrating its reliability and usability by experts and nonexperts, and its use across continents.³⁰

As outlined earlier, the Vancouver system divides the femur into three regions with reference to the stem: the trochanteric (A); around or just below the stem (B); and distal to that (C). Furthermore, to integrate this with treatment, the B type is subdivided into those with a well-fixed stem (B1), a loose stem (B2), and a loose stem with poor bone stock (B3).

Recommendation

- The Vancouver classification for postoperative periprosthetic fractures of the femur is reliable and valid for both experts and nonexperts [overall quality: high].

Question 3: What is the optimal management and outcome of Vancouver type A fractures?

Case clarification

An 82 year old woman has radiographs that demonstrate an uncemented THA with a fully porous-coated stem. She has an undisplaced fracture of the greater trochanter. The stem appears to be stable.

Current opinion

Current opinion suggests that proximal femoral periprosthetic fractures (Vancouver A type) can be treated either nonoperatively or operatively, depending on the stability and displacement of the fracture, assuming the stem is stable.

Finding the evidence

- PubMed (Clinical queries) (etiology): “periprosthetic hip fracture”
- PubMed: “periprosthetic hip fracture” AND (“risk factor” OR “epidemiology”)
- MEDLINE: “periprosthetic hip fracture” AND “risk factors” OR “epidemiology”

Quality of the evidence

Level IV

- Retrospective cohort studies

Findings

The fractures are classified as type A_G (involving the greater trochanter) or A_L (involving the lesser trochanter). Those of the greater trochanter are often stable, and can be treated nonoperatively if displaced less than 2 cm³² including limitation of active abduction for 3 months. If displaced more than 2 cm they can be managed with open reduction and internal fixation (ORIF) using a trochanteric claw plate. Vancouver A_L fractures are rare, and do not generally require surgical management, unless the stability of the implant is impaired by substantial disruption of the proximal medial femur, such as fractures associated with a substantial tongue of cortical bone. These are technically a B2 type fracture and management should be along those principles. The presence of trochanteric fractures is usually related to osteolysis and polyethylene wear, and treatment should be directed towards the cause of the osteolysis.

Recommendations

- Vancouver type A_G fractures that are displaced greater than 2 cm can be managed with ORIF [overall quality: low]
- Vancouver type A_L do not require surgical intervention unless they are technically a B2 fracture

Question 4: What is the optimal management and outcome of Vancouver type B fractures?**Case clarification**

A 70 year old woman with an uncemented THA has an oblique fracture around the stem from the subtrochanteric region to a point just distal to the tip of the stem.

Relevance

The treatment is based on the stability of the stem, as well as the quantity and quality of the bone stock available in that location.

Current opinion

Although there is variability between centers on many specific details, the guiding principles include revision of the stem, replenishment of bone stock unless its loss is so severe that segmental replacement is needed, and reduction of the fracture around the underlying reconstruction.

Finding the evidence

- PubMed (Clinical queries) (etiology): “periprosthetic hip fracture”
- PubMed: “periprosthetic hip fracture” AND (“risk factor” OR “epidemiology”)

- MEDLINE: “periprosthetic hip fracture” AND “risk factors” OR “epidemiology”

Quality of the evidence

Level IV

- Retrospective cohort studies

Findings

Type B1 Type B1 fractures are located around or adjacent to a stable femoral implant. The guiding principles include reduction, stable fixation and when necessary, the addition of bone graft. The surgical approach may be standard or minimally invasive (MIPO).

Haddad demonstrated 98% union (39/40) when onlay allografts were used with, or without, a plate. In this series, there was only one nonunion and no malunions above 10°. ³³ Similarly, Chandler’s report on 19 B1 cases with a cortical onlay allograft revealed union in 17 and malunion in only one of these 19 fractures. ³⁴ This treatment technique has been well documented. ³⁵

Ebraheim reports 13 consecutive B1 fractures treated with reversed distal femoral locking plates. All fracture healed, with only one delayed union. ³⁶ Conversely, Buttaro reports on 14 B1 fractures treated with locked compression plating with unicortical screw fixation with or without additional strut allograft. Because of over 50% failure in the plate-only group, and only a 20% failure in the combination allograft/plate constructs, the authors favored the latter approach. ³⁷ This is supported by other authors, including Holley who suggests that for the B1 fracture the plate and strut are superior to the plate alone. ⁵ Recent biomechanical studies by Zdero also support this finding. In this study a variety of fixation strategies were examined for a periprosthetic fracture just distal to the tip of a well-fixed stem. Among the fixation strategies used, the authors demonstrate that a non-locking plate with cabled allograft provides the stiffest construct in vivo. ³⁸ This finding is in keeping with previous biomechanical studies. ³⁹

Ricci et al. advocate the use of the minimally invasive plate osteosynthesis technique (MIPO), with indirect reduction and minimal soft tissue stripping. A union rate of 100% in 41 fractures was reported, at a mean of 12 weeks using a variety of plates. Minor implant failure was observed in only three instances, without influencing union. ⁴⁰ In contrast, Tadross reports on four failures in a small series of seven fractures treated with the Dall–Miles cable plate system, including two nonunions and two malunions. This outcome was attributed to varus malalignment of the femoral component, which caused distraction at the fracture site. ⁴¹

It is clear from the literature that B1 fractures should be treated with open or minimally invasive reduction and internal fixation, with or without cortical strut allograft.

Type B2 and B3 Types B2 and B3 fractures are characterized by the presence of fracture around or just below the stem, with a loose femoral implant. The discriminating feature is the quality and quantity of the surrounding bone stock; adequate (B2) or poor (B3). Numerous surgical strategies have been successfully employed in managing both B2 and B3 fractures.

Tsiridis retrospectively reviewed the results of 106 patients with types B2 and B3 fractures; 89 treated with impaction allografting, and 17 treated with cemented revision stems alone. Fractures treated with impaction grafting and a long stem had increased union compared to impaction grafting with a short stem (odds ratio 5.5, 95% CI 1.54–19.6, $p = 0.009$). Also, in this setting, impaction allografting with a long stem achieved higher union rates than long-stem revision alone (odds ratio 4.07, 95% CI 1.10–15.0, $p = 0.035$).¹³

Some authors have advocated the use of allograft in the management of the B3 fracture.⁴² In a 1999 study, Wong and Gross report successful outcomes on 15 patients with B3 fractures treated with proximal femoral circumferential allografts. In their series they report one nonunion of the host–allograft junction requiring plating and grafting and one revision due to aseptic loosening of the femoral implant. 13/15 had good results, with postoperative Charnley scores of 5.1 with satisfactory pain relief and returned to their preoperative level of function.⁴²

Using another successful technique, Maury reports on his outcomes of 25 Vancouver B3 fractures treated with allograft prosthetic composites, with 20 hip scores at 2 years of 70.8.⁴³ The majority of their patients were ambulatory (23/24) and pain-free (21/24) at this time. Notably, patients who had died or who were lost to follow-up ($n = 8$) prior to the 2 year mark had lower 20 hip scores (62.5) and more pain (3/8 pain-free). Four of the 25 hips required repeat revision.

Park et al. recently reported encouraging results for treating B2 and B3 fractures with fluted modular titanium, with a 92.6 % (25 of 27) successful outcome.⁴⁴

Finally, in elderly patients with B3 fractures, the use of proximal femoral replacement prostheses is advocated due to a reduced rehabilitation time and immediate weight-bearing capacity that these implants allow.⁴⁵ Proximal femoral replacements have been shown to be effective, and survivorship at 12 years is reported at 64%, which is adequate for elderly patients with a limited life expectancy.

As with most revision operations, complication rates are higher than in the primary setting. Data obtained from early series of surgically managed periprosthetic femoral fractures shows high complication rates and significant patient morbidity.^{6,16} Variable rates of complications have been published in the literature for the B3 fracture, as high as 29–66%. Major complications include dislocations, deep-seated infections, nonunion, refracture, heterotopic ossifi-

cation, pulmonary embolism, and cerebrovascular incidents.^{5,16,25} Lindahl noted an overall complication rate of 23%, including nonunion, refracture, aseptic loosening, recurrent dislocation, deep infection, and ORIF failure in 1049 surgically managed fractures. In spite of this finding, Lindahl reports 76% patient satisfaction following revision for periprosthetic fracture (407 respondees). In the same group, 30% had at least one reoperation, 39% had no pain, and 61% had variable rates of pain.³

Recommendations

- B1 fractures generally can be treated by ORIF with plate devices and/or the use of cortical strut allografts. Augmentation with strut allograft may be beneficial [overall quality: moderate]
- B2 and B3 fractures can be treated with revision to a long-stem femoral component, with or without the addition of plate or allograft augmentation. Cementless, cemented, or cemented within impaction allografting can be used to address the pathology [overall quality: moderate]
- B3 fractures can be treated with an allograft–prosthetic–composite revision, segmental prosthesis, or with modular titanium fluted stems with or without allograft struts [overall quality: moderate]
- In the presence of a loose femoral component, internal fixation alone is inadequate in managing the periprosthetic fracture [overall quality: moderate]

Question 5: What is the optimal management of Vancouver type C fractures (intraoperative and postoperative)?

Case clarification

An 82 year old woman has radiographs that demonstrate an uncemented THA, with a proximal porous-coated taper wedge stem. The stem is well fixed, and there is no fracture of the proximal femur. A fracture is seen in the metadiaphyseal region of the distal femur.

Current opinion

Vancouver type C fractures can be treated nonoperatively or operatively, and can be typically addressed independent of the proximal femoral implant. Operative options include locked plating, nonlocked plating, and combi-plating (cable and screw combination).

Finding the evidence

- PubMed (Clinical queries) (etiology): “periprosthetic hip fracture”
- PubMed: “periprosthetic hip fracture” AND (“risk factor” OR “epidemiology”)
- MEDLINE: “periprosthetic hip fracture” AND “risk factors” OR “epidemiology”

Quality of the evidence*Level IV*

- Retrospective cohort studies

Findings

Postoperative type C fractures are those that occur well distal to the tip of the stem. Their morphology is quite variable. Nonoperative management is not considered suitable except in the sickest of patients because of poor results (malunion, nonunions) with high morbidity to the patient (partly due to prolonged bed rest).⁴⁶ Operative management of these fractures entails reduction and fixation, independent of the proximally located stem,⁴ and is beyond the scope of this chapter.

Recommendation

- Type C periprosthetic fractures (displaced fracture) can be treated with ORIF using traditional fixed-angle devices, or combination cable/screw-based implants. In addition they should be managed with touch weightbearing status for 6–8 weeks postoperatively, predicated on clinical and radiographic features of healing [overall level: low]

Summary of recommendations

- Patients with osteoporosis or otherwise weak bone (e.g., RA) and a loose femoral component are at higher risk of having a periprosthetic fracture
- The Vancouver Classification for postoperative periprosthetic fractures of the femur is reliable and valid for both experts and nonexperts
- Type A_C fractures do not require operative management unless displaced
- Type A_L fractures are rare and do not require operative management
- Type B fractures are managed based on the stability of the femoral implant and integrity of the host bone around the implant. B1 fractures are treated with open or minimally invasive reduction, and internal fixation, with consideration given to strut allograft. B2 and B3 fractures can be treated with a variety of techniques including impaction allograft, cemented or cementless revision stems for bypass fixation, allograft–prosthetic–composites, or proximal femoral replacement
- Type C fractures are treated independent of the femoral prosthesis, using current trauma techniques and strategies

Evaluation of the Painful Total Hip Replacement

Matthew Oliver and James N. Powell

University of Calgary, Calgary, AB, Canada

Case scenario

A 70 year old man, with no medical comorbidities, underwent a cementless total hip arthroplasty for osteoarthritis of the hip joint 3 years ago. He returned to an active lifestyle. He now presents with a 2 month history of thigh pain.

Importance of the problem

Total hip arthroplasty (THA) is undoubtedly one of the most successful innovations of the last millennium. In the United States, 231,000 THAs were performed in 2006 and it is projected that the number will reach in excess of 500,000/year by 2030.^{1,2} The National Joint Registry of England and Wales recorded 71,367 total hip procedures in 2008, an increase of 3.6% compared to the previous year.³

THA provides excellent pain relief⁴ and an improved level of function.⁵ It has been shown to be one of the most cost-effective healthcare interventions as measured by cost per quality-adjusted life years gained.⁶

The rise in the number of arthroplasties being performed, especially in young and obese patients, coupled with an increase in life expectancy, will lead to patients outliving their prosthesis. In the US between 1990 and 2002 the number of revision hip procedures increased by 79%.⁷ The average billed charges in the US for all types of revision hip surgery were estimated at \$54,553.⁸ The massive financial impact that revision hip surgery has upon healthcare resources can therefore be appreciated. It must not be forgotten that revision surgery is associated with significant morbidity. The goal of this chapter is to provide a modern evidence-based approach to the evaluation of a painful THA.

Top six questions

1. What important symptoms and signs can be elicited from the history and clinical examination?
2. What is the role of plain radiographs in the evaluation of a painful THA?
3. Which is the best preoperative test to diagnose infection?
4. What role do nuclear imaging investigations have in the evaluation of a painful THA?
5. What is the role of ultrasound, CT, and MRI in the evaluation of a painful THA?
6. Are metal ion levels useful in evaluating painful metal-on-metal bearings?

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "topic of interest AND total hip replacement AND systematic reviews"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) broad sensitivity search, diagnosis category using keywords "topic of interest AND total hip replacement"
- General MEDLINE search identifying the population (total hip replacement), the intervention (diagnostic tests), and the methodology (clinical trial)
- Cross-referencing from clinical papers obtained by the above methods

Question 1: What important symptoms and signs can be elicited from the history and clinical examination?

A complete history from the patient combined with a thorough physical examination is critical to successful

Table 20.1 Differential diagnosis of a painful total hip arthroplasty

Intrinsic etiology	Extrinsic etiology
Infection	Lumbar spine pathology
Aseptic loosening	Peripheral vascular disease
Distal stem pain (modulus mismatch)	Neurological injury
Periprosthetic fracture	Metabolic bone disease
Osteolysis	Malignancy
Recurrent instability/dislocation	Hernia
Bursitis	Complex regional pain syndrome
Tendonitis	Gynecological
	Urological

acquisition of any diagnosis in medicine. The differential diagnosis of a painful THA is extensive and has been categorized by various authors^{9,10} into intrinsic (directly related to the hip) and extrinsic causes (Table 20.1).

Pain is the most important descriptor in the history. The natural history of pain after THA was studied in over 2000 patients by Britton et al.¹¹ It was noted that the pain level was the most informative outcome as a predictor of revision and correlated well with patients' opinions of their outcomes. Pain is a highly subjective outcome measure, however, and needs to be interpreted with caution.

It is crucial to elicit the temporal onset of pain. An initial pain-free time period would suggest an intrinsic etiology such as aseptic loosening. If the patient was never pain free postoperatively then emphasis on searching for causes such as infection, initial failure of the implant to stabilize, or occult fracture perioperatively would be appropriate.

The site of pain serves as a useful diagnostic aid.¹² Pain localized to the buttock is suggestive of neurogenic or vascular claudication. This pain can radiate down the leg, and nerve root entrapment will need to be distinguished from arterial disease. Pain felt in the groin may indicate acetabular loosening or osteolysis or iliopsoas impingement/tendinopathy, or it can be due to a variety of herniae.¹³ Iliopsoas impingement should be considered in patients complaining of pain in the groin during activities that require active hip flexion.¹⁴ Gynecological and urological causes must not be ignored.

Thigh pain is suggestive of a loose femoral implant. It is acknowledged that patients with well-fixed femoral implants, either cemented or cementless, can still have low-intensity thigh pain. A mismatch in the modulus of elasticity of the host bone and a stiffer femoral implant has been

recognized as a possible pain generator in the thigh.^{15,16} Persistent or resting pain felt should alert the clinician to an infective or malignant process. Pain exacerbated by activity suggests loosening of the implants.

It is imperative to question the patient about their early postoperative recovery. Any wound infection, persistent wound discharge, or any course of empirical antibiotics, strongly points towards an infection as the pain generator.

Recent infections of other body systems such as a dental abscess or a urinary tract infection need to be documented. It is important to quantify the patient's comorbidities such as obesity, ischemic heart disease, diabetes, or immunosuppression, as these have a bearing on the diagnosis as well as the definitive treatment plan.

A comprehensive examination of both hips, both knees, and the spine is obligatory. The patient's gait must be observed for evidence of antalgia, limb length discrepancy, and muscle weakness. A Trendelenburg gait is indicative of abductor muscle dysfunction. Progressive limb shortening is suggestive of subsidence of the femoral component.

It is imperative to inspect the operative site to ensure it has healed without complication.

The active and passive range of motion of the hip must be assessed. Any apprehension by the patient during this assessment of motion, especially in extreme positions, may indicate hip instability. Anterior and posterior impingement tests should be performed. This is important in hip resurfacing patients due to a decreased head-neck diameter ratio.

A neurovascular examination of the lower extremities is mandatory.

Question 2: What is the role of plain radiographs in the evaluation of a painful THA?

Case clarification

The patient's AP pelvis radiograph revealed extensive reactive lines around the cementless femoral component.

Relevance

Plain radiographs are a cheap and noninvasive first line investigation. However, the radiographs are open to misinterpretation, which can lead to a wrong diagnosis.

Current opinion

Current opinion suggests that plain radiographs provide useful information, but, as a single investigation, rarely lead to a confirmed diagnosis.

Quality of the evidence

- Level I: 2 meta-analyses/systematic reviews
- Level II: 1
- Level III: 3
- Level IV: 1

Findings

A critical review of serial plain radiographs from the time of surgery to the present date is ideal. This enables the clinician to evaluate for signs of osteolysis, loosening, or migration of the implants.

The most recognized criteria for radiographic loosening of cemented femoral stems were proposed by O'Neill and Harris.¹⁷ In their study, plain radiographs were found to be accurate in predicting loose cemented femoral stems with a sensitivity of 89% and specificity of 92%. This study reported less impressive results for predicting loose acetabular components, with a sensitivity of 37% and specificity of 63%.¹⁷

With regard to cementless femoral prostheses, Engh et al. have defined the major and minor radiographic signs of osseointegration.¹⁸ Engh et al. also devised a fixation/stability scoring system to help predict implant failure.¹⁸

A meta-analysis by Temmerman et al. reported on the accuracy of diagnostic imaging techniques in the diagnosis of aseptic loosening of femoral components. The meta-analysis stated that plain radiography had a mean sensitivity and specificity of 82% (95% CI 76–87) and 81% (95% CI 73–87) respectively in diagnosing aseptic loosening. The study concluded that the diagnostic performance of plain radiography, subtraction arthrography, nuclear arthrography, and bone scintigraphy was not significantly different. It recommended plain radiography, supplemented if necessary by bone scintigraphy, for the evaluation of suspected aseptic loosening of the femoral component because of their efficacy and lower risk of patient morbidity.¹⁹ Of note, the meta-analysis commented that the methodological quality of the studies analyzed was limited, being either confounded by verification bias or an appropriate “gold standard” not being applied to all patients, leading to a possible overestimation of diagnostic accuracy.¹⁹

Temmerman et al. also published a systematic review assessing the diagnostic performance of the above modalities in determining a loose acetabular component.²⁰ This review stated the pooled sensitivity and specificity rates for plain radiography were 70% (95% CI 59–79%) and 80% (95% CI 73–86%), respectively. Bone scintigraphy had a sensitivity of 67% (95% CI 57–76%) and specificity of 75% (95% CI 64–83%). Subtraction arthrography had a sensitivity of 89% (95% CI 84–93%) and 76% (95% CI 68–82%). It was therefore recommended to use subtraction arthrography as an additional test when plain radiography was found to be inconclusive in determining a loose acetabular component.²⁰ However, the use of arthrography has declined in recent years, mainly because of problems with standardizing and interpreting the test.

Differentiation of septic from aseptic loosening on plain radiographs is difficult unless the infection is locally aggressive or advanced. In this case the radiographic signs are usually obvious and include endosteal scalloping, oste-

openia, periosteal new bone formation, and extensive osteolysis.

Serial evaluation of plain radiographs can reveal eccentric wear of the polyethylene liner of an acetabular component and alert the clinician to look for associated osteolysis. Several methods have been described to quantify polyethylene wear rates.^{21–23} Early osteolysis is often asymptomatic and therefore the patient should be carefully followed up with serial radiographs to prevent catastrophic failure and avoid a challenging revision operation at a later date.

Recommendations

The evidence suggests:

- Plain radiographs are an easily obtainable, relatively cheap, and noninvasive investigation with an acceptable level of diagnostic accuracy [overall quality: moderate]

Question 3: Which is the best preoperative test to diagnose infection?

Case clarification

A complete blood cell count (CBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) were performed. The ESR and CRP were elevated above the normal range. This prompted a preoperative hip aspiration for bacterial culture.

Relevance

The clinician needs to exclude between septic and aseptic etiologies as the treatment plans of each differ considerably.

Current opinion

A CBC and nonspecific inflammatory markers (CRP and ESR) are routinely requested to rule out an infective etiology.

Quality of the evidence

- Level II: 3
- Level III: 1
- Level IV: 6

Findings

Serological white cell count Canner et al. stated that only 15% of patients with a confirmed periprosthetic infection had an abnormally elevated white cell count.²⁴ Spangehl et al. found that an elevated white cell count had a sensitivity of only 20% (95% CI 9–38%), a specificity of 96% (95% CI 91–98%), a positive predictive value (PPV) of 54% (95% CI 24–76%) and a negative predictive value (NPV) of 85% (95% CI 79–90%).²⁵

ESR This test showed a sensitivity of 82% (95% CI 65–93%), a specificity of 85% (95% CI 78–91%).²⁵ Other studies have shown that patients with documented periprosthetic

infections have significantly elevated ESRs (mean 60mm/hour), whereas those with mechanical loosening or those that are asymptomatic have lower or normal levels (<20mm/hour).²⁶

CRP This test showed a sensitivity of 96% (95% CI 78–100%) and a specificity of 92% (95% CI 85–96%).²⁵ Four studies have stated that CRP is a more sensitive test than ESR in differentiating between septic and aseptic loosening.^{25–29}

Combined CRP and ESR Both these tests may be elevated in patients with chronic diseases unrelated to the hip joint and thus these tests are often criticized for their lack of specificity. However, if the clinician has performed a detailed medical history and examination and taken into account any factors that could result in a falsely elevated test, these tests are valid screening tools for possible infection. In fact, Spanghel et al. stated that when ESR and CRP both reveal negative findings then the probability of infection is zero (95% CI 0–4%). If they both report a positive result then the probability of infection is 83% (95% CI 62–95%).²⁵ Sanzen and Carlsson reported similar results in a previous study.²⁹

Preoperative hip aspiration, culture, and sensitivity It is recommended to perform this investigation only when there is a high index of suspicion for infection with positive CRP and ESR results. If routinely performed for all patients in pain this test has poor specificity.³⁰ The patient should not have taken antibiotics for a minimum of 2 weeks prior to aspiration. Such investigations have shown sensitivities ranging from 50% to 92% and specificities of 88–97%.^{25,31,32,33} The variability in results is due to the difference in sampling technique, interpretation of positive findings, and the potential for unrecorded use of antibiotics. In the study by Spanghel et al., the preoperative aspiration had a sensitivity of 86% and a specificity of 96% when patients taking antibiotics were excluded.²⁵

Combined CRP, ESR, and preoperative hip aspiration When all three tests have negative results, the probability for an infected hip arthroplasty has been calculated at zero (95% CI 0–4%). When all three tests are positive, the probability has been calculated at 89% (95% CI 52–100%).²⁵

Recommendations

In the evaluation of periprosthetic infection:

- Normal levels of CRP and ESR reliably exclude periprosthetic infection [overall quality: moderate]
- The combined use of hip aspiration with ESR and CRP (when elevated) yields the highest diagnostic accuracy for infection [overall quality: moderate].

Question 4: What role do nuclear imaging investigations have in the evaluation of a painful THA?

Case clarification

The patient underwent a triple-phase isotope bone scan (TPBS) and a leukocyte labeled bone scan to confirm whether both implants were loose and infected.

Relevance

The clinician needs to exclude between septic and aseptic etiologies as the treatment plans of each differ considerably.

Current opinion

The isotope bone scan is a valuable screening tool but lacks specificity. However, it is readily available and relatively cheap. Clinicians commonly use leukocyte labeled scans to aid confirmation of periprosthetic infection.

Quality of the evidence

- Level I: 3 meta-analyses/systematic reviews
- Level III: 3
- Level IV: 3

Findings

Technetium-99 methylene diphosphonate (Tc-99 MDP) bone scintigraphy Clinicians find this test most useful when the result is negative as it means the hip implants are not likely to be involved in a pathological process. The problem is this test lacks specificity.³⁴ The test can be positive for up to 2 years in well-fixed cemented and cementless prostheses.³⁵ The meta-analysis by Temmerman et al. stated this test had an overall sensitivity of 85% (95% CI 79–89) and specificity of 72% (95% CI 64–79) in detecting aseptic loosening of the femoral component. Only one study analyzed cementless femoral components, reporting a sensitivity of 82% (95% CI 57–96) and a specificity of only 43% (95% CI 43–71).¹⁹ The overall results for the acetabular component were a sensitivity and specificity of 67% (95% CI 57–76) and 75% (95% CI 64–83) respectively. Again, only one study analyzed cementless acetabular components, reporting a sensitivity of 75% (95% CI 61–85) and a specificity of 41% (95% CI 18–67).²⁰ Lieberman found that technetium bone scans had a lower sensitivity and specificity than serial plain radiographs for diagnosing component loosening, recommending the use of bone scans only if radiographs were inconclusive.³⁴

When a Tc-99 MDP scan is positive, a gallium-67 scan can help increase the specificity for differentiating between aseptic and septic loosening.³⁶ When the two techniques are combined the sensitivity lowers considerably to 57%, thus limiting its usefulness.³⁷

TPBS Nagoya et al. reported that TPBS had PPV and NPV for infection of 83% and 93%, respectively. This group also reported a diagnostic sensitivity of 88% and specificity of 90%. Their conclusion was that it was a cost-effective method of screening.³⁸ A systematic review analyzing the accuracy of TPBS, white cell imaging (WBC), and positron emission tomography (PET) reported that TPBS yielded the least favorable results, with an accuracy of 80% in diagnosing infection.³⁹ The systematic review concluded that TPBS still has a role, especially in units without facilities for PET scans and WBC scans, as it excels in simplicity and cost-effectiveness.³⁹

Labeled leukocyte scan (WBC scan) A dual tracer technique has delivered vast improvements in diagnostic accuracy, namely with a leukocyte scan performed simultaneously with a Tc-99 MDP bone scan. The accuracy is further improved by performing bone marrow scintigraphy with Tc-99 sulfur colloid. The systematic review reported that the leukocyte labeled scan had the highest diagnostic accuracy when compared to TPBS and PET, yielding an accuracy of 91%. The accuracy was even higher in the studies using bone marrow scintigraphy and leukocyte labeled scans.³⁹ However, this imaging modality is invasive, labor intensive, and expensive, and requires delayed imaging after 24 hours.³⁹

FDG-PET PET has shown great promise for diagnosing infection, with a sensitivity and specificity of 94% and 95% respectively. However, there are no consistent assessment criteria in the literature.⁴⁰ FDP-PET ranked second in the systematic review with an overall accuracy of 89%.³⁹ This test is expensive and limited to specialist centers.

Recommendations

In routine practice:

- TPBS is a useful and cost-effective screening tool for aseptic and septic loosening [overall quality: moderate]
- The leukocyte labeled scan combined with Tc-99 sulfur colloid bone marrow scintigraphy should be considered the gold standard nuclear imaging test for diagnosing periprosthetic infection [overall quality: moderate]

Question 5: What is the role of ultrasound, CT, and MRI in the evaluation of a painful THA?

Relevance

Further imaging modalities—ultrasound, CT, and MRI—can add important information when used appropriately to answer a specific question.

Current opinion

Ultrasound has both a diagnostic and therapeutic role. Modern MRI and CT scanners have metal artifact reduction capabilities, improving their diagnostic value.

Quality of the evidence

- Level II: 1
- Level III: 8
- Level IV: 4

Findings

Ultrasound Advantages of ultrasonography over other cross-sectional imaging modalities are that it is less expensive, employs no exposure to radiation, and it has dynamic real time assessment capabilities. It can be used to image the soft tissue envelope around the hip joint, enabling the diagnosis of joint effusions, soft tissue masses, and iliopsoas impingement.^{41,42} It can also be used to guide aspiration of a joint effusion distinguishing between a superficial fluid collection, a fluid collection communicating with the joint, or an intra-articular effusion. In a therapeutic role, it can be used to guide local anesthetic and steroid injections into peritendinous regions such as the iliopsoas or trochanteric bursa.⁴¹⁻⁴⁴

CT CT has been proven to demonstrate areas of osteolysis with greater sensitivity than plain radiographs and enables accurate quantification of volume of bone loss.^{45,46} It can detect subtle fractures and has been regarded as the gold standard in the assessment of iliopsoas impingement.^{14,42,47}

Hart et al. reported promising results using three dimensional (3-D) CT scans to assess failing hip resurfacings when mechanical symptoms were diagnosed clinically.⁴⁸ These 3-D CT scans are able to confirm a clinical diagnosis of impingement and identify components at risk of high wear by calculating the true version and inclination of the acetabular component.⁴⁸

MRI If technical adjustments to counteract metal artifact are employed, the MRI scan is a sensitive and all-inclusive modality for evaluating a painful hip arthroplasty. It can detect periprosthetic fatigue fractures even before completion of the fracture, enabling the surgeon to intervene at an earlier stage.⁴⁹

MRI is also able to diagnose periprosthetic collections and allows evaluation of neurovascular structures, particularly if there is concern about entrapment by heterotopic bone or extravasated cement,⁵⁰ and is able to diagnose abductor muscle detachment.⁵¹

Studies have shown that MRI can more accurately demonstrate the presence and extent of osteolysis than plain radiographs.⁵⁰ This was validated with a cadaveric model yielding a sensitivity, specificity, and accuracy of 95%, 98%, and 96% respectively when compared to plain radiographs including Judet views.⁵²

Hart et al. used a metal artifact reduction sequence (MARS) MRI to assess 26 patients with unexplained pain

following a metal-on-metal bearing hip arthroplasty. The MARS MRI revealed 16 periprosthetic lesions, 2 of which were solid masses.⁴⁸ These masses have been labeled “pseudo-tumors.” A pseudo-tumor is a periprosthetic soft tissue mass that has occurred as a result of a hypersensitivity immune reaction to metal debris. It is highly destructive to the soft tissue envelope of the hip. Results of revision surgery for pseudo-tumors have been poor.⁵³

Recommendations

In routine practice:

- Ultrasound should be considered before CT and MRI if there is a targeted clinical question to a specific area of interest (i.e., impingement) or if a diagnostic or therapeutic injection/aspiration is required [overall quality: moderate]
- MRI can diagnose intraosseous, intra-articular and peri-articular pathology and its use for evaluating nonspecific hip symptoms or a suspected regional nerve injury is valid [overall quality: moderate]

Question 6: Are metal ion levels useful in evaluating painful metal-on-metal bearings?

Relevance

The national joint registries indicate that hip resurfacing is failing earlier than conventional THA.^{3,54} The main reason has been femoral neck fracture (25%), but failures due to unexplained pain (23%) are of concern.³

Current opinion

Hip resurfacings seem to have specific modes of failure that are not detectable using traditional work-up algorithms. The mechanisms of failure appear to be high wear rates with associated high metal ion concentrations and a local metal hypersensitivity reaction.

Quality of the evidence

- Level II: 4
- Level III: 2
- Level IV: 0

Findings

Metal ion levels and acetabular component orientation Excess chromium and cobalt ions are known to have potentially toxic effects in humans.⁵⁵ It has been postulated that high metal ion levels of chromium and cobalt in a patient indicate a failing bearing surface. In a study by De Smet et al. a highly significant correlation was found between the maximum wear scar depth on explanted femoral components and the metal ion concentrations in both serum and joint fluid. The study recommended routine metal ion measurement in patients with metal-on-metal hip arthroplasties. De Smet et al. found there was more likely to be

metallosis in the hip joint in patients with concentrations of serum chromium greater than 17 µg/L and serum cobalt greater than 19 µg/L.⁵⁶

Several studies have found a strong correlation between high metal ion levels and increased inclination of the acetabular component (>50°).^{49,57-59} Hart et al. recommended using a low-dose 3-D CT protocol to more accurately calculate acetabular component position.⁴⁸

Increased metal ion levels were seen in one study with acetabular components positioned with more than 20° of anteversion, less than 10° of anteversion and more than 55° of inclination.⁶⁰

Recommendations

In routine practice:

- Symptomatic patients should have blood chromium and cobalt ion measurements [overall quality: moderate]
- There is no published data on its diagnostic accuracy due to some control subjects having raised ion levels and indecision on setting normal threshold values. The use of routine testing of every patient cannot be recommended at this stage [overall quality: low]

Summary of recommendations

- Plain radiographs are an easily obtainable, relatively cheap and noninvasive investigation with an acceptable level of diagnostic accuracy
- Normal levels of CRP and ESR reliably exclude periprosthetic infection
- The combined use of hip aspiration with ESR and CRP (when elevated) yields the highest diagnostic accuracy for infection
- The TPBS is a useful and cost-effective screening tool for aseptic and septic loosening
- The leukocyte labeled scan combined with Tc-99 sulfur colloid bone marrow scintigraphy should be considered the gold standard nuclear imaging test for diagnosing periprosthetic infection
- Ultrasound should be considered before CT and MRI if there is a targeted clinical question to a specific area of interest (i.e., impingement) or if a diagnostic or therapeutic injection/aspiration is required
- MRI can diagnose intraosseous, intra-articular, and peri-articular pathology and its use for evaluating nonspecific hip symptoms or a suspected regional nerve injury is valid
- Symptomatic patients with metal-on-metal bearings should have blood chromium and cobalt ion measurements
- There is no published data on its diagnostic accuracy due to some control subjects having raised ion levels and indecision on setting normal threshold values. The use of routine testing of every patient cannot be recommended at this stage

Conclusions

- Complete clinical assessment of the pain is mandatory
- Serial plain radiographs reveal useful diagnostic information
- Preoperative hip aspiration when ESR and CRP are elevated yields the highest diagnostic accuracy for infection
- Leukocyte labeled scan plus bone marrow scintigraphy is the best nuclear imaging test for diagnosing infection
- The MRI scan is an all-inclusive modality for evaluating a painful hip arthroplasty, especially for nonspecific pain
- Symptomatic patients with metal-on-metal bearings should have blood metal ion levels measured as well as assessment of the acetabular component version

Revision of the Femoral Components: Role of Structural Bulk Allografts and Impaction Grafting

Christopher R. Gooding, Bassam A. Masri, Donald S. Garbuz, and Clive P. Duncan

University of British Columbia, Vancouver, BC, Canada

Case scenario

A 55 year old man presents to the clinic with a 12 month history of left groin pain. He had a total hip arthroplasty (THA) on that side 15 years ago. The pain is getting worse and he is now housebound. On examination, he walks with an antalgic gait and the surgical scar over the left hip is well healed with no clinical evidence of infection. He has equal leg lengths, a fixed flexion deformity of 15° and joint motion is limited in every direction because of pain. Examination of the spine, as well as the vascular and neurological status of the left lower limb, reveals no remarkable findings.

Relevant anatomy

Revision of the femoral component of a THA can be technically challenging. Careful analysis of bone loss, and planning, are key to success. With so many options available for reconstruction it is helpful to have a system for classifying the femoral defects to help the surgeon achieve a thorough understanding of the problem and to be appropriately prepared with the necessary implants and instruments.

The most widely used classification system is that proposed by Paprosky et al.,¹ the 2000 version is summarized here.

Classification of femoral defects¹

- *Type I*: A well preserved metaphyseal cancellous bone with an intact diaphysis. This is often seen following the removal of a cementless femoral component without any ingrowth.
- *Type II*: Considerable loss of metaphyseal cancellous bone but with an intact diaphysis. This pattern is commonly seen following the removal of a cemented femoral component.
- *Type IIIA*: Severely damaged metaphysis that is unable to support an implant but more than 4cm of intact diaphyseal bone is available for distal fixation. Paprosky gives the example of a loose femoral component that has been inserted with first-generation cementing techniques, i.e., poor cement pressurization.
- *Type IIIB*: A severely damaged metaphysis as for type IIIA but with less than 4cm of diaphyseal bone available for distal fixation. Such a picture of bone destruction can be seen following a failed cemented stem, inserted with a cement restrictor. As well as osteolysis proximally in the metaphysis there is also considerable osteolysis surrounding the polyethylene cement restrictor. A similar pattern can also be seen with an uncemented femoral stem associated with distal osteolysis.
- *Type IV*: With this pattern of bone destruction there is considerable damage to both the metaphysis and diaphysis associated with a widened femoral canal as a result of which the isthmus is unable to support an implant.

Importance of the problem

In 2000 it was estimated that 183,000 total hip replacements were performed in the United States and that 31,000 (17%) were revision procedures.² By 2003 these figures had increased to approximately 200,000 and 36,000 respectively.³ In England and Wales the 2007 report from the National Joint Registry recorded 62,253 primary hip replacements and 6353 revision hip replacements.⁴ This was a substantial increase compared to the figures for 2003–2004 when 3012 revisions were reported, representing more than double the number of revision procedures.⁴ However, this may represent a degree of under-reporting, as the UK National Joint Registry was in its infancy in 2003–2004. Nonetheless it is clear that revision hip arthroplasty is becoming an increasing problem with an increasing number being done worldwide and an aging population who have had a THA. In 2006, Hootman et al. estimated that the number of revision hip procedures increased by 60% in the previous decade compared to an increase of 50% for primaries.⁵

Revision hip surgery places a greater financial burden on healthcare expenditure, as the majority of patients require longer hospital stays and generally have higher rates of morbidity.⁶ The rate of readmission for any cause within 30 days from the date of surgery has been reported at 8.48% for revision hip surgery compared to 4.91% for primaries.³

Orthopedic surgeons and their patients have access to a large amount of information about revision hip surgery. The Google search engine finds over a quarter of a million hits when the search term “revision hip surgery” is entered. Even if the more specific search term “bone allografts in revision hip surgery” is used, there are more than 124,000 hits. Clearly, this type of review will yield a lot of information but of variable quality, highlighting the need for the development of an evidence-based approach.

Top ten questions

Basic science

1. How does morselized impaction graft and structural allograft become incorporated into the host bone?
2. What biomechanical factors contribute to long-term success?

Therapy

3. What are the technical aspects of impaction allografting for revision of a femoral component in THA?

4. What are the results of impaction allografting in femoral revision in revision THA?
5. What are the technical aspects in using a structural allograft in femoral revision in revision THA?
6. What choices of femoral implant are available when using a structural bone allograft?
7. What are the results of using a structural allograft in revision THA and what are its advantages and disadvantages?

Harm

8. What are the complications of impaction allografting for revision of a femoral component in THA?
9. What are the complications of using a structural bulk allograft for revision of a femoral component in THA?

Current practice and the future

10. What is the current state of the popularity of these techniques? Are there better alternatives?

Question 1: How does morselized impaction graft and structural allograft become incorporated into the host bone?

Allograft bone can be used to replace or reinforce the proximal femur,^{7–9} as a cortical strut graft to reinforce the calcar or lateral cortex, or as morselized graft, as in impaction grafting.¹⁰

Bone graft can become incorporated within the host bone by different processes. These include osteoinduction and osteoconduction as well as osteogenesis. *Osteoinduction* refers to the ability of the graft to stimulate new bone formation by recruiting pluripotential stem cells from the surrounding host bone. This is mediated by a number of bone matrix proteins of which the bone morphogenic proteins (BMP) are the best characterized. *Osteoconduction* refers to the ability of bone graft to function as a scaffold for the ingrowth of new capillaries as well as the migration of osteoprogenitor cells from the host. This bone graft scaffold is gradually replaced over time with host bone by a process called *creeping substitution*. *Osteogenesis* refers to bone's ability to regenerate itself by producing new bone. This process is mediated by osteoblasts. Bone resorption is also a fundamental process by which bone grafts eventually become incorporated into the host bone, and is mediated by osteoclasts. Unlike autograft bone, which can become incorporated into the host bone via osteoinduction, osteoconduction, or osteogenesis, allograft bone becomes incorporated via osteoconduction alone.

In the context of femoral impaction grafting, morselized allograft is used as filler. The graft has a rich vascular bed provided by the endosteal blood supply. This type of

construct will incorporate through a combination of revascularization, osteoconduction, and remodeling. It becomes incorporated with the host bone similar to autogenous cancellous bone graft, albeit at a slower rate, and necrotic bone graft may persist at the site of implantation.¹¹

Histological studies of biopsies from patients who have had impaction allografting have shown incorporation.¹²⁻¹⁴ Examination of a femur from a patient who had impaction grafting with cement 3.5 years before postmortem examination showed that the graft had organized into three zones: a zone of regenerated cortical bone, an interface between cement and bone, and nonviable bony trabeculae embedded in cement.¹⁵ There were some islands of nonviable bone but more than 90% of the outer neocortex was viable.

Structural allograft incorporation has been extensively studied in animals; the results may not be directly applicable to humans but give us some idea of how allografts become incorporated in the host. Fresh allografts stimulate a rejection reaction, which may lead to graft resorption. Processing allografts by freezing or freeze-drying decreases the immunogenicity,¹⁶⁻¹⁸ but the biologic activity is also reduced by removing all live cells.¹⁹

The structural allograft first incites an inflammatory response that brings in the pluripotential cells needed for new bone formation. The union and incorporation processes are initiated by osteoclasts which resorb the haversian systems of the allograft until the osteoblasts appear (derived from the endosteal lining of the host and from the surrounding soft tissues) and fill in this area. This process is slow and can take as much as eight times longer to heal than an autogenous bone graft.^{20,21} Unlike morselized allografts, revascularization, creeping substitution, and remodeling occur only to a limited extent^{21,22} and are usually limited to the periphery of the graft adjacent to the host-graft junction. Human retrieval studies have also shed some light on the behavior of frozen allografts.^{23,24} Enneking showed that union at the cortical host-graft junction initially starts with callus formation. Less than 20% of the graft remodeled and this only took place at the superficial ends of the graft.²³ Soft tissues appeared to become firmly attached to the graft by a layer of new bone.

Union between the graft and host can be improved by placing autograft at the graft-host junction. This autograft can be obtained from the iliac crest, or from reamings from the host femur that can be wrapped around the graft-host junction as suggested by Gross.²⁵ Since autograft possesses osteoblasts it is capable of osteogenesis, as well as possessing osteoinductive substances.

It is clear that allograft incorporation is a somewhat complex process that is dependent on many factors. The complete incorporation of a graft, i.e., the removal of the donor bone and its replacement by new bone from the host, is not necessary in all clinical situations. The goal in cortical

grafts is union at the graft-host junction together with some limited remodeling so that the graft can provide some mechanical support and is able to withstand physiologic weightbearing without pain or fracture.²²

Question 2: What biomechanical factors contribute to long-term success?

Processed structural allograft can be described as biologically inert and therefore functions like an implant. The biomechanical consequence of this is that the allograft supported by internal fixation, such as a femoral stem, is as strong as living bone because it is the mineralized matrix of bone that gives it its strength. Therefore, an allograft-prosthesis construct can be considered a success when union has occurred at the graft-host junction. But, unlike living bone, it is unable to remodel in response to accumulated load and is therefore prone to fatigue failure with time. In addition, revascularization can lead to graft resorption.

The problems facing impaction allografting are different to those faced by structural allografting. Some reports have indicated a high prevalence of intra and postoperative fractures²⁶⁻²⁹ and high levels of implant migration of more than 10 mm.³⁰⁻³³ Inadequate compaction of the graft³⁴⁻³⁷ and defects in the cement mantle^{35,38} as well as resorption of the endosteal layer³⁹ are thought to play a role. Although studies have shown radiological evidence of remodeling of the impacted allograft,⁴⁰⁻⁴² histological reports have revealed that the graft does not fully remodel into viable bone even up to 8 years following the index procedure.^{13,43} Additionally, there are some reports that the cement can penetrate all the way to the endosteal cortex.^{39,44} It is uncertain whether this is desirable in terms of achieving initial composite stability, or undesirable by compromising bone graft remodeling. Reducing cement pressure or increasing its viscosity can reduce the amount of cement penetration which may enhance local vascularization around the graft and hence its ability to be remodeled.⁴⁵ However, this may have the deleterious result of reducing the shear strength of the endosteal interface, leading to excessive migration of the stem.⁴⁶ Albert et al.⁴⁷ used a cadaveric model to assess pressurization of the cement and its penetration through the impacted allograft. They observed that impaction grafting without cement pressurization led to a reduction of cement contact with the endosteal cortex; however, the migration and micromotion of the implant were significantly increased. The authors went on to conclude that longer-term stability of the implant is likely to be compromised if the cement is not pressurized.

Clearly a balance is desirable, but how to achieve that in the highly variable surgical setting is a challenge. If the cement reaches the endosteal bone then it will impede remodeling and integration of the impacted allograft.

However, a cement mantle which is less than 2mm thick will lead to excessive implant subsidence.^{35,38} This conflict of biological and structural goals of impaction allografting has been highlighted by other studies which have shown that the strength of the endosteal surface with the graft/cement is proportional to the amount of cement contact.^{44,46} Albert et al.⁴⁷ showed that with more than 50% of cement contact to the endosteal surface resulted in lower distal migration and micromotion than if there was less contact.

In summary, a number of biomechanical factors are implicated in the long-term success of structural and impaction allografting. With proximal structural allografts the femoral implant serves as an intramedullary fixation device, reducing the risk of fracture of the allograft as well as stabilizing it and so promoting union of the graft to the host.⁴⁸⁻⁵⁰ For impaction allografting to be a success the graft has to be sufficiently compacted to be able to support a femoral implant and a balance has to be established between sufficient cement pressurization to ensure stability of the construct but not so much as to interfere with incorporation of the morselized allograft into the host bone.

Question 3: What are the technical aspects of impaction allografting for revision of a femoral component in THA?

Concerns have been raised about the incidence of massive (>10mm) early subsidence following impaction grafting with allograft. Eldridge et al.³¹ reported on 79 consecutive cases of revision THA using morselized allograft, polymethylmethacrylate cement, and a double tapered, polished, collarless stem. Nine patients (11%) showed evidence of massive subsidence, with another nine patients subsiding to a lesser extent. Similar concerns have been raised in other studies.³⁸ This subsidence is significant as it subsequently leads to early implant failure.

The biomechanical factors which may have some influence whether a revision with impaction allografting is a success or failure have been discussed. In this section the surgical factors are outlined.

Nelissen et al.³⁵ reviewed 18 patients who underwent revision surgery with impaction grafting and a tapered, cemented stem. The femoral defects were classified according to the 1993 version of the Paprosky classification system.^{50a} 1 type IIA (absent calcar extending just below the intertrochanteric level), 3 type IIB (anterolateral metaphyseal bone loss), 10 type IIC (absent calcar with posteromedial metaphyseal bone loss), and 4 type III (type II defects with additional diaphyseal bone loss). From this study two factors appeared to influence migration of the femoral stems. The first was the extent of the femoral defect and the second was the presence of cement mantle defects. However the difference of stem migration between the Paprosky groups was small and was discounted. The great-

est increase in migration occurred during the first 3 months after surgery. Subsidence that occurs during the first few weeks can be attributed to additional graft compaction, as seen in other studies.⁵¹ The pattern of stem migration was subsidence and varus rotation and antetorsion. This pattern could be due either to cement mantle defects at the medial Gruen zones or to less impacted allograft chips. All of the eight cases that showed continuous migration of the femoral implant had cement mantle defects (thickness of cement ≤ 2 mm) in at least two Gruen zones. The cement mantle allows for a smooth transition of forces from the femoral implant to the adjacent bone. Since the bone graft deforms permanently during the process of creeping substitution, cement mantle defects may cause progressive migration and failure of the construct. This finding is similar to the findings from other studies which have concluded that the durability of a cemented stem albeit in the primary setting is related to the quality of the cement mantle.⁵²⁻⁵⁷

Masterson et al.^{30,38} concluded that the cement mantle defects that they observed were due to poor instrumentation and that a good cementing technique was essential for impaction allografting to be successful. This finding has been further corroborated by other studies.³⁵ Another reason for massive stem subsidence is poor packing of the allograft. Knight et al.²⁶ reported that this was a problem in 94% of their cases which resulted in varus or valgus alignment and a medial or lateral stem displacement. They attributed this to the technically demanding nature of the procedure, which was not helped by the lack of appropriate instruments to facilitate the technique.

More recently a variety of instrument systems have been introduced to help standardize the impaction technique. The difficulty is deciding when the construct has achieved adequate stability. In answer to this problem, one study has suggested the use of a torque wrench to assess rotational stability of the impactor.⁵⁸

By the very nature of revising the femoral component of a THA there is a risk of fracture. Ornstein et al.²⁷ reported on 144 consecutive revision hip arthroplasties of which 108 involved revising the femoral component with impaction allografting. Thirty-nine femoral fractures occurred in 37 hips, 29 of which occurred intraoperatively and 10 within 5 months of surgery. Additionally they reported that in 7 cases they created a femoral cortical window and inadvertently perforated the femoral cortex in 14. Knight et al.²⁶ reported a 16% technique related fracture rate and Fetzer et al.²⁸ reported on 3 postoperative fractures out of a total of 26 femoral revisions with impaction allografting. Schreurs et al.⁵⁹ reported on 33 cases of femoral component revision with impaction allografting; there was 1 unrecognized intraoperative fracture and 3 postoperative femoral fractures which were all through cortical defects at the level of the tip of the prosthesis.

As mentioned earlier, tight packing of the morselized allograft is essential for the impaction grafting to be a success. However, this can lead to intraoperative fracture which can go unrecognized. The proponents of the technique quote a prevalence of only 4%, in contrast to the figures already mentioned.⁶⁰ However, it is apparent that the fractures occur through areas of weakened bone at the level of the tip of the prosthesis. As a result, the use of a longer stem would be expected to decrease the prevalence of fractures in patients with major femoral deficiencies. Sierra et al.⁶¹ reported on 42 consecutive long-stem revisions (stems >220mm) where a long stem was chosen to bypass an area of bony deficiency. This represented 7.4% of all femoral impaction grafting that occurred during the period of study. At a mean follow-up of 7.5 years only two postoperative fractures were reported. The authors recommended that cortical defects should be bypassed by the implant/cement/allograft construct by at least two diaphyseal diameters. Although they suggested that additional struts and plates can be used to augment fixation in the case of periprosthetic fractures, these were unnecessary in areas of smaller cortical defects that can be covered with a stainless steel mesh and then bypassed by a longer stem (Figure 21.1). They added that in many instances the fractures could be avoided by releasing the tight soft tissues around the proximal part of the femur, ensuring a good exposure of the entrance to the femoral canal and so avoiding any bending stresses and torque within the femur at the time of impaction. As with other revision techniques, fractures associated with cement removal, as well as debridement of the canal, were also seen. They acknowledged that an extended trochanteric osteotomy could facilitate cement removal although they only used this technique in

Figure 21.1 Intraoperative photograph showing a revision total hip arthroplasty with impaction allografting along with a cortical strut graft and mesh for a proximal femoral defect.

four cases. The use of a prophylactic cerclage wire prior to proximal impaction, in areas in which the calcar is still present and thin, would be prudent. Prophylactic cerclage wires or cables should also be placed around the diaphysis in areas of thin cortical bone.

Others have also confirmed that long stems as well as extramedullary augmentation have a role when revising a femoral stem with the impaction allografting technique. Barker et al.⁶² demonstrated that both extramedullary augmentation and longer stems reduced the strain around a femoral defect by 31–50%.

Impaction allografting is a technically demanding procedure but with the appropriate instrumentation and an awareness of its pitfalls a successful outcome can be achieved (Figure 21.2).

Question 4: What are the results of impaction allografting in femoral revision in revision THR?

Case clarification

The patients' radiographs reveal a failed uncemented femoral component with a Paprosky type IIIB defect.

Relevance

As the indications for THA expand, including younger and more active patients, some may require two or more revisions during their lifetime. With implant failure, host bone is lost as a result of a combination of stress shielding, osteolysis, instability, implant failure, and/or infection. This

Figure 21.2 Postoperative AP radiograph of the proximal femur showing the revision of a failed total hip arthroplasty with impaction allografting and a cortical strut graft for a proximal femoral defect.

problem may be exacerbated by additional bone loss during the removal of the failed implant.

As well as choosing a suitable implant for revision of a failed femoral component it is also important, particularly in a younger patient, to minimize bone loss and restore bone stock. Of the many methods of reconstruction available to the surgeon performing a revision, there are only two techniques that have the aim of reconstituting bone stock: impaction bone grafting and the use of structural allograft. In the answer to this question, the results of impaction allografting will be considered and the results of structural allografts will be addressed in answer to Question 7.

Current opinion

Current opinion suggests that good results for impaction allografting can be achieved in specialist centers.

Findings

When it comes to reviewing the results for femoral revision with impaction grafting a number of problems are encountered. The first problem is the inconsistent use of inclusion criteria. A number of studies have limited their inclusion criteria to femurs with more advanced stages of bone loss^{38,42,63} whereas others, particularly in their early series, have specifically excluded some of those femurs⁴¹ because of concerns about expanding the indications for impaction allografting to the most challenging cases.⁶⁴ Another difficulty encountered when reviewing the results is the large number of potential confounding factors that may affect the outcome of the technique. These may include differences regarding the type and viscosity of cement used as well as the technique of cementing; the source, consistency, and pretreatment of the allograft itself; the operative approach; and the postoperative care, to name but a few.

The majority of studies published to date using the impaction grafting technique have identified the polished, tapered femoral stem as the implant of choice. In Gie et al.'s⁴¹ first authoritative report on the technique, 58 hips were revised by 11 different surgeons with a mean follow-up of 30 months. The average clinical scores for pain, function, and mobility had improved at the final follow-up. In 89% of the cases radiographic evidence of incorporation of the allograft or reconstitution of the cortical bone stock was

demonstrated. The exclusion criteria in this study were different from those quoted in other studies. Femurs which displayed "endosteal bone lysis associated with a large cortical diaphyseal defect" at the time of revision were excluded; however, more recent studies have identified this pattern of femoral bone deficiencies as a prime indication for impaction grafting. This may explain some of the differences in results between this group and other studies looking at impaction grafting.^{38,42,63}

Elting et al.⁶⁵ reported on their early results of revision of the femoral component with impaction grafting and a CPT femoral stem. Of the 56 patients available for follow-up, 50 (89%) reported mild or no pain and only 8 (14%) needed a walking aid. However, similar to the study of Gie et al.,⁴¹ the majority of patients had minimal bone loss.

Because of the initial concerns of subsidence with polished tapered stems^{31,42} some have used a precoated, collared straight stem that has previously been proven to be a durable option in femoral reconstruction with cement.^{66,67} Leopold et al.⁶³ reviewed 29 patients with a mean follow-up of 48 months, Harris hip scores (HHS) improved from a mean of 54 (out of 100) preoperatively to mean of 87 at the time of most the most recent follow-up. Kaplan–Meier survival analysis with aseptic radiographic failure or clinical failure as the endpoint suggested a survival rate of 92% at 6 years. Radiographic incorporation of allograft was seen in only 24% of patients, which is much lower than that reported in other studies with different femoral stems.^{31,41,42,65}

However, the authors of this study argued that more than 90% of the stems appeared radiographically stable at a mean of more than 5 years, which may suggest that bone remodeling may be occurring although not evident on plain radiographs. This has been supported by other studies which have identified patients where there is no evidence of allograft incorporation on plain radiographs but it is found on histological analysis of biopsy specimens.¹³

Van Biezen et al.³² reviewed 21 hips with severe femoral defects after a mean follow-up of 60 months. The mean HHS improved by 39 to 78 points and none of the patients required a further revision.

Knight et al.²⁶ used a collarless polished tapered stem with impaction grafting to revise 31 femoral components. At a mean follow-up of 31 months the modified HHS improved from 41 points preoperatively to 86 points. No stem subsidence was seen in 50%, subsidence of less than 5mm in 33%, subsidence of between 6 and 8mm in 13%, and subsidence of more than 10mm in 1 patient (4%). From a subjective view, 87% patients thought the procedure had improved their function with 97% saying that they would recommend it.

Fetzer et al.²⁸ reviewed 26 cases of cemented femoral revisions with impaction allografting but using a collared femoral implant in patients with severe femoral bone loss.

Openmirrors.com

The mean follow-up was 6 years and 20 patients were available at final follow-up. None of the patients required a further revision and there was no radiographic evidence of loosening at final follow-up. In one of the cases the femoral component had subsided, but this was less than 5 mm.

Piccaluga et al.³³ used a Charnley stem with morselized impacted allograft to revise 59 loose femoral components. The mean clinical follow-up was 56.7 months and the mean radiographic follow-up was 54.4 months. The latest follow-up radiographs in 56 reconstructions showed evidence of a stable, well-fixed stem in 52 (93%) cases but evidence of loosening in 4 (7%). Of these 4, 2 required revision to give a re-revision rate of 3.5% and the other two were asymptomatic after follow-up at 120 months. Of the 52 successful revisions the mean subsidence was 0.38 mm (0–4 mm).

Ullmark et al.⁶⁸ reported on 57 hips in 56 patients who were revised using the Lubinus SP-II prosthesis or the Charnley prosthesis together with morselized impaction grafting. They reported a significant improvement of the Modified Merle d'Aubigné–Postel score in those patients with a mean follow-up of 64 months with radiographic evidence of remodeling of the graft.

Cabanela et al.⁴⁰ reviewed 57 femoral revisions in 54 patients using a collarless, tapered, polished stem and impaction grafting. Additionally, 40 hips required strut allografts for reinforcement of the femoral shaft. The clinical results after 6.3 years were judged excellent and radiographic evaluation did not show any evidence of loosening in any of the surviving 53 hips. Subsidence of 1–3 mm was seen in 40 hips and 4–6 mm in 2. Evidence of remodeling was seen in 42 hips.

Halliday et al.⁶⁰ reviewed 207 patients (a total of 226 hips) at one center involving 32 surgeons. The survivorship of the revisions with further surgery on the femur as the endpoint was 90.5%, whereas the survivorship based on femoral reoperation for symptomatic aseptic loosening alone was 99.1% at 10–11 years. From the authors' review of their own experience they concluded that long stems are indicated when the host bone around the tip of a short stem is compromised, such as patients with large femoral defects or when a femoral fracture occurs.

Arif et al.⁶⁹ reviewed eight patients who underwent a revision THA with an Exeter stem and impaction allografting as well as strut allografts. They used an anterior approach to gain exposure to the hip and an anterior cortical window to remove the old implant. The mean follow-up was 74 months. The strut allografts incorporated in all cases, there was one femoral implant that had subsided 2 mm within the cement mantle, two that subsided by 1 mm at the cement bone interface, and one that subsided 15 mm and required revision. The authors concluded that the use of an anterior cortical window did not predispose the construct to failure.

Schreurs et al.⁵⁹ reviewed 33 femoral revisions with the use of the impaction grafting technique and a cemented polished stem. None of the patients required revision at a mean of 10.4 years follow-up. The mean stem subsidence was 3 mm. The average HHS improved from 49 points preoperatively to 85 postoperatively with an 8–13 year follow-up. Kaplan–Meier analysis with an endpoint of femoral revision for whatever reason showed a survivorship of 100% at 10.4 years.

A more recent review by Ornstein et al.⁷⁰ from the Swedish Hip Registry identified 1188 patients who had femoral impaction allografting with follow-up between 5 and 18 years. Kaplan–Meier survivorship analysis for all causes of failure was 94% for women and 94.7% for men at 15 years. Survivorship for aseptic loosening was 99.1%, for infection 98.6%, for subsidence 99%, and for fracture 98.7% at 15 years. The authors also identified statistically significant predictors for failure which included the year in which the revision was conducted post index surgery and the number of previous revisions, which almost reached statistical significance ($p = 0.056$). Interestingly, the age of the patient, gender, length of the stem, and previous septic loosening were not predictors for failure.

Table 21.1 summarizes the results for impaction grafting

Recommendations

In patients requiring revision arthroplasty for loose femoral stems with considerable proximal bone loss, evidence suggests:

- Impaction allografting is not for the inexperienced surgeon [overall quality: high]
- Excellent preliminary results for impaction grafting in femurs without endosteal bone lysis and without large cortical diaphyseal defects can be achieved [overall quality: moderate]
- There is a significant risk of intraoperative fracture with impaction allografting [overall quality: high]
- Subsidence of the femoral implant is a concern with this technique [overall quality: moderate]
- The risk of postoperative fracture continues for months after the reconstruction [overall quality: moderate]

Question 5: What are the technical aspects in using a structural allograft in femoral revision in revision THA?

Before considering reconstruction of the proximal femur with a structural allograft, careful planning is essential to ensure the best possible outcome. This includes excluding infection as a cause for failure of the implant, detailed templating, and making sure that suitable allograft is available together with the necessary implants and instruments.

Table 21.1 Summary of the results of impaction allografting in femoral revision in revision total hip arthroplasty

Author	No. of cases	Mean follow-up	Results
Gie ⁴¹	58 hips	30 months	89% demonstrated radiographic evidence of incorporation of allograft. Mean pain/function/mobility scores improved
Elting ⁶⁵	56 patients	31 months	89% (50 patients) mild/no pain, 14% (8 patients) needed walking aid
Leopold ⁶³	29 patients	48 months	HHS improved from a mean of 54 preoperatively to a mean of 87 postoperatively. 92% survivorship rate 6 years. Radiographic incorporation only 24%, but 90% radiographically stable at 5 years
Van Biezen ³²	21 hips	60 months	HHS improved by 39 points to 78 postoperatively
Knight ²⁶	31 hips	31 months	HHS improved from a mean of 41 points preoperatively to 86 points postoperatively
Fetzer ²⁸	20 hips at final follow-up	6 years	No further revisions and no radiographic evidence of loosening
Piccaluga ³³	59 cases	56.7 months	Of the 56 patients available for radiographic follow-up, 93% were stable
Ullmark ⁶⁸	57 hips	64 months	Significant improvement of the mean modified Merle d'Aubigné–Postel score following surgery
Cabanela ⁴⁰	57 hips	6.3 years	Excellent clinical results, with no radiographic evidence of loosening of the 53 surviving hips
Halliday ⁶⁰	226 hips	10–11 years	90.5% survivorship with further surgery on the femur as the endpoint
Arif ⁶⁹	8 patients	74 months	All patients had impaction grafting with an anterior cortical window and a large strut allograft. The strut allografts incorporated in all cases
Schreurs ⁵⁹	33 hips	10.4 years	HHS improved from 49 preoperatively to 85 postoperatively. 100% survivorship at 10.4 years with further surgery on the femur as the endpoint
Ornstein ⁷⁰	1188 patients 1305 hips	15 years	Survivorship analysis revealed 94% at 15 years for all causes of failure in women and 94.7% in men. Survivorship for aseptic loosening 99.1%, infection 98.6%, subsidence 99%, fracture 98.7%

HHS, Harris hip score.

Full circumferential allografts (proximal femoral allografts) are reserved for Paprosky type IIIB and IV defects, whereas noncircumferential allografts (cortical struts) are used in the less severe defects. Cortical struts also have a role in reinforcing cortical windows and in stabilizing periprosthetic fractures as well as osteotomy sites, and for augmenting the graft–host junction in proximal femoral allografts. For small defects whole fibular diaphyseal segments can be used, although their shape and size are awkward for the task. For larger defects segments of tibia, humerus, or femur can be utilized. The surgical technique for cortical strut grafts is relatively straightforward. The grafts are tailored to fit the femur and secured to the host femur with cerclage wires or cables. Additionally, some of the autogenous reamings from the femur can be placed along the allograft–host junction to facilitate union. Soft tissue stripping of the host femur should be kept to a

minimum to preserve as much of the periosteal blood supply as possible.

The surgical technique for proximal femoral allografts is technically more demanding. Possible surgical approaches that may be used include either a trochanteric slide^{71,72} or a longitudinal trochanteric splitting approach. The advantage of the slide is that it very much reduces the risk of proximal migration of the trochanter⁷³ and its consequences as compared to classic trochanteric osteotomy. Once the proximal femur is exposed, an assessment of the length of allograft required is made by implanting the femoral prosthesis into the host femoral canal and reducing it into the cup. The length of allograft depends on the stability of the reduced hip and assessment of limb lengths.

The majority of allografts are processed to reduce the risk of disease transmission and to reduce the immunogenicity of the graft. The commonest methods of processing are

freezing and freeze-drying. This enables long-term graft preservation, with bone frozen at -70°C lasting for 5 years or more.⁷⁴ Additional processing with irradiation reduces the risk posed by viral transmission⁷⁵ and may further reduce immunogenicity. At the time of surgery when the allograft is brought into the operating room, specimens should be taken from it for culture and then it should be immersed in an antibiotic-containing solution.

Since the allograft is biologically inactive, bone ingrowth onto an implant cannot occur and therefore an uncemented prosthesis is likely to fail due to subsidence or fracture of the allograft.^{71,76} For this reason the prosthesis should be fixed to the allograft with cement to which antibiotics have been added.⁷⁷ Another caveat is to avoid over-reaming of the allograft so as to maintain its strength and reduce the risk of fracture even when the host canal is larger, as is usually the case.⁷⁸ If there is a large discrepancy between the diameter of the host femur and the allograft and stabilization of the graft–host junction is proving difficult, then telescoping the graft inside the host femur is an option.

For this technique to be successful the graft–host junction must unite, which is by and large host-dependent. For union to occur, the junction between host and allograft must be stable. One technique that has been described is a step-cut or an oblique cut, which is then reinforced with cerclage wires or cables at the junction to attain rotational stability (Figure 21.3).^{25,79–83} Other suggestions have

Figure 21.3 Postoperative AP radiograph of the proximal femur showing the revision of a failed total hip arthroplasty with a long-stemmed implant with a proximal femoral structural allograft. The implant has been cemented to the allograft but is uncemented distally to the host femur.

included the use of two plates,^{48,71} allograft struts,⁸⁴ and cementing of the prosthesis into the allograft and the allograft to the host.⁸⁵ There are some concerns that screws placed through a plate may disrupt the fixation of the stem and lead to stress risers which may fracture the allograft,⁸⁶ and struts may fail before union of the graft–host junction has been achieved.⁷¹

In summary, the chances of union are improved if the host femur is carefully exposed preserving as much of its soft tissue attachments and blood supply. The graft–host junction should be kept free of cement and augmented with autogenous bone graft. Additionally, a step or oblique cut should be used and augmented with an additional strut allograft with wires/cables if needed. Once initial fixation is achieved, any of the remaining proximal host femoral bone can be wrapped around the graft–host junction as additional autogenous bone graft. The risk of dislocation can be decreased by reattaching the greater trochanter remnant to the proximal femur with cerclage wires or with the use of a cable-grip system. If there is no greater trochanteric fragment available then reattaching the abductors to the fascia lata or allograft can also be worthwhile.

Question 6: What choices of femoral implant are available when using a structural bone allograft?

A wide range of femoral implants have been employed with no uniformity of methods of fixation either to the allograft or within the host femur. The options for distal fixation have included distal cementing, which is not recommended, a distal press-fit,^{71,87} interlocking fixation,⁸⁸ the use of a step-cut and wires⁷⁹ to provide stability, or plates. Cementing has proved unpopular in this setting since although cadaveric biomechanical testing showed good stability with distal cementing,^{89–91} there is a risk that some of the cement may get into the gap at the graft–host interface and prevent union. Additionally, rigid fixation distal to the junction may reduce the load at the junction and lead not only to nonunion of the junction but to potential resorption of the allograft. Also, should the implant/allograft construct need to be removed, e.g., because of infection, it would prove more of a challenge if the implant is cemented distally with the risk of causing additional damage to the remaining femur. For these reasons an uncemented component that can achieve fixation to the host bone by a press or wedge fit distally has been gaining popularity.⁷¹ Gross et al.⁹² cautioned against this, however, because of the risk of having to use a large implant to get a press fit distally, which reduces the amount of cement mantle between the allograft and prosthesis proximally and also increases the probability of having to ream the allograft to make room for the implant. They also argued that a tight distal fit may

result in distraction at the graft–host junction and thereby increasing the risk of nonunion. In answer to some of these criticisms, some have advocated the use of a modular, long, thin uncemented femoral components, with the majority of the stability of the construct being achieved through the graft–host junction.

Question 7: What are the results of using a structural allograft in revision THA and what are its advantages and disadvantages?

Case clarification

Having obtained further radiographic views of the proximal femur it is concluded that there is insufficient bone stock for the patient to have a femoral reconstruction with impaction allografting. Instead, the decision is made to proceed with a proximal femoral allograft.

Current opinion

Current opinion suggests that very few centers today favor the use of circumferential segmental allograft as a preferred method of managing substantial proximal femoral bone loss during revision hip replacement.

Finding the evidence

Quality of the evidence

Level IV

- 10 case series

Findings

Wong et al.⁹³ reviewed 52 patients who underwent revision THA with the use of cortical strut grafts derived from the fibula. In this study 33 patients had graft plus a porous-coated femoral implant without cement; 5 with a press-fit stem; 7 with a cemented component; and 7 in association with a proximal femoral allograft. Mean follow-up was 4.8 years. From review of the radiographs there was evidence of graft resorption in 45 of the 47 hips, with a mean decrease in length of the cortical strut of 8%. However, there were two patients whose grafts resorbed by more than 50%. There were two cases of nonunion of the struts but neither of them had fractured, therefore there was a rate of union of 96% and the average time to union was 10 months.

The authors commented that the majority of resorption occurred at the ends of the grafts and appeared to be part of the remodeling process, except in the two patients whose grafts resorbed by more than 50%. Although average time

for the grafts to unite was 10 months, the process of incorporation would continue for up to 2 years. The HHS improved from a mean of 39.4 points to 65.6 points. The rate of a further revision was 12% at 10 years. Some of the stems subsided, but the cortical graft was not being used to support the implant and was not considered a causative factor.

Chandler et al.⁸⁴ reviewed 29 patients (30 hips) who had a mean follow-up of 22 months. All patients were revised with a long-stemmed modular prosthesis which was fixed with cement to the proximal femoral allograft and secured to the host femur distally with a press-fit uncemented stem. The mean HHS improved from 35 preoperatively to 78 points postoperatively. There were two nonunions and one hip that had evidence of graft resorption on radiographic review. Four hips (13%) needed an additional operation.

Head et al.⁹⁴ reported their results of 22 patients who had a revision hip arthroplasty with a proximal femoral allograft with a mean follow-up of 28 months. Ten patients had cement fixation of the implant to the graft as well as cementing of the implant distally to the host; in three patients the implant was secured to the host distally with cement and the allograft was not cemented proximally; and nine patients had no cement fixation either proximally or distally. Sixteen patients (73%) had a significant functional improvement based on the HHS (mean preoperative score of 29 points and mean postoperative score of 65), and four patients had a poor result. Two hips went on to develop a nonunion with a stable implant and one had a nonunion with partial resorption of the graft.

Roberson⁹⁵ reviewed 21 patients (24 hips) who had a revision hip arthroplasty with a structural femoral allograft after a failed total hip replacement with a mean follow-up of 4 years. Based on the HHS, 12 patients had a good or excellent result, 6 had a fair result and 2 had a poor result, and for 1 patient no data was available. There were two nonunions and five hips showed evidence of graft resorption.

Zmolek et al.⁷⁶ reviewed 11 patients with a mean follow-up of 4 years who had an uncemented revision THA with a proximal femoral allograft. Nine hips had evidence of a radiographic union at a mean of 13 months and two failed because of nonunion.

Masri et al.⁹⁶ reviewed 58 reconstructions with a proximal femoral allograft–prosthetic composite; 41 were available for follow-up with a mean duration of 4 years. The mean HHS was 83 points. Four patients (10%) had a nonunion of the graft–host junction and severe graft resorption was reported in 10 patients (24%). Five patients (12%) required revision of the allograft for a fracture, nonunion, infection, or resorption.

Gross et al.⁷ reviewed 168 hips that had been treated with a revision hip arthroplasty with a proximal femoral

allograft with mean follow-up of 4.8 years. Of the 132 patients who were available for follow-up, the mean HHS increased from a preoperative score of 30 to 66 points postoperatively. Only 17 hips required further surgery, 5 hips had a nonunion, and 6 hips showed evidence of resorption of the graft. A further review by Gross et al.,⁸¹ where 200 reconstructions were reviewed using a circumferential allograft that was more than 5cm long, 25 patients (13%) required a further revision procedure. Of these revision procedures, two failed again and required an excision arthroplasty. Nonunion was seen in seven hips and were all treated successfully with the use of a plate and autogenous bone grafting and leaving the allograft construct in situ. Graft resorption was identified in six hips and observed to occur on the periosteal side of the graft. It was never full thickness and was less than 1 cm long, except in one hip in which it was 4cm long. However, no revisions were indicated for graft resorption. Of the 130 patients, 111 (85%) had an increase of the HHS of 20 points, a stable implant, and no further operations related to the allograft at a mean follow-up of 4.8 years; they were deemed successful.⁷ A further study by Hutchison and Gross presented at the American Academy of Orthopedic Surgeons with a longer mean follow-up of 9 years reported a similar success rate (55 out of 65 hips).⁸¹

Blackley et al.⁹⁷ performed a comprehensive review of 60 revision total hip arthroplasties done by Dr. A.E. Gross that involved a proximal femoral allograft. These patients had a circumferential proximal femoral deficiency of more than 5cm in length and required a proximal femoral allograft of a minimum length of 10cm with a mean length of 15cm. The mean number of previous arthroplasties was 3.8, but one patient had had nine. At 9.3 years after surgery, 45 patients were available for follow-up. The mean HHS improved from 30 points preoperatively to 71 points at a mean follow-up of 11 years. Radiographically, four hips (6%) had a nonunion at the graft–host junction. Significant trochanteric escape of more than 1cm occurred in 14 hips (22%). Graft resorption was seen in 33% of the surviving patients who had more than 9 years of follow-up. The resorption occurred around the cerclage wires in 9 of the 13 hips, but no revisions were performed for graft resorption. Kaplan–Meier survival analysis estimated a survival rate of 90% at 5 years and 86% at 10 years.

Haddad et al.⁸ reviewed a consecutive series of 40 proximal femoral allografts with a mean follow-up of 8.8 years. In this study the stem was cemented into both the allograft and host femur in all patients. The mean HHS improved from 39 to 79. There were four cases of patients requiring further surgery, two for infection, one for nonunion of the graft–host junction, and one for allograft resorption which was noted at the time of revision of a failed acetabular component.

Graft resorption which was full thickness was seen in seven patients (17.5%) although none of these cases was associated with failure of the reconstructions.

Table 21.2 summarizes the results for structural allografts in revision hip surgery.

There remains some controversy regarding the use of structural allografts in revision hip arthroplasty. Nonetheless, they do present certain advantages. Allograft possesses a limited capacity to become incorporated into the host bone and also has the potential for soft tissues to attach to it. It provides a good interface for cementing, with the added advantage of not requiring cement fixation to the distal femur, and therefore should not compromise any revision in the future, if needed. Once the allograft incorporates into the host femur it potentially increases the surface area for distal fixation of the femoral implant and therefore reduces the risk of loosening. Although there is no exact consensus on the indications for a proximal femoral structural allograft, the majority would agree that the deficiency should be circumferential and of more than 5cm long with grade III bone loss according to the system described by the American Academy of Orthopaedic Surgeons.⁹⁸

Disadvantages include the fact that the construct itself is technically demanding and is expensive and difficult to obtain. It is a technique that is not without potential complications and requires careful follow-up to identify them early should they occur. The greatest concern to patients and surgeons alike is the risk of disease transmission, and this deters a number of patients from having the procedure. HIV and hepatitis virus are the agents that attract the greatest attention, but other viruses can also be implicated.^{99,100} This risk can be reduced by adhering to well-established standards of donor selection such as that provided by the American Association of Tissue Banks which reduce the risk of transmission of HIV to less than 1 in a million.^{101,102} Graft irradiation may reduce the risk further,⁷⁵ although it may also weaken the bone.¹⁰³ Other concerns include the risk of fracture, graft resorption and nonunion.

Recommendations

In patients requiring revision arthroplasty for loose femoral stems with considerable proximal bone loss, evidence suggests:

- In the short to medium term good results can be achieved with revision THA involving a proximal femoral allograft [overall quality: low to moderate]
- Although graft resorption is seen following revision THA with a proximal femoral allograft it is rarely an indication on its own for further surgery [overall quality: moderate]
- Nonunion is a significant problem following revision THA with a proximal femoral allograft leading to the

Table 21.2 Summary of the results of using a structural allograft in revision total hip arthroplasty

Author	No. of cases	Mean follow-up	Results
Wong ⁹³ (cortical strut allografts)	52 patients	4.8 years	Graft resorption in 45 of 47 hips. Nonunion in 2 cases (union rate 96% at a mean of 10 months). HHS improved from a mean of 39.4 preoperatively to 65.6 postoperatively. Risk of further revision of 12% at 10 years
Chandler ⁹⁴	29 patients (30 hips)	22 months	HHS improved from 35 preoperatively to 78 postoperatively. 2 nonunions, 1 case of graft resorption, and 13% required further surgery
Head ⁹⁴	22 patients	28 months	73% had a significant functional improvement. HHS improved from 26 preoperatively to 65 postoperatively. 4 patients had a poor result. 2 hips had a nonunion but with a stable implant. 1 hip had a nonunion with graft resorption
Roberson ⁹⁵	21 patients (24 hips)	4 years	12 good/excellent results based on the HHS, 6 fair and 2 poor. 2 cases where the graft failed to unite and 5 where the graft appeared to resorb radiographically
Zmolek ⁷⁶	11 patients	4 years	9 hips showed radiographic evidence of union at 13 months. 2 cases of failure due to nonunion
Masri ⁹⁶	41 hips available for follow-up	4 years	Postoperative HHS of 83. 4 (10%) hips showed evidence of nonunion, 10 (24%) showed evidence of severe graft resorption. 5 (12%) patients required revision of the allograft for either fracture, nonunion, infection, or resorption
Openmirrors.com			
Gross ⁷	132 hips available for follow-up	4.8 years	HHS improved from 30 preoperatively to 66 postoperatively. 17 hips required further surgery. 5 cases of nonunion and 6 of graft resorption
Gross ⁸¹	200 hips	4.8 years	25 (13%) patients required an additional revision procedure. 7 cases of nonunion and 6 of graft resorption. Of the 130 patients available for follow-up, 111 (85%) had an increase in the HHS postoperatively of 20 points, a stable implant, and did not require any further surgery
Blackley ⁹⁷	45 hips available for follow-up	11 years	HHS improved from a preoperative score of 30 to a postoperative score of 71. 4 cases (6%) of nonunion and 13 (33%) of graft resorption. 90% survival rate at 5 years and 86% at 10 years
Haddad ⁸	40 patients	8.8 years	HHS improved from a preoperative score of 39 to a postoperative score of 79. 4 cases requiring further surgery and 7 (17.5%) cases of severe graft resorption, although not associated with failure

HHS, Harris hip score.

failure of the construct in the medium to long term [overall quality: moderate]

Question 8: What are the complications of impaction allografting for revision of a femoral component in THA?

Impaction grafting is a technically demanding procedure as reflected by the early results of the technique and the incidence of reported complications. The majority of failures following impaction allografting have been due to periprosthetic fractures^{38,41,42} requiring further surgery. The reported prevalence of fractures ranges from 5% to 24%.^{27,38,41,42,60,63,65} Not surprisingly, those patients with the greatest proximal bone loss were associated with the higher rates of fracture.^{38,42,63} Intraoperative fractures tend to occur during impaction of the allograft,⁴² which can be partially avoided by adequate exposure, prophylactic cerclage fixation, and augmentation of the femoral shaft with cortical strut grafts.^{42,65} Intraoperative perforation of the shaft usually occurs during cement removal and has been reported in up to 10% of cases of impaction allografting.²⁷ The key is to recognize this complication when it happens and augment with a cortical strut graft.¹⁰⁴ Postoperative fractures may be due to an unrecognized intraoperative fracture or perforation, or can occur through areas of osteolysis which have not been adequately addressed. In the first year after surgery Ornstein et al.²⁷ reported that 6% of their patients sustained a diaphyseal fracture. Fractures, whether they occur intra- or postoperatively, are associated with failure of the construct^{41,42} and invariably lead to further surgery.^{38,41,42,65}

Component subsidence of more than 1mm has been reported to be as high as 79% (44 out of 56 hips) following impaction allografting with a polished, tapered stem.⁶³ In the same study, subsidence at the interface between the graft–cement composite and host bone was 20% (11 out of 56 hips) and in 11% of patients (6 out of 56 hips) continued for more than 2 years.

Initially, subsidence of the implant was thought to be desirable. Gie et al.⁴¹ suggested that the wedge-shaped stem facilitated the incorporation of the allograft by the compression it produced as it subsided. However, significant subsidence may be undesirable because it may imply mechanical failure of allograft–cement composite, and ultimate failure of the reconstruction. This has been supported by other studies on polished, tapered, cemented stems.^{65,105} The implication of subsidence on the clinical result may be related to the type of femoral implant used. Subsidence of cemented implants that have a coating or roughened surface suggests aseptic loosening of the stem.^{66,67,106} The difficulty with polished stems is defining when a subsiding stem is loose. Gie et al.⁴¹ suggested that the implant can subside at either the stem–cement interface or the cement/

graft–host bone interface, with evidence of radiolucent lines, and still not necessarily be loose. Elting et al.⁶⁵ reported that almost 50% of the stems subsided at the implant–stem interface with nearly 20% demonstrating substantial subsidence of more than 2mm. With polished stems any subsidence that occurs is thought to allow the wedge-shaped stem to “self-tighten” because of the cold flow of the cement.^{41,65,105} However, Masterson et al.³⁸ observed that there was a high prevalence of early cement fractures around stems that had subsided, which suggests some limitations to the cold flow theory. This observation has been further supported from data provided by a study using radiostereometric analysis.¹⁰⁷ Other associations with stem subsidence have been thigh pain,³¹ particularly in those with subsidence of more than 10mm, and dislocation.³⁸ The implications of stem subsidence are still not fully known and further studies are needed to clarify its role in impaction allografting.

General complications such as dislocation have been reported of between 3%⁶⁵ and 6%,^{27,38} with similar infection rates. Other reported complications have included trochanteric bursitis related to prominent metalwork⁶³ as well as heterotopic ossification.^{41,42,63,65} Whether the presence of morselized allograft increases the risk of heterotopic ossification compared with other reconstructive techniques is not known, as no comparison studies have been performed to date. In those patients who have had an osteotomy of the greater trochanter there has been a high incidence of nonunion with reports of between 33%⁶³ and 50%;⁴² this could be because of the poor proximal bone stock or because of the presence of cement at the osteotomy site preventing union.

Among the complications encountered following impaction allografting, intraoperative fractures are responsible for the majority of failures of this technique and can be partially avoided by augmenting the porotic femoral shaft with a cortical strut graft.

Question 9: What are the complications of using a structural bulk allograft for revision of a femoral component in THA?

The most commonly reported complications associated with the use of structural allografts in femoral revision after a failed THA are infection, instability, nonunion and fracture.

The prevalence of infection following a revision arthroplasty performed with the use of a structural allograft has been reported to be between 4% and 13%.^{48,81,97,108–110} The duration of the procedure, soft tissue dissection, contamination of the graft, and blood loss have all been associated with increased risk of infection.^{79,110,111} Great care must be taken in preparation of the graft, and prophylactic antibiotics should be given both systemi-

cally and in the bone cement used to secure the graft.⁷⁷ Should the construct get infected then a standard two-stage procedure with reimplantation of a fresh allograft can be used.^{7,108}

The rate of dislocation has been reported to be as high as 6% in some series.⁹⁷ Certainly, the risk of dislocation is higher if the femoral component alone is revised,⁷ although we would not suggest revising a well-fixed acetabular component unless it is malpositioned. Undoubtedly, a significant proportion of the instability following reconstruction of the proximal femur with allograft is due to the lack of soft tissue stabilization.

The rate of nonunion has been reported between 4%⁷ and 23%.¹¹² As pointed out earlier, a considerable number of these nonunions are related to the interposition of cement at the graft–host junction.⁸⁴ Additionally, insertion of cement into the distal host femur may distract the graft–host junction and affect bony union.¹¹³ This problem can be successfully addressed with autogenous bone grafting and the use of a plate.^{48,81} Trochanteric nonunion is only a problem should the trochanter escape and result in defunctioning of the abductors. Nonunion of the trochanter is common because of the fact that it is under distraction as opposed to compression, and also the blood supply to the junction of the trochanter and the graft comes from the trochanter alone. This problem can be avoided by performing a trochanteric slide rather than a transverse trochanteric osteotomy.

Fractures tend to occur between 2 and 3 years following reconstruction with a structural allograft.^{81,112,114} This could be because the graft has fatigued after it has failed to unite to the host, or because of a stress riser such as a screw hole, or due to excessive reaming of the graft.

Graft resorption has also been a problem following reconstruction with a structural allograft, with some reports of up to 34%.⁹⁶ It is not clear whether this resorption is due to an immune phenomenon, the way the allograft is processed, or the bone cement. Others have concluded that the resorption is related to a local vascular phenomenon caused by the cerclage wires.¹⁰⁸

In summary, infection and nonunion are responsible for the majority of complications following reconstruction with a proximal femoral allograft. Careful attention to surgical technique should help keep these complications to a minimum.

Question 10: What is the current state of the popularity of these techniques? Are there better alternatives?

Morselized allograft bone has many potential advantages, including the avoidance of morbidity associated with harvesting autogenous bone graft. However, the disadvantages include the immune response that is initiated by

the host, the lack of osteogenic cells, decreased osteoinductive factors, and the risk of infection. Furthermore, the use of structural allografts in revision hip arthroplasty remains controversial since, although early results have been successful, the long-term results have been inconsistent.

An alternative to morselized allograft bone includes demineralized bone matrix (DBM) which is made by acid extraction of the mineralized phase of bone. The product of this process is composed of noncollagenous proteins and growth factors as well as collagen.¹¹⁵ In animal studies DBM was thought to be capable of inducing osteogenesis by recruiting mesenchymal stem cells from the host tissues,^{116–118} although more recent reports have suggested that DBMs have excellent osteoconductive potential but limited osteoinductive capacity.^{119,120} However, adding bone marrow to DBM does seem to increase its osteogenic potential in certain clinical situations such as the grafting of contained bony defects.

Other alternatives to morselized allografts include ceramics. Ceramics provide an osteoconductive matrix usually consisting of hydroxyapatite, tricalcium phosphate, or calcium sulfate.¹²¹ However, these ceramics have minimal tensile strength and so the surrounding bone must be stable or the defect must be contained for it to be successfully used. Although a number of ceramics are approved for the use in filling non-weight-bearing areas in hip revision,¹²² the efficacy of these materials in this clinical scenario are not known.

Growth factors, specifically the BMPs and recombinant BMPs may be used in revision hip surgery to treat cavitary defects or as an adjunct in encouraging the healing and incorporation of allografts. In a canine model, osteogenic protein 1 (OP-1) combined with bovine type 1 collagen significantly improved the healing and incorporation of a cortical onlay strut allograft based on radiographic and histologic evidence.¹²³ However, this model does not accurately reproduce the clinical situation found in revision THA. Early results using OP-1 in revision THA in conjunction with a proximal femoral allograft, bulk femoral head allograft, cortical strut allograft, or morselized allograft have shown that new bone formed earlier and graft incorporation was more rapid than would be expected without OP-1.¹²⁴

Other potential adjuncts in revision hip surgery include the use of autologous cells as bone graft substitutes, as well as gene therapy and tissue engineering, but further research is needed to assess their contribution in this field.

Current alternatives to reconstruction of the proximal femur using either impaction allografting or a proximal femoral structural allograft have been the use of an uncemented stem which is designed to gain fixation in the distal femur. The most popular methods at present of uncemented fixation in the diaphysis is by an extensively porous-coated stem or a fluted, tapered, grit-blasted stem.

Uncemented, extensively porous-coated stems have been considered the gold standard of uncemented revision femoral stems in North America for some years¹²⁵⁻¹³⁷ and, although it has been successful in the revision setting,^{126,136,137} stress shielding remains a concern because of the relative stiffness of the implant. An alternative method of uncemented diaphyseal stem fixation is the use of a modular, fluted, tapered, grit-blasted stem. These stems are able to gain axial and rotational stability in the diaphysis of the femur by their tapered design. The distal part of the implant, which is cone shaped, is wedged into the diaphysis to achieve primary stability. Limiting the contact zone between the implant and bone helps to reduce the stiffness of the construct. Stems with flutes enable the use of a less stiff implant and as a result will reduce the stress shielding seen with the fully porous-coated cylindrical implants. Additionally, using a modular stem allows the surgeon to implant the distal part of the stem in the diaphysis, ensuring a good wedge fit, with a number of options available for the proximal part that optimize leg length, femoral offset, femoral version, and stability. Good results have been reported with this implant design. McInnis et al.¹³⁸ retrospectively reviewed 70 patients with a mean follow-up of 47 months. Combined metaphyseal/diaphyseal bone loss was observed preoperatively in 36 (51%) of 70 hips. At the final review, restoration of the proximal bone was noted in 56% of patients. Park et al.¹³⁹ reviewed 62 patients who underwent a revision THA with a fluted, tapered, modular femoral stem. The mean HHS was 87.3 points postoperatively with a mean follow-up of 4.2 years. Similar results have been reported by other authors with survivorship of up to 97% at 9 years.^{140,141}

A disadvantage of the modular, tapered, fluted stem design in the elderly patient is that normally patients are required to undergo a period of toe-touch weightbearing because of the poor cortical bone stock that is prevalent in this patient population. In some patients toe-touch weightbearing is an unrealistic aim, and so the substitution of the proximal femur with a modular oncology prosthesis may be more appropriate and will enable the patient to fully weightbear from day 1 postoperatively.

Summary of recommendations

- Impaction allografting is not for the inexperienced surgeon
- Excellent preliminary results for impaction grafting in femurs without endosteal bone lysis associated or large cortical diaphyseal defects can be achieved
- There is a significant risk of intraoperative fracture with impaction allografting
- Subsidence of the femoral implant is a concern with impaction allografting

- The risk of postoperative fracture continues for months after the reconstruction
- In the short to medium term good results can be achieved with revision THA involving a proximal femoral allograft
- Nonunion is a significant problem following revision THA with a proximal femoral allograft leading to the failure of the construct in the medium to long term
- Although graft resorption is seen following revision THA with a proximal femoral allograft it is rarely an indication on its own for further surgery

Conclusions

Both impaction allografting and reconstruction of the proximal femur with a bulk structural allograft in revision hip surgery are technically demanding procedures. The current literature suggests that these techniques are best performed in specialist centers. However, newer implants such as the tapered, modular, fluted stem are showing encouraging preliminary results and may have a considerable contribution to make in the treatment of this challenging patient group.

Revision of the Acetabular Components: Role of Structural Bulk Allografts and Porous Tantalum Implants

John Antoniou, Alan J. Walsh, and Vassilios S. Nikolaou

McGill University, Montreal, QC, Canada

Case scenario

A 41 year old man presented with a 2 year history of progressive left groin pain on weightbearing. He had a total hip arthroplasty (THA) performed 15 years ago for osteoarthritis of his left hip secondary to a displaced fracture of the acetabular dome. Clinical examination of the left hip showed restricted motion and antalgia, but good abductor muscle function.

Relevant anatomy

The three-dimensional anatomy of the acetabulum is difficult to interpret from plain radiographs alone. CT can help define the topography of missing bone. The landmarks of the bony acetabulum relevant to the classification of bony defects prior to revision acetabular reconstruction are shown on a pelvic radiograph (Figure 22.1).

Importance of the problem

THA is one of the most widespread and successful surgical procedures performed worldwide. In the United States, over 168,000 primary and 30,000 revision hip arthroplasties are performed every year.¹ The rate of primary THA has recently increased and the number of revisions could more than double by 2030.² Nordic arthroplasty registers have reported failure of 7% of primary prostheses within 10 years.³ Expanded indications for THA in younger patients and improved lifespans of all THA patients will lead to even more revision surgery. The acetabulum with significant bone loss is a major surgical challenge and there is debate concerning the surgical techniques most appropriate for such revisions. Surgical decision-making preopera-

tively is key to the longevity and re-revisability of revision hip arthroplasties.

Top three questions

1. Which classification systems quantify acetabular bone deficiency prior to revision hip arthroplasty?
2. What options has the orthopedic surgeon for reconstruction of acetabular bone loss?
3. What is the role of porous tantalum implants in revision acetabular arthroplasty?

Question 1: Which classification systems quantify acetabular bone deficiency prior to revision hip arthroplasty?

Case clarification

An AP view of both hips of our patient (Figure 22.2) and a lateral view of the left hip (Figure 22.3) are shown after a first-stage revision THA performed elsewhere for infection. A second-stage procedure was planned after a period of appropriate antibiotic therapy and normalization of inflammatory markers.

Relevance

Classification of the defect preoperatively is important to quantify the deficiency of acetabular bone stock. This facilitates surgical planning and highlights requirements for bone graft or particular reconstructive hardware.

Current opinion

The three classification systems for acetabular bone loss commonly used are those of D'Antoniou,⁴ recommended by the American Academy of Orthopaedic Surgeons (AAOS), Paprosky et al.⁵ and Gross et al.⁶

Figure 22.1 AP radiograph of a patient with bilateral cemented total hip arthroplasties showing cup loosening on the right side and a high hip center with a healed bulk femoral head allograft on the left side. The four main anatomic landmarks relevant to the Paprosky classification of acetabular bone loss are indicated (superior transverse obturator line, ilioischial line, teardrop, typical zone of ischial lysis).

Figure 22.3 Lateral radiograph of the left hip of the clinical case showing a fractured cement spacer in situ after a first-stage revision left total hip arthroplasty.

Figure 22.2 AP radiograph of both hips of the clinical case showing a fractured cement spacer in situ after a first-stage revision left total hip arthroplasty.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/)—sensitivity search using keywords “bone loss” AND “acetabulum” AND “classification”

Quality of the evidence

- Level II: 1
- Level V: 3

Table 22.1 AAOS classification

Type	Description of deficiency
IA	Segmental (peripheral)
IB	Segmental (central)
II	Cavitary
III	Combined
IV	Pelvic discontinuity
V	Arthrodesis

Findings

The AAOS classification (Table 22.1) of D’Antoniou⁴ is a descriptive classification. Cavitary defects are contained, whereas segmental defects involve the acetabular rim or columns. Pelvic discontinuity occurs when there is deficiency of both the acetabular columns.

The Paprosky classification⁵ uses anatomical landmarks to classify the extent of bony deficiency (Table 22.2) and guides reconstruction based on available techniques. Defects can be graded as completely (type 1), partially (type 2), or non (type 3) supportive. Superior cup migration implies damage to the superior dome whereas medial migration implies medial wall deficiency. Lysis involving the teardrop or ischium represents damage to the anterior and posterior acetabular columns respectively. Gross et al.⁶ devised a classification based on the type of bone graft

Table 22.2 Paprosky classification

Type of defect	Superior migration of hip center ^a	Medial migration of hip center ^b	Osteolysis of teardrop ^c	Osteolysis of ischium ^d
I	Minimum	None	None	None
2A	Minimum	Grade I	Mild	Mild
2B	Minimum to Marked	Grade II	Mild	Mild
2C	Minimum	Grade III	Moderate or Severe	Mild
3A	Marked	Grade II+ or III	Moderate	Moderate
3B	Marked	Grade III+	Severe	Severe

^aMinimum is ≤3 cm proximal to the superior transverse obturator line, and marked is >3 cm proximal to the superior transverse obturator line.

^bGrade I, lateral to Kohler's ilioischial line; grade II, to Kohler's line; grade II+, medial expansion of Kohler's line into the pelvis; grade III, violation of Kohler's line with some migration into the pelvis; grade III+, marked migration into the pelvis.

^cMild, minimum loss of the lateral border; moderate, complete loss of the lateral border; severe, loss of the lateral and medial borders.

^dMild, 0–7 mm distal to the superior transverse obturator line; moderate, 8–14 mm distal to the obturator line; severe, ≥15 mm distal to the obturator line.

Table 22.3 Gross classification

Type	Description of deficiency
I	Contained defect with intact rim and columns
IIA	Noncontained defect—minor column (>50% of host acetabulum in contact with cup)
IIB	Noncontained defect—major column (<50% of host acetabulum in contact with cup)

required for revision (Table 22.3). Campbell et al.⁷ have critically evaluated the reliability of these three classification systems, showing inconsistency in both interobserver and intraobserver reliability.

Recommendation

- These classifications show limited reliability and should be considered a general guide to discern between simple and complex reconstructive scenarios [overall quality: low]

Question 2: What options has the orthopedic surgeon for reconstruction of acetabular bone loss?

Case clarification

The patient required reconstruction of his acetabular deficiency. After classification of preoperative bone loss, a

decision was made on the appropriate reconstructive technique.

Relevance

There is no consensus regarding the optimal method of reconstruction in cases of revision hip arthroplasty with severe bone loss. The major decisions regarding surgical technique for complex acetabular revision concern the use of bone graft, cages and cemented vs. cementless components. The plethora of potential combinations of grafts and metallic devices has lead to a huge diversity of reconstructive options in revision acetabular arthroplasty. This creates significant difficulty for systematic analysis of clinical literature incorporating a very heterogenous mix of surgical techniques.

Current opinion

Acetabular bone loss can be compensated by placing a high hip center or by using asymmetrical or bilobed acetabular components. Cementless hemispherical cups provide durable survivorship in the revision setting if initial stability and contact with sufficient host bone is possible. Cemented fixation of a polyethylene cup or liner into a supporting cage has often been the construct of choice where allograft is required to support more than 50% of the new acetabular component. Supplementary acetabular fixation may be necessary to stabilize pelvic discontinuity and protect or support bone graft and/or cups. Trabecular metal shells can be used for severe acetabular defects where bone grafting has traditionally performed poorly.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "treatment options revision hip" AND "revision hip acetabulum"

Quality of the evidence

- Level III: 2
- Level IV: 28
- Level V: 8

Findings

Contained or cavitary defects (Paprosky types 1 and 2, Gross type I) can be treated with impacted morsellized cancellous allograft bone chips. Satisfactory outcomes have been reported using cementless porous hemispherical acetabular components for these defects.^{8–10} Noncontained, segmental defects are subdivided into those where host bone support for the implant is more than 50% (Paprosky 3A, Gross IIA) or less than 50% (Paprosky 3B, Gross IIB). Radiologically these defects produce significant superolateral and superomedial cup migration respectively. Sporer et al.¹¹ achieved 78% 10 year survival with cementless acetabular components

supported by distal femoral structural bulk allograft buttress for 3A defects. Others have shown either good medium-term survival with bulk grafts¹²⁻¹⁴ or frequent loosening with graft resorption.^{15,16} Options for 3B defects include placing the component high on remaining host bone, implanting a large cementless acetabular component, using structural bone graft or replacing lost bone with massive partial or total acetabular allograft, protected with an antiprotrusion cage, containing a cemented liner. Reconstructing the acetabulum with a high hip center has been associated with early loosening,¹⁷ although 94% survival at 10.4 years is reported.¹⁸ Treatment of type 3B defects with cemented polyethylene cups and large allografts alone has produced poor results.^{19,20} The use of reconstruction cages improves their survival despite implantation difficulties and low potential for biological bone ingrowth.²¹ Use of porous tantalum acetabular shells, cups, and augmentations can address these difficulties.²²⁻³⁶ Brubaker et al.³⁷ proposed specific interventions for different grades of acetabular defect based on a modification of the classification of Gross et al.,⁶ validated by Saleh et al.³⁸ They calculated a prognosis for each intervention based on the available literature (Table 22.4). Kosashvili et al.³² reported good short term outcomes with the “component-cage technique,” combining ilioischial cages with trabecular metal shells for pelvic discontinuity.

Recommendation

- There are no trials in the clinical literature to differentiate between treatment modalities for each grade of acetabular bone loss in revision hip arthroplasty. Evidence for different surgical techniques is limited to comparison of case series and expert reviews [overall quality: low]

Table 22.4 Modified Gross classification

Defect type	Bone loss	Treatment	Survival (min 5 years)
I	None	Primary component	As for primary THA
II	Contained	Morcelized allograft ± roof ring	84–95%
III	Segmental <50%	Minor column structural allograft + cage, or bilobed cup, or tantalum component	76–94%
IV	Segmental >50%	Major column or acetabular structural allograft with cage, or custom implant	77–100%
V	Discontinuity	As for type IV + fixation of discontinuity	As for type IV

Question 3: What is the role of porous tantalum implants in revision acetabular arthroplasty?

Case clarification

A large porous tantalum trabecular metal acetabular implant with supplementary screw fixation was chosen for reconstruction (Figure 22.4). Allograft reconstruction of the acetabulum was avoided in this patient to reduce the risk of recurrent infection.

Relevance

The advent³⁹ and validation⁴⁰ of porous tantalum trabecular metal shells signalled a new era in the management of severe acetabular defects. Tantalum is more porous, less stiff, and creates more friction with bone than conventional porous-coated acetabular implants.

Current opinion

Porous tantalum acetabular implants represent an improvement from conventional porous materials by achieving increased bone ingrowth and enhanced interface fixation strength for acetabular revision surgery with severe bone loss.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “porous” AND “tantalum” AND “hip arthroplasty” as well as “trabecular metal” AND “hip arthroplasty”

Figure 22.4 AP radiograph of both hips of the clinical case showing a trabecular metal shell in situ after a second-stage revision left total hip arthroplasty.

Quality of the evidence

- Level III: 4
- Level IV: 16
- Level V: 8

Findings

Conventional porous-coated acetabular implants have proven effective in revision THA where bone stock is sufficient for stability and ingrowth and success with these implants occurs when contact with host bone is greater than 50%.⁸⁻¹⁰ Antiprotrusio cages are recommended for host support less than 50%, but implantation is problematic and biological bone ingrowth is not possible.^{21,41} Porous tantalum acetabular cups may provide a solution.²²⁻³⁶ The porosity of materials commonly used to manufacture acetabular shells approximates 30–50% of their volume. Porous tantalum exhibits almost double this porosity (80%) for bone-metal interdigitation.⁴² Porous tantalum implants display high surface frictional characteristics and good osseointegration properties.⁴²⁻⁴⁴ Trabecular metal revision shells are made completely of porous tantalum and have perforations for screw fixation. These shells can be positioned for maximal bone contact using a polyethylene liner locked within or cemented at the required orientation.^{24,35,45} When less than 50% host bone is available to support the shell, tantalum augments are used to help fill the defect. A thin layer of cement between the shell and each augment minimizes metal fretting.⁴⁵ For pelvic discontinuity, tantalum cup and reconstruction cage constructs can be used. The cage is positioned over the cup, bridging the acetabular defect, and a polyethylene liner is cemented into the cage.^{22,45,46} Trabecular metal constructs have been used effectively for severe acetabular defects. The published results to date^{24-26,29-32,34-36,46-48} are presented in Table 22.5.

Year	Author	Number of Patients	Mean Follow-up (Years)	Survival (%)
2005	Unger	59	3.5	88
2006	Sporer	13	2.6	100
2007	Boscainos	14	2.5	100
2007	Weeden	43	2.8	100
2008	Flecher	23	2.9	100
2008	Kim	46	3.3	98
2009	Fernandez-Fairen	263	6.1	100
2009	Kosashvilli	26	3.7	88.5
2009	Lakstein	53	3.8	96
2009	Malkani	22	3.3	100
2009	Siegmeth	34	2.8	94
2009	Van Kleunen	97	3.8	100

Recommendation

- Porous tantalum trabecular metal shells have good survival statistics for reconstruction of severe acetabular defects in case series with short- to medium-term review [overall quality: low]

Summary of recommendations

- Classification systems for acetabular bone loss show limited reliability and should be considered a general guide to discern between simple and complex reconstructive scenarios
- There are no trials in the clinical literature to differentiate between treatment modalities for each grade of acetabular bone loss in revision hip arthroplasty. Evidence for different surgical techniques is limited to comparison of case series and expert reviews
- Porous tantalum trabecular metal shells have good survival statistics for reconstruction of severe acetabular defects in case series with short- to medium-term review

Conclusions

Revision THA where complex reconstruction of deficient acetabular bone stock is necessary provides challenges to both patients and their orthopedic surgeons.

The classification systems for acetabular bone loss vary in their description and relevance to treatment options. Most authors agree that defects where less than 50% coverage of the revision acetabular cup by remaining host bone is possible provide a much greater challenge to successful reconstruction.

There is as yet no universal agreement on which reconstructive techniques to use for each grade of periprosthetic acetabular bone deficiency. A lack of high-level evidence exists in the scientific literature to discern between different techniques.

Cavitary defects can be successfully managed with either cemented or cementless components, with or without morsellized allograft, with results approximating those of primary surgery. Segmental and mixed defects can be treated with various combinations of morsellized or structural allograft, metallic reinforcement devices and cemented or cementless components, but results for many of these constructs have been unsatisfactory.

The use of porous tantalum trabecular metal components for severe defects shows encouraging short- to medium-term results, but cannot restore bone stock for future revisions.

Clinical trials, to identify the ideal allograft, reinforcement device, and acetabular component combination may be necessary to maximize survival of revision hip

arthroplasty while preserving adequate bone stock for future revision surgeries in younger patients.

Acknowledgement

The authors wish to thank Dr. David Zukor for his contribution to the clinical case.

Antibiotic Cement in Total Knee Arthroplasty

Philip A. O'Connor and Steven J. MacDonald

University of Western Ontario and University Hospital, London, ON, Canada

Case scenarios

Case 1

A 49 year old woman with tricompartmental osteoarthritis undergoes a primary total knee arthroplasty (TKA).

Case 2

A 75 year old man, with a history of type 2 diabetes mellitus, undergoes a revision of an infected TKA.

Top six questions

Therapy

1. What are the benefits of routine use of antibiotic-loaded bone cement in primary TKA?
2. Is the routine use of antibiotic-loaded bone cement in primary TKA cost-effective?
3. What is the role of antibiotic-loaded bone cement in the treatment of established prosthetic knee infection?

Prognosis

4. Does the use of antibiotic-loaded bone cement in primary TKA lead to earlier mechanical failure rates?

Harm

5. Can the routine use of antibiotic-loaded bone cement lead to the development of resistant organisms in TKA?
6. Is there a risk of developing systemic toxicity or an allergic reaction with the use of antibiotic-loaded bone cement in TKA?

Question 1: What are the benefits of the routine use of antibiotic-loaded bone cement in primary TKA?

Case clarification

Antibiotic laden bone cement (ALBC) has two distinct roles in TKA. It can be used as a prophylactic measure or as treatment modality for established implant-related infection. Dosages of combined antibiotics can be arbitrarily divided into *low* (<2g antibiotic per 40g acrylic cement) and *high* (>2g per 40g acrylic cement). It is the use of low-dose ALBC for supplemental prophylaxis in TKA that remains controversial.

Relevance

The use of systemic perioperative prophylactic antibiotics is well-accepted practice but deep infection rates persist and on average occur in 2% of cases with osteoarthritis and in 4% of patients with rheumatoid arthritis.¹

Current opinion

Current opinion is divided on this subject. There are significant geographic differences. In North America, the majority of primary TKAs use acrylic bone cement that does not contain antibiotics. In Europe, ALBC is commonly employed for primary TKAs.

Finding the evidence

- Cochrane Database: no reviews on this topic were identified.
- PubMed, using the following search terms: “antibiotic cement primary knee arthroplasty,” “antibiotic laden bone cement”
- Manual review of cited references from identified articles

Quality of the evidence

We found 37 articles, 3 of which were review articles.²⁻⁴

Level I

- 3 randomized trials⁵⁻⁷

Level II

- 1 systemic review of cohort studies⁸
- 4 individual cohort studies⁹⁻¹²

Findings

The advantage of using ALBC is a reduction of perioperative infections following TKA. With an already low rate of deep periprosthetic infection, most studies are underpowered to demonstrate efficacy in the use of ALBC. It is estimated that 8,800 patients would have to be entered into a randomized controlled trial (RCT) to detect a significant effect. To date only three RCTs have been identified that have reported on the prophylactic use of ALBC in arthroplasty.⁵⁻⁷

McQueen⁶ reported on a prospective randomized trial of 295 arthroplasties (both hip and knee). Patients were randomized to receive cefuroxime either in bone cement or parenterally. No statistically significant difference in the rate of superficial or deep infection between the groups was observed. Follow-up was for 3 months only and the method of randomization was not made clear. A follow-up report¹³ of 401 patients confirmed their earlier results.

Josefsson performed a prospective RCT, again comparing systemic antibiotic administration with ALBC (containing gentamicin) in 1688 consecutive total hip arthroplasties (THAs). Three separate reports at follow-up intervals of 2, 5, and 10 years were published.^{7,14,15} This was a multicenter trial, with different regimes of parental antibiotic administered and compared against ALBC with gentamicin. At intervals of 2 and 5 years postoperatively, a statistically significant difference was observed in favour of the use of ALBC. However, no difference was detected at follow-up

after 10 years postoperatively. Reclassification of cases had ensued at the latest follow-up.

Chiu et al.⁵ performed an RCT of 340 primary TKAs on the use of ALBC against plain bone cement (PBC). There was a statistically significant reduction ($p = 0.02$) in the rate of deep infection in ALBC group (0 out of 162) vs. PBC (5 out of 162). In a further trial the same authors¹⁶ examined the role of antibiotic-impregnated cement in the prevention of deep infection at primary TKA in a cohort of diabetic patients undergoing TKA. In this study 41 TKAs were randomized to receive ALBC (with cefuroxime) vs. 31 TKAs with PBC. There was a statistically significant difference between the two groups, with five cases of deep infection occurring in the PBC group (5/37) and none in the ALBC group (0/41).

The strongest evidence for the use of ALBC comes from large registries; the Scandinavian countries have the longest history of data collection. In a study from the Finnish Arthroplasty Register, Jämsen¹² reports on all primary and revision knee arthroplasties that were performed from January 1997 to June 2004. The minimum duration of follow-up was 6 months. The data of the study related to 43,149 operations, of which 40,135 were primary TKAs, 2166 were revision TKAs and 848 were partial revision arthroplasties. Antibiotic-impregnated cement was used for the fixation of at least one prosthetic component in 84% of the knees. The combination of parenteral antibiotic prophylaxis and prosthetic fixation with antibiotic-impregnated cement was found to protect against septic failure. Specifically, the risk of periprosthetic infection following a primary TKA was 0.68% when antibiotics were used both in the cement and intravenously, 0.81% when used in the cement only, and 1.05% when used intravenously only.

Epehaung et al.⁹ published data from the Norwegian arthroplasty registry on 10,905 primary THAs. The infected revision rate of patients who had combined prophylaxis with systemically administered antibiotics and the use of ALBC had the lowest revision rate when compared with the use of either prophylactic regimen in isolation (systemically administered antibiotics alone 4.3 times higher, ALBC alone 6.4 times higher). The authors also report that the use of ALBC resulted in reduced rate of aseptic loosening. The conclusion was that some of these cases represent subclinical infections and that the use of ALBC leads to a reduction in the incidence of these cases.

In a report on the Swedish register of 120,000 arthroplasty cases, Persson et al.¹⁰ documents a deep wound infection rate of 0.44% (72/16,400) with the use of systemic antibiotics and a reduction to 0.23% (18/7,674) when combined with ALBC. All cases were performed in an ultra-clean environment.

In contrast, Namba et al. analyzed a community-based total joint registry in the United States.¹¹ They found that ALBC was used in 8.9% of 22,889 primary TKAs. The rate

of deep infection was found to be statistically higher with the use of ALBC. In their analysis, diabetes (2,449 cases) and operative time were not found to be factors associated with the development of infection.

Recommendation

- The use of ALBC decreases the rate of deep infection following TKA [overall quality: moderate]

Question 2: Is the routine use of ALBC in primary TKA cost-effective?

Case clarification

The question related to the use of low-dose ALBC as supplemental prophylaxis against infection for the patient in Case 1.

Relevance

TKA is a cost-effective and successful solution to gonarthrosis.¹⁷ Infection is a devastating event and associated with poorer outcomes.

Current opinion

Opinion is divided on the subject. The unavailability of commercially premixed ALBC in North America resulted in surgeons hand-mixing antibiotics into bone cement at the time of surgery. In May 2003 the US Food and Drug Administration (FDA) approved the use of commercially premixed ALBC but only for reimplantation as part of a staged arthroplasty for the treatment of implant-related sepsis. Off-label use in primary arthroplasty is increasing. A survey of 1,015 orthopedic surgeons in the United States revealed that 56% use ALBC for at least some cases. Surgeons specializing in joint reconstruction were more likely to use antibiotic in bone cement (88%),¹⁸ and 13% always used ALBC in primary joint arthroplasty. Historically, the majority of THAs in North America have not involved the use of bone cement, but it is estimated that cemented components are used in 85% of all TKAs performed in the US.¹⁹ Some advocate the use of ALBC only in high-risk patients.⁴

Finding the evidence

- PubMed, using search terms: "cost effectiveness arthroplasty bone cement antibiotic" with limits: "Humans," "All Adults: 19 + years," and "English language"

Quality of the evidence

Level II

- 2 studies^{10,20}

Findings

Cummins²⁰ performed an economic modelling analysis of the cost-effectiveness of using antibiotic-impregnated bone

cement in THA. Data from published cohorts, the National Inpatient Survey, and local purchase costs were entered into a computerized decision tree model to tabulate costs and quality-adjusted life years (QALYs) accumulated per patient. All cost were in US dollars and based on 2002 values. The estimated cost differential per case for ALBC vs. PBC was \$600 per primary THA. The cost assigned to a revision due to infection was \$96,166. The model was strongly influenced by the average age of the patients and by the cost of bone cement. Older patients undergoing revision due to infection have reduced cost efficiency based on calculated QALYs. The analysis concluded that the use of ALBC is cost-effective until the average age of patients exceeds 71 years.

Proponents of the use of ALBC cite a reduction in the rate of infection as a direct result of their usage. The higher cost (US\$284–\$349²¹) is accepted to offset the cost of treating an infected arthroplasty. Jiranek has proposed that a reduction of the rates of infection from 1.5% to 0.3% would need to be achieved in order to offset the extra cost incurred by the routine use of ALBC.

Effective treatment of deep-seated infection following TKA often entails exchange arthroplasty, usually staged, and with the prolonged administration of systemically administered antibiotics. This represents a significant burden for the patient. The cost of treatment in the US has been estimated to exceed \$55,000.²² This fails to account for the hidden costs incurred by the patient and for the morbidity and mortality associated with treatment. Eradication is not always possible and rates of success for revision arthroplasty following infection are typically no greater than 90%.²³ Hence, prevention of infection in the performance of arthroplasty is vital.

Recommendations

- The use of ALBC is cost-effective and its use is fully justified based on potential savings from the reduction of the number of revision procedures performed for infection and the avoidance of the associated morbidity which may be unquantifiable [overall quality: poor]
- There are no proven disadvantages with the routine use of ALBC in primary TKA [overall quality: moderate]

Question 3: What is the role of ALBC in the treatment of established prosthetic knee infection?

Case clarification

Use of high-dose ALBC (at least 3.6g antibiotic per 40g bone cement) is required for the treatment of deep infection following arthroplasty and is typically used as a spacer during staged exchange arthroplasty. With high-dose ALBC the mechanical properties of the acrylic bone cement are altered, rendering it unsuitable for long-term fixation of components.²⁴

Relevance

Buchholz and Engelbrech were the first to combine antibiotics with acrylic bone cement as a prophylactic measure in arthroplasty.²⁵ Antibiotics can be added to acrylic cement in the form of powder, either commercially mixed or mixed by hand at the time of surgery. Elution characteristics for various antibiotics have been documented.^{26,27}

Current opinion

The value of high-dose ALBC in established prosthesis-related infection is well established.

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 1 case series²⁸

Findings

Antibiotics added to acrylic bone cement must be thermally stable to resist the heat of polymerization. Elution characteristics vary between antibiotics and between bone cement types. Gentamicin added to bone cement has been the most extensively studied. It elutes levels above the minimum concentration level for staphylococci and aerobic gram-negative rods for up to 5 days.²⁹ In North America tobramycin is more commonly employed, due to its availability in powdered form. The elution characteristics of ALBC are enhanced with the addition of more than one antibiotic.²⁷ The value of ALBC in established prosthesis-related infection is irrefutable.^{28,30,31}

Recommendations

- High-dose ALBC is an established regime for the treatment of infection in TKA [overall quality: moderate]
- High-dose ALBC is unsuitable for long-term fixation of components in revision TKA [overall quality: moderate]

Question 4: Does the use of ALBC in primary TKA lead to earlier mechanical failure rates?**Case clarification**

See Question 1.

Relevance

Mentioned as a theoretical adverse effect to the use of ALBC in primary TKA.

Current opinion

See Question 1.

Finding the evidence

See Question 1.

Quality of the evidence

- Level II^{9,32,33}

Findings

There is good evidence that the addition of low-dose antibiotics to bone cement does not alter its mechanical properties to any clinically relevant extent and is suitable for long-term implant fixation.³⁴ In-vitro testing has shown that low-dose ALBC shows negligible reduction in fatigue strength.³⁵ To date, clinical studies and joint registries have not shown an increased mechanical loosening rate with the use of low-dose ALBC.

Recommendation

- No adverse effect on mechanical loosening rates has been documented with the routine use of low-dose ALBC in TKA [overall quality: moderate]

Question 5: Can the routine use of ALBC lead to the development of resistant organisms in TKA?**Case clarification**

See Question 1.

Relevance

Reports of infected joint replacements with microbes resistant to gentamicin have raised concern regarding the routine use of low-dose ALBC in TKA.

Current opinion

This is a subject of controversy.

Finding the evidence

- PubMed, using the search term: "microbiology of the infected knee arthroplasty"

Quality of the evidence

Level II

- 1 systemic review of cohort studies³⁶

Findings

Recently, antimicrobial resistance among bacteria found after use of ALBC in prosthesis-related infection has been ascribed to the use of ALBC. In a report on 426 surgically revised knee arthroplasties over a 14 year period, gentamicin resistance was found in 1/28 tested isolates of *Staphylococcus aureus* and 19/29 of tested coagulase-negative staphylococci.³⁶ In an animal model of ALBC vs. PBC, Thornes³⁷ noted a lower rate of infection with the addition of gentamicin to bone cement. A statistically significant increase in gentamicin-resistant *Staphylococcus epidermidis* was reported. It is unknown whether this represents eradication of gentamicin-sensitive strains of bacteria and the resultant demonstration of resistant strains.

Recommendation

- There is no evidence to support the hypothesis that the emergence of bacterial resistance is related to the use of ALBC as a prophylactic measure [overall quality: low]

Question 6: Is there a risk of developing systemic toxicity or an allergic reaction with the use of ALBC in TKA?**Case clarification**

See Question 1.

Relevance

This has been mentioned as a theoretical adverse effect to the use of ALBC.

Current opinion

Low- or high-dose ALBC cement has been proven to be safe through three decades of use.

Finding the evidence

- PubMed, using the search term: “nephrotoxicity antibiotic bone cement”

Quality of the evidence

Level IV

- 3 case reports³⁸⁻⁴⁰

Findings

No reports of systemic toxicity have been reported from the routine use of low-dose ALBC despite three decades of documented usage decades in Scandinavia and other European countries. Scant reports exist of patient toxicity following use of high-dose ALBC.³⁸⁻⁴⁰ Gentamicin is the most studied antibiotic in ALBCs. It is typically associated with a lack of allergic reactions. There have been no reports of allergic reactions associated with its use in ALBC in more than 100,000 arthroplasty cases in the literature thus far.³

Recommendation

- Low- or high-dose ALBC cement has been proven to be safe through three decades of documented use [overall quality: very low]

Summary of recommendations

- The use of ALBC decreases the rate of deep infection following TKA
- The use of ALBC is cost-effective and its use is fully justified based on potential savings from the reduction of the number of revision procedures performed for infection and the avoidance of the associated morbidity which may be unquantifiable

- There are no proven disadvantages with the routine use of ALBC in primary TKA
- High-dose ALBC is an established regime for the treatment of infection in TKA
- High-dose ALBC is unsuitable for long-term fixation of components in revision TKA
- No adverse affect on mechanical loosening rates have been documented with the routine use of low-dose ALBC in TKA
- There is no evidence to support the hypothesis that the emergence of bacterial resistance is related to the use of ALBC as a prophylactic measure
- Low- or high-dose ALBC cement has been proven to be safe through three decades of documented use.

Conclusions

Infection following TKA is associated with poor outcomes. The routine use of low-dose ALBC has excellent outcomes documented for over three decades. The incidence of septic loosening is reduced. Current evidence indicates that ALBC should be used routinely in all primary TKAs. The studies reviewed here are summarized in Figure 23.1 and Table 23.1.

Figure 23.1 Survival analysis in total hip arthroplasty. Cox-adjusted survival curves with infection as endpoint for uncemented total hip arthroplasties (THAs), cemented THAs with antibiotic-loaded cement, and cemented THAs without antibiotic cement. (Reprinted with permission from Engesaeter LB, Epshaug B, Lie SA, Furnes O, Havelin LI Does cement increase the risk of infection in primary total hip arthroplasty? Cemented vs. Uncemented Fixation in Total Knee Arthroplasty

Eric R. Bohm¹, Ili Slobodian¹, Thomas R. Turgeon¹, and Martin Petrak²

¹University of Manitoba and Concordia Joint Replacement Group, Winnipeg, MB, Canada

²Concordia Hip and Knee Institute, Winnipeg, MB, Canada

Case scenario

A 58 year old nurse tells you that she has exhausted non-operative management of her bilateral knee osteoarthritis. She is tired of the resulting pain and disability, and wants to proceed with total knee arthroplasty (TKA). Physical examination reveals a body mass index (BMI) of 34, an antalgic gait, painful passive range of motion of both knees, correctable varus deformity, and a normal neurovascular examination. Radiographs confirm medial and patellofemoral osteoarthritis. She tells you that she wants the “best” type of knee replacement.

Relevant background

The three components that make up a total knee replacement (Figure 24.1) can be secured to bone using either cemented or cementless fixation. Cemented fixation relies on the polymer polymethylmethacrylate (PMMA) to secure the implants. Cementless fixation relies on either a porous metal surface or a contoured surface coated with hydroxyapatite (HA) to promote bone ingrowth and subsequent stability (Figure 24.2).¹ The articulation (and wear) occurs between the metal femoral component and the polyethylene of the tibial component. Tibial components can either be manufactured entirely from polyethylene, or from metal on to which a polyethylene insert is secured. Although cementless patellas have fallen out of favor due to high failure rates² (a result of thin polyethylene necessitated by the metal backing), there still remains some interest within the orthopedic world about the role of cementless fixation, particularly of the tibial component. This is because the most common noninfectious failure mechanism of TKA is loosening of the tibial component secondary to tibial bone osteolysis (resorption) caused by polyethylene debris

arising from wear of the bearing surface.³ It is postulated that cementless fixation may ultimately result in improved TKA longevity by preventing polyethylene debris from gaining access to the bone–implant interface.

Importance of the problem

TKA is on the rise worldwide. Canadian volumes increased by 141% between 1996 and 2006,³ volumes in the UK increased by 43% between 2003 and 2008 (Professor Paul Gregg, personal communication) and in the United States volumes are predicted to increase by 674% between 2005 and 2030.⁴ TKA has a finite survivorship, with approximately 5% of implants being revised by 10 years.⁵ The increasing volumes of primary TKAs will ultimately lead to increasing numbers of revision TKAs, the clinical results of which are inferior to⁶ and the costs approximately 140% higher⁷ than the primary surgery.

The assumption of improved outcome with cementless implants was predicated on the survival being at least equal to that of traditional cemented designs. Some early cementless designs did not meet the goals for long-term survival, with early loosening occurring more commonly with the tibial component.^{2,8-9} The large majority of TKAs performed today use cemented fixation,¹⁰⁻¹³ but cementless technology continues to evolve and develop in an attempt to achieve the original goals of improved survival and outcomes in younger, active patients.

Top five questions

1. Are there differences in survivorship between cemented and noncemented TKA?
2. Is there a difference in functional outcome between the two fixation types?

3. Are there differences in complication rates between the two fixation methods?
4. Are there differences in ease of revision or quality of outcome of revision following cemented and cementless TKA?
5. Are there differences in costs between cemented and cementless TKA?

Question 1: Are there differences in survivorship between cemented and noncemented TKAs?

Case clarification

Patients often ask how long they can expect their knee replacement to last.

Figure 24.1 Modular total knee replacement system.

Relevance

Young patients appear to be at higher risk of revision due to loosening,⁵ it is therefore worthwhile to explore other fixation options that may improve longevity.

Current opinion

Worldwide registry data demonstrates that the majority of TKAs are inserted using cement.^{5,14-17}

Finding the evidence

- Cochrane Database: search terms “cemented knee,” “uncemented knee,” and “cementless knee”
- PubMed: search terms “cemented knee,” “uncemented knee,” “cementless knee,” “cemented fixation,” “total knee arthroplasty.” Limited to humans, clinical trials, meta-analysis, practice guidelines, randomized controlled trial, review, comparative study, controlled clinical trial, English
- Google: joint replacement registries

Quality of the evidence

Level I

- 1 randomized controlled trial (RCT) specifically powered to detect clinically significant functional differences based on tibial component fixation method¹⁸

Level II

- 1 meta-analysis with methodological flaws (inconsistent application of trial inclusion criteria, inclusion of two RCTs reporting on the same set of patients)¹⁹
- 2 RCTs comparing cementless to cemented TKA (randomization method flaws)^{20,21}
- 10 RCTs comparing hybrid fixation (typically a cemented femur combined with a cementless tibia) to either entirely cemented or cementless fixation (either no a-priori sample size calculation, powered to detect radiographic changes only, insufficient power to detect clinically significant differences, or unclear description of fixation method)²²⁻³¹
- 13 cohort studies with control groups (usually matched control groups)^{2,32-43}
- 4 national joint replacement registries contain information on TKA survival based on fixation method^{5,14-16}

Figure 24.2 (a) Porous metal surface. (b) Hydroxyapatite coating.

Findings

A recent meta-analysis compared survival and clinical outcomes of cemented and cementless TKAs.¹⁹ It included 5 RCTs and 10 cohort studies with control groups. Limitations in the analysis include the overall quality of studies, inconsistent application of their criteria for determining if a study should be included in the analysis, and inclusion of 2 RCTs that reported two different follow-up periods on the same cohort of patients. Nonetheless, they concluded that the combined odds ratio for failure of cementless TKA was 4.2 (95% CI 2.7–6.5) compared to cemented TKA.

Thirteen RCTs were found; however none were either adequately powered or had sufficient follow-up to detect clinically significant differences in survival. Three RCTs reported on the same cohort of patients,^{20,44,45} two of these were therefore excluded from the current analysis.^{44,45}

Several studies employing radiostereometric analysis (RSA) to examine differences in implant–bone micromotion between the fixation methods were found.^{22–25,27–31,40,46–49} RSA is a highly accurate, noninvasive radiographic method that can predict long-term survivorship of an implant based upon micromotion occurring between the implant and surrounding bone.^{46,47,50,51} It requires small numbers of subjects and a relatively short postoperative follow-up period (typically 2 years).^{46,47,50,51} It appears that the femoral fixation method has little impact on component migration. However, cementless tibial components tend to migrate for the first 3–12 months before final bone ingrowth and subsequent stability occurs.^{23,40,46} The addition of HA to the cementless tibial component appears to improve stability through improved bone ingrowth.^{22,25,31} Cemented tibial components tend to have increasing migration with time,^{28,48} but the impact of this late migration on long-term survivorship is poorly understood.

Thirteen cohort studies that had a control group were identified. Five of these studies^{2,13,34,35,38} with a total of 1958 TKAs found that cemented TKAs had higher survivorship than cementless TKAs primarily due to a lower aseptic loosening rate. Basset reported on his personal series of 584 cementless TKAs and 416 cemented TKAs and found no difference in survivorship at 5 years. The decision to use cement was subjectively based upon the amount of porosity of the cut tibial surface, with the more porous tibias receiving cemented fixation.³³ Seven studies had insufficient power to detect clinically significant differences.^{36,37,39–43}

Four national joint registries examine TKA survivorship in relation to fixation method: those of England and Wales,¹⁴ New Zealand,¹⁵ Australia,¹⁶ and Sweden.⁵ All four report that cemented fixation is most common, followed by hybrid and then cementless. The Swedish registry has the longest follow-up data (18 years), and has found a 1.5 (1.2–2.8) times higher revision rate for cementless TKAs secondary to tibial component failure; subsequently they have essen-

tially abandoned the use of cementless TKA. The Australians have data on 3713 TKAs equally divided into cementless and cemented fixation out to 7 years; they are unable to detect any differences in survival based on fixation method. The National Joint Registry of England and Wales have followed more than 111,000 TKAs out to 3 years (13% cementless). Although they found a trend towards higher revision rates in the cementless and hybrid groups, it did not reach statistical significance. New Zealand surgeons have found that uncemented TKAs have twice the revision rate of either cemented or hybrid TKA. It appears that the majority of their hybrid TKAs employ a cementless femur and a cemented tibia, a configuration that one would expect to have good survivorship, as it appears that the uncemented tibial component is usually the reason for revision in cementless TKAs.⁵

Recommendation

- Cemented fixation demonstrates improved survivorship over cementless procedures in TKA [overall quality: high]

Question 2: Is there a difference in functional outcome between the two fixation types?

Case clarification

While the patient is concerned about the longevity of her impending knee replacement, she is also concerned about any functional differences that may exist between the two fixation methods.

Relevance

Patient satisfaction following knee replacement is tied closely to relief of pain and restoration of function.⁶ Any differences in functional outcome according to fixation method would therefore be of interest.

Current opinion

The vast majority of total knees are inserted using cemented fixation,^{3,5,13,15–17} implying that surgeons may feel that no significant functional benefit is realized from cementless fixation.

Finding the evidence

The same search method employed to answer Question 1 above was used. Due to a general lack of functional data, joint replacement registries were excluded.

Quality of the evidence

See Question 1 above.

Findings

As noted above, a recent meta-analysis¹⁹ with some design limitations was found. Analyzing pooled data from both RCTs and cohort studies, they could not detect any differ-

ences in joint function as measured by the Knee Society score.⁵²

A review of the 13 RCTs found in our search revealed one well-designed study¹⁸ powered to detect clinically significant differences in WOMAC knee function scores⁵³ between 81 patients randomized to receive either cementless or cemented tibial component fixation. They found that those patients receiving cementless fixation reported higher pain at the 6 month assessment as measured by both the SF-36 and WOMAC; however, this difference disappeared by 5 years postoperatively. They postulated that the higher pain scores were a result of early migration of the tibial component before ingrowth occurred. This clinical finding of slower pain resolution in cementless components has previously been reported in an RCT whose authors also noted that, when assessed using RSA, cementless tibial components demonstrate higher early micromotion before ingrowth and stabilization occurs.²⁷ The remaining 11 RCTs either did not report on functional outcomes (as they focused mainly on radiographic differences), or had an inadequate sample size to detect clinical differences, or did not do appropriate statistical testing

Thirteen cohort studies that had a control group were identified. Barrack's study of 158 knees found that cementless TKAs had poorer postoperative Knee Society scores; this was likely due to loose and painful tibial components that led to a higher rate of revision in this group.³² Two adequately powered studies incorporating a total of 1118 knees found no differences in functional scores; both reported low rates of revision for either cementless femoral or tibial components.^{13,33} However, patients in both cementless groups were younger, and in Rand's study the cementless group started with higher preoperative scores, both of which should bias scores towards the cementless groups. The remaining studies had inadequate statistical power,^{36,37} did not report on functional outcomes,^{34,35,38-41} or did not do appropriate statistical testing.^{42,43} It would appear that functional scores are equivalent as long as bony fixation is obtained with cementless implants; if not, both revision rates and functional scores are worse.

Recommendation

- Cementless TKAs appear to provide equivalent mid-term (5 year) functional outcomes compared to cemented TKAs as long as loosening does not occur [overall quality: high]

Question 3: Are there differences in complication rates between the two fixation methods?

Case clarification

After you review the risks generally associated with elective knee replacement surgery, the patient asks if com-

plication rates are different between the two fixation methods.

Relevance

Since TKA is an elective surgical procedure, one always aims to minimize the possibility of complications.

Current opinion

The surgical technique for cemented and cementless TKA is essentially identical. Both involve bone cuts to tibia and femur, soft tissue releases as required, and then insertion of components. In the case of cemented fixation, cement is applied to the bone surfaces immediately before component insertion. It is the authors' experience that most intraoperative complications (ligament rupture or bone fracture) occur before insertion of the final implants, and arise as a result of difficulties encountered undertaking the bone cuts or ligament balancing. Accordingly, we have not found any differences in intraoperative complications.

The use of cement during TKA offers two theoretical advantages: antibiotics can be added in an effort to reduce infection rates, and the application of cement to the cut bone surfaces may reduce postoperative blood loss.

Finding the evidence

The RCTs and controlled series identified for Question 1 were reviewed.

Quality of the evidence

See Question 1 above.

Findings

Intraoperative complications during TKA are quite infrequent,⁵⁴ accordingly, none of the RCTs or series identified were adequately powered to detect differences in these areas. One RCT reported more blood loss in the cementless group (783mL vs. 519mL, $p = 0.02$) but did not indicate how this was measured or if it had any effect on transfusion rates. The Australian Joint Registry is the only registry to report on the impact of cement type (with or without antibiotics) on revision rates; they noted a trend towards a lower revision rate for infection in cemented knees when antibiotics were present in the cement. However, they did not make a comparison in rates of revision for infection between cemented knees (containing cement) and cementless knees.

Recommendation

- The use of cement for TKA fixation may result in lower blood loss [overall quality: very low]

Question 4: Are there differences in ease of revision or quality of outcome of revision following cemented and cementless TKA?

Case clarification

Given the relatively young age of the patient, you consider her need for future revision TKA and consider whether cemented or uncemented implants will serve the patient in preservation of bone and other tissue for possible future revision.

Relevance

Uncemented implants tend to be used in younger patients, based on the premise that the bone adjacent to the implant may be better preserved for future surgeries.

Current opinion

The majority of TKAs performed in both young and old patients continue to be cemented.

Finding the evidence

Search terms used were:

- Uncemented knee revision
- Cementless knee revision
- (Cemented OR cementless) AND knee AND bone AND (density OR densitometry)
- Trabecular metal AND knee AND bone (density OR densitometry)

Quality of evidence

Level II

- 2 randomized trials with methodologic limitations

Level III

- 3 retrospective cohort studies

Findings

There are five published comparative studies assessing the bone mineral density adjacent to total knee implants between cemented and cementless designs. Three of the studies compared cemented to cementless versions of the same implant system, while the other two studies used cemented and cementless designs from different arthroplasty systems.⁵⁵⁻⁵⁹ Measurement technique of bone density varied between the studies as well, with some studies using radiograph measurements and others using triple or dual energy X-ray absorption (DEXA). Additionally, the areas of bone assessed relative to the implants varied. Bone density findings were inconsistent between the studies. One study found a 50% reduction in bone density posterior to the anterior femoral flange with cemented implants vs. cementless.⁵⁹ A second study found a trend toward this finding that did not achieve statistical significance with a slightly smaller difference between the two fixation types.⁵⁶

The remaining studies found no change in femoral bone density. Of the three studies that assessed bone density of the tibia, one found reduced bone density,⁵⁸ one a trend to reduced density,⁵⁶ and the third increased density⁵⁵ of one zone of the tibia adjacent to the implant with cementless implants. The location of the altered bone density differed, as did the design of the implants. There were no comparative assessments of the results of revision of the two fixation techniques.

Recommendations

- Some possible improvement in bone density under the anterior flange of the femoral component with the use of cementless implants vs. cemented [overall quality: very low]
- No reported evidence of improved ease of revision or beneficial effect from cementless implants beyond measurement of bone density [overall quality: very low]

Question 5: Are there differences in costs between cemented and cementless TKA?

Case clarification

Your hospital resists the use of cementless knee components and suggests that patients should be responsible for any additional implant costs.

Relevance

Cementless TKA components generally carry a 30–100% premium cost compared to cemented implants. However, there is a reduction in costs from cement, cement gun, and mixing equipment disposables. There is also the potential for reduced operating room time by avoiding the cementing steps and no longer having to wait for cement to cure.

Current opinion

Cementless TKA is viewed as a more costly option for the healthcare payer.

Finding the evidence

Search terms used were:

- PubMed: (uncemented OR cementless) AND knee and (cost OR financial) 2000–2009
 - No results
- Econlit: Knee AND replacement, Knee AND arthroplasty
 - No results
- Health Reference Centre: Knee replacement cost, Knee arthroplasty cost
 - No results
- Business Source Premier: Knee replacement cost, Knee arthroplasty cost
 - No results

Quality of the evidence

- Level V: 2

Findings

Due to the complex nature of implant pricing, little information has been published allowing for comparison of cemented vs. cementless TKA. Cementless implants are 30–100% more expensive than cemented implants of the same design.⁶⁰ The addition of cement and related disposables adds \$500–1000 per case depending on contract pricing, number of units of cement used, use of premixed antibiotics in the cement, and the types of mixing disposables selected. At best, cementless TKA will break even with cemented TKA, but in most contract scenarios the cementless implants will cost more for the healthcare payer

Recommendation

- While the cost of implants must be considered in all arthroplasty cases, ultimate selection of implants should be determined by the clinical effectiveness [overall quality: very low]

Summary of recommendations

- Cemented fixation demonstrates improved survivorship over cementless procedures in total knee arthroplasty
- Cementless TKAs appear to provide equivalent mid-term (5 year) functional outcomes compared to cemented TKAs as long as loosening does not occur
- The use of cement for TKA fixation may result in lower blood loss
- Some possible improvement in bone density under the anterior flange of the femoral component may occur with the use of cementless implants
- No reported evidence of improved ease of revision or beneficial effect from cementless implants beyond measurement of bone density
- While the cost of implants must be considered in all arthroplasty cases, ultimate selection of implants should be determined by the clinical effectiveness

Conclusions

Cemented TKA appears to more reliably provide early fixation and relief of pain compared to cementless TKA; however, mid-term (5 year) functional outcomes appear equivalent if loosening does not occur. Differences in cost, complications, and ease of revision are not well studied in the available literature. Interest in cementless fixation, particularly with the use of HA coating to improve ingrowth, will likely remain high as efforts continue to

improve long-term (>15 year) survivalship of implants. High-quality long-term data is required in order to make this determination.

High-Flexion Implants vs. Conventional Design Implants

Nicholas Paterson¹, Robert J. Orec², and Douglas D.R. Naudie¹

¹University of Western Ontario, London, ON, Canada

²Middlemore Hospital, Otahuhu, Manukau, New Zealand

Case scenarios

Case 1

A 65 year old man is referred to an orthopedic surgeon with a diagnosis of primary knee osteoarthritis. He complains of global knee pain that is insufficiently relieved by rest, anti-inflammatory medication, bracing, or injections. He has a good range of motion (ROM) and no flexion contracture. Radiographic findings indicate bicompartamental joint space narrowing and presence of osteophytes. He wishes to return to his previous recreational activities, including golf and yoga.

Case 2

A 55 year old Muslim woman presents with endstage degenerative joint disease of her knee. She has marked varus angular deformity with limited knee flexion to 100°. Radiographic evaluation demonstrates severe varus osteoarthritis. The patient has exhausted conservative treatment, experiences night pain, and wishes to pursue surgical relief. She explains how it is very important for her to position herself properly for prayer. She has read about high-flexion total knee replacement prostheses and insists this is the only solution for her.

Importance of the problem

Total knee arthroplasty (TKA) is a highly successful operation that delivers noticeable and measurable improvement in pain, function, and satisfaction. The ultimate goal of a

painless knee with normal function that lasts indefinitely has yet to be reached. A prominent source of dissatisfaction among TKA patients is postoperative stiffness and an inadequate ROM to perform everyday activities. The concept of a knee replacement with a greater ROM while retaining the overall success of TKA has become a strong marketing point, both for companies to surgeons and for surgeons to their patients.

Relevant anatomy and background

The native knee achieves flexion past 120° by the lateral femoral condyle rolling back and perching on the edge of the lateral tibial plateau, while the medial femoral condyle rides up on to the posterior horn of the medial meniscus, effectively “lifting-off” and losing contact with the tibial plateau.¹ The re-creation of such kinematics has been actively avoided by arthroplasty designers for fear of excessive forces being applied to the polyethylene inserts and potential dislocation of the prosthetic components. Currently, conventional primary TKA systems are designed to achieve maximum flexion up to 130°.²

High-flexion (HF) implants have embraced design modifications including: changes to the posterior femoral condylar resection, femoral component, and polyethylene liner. Different companies have incorporated some or all of these changes into their HF designs in the hope of creating a stable knee that can achieve flexion up to 150° or more. The changes to the femoral component aim to make the most posterior lip of the posterior femoral condyles more rounded in order to increase the weightbearing area of this edge while the prosthesis is in deep flexion (Figure 25.1). These changes are necessary to avoid impingement or edge

Figure 25.1 Schematic drawing of a high-flexion femoral component demonstrating the increased thickness of the posterior condyles required to avoid impingement of the flanges into the polyethylene at high flexion angles.

loading of the component into the polyethylene insert, thus preventing fractures and/or delamination of the insert.³ The femoral modifications require resection of extra host bone, which is replaced by the more rounded edge of the implant. Changes to the polyethylene insert have consisted of decreasing the congruency of the posterior portion to avoid impingement on the femur and creating a recess in the polyethylene anteriorly to accept the patellar tendon as it “leans back” in deep flexion. Additionally, in posterior stabilizing (PS) models, increasing the height of the posterior cam and altering its geometry has been addressed to decrease the chance of “jumping the post” with increased flexion (Figure 25.2).

Top four questions

Complications

1. Have the design changes associated with HF implants resulted in increased complication rates?

Outcome measures

2. What are the available clinical tools to measure ROM and what are their limitations?
3. Do HF implants achieve greater postoperative ROM and patient satisfaction scores than conventional TKA?

Indications

4. Are there specific patient population demographics or individual traits that indicate the use of HF implants?

Figure 25.2 (a-b) Schematic drawings showing differences between a Genesis II (Smith and Nephew, Memphis, TN) standard posterior stabilized (white, background) and high-flexion posterior stabilized (gray, foreground). (a) The cutout of polyethylene at the anterior aspect of the inserts is shown. (b) The slope of the polyethylene at the proximal anterior portion of the post is demonstrated. (c) Changes in the radius of curvature of the posterior portion of the articulating surfaces is shown. (With kind permission from Springer Science+Business Media: McCalden RW, Macdonald SJ, Charron KD, Bourne RB, Naudie D. The role of polyethylene design on postoperative TKA flexion: an analysis of 1534 cases. *Clin Orthop Relat Res* 2010;468(1):108–114.)

Question 1: Have the design changes associated with HF implants resulted in increased complication rates?

Case clarification

In both Cases 1 and 2, while the patients are concerned about their ability to achieve deep flexion postoperatively, they are aware of the importance of implant longevity and ask if there are any trade-offs.

Relevance

In HF TKA, multiple implant modifications were simultaneously introduced. Teasing their effects apart can be difficult. As HF TKA data does not yet exist beyond 5 years, it is critical that we continue to monitor and appraise these new designs.

Current opinion

The design modifications in HF TKA pose no added risk to the patient during surgery. Similarly, the rates of adverse events and complications remain parallel to conventional TKA at short-term follow-up.

Finding the evidence

- PubMed: search terms “high flexion knee arthroplasty,” “high flexion TKA,” “high flexion knee complications” with limits: “humans” and “English language”

Quality of the evidence*Level I*

- 3 randomized controlled trials powered to detect outcomes and differences in ROM⁶
- 1 meta-analysis examining only RCTs⁷

Level II

- 5 RCTs with methodological limitations: lacking a-priori sample size calculation;^{8,9} insufficient power or flawed inclusion confounders¹⁰⁻¹²
- 2 meta-analyses including lower-level study methodologies^{13,14}
- 4 prospective cohort studies with matched control groups¹⁵⁻¹⁸

Level III

- 5 retrospective case-control studies (comparison observational studies)¹⁹⁻²³

Level IV

- 1 study with methodological limitations: a retrospective single-surgeon series following a small sample of HF PS knees²⁴

Findings

Concerns have been expressed regarding the HF design changes and their potential long-term indications. Any knee joint that undergoes deep flexion is subject to high shear forces between the tibia and femur, estimated to be several orders of magnitude more than the one's body weight.^{25,26} To reach deep flexion the amount of posterior translation required by the normal knee leads to posterior subluxation of the lateral femoral condyle and a small amount of lift-off of the medial femoral condyle as it rides up on the more tethered posterior horn of the medial meniscus. This mechanism causes significant posterior loading on the polyethylene insert and tibial tray.¹

Although HF designs have improved the amount of articulating surface area when compared to standard designs according to dual fluoroscopy and three-dimensional modeling in vivo,²³ the contact area of all designs is known to decrease markedly in deep flexion. During deep flexion, as contact area is decreased, contact pressure stresses demonstrate corresponding increases.²⁵ What is not known is how much stress is problematic with contemporary polyethylene inserts.

The introduction of multiple implant modifications introduced simultaneously raised warranted initial concerns. Both the structural integrity of a thinner and taller cam-post mechanism in PS designs and the necessary extra bone resected to allow HF femoral components were anticipated to be problematic.^{24,27,28} Han et al. reported a 38% incidence of aseptic loosening of the femoral component at just less than 3 years in one manufacturer's HF design.²⁴ That being said, all of the level I and II evidence at short- and mid-term follow-ups suggests there are no differences between complication rates in HF and conventional TKA.^{5-12,29}

Recommendations

- HF TKA may result in higher rates of short-term aseptic loosening [overall quality: very low]
- HF components have better contact forces in deep flexion [overall quality: low]
- Rates of complications are comparable in conventional and HF TKA at short-term follow-up [overall quality: high]

Question 2: What are the available clinical tools to measure ROM and what are their limitations?**Case clarification**

When discussing with the patient the increased ROM they may receive from a HF implant it is important to consider and explain the limitations of our measurement techniques, and whether these gains may be clinically significant in their everyday life.

Relevance

The simple act of measuring knee flexion has been debated. The clinically predictive worth of passive, active, or “drop” flexion is unclear. Comparing ROM between HF and conventional models in most of the studies reveals differences in flexion that are small enough to be clinically irrelevant. A difference of several degrees may reach significance but is often well within the accuracy limitations of any measurement tool used.

Current opinion

The measured radiographic angulations between the long axis of the tibia and the long axis of the femur under active

and passive knee ROM is widely considered the gold standard.³⁰

Finding the evidence

PubMed: search terms “knee kinematics,” “knee ROM,” “deep knee flexion,” “ROM knee arthroplasty” with limits: “humans” and “English language”

Quality of the evidence

Level III

- Case-control studies and exploratory validation observational studies,^{30–32} prospective³³ and retrospective observational studies^{34,35}

Findings

Goniometric measurements used by a single assessor are seen as being reliable^{30,31,36} but do not guarantee comparability between studies. Electrogoniometry and deep flexion radiography are also used at an increased expense and can introduce sources of error such as marker placement and stability or operator variation.³⁶ The justification of using such techniques under the pretense of improving accuracy is questionable given the increase in flexion required to be clinically relevant—an undefined amount that is unique to each patient’s demands. Roentgenographic measurements remain the gold standard but are less used clinically compared with visual ROM estimations and goniometric measurements. Several studies have found that assessors tended to underestimate flexion,^{30,36} increasingly so as the flexion angle increased, when using visual and goniometric measurements compared against radiographic standards.³⁶ It is important to note that while gains obtained in conventional and HF studies may appear statistically different; they may not be clinically significant given the limitations of accuracy for goniometric measurement.^{30,36}

Active ROM testing has been shown to under-represent the flexion when compared to passive methods of testing.^{6,30} However, proponents of the use of active ROM claim that it is a better representation of the range used functionally.^{32,33,35} Others feel that preoperative and early postoperative assessments are hampered by pain and that patients would not perform an active test exercise (kneeling) in the early postoperative period for fear of damaging the implant.³⁴

Clinical outcome tools are too blunt and limited in their ability to detect changes in deep-flexion specific tasks.³⁷ For instance, Knee Society scores lack an option to record flexion beyond 125° and Oxford knee scores have only a single question that addresses deep flexion. This creates a ceiling effect where assessment scores are inadequate in patients with higher function.²⁹

Recommendations

- Goniometry provides reliable and accurate ROM results [overall quality: moderate]

- Visual assessment may underestimate flexion, especially deep flexion [overall quality: low]

Question 3: Do HF implants achieve greater postoperative ROM and patient satisfaction scores than conventional TKA?

Case clarification

When recommending (or not recommending) a particular implant to a patient, such as those in Cases 1 or 2, it is important to consider the available evidence that should guide our clinical practice.

Relevance

Patient satisfaction following TKA is closely associated with restoration of function (including ROM and the ability to perform activities of daily living)³⁸ and as such warrants discussions of whether the patients may benefit from a HF implant.

Current opinion

HF implants perform at least on a par to conventional TKA in increasing ROM postoperatively. Some HF designs have shown improved ROM compared to conventional TKA, but it remains unclear whether these ROM changes are clinically significant and lead to improved patient satisfaction in the long-term.

Finding the evidence

See Question 1.

Quality of the evidence

See Question 1.

Findings

Studies utilizing *in-vivo* fluoroscopy comparing flexion, contact areas and contact stresses have found either no significant differences between standard and HF designs or a small improvement in favor of the HF design.^{23,39,40}

A number of *nonrandomized* studies compared flexion and clinical outcomes between a variety of standard and HF designs,^{15–18,20–23} and reveal conflicting results and conclusions. Five of these studies revealed a modest improvement in flexion,^{17,18,20–22} with no improvement in clinical rating scores found in any of the studies that utilized them. An early meta-analysis¹³ included two RCTs^{4,12} and four non-RCT studies.^{19–22} The authors concluded that while there are marginal gains in knee flexion and ROM, there is no clinical advantage over traditional TKA. A more recent systematic review²⁹ included RCTs,^{4,8,12} retrospective^{15,20–22} and prospective¹¹ studies. The authors contend that methodological limitations and inconsistent results in HF TKA research suggests that there is currently no established benefit in postoperative ROM or physical function when

using these implants. Additionally, two recent meta-analyses with stronger inclusion criteria^{7,14} suggested that no clinically relevant or statistically significant improvement was obtained in flexion with the HF prostheses.

Table 25.1 summarizes the relevant methodological details of eight randomized controlled trials.^{4-6,8-12} Of these eight studies, only Weeden et al.⁸ and Seng et al.⁹ found a significant advantage to the HF design implants. Moreover, the study by Seng et al.⁹ found that at 5 years, the increase in postoperative knee flexion correlated with a significant improvement in general health, vitality, and physical functioning scales of the SF-36.

Although they are RCTs, these studies do have several of the limitations mentioned above. The validity of performing simultaneous knee replacements (one of either design) and using the patient as their own control^{6,12} is debatable. While bilateral simultaneous TKA may be ideal for comparison as

it controls for patient motivation,¹⁵ others contend that it may confound results with the patient comparing the two sides in an attempt to keep the sides equal in their flexion.²⁹ Moreover, performing simultaneous bilateral TKA may confound clinical scoring parameters, with scoring systems unable to detect which knee is causing an inability to perform a global function such as climbing stairs.⁶

Recommendations

- No short-term differences in ROM or patient satisfaction scores exist between conventional and HF implants [overall quality: high]
- HF TKA produces greater ROM and deep flexion [overall quality: moderate]
- HF TKA can increase patient scores on the general health, vitality, and physical functioning scales of the SF-36 [overall quality: low]

Question 4: Are there specific patient population demographics or individual traits that indicate the use of HF implants?

Case clarification

Patients may ask if they are suitable candidates for this design or directly request it as a result of their desire to achieve deep flexion for cultural, recreational, or religious reasons.

Relevance

A notable shortfall of contemporary TKA is the ROM routinely obtained after surgical intervention and its comparison to the amounts necessary to perform routine activities of daily living (ADLs) (Table 25.2). Postoperative outcome studies reveal stiffness as a leading cause of dissatisfaction amongst patients.^{38,41}

Current opinion

It is important to consider patient, instrument, design, and material factors in recommending the use of an HF implant. A patient's preoperative ROM is an important predictor of their postoperative ROM. Many implant and material (such as highly cross-linked polyethylene) modifications have been introduced simultaneously, making it difficult to tease out the individual effects of a HF design.

Sitting on calves plantar flexed (Japanese formal floor sitting or Islamic Su'ud sitting)	≤160

Findings

Cultural, religious, and recreational considerations should be weighed into the decision to use a HF implant. Table 25.2 lists commonly quoted values of knee flexion used in various routine daily activities. Although the highest-flexion actions listed in Table 25.2 appear to be more relevant in Eastern cultures, Western cultures still regularly partake in activities using these movements, such as golf, gardening, yoga, and kneeling.^{49,50} Variations between cultures in normal knees have been noted⁵¹ and are attributed to differences in routine daily activities. Similarly, ADLs have accounted for different wear patterns in osteoarthritic knees of Arabian and North American people.⁵²

Patients' expectations are also a determining factor. One study found that patients who were less mobile than they expected postoperatively were highly likely to be dissatisfied with the TKA,³⁷ suggesting that significant postoperative ROM gains may improve mobility and thus patient satisfaction. Moreover, while an improvement in the ability to kneel is often anticipated,⁴⁵ preoperative expectation surveys in one study revealed that, while the inability to perform HF activities was seen as the most disabling, they were not perceived as being the most important.⁴² Pain relief, perioperative complications, and the ability to perform basic ADLs were all valued as being of greater significance.⁴² These results mirrored previous studies of European patients⁵³ and Indian patients.⁴⁷ Similarly, postoperative outcome studies have shown that while a severe lack of flexion (<90°) correlates with overall physical impairment and dissatisfaction,^{38,44,54} factors such as pain, inability to meet expectations, operative complications, and mental, social, and emotional scores have been shown to be stronger indicators of unsatisfied patients.^{37,38,44,50,55,56} However, while poor ROM has been quoted as a leading cause of dissatisfaction,² there is no guarantee that higher flexion will lead to greater satisfaction.⁴⁷ This idea is supported by studies that show no increase in clinical outcome scores despite those individuals achieving high flexion.^{18,20-22}

Preoperative ROM remains the greatest predictor of postoperative ROM in TKA and HF TKA alike.^{43,46} Controlling for implant design, patients with good preoperative ROM, especially with very high preoperative ROM (>120°), may be more likely to gain flexion with a HF than a conventional TKA design.⁴⁸ Patients' anatomy and quality of cruciate ligaments may also be important as one study found HFPS designs to achieve greater improvements in ROM over HFCD designs.³

Recommendation

- Patients with high preoperative flexion may be more likely to gain flexion with a HF over a conventional TKA design [overall quality: low]

Summary of recommendations

- HF TKA may result in higher rates of short-term aseptic loosening
- HF components have better contact forces in deep flexion
- Rates of complications are comparable in conventional and HF TKA at short-term follow-up
- Goniometry provides reliable and accurate ROM results
- Visual assessment may underestimate flexion, especially deep flexion
- No short-term differences in ROM or patient satisfaction scores exist between conventional and HF implants
- HF TKA produces greater ROM and deep flexion
- HF TKA can increase patient scores on the general health, vitality, and physical functioning scales of the SF-36
- Patients with high preoperative flexion may be more likely to gain flexion with a HF over a conventional TKA design

Conclusion

Postoperative ROM after TKA is related to many factors. New HF TKA design changes have aimed to improve postoperative flexion and ameliorate patient satisfaction outcomes. There remain inconsistent results, despite the vast array of clinical evidence evaluating these designs over the past half-decade. Reported improvements in ROM have been identified in high (level I) and lesser quality (level II) RCTs. However, these improvements have not proven to be of major clinical significance with the exception of one study by Seng et al.⁵¹ with a mid-term follow-up. One major limitation in performing these studies remains our rudimentary tools for measuring ROM changes. The concept of performing or receiving a TKA with a higher ROM remains attractive to companies, surgeons, and patients alike. However, the long-term effects of these design changes are as of yet unknown, and we as surgeons and consumers must continue to evaluate them before fully embracing this technology.

²McMaster University, Hamilton, ON, Canada

Case scenario

A 55 year old woman diagnosed with spina bifida occulta and relative insensate lower limbs presents to clinic using two canes and a lateral unloading brace. She states that over the past month she has been having increasing pain to the lateral joint line and major instability on weightbearing without her brace. She has tried anti-inflammatories, bracing, non-weightbearing, and physiotherapy with limited benefit. She has become a minimal ambulatory and has had to go on sick leave from work. On examination, weightbearing without the brace reveals a 45° valgus deformity correctable to neutral. She has some sensory deficit in the peroneal nerve distribution but has intact motor and vascular function. Radiographs show severe lateral compartment arthritis with bony fragmentation in the surrounding synovial tissue and medial subluxation of tibiofemoral joint. The patella was subluxed laterally. She was diagnosed with a Charcot joint.

Relevant anatomy

The knee joint moves in both flexion/extension and internal/external rotation and is determined by the shape of the articulating surfaces and the orientation of the four major knee ligaments. This four-bar linkage system includes the anterior and posterior cruciate ligaments and the medial and lateral collateral ligaments. The posterior cruciate ligament (PCL) also facilitates the femoral rollback, which allows for increased flexion. Due to asymmetry of the lateral and medial femoral condyles, the lateral condyle

rolls a greater distance than medial at 20° flexion causing external rotation of the tibia, called the screw-home mechanism.

The primary function of the medial collateral ligament (MCL) is to restrain valgus rotation, while its secondary function controls external rotation. The lateral collateral ligament (LCL) restrains varus rotation and resists internal rotation. Numerous implants are available to accommodate for ligamentous laxity and bone loss. Cruciate retaining (CR) and posterior stabilizing (PS) knee implants are generally used for knees with a competent MCL and LCL. Total stabilizing (TS) knee implants are used for knees with incompetent collateral ligaments, while rotating hinged implants are reserved for complex instability involving bone loss and ligament incompetence.¹

Importance of the problem

Charcot arthropathy or neuropathic arthropathy is a progressive, relatively painless degenerative condition of the musculoskeletal system, caused by an underlying neurological or neurovascular disorder.²⁻⁵ It is a progressive arthropathy characterized by joint dislocations, pathologic fractures, pronounced new bone formation, and debilitating deformities with severe destruction and elongation of supporting structures.⁶ This disorder results in progressive destruction of bone and soft tissues, mainly at weightbearing, lower extremity joints. Definitive treatment for individuals suffering from this devastating disease remains controversial.⁵⁻⁹

The actual incidence of Charcot arthropathy is perhaps greater than reported, as a result of delay or missed diag-

nosis in as many as 25% of patients.¹⁰⁻¹² Disorders that have the potential to produce Charcot joints include amyloidosis, alcoholism, cerebral palsy, Charcot-Marie-Tooth disease, congenital insensitivity to pain, idiopathic sensorimotor neuropathy, infection, leprosy, pernicious anemia, poliomyelitis, steroids, syringomyelia, spina bifida, spinal or peripheral nerve injury, and trauma. Tabes dorsalis due to syphilis was the most predominant cause until improved antimicrobial therapy was implemented; diabetic neuropathy has now replaced it as the leading cause of Charcot joint disease.^{2,3,12,13}

The overall international incidence of Charcot arthropathy seems to be the same as that found within the United States alone. The incidence ranges from 0.10% to 3% in a general population of diabetics and up to 13% in high-risk diabetic patients presenting to specialized clinics.¹³ Radiographic changes have been noted in up to 29% of patients with established peripheral neuropathy.^{13,14} The most common sites affected include the foot, ankle, and rarely the knee.⁴

The neuropathic joint causes immense morbidity to patients. Because of the rarity of this clinical entity, no management guidelines have been established to date. A few retrospective studies have been identified within the literature, but no prospective, case-control studies, or randomized control trials have been identified. Despite difficulty in diagnosis and treatment, patient interest remains strong. Over 250,000 hits result from a Google search using the terms "Charcot joint" and over 150,000 hits appear when searching the terms "neuropathic arthropathy."

Finding the evidence

Since the evidence in the literature is lacking, it is difficult to critically analyze and formulate knowledgeable answers to the key clinical questions. As such, we present all the available evidence within Charcot neuroarthropathy first, followed by attempts to answer the clinical questions.

- Cochrane Database, with search term "neuropathic arthropathy," "Charcot arthropathy," "neuroarthropathy"
 - No articles found
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: "neuropathic arthropathy," "Charcot arthropathy," "neuroarthropathy"
 - No articles found
- MEDLINE search identifying the population ("knee" AND "neuropathic arthropathy")
 - 29 articles identified
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "knee neuropathic arthropathy"
 - 145 hits and, after review, 25 potentially relevant articles

Quality of evidence

High-quality evidence is lacking within this field.

Top four questions

Diagnosis

1. How accurate is the clinical and radiographic examination in the diagnosis of Charcot neuroarthropathy?

Therapy

2. What is the role of nonoperative treatment for the Charcot joint?
3. Is arthroplasty better than fusion for large joints affected by neuroarthropathy?

Harm

4. What are the complications of fusion and total joint arthroplasty?

Question 1: How accurate is the clinical and radiographic examination in the diagnosis of Charcot neuroarthropathy?

Case clarification

This 55 year old woman presented with a warm, effused knee in valgus alignment which was accentuated during her unstable gait. Radiographs showed complete lateral compartment joint space loss with bone fragmentation and debris within the synovium. Marked (45°) clinical valgus malalignment was noted in stance without the valgus unloading brace.

Relevance

Because of its rarity, delay in diagnosis is one of the common problems when dealing with patients with neuroarthropathy. Commonly, once presented to the orthopedic surgeon,

the disease is markedly advanced, beyond nonoperative treatment. In fact, up to 25% cases of Charcot neuroarthropathy are missed.

Current opinion

It is not surprising that Charcot neuroarthropathy is commonly missed since the presentation can be confused with cellulitis, rheumatoid arthritis, and advanced osteoarthritis. Attention to a detailed history, the extent of disease progression, and radiological appearance should alert one to the diagnosis. The patient commonly presents with a hot, swollen joint (typically more than 2°C warmer than the opposite limb), relatively little pain considering the extent of disease, and deformity. Radiography reveals an advanced degenerative joint with fragmentation and joint line collapse. Commonly there is bony debris within the synovium with associated stress fractures or joint line subluxation. Abutting articular bone may show signs of osteonecrosis.

Findings

Despite the lack of high-quality data, a retrospective descriptive study of 24 patients with tabes arthropathy was performed from 1983 to 2003.¹⁵ Their inclusion criteria were typical radiological findings and positive syphilitic serology in blood and/or synovial fluid and/or cerebrospinal fluid. Fifteen men and nine women with mean age of 53.71±12.25 years were included, with the delay in diagnosis being 36.83±53.03 months. Overall clinical, biological, and radiological characteristics were described.

They found most patients presented with a single painless, swollen, and deformed joint with significant crepitations. Peripheral neuropathy was found in 29% patients. Loosening of periarticular soft tissues and bone destruction both lead to articular subluxation.¹⁵ Most patients have symptoms that are much milder than would be expected on the basis of radiological findings.

Typical radiological findings include joint destruction, disorganization, and effusion with osseous debris. Additionally, subchondral sclerosis, osteophytosis, subluxation, and soft tissue swelling are also typically seen.¹⁶

A prognostic level II paper showed that in 44 of 547 patients with hereditary sensory and autonomic neuropathies type III, osteonecrosis is the initial lesion preceding destructive arthropathy. Osteonecrosis and osteochondral fragmentation were always isolated at the distal posterior lateral femoral condyle in the knee.¹⁷

The differential diagnosis of the neuropathic joint includes infection, osteonecrosis, calcium pyrophosphate dihydrate crystal deposition disease, psoriatic arthritis, osteoarthritis, and osteolysis with detritic synovitis. Advanced imaging combined with physical examination may help differentiate.^{15,16,18}

Recommendations

- Clinical manifestations of this disorder classically include gross deformity, crepitus, lack of proprioception, warm joint with an effusion, and decreased awareness of pain in the affected joint [overall quality: low]
- Radiological findings include joint destruction, disorganization, effusion with osseous debris, subchondral sclerosis, osteophytosis, subluxation, and soft tissue swelling [overall quality: moderate]

Question 2: What is the role of nonoperative treatment for the Charcot joint?

Case clarification

Our 55 year old patient with spina bifida had noticed some improved stability in an unloader brace which became less effective over time as the deformity progressed. Given her relatively young age and productive lifestyle, the utility of nonoperative treatment provided relative short-term benefit.

Relevance

Generally, patients diagnosed with neuroarthropathy are younger and concern is typically raised about the longevity of operative treatment. As such, optimizing non-operative treatments, especially early in the disease is beneficial to delay operative treatment as long as possible.

Current opinion

Optimizing nonoperative treatment is beneficial primarily in early stages of the disease. Unfortunately, many of these patients present with advanced disease.

Findings

Extremely poor (level V) evidence, exists for nonoperative treatment for the neuropathic joint. This is likely due to the delayed presentation to the orthopedic surgeon.²⁻⁶ During the early stages, conservative treatments, such as bracing and protective weightbearing, are effective. It has been stressed that early recognition and conservative treatment may alter the course of the disease.^{19,20}

Recommendation

- Bracing and protective weightbearing may be effective early in the course of the disease [overall quality: very low]

Question 3: Is arthroplasty better than fusion for large joints affected by neuroarthropathy?

Case clarification

Having failed nonoperative treatment with progressive functional decline, our patient elected to proceed with a surgical alternative. Given her advanced disease and severe

instability and deformity, both knee arthrodesis and total joint arthroplasty were discussed.

Relevance

The goals of surgery are to achieve patient satisfaction through relieving pain, correcting deformity, and improving function. This must be weighed against the risks and complications relating to the surgical intervention.

Operative treatments on the neuropathic joint have resulted in high complication rates. A few case series have reported complications in up to 47% of cases treated with total knee arthroplasty (TKA).^{8,9} Similar high complication rates are seen in knee arthrodesis for this problem with a high incidence of nonunion.^{4,5,21} Arthrodesis, if successful, can yield a long-term durable result, but patient satisfaction and function remain poor.²² This must be weighed against the improved patient satisfaction and function from a TKA that may ultimately fail and require revision surgeries and more potential future risk.^{8,9}

Current opinion

There remains limited use for arthrodesis as joint implants improve with time. The increased patient satisfaction and continued knee range of motion (ROM) and ability to maintain arthrodesis as the fallback plan strengthen the arthroplasty decision. With meticulous ligamentous balancing, bony alignment, augmentation of bony defects, selection of appropriate prosthesis, and patient compliance, TKA is the current preferred surgical intervention.

Findings

At present there are no comparative trials to solve this question definitively. Historically, arthrodesis was the surgical treatment for the neuropathic knee joint.^{2,4,5} However, the results were variable and solid arthrodesis was difficult to obtain. It was emphasized that a successful arthrodesis was promoted by adequate bone resection, complete synovectomy, and rigid internal fixation.^{4,5,21} This procedure had a wide spectrum of results and a relatively small number within each series, not lending itself to the conclusive treatment.

No randomized controlled trials (RCTs) or prospective studies exist to date. The best available evidence stems from a retrospective review of 40 condylar TKAs in 29 patients with 7.9 years of clinical and 6.4 years of radiographic follow-up. They found a significant improvement in the Knee Society pain and function scores and ROM after TKA.⁹

Due to increased complexity of bone loss and ligamentous attenuation or incompetence resulting in instability, it may become necessary to place a more constrained prosthesis or stems. Proper arrangements must be made prior to beginning any surgical intervention to make sure reconstruction prostheses are available.^{2,5,8,9} The key to successful

TKA in the neuropathic joint is to achieve adequate post-operative stability.

Earlier reports have emphasized the importance of surgical timing in the treatment of the Charcot joint. Osteolysis and bone destruction must have ceased and bone reconstruction or coalescence must have begun prior to surgical intervention.⁴ Difficulty exists, however, when attempting to categorize radiographs into distinct presentations, since fragmentation, destruction, and coalescence often exist simultaneously.⁹ Controversy as to the timing of intervention therefore still remains.

Recommendation

- Total joint arthroplasty is the current preferred method of treatment for neuropathic joint arthropathy [overall quality: moderate]

Question 4: What are the complications of fusion and total joint arthroplasty?

Case clarification

Our patient was informed of the potential consequences of all treatments. She discounted nonsurgical treatment because of her desire for improved mobility and pain relief while she remains relatively young. She chose surgery, with the understanding that it may result in a complication and potential for loss of function later in life. The reality is that an above-knee amputation is a possible outcome with or without treatment in this individual's lifetime, and she has accepted this possibility prior to embarking on a surgical treatment.

Relevance

Medicine is a continuous balance between benefit and harm. Without a clear understanding of these complications weighed against the potential benefits, appropriate decisions cannot be made.

Current opinion

Charcot joint arthropathy of the knee is a devastating problem, with the potential for a poor outcome with or without surgery. With this in mind, both patient and surgeon accept a higher tolerance for risk in the hopes of achieving a better outcome, even if it has limitations. When given the choice between no surgery, arthrodesis, and arthroplasty, with complications and functional outcomes discussed for each, patients invariably choose arthroplasty.

Findings

No adequate studies exist that adequately document the complications after operative (TKA or arthrodesis) fixation of a neuropathic joint. Only expert opinions and case reports (level V) discuss the complications. For fixation by

arthroplasty these include aseptic loosening, further collapse, infection, progressive ligamentous instability, and periprosthetic fractures.^{4,5,9} Complications of knee arthrodesis include nonunion, malunion, infection, shortening, and loss of fixation.^{2,5,21}

Although not commonly reported, advancing to a more highly constrained prosthesis is possible.⁹ If continued instability exists despite trying to achieve a stable joint, arthrodesis, despite being much more difficult, can be considered at a later stage.⁹

Overall, patients treated with arthrodesis do not function well long term. In fact, a level III retrospective study with a small sample population of 15 patients with average follow-up of 7 years showed overall decreased functional status compared with comparable age group norms by SF-36 score. Patients treated with arthrodesis did significantly worse with regard to physical functioning, physical role, bodily pain, vitality, and social functioning. A second retrospective study observed 29 patients at an average of 48 months with arthrodesis secondary to infected TKA. They found 28% of the patients who achieved fusion complained of pain in the fused knee, 16% remained nonambulatory, and 68% required some sort of walking aid.²³

Recommendations

- Complications of TKA include aseptic loosening, further collapse, infection, progressive ligamentous instability and periprosthetic fractures (overall quality: low)
- Complications of arthrodesis include nonunion, malunion, infection, shortening, and loss of fixation (overall quality: low)

Summary of recommendations

- Clinical manifestations of this disorder classically include gross deformity, crepitus, lack of proprioception, joint effusion, calor, and decreased awareness of pain in the affected joint
- Radiological findings include joint destruction, disorganization, effusion with osseous debris, subchondral sclerosis, osteophytosis, subluxation, and soft tissue swelling
- Bracing and protective weight bearing may be effective early in the course of the disease
- Total joint arthroplasty is the current preferred method of treatment for the neurogenic joint arthropathy
- Complications of TKA include aseptic loosening, further collapse, infection, progressive ligamentous instability and periprosthetic fractures
- Complications of arthrodesis include nonunion, malunion, infection, shortening, and loss of fixation

Conclusion

Owing to the extreme lack of high-quality literature, many questions remain unanswered or poorly answered. Due to the rarity of this condition, an RCT would likely be difficult. However, strong case-control or cohort studies may be appropriate and attainable. As such, more research within this area needs to be performed.

Our 55 year old patient with spina bifida did in fact elect to proceed with a TKA. Despite preparing for either a TS or rotating hinged prosthesis, a well-balanced knee was achieved allowing full ROM and adequate static stability using a PS knee prosthesis. The MCL and LCL were both competent and intact, and minimal constraint was chosen to reduce stress at the bone fixation interface and improve implant longevity. This will allow for more constraint if future revision is required. Our patient is currently happy with her short-term outcome.

Cemented vs. Uncemented Stems in Revision Knee Arthroplasty: Indications, Technique, and Outcomes

Gerard M.J. March and Paul R. Kim

University of Ottawa, Ottawa, ON, Canada

Case scenario

An 82 year old woman presents with a painful cemented primary total knee arthroplasty (TKA) done 10 years ago for osteoarthritis. Radiographs show tibial and femoral component loosening with loss of medial tibial bone stock and osteolysis (Figure 27.1).

Importance of the problem

The use of stemmed components in revision TKA surgery has been well established. Stems can aid in diaphyseal referencing which is thought to improve mechanical alignment intraoperatively in addition to offloading stress on damaged or absent metaphyseal bone.¹⁻⁹ The optimal fixation method of these stemmed components is still not established. A press-fit stem has the theoretical advantage of reduced bone loss with component insertion and provides for ease of extraction if this becomes necessary. The primary concerns with uncemented stems include a lack of long-term fixation, increased incidence of malalignment, and an increased incidence of clinically significant stem-tip pain.^{10,11} Fully cemented stems have a good long-term clinical track record, but potential difficulty with future extraction is a major downside to their use.^{9,12,13} Presently cemented fixation of a stemmed revision prosthesis is considered the gold standard.^{9,12,13} Hybrid fixation with

cemented articular components and a press-fit uncemented stem has gained increasing use recently. This chapter reviews the available literature regarding revision TKA with a focus on the use of cemented vs. uncemented stemmed components.

Top three questions

1. What are the advantages and disadvantages of uncemented revision components?
2. What are the advantages and disadvantages of hybrid revision components?
3. What are the advantages and disadvantages of cemented revision components?

Question 1: What are the advantages and disadvantages of uncemented revision components?

Relevance

Further interest in uncemented components has increased in recent years with the advancement of foam metal technology. These implants are made of elemental tantalum or titanium and are highly porous to allow for significant bio-interlock. Foam metal has a modulus of elasticity similar to cancellous bone, allowing for physiological transfer of force and stress from implant to the periprosthetic bone interface. In 2008, Meneghini et al. showed early results of

Figure 27.1 Preoperative radiographs (a, AP; b, lateral) demonstrating a loose primary TKA with significant loss of both tibial and femoral bone stock:

a porous tantalum cone used for severe metaphyseal bone stock deficit. Results were considered successful in all 15 revision TKAs, but the average follow-up was only 34 months (range 24–47).¹⁴ These components may help to decrease bone loss during insertion, lead to stable long-term fixation, and have predictable bony ingrowth with a reduction of proximal stress shielding.¹⁵

Finding the evidence

- PubMed: (www.ncbi.nlm.nih.gov/pubmed): clinical queries and systematic review search using keywords: “total knee replacement revision uncemented”

Quality of the evidence

None of the evidence was higher than level III.

Findings

End-of-stem pain can occur with both cemented and uncemented stems. Methods to reduce stem stiffness with fluting or slots have been undertaken by most manufacturers to try to minimize stem-tip pain. So far there are no clinical results comparing these types of stems to nonfluted stems with respect to stem-tip pain. In 1999, Barrack et al. reported a retrospective review of 80 consecutive revision TKAs. With a minimum follow-up of 2 years they reported localized pain at the end of the stem in 11% of uncemented femurs and 14% of uncemented tibias.⁶ It was also noted that end-of-stem pain does not seem to be eliminated completely by the use of a cemented prosthesis.⁶

Concerns about proximal stress shielding remain, especially if the stem is well fixed distally. Presently, highly polished titanium alloy stems are used to reduce the possibility of osteointegration.¹⁶ The cylindrical smooth stem is used for prosthesis positioning and stability only. Axial load transfer occurs mainly proximally and not through the

stem itself.^{13,17,18} There is also no definitive answer on optimal stem size relative to the endosteal canal. Canal-filling stems would seem to provide better initial stability and alignment compared to thin dangling stems, but long-term concerns with proximal stress shielding remain with canal-filling stems.^{19–21}

Theoretical concern exists with greater access areas for polyethylene wear debris to enter the metaphyseal bone compared to a cemented implant.¹² It is thought that cement offers an immediate barrier to third-body debris that is absent with an uncemented prosthesis. This is especially concerning if one considers that increased levels of constraint (and hence polyethylene wear) are commonly needed in revision TKA surgery. The presence of radiolucent lines and its potential association with loosening also remains a concern with uncemented prostheses.²¹

It has been demonstrated that establishing secure initial stability is crucial when trying to encourage biological interlock. Minimal tolerances of micromotion must exist if true osteointegration is to occur.^{22,23} Porous tantalum metal has the potential for greater bony ingrowth (80%) compared to fibre metal coatings (50%). However, it is postulated that the rate of fixation or time to secondary stabilization is more important to long-term clinical outcome.²⁴ Finally, a long uncemented stem will not be useful in all deformities. The basis of press-fit stability is reliant upon complete canal fill in cases with significant proximal bone loss. This process can be disrupted by deformities that affect the diaphysis of either the femur or tibia.²⁵

An uncemented total knee revision technique offers several advantages, including endosteal referencing and subsequent stabilization of the construct without the difficulty of future extraction compared to cemented stems. Reported results with uncemented components in revision

TKA have been good in the short term.²⁶ However, no long-term results have been published.

Recommendations

- In the setting of severe bone loss, cement augmentation may be less than ideal. Uncemented TKA in these situations is an attractive option with published results^{14,27,28} [overall quality: low]
- Application of foam metal technology to revision TKA is in its early stages. It is hoped that the use of these metals in the setting of uncemented revision knee surgery will lead to stable long-term fixation and a reduction of proximal stress shielding. This is dependent upon reliable bony ingrowth^{14,15} [overall quality: low]
- It has yet to be characterized if an uncemented prosthesis is more or less susceptible to third-body-induced osteolysis. This remains a theoretical concern for the long-term clinical outcome of uncemented revision procedures¹² [overall quality: low]
- For long-term stable fixation of uncemented components, biological interlock is a necessity. In order for this to occur, initial press-fit stability must be achieved, otherwise fibrous ingrowth will occur ensue secondary to micromotion.^{12,22} This is a concern with uncemented components in revision TKA²⁴ [overall quality: low]

Question 2: What are the advantages and disadvantages of hybrid revision components?

Finding the evidence

- PubMed: (www.ncbi.nlm.nih.gov/pubmed): clinical queries and systematic review search using keywords: "total knee replacement revision hybrid fixation"

Quality of the evidence

None of the evidence was higher than level III.

Findings

Early work by Bertin et al. introduced smooth uncemented intramedullary stems with cemented tibial components. The polymethylmethacrylate bone cement replaced small surface defects and afforded immediate stable fixation.^{7,29} Bertin reviewed 53 revision TKAs with an average follow-up of 18 months. There were no radiographic failures and they found no evidence of progressive radiolucent lines near the prosthesis or the bone–cement interface.⁷ Parsley et al. showed in a 2003 retrospective study that tibial AP alignment was more predictable with long canal-filling cementless stems.³⁰

Gofton et al. published a review of 89 revision TKAs completed with a hybrid fixation technique. The results showed survivorship of 93.5% at 8.6 years.⁴ They found the rate of aseptic loosening either clinically or radiographically in this patient group matched previously published

results. In 1995 Vince et al. reported on a series of 44 revision TKAs. Of the 13 patients who needed a constrained articulation due to intraoperative instability, 3 failed. No patients with a nonconstrained insert showed signs of failure at the time of final review (range 2–6 years).²⁹

Wood et al. in 2009 reported on 135 revision TKAs using a press-fit hybrid technique. Kaplan–Meier survivorship analysis calculated a 13% revision rate at 12 years.³ Use of antibiotic-impregnated cement is a common stated advantage to the fully cemented stem technique. In this retrospective review of hybrid press-fit stems, there was no increase in the rate of septic loosening with uncemented stems.³ Barrack et al. published a retrospective review of 80 consecutive revision TKAs. They reported their early results showing no radiographic or clinical sign of loosening. The majority of patients received hybrid fixation but 16 (20%) had fully cemented tibial components based on surgeon discretion.⁶

Bottnar et al. reported on 33 revision TKAs completed with hybrid fixation with an average follow-up of 38 months. They had a revision rate of 9.1%.³¹ Concerns were raised regarding the ability to gain appropriate fixation in the face of poor bone quality, which is commonly found in revision knee arthroplasty. Loss of cortical contact by the tibial tray can increase strain across the proximal tibia by up to 60%. It has been reported that a cemented long intramedullary stem can reduce the axial load to the tibia plateau by up to 38%.² Despite the acceptable outcome in this series of hybrid fixation revision knees, they recommended that fully cemented stems be considered in scenarios of severe bone loss with increased strain to the periarticular region.¹¹

Haas et al. reviewed 76 revision TKAs from 1980–1989 completed with a press-fit stem hybrid technique.³² They felt that fluted or splined press-fit stems would offer an alternative to cementation in the situation of poor proximal bone stock. A failure rate of 7.9% was reported at an average of 42 months follow-up. In 2005, Peters et al. reviewed 50 revision press-fit TKAs at an average of 36 months.³³ Despite good results the authors stated that at that time there was no evidence that the press-fit method provided durable long-term fixation.

In 2003 Shannon et al. presented a retrospective review of 63 revision TKAs with a mean follow-up of 5.75 years. They reported a relatively high failure rate of their hybrid fixation components. Twelve knees (19%) failed, of which half were revised a second time for aseptic loosening.³⁴ Nonprogressive radiolucencies were also found in over 90% of the surviving prostheses but had no effect on clinical outcome. A further 10 knees (16%) were deemed at risk for failure based on radiographic signs.³⁴

The hybrid fixation technique was developed out of a desire to avoid bone loss associated with revision of a fully cemented stem. The cemented articular prosthesis is able to accommodate minor bony defects at the revision

surface.^{7,29} The uncemented stem attempts to achieve press-fit stabilization within the diaphysis.^{32,33} Results in the literature show that the hybrid technique is able to achieve immediate and stable fixation of the prosthesis.³⁴ It appears that in the properly selected patient, one with adequate bone stock and minimal diaphyseal deformity, the hybrid technique is a viable option. Long-term studies have yet to be completed, thus the question of hybrid fixation longevity remains outstanding.³³

Recommendations

- The cemented articular prosthesis in a hybrid technique is able to achieve immediate and stable fixation. Additionally, small bony surface defects are easily dealt with by a cemented articular prosthesis^{7,29} [overall quality: low]
- Short-term clinical review show the hybrid technique has a high percentage of good to excellent outcomes and universal improvement to Knee Society scores^{3,4,6,7,11,32,33} [overall quality: low]
- Published reviews of hybrid technique revision TKAs included selection bias. Cases not deemed appropriate in terms of bone stock were treated with a fully cemented prosthesis. Selection criteria for full cementation include low-demand patients, large canals, diaphyseal deformity, or severe loss of bone stock^{3,6,11} [overall quality: low]
- Despite good short-term outcomes of hybrid fixation, the longevity of this construct cannot be clarified at this point in time because of a lack of long-term studies [overall quality: low]

Question 3: What are the advantages and disadvantages of cemented revision components?

Current practice

Proponents of fully cemented fixation are supported by the successful published long-term results of cemented tibial components in primary knee arthroplasty. The use of cement has an important advantage of offering stable and immediate fixation.^{26,35,36} Additionally, cemented fixation is able to distribute load evenly across the prosthesis to the available bone stock thereby preventing point stress shielding.

Finding the evidence

- PubMed: (www.ncbi.nlm.nih.gov/pubmed): clinical queries and systematic review search using keywords: "total knee replacement revision cemented"

Quality of the evidence

None of the evidence was higher than level III.

Findings

In 1994, Murray et al. published on 40 cemented long-stemmed kinematic stabilizer revision TKAs.⁵ No revisions

were performed for mechanical loosening. The early incidence of radiolucent lines was high (32%) but progression was not seen.⁵ In 2007 Mabry echoed the concern of stress shielding with cemented stems in revision TKA. This retrospective review of 70 fully cemented revision TKAs showed a 10-year survivorship of 92%.²⁶

In an attempt to directly compare stem fixation in revision TKA, Fehring in 2003 presented a retrospective review of 475 revision TKAs completed from 1986 to 2000. They identified 113 cases with 202 metaphyseal engaging stems. Of these, 107 were fully cemented and 95 had press-fit fixation.³⁷ The choice of cemented vs. cementless technique was not randomized but remained at the discretion of the treating surgeon. The authors showed that implants with fully cemented fixation appeared radiographically more stable.³⁷ Of the cemented population, 93% were found to be stable, 7% required close follow-up, and none were found to be overtly loose. By comparison, in the uncemented population, 71% were classified as stable, 19% required close follow-up due to possible loosening, and 10% were documented as being loose. The uncemented stems had a re-revision rate for aseptic loosening of 4% while the cemented group had no such cases. They concluded that cemented metaphyseal stemmed components were more stable than their uncemented counterparts ($p = 0.0001$).³⁷

Biomechanical data has also shown support for cemented stem fixation. In 1997, Stern et al. submitted cadaveric tibial base plates to axial and eccentric loading cycles. They compared cemented to cementless specimens documenting micromotion and evidence of subsidence. Results showed that for all configurations of stem length and loading pattern tested, the cemented components showed significantly less micromotion and migration when compared with an uncemented component.³⁸ In 2001, Jazrawi et al. investigated 12 cadaveric tibial base plates under central, varus, and valgus loading conditions. They were able to show a statistically significant improvement in stability with 75mm and 150mm cemented stems when compared to their uncemented press-fit counterparts.

Despite reservations about stress shielding and stress riser formation, the literature supports the use of fully cemented stemmed components as a stable and durable construct. The lack of randomized trials comparing these two fixation methods presents a challenge for selection of implant technique. It is clear that the fully cemented option has shown favourable survivorship in the long-term. Cadaveric experiments indicate reduced micromotion with cemented stemmed components compared to their uncemented counterparts.^{38,39} Despite the acknowledged difficulty with component extraction if the need for re-revision arises, cemented stemmed components remain the gold standard in revision TKA.

Recommendations

- Apprehension with the use of fully cemented stems due to concerns regarding stem length stress shielding and stem-tip stress riser formation have not been confirmed with currently published retrospective reviews. The major concern with fully cemented stems is the difficulty with later extraction if necessary^{5,26} [overall quality: low]
- In a retrospective comparison of cemented and uncemented metaphyseal engaging stems, the cemented group had better radiographic stability and less revisions for aseptic loosening (0 vs. 4%) compared to the uncemented stem group³⁷ [overall quality: low]
- A 2003 retrospective review of 38 fully cemented revision TKAs showed component survivorship of 96.7% at 10 years indicating that cemented stemmed revision TKA offers reliable long-term fixation³⁴ [overall quality: low]
- Biomechanical data in cadaveric studies support the stability of fully cemented stemmed tibial components^{38,39} [overall quality: low]

Case scenario continued

The patient was diagnosed with aseptic loosening and underwent revision TKA. Fully cemented stemmed components with metal augmentation were used because of the significant loss of tibial and femoral bone stock (Figure 27.2).

Summary of recommendations

- In the setting of severe bone loss, cement augmentation may be less than ideal. Uncemented TKA in these situations is an attractive option with published results^{14,27,28}

Figure 27.2 Postoperative radiographs (a, AP; b, lateral) showing a revision TKA utilizing a fully cemented stem technique on both the tibial and femoral sides.

- Application of foam metal technology to revision TKA is in its early stages. It is hoped that the use of these metals in the setting of uncemented revision knee surgery will lead to stable long-term fixation and a reduction of proximal stress shielding. This is dependent upon reliable bony ingrowth^{14,15}
- It has yet to be characterized if an uncemented prosthesis is more or less susceptible to third-body-induced osteolysis. This remains a theoretical concern for the long-term clinical outcome of uncemented revision procedures¹²
- For long-term stable fixation of uncemented components, biological interlock is a necessity. In order for this to occur, initial press-fit stability must be achieved, otherwise fibrous ingrowth will occur ensue secondary to micromotion.^{12,22} This is a concern with uncemented components in revision TKA²⁴
- The cemented articular prosthesis in a hybrid technique is able to achieve immediate and stable fixation. Additionally, small bony surface defects are easily dealt with by a cemented articular prosthesis^{7,29}
- Short-term clinical review show the hybrid technique has a high percentage of good to excellent outcomes and universal improvement to Knee Society scores^{3,4,6,7,11,32,33}
- Published reviews of hybrid technique revision TKAs included selection bias. Cases not deemed appropriate in terms of bone stock were treated with a fully cemented prosthesis. Selection criteria for full cementation include low-demand patients, large canals, diaphyseal deformity, or severe loss of bone stock^{3,6,11}
- Despite good short-term outcomes of hybrid fixation, the longevity of this construct cannot be clarified at this point in time because of a lack of long-term studies³³
- Apprehension with the use of fully cemented stems due to concerns regarding stem length stress shielding and stem-tip stress riser formation have not been confirmed with currently published retrospective reviews. The major concern with fully cemented stems is the difficulty with later extraction if necessary^{5,26}
- In a retrospective comparison of cemented and uncemented metaphyseal engaging stems, the cemented group had better radiographic stability and less revisions for aseptic loosening (0 vs. 4%) compared to the uncemented stem group³⁷
- A 2003 retrospective review of 38 fully cemented revision TKAs showed component survivorship of 96.7% at 10 years indicating that cemented stemmed revision TKA offers reliable long-term fixation³⁴
- Biomechanical data in cadaveric studies support the stability of fully cemented stemmed tibial components^{38,39}

Conclusions

Stemmed components are the implant of choice in revision TKA. The type of stem fixation continues to remain contro-

versial. Direct comparisons of fixation methods are rare, and choice of technique is left to an analysis of retrospective reviews complemented by biomechanical results from cadaveric experiments.

On the basis of available data, we recommend the use of a hybrid cement technique in the optimal patient where press-fit stemmed components are appropriate. This is contingent upon the presence of adequate periarticular bone stock (cortical/metaphyseal) allowing for successful cementation of the articular portion of the prosthesis. Overall alignment and component stability are supplemented with the use of an uncemented stem which is canal filling. Surgeon discretion should be used to identify patients better suited for a fully cemented technique. Patients with large intramedullary canals, diaphyseal deformity, or severe bone loss would be better served with a cemented component which includes a cemented stemmed component. The choice of stem length for cementation depends on available proximal bone stock and the possibility of future revision surgery. Our recommendation is to cement the shortest stem possible, as this avoids loss of bone stock and may make future revision surgery easier if component extraction becomes necessary. Use of a cement restrictor and having an adequate cement mantle around the stem are recommended technical points for this technique.

Management of Structural Defects in Revision Knee Arthroplasty: Femoral Side

Sandor Gyomory¹, Paul T.H. Lee², and David J. Backstein³

¹William Osler Health Center, Etobicoke General Hospital, Toronto, ON, Canada

²The Royal Orthopaedic Hospital, Birmingham, UK

³Mount Sinai Hospital, Toronto, ON, Canada

Case scenario

An active 69 year old man with history of remote right total knee arthroplasty (TKA) presents with increasing right knee pain and instability. On examination, the right knee is unstable to varus and valgus forces with good range of motion (ROM). The neurovascular examination is normal.

Importance of the problem

Among the major challenge of revision TKA is assessment and restoration of bony defects. Bone loss is often classified according to the Anderson Orthopaedic Research Institute (AORI) bone defect classification (Table 28.1).¹

Defects may be characterized as contained or uncontained. *Contained defects* may be cavitory or central, representing loss of cancellous bone with intact cortical rim. *Uncontained defects* represent cancellous bone loss in addition to significant loss of surrounding supportive cortical bone. Uncontained defects may be *segmental*, involving the medial or lateral side of the femur, or *circumferential*, involving the entire bone.²

For patients with endstage knee arthritis, TKA is a common and successful procedure with 90% survivorship at more than 15 years follow-up.³⁻⁵ It is estimated that from 1996 to 2030 the number of TKAs will increase by 85%, raising the annual rate to almost 500,000 in the United States.⁶ The number of revision TKAs is also on the rise.⁷⁻⁹ In 1995, 19,138 revision TKAs were performed in the US.¹⁰ Coyte et al. estimated an annual increase of 14.1% for primary TKA and 19.3% for revision TKA.¹¹

In the US the yearly costs for arthroplasty procedures are estimated at \$10 billion.¹² A primary TKA has been estimated to cost \$11,826, whereas a revision TKA cost nearly double that at \$21,888.^{12,13} Revision TKA requires longer operating times, costlier implants, additional materials, longer hospital stays, and longer periods of convalescence; it also has higher complication rates.¹⁴

Unfortunately, outcomes and success rates of revision TKA are not comparable with those for primary TKA.^{15,16} Structural bone defects commonly contribute to the complexity of revision TKA.^{17,18} The major etiologies of bone loss being: aseptic loosening, infection, osteolysis, stress shielding, wear and implant loosening.^{19,20}

Top five questions

Diagnosis

1. How effective are radiographs and CT scans in assessing defect size?

Therapy/prognosis

2. How can smaller defects be managed?
3. How can large uncontained defects be managed?
4. What is the role of tumor prostheses in the treatment of massive defects?

Future direction

5. What is the role of trabecular metal in the treatment of defects?

Table 28.1 AORI classification of bone defects

AORI type	Characteristic	Treatment
1	Intact structural bone (contained, minor defect): good cancellous bone at or near a normal joint-line level not compromising implant stability	Cement or morselized bone graft
2	Deficient structural (noncontained) bone: bone damage with loss of cancellous bone, which requires the use of cement fills, augments, or small bone grafts to restore the joint line	<5 mm: cement >5–10 mm: augmentation and bone grafts may be required
3	Severe structural (noncontained) bone loss with ligamentous instability: deficiencies that compromise major portion of either condyle with associated ligamentous dysfunction	Femoral defects >10–20 mm: A custom or stemmed (collateral constrained) component with a structural allograft is required or allograft-prosthesis composite

Question 1: How effective are radiographs and CT scans in assessing defect size?

Case clarification

Although radiographs demonstrate the process of osteolysis, CT scans are more effective in demonstrating the extent of the defect, as seen in Figure 28.1 and Figure 28.2.

Relevance

Delineating the extent of osteolysis is essential for proper planning and management.

Current opinion

A thorough clinical assessment is essential prior to surgery to evaluate the patient's health status, with possible consultation from Internal Medicine and Anesthesia. The operative site is assessed for previous incisions and potential wound complications and work-up for infection is performed using blood work, imaging, and possibly joint aspiration.

Component loosening and position and degree and location of bone loss should be assessed with radiography and CT. The reason for failure should be established and a management plan formulated.

Figure 28.1 Representative radiographs of a 69 year old man with osteolysis around TKA implants. (a) AP and (b) lateral radiograph of TKA with femoral bone loss secondary to osteolysis.

Finding the evidence

- PubMed: search terms “osteolysis,” “radiographic,” “evaluation,” “total knee arthroplasty”

Quality of the evidence

Level II

- 1 prospective study²¹
- 1 cadaveric study²²
- 2 retrospective studies^{23–25}

Findings

Assessment of bone loss using routine radiographs is known to lead to underestimation and further imaging should be obtained including oblique views or CT to achieve reasonable prediction of defect size (Figures 28.1, Figure 28.2).^{21–24} Agreement between plain radiographs and intraoperative assessment of bone loss has been shown to be fair, based on the AORI classification.²² Also, in an analysis of 31 patients who had osteolytic lesions confirmed by multidetector CT, plain radiography detected only 17% of lesions.²⁵

Recommendation

- Although plain radiographs can aid in the assessment of osteolysis, CT scans should be performed for more accurate delineation of defect size and location [overall quality: moderate]

Question 2: How can smaller defects be managed?

Case clarification

The defects seen in Figure 28.1 and Figure 28.2 appear to be a combination of contained and uncontained defects

Figure 28.2 CT scan showing femoral bone loss due to osteolysis on cross-sectional imaging in the same 69 year old patient. Representative (a) sagittal, (b) coronal, and (c) axial images showing degree of bone loss.

and may require more than just cement or bone graft for stabilization.

Relevance

Defect size and character will determine the method of reconstruction for achievement of a stable joint.

Current opinion

Few studies report on treatment of femoral defects in TKA (Table 28.2). Contained defects are generally simpler to manage. Small contained defects can be addressed with impacted morselized bone graft or cement. Although the primary function of cement is to supply component fixation, small defects (<5 mm) may be filled with cement.^{26,27} Cement provides inferior load transfer with poor fatigue properties,²⁸⁻³⁰ however, and bone grafting is preferable to cement augmentation because of its biological advantage.^{31,32}

Finding the evidence

- PubMed: search terms “osteolysis,” “femoral,” “defect,” “small,” “revision,” “treatment,” “total knee arthroplasty,” “augmentation,” “bone grafting”

Quality of the evidence

Level II

- 3 prospective studies^{32,35,36}
- 3 retrospective studies^{31,38,39}
- 1 case report³⁴

Findings

The majority of studies assessing patients treated with morselized bone graft are reported in combined series for tibial/femoral reconstruction and report good outcomes.^{2,32-35} Van Loon et al.³⁶ reported on a series of 22 patients treated for femoral defects with bone grafting and advocated the use of impacted morselized bone grafts for

contained and uncontained defects (up to 4–10 cm³) in combination with cemented TKA.

Uncontained defects are more challenging. Small uncontained defects on the femoral side can be managed with metallic blocks or wedges. These metal inlays are fixed to the distal and posterior parts of the femoral component, providing a stable platform for support and allowing for rebuilding of condyles. Uncontained, segmental defects larger than 5 mm can be treated with metal augments; however, most systems have a limit of 20 mm for augment size. Radney et al.³⁷ recommended the use of cement for defects smaller than 5 mm, and metal augmentation for defects 5–10 mm. Hass et al.³⁸ have reported 83% survival at 8 years follow-up of distal femoral augments.

Interestingly, Hockman et al.³⁹ reported on a series of revision TKAs in which modular femoral augmentation was used in 35 knees. They found a trend towards increased failure rates (59%) in knees with less severe bone defects, which were revised with metal augmentation alone. They speculated that this might be a result of reduced surface area for bonding between host bone and implant and secondly due to lack of cancellous bone structure reducing the quality of the cement–bone bond.

Recommendation

- Small contained defects can be addressed with impacted morselized bone graft or cement. Small uncontained defects on the femoral side can be managed with metallic blocks or wedges and may also require bone grafting for a successful outcome [overall quality: moderate]

Question 3: How can large uncontained defects be managed?

Case clarification

As the CT scans (Figure 28.2) indicate, bone grafting and augmentation may not be enough for reconstruction of the

Table 28.2 Treatment of femoral defects in TKA

Study	Number of femurs	Procedures	Level of evidence	Survivorship
Mow et al. ³¹	7 femurs 1 segmental 4 cavitory 2 combined	Cavitory: Femoral head allograft Segmental/combination defects: size-matched allografts were used	Retrospective Level II	80% at 47 mnth

Bauman et al. ⁴⁸	50 femurs uncontained	Allograft-prosthesis composites and large structural allografts: 33 femoral head 17 femoral head and allograft-prosthesis composites	Retrospective Level II	5 yr 80%

femoral defects in the case presented, and other methods of reconstruction may be needed to regain joint stability and function.

Relevance

Large defects are not only difficult to manage intraoperatively, but also present a great challenge with respect to functional outcomes and survival of the construct.

Current opinion

Very large segmental or circumferential uncontained defects may be beyond the capacity of augments and require structural allografts to rebuild a cortical rim to support the femoral component. These can be managed with an allograft–implant composite, which consists of a stemmed femoral component cemented to a corresponding distal femoral allograft. This allograft–implant composite is in turn fixed to host bone via a step-cut, with circlage wires and a bridging strut–allograft in some circumstances.

Finding the evidence

- PubMed: search terms “revision total knee arthroplasty,” “femoral,” “structural allograft,” “outcomes”

Quality of the evidence

Level II

- 2 prospective studies^{41,45}
- 6 retrospective studies^{2,40,42,43,47,48}

Findings

In the short term, good success has been reported with 100% incorporation of structural allograft and improved functional outcomes.⁴⁰ Stockley et al.² showed union of the allograft to host in 16 of 16 cases at an average of 4.2 years follow-up. In the intermediate to long term, Clatworthy et al.⁴¹ reported on treatment of large bony defects with structural allograft and showed that the rate of survival of the allografts was 92% (95% CI 89–95%) at 5 years and 72% (95% CI 69–75%) at 10 years. Similar findings were reported by Ghazavi et al.⁴² on the management of uncontained defects larger than 3cm using massive structural allograft. Their success rate was 77% at a mean of 50 months, with a Kaplan–Meier probability of graft survival at 5 years of 67%. Backstein et al.⁴³ reported satisfactory results after 5 years when using structural allograft in 58 patients with uncontained bone defects which were too large to be reconstructed with metal augments. Radiological allograft–host union was observed in 98%, although allograft-related complications required additional intervention in 21% with one graft nonunion and three graft resorptions. Parks and Engh have reported peripheral new bone formation at 41 months through histological assessment confirming the clinical assessment of graft incorporation.⁴⁴

Using 14 large allografts for reconstruction of massive defects of the distal femur and proximal tibia in failed TKA, Mnaymneh et al.⁴⁵ reported 86% survival at an average of 40 month follow-up. Similar results were reported in treating 15 patients with large segmental, cavitary, or combination defects of the femur and/or tibia with an average follow-up of 47 months showing full incorporation of all allografts.⁴⁶

Engh et al.⁴⁷ reported an 87% excellent to good clinical outcome of solid allografts for the treatment of femoral and/or tibial bone loss at an average of 50 months and suggested the use of stemmed femoral components when large structural allografts are used to protect the graft. More recently Bauman et al.⁴⁸ retrospectively reviewed outcomes of treatment of major bone defects for 74 patients treated with structural allografts and showed revision-free survival of grafts of 80.7% (95% CI 71.7–90.8) at 5 years and 75.9% (95% CI 65.6–87.8) at 10 years with good clinical outcomes.

Recommendation

- Massive bony defects can successfully be managed with structural allografts or allograft-implant composites [overall quality: moderate]

Question 4: What is the role of tumor prosthesis in the treatment of massive defects?

Openmirrors.com Case Clarification

Our patient is 69 years old with an active lifestyle, so reconstructive measures have to focus on regaining his quality of life while keeping in mind the potential need for future revision.

Relevance

The patient’s age, activity level, and health status play an important role in the choice of reconstructive method to optimize quality of life.

Current opinion

An alternative management option for massive distal femoral bone loss is distal femoral replacement with so-called “tumor prostheses.” These devices provide immediate ligamentous and bony stability without the need for bone graft ingrowth. However, a high degree of constraint predisposes to early prosthetic loosening, particularly in active patients. It is therefore the authors’ recommendation that distal femoral replacement implants be used for older, more sedentary individuals while allograft–implant composites should be the treatment of choice for younger, more active patients.

Finding the evidence

- PubMed: search terms “revision total knee arthroplasty,” “tumor prosthesis,” “hinged knee,” “outcomes”

Quality of the evidence*Level II*

- 4 retrospective studies^{49–52}

Findings

Jones et al.⁴⁹ reported satisfactory results on 15 patients with a mean follow-up of 3.9 years using a mobile-bearing hinged prosthesis. The mean age at surgery was 63 years. There was no evidence of loosening, and complete bone apposition was seen in nearly all cases. Pour et al.⁵⁰ reported 79.6% survival at 1 year and 68.2% at 5 years with the use of rotating hinged knee implants in 44 cases with a mean follow-up of 4.2 years. The mean patient age at surgery was 71.8 years and the authors cautioned against the use of these prostheses in active or younger patients. Survivorships following megaprosthesis reconstruction of the distal femur are mainly available for patients post tumor surgery and reveal average implant survival of 85% at 3 years, 65% at 5 years, and 45% at 10 years.^{51–52}

Recommendation

- Although proper assessment of bony defects is important when selecting the method of reconstruction, consideration must also be paid to potential future revision on an individual basis, factoring in comorbidities, functional demand, and life expectancy of the particular patient. Thus, restoration of bone stock becomes more important if future revision surgery is more likely [overall quality: moderate]

Question 5: What is the role of trabecular metal in the treatment of defects?**Case clarification**

The defects in the sample case may be amenable to reconstruction using trabecular metal.

Relevance

Recently, encouraging results using new technologies have been utilized in the treatment of large distal femoral bony defects.

Current opinion

The use of trabecular metal may provide a means of structural reconstruction with a biologic advantage, allowing for faster bony ingrowth and reconstitution than structural allografts.

Finding the evidence

- PubMed: search terms “revision total knee arthroplasty,” “new technology,” “trabecular metal,” “cones,” “tantalum”

Quality of the evidence*Level II*

- 1 prospective study⁵³

Findings

Trabecular metal cones, constructed of highly porous tantalum with excellent ingrowth potential, are designed to fill defects. Radney and Scuderi⁵³ reported on the use of nine trabecular metal cones for severe defects in the intercondylar area at the metaphyseal–diaphyseal junction, with a mean follow-up of 10.2 months. The cones provided support for the femoral component and created a base onto which further femoral augmentation could be added. Radiographic evaluation revealed incorporation of the femoral cones into adjacent bone with no evidence of subsidence, change in position, or bone resorption.

Recommendation

- The use of trabecular metal in the reconstruction of femoral defects holds potential solution to the provision of structural support in combination with biologic ingrowth [overall quality: moderate]

Summary of recommendations

- Determination of the extent of femoral defects: CT scans are essential for more accurate delineation of defect size and location
- Treatment of small defects:
 - Small, contained: impacted morselized bone graft or cement.
 - Small, uncontained: metallic blocks or wedges and may also require bone grafting for a successful outcome
- Treatment of large defects: Massive bony defects can successfully be managed with structural allografts or allograft-implant composites
- Use of megaprosthesis to be considered in the low-demand patient with low likelihood of future revision surgery
- Use of trabecular metal may provide a potential solution to the provision of structural support in combination with biologic ingrowth

Conclusions

Massive bone defects are a reconstructive challenge in revision TKA. Management decisions for femoral-sided structural defects must take into account size and degree of containment. Contained defects may be treated using cement filling for very small areas or morselized allografts for larger defects. Most complex to treat are the large uncontained defects, which require structural allograft for reconstruction. Clinical outcomes are not on a level with primary TKA, although evidence suggests that allograft reconstruction has the potential to result in satisfactory

outcomes. The use of megaprotheses should be reserved for patients with a low likelihood for revision surgery. The more active patients may benefit from newer technologies such as trabecular metal augmentation for large defects as an alternate to allograft reconstruction.

Patellar Options in Revision Knee Arthroplasty

Hatem Al-Harbi and Paul Zalzal

McMaster University, Hamilton, ON, Canada

Case scenario

A 75 year old relatively active woman with a right total knee replacement 14 years ago complains of pain and instability in her right knee. She has difficulty ascending and descending stairs, requires a cane for walking, and can only walk for short distances. On examination, the right knee has an effusion and varus and valgus instability.

Relevant anatomy

Revision knee arthroplasty can consist of replacement of some or all of the existing components of a total knee replacement. It can include the revision, excision, or addition of a patellar component. These procedures can be complicated by reduced bone stock. This chapter will focus on the surgical options available for the patella during revision knee arthroplasty.

Importance of the problem

The number of total knee arthroplasties (TKAs) being performed in North America and around the world is increasing at a steady rate.¹⁻³ In addition, TKA is being used to treat endstage osteoarthritis in younger, more active people

compared to a decade ago. Many TKA recipients are still active members of the workforce, while others who may be retired expect to remain active throughout their later years. This combination of an increasing number of procedures and a younger, more active patient population will likely lead to an increased number of revision TKAs being performed, and some patients may require more than one revision in their lifetime. Currently, however, the functional outcome and survivorship of revision TKA are thought to be inferior to those of a primary TKA. In addition, the leading cause of failure of a primary TKA has been shown to be problems with the extensor mechanism.⁴⁻⁶ Therefore treatment of the patella, which is an integral part of the knee extensor mechanism, is an important consideration during revision TKA. A better understanding of options available for the patella during revision TKA may serve to improve functional outcomes and survivorship of these procedures.

Although the patella and extensor mechanism play an important role in primary and revision TKA, there is a paucity of information available in the medical literature regarding how to treat the patella during revision TKA. A PubMed search for "patella and revision TKA" yielded only 47 results. There is little high-level evidence available, making it difficult to guide practice, and most of the review literature available reports on case series and expert opinion.⁷ It is therefore necessary to develop a guide based on the best data available, but the quality of the data must be scrutinized and highlighted.

Top five questions

1. How can patellar problems in a TKA be preoperatively diagnosed?
2. Can an existing patellar implant be left in place at the time of revision TKA?
3. Should an unresurfaced patella be resurfaced during revision TKA?
4. What options are available for the patella in the presence of poor patellar bone stock?
5. Should an isolated patellar procedure be performed in a TKA with a loose patellar component and well-fixed tibial and femoral components?

Question 1: How can patellar problems in a TKA be preoperatively diagnosed?

Case clarification

The patient is complaining of anterior knee pain. Radiographs show the patella has been resurfaced and a lucency is detected at the interface between the patellar cement and the bone.

Relevance

Several options are available for the patella during revision TKA. The key to successful surgical outcome in revision TKA is identifying a clear cause for patient symptoms.⁸ Therefore, it is important to have as much information as possible about the patella before the revision procedure is performed. This can help the surgeon choose which patellar option may be appropriate so that a proper preoperative plan can be achieved and the necessary equipment and components can be made available for the revision procedure.

Current opinion

A thorough history and physical examination with specific attention paid to the patella and the extensor mechanism is required for all patients undergoing a revision TKA. Infection needs to be ruled out if the surgeon is considering keeping a well-fixed patellar component. A full set of radiographs including skyline views should be obtained preoperatively to look for signs of loosening, fracture, and patellar maltracking. Bone scans can also be helpful.

Finding the evidence

• Cochrane, PubMed, and Ovid MEDLINE databases were searched with the following terms: “patella revision,” “loose patella,” “diagnosis of loose patella,” “maltracking patella”

Quality of the evidence

- Level IV: 4

Findings

In order to perform an effective preoperative workup for a patient undergoing a revision TKA, it is important to be cognizant of the possible indications for revising a patella. These include a loose or worn patellar component, malpositioning of the patellar component, maltracking, poor implant design, periprosthetic patellar fracture, and in some cases anterior knee pain. History starts with gathering detailed information from the preoperative, perioperative, and postoperative periods around the initial TKA from the patient and any available medical records and previous operative notes. The physical examination starts with assessing gait, alignment, and extensor mechanism continuity. Palpation of the patella during active range of motion may detect the presence of patella subluxation or dislocation. Preoperative workup should include a complete blood count, C-reactive protein, erythrocyte sedimentation rate (ESR) and a joint aspirate for cell count, Gram stain, and culture which have been recommended for diagnosing prosthetic infection.⁹ Imaging also plays an important role in identifying the etiology of patient symptoms. Features associated with patellar component loosening on radiograph include bone-cement radiolucency, increased bone density, trabecular collapse, fragmentation, and fracture.¹⁰ A CT scan can add valuable information about femoral component rotation which may affect patellar tracking.¹¹

Recommendation

- In order to diagnose patellar problems preoperatively, a thorough history, physical examination, blood work, and radiological workup is required [overall quality: low]

Question 2: Can an existing patellar implant be left in place at the time of revision TKA?

Case clarification

Review of the operative notes of the primary TKA indicate that the patella was resurfaced using a universal dome, all-polyethylene, onset patella. The preoperative radiographs do not suggest loosening of the patellar component.

Relevance

Surgical time, exposure, risk of fracture, and morbidity of revision TKA can be reduced by retaining an existing patellar component. In addition, patellar bone stock is preserved. However, disadvantages of retaining an existing patellar component include the fact that the component may be damaged or a geometric mismatch may occur between the patella and the femoral component, which could lead to increased polyethylene wear and pain.

Current opinion

Current opinion suggests that the majority of arthroplasty surgeons would leave a well-fixed, well-tracking, and well-articulating patella in place at the time of revision surgery.

Finding the evidence

- Cochrane, PubMed, and Ovid MEDLINE databases were searched with the following terms: “patella revision,” “loose patella,” “well-fixed patella,” “metal-backed patella”

Quality of the evidence

- Level IV: 4
- Level V: 1

Findings

The results of patellar component revision have been reported by several authors. Barrack et al.¹² retrospectively compared the results of retention vs. revision of patellar components in 73 knees with a minimum and mean follow-up of 24 and 36 months respectively. In 34 cases a well-fixed and well-positioned patellar component with minimal to no surface damage was retained; 12 of these knees had metal-backed components. The remaining 39 cases involved patellar component revision for reasons such as loosening, wear, osteolysis, and malpositioning. For patients with metal-backed components, revision was undertaken only if the surgeon thought that the remaining bone stock would allow for implantation of another component. Both groups were assessed clinically and radiographically. The authors found no difference between the two groups. Lonner et al.¹³ reviewed a series of revision TKAs that retained the all-polyethylene patella. They reported that 10% of patients had anterior knee pain at an average period of 7.3 years and concluded that retaining a well-positioned, stable all-polyethylene patellar component at the time of revision TKA can be successful, provided that the polyethylene has not oxidized. Manufacturing mismatch is acceptable with most contemporary designs, provided that the patellar component articulates appropriately with the femoral implant.

The type of patellar prosthesis (all-polyethylene vs. metal-backed) is thought to be an important variable. Most of the authors recommend revising the metal-backed prosthesis at the time of revision TKA if possible because of the high failure rates associated with metal-backed patellar components.^{7,14-16}

Recommendations

- If the patella is an all-polyethylene design, well fixed, and articulates well with the revision femoral component it should be left in place [overall quality: low]
- If the patella is of a metal-backed design and there is good bone stock, it should be revised at the time of revision TKA even if it is well fixed [overall quality: low]

Question 3: Should an unresurfaced patella be resurfaced during revision TKA?**Case clarification**

The patient is complaining of anterior knee pain. Radiographs and operative records indicate that the patella was not resurfaced during the initial TKA. Radiographs also suggest minimal joint space narrowing under the patella.

Relevance

There is no consensus in the orthopedic literature regarding whether or not to resurface the patella during primary TKA.¹⁷ Therefore, it is possible to encounter a situation where a patient requires a revision TKA and the patella was not resurfaced. The decision whether or not to resurface the patella at the time of revision needs to be made.

Current opinion

Current opinion suggests that if a patient has anterior knee pain in the presence of a TKA with an unresurfaced patella, going to the operating room for the sole purpose of resurfacing the patella may be of some benefit. If the patient is undergoing revision TKA for another reason, such as loosening of the tibial or femoral components, and the patient is not complaining of anterior knee pain, the patella may be left unresurfaced.

Finding the evidence

- Cochrane, PubMed, and Ovid MEDLINE databases were searched with the following terms: “anterior knee pain,” “unresurfaced patella”

Quality of the evidence

- Level IV: 4
- Level V: 1

Findings

There is very little information in the literature regarding whether or not to resurface an unresurfaced patella during a revision TKA. Deirmengian and Israelite recommend resurfacing an unresurfaced patella during revision TKA, but this appears to be expert opinion only and is not backed by clinical data.¹⁸ However, there is some clinical data available regarding performing a revision procedure for a TKA with an unresurfaced patella and persistent anterior knee pain. Barrack reported on seven patients who underwent a secondary resurfacing of the patella: four of the seven patients continued to experience anterior knee pain.¹⁹ Muoneke et al. reported on 20 patients who underwent a revision procedure to resurface only the patella for anterior knee pain and found that 44.4% reported some improvement.²⁰ Other investigators also reported poor outcome with secondary resurfacing procedures, based on

retrospective reviews.²¹ Karnezis et al. reported significant clinical improvement after secondary patellar resurfacing, however, the results were inferior to primary patellar resurfacing.²²

Recommendation

- If a patient has an unresurfaced patella and anterior knee pain with a TKA and no other etiology for pain, performing a secondary patellar resurfacing may be of some benefit [overall quality: low]

Question 4: What options are available for the patella in the presence of poor patellar bone stock?

Case clarification

Review of the radiographs suggest the patella is loose and the underlying bone stock is extremely poor.

Relevance

Revision of the patellar component in the presence of poor bone stock can be challenging and can lead to poor outcomes. With insufficient bone, it is difficult to achieve good fixation and the risk of patella fracture is increased.

Current opinion

If the bone stock is poor and the patellar component is loose, the component should be removed and patelloplasty should be performed to insure the remaining bone articulates as well as possible with the femoral component without catching or locking.

Finding the evidence

- Cochrane, PubMed, and Ovid MEDLINE databases were searched with the following terms: "patella revision," "loose patella," "poor bone stock," "patelloplasty," "patellectomy," "trabecular metal," "patellar bone graft"

Quality of the evidence

- Level IV: 9

Findings

Available surgical options to treat the bone-deficient patella include patelloplasty, patellectomy (partial or total), the use of a porous metal implant, and bone grafting procedures. Patellectomy has been shown to result in poor functional outcomes with persistent pain, quadriceps weakness, and extensor lag.^{23,24} Patelloplasty usually results in better clinical outcomes than patellectomy. It consists of removing the old implant and using a rongeur or high-speed burr to smooth out the remaining patellar bone. The results are still less than ideal, as shown by generally low knee scores and complications such as patellar maltracking, fracture, and avascular necrosis (AVN).²⁵⁻²⁷ Bone grafting procedures have been described to address poor

patellar bone stock. Two such techniques have shown promising clinical results, possibly due to the restoration of patellofemoral biomechanics and quadriceps function.^{28,29} These techniques appear to be technically demanding and are described by only a few authors. An emerging technology involves the use of a porous metal-backed implant with a polyethylene articulating surface. Early results suggest reasonable clinical results.^{30,31}

Recommendations

- Patelloplasty is an option for treatment of a patella during revision TKA with poor patellar bone stock, however results are not ideal and may be associated with complications [overall quality: low]
- Patellectomy should be avoided due to poor functional outcomes, pain, and extensor lag [overall quality: low]
- Porous metal-backed implants represent a new technology with promising results [overall quality: low]

Question 5: Should an isolated patellar procedure be performed in a TKA with a loose patellar component and well-fixed tibial and femoral components?

Case clarification

The patient is complaining of anterior knee pain. Physical examination revealed an effusion and crepitus with range of motion. Radiographs and a bone scan suggest the tibial and femoral components are well fixed, but the cemented all-polyethylene patella appears to be loose.

Relevance

Extensor mechanism problems are the leading cause for revision TKA. Therefore, the situation may be encountered where the tibial and femoral components are well fixed and the patellar component is loose. Treating the patellar problem, such as revising or removing the patellar component, and leaving the femoral and tibial components in situ, is a technically easier and quicker procedure than revising all the components. However, the functional outcome and survivorship of isolated patellar revision needs to be determined.

Current opinion

Isolated patellar revision in the setting of a well-fixed tibia and femur is an attractive option due to the suspected reduced morbidity and quicker recovery compared to a revision procedure where all components are replaced. Furthermore, isolated patellar revision avoids the need for stemmed tibial and femoral components.

Finding the evidence

- Cochrane Database, PubMed, and Ovid MEDLINE were searched with the following terms "patella revision,"

“loose patella,” “isolated patellar revision,” “secondary patellar revision”

Quality of the evidence

- Level V: 5

Findings

Leopold et al.³² investigated the success of isolated patellar component revision in 40 knees with a mean follow-up of 62 months. The authors found a 38% rate of subsequent failure of the patellar component with about half of these patients requiring further surgical intervention. Berry and Rand³³ found 83% of patients achieved good or excellent results, significant improvement in knee scores, and no definite radiographic loosening at an average of 3.5 years. However, this procedure is associated with a high rate of complications: 33% of patients had a significant complication and 19% of patients had reoperation for problems directly related to the patellar revision. Most common complications were patellar fracture and patellar instability. Parvize²⁵ found that individuals who had isolated patellar procedures had more pain and more reoperations compared with those who had a combined procedure with femoral revision. It is important to evaluate the rotation of the tibial and femoral components before deciding to do an isolated patellar revision.³⁴ Malrotation of either or both of these components can lead to patellar maltracking or anterior knee pain that would likely not be corrected with an isolated patellar procedure.

Recommendation

- Isolated patellar revision can be undertaken only after all other possible causes of patellar problems, such as femoral or tibial malrotation, have been ruled out, but a high complication rate has been reported [overall quality: low]

Summary of recommendations

- In order to diagnose patellar problems preoperatively, a thorough history, physical examination, blood work, and radiological workup is required
- If the patella is an all-polyethylene design, well fixed, and articulates well with the revision femoral component it should be left in place
- If the patella is of a metal-backed design, it should be revised at the time of revision TKA
- If a patient has an unresurfaced patella and anterior knee pain with a TKA and no other etiology for pain, performing a secondary patellar resurfacing may be of some benefit
- Patelloplasty is an option for treatment of a patella during revision TKA with poor patellar bone stock, however results are not ideal and may be associated with complications

- Patellectomy should be avoided due to poor functional outcomes, pain, and extensor lag
- Porous metal-backed implants represent a new technology with promising results
- Isolated patellar revision can be undertaken only after all other possible causes of patellar problems, such as femoral or tibial malrotation, have been ruled out, but a high complication rate has been reported

Conclusion

Several options are available for dealing with the patella during a revision TKA. Unfortunately, there is a lack of high-level evidence in the literature to help guide the surgeon in deciding which option will result in the best functional outcome. Most of the published data available is based on retrospective case series.

Total Shoulder Replacement vs. Hemiarthroplasty in the Treatment of Shoulder Osteoarthritis

Olivia Y.Y. Cheng and Michael D. McKee

St.Michael's Hospital, University of Toronto, Toronto, ON, Canada

Case scenario

A 65 year old healthy woman presents with right shoulder stiffness and pain. Physical examination shows that she is neurologically intact. She is able to externally rotate to neutral with pain at extremes of motion. Rotator cuff examination is normal (Figure 30.1).

Relevant anatomy

The glenohumeral joint is the most important joint of the shoulder. It is a spheroidal joint. The glenohumeral contact occurs between the spherical humeral head and a shallow glenoid fossa. The shallow glenoid articular surface allows for large range of motion at the expense of stability. The normal glenohumeral motion is dependent on the shape of the bony architecture and the soft tissue balances. There are static and dynamic restraints of shoulder motion. Static restraints include articular anatomy, glenoid labrum, negative pressure, capsule, and ligaments. Dynamic restraints include the rotator cuff muscles and the biceps tendon.

In primary osteoarthritis (OA) of the glenohumeral joint, the cartilage wears away and the bones begin to grind against each other, leading to pain and stiffness. It is commonly associated with osteophyte formation and eccentric posterior glenoid wear. The osteoarthritic shoulder demonstrates increased stress of the posterior glenoid which leads

to increased bone remodelling and posterior subluxation.¹ The goal in the treatment of severe osteoarthritis is to eliminate pain, to restore shoulder soft tissue balance and improve function.²

Importance of the problem

Musculoskeletal disorders have a significant impact on the world's population. In the United States, musculoskeletal conditions account for 131 million patient visits per year, costing society about \$215 billion. The incidence of primary OA of the shoulder is not as common as that involving the knee or the hip and is estimated to be less than 1% of the population.³ Although shoulder OA is not as common as other locations, loss of function can lead to depression, anxiety, activity limitations, and job performance problems.⁴

Over 11,000,000 hits appear on Google when the search term "shoulder osteoarthritis" is entered. The vast number of websites targeted at this topic and the lack of quality control of the information provided indicates a need for a preappraised, evidence-based guide for patients and surgeons.

Top six questions

Diagnosis

1. How much do the radiological findings correlate with clinical symptoms?

Figure 30.1 Radiograph of right shoulder with endstage osteoarthritis.

2. CT scan vs. plain radiographs as tools in estimating posterior glenoid wear and glenoid bone stock?

Treatment

3. What is the outcome of total shoulder arthroplasty (TSA) vs. humeral head replacement (HHR) for the treatment of shoulder OA?
4. What is the survivorship of TSA in young, active patients?

Complications

5. What are the results of converting a HHR to TSA after glenoid erosion?
6. How do the rates of revision in HHR compare with TSA?

Question 1: How much do the radiological findings correlate with clinical symptoms?

Case clarification

In this 65 year old woman who complains of shoulder pain and stiffness, the radiographs are consistent with severe shoulder OA. How do the radiological findings correlate with her clinical presentation?

Relevance

Surgeons use radiographs as part of the assessment in patients with shoulder OA. What degree of correlation is there between radiographic findings and patient's clinical symptoms?

Current opinion

Most surgeons would agree that TSA and HHR are the main treatments for patients with primary OA of the shoul-

der who experience pain. Radiographic findings are used as adjuncts in making this decision, but alone are not sufficient to justify surgical intervention.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "radiological parameters" AND "shoulder osteoarthritis" as well as "symptoms" AND "functions"

Quality of the evidence

Level III 1 retrospective review

Findings

Kircher et al. retrospectively examined 120 standardized radiographs of patients with advanced shoulder OA using the true AP and axillary views.⁵ Seventy-five of these patients had a complete record that documented pain, active and passive range of motion, and the Constant Score. The result of this study showed that the joint space width was not correlated with pain or range of motion. The size of the osteophytes were negatively correlated with range of motion. The size of the caudal humeral osteophyte was a predictive factor for function. Overall, the primary clinical feature, pain, as the main indication for surgery, is not related to radiological parameters.

Recommendation

- Radiographic parameters of osteoarthritis do not correlate with degree of pain. Therefore, isolated radiographic shoulder OA is not an indication for operative intervention in the absence of symptoms [overall quality: low]

Question 2: CT scan vs. plain radiographs as tools in estimating posterior glenoid wear and glenoid bone stock?

Case clarification

Examination of this 65 year old woman with primary shoulder OA and pain showed decreased range of motion and pain. The radiographic findings were consistent with severe OA. The axillary view shows posterior glenoid wear. Do we need a CT scan of the glenoid for preoperative planning for this patient?

Relevance

Abnormalities of glenoid version have been associated with abnormal loading of the glenoid component and poor clinical results. CT scans provide better imaging of the glenoid than plain radiographs, at higher cost and radiation exposure.

Current opinion

Pathological processes involving OA of the shoulder leads to severe geometric bony changes. Most surgeons would

obtain a CT scan of the glenoid for preoperative planning of TSA in patient with radiographic images showing medial erosion of the glenoid to the level of the coracoid, or posterior glenoid wear on the axillary view.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “computed tomography” AND “radiography” as well as “shoulder arthroplasty”

Quality of the evidence

Level III

- 2 retrospective reviews

Findings

Nyffeler et al. compared conventional radiographs with CT scans for the measurement of glenoid version.⁶ Three independent observers retrospectively analyzed the radiographs and CT scans of 50 patients. The results from this study indicated poor correlation between plain radiographs and CT scans in measuring glenoid version. Glenoid retroversion was overestimated on plain radiographs in 86% of the cases, with a maximum difference of 21° (mean 6.4°) compared with the values measured on CT scan. This study indicated that glenoid version cannot be determined accurately on standard axillary radiographs, either preoperatively or postoperatively.

A previous study by Friedman et al. also demonstrated the usefulness of CT images in determining glenoid morphology.⁷ In that study, CT was done preoperatively on 20 shoulders with severe arthritic change. This was compared with CT scans of 63 shoulders without evidence of arthritis. In the group with severe arthritis the mean glenoid orientation was 11° of retroversion (range 2–32° of retroversion). The glenoid version in the control group was 2° of anteversion (range 14° of anteversion to 12° of retroversion). The difference between the two groups was significant ($p < 0.0001$). This study concluded that in severe shoulder arthritis, the glenoid is retroverted and CT scan accurately reveals the extent and pattern of erosion.

Morphologic changes such as humeral head subluxation, humeral and glenoid version, glenoid tilt, or changes in dimensions are generally assessed by measuring geometric parameters on medical images. Successful TSA is highly dependent on the quality and morphology of the glenoid bone. Therefore, accurate preoperative assessment of the bone quality can help surgeons in planning the surgery.

Recommendation

- In patients with severe osteoarthritis of the shoulder with bone loss on the glenoid side, CT scanning is useful in assessing glenoid version, glenoid tilt, and glenoid bone stock when planning a TSA procedure [overall quality: low]

Question 3: What is the outcome of HHR vs. TSA for the treatment of shoulder OA?

Case clarification

HHR (Figure 30.2) and TSA (Figure 30.3) are the two primary methods of treatment for shoulder OA. What is the outcome of HHR vs. TSA?

Relevance

There is ongoing controversy concerning the ideal management of primary glenohumeral OA^{8–12}

Figure 30.2 Postoperative radiograph of a patient with total shoulder replacement.

Figure 30.3 Postoperative radiograph of a patient with hemiarthroplasty of the shoulder.

Current opinion

Most surgeons would perform TSA for primary osteoarthritis of the shoulder with an intact rotator cuff and adequate glenoid bone stock.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “total shoulder arthroplasty” AND “hemiarthroplasty of the shoulder” as well as “shoulder arthritis” AND “outcome”

Quality of the evidence*Level I*

- 1 prospective randomized trial
- 2 systemic reviews and meta-analysis

Level II

- 1 prospective comparative study

Findings

In HHR the humeral articular surface is replaced with a stemmed humeral component coupled with a humeral head. TSA involves replacement of the humeral articular surface as well as replacement of the glenoid articular surface with a polyethylene glenoid component. HHR of the shoulder is technically easier to perform. For patients who have undergone HHR, pain and the radiographic appearance of subchondral sclerosis and joint space narrowing may develop, leading to revision surgery. TSA is associated with risk of glenoid loosening. However, multiple studies have shown that the risk of symptomatic glenoid loosening is low and overall revision surgery for TSA is significantly lower than HHR (especially when current cemented all-polyethylene glenoid components are used).^{12–22}

Edwards et al. conducted a large multicenter retrospective study (n = 690) comparing HHR vs. TSA in the treatment of primary glenohumeral OA,¹¹ with an average follow-up of 43 months. The following parameters were significantly better for patients receiving TSA: active forward elevation (p < 0.0005), active external rotation (p < 0.015), Constant Score (p < 0.0005), incidence of radiolucent lines around the humeral component (p < 0.001), and humeral implant migration (p < 0.033). Good or excellent results were seen in 86% of HHR and 94% of TSA. Overall, this study shows that TSA is more effective than HHR in patients with primary glenohumeral osteoarthritis with no significant increase in complication rate associated with glenoid resurfacing.

In contrast, Lo et al. found no significant difference in quality of life measures between HHR and TSA in a prospective, randomized study with minimum 2 year follow-up.¹⁹ In this study 42 patients with OA of the shoulder were randomized to receive a HHR or a TSA. All patients were

evaluated preoperatively and at 6 weeks and 3, 6, 12, 18, and 24 months postoperatively with both subjective and objective parameters. The primary outcome measure in this study was the Western Ontario Osteoarthritis of the Shoulder (WOO) index. Significant improvements in disease-specific quality of life were seen at 2 years for both the TSA and HHR. There were no significant differences in the WOO score between the two groups. However, there was a trend toward superior results in the TSA group. It is possible that there was a beta error due to the study being underpowered (n = 42).

In a recent meta-analysis comparing HHR with TSA for the treatment of primary glenohumeral OA, Radnay et al. identified 23 studies published between 1966 and 2004, (total of 1952 patients), and a mean follow-up of 43.3 months.²³ The results showed significantly greater pain relief (p < 0.0001), forward elevation (p < 0.0001), gain in forward elevation (p < 0.0001), gain in external rotation (p = 0.0002), and patient satisfaction (p < 0.0001) with TSA compared with HHR. Furthermore, the TSA group had a significantly lower revision rate than the HHR group. Overall, the conclusion reached by this study was that TSA is the surgical treatment of choice for patients with end-stage primary glenohumeral OA.

Recommendation

- In recent years, multiple studies show that with proper patient selection TSA is superior to HHR for patients with endstage primary shoulder OA [overall quality: high]

Question 4: What is the survivorship of TSA in young, active patients?**Case clarification**

A 50 year old man, active and healthy, has severe primary OA of the shoulder. Before he proceeds with a TSA he would like to know what the survivorship of TSA is in individuals like him.

Relevance

TSA is a reliable treatment option for patients with primary osteoarthritis. Many surgeons are reluctant to perform TSA on young and middle-aged patients because of the risk of late implant loosening.

Current opinion

- Most orthopedic surgeons would caution against doing a TSA in a young, active patient due to the risk of implant loosening and possible future revision surgeries.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “total shoulder arthroplasty” AND

“young patient” as well as “total shoulder arthroplasty” AND “outcome”

Quality of the evidence

Level II

- 1 prospective comparative study

Level III

- 1 retrospective review

Findings

Sperling et al. published a retrospective series of 98 patients younger than 50 years old who underwent HHR or TSA between 1976 and 1985 with a mean follow-up of 12.3 years.¹⁰ Both TSA and HHR resulted in significant long-term pain relief and improvement in function. The estimated survival of the HHR prostheses was 92% (86–98%) at 5 years, 83% (75–93%) at 10 years, and 73% (59–88%) at 15 years. The estimated survival of the TSA was 97% (92–100%) at 5 years, 97% (91–100%) at 10 years, and 84% (70–100%) at 15 years. The data from this study indicates that TSA provides marked long-term relief of pain and improvement in motion; however, nearly half of all young patients who have a shoulder arthroplasty have an unsatisfactory result according to a strict rating system. Care should be exercised when either a HHR or a TSA is offered to patients who are 50 years old or less.

A recent prospective study done by Raiss et al., looking at TSA in young and middle-aged patients with glenohumeral OA, showed that third-generation TSA is a viable method of treatment with a low complication rate and excellent mid-term results.²⁴ They studied 21 patients less than 60 years old (mean age 55 years) with primary shoulder OA treated with either HHR or TSA. At a minimum of 5 years follow-up there were no revisions. Significant improvements in Constant scores, pain relief, power, activity, mobility, and range of motion were noted at a mean follow-up of 7 years. This study showed the patient satisfaction rate after TSA was 95% with significant relief from pain and improvement in range of motion. For young and middle-aged patients with OA, third-generation TSA is a viable treatment method with low rate of complications and excellent mid-term results.

Recommendations

- TSA is a safe method of treatment for middle-aged active patients with primary OA of the shoulder in patients who are more than 50 years old [overall quality: moderate]
- Caution needs to be exercised when performing TSA in active patients who are less than 50 years old [overall quality: moderate]

Question 5: What is the result of converting hemiarthroplasty into TSA after glenoid erosion?

Case clarification

A 65 year old woman with endstage OA of the shoulder would like to know if HHR converted to TSA would have the same result as a primary TSA.

Relevance

For patients who had HHR for primary glenohumeral OA, the glenoid can undergo progressive erosion over time (Figure 30.4). This often leads to conversion to TSA at a later date. What are the results of revision of HHR to TSA?

Current opinion

Most orthopedic surgeons would agree that patients undergoing revision surgery from HHR to TSA after failed HHR due to glenoid arthrosis do not do as well as patients who underwent primary TSA.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “shoulder hemiarthroplasty” AND “revision surgery” as well as “total shoulder arthroplasty” AND “outcome”

Quality of the evidence

Level III

- 1 retrospective review

Figure 30.4 Patient with shoulder hemiarthroplasty 10 years ago now showing evidence of glenoid erosion.

Findings

The revision of HHR to TSA for glenoid arthrosis is not as successful as primary TSA for glenohumeral OA. Carroll et al. identified 16 consecutive patients who underwent revision TSA for failed HHR.²⁵ The mean interval from the time of HHR to revision TSA was 3.5 years. All patients had significant glenoid arthrosis on radiograph. They found that 47% of patients had an unsatisfactory clinical result at a mean of 5.5 years after the revision and one-third had incomplete pain relief after the conversion of failed HHR to TSA. Furthermore, HHR did not preserve glenoid bone stock, with posterior and superior glenoid wear evident in many patients. In addition, many of these patients had contractures of the anterior capsule and the subscapularis. The combined bony and soft tissue abnormalities made revision surgery much more challenging.

Recommendation

- After assessing the evidence, we do not recommend HHR as the first line of treatment for primary OA of the shoulder due to its high rate of revision and the inferior results of the revision surgeries when compared to primary TSA.

Question 6: How do the rates of revision in HHR compare with TSA?**Case clarification**

A 65 year old woman with severe OA of the shoulder understands that both HHR and TSA are options for treating her shoulder. However, how do the revision rates differ between the two surgical options?

Relevance

For primary OA of the shoulder, both HHR and TSA are treatment options. Each has its own advantages and disadvantages. So how do the rate of revision between these two procedures compare?

Current opinion

Most surgeons feel that revision surgery involving conversion of HHR to TSA for glenoid arthrosis is higher than revision surgery involving TSA for glenoid loosening. This is especially true with modern cemented all-polyethylene pegged glenoid components.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "total shoulder arthroplasty" AND "revision surgery" as well as "hemiarthroplasty of the shoulder"

Quality of the evidence

Level I

- 2 randomized control trials
- 2 systemic review and meta-analyses

Findings

Gartsman et al. performed a randomized prospective study comparing TSA with HHR in patients with shoulder OA.²⁶ In this study 51 patients were randomized to be treated with either TSA (27 shoulders) or HHR (24 shoulders) and were evaluated at a mean of 35 months postoperatively. The TSA group had significant improvements in pain relief and internal rotation compared to the HHR group. There were no revisions in the TSA procedures. Three shoulders that had been treated with a HHR were revised to TSA secondary to increased pain and glenoid wear.

Bryant et al. published a systemic review and meta-analysis comparing HHR and TSA in patients with shoulder OA.¹⁵ This study included 112 patients (50 received HHR and 62 received TSA) with a minimum of 2 years of follow-up, and 10 patients from the HHR group crossed over to the TSA group because of excess pain or stiffness. There were no revisions in the TSA group.

A recent meta-analysis looking at HHR vs. TSA examined 23 studies involving 1952 patients.²³ Only 80 of 1238 TSAs (6.5%) required revision surgery for any cause. Of the TSAs that used metal-backed glenoids, 6.8% required revision. However, the revision rate for loosening in TSAs with all-polyethylene glenoids was only 1.7%. Meanwhile, 10.2% of HHRs required additional surgical procedures for any cause; 8.1% of HHRs required conversion to TSA because of pain. The difference in the rate of revision surgery was significantly in favor of TSA.

Recommendation

- TSA has a lower rate of revision surgery than HHR, especially when cemented all-polyethylene glenoid components are used [overall quality: high]

Summary of recommendations

- Isolated radiographic shoulder OA is not an indication for operative intervention in the absence of symptoms
- CT scan is useful in assessing glenoid version, glenoid tilt, and glenoid bone stock when planning a TSA procedure
- TSA outperforms HHR for the treatment of primary shoulder OA in terms of pain relief, range of motion, and patient satisfaction. In addition, the revision rate for TSA is significantly lower than for HHR
- TSA is a safe method of treatment for middle-aged active patients with primary OA of the shoulder in patients who are older than 50
- Caution needs to be exercised when performing TSA in active patients who are younger than 50 years old
- After assessing the evidence, we do not recommend HHR as the first line of treatment for primary OA of the shoulder due to its high rate of revision and the inferior

results of the revision surgeries when compared to primary TSA

- TSA has a lower rate of revision surgery than HHR, especially when cemented all-polyethylene glenoid components are used

Cemented vs. Uncemented Fixation in Shoulder Arthroplasty

Shahryar Ahmadi¹ and Christian Veillette²

¹University of Arkansas for Medical Sciences, Fayetteville, AR, USA

²Toronto Western Hospital, University Health Network and University of Toronto, Toronto, ON, Canada

Case scenario

A 65 year old man who is right-hand dominant and a semi-retired chartered accountant presents with progressively increasing left shoulder pain and decreased range of motion. He complains of pain with any range of motion of his shoulder and has noted difficulty golfing. He has difficulty sleeping at night due to shoulder pain. On examination, his active and passive range of motion is forward elevation to 100°, abduction to 60°, and external rotation to neutral. There is abundant grinding and catching with motion. He is neurovascularly intact. Relevant radiographs are shown in Figure 31.1.

Relevant anatomy

Shoulder arthritis is a condition in which the cartilage that normally provides a smooth surface over the humeral head and glenoid is lost. The cartilage loss can result from either primary or secondary causes such as trauma, inflammatory disease, infection, rotator cuff disease, instability, or avascular necrosis of humeral head. Patients with shoulder arthritis often have coexisting synovial joint pathology, including bursitis, synovitis, loose bodies, labral tears, osteophytes, and capsular contractures. The final common clinical pathway is disabling pain, decreased range of motion, and functional limitations. Joint replacement surgery is the most reliable treatment for advanced shoulder osteoarthritis.

The angle between the humeral neck and shaft is about 130°. The humeral head is retroverted 20–40° relative to the epicondylar axis. The glenoid in the resting position has an

average of 5° superior tilt and 7° retroversion (range from 10° anteversion to 10° retroversion). The glenoid fossa provides a shallow socket in which the humeral head articulates. It is composed of the bony glenoid and the glenoid labrum. The fibrocartilaginous labrum provides a 50% increase in the depth of the concavity. The glenoid has an average depth of 9 mm in the superoinferior direction and 5 mm in the anteroposterior direction with an intact labrum.

Importance of the problem

The shoulder is the third most common joint for replacement. Cofield et al. reported a rate of 10.1 per 100,000 person-years for shoulder arthroplasty from 1996 to 2000 in Olmsted County, Minnesota. In contrast, the rates for hip and knee replacement were 125 and 60.8 per 100,000 respectively.¹

Since the first shoulder arthroplasty by Pean in 1893, there has been a significant improvement in both implant design and technique. Based on the Nationwide Inpatient Sample database, 12,758 total shoulder arthroplasties (TSAs) were performed in the US from 1990 to 2000.² In addition, a steady increase has been shown in the age- and sex-adjusted annual operative incidence rate of 1.4 per 100,000 person-years in 1976–1980 to 10.1 per 100,000 person-years in 1996–2000.¹ This increased use of shoulder arthroplasty was mainly due to increased use for osteoarthritis (OA).

Shoulder arthroplasty for OA is very effective in improving pain, function, and patient satisfaction.³ Boorman et al. showed that improvement in self-assessed health status is comparable to total hip arthroplasty and coronary artery bypass grafting.⁴

Figure 31.1 Standard AP radiograph (a) demonstrates endstage osteoarthritis with joint space narrowing, subchondral sclerosis, inferior humeral head osteophyte. Axillary radiograph (b) shows flattening of humeral head, joint space narrowing and posterior glenoid wear.

Top nine questions

Diagnosis

1. Is there a role for CT scan/MRI in preoperative planning?

Therapy

2. What is the relative effect of a cemented vs. uncemented humeral component on the functional outcome of patients with shoulder OA?
3. Is there a role for the use of antibiotic-impregnated cement?
4. What is the optimal approach to a cemented humeral component?
5. What is the optimal approach to an uncemented humeral component?
6. What is the optimal approach to cementing a glenoid component?
7. What is the relative effect of all-polyethylene vs. metal-backed glenoid component?

Prognosis

8. Is postoperative management different for cemented vs. uncemented arthroplasty?
9. Is there a significant difference in survival of cemented vs. uncemented arthroplasty?

Question 1: Is there a role for CT scan in preoperative planning?

Clarification

The patient's radiographs shows severe OA of the left shoulder. There is mild posterior glenoid erosion on the

axillary view. A CT scan accurately shows the amount of glenoid bone loss and its correct version.

Relevance

Glenoid component loosening is one of the most common reasons for revision surgery after TSA.⁵⁻⁷ Malposition of the glenoid component increases the risk of glenoid component loosening.⁸⁻¹¹

Current opinion

Current opinion suggests that the majority of surgeons use CT scan for preoperative assessment of glenoid bone stock and more accurate assessment of version if an axillary radiograph shows any evidence of erosion in the glenoid.

Finding the evidence

- PubMed, with search terms: "glenoid loosening" AND "total shoulder arthroplasty," "glenoid version" AND "total shoulder arthroplasty," "complication of total shoulder arthroplasty," "preoperative CT scan AND total shoulder arthroplasty"

Quality of the evidence

- 3 biomechanical studies
- 3 basic science studies

Findings

Effect of glenoid component version in TSA. Three different biomechanical studies showed that:

- Every 4° change in version caused a 2° change in the force vector away from the center of glenoid⁸
- Retroversion was worse than anteversion, and superoinferior misalignment was worse than anteroposterior⁹
- Glenoid retroversion induced a posterior displacement of the glenohumeral contact point during internal and external rotation, inducing a significant increase of stress

within the cement mantle (+326%) and within the glenoid bone (+162%)¹⁰

Accuracy of plain radiograph compared to CT scan in assessing glenoid version

- The medial border of scapula cannot be seen in axillary view (mean visible length 4.9cm) and thus it will be difficult to define the true scapular axis. Also glenoid version (n = 50 patients) varied from 11° of anteversion in extension to 7° of retroversion in flexion¹²
- The glenoid version angle measured from the three-dimensional (3-D) CT imaging (12 normal cadaveric scapula) was within 1.0 ± 0.7° (mean ± SD) of those from the actual specimen (95% CI <2.2° for all observers)¹³
- Surgical decisions that were made on the basis of two-dimensional (2-D) data differed from those that were made on the basis of 3-D data in 37 of 96 cases (39%)¹⁴

Recommendation

- Pattern and extent of glenoid bone loss and glenoid version can be most accurately assessed by 3-D CT imaging [overall quality: high]

Question 2: What is the relative effect of a cemented vs. uncemented humeral component on the functional outcome of patients with shoulder OA?

Clarification

The patient wishes to proceed with a TSA. Should a cemented or uncemented humeral component be used to optimize functional outcome?

Relevance

The survivorship of the humeral component in TSA has been reported as 86.7% (95% CI 84.2–89.4) at 15 years and 82.8% (95% CI 78.5–87.5) at 20 years.¹⁵ Revision of an uncemented humeral stem is often easier than a cemented humeral stem. Bone ingrowth into the proximal porous coating of uncemented humeral stems may provide improved survivorship and functional outcome. Based on these factors, should uncemented TSA be performed in younger patients? Is there any significant difference in functional outcome after shoulder arthroplasty between cemented and uncemented humeral components?

Current opinion

Current opinion suggests that the majority of surgeons preferentially use an uncemented humeral component in the management of shoulder OA in patients in North America. Implant manufacturers have preferentially developed and marketed uncemented implants over recent years.

Finding the evidence

- PubMed, with search terms: “cemented versus uncemented humeral component” AND “total shoulder

arthroplasty,” “cemented versus uncemented humeral component”

Quality of the evidence

Level I

- 1 prospective randomized study

Findings

In a prospective randomized study, Litchfield et al. compared cemented (n = 80 patients) with uncemented (n = 81) humeral components (Bigliani/Flatow, Zimmer) for TSA. They showed a significant difference in WOOS score at post-operative intervals of 12, 18, and 24 months (p = 0.009, 0.001, 0.028 respectively) in favor of the cemented humeral component. Also they noticed better strength (3mo p = 0.038, 12mo p = 0.036, 18mo p = 0.051, 24mo p = 0.053) and forward flexion (6mo p = 0.031, 12mo p = 0.04) in the cemented group. Operative time was significantly less for the uncemented group (C = 2.26 ± 0.63h; U = 1.69 ± 1.9h, p = 0.03). The authors concluded that a cemented humeral component provides better quality of life, strength, and range of motion than an uncemented humeral component.¹⁶

Recommendation

To best of our knowledge, this is the only level I study that has compared the functional outcome after cemented vs. uncemented humeral component fixation. The major limitation of this study is that results can only be applied to the use of the Zimmer BF implant and are not necessarily generalizable to all uncemented humeral components. In addition, this study only reports on the short term outcome and we do not know if the results can be extrapolated to long term follow-up.

- The authors recommend that all of the factors, including potential difference in functional outcome, ease of revision, survivorship, and complications, be discussed with the patient. Also the patient’s age, expectations, functional level, and proximal humeral bone quality must be considered. The final decision should be individualized on the basis of these parameters [overall quality: low]

Question 3: Is there a role for the use of antibiotic-impregnated cement?

Clarification

The patient wishes to proceed with a TSA. Should antibiotics be added to the cement for the glenoid component and/or the humeral component?

Relevance

The addition of antibiotics to cement can potentially affect the properties of the cement and subsequent fixation. In addition, antibiotics may decrease infection rates but increase the risk of developing antibiotic-resistant bacteria.

Current opinion

Current opinion suggests that the majority of North American surgeons use antibiotic-impregnated cement if cement is utilized for glenoid or humeral component fixation in TSA.

Finding the evidence

- PubMed, with search terms: “antibiotic cement” AND “total shoulder arthroplasty”

Quality of the evidence*Level I*

- 1 prospective randomized study

Level II

- 1 prospective randomized study
- 1 review study

Findings

A prospective randomized study of 1688 total hip replacements in Sweden with a follow-up of 10 years did not show any significant difference between the systemic antibiotic group and the gentamicin-impregnated cement group ($p < 0.05$).¹⁷

A prospective randomized study of 401 total hip and knee arthroplasties in two British centers with a follow-up of 2 years, did not show any significant difference between the systemic cefuroxime group and the cefuroxime-impregnated cement group.¹⁸

Recommendation

To the best of our knowledge, there are no studies that evaluate the use of antibiotic-impregnated cement for TSA. The reviewed studies are from total hip and knee arthroplasty and therefore we are uncertain whether the conclusions are applicable in TSA.

- In conclusion, there is no evidence to justify using antibiotic-impregnated cement in TSA [overall quality: low]^{17–19}

Question 4: What is the optimal approach to a cemented humeral component?**Relevance**

Does first-, second-, or third-generation cementing technique or use of cement restrictor make any significant difference in complication, component survival or functional outcome?

Current opinion

Current opinion shows that all—first-, second-, or third-generation—cementing techniques are being used by sur-

geons. The use of cement restrictors for humeral component cementing is not routine. The presence of a poor cement mantle and early postoperative radiolucent lines may lead to higher loosening rates.

Finding the evidence

- PubMed, with search terms: “cement technique” AND “total shoulder arthroplasty,” “cement technique” AND “humeral component”

Quality of the evidence

There are no studies comparing cementing techniques or the use of cement restrictors for shoulder arthroplasty.

Recommendation

There are a few case reports of radial nerve palsy due to cement extrusion after using a cemented humeral component.²⁰ However, there is no evidence whether using a cement restrictor or different cementing technique affects the risk of this complication. In addition, there is no evidence that cementing techniques affect the survivorship of the humeral component [overall quality: low].

Question 5: What is the optimal approach to an uncemented humeral component?**Relevance**

Is there any evidence to support the use of hydroxyapatite (HA) coated compared with non-HA-coated implants or press-fit compared with porous ingrowth fixation for uncemented humeral components?

Current opinion

Current opinion suggests that HA-coated, non-HA-coated, press-fit, and porous ingrowth implants are all commonly used for uncemented humeral component fixation.

Finding the evidence

- PubMed, with search terms: “hydroxyapatite” AND “total shoulder arthroplasty,” “hydroxyapatite coated humeral component,” “ingrowth humeral component,” “press fit humeral component,” “humeral fixation press fit,” “humeral fixation porous ingrowth”

Findings

There is no evidence to show that a specific method of uncemented humeral component fixation provides improved implant survivorship.

Recommendation

- Surgeons need to be aware of the lack of comparative studies that evaluate different methods of uncemented humeral component fixation

Question 6: What is the optimal approach to cementing a glenoid component?**Clarification**

How should the glenoid be prepared for cementing?
Should the cement be pressurized?

Relevance

Preparation and cementing technique have very important implication for outcome.

Current opinion

Current opinion suggests that the majority of surgeons pressurize the cement using a variety of techniques and there is a lack of consensus on glenoid preparation methods.

Finding the evidence

- PubMed, with search terms: “optimal cementing technique” AND “glenoid,” “glenoid preparation,” “glenoid cemented fixation”

Quality of the evidence*Level I*

- 1 prospective randomized study

Nonclinical studies

- 3 biomechanical studies

Findings

In a prospective randomized study, Edwards et al. compared the immediate postoperative periglenoid radiolucencies between three glenoid-drying techniques (n = 71 patients). They prepared the glenoid with thrombin-soaked gel foam compresses, gas lavage, and saline solution lavage with sponge drying. The mean total radiolucent line score was 0.63 (p = 0.94), with no significant difference among the three groups (p = 0.89).²¹

In a biomechanical study on glenoid cement mantle, Terrier et al. demonstrated that, cement thickness less than 1 mm weakens the cement mantle and puts excessive peak stress at the bone–cement interface, around the back-keel edges. Also, thickening of the cement mantle rigidifies the cemented implant and increases the stress at the bone–cement interface and the underlying bone. They identified an ideal value of 1 mm for cement mantle to avoid both excessive cement fatigue and fatigue of the bone–cement interface.²²

A biomechanical study by Nyffeler et al. compared two cementing techniques for glenoid component fixation. In the first group they put cement on the back of the glenoid component and into the peg-receiving holes of the glenoid and pressurized them with a syringe. In the second group, they applied cement just into the peg-receiving holes of

glenoid and pressurized them with finger pressure. They assessed all of the specimens with microCT scan. There was an intact cement mantle around all 12 pegs (100%) in first group and an incomplete cement plug in 7 of 15 pegs (47%) in second group.²³

In a cadaver study Hassan et al. compared syringe pressurization (SP) with weep-hole technique (WH) and modified weep-hole technique (MWH). Both WH and MWH techniques increase cement mantle volume around individual pegs and decrease the amount of glenoid face cement compared to conventional SP. Whether this improves the clinical outcome and survivorship requires further study.²⁴

Recommendation

- On the basis of current evidence we recommend saline solution lavage with sponge drying for glenoid preparation, and also pressurizing glenoid cement with a syringe associated with application of cement on the back of glenoid component and 1 mm cement mantle thickness [overall quality: moderate]

Question 7: What is the relative effect of all-polyethylene vs. metal-backed glenoid component?**Clarification**

There are two option for glenoid component fixation—cemented all-polyethylene glenoid components and uncemented metal-backed glenoid components.

Relevance

There is a significant difference in survival of these two components.

Current opinion

Current opinion suggests that the majority of surgeons use all-polyethylene glenoid components.

Finding the evidence

- PubMed, with search terms: “metal backed glenoid,” “cemented” AND “uncemented glenoid”

Quality of the evidence*Level I*

- 1 prospective double-blind randomized study

Level IV

- 2 case series

Findings

In a prospective double-blind randomized study of cemented polyethylene vs. uncemented metal-backed glenoid component (n = 39) with a 3 years follow-up,

Boileau et al. showed 20% (4 cases) loosening of metal-backed implant vs. 0% of polyethylene glenoid components ($p < 0.001$).²⁵

In a review of 83 metal-backed glenoid components with 9.5 years follow-up, Cofield et al. showed a 5 year survival of 79.9% (95% CI 71.6–89.3%), and a 10-year survival of 51.9% (95% CI 41.0–65.8%).²⁶

In a review of 147 metal-backed glenoid components with 7.5 years follow-up, Martin et al. showed a 5 year survival of 95%, and a 10 year survival of 85%. These authors report a higher failure rate of metal-backed glenoid compared to a previous report of polyethylene glenoid.²⁷

Recommendation

- On the basis of current evidence we recommend use of a cemented all-polyethylene glenoid component [overall quality: moderate]

Question 8: Is postoperative management different for cemented vs. uncemented arthroplasty?

Clarification

There are several rehabilitation protocols after TSA.

Relevance

There is no study suggesting different protocol for cemented vs. uncemented TSA.

Current opinion

Current opinion suggests that the majority of surgeons set the postoperative rehabilitation protocol based on the following factors:

- Underlying pathology and preoperative function of shoulder
- Surgical approach
- Quality of component fixation and soft tissue repair
- Quality of bone and soft tissue, including rotator cuff
- Presence of intra-/postoperative complication
- Patient factors: age, functional level, comorbidities, cooperation, etc.

Finding the evidence

- PubMed, with search terms: “post operative management” AND “total shoulder arthroplasty,” “rehabilitation” AND “total shoulder arthroplasty,” “physiotherapy” AND “total shoulder arthroplasty”

Quality of the evidence

Level V

- 1 expert opinion

Findings

Millett et al. in their article about rehabilitation after TSA emphasized the importance of underlying pathology and

tissue healing time frame as a base for rehabilitation protocol after surgery.²⁸

Recommendation

There is inadequate evidence to support different rehabilitation protocols for cemented vs. uncemented TSA.

- We recommend that the surgeon consider the six factors outlined above and tailor the protocol accordingly [overall quality: low]

Question 9: Is there a significant difference in survival of cemented vs. uncemented humeral component fixation in shoulder arthroplasty?

Clarification

The two options for humeral component fixation in shoulder arthroplasty are cement fixation and uncemented tissue ingrowth or press-fitted fixation.

Relevance

Loosening of the humeral component is rarely a cause for revision in shoulder arthroplasty. There is no long-term comparative level I evidence to justify the use of cemented or uncemented (either press-fit or ingrowth) for humeral component fixation. However, each option has its own advantages and disadvantages.

Current opinion

Current opinion suggests that the majority of surgeons use uncemented humeral component fixation when possible.

Finding the evidence

- PubMed, with search terms: “survival” AND “total shoulder arthroplasty,” “outcome” AND “total shoulder arthroplasty”

Quality of the evidence

Level I

- 1 prospective randomized study

Level IV

- 4 case series

Findings

In a review of 1584 shoulder arthroplasties, Cil et al. reported no significant difference in survivorship (HR 0.79; 95% CI 0.22–2.83; $p = 0.72$) between uncemented and cemented Neer II implants.¹⁵ For the Cofield 1 humeral component, survivorship was significantly increased for cement fixation relative to fixation without cement (HR 0.33; 95% CI 0.13–0.81; $p = 0.02$). Overall, there was an increased survivorship across all implants (Neer II, Cofield I and II) for cement fixation compared to a component without cement fixation (HR 0.37; 95% CI 0.18–0.76; $p = 0.007$).

In a review of 37 uncemented shoulder replacements with a mean follow-up of 9.2 years (range 5.8–13.6 years), Verborgt et al. reported 0% loosening.²⁹

In a review of 730 cemented shoulder arthroplasty and 570 uncemented shoulder arthroplasty from different centers, Cofield reported 6 implants with radiographic and 0 implants with clinical evidence of humeral component loosening in the cemented group compared with 63–70 implants with radiographic evidence and 2 implants with clinical evidence of humeral component loosening in the uncemented group.³⁰

In a prospective randomized study of 26 total shoulder replacements in patients with rheumatoid arthritis with 2 year follow-up, Rahme et al. reported no loosening or difference in micromotion between cemented and uncemented groups.³¹

In a review of 431 shoulder arthroplasty with an average follow-up of 4.2 years, Cofield et al. reported no significant difference in complication rate between cemented and uncemented humeral stems in shoulder arthroplasty.⁷

Recommendation

Based on current evidence, the result of new designs of uncemented (tissue ingrowth) humeral component fixation is similar to cemented fixation. The choice between the use of a cemented or uncemented humeral component, should be individualized based on patient and diagnostic factors.¹⁵

- There is currently insufficient evidence to recommend the routine use of a single method of fixation; however, in younger patients with good bone quality uncemented humeral fixation is recommended [overall quality: moderate]

Summary of recommendations

- Pattern and extent of glenoid bone loss and glenoid version can be most accurately assessed by 3-D CT imaging
- 3-D CT imaging is not recommended for routine use
- We do not recommend routine use of antibiotic-impregnated cement in primary TSA
- There are a few case reports of radial nerve palsy due to cement extrusion after using a cemented humeral component.²⁰ However, there is no evidence whether using a cement restrictor or different cementing technique affects the risk of this complication. In addition, there is no evidence that cementing techniques affect the survivorship of the humeral component
- Surgeons need to be aware of the lack of comparative studies that evaluate different methods of uncemented humeral component fixation
- We recommend saline solution lavage with sponge drying for glenoid preparation and also pressurizing glenoid cement
- We recommend that cement fixation of an all-polyethylene glenoid component be used for glenoid resurfacing

- The patient's age, expectations, functional level, and proximal humeral bone quality must be considered in the selection of method of humeral component fixation
- We recommend that the surgeon consider the six factors outlined on p. 275 and tailor the protocol accordingly
- In younger patients with good bone quality, uncemented humeral fixation is recommended

Conclusion

In conclusion, advanced imaging modalities such as 2-D and 3-D CT scans are valuable in selected cases with significant and/or asymmetric glenoid erosion to improve glenoid component placement. There is sufficient evidence to recommend the use of cement fixation over tissue ingrowth fixation for the glenoid component. There are no clear-cut indications for cement fixation vs. uncemented tissue ingrowth fixation for the humeral component other than those intuitively based on bone quality and perceived ease of revision.

Ryan T. Bicknell

Queen's University, Kingston, ON, Canada

Case scenario

A 75 year old woman who is living independently is seen with complaints of right shoulder pain. She has no history of trauma and the pain has been progressive over the past 2–3 years. On examination, she has very limited active movement and crepitus. She is neurovascularly intact.

Relevant anatomy

A rotator cuff tear can be classified as acute (no irreversible muscular fatty atrophy and generally reparable) or chronic (with irreversible muscular fatty atrophy and generally irreparable). Instability of the glenohumeral joint due to a long-standing irreparable rotator cuff tear often occurs in an anterior and superior direction, called *anterosuperior escape*, often leading to a pseudoparalysed shoulder, generally defined as a loss of active forward elevation with maintained passive movement.

Importance of the problem

Shoulder arthritis can include osteoarthritis (OA), rheumatoid arthritis (RA), post-traumatic arthritis, and cuff tear arthropathy. Each type of arthritis is not infrequently seen in combination with a rotator cuff tear. A conventional total shoulder arthroplasty (TSA) is used to relieve pain and improve function in arthritic shoulders. The articular surfaces are unconstrained and allow the healthy rotator cuff and extrinsic shoulder muscles to restore shoulder function. In most arthritic shoulders, with or without a rotator

cuff tear, this “ball-and-socket” biomechanics of the glenohumeral joint are maintained. However, each type of arthritis may present in combination with rotator cuff dysfunction and loss of the normal biomechanics, often leading to instability and pseudo-paralysis. In this situation, the outcome of a traditional shoulder arthroplasty is substantially compromised.^{1–3}

The incidence of rotator cuff tear dysfunction in the population of shoulder arthritis patients is difficult to determine, but occurs in a minority of patients. Although shoulder arthritis is much less common than hip or knee arthritis, the incidence and indications for shoulder arthroplasty continue to increase.

Even though reverse total shoulder arthroplasty (RTSA) is a relatively new procedure, surgeons and patients are inundated with an everincreasing easily accessible body of information. A Google search for “reverse shoulder arthroplasty” returns over 600,000 hits.

Top five questions

Diagnosis

1. What are the indications for an RTSA?

Therapy

2. What patient factors predict function after an RTSA?
3. What technical factors may affect outcome of an RTSA?

Prognosis

4. What are the results of an RTSA?

Harm

5. What complications are associated with an RTSA?

Question 1: What are the indications for an RTSA?**Case clarification**

The patient has active forward elevation to 45°, but maintained passive forward elevation to 160°. The patient's radiograph reveals humeral head elevation with a complete loss of acromiohumeral distance and complete loss of glenohumeral joint space.

Relevance

Traditionally, shoulder arthritis associated with rotator cuff dysfunction has been treated with a hemiarthroplasty. However, in patients with a pseudo-paralyzed shoulder, this may not provide an improvement in active range of motion (ROM) and requires re-establishing the ball-and-socket mechanics of the shoulder.

Current opinion

Current opinion suggests that the majority of surgeons use an RTSA for the treatment of patients with shoulder arthritis and rotator cuff dysfunction that results in a pseudo-paralyzed shoulder.

Finding the evidence

- Cochrane Database, with search term "reverse arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): clinical queries search/systematic reviews: "reverse shoulder arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): search using keywords "reverse arthroplasty" OR "reverse shoulder arthroplasty" OR "reverse total shoulder arthroplasty"

Quality of the evidence

Level IV

- 1 case series

Level V

- 2 expert opinions

Findings

Overall indication RTSA may be considered when the patient presents with a clinically symptomatic, irreparable rotator cuff tear associated with an irrecoverable pseudo-paralysis. However, deltoid function must be preserved. As well, adequate glenoid bone stock must be available to allow secure glenoid component fixation. RTSA should be reserved for elderly patients with low functional demands.^{1,4}

Contraindications Contraindications include infection, neuroarthropathy, and glenoid bone erosion.¹

Specific diagnoses The initially described, and main, indication for an RTSA is cuff tear arthropathy.^{1,4,5} A massive cuff tear without glenohumeral OA can also be considered. An RTSA can be considered in RA if sufficient bone stock exists, for some three- and four-part proximal humerus fractures, and revision of failed prosthesis.^{1,4}

Recommendations

- In patients greater than 70 years of age, a RTSA can be considered when rotator cuff dysfunction leads to antero-superior escape and a pseudo-paralyzed shoulder [overall quality: low]
- The most common indication is cuff tear arthropathy or a massive cuff tear with glenohumeral arthritis. However, patients with RA, proximal humerus fractures, and failed arthroplasty may also be considered, when all other options are exhausted [overall quality: moderate]

Question 2: What patient factors predict function after an RTSA?**Case clarification**

The patient is offered an RTSA. Preoperatively, she has no active external rotation and a positive Hornblower's sign. A preoperative CT scan is ordered.

Relevance

The level of shoulder function preoperatively may predict function postoperatively and may suggest to the surgeon to add other procedures at the time of RTSA.

Current opinion

Current opinion suggests that an RTSA does not result in an improvement in active external rotation. As well, results after an RTSA are inferior in the absence of an intact teres minor.

Finding the evidence

- Cochrane Database, with search term "reverse arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): clinical queries search/systematic reviews: "reverse shoulder arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): search using keywords "reverse arthroplasty" OR "reverse shoulder arthroplasty" OR "reverse total shoulder arthroplasty"

Quality of the evidence

Level IV

- 5 case series

Level V

- 1 expert opinion

Findings

Loss of active external rotation cannot be treated with an RTSA. Results are inferior with a nonfunctioning teres minor.⁶⁻⁸ An RTSA combined with a latissimus dorsi transfer may offer an improvement in active external rotation.^{9,10}

Recommendation

- In patients undergoing an RTSA, improvement in active external rotation cannot be expected, but a latissimus dorsi tendon transfer may offer some improvement [overall quality: moderate]

Question 3: What technical factors may affect outcome of an RTSA?

Case clarification

Intraoperatively, the patient undergoes an RTSA through a deltopectoral approach.

Relevance

There is debate as to preferred surgical approach and correct positioning of both the humeral and glenoid components.

Current opinion

Use of either a superolateral or deltopectoral approach is generally based on the surgeon's comfort level with either approach. The deltopectoral approach is thought to have a higher risk of instability, while the superolateral approach is thought to have a higher risk of glenoid component malpositioning and scapular notching. Subscapularis repair is thought to help prevent instability. An inferior tilt and inferior positioning of the glenoid component may prevent loosening and notching, respectively. Generally, the humeral component is inserted in neutral rotation.

Finding the evidence

- Cochrane Database, with search term "reverse arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "reverse shoulder arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): search using keywords "reverse arthroplasty" OR "reverse shoulder arthroplasty" OR "reverse total shoulder arthroplasty"

Quality of the evidence

Level II

- 1 nonblinded randomized controlled trial

Level III

- 2 retrospective comparative studies

Level IV

- 1 case series

Level V

- Expert Opinion: 2

Findings

RTSA performed through a superolateral approach has been found to have a lower incidence of postoperative instability than a deltopectoral approach (0% vs. 5.1%, $p < 0.05$), but a superolateral approach has been shown to be better for preventing fractures of the scapular spine and acromion ($p < 0.05$).⁷ A deltopectoral approach has been shown to have better preservation of active external rotation, better orientation of the glenoid component, and decreased glenoid loosening and scapular notching.⁷ Revision surgery is more frequently and easily performed through a deltopectoral approach, but when instability is a concern, a superolateral approach is preferable.^{1,4}

Subscapularis repair may decrease the rate of instability by creating an anterior envelope.¹ However, repair has no statistical effect on outcome.⁷

Inferior tilt of the glenoid component may increase notching,^{11,12} but prevent glenoid loosening.¹ Placing the glenoid baseplate as inferior as possible prevents notching and improves ROM.^{11,12} A larger-diameter glenosphere is associated with less pain and better strength.^{7,13}

Neutral rotation of the humeral component (compared with 20° retroversion) has better outcomes in terms of activities of daily living, strength, Constant score, radiologic loosening, and glenoid complications.⁷

Recommendations

Technical considerations when performing a RTSA include:

- Surgical approach is determined by surgeon preference; however, if instability is a concern, a superolateral approach may be preferable [overall quality: high]
- Subscapularis repair, if possible, is recommended [overall quality: low]
- Glenoid component positioning should include an inferior position and inferior tilt [overall quality: moderate]
- A larger-diameter glenosphere is recommended [overall quality: low]
- Humeral component should be in neutral rotation [overall quality: low]

Question 4: What are the results of an RTSA?

Case clarification

Three months postoperatively, the patient has good pain relief and active elevation of 115°.

Relevance

The results of RTSA are very good in some situations but are highly dependent on the indication. Long-term outcomes are uncertain.

Current opinion

Results of RTSA are very good for pain relief and improved active elevation in patients with cuff tear arthropathy and massive cuff tears. However, the results when performed for other indications are unclear. Long-term outcomes are unclear.

Finding the evidence

- 8 case series

Findings

At 2–10 year follow-up, RTSA is effective in treating loss of active elevation associated with massive rotator cuff tears.^{5,7,13–15} For cuff disease, RTSA can reliably restore elevation.^{5,7,14,15} Constant score, pain scores, and elevation improve and satisfaction is high. At 10 years, survivability is approximately 90% for implant retention and 70% for a Constant score greater than 30 points.^{7,15–18} Radiographic results deteriorate after 6 years, and clinical results after 6–8 years.^{7,14}

Results are dependent on the indication, with cuff disease having the best results. Results are better in primary vs. revision cases.^{5,13–15}

Recommendations

- Results are dependent on the indication, with cuff disease have the best results, and revision cases having the worst [overall quality: low]
- RTSA for cuff disease allows predictable improvement in pain and active elevation [overall quality: low]

Question 5: What complications are associated with an RTSA?**Case clarification**

At 9 months postoperatively, the patient presents with an acute worsening of pain and an inability to move her shoulder. Radiographs reveal an anterior dislocation.

Relevance

Early series of RTSA have had high complication rates.

Current opinion

Complication rates are high but dependent on the indication.

Finding the evidence

- Cochrane Database, with search term “reverse arthroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): clinical queries search/systematic reviews: “reverse shoulder arthroplasty”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): search using keywords “reverse arthroplasty” OR “reverse shoulder arthroplasty” OR “reverse total shoulder arthroplasty”

Quality of the evidence*Level II*

- 1 nonblinded randomized controlled trial

Level III

- 4 retrospective comparative studies

Level IV

- 5 case series

Level V

- 1 expert opinion

Findings

The most common complications include dislocation, infection, hematoma, acromial fracture, humeral fracture, and transient nerve palsy.¹ The reported complication rate is from 0 to 68%, with a 5–40% revision rate.^{5,17,19} Revision rates are higher for revision surgery.¹⁵

Instability Rate of 3.4% in primary cases,⁷ usually anterior with arm in extension and internal rotation.¹ Preventive measures include using a superolateral approach, avoiding retroversion of humerus, avoiding anteversion of glenoid, establishing optimal humeral length, and repairing subscapularis when possible.^{7,20,21} When instability occurs within the first 3 months, closed reduction is generally not successful. However, a later dislocation (>1 year) can usually be successfully treated with closed reduction.⁷

Infection Rate of 5.1% in primary cases,⁷ higher in revision cases.¹⁵ Most infections occur early and can be treated by lavage and antibiotics, but some occurring after 3 months do not respond to prosthesis retention.⁷

Glenoid loosening Rate of 4.1%, 55% of which occur within the first 2 years postoperatively.⁷ Risk factors are younger patient age (<70 years), female gender, and a superolateral approach.¹

Scapular notching Rate of 44–96%.^{12,15,22,23} Generally observed within the first 6 months postoperatively and appears to stabilize in some studies,^{12,13} but increase in incidence and severity with time in other studies.²² A superolateral approach leads to more notching ($p < 0.0001$).²² Notching has been found to be associated with poorer clinical results.¹² Placing baseplate as inferior as possible prevents notching.^{11,12}

Acromion fracture An acromion stress fracture does not affect outcome and may be neglected, but a scapular spine fracture often leads to painful dysfunction and may require operative treatment.^{7,24}

Recommendations

- Complication rates are high but dependent on the indication, with cuff disease having the lowest complication rate and revision cases the highest [overall quality: moderate]
- The most common complications include dislocation, infection, and hematoma [overall quality: moderate]
- Scapular notching is common, but may not affect outcome [overall quality: low]

Summary of recommendations

- In patients greater than 70 years of age, a RTSA can be considered when rotator cuff dysfunction leads to antero-superior escape and a pseudo-paralyzed shoulder
- The most common indication is cuff tear arthropathy or a massive cuff tear with glenohumeral arthritis; however, patients with RA, proximal humerus fractures, and failed arthroplasty may also be considered, when all other options are exhausted
- In patients undergoing a RTSA, improvement in active external rotation cannot be expected, but a latissimus dorsi tendon transfer may offer some improvement in active external rotation
- Technical considerations when performing a RTSA include:
 - Surgical approach is determined by surgeon preference, but if instability is a concern a superolateral approach may be preferable
 - Subscapularis repair, if possible, is recommended
 - Glenoid component positioning should include an inferior position and inferior tilt
 - A larger diameter glenosphere is recommended
 - Humeral component should be in neutral rotation
- Results are dependent on the indication, with cuff disease have the best results, and revision cases having the worst
- RTSA for cuff disease allows predictable improvement in pain and active elevation

- Complication rates are high but dependent on the indication, with cuff disease having the lowest complication rate and revision cases the highest
- The most common complications include dislocation, infection, and hematoma
- Scapular notching is common, but may not affect outcome

Conclusion

In patients greater than 70 years of age, a RTSA can be considered when rotator cuff dysfunction leads to antero-superior escape and a pseudo-paralyzed shoulder. Results are dependent on the indication. RTSA allows predictable improvement in pain and active elevation. Complication rates are high but dependent on the indication. The most common complications include dislocation, infection, and hematoma.

Glenoid Fixation in Total Shoulder Arthroplasty: What Type of Glenoid Component Should We Use?

Eric C. Benson¹, Kenneth J. Faber², and George S. Athwal²

¹University of New Mexico, Albuquerque, NM, USA

²St. Joseph's Health Care, University of Western Ontario, London, ON, Canada

Case scenario

A 72 year old right-hand dominant man has been experiencing 3 years of right shoulder pain. He denies previous trauma. Instead, the pain has been insidious in onset and has failed nonoperative treatment. Radiographic studies including conventional radiographs and CT scan show considerable degenerative changes with loss of joint space, marginal osteophytes, subchondral sclerosis, and significant posterior glenoid erosion (Figure 33.1a,b,c).

Relevant anatomy

Total shoulder arthroplasty (TSA) appears to be the most reliable treatment option for patients with shoulder arthritis that is unresponsive to nonoperative management. Despite improvements in our understanding of the relevant anatomy and factors that influence glenoid fixation, failure of the glenoid component remains the most common mode of failure for shoulder arthroplasty. Glenoid version, the orientation of the glenoid articular surface relative to the transverse axis of the scapula, is typically between 2° of anteversion and 9° of retroversion.^{1,2} Patients with osteoarthritis (OA) typically have significantly increased retroversion of the glenoid compared to normal anatomy, with up to 30° or more of retroversion.³ This affects glenoid fixation and shoulder mechanics, and may ultimately affect the longevity of the glenoid component.

Importance of the problem

Roughly 20,000 TSAs are performed in the United States each year for OA.⁴ This is compared to 7000 annually from

1996 through 2002, indicating a 185% increase.⁵ As the frequency of TSA increases, the anticipated burden of revision arthroplasty is also expected to increase. One of the most important outcome measures for any joint replacement procedure is the rate of revision-free survivorship. In TSA, the most frequent cause for revision in mid- and long-term follow-up is glenoid component failure. Bohsali et al. performed a retrospective review of the literature from 1996 to 2005 to identify complications associated with TSA. They found that glenoid loosening accounted for 32% of all complications and occurred in 5.3% of 2540 shoulders.⁵

Pain, functional limitation, and occasionally mechanical symptoms can accompany glenoid loosening leading to the need for revision. Buckingham et al. evaluated the changes in patients' functional self-assessment at an average of 7.4 years after primary TSA and just prior to revision for glenoid component loosening. Although the numbers in their study were small, the data are telling of the functional decline with a failed glenoid component: mean simple shoulder test scores prior to initial arthroplasty were 4.4, they rose to 11.3 at their peak, but fell back to 4.6 just prior to revision. In addition, at the time of revision less than 50% of patients reported comfortable sleep (17%), the ability to wash the back of the contralateral shoulder (8%), place their hand behind their head (33%), lift 8lbs (3.6kg) to shoulder level (35%), throw a softball 20 yards (18m) (0%), or work at their regular job (25%).⁶ Failure of glenoid fixation may contribute to dramatic changes in patients' quality of life and overall functional status, emphasizing the importance of improving techniques and technologies to maximize glenoid component longevity.

As the volume of TSA increases over time, so too does the body of information related to the procedure. The available information is not always founded in sound methodology or evidence-based principles. 106,000 hits resulted from a Google internet search of the terms "glenoid

Figure 33.1 AP and axial radiographs (a,b) and axial CT scan (c) show characteristic findings in glenohumeral osteoarthritis.

fixation.” The goal of this chapter is to identify and compile the best-quality information available to generate evidence-based treatment guidelines for glenoid fixation based on evidence from the last 10 years.

Top five questions

Diagnosis

1. What is the best method of determining clinically relevant glenoid loosening?

Therapy

2. What is the optimal degree of radial mismatch?
3. Which is optimal: all-polyethylene cemented or metal-backed uncemented?
4. Which is optimal: keel or pegged glenoid?

Prognosis

5. Do early radiographic lucent lines around the glenoid component predict outcomes?

Question 1: What is the best method of determining clinically relevant glenoid loosening?

Case clarification

A patient who had a previous TSA now presents with shoulder pain and popping with range of motion (ROM) of the shoulder. Their pain has returned to the level they experienced prior to their initial replacement.

Relevance

The decision to revise a loose glenoid component depends on radiographic criteria as well as clinical assessment. It is

important that our imaging criteria accurately correlate to the clinical picture if they are to help guide our treatment decisions.

Current opinion

CT scan provides data that better correlates radiographic evidence of loosening and clinical symptoms when compared to conventional radiographs.

Finding the evidence

- Cochrane Database: no Cochrane reviews found
- PubMed clinical queries search/systematic reviews: “total shoulder arthroplasty” as well as “glenoid”
- PubMed sensitivity search. The following is the Query Translation:
 - (glenoid[All Fields] AND total[All Fields] AND (“shoulder”[MeSH Terms] OR “shoulder”[All Fields]) AND (“arthroplasty”[MeSH Terms] OR “arthroplasty”[All Fields])) OR (total[All Fields] AND (“shoulder”[MeSH Terms] OR “shoulder”[All Fields]) AND (“replantation”[MeSH Terms] OR “replantation”[All Fields] OR “replacement”[All Fields])) NOT resurfacing[All Fields] NOT reverse[All Fields] NOT (“fractures, bone”[MeSH Terms] OR (“fractures”[All Fields] AND “bone”[All Fields]) OR “bone fractures”[All Fields] OR “fracture”[All Fields]) AND (“1999/09/30”[PDat] : “2009/09/26”[PDat])

Quality of the evidence

Level III

- 3 observational studies

Findings

Currently, the majority of clinical trials use conventional radiographs to determine glenoid loosening, but the reliability of this method remains uncertain (Figure 33.2). Mileti found that there was no correlation between pain,

Figure 33.2 AP radiograph of a keeled glenoid component without evidence of radiolucent lines.

ROM, or satisfaction relative to conventional radiographic criteria for glenoids considered stable or those at risk for loosening.⁷ In a study by Nho, conventional radiographs significantly underestimated intraoperative findings of loosening. In this retrieval study, including 73 glenoid components, the mean pre-revision radiolucency score was 7.1 (indicating they were possibly loose) whereas at revision 92% of glenoids were loose.⁸ These studies, then, raise the question of whether conventional radiographic criteria accurately represent true clinical loosening.

Yian evaluated conventional radiographs and CT scans as tools to assess radiographic lucency about glenoid components. He found that conventional radiographic lucency scores did not correlate to clinical outcomes such as the Constant score, pain score, or active shoulder mobility. In contrast, he found the CT scan scores significantly, though weakly, correlated with pain scores and abduction strength. In addition, inter- and intraobserver reliability scores were both higher for CT scan evaluation (0.89 and 0.95, respectively) than for conventional radiographs (0.47 and 0.70, respectively).⁹

Recommendations

- Compared to conventional radiographic scoring criteria, CT scan radiolucency scoring criteria correlate better with clinical outcome measures [overall quality: low]
- CT scan scoring systems have better inter- and intraobserver reliability [overall quality: low]

Question 2: What is the optimal degree of radial mismatch?

Case clarification

The patient's CT scan shows 20° of glenoid retroversion preoperatively. There is no history of prior instability. You must decide whether to use a glenoid component with more or less radial mismatch.

Radial mismatch refers to the difference in radius of curvature between the glenoid component and the humeral head.

Relevance

Glenoid component radial mismatch is broadly categorized as either more conforming (small mismatch) or less conforming (large mismatch). There remains considerable debate regarding the optimal amount of articular congruity of these implants. Theoretical advantages of a more conforming device include joint stability, concentric loading, and greater contact surface area with decreased wear rates; the disadvantages are that it does not allow coupled translation of the shoulder with resulting increased stress at the implant-bone junction as well as increased shear forces. Theoretical advantages of the less conforming device include better-coupled translation but at the risk of joint instability, decreased contact surface area with increased wear rates, and component fracture.^{10,11}

Finding the evidence

- Cochrane Database: no Cochrane reviews
- PubMed clinical queries search/systematic reviews: "total shoulder arthroplasty" as well as "glenoid"
- PubMed sensitivity search: the Query Translation was the same as for Question 1

Quality of the evidence

Level III

- 1 observational study
- 2 biomechanical studies

Findings

The biomechanics of the shoulder joint demonstrate coupled translation of the humeral head during rotation.¹² Biomechanical studies demonstrate that implant designs with less conformity better recreate the normal coupled translation of the glenohumeral joint. Anglin concluded that greater radial mismatch performed better with less distraction than did the lower radial mismatch device. The authors' numbers were quite small, however, looking at only three implants of each type.¹³ Harryman used seven cadaveric shoulders to compare the effect of various amounts of radial mismatch on glenohumeral translation.

Measuring radial mismatches of 0–5 mm he concluded that a radial mismatch of 5 mm best reproduces the normal joint translation. The translation was 1.5 mm for the native glenoid and 1.7 mm with a radial mismatch of 5 mm for the TSA.

In order to determine the clinical applicability of some of these results, Walch, in a retrospective multicenter trial, looked at the correlation between radial mismatch and clinical outcomes. At a mean follow-up of 53.5 months, there was a significant difference in the mean radiolucency score on AP radiographs based on the amount of joint congruity. In 319 TSAs, those with a radial mismatch of greater than 6 mm demonstrated significantly lower radiolucency scores than those with a mismatch of 4 mm or less. Patients with a mismatch of 6–7 mm had the highest Constant scores at final follow-up, but this was not statistically significant. In fact, the only significant parameter correlated with radial mismatch in this study other than mean radiolucency score was improved external rotation in patients with radial mismatch of 4.5–7 mm. There was no effect of radial mismatch on rate or type of complication (instability), forward elevation, internal rotation, the Constant score, or any component of the Constant score (pain, activity, mobility, or strength).¹⁰

Recommendations

- Radial mismatch of 5–7 mm best recreates normal glenohumeral joint kinematics [overall quality: low]
- Radial mismatch of 6–7 mm improves radiolucency scores at 4.5 years [overall quality: low]
- At present, no recommendation can be made regarding the effect of radial mismatch on clinical outcomes or survivorship of glenoid implants.

Question 3: Which is optimal: all-polyethylene cemented or metal-backed uncemented?

Case clarification

The patient elects to proceed with TSA and you have decided on a glenoid component with 5 mm of radial mismatch. Next, you must decide whether to use an all-polyethylene cemented component or a metal-backed uncemented component.

Relevance

Securing durable and reliable fixation of the glenoid component is critical to success in TSA. Two main categories of implant design have been widely used and studied: cemented pegged or keeled all-polyethylene components, or uncemented metal-backed components. The theoretical advantage of the uncemented designs is that the initial stability afforded by screw fixation ultimately allows for durable bone ingrowth or bone ongrowth. The theoretical disadvantage of cemented components is that tempera-

tures generated with methylmethacrylate may rise to levels risking bone necrosis. Churchill showed that mean bone temperatures adjacent to cemented components exceeded 64 °C, well above the threshold for thermal-induced bone necrosis.¹⁴

Finding the evidence

- Cochrane Database: no Cochrane reviews
- PubMed clinical queries search/systematic reviews: “total shoulder arthroplasty” as well as “glenoid”
- PubMed sensitivity search. The Query Translation was the same as for Question 1

Quality of the evidence

Level II

- 1 randomized trial with limitations

Level III

- 5 observational studies
- 3 biomechanical studies

Level IV

- 1 systematic review

Findings

There is no level I study and only one level II study comparing uncemented metal-backed glenoids to cemented all-polyethylene components. In a prospective randomized study, Boileau compared 20 shoulders in each of two groups: cemented all-polyethylene keeled glenoids and uncemented metal-backed glenoids. Glenoid type was not chosen until after humeral preparation was complete and so patient and surgeon were blinded until this point. Four patients died in the study, leaving 90% follow-up of at least 3 years with a mean of 38.4 months for the metal-backed and 37 months for the polyethylene group. Clinical outcome measures included the Constant score, forward elevation, and external rotation. There was no statistical difference between the two groups at any time point, including at final follow-up for any of these outcome measures. Radiographic lucency was noted in 85% of polyethylene components vs. 25% of metal-backed components, and this was a significant difference ($p < 0.001$). Progression to radiographic loosening and need for revision surgery did not occur in the polyethylene group, but did occur in four shoulders (20%) of the metal-backed group. This difference in revision surgery rate (0% vs. 20%) was statistically significant. Ultimately, despite equivalent results between the two glenoid component types in this short-term follow-up study, the higher revision rate for metal-backed glenoids led the author to conclude that use of metal-backed components should be abandoned.¹⁵ (Figure 33.3)

In addition, Boileau drew some conclusions regarding the proposed mechanisms of failure of the metal-backed

Figure 33.3 AP radiograph demonstrating severe osteolysis about an uncemented, metal-backed glenoid component.

glenoid implants. The modes of failure he described were insufficient polyethylene thickness, overtensioning of the rotator cuff due to a thicker glenoid component, stress shielding of underlying cancellous bone, increased component rigidity leading to increased polyethylene wear, and eccentric loading leading to dissociation of the polyethylene.¹⁵

There are several retrospective studies comparing these two groups of glenoid components. The most recent, by Fox, retrospectively assessed survival of the glenoid component in TSA. Six types of glenoid components used in 1542 TSAs are analyzed. Among these were two metal-backed designs: one cemented and one uncemented. Out of all the cases there were 121 revisions. Survival free of revision or removal for all four types of the all-polyethylene cemented glenoid designs combined were: 98% (95% CI 98–99%) at 5 years, 95% (95% CI 93–98%) at 10 years, and 92% (95% CI 88–96%) at 15 years. Revision-free survival rates for the Neer II metal-backed glenoid were 96%, 94%, and 89%; for the Cofield 1 metal-backed component they were 86%, 79%, and 67%. Metal-backed component types in this study were significantly associated with component revision ($p < 0.001$).¹⁶

There are two studies that individually analyze the results of uncemented and cemented metal-backed components. These both represent cases from the same institution and from a time period overlapping the study by Fox above, so it cannot be determined whether these are separate cases

or if they represent data points used in the calculations from Fox's analysis. The first of these, a retrospective study by Taunton, looked at the survivorship of uncemented metal-backed glenoids after 9.5 years, and it reports a calculated 10-year Kaplan–Meier survival estimate of 78.5%.¹⁷ In an analysis of 100 metal-backed cemented glenoids, Tammachote found the following survival rates: 98% (95% CI 95–100%) at 5 years, 97% (95% CI 93–100%) at 10 years, and 93% (95% CI 87% to 99%) at 15 years.¹⁸

In a retrospective study of metal-backed glenoids from a different institution, Martin calculated an 85% 10-year survivorship based on 7.5 years of follow-up on 140 glenoids.¹⁹

Some information can be drawn from several studies comparing hemiarthroplasty to TSA. Edwards evaluated 601 TSAs in a retrospective multicenter series, of which 238 used uncemented metal-backed glenoid components. Of the 601 cases, 23 of the 25 that required revision for glenoid complications were in the metal-backed group, or 9.7%. Only 2 of the remaining cases, all of which used all-polyethylene cemented glenoids, required revision.²⁰

In a systematic review investigating the results of TSA vs. hemiarthroplasty, Radnay was able to extract data specific to revision rates for all-polyethylene and metal-backed glenoid components. The mean level of evidence of the 23 studies included in this review was 3.73, and the mean follow-up was 43.4 months. Of 1238 TSAs, 6.5% required revision. Of the metal-backed glenoid components, 6.8% required revision vs. only 1.7% of all-polyethylene components. They did not report if this difference demonstrated statistical significance.²¹

In biomechanical studies, both Stone and Gupta showed that there are high stress levels at the polyethylene–metal interface, leading to the potential for backside wear.^{22,23} Both Stone and Pelletier demonstrated evidence of stress shielding associated with metal-backed glenoids as compared to all-polyethylene glenoids, results that support one of Boileau's proposed mechanisms of failure of these devices.^{22,24}

Recommendation

- With current designs, all-polyethylene cemented glenoid components have lower revision rates than uncemented metal-backed glenoids, and the use of metal-backed glenoids should be abandoned [overall quality: moderate]

Question 4: Which is optimal: keel or pegged glenoid?

Case clarification

In this patient with primary OA of the shoulder you have decided to use a glenoid with 5mm of radial mismatch that is an all-polyethylene, cemented component. Now you must decide whether to use a keel or a pegged design.

Relevance

Equally important in the discussion of optimal designs for secure glenoid fixation, there remains the choice between cemented keeled and pegged glenoids. There are two considerations with regard to these two designs. Keeled glenoids are typically easier to implant, requiring somewhat less exposure for instrumentation. Pegged glenoids involve less removal of glenoid bone, potentially exposing less bone to the risk of thermal necrosis. Ultimately, however, the most important question remains: which of these two designs yields improved clinical outcomes and improved longevity?

Finding the evidence

- Cochrane Database: no Cochrane reviews
- PubMed clinical queries search/systematic reviews: no results with any search terms
- PubMed sensitivity search: the Query Translation was the same as for Question 1

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 randomized trial with limitations

Level IV

- 3 observational studies
- 5 biomechanical studies

Findings

The literature search for this question identified one level I study, one level II study, and three level III observational clinical studies. There are multiple biomechanical studies that investigate the properties of keeled and pegged glenoids.

In the only level I study pertaining to this question, Gartsman conducted a prospective randomized trial in which 23 patients were randomized to a keeled component and 20 were randomized to a pegged component. In this study, keeled components showed a higher incidence and higher overall grade of radiographic lucency as compared to pegged components. At 6 weeks, 9 of 23 (39%) of the keeled glenoids compared to 1 of 20 (5%) of the pegged glenoids showed evidence of radiographic lucency ($p = 0.026$). (Figure 33.4) The two main limitations to this study include the inherent limitation of radiographic interpretation and that it only addresses the acute postoperative time period. Longer follow-up is needed to see if the initial radiographic lucency correlates to increased revision rates or clinical failure. Gartsman raises the question that it is unclear how radiographic evaluation of peg and keel glenoids correlate.

Figure 33.4 AP radiograph of a pegged glenoid component without evidence of radiolucent lines.

CT scan might have been a better imaging modality to determine outcomes in this study.²⁵

One level II study, a prospective randomized trial with some limitations, pertains to this question. In this study, Nuttall randomized 10 patients each to pegged or keeled components. Radiostereometric analysis was used to identify movement of the glenoid implant relative to the scapula over 24-month follow-up. Keeled components showed significantly more movement than the pegged glenoids. Both types of components demonstrated positional changes over the 2 years, but the keeled components migrated to a significantly greater degree based on radiostereometric analysis. It remains unclear, however, whether there is any clinical correlation with these findings. Nuttall reports significant improvement for both types of glenoid with regard to clinical outcome measures ($p < 0.001$): visual analog pain score, abduction, forward flexion, American Shoulder and Elbow Surgeons (ASES) score, and Constant–Murley score. However, in interpreting the data provided, the keeled components actually showed better final ROM and ASES and Constant–Murley scores, and larger improvements for these outcomes than did the pegged components. The author does not comment on this, nor are statistical analyses provided to determine whether these differences are significant.²⁶

There are three observational studies identified by this literature search that are all level IV evidence. Lazarus reviewed the initial postoperative radiographs of 328 TSAs

and found a significant difference in radiolucency score favoring pegged components (1.3 vs. 1.8, $p = 0.0004$). He concedes that the results may be biased in that intraoperative conversion from a planned pegged implant to a keeled implant for difficulties with exposure may indicate discrepancies in the patient groups, and these cannot be accounted for in this retrospective study.²⁷ Klepps, in a study analyzing old vs. new cementation techniques, extrapolated significant differences favoring pegs in average radiolucency score ($p < 0.05$), and in a single zone showed a significantly decreased incidence of radiolucent lines greater than 1 mm. He concludes that despite these results, it is impossible to claim either design as superior to the other.²⁸ Trail showed a lower incidence of at least one zone with 1 mm lucency for pegs (36%) vs. keels (90%, $p = 0.005$) at 8-year follow-up, but none of these components were grossly loose.²⁹ Although all three of these studies demonstrate statistically better radiographic lucency scores for pegged vs. keeled components, at present this data cannot be correlated to improved clinical outcomes.

Four out of the five biomechanical studies also conclude that peg fixation is superior to keel fixation for the glenoid.^{13,14,30,31} One biomechanical study by Roche concludes that there is no difference in glenoid fixation using keel or pegged components. This study has several limitations, including insufficient power and the use of polyurethane bone substitute rather than human bone.

Recommendations

- Based on the available outcome measures, pegged glenoid components outperform keeled components [overall quality: low]
- With the data available, and given the lack of correlation between the outcome measures and clinical results, it is impossible to recommend one component design over the other.

Question 5: Do early radiographic lucent lines around the glenoid component predict outcomes?

Case clarification

The patient underwent a right TSA and on follow-up postoperative radiographs, there is evidence of minor (<1 mm) radiolucency around part of the glenoid. How should you now counsel the patient with regard to outcomes?

Relevance

The ability to predict long-term outcomes is important in any arthroplasty setting. Many published papers that address glenoid stability and survivorship use radiographic lucency scores as one of the main outcome measures, basing this choice on the assumption that lucency may predict glenoid loosening or clinical failure. (Figure

Figure 33.5 AP radiograph of a pegged component demonstrating lucent lines around the entire component.

33.5) In one paper frequently cited to support this assumption, Torchia showed that 93% of glenoids with progressive radiographic lucency had lucencies on immediate postoperative radiographs. In contrast, only 44% of glenoids without initial lucencies showed evidence of progression.³² Despite this data, without appropriate statistical analysis and power, this observation must be interpreted with caution. The question remains, does radiographic lucency correlate with progressive loosening, clinical outcomes, or decreased survivorship? Put another way, is the use of radiographic lucency scores appropriate as a primary outcome measure for studies investigating glenoid fixation and survivorship?

Finding the evidence

- Cochrane Database: no Cochrane reviews
- PubMed clinical queries search/systematic reviews: no results with any search terms
- PubMed sensitivity search: the Query Translation was the same as for Question 1

Quality of the evidence

Level II

- 1 randomized trial with limitation

Level IV

- 4 observational studies

Findings

The literature search for this question yielded one level II study and four level IV studies. As part of his prospective randomized investigation of cemented all-polyethylene vs. uncemented metal-backed glenoids, Boileau was able to extract data regarding radiographic lucency for glenoids at 3 years follow-up. He noted that 60% of glenoids had less than 1mm lucency on immediate postoperative radiographs, but 85% showed radiolucent lines at 3 years. He reported a 25% incidence of progression. No analysis was performed comparing progression in those with and without early radiographic lucency. Nonetheless, over 3 years, 25% showed some progression.¹⁵

All four level IV studies showed similar findings. Radiographic lucent lines typically progressed in short- and mid-term follow-up, but there was no correlation between initial radiographic lucent lines and progression, clinical outcome measures, or glenoid loosening.

In a study of 70 TSAs with cemented keeled glenoids, Mileti showed that in cases without initial radiolucency, 73% progressed. In those with radiolucency postoperatively, 76% progressed. There was no correlation between initial radiographic lucency and the risk of progression. There was no correlation between radiographic criteria and clinical loosening.⁷

Yian's results on 47 total shoulder replacements indicate radiolucency in 11% immediately after surgery and in 45% at 40 months. There is no comment whether there is increased risk of progression in those with early radiolucency.⁹ Edwards' results were similarly inconclusive: in this study 57% of glenoids showed radiolucent lines and 50% of these progressed, but there is no description of results for those glenoids that had no radiolucencies. Progression occurs, but no predisposing factors were identified and no conclusions could be drawn with regard to clinical outcomes.²⁰

Phaler's level IV series was the largest and included 705 TSAs. He used a combination of 585 keeled flat glenoids, 62 pegged flat glenoids, and 58 keeled convex glenoids. Of the entire cohort, 68% of glenoids showed some radiolucent lines at some point. In 129 shoulders where appropriate serial radiographic imaging was done, 50% were stable and 50% progressed. These scores did not correlate with functional results as determined by the Constant score. Even progression did not correlate with Constant scores.³³

Recommendations

- With current techniques, 25–50% of cemented all-polyethylene glenoids may show progression of radiographic lucency [overall quality: moderate]
- Early radiolucent lines do not predict progression of radiolucency, clinical outcome measures, or loosening [overall quality: low]

Summary of recommendations

- Compared to conventional radiographic scoring criteria, CT scan radiolucency scoring criteria correlate better with clinical outcome measures
- CT scan scoring systems have better inter- and intraobserver reliability
- Radial mismatch of 5–7mm best recreates normal glenohumeral joint kinematics
- Radial mismatch of 6–7mm improves radiolucency scores at 4.5 years
- At present, no recommendation can be made regarding the effect of radial mismatch on clinical outcomes or survivorship of glenoid implants
- With current designs, all-polyethylene cemented glenoid components have lower revision rates than uncemented metal-backed glenoids, and the use of metal-backed glenoids should be abandoned
- Based on the available outcome measures, pegged glenoid components outperform keeled components
- With the data available, and given the lack of correlation between the outcome measures and clinical results, it is impossible to recommend one component design over the other
- With current techniques, 25–50% of cemented all-polyethylene glenoids may show progression of radiographic lucency
- Early radiolucent lines do not predict progression of radiolucency, clinical outcome measures, or loosening

Conclusions

Since Neer first published his report of glenohumeral joint replacement in 1975, the volume of TSAs performed worldwide has continued to increase.^{4,5,34} Successful TSA requires secure and lasting fixation of the glenoid component. To date, the optimal type of glenoid design has not been determined. The current literature that addresses glenoid design and fixation lacks adequate randomization as well as statistical analysis and power to confidently report evidence-based treatment guidelines. Overall, it seems clear that existing metal-backed, uncemented glenoid components are to be abandoned due to poor survivorship relative to all-polyethylene, cemented components. Low-quality evidence suggests that glenoid implants with radial mismatch of 5–7mm and either pegged or keeled design may represent the best choice of component. CT scans are likely useful to determine clinically significant loosening. Current evidence does not support any correlation between early radiolucent lines and clinical or functional outcomes or radiographic progression of lucency.^{11,15}

Glenoid fixation is challenging as a result of the local anatomy and bone stock. Further investigation is required with better randomization, better controls, better statistical analysis and more relevant outcome measures before evidence-based guidelines of treatment can be generated.

Fusion vs. Arthroplasty in the Treatment of Ankle Arthritis

Timothy R. Daniels¹, Mark Glazebrook,² Terence Chin², and Roger A. Haene¹

¹St. Michael's Hospital, University of Toronto, Toronto, ON, Canada

²Queen Elizabeth II Health Sciences Centre, Halifax, NS, Canada

Case scenario

A 58 year old man in good general health but with a past history of a previous tibial pilon fracture presents with signs and symptoms of endstage ankle osteoarthritis (OA) (Figure 34.1). On examination, he has a well-aligned hind-foot with stiffness and irritability of the ankle joint. He has a supple and pain-free subtalar joint complex. He wishes to consider surgical intervention and in particular, wants to discuss the role of ankle arthrodesis vs. total ankle arthroplasty (TAA).

Top eight questions

1. What is the long-term clinical outcome of ankle arthrodesis?
2. What is the best technique for performing ankle arthrodesis?
3. Does ankle arthrodesis accelerate the development of ipsilateral subtalar complex OA?
4. What is the medium- to long-term outcome of modern TAA?
5. What are the main complications of TAA?
6. Does TAA protect the subtalar joint complex from accelerated degeneration?
7. Are there any direct comparisons of ankle arthrodesis vs. TAA in the literature?
8. Does TAA result in more normal gait compared to ankle arthrodesis?

Question 1: What is the long-term clinical outcome of ankle arthrodesis?

Case clarification

The surgical management of endstage ankle arthritis has been an area of much debate.

Relevance

For over a century now, ankle arthrodesis (Figure 34.2) has been the most commonly performed surgical procedure for the treatment of endstage ankle arthritis.¹⁻¹² Concerns exist regarding the long-term durability of ankle arthrodesis, especially in regard to the development of ipsilateral hind-foot degeneration leading to significant pain and impaired function.¹³⁻¹⁵

Current opinion

Ankle arthrodesis has traditionally been seen as the most reliable surgical method of treating ankle arthritis.

Finding the evidence

- PubMed, using search terms: "ankle," together with "osteoarthritis" OR "arthrosis" OR "fusion" OR "arthrodesis". Limits included: "English language" AND "humans"
- The reference list of all eligible papers was also cross-referenced for further studies which did not come up on the original PubMed search.

Quality of the evidence

Most studies contain level III and IV evidence. The vast majority are in fact retrospective level IV case series with

Figure 34.1 Endstage ankle arthritis.

Figure 34.2 Open ankle arthrodesis with internal fixation.

heterogeneous populations, small patient numbers, and high rates of patients lost to follow-up, and do not use standardized or validated functional outcome instruments.^{1-3,5-7,9,11,16-25}

Findings

The published reports on the outcomes of ankle arthrodesis have mainly been favorable, with good relief of ankle pain and high rates of patient satisfaction. Good results have

been reported in 66–90% of patients in the medium term.^{1,2,5,6,10,12,16,19-23,26-29} In a meta-analysis comparing the results of ankle arthrodesis and TAA, Haddad et al. reviewed 39 studies on ankle arthrodesis from 1990 to 2005, and found between 67% and 73% good/excellent results.³⁰ The authors warn caution in interpreting these results as most studies reviewed are of poor scientific quality, with many studies lacking key data elements, having variable patient baseline characteristics, outcome reporting, and surgical procedures. In a recent level III study assessing functional outcomes and gait analysis, Thomas et al. reviewed 26 patients with ankle arthrodesis performed using modern screw fixation techniques with age-matched normal controls.¹⁵ The authors utilized validated outcome scores—ankle osteoarthritis score (AOS) and the Musculoskeletal Outcomes Data Evaluation and Management Systems (MODEMS) questionnaire. Using intermediate-term follow-up of patients with ankle arthrodesis this study demonstrated acceptable pain relief, improvement in overall function, and high rates of patient satisfaction, but persistent disability with reduced foot and ankle function when compared to controls.¹⁵

Recommendation

- Good results may be expected in 66–90% of patients in the medium term [overall quality: very low]

Openmirrors.com **Question 2: What is the best technique for performing ankle arthrodesis?**

Case clarification

Arthrodesis technique in the ankle will not only influence the union process, but will also affect the long-term mechanics of the lower limb.

Relevance

Prior to the 1950s, ankle arthrodesis was performed with plaster of Paris cast immobilization.¹⁶ Recognizing the importance of eliminating shear strain and gap formation between cut bone surfaces, Sir John Charnley described the method for compression arthrodesis of the ankle joint in his landmark paper of 1951.⁶ This technique and modifications thereof was to be widely used over the next 20 years.^{8,21,23,31,32} Internal fixation gained popularity in the 1970s.

Current opinion

To date, up to 35 different methods of internal fixation (screws, plates, and staples with or without inlay/onlay bone graft) have been described.^{8-10,23,25,33-43}

Finding the evidence

- PubMed, using search terms: “ankle,” together with “osteoarthritis” OR “arthrosis” OR “fusion” OR “arthrodesis.” Limits included: “English language” AND “humans”

- The reference list of all eligible papers was also cross-referenced for further studies which did not come up on the original PubMed search

Quality of the evidence

Current recommendations on the optimum position for ankle arthrodesis are based on level III studies.

Findings

Current recommendations on the optimum position for ankle arthrodesis conclude that the ideal position is neutral dorsiflexion, 0–5° of valgus, external rotation of 5–10° or equal to the contralateral side, and with the talus positioned directly under or slightly posterior to the anatomic axis of the tibia. The latter reduces the anterior lever arm of the foot on the arthrodesis site and also improves ground clearance.^{11,29,44–46} This position maximizes the compensatory potential of the subtalar and transverse tarsal joints and allows the closest approximation to normal gait patterns for the knee, foot, and ankle.⁴⁴

Level III/IV evidence indicates lower nonunion (<10% vs. 40%) and infection rates (<5% vs. up to 40%) when ankle arthrodesis is performed with modern screw internal fixation compared to large pin external fixation.^{10,12,28,29,33,36,37,47–49}

In terms of rigidity of internal fixation, biomechanical testing on cadaver models has shown the following:

- two crossed screws provide a more rigid construct than two parallel screws
- three screws provide greater compression and resistance to torque compared to two
- the addition of a fibular strut graft provides added stability compared to a two-screw construct, especially if the bone quality is poor.^{50–52}

Most surgeons agree that a minimum of two screws are required for rigid fixation, and good results have been obtained with both two and three screws.^{10,28,29,36,37,48}

Currently, external fixation with fine-wire or hybrid frames is recommended for complex ankle fusions in the setting of infection, poor-quality soft tissues, significant bone loss or deformity correction, and salvage of failed TAA.^{53–55} Satisfactory outcomes are reported in level IV studies. The Ilizarov construct provides excellent stiffness and shear rigidity in bending and torsion while allowing for axial compression.⁵⁶ It also allows for continued adjustment to correct deformity and improve compression throughout the treatment period.

Schneider first described the technique of arthroscopic ankle arthrodesis in 1983.⁵⁷ There is level III/IV evidence suggesting lower infection rates, shorter hospital stays, shorter fusion times, and union rates at least equivalent to open ankle arthrodesis.^{7,58–63} The reported advantages of arthroscopic ankle arthrodesis should, however, be interpreted with caution, as most studies report on patients with minimal ankle deformity. Level III studies comparing

arthroscopic and open ankle arthrodesis are similarly biased by having patients with lesser deformities in the arthroscopic group.^{61,62,64} Nevertheless, arthroscopic ankle arthrodesis is less invasive and, is theoretically beneficial in patients with poor soft tissues (previous open fractures, skin grafts, and soft tissue flaps) or those with risk factors for soft tissue complications.^{61,62} Arthroscopic ankle arthrodesis requires a surgeon with experience in ankle arthroscopy.^{58,61,62} Current level III/IV evidence would support its use in ankle OA with minimal deformity (<15°), although recent studies suggest its efficacy with greater degrees of deformity.^{60,63}

As the outcomes of TAA improve, there is an increasing consideration to convert an arthrodesed ankle to TAA.^{43,65,66} Having intact malleoli is a prerequisite for this. More recently, surgical approaches to ankle arthrodesis that preserve the malleoli have been performed. These include the fibular sparing z-osteotomy lateral approach (Figure 34.2), open anterior approach, and arthroscopic ankle arthrodesis (Figure 34.3).^{7,43,61,62}

Recommendations

With regard to ankle arthrodesis, level III evidence exists to support the following:

- Use of modern internal fixation methods over older mainly external fixation techniques; three screws provide greater stability than two; any form of adjacent plate or fibular strut neutralization provides greatest stability (biomechanical cadaveric studies)
- The optimum fusion position of neutral plantar flexion, is 0–5° of valgus, external rotation of 5–10° or equal to the

Figure 34.3 Arthroscopic ankle arthrodesis.

opposite limb, and with the talus directly under or slightly posterior to the anatomic axis of the tibia

Recommendations for ankle arthrodesis can be made for the following:

- Equivalent fusion rates, shorter time to fusion lower morbidity, and shorter hospital stays may occur with arthroscopic ankle arthrodesis (although the level III/IV evidence base for this is still debated because of potential patient selection bias in some studies) [overall quality: low to fair]

Question 3: Does ankle arthrodesis accelerate the development of ipsilateral subtalar complex OA?

Case clarification

The younger the candidate for ankle arthrodesis, the more important it becomes to consider the more distant effects of ankle arthrodesis.

Relevance

Since our patient is 58 years old and in good general health, he might reasonably expect another 10–20 years of active use from the ipsilateral lower limb. The potential to develop hindfoot degeneration may be an important factor in reaching a decision.

Current opinion

There is increasing concern regarding the detrimental effect of a fused ankle on adjacent subtalar and transverse tarsal joints, with degeneration of these joints an important contributor to pain and impaired function after ankle arthrodesis (Figure 34.4).^{13–15,37,49,67,68}

Finding the evidence

- PubMed, using search terms “ankle,” together with “osteoarthritis” OR “arthrosis” OR “fusion” OR “arthrodesis.” Limits included “English language” AND “humans”
- The reference list of all eligible papers was also cross-referenced for further studies which did not come up on the original PubMed search.

Quality of the evidence

Most studies are of level III and IV evidence, mainly retrospective. There is one level III prospective study.

Findings

Hallock in 1945 reported poor results following ankle arthrodesis in patients who had subtalar and midtarsal OA.¹⁶ He noted that the ipsilateral hindfoot OA is usually due to the original trauma but may develop after ankle fusion. In a recent level III prospective study Thomas et al. reported on the development of moderate to severe subtalar OA in 4 of 26 patients at an average follow-up of 4.4

Figure 34.4 Ipsilateral hindfoot osteoarthritis after ankle arthrodesis.

years.¹⁵ Retrospective level III/IV studies with long-term follow-up (9–23 years) report 50–90% incidence of ipsilateral hindfoot (mainly subtalar joint) degeneration following ankle arthrodesis.^{13,14,49,68} Most of these studies however, use the older methods of fixation,^{13,14,68} do not assess for degenerative changes in these ipsilateral joints preoperatively^{14,49,68} and have a substantial proportion of patients fused in unsatisfactory positions (varus, equinus).^{14,49,68} Sheridan et al. (level IV evidence) showed that a significant proportion of patients have ipsilateral hindfoot and midfoot arthritis prior to ankle arthrodesis, and therefore ipsilateral joint degeneration may not be a direct consequence of the ankle arthrodesis.⁶⁹ In a population-based level III retrospective study, SooHoo et al. noted a significantly higher rate of subtalar joint fusion following ankle arthrodesis (2.8%) compared to TAA (0.7%).⁷⁰ Evidence from level III retrospective studies suggests the presence of subtalar OA after ankle arthrodesis correlates with poorer outcomes.^{13,14,68} Despite the high incidence of ipsilateral hindfoot OA after ankle arthrodesis, most patients remain satisfied.^{13,14,68}

In summary, there is level III and IV evidence in the literature indicating a high incidence of ipsilateral subtalar, and to a lesser extent, talonavicular OA in the setting of an ankle arthrodesis.^{1,4,13–16,67,68} A recent prospective study using modern techniques of ankle arthrodesis has shown a 15% incidence of progressive subtalar OA at 4 year follow-up.¹⁵

Current literature suggests that the high incidence of ipsilateral hindfoot arthritis observed in long-term outcome studies is the result of abnormal hindfoot mechanics,⁷¹ poor technique,^{13,14,68} and an increased incidence of pre-existing

ipsilateral hindfoot arthritis,⁶⁹ it is highly likely that with modern techniques the incidence will be lower but still substantial. Despite a high incidence of ipsilateral hindfoot OA following ankle arthrodesis, most patients derive definite benefit from the procedure, generally remain satisfied with the outcomes and many (>80–90%) would have the procedure again.^{4,10,13–15,19,28,29,47,68}

Recommendation

- Improvements in pain with high rates of patient satisfaction despite a high incidence of ipsilateral (predominantly subtalar joint) OA (mainly older level IV long-term studies with one recent level III short-term study) [overall quality: low to fair]

Question 4: What is the medium to long-term outcome of modern TAA?

Case clarification

First-generation TAA designs were two-component prostheses that were fixed using bone cement. In order to accommodate the cement mantle, bone resection was substantial. Since then, much progress has been made in the biomechanics of TAA, with a change to semiconstrained, uncemented, anatomic three-component designs with mobile meniscal bearings (Figure 34.5).^{72–75}

Relevance

Patients will want to know what the medium to long-term outcomes are for the newer generation designs of TAA.

Figure 34.5 Third-generation total ankle arthroplasty

Current opinion

The first-generation versions of TAA in the 1970s and 1980s showed disappointing results, leading Kitaoka et al.⁷⁶ to recommend that surgical treatment of rheumatoid arthritis (RA) and OA using TAA should be abandoned.

A resurgence of interest in TAA for treatment of endstage ankle arthritis has emerged due to improved second- and third-generation implant results^{77–80} and concurrent concerns regarding the long-term durability of ankle arthrodesis, especially in regard to the development of ipsilateral hindfoot OA leading to significant pain and impaired function.^{13–15}

Finding the evidence

- PubMed, using search terms: “ankle,” together with “osteoarthritis” OR “arthrosis” OR “arthroplasty” OR “replacement.” Limits included “English language” AND “humans”
- The reference lists of all eligible papers were also cross-referenced for further studies which did not come up on the original PubMed search

Quality of the evidence

The majority of TAA evidence is level IV, from small numbers of patients drawn from heterogeneous populations, followed for short periods of time and assessed using inconsistent and nonvalidated measures. There are very few independent studies presenting long-term TAA outcomes. In the past decade, there has been one study with level II evidence⁸¹ and none with level I evidence.

In spite of level III and IV studies, controversy still exists regarding the following:

- Whether patient age at time of TAA negatively influences outcome
- What the effect of preoperative coronal plane deformity has on TAA survivorship
- The significance of the relatively common finding of heterotopic ossification seen on radiographs following TAA.

Findings

Patient satisfaction Level IV evidence supports that marked pain improvement occurs after TAA in nearly all patients; however, some persistent pain is common. Postoperative range of motion following TAA will be roughly equivalent to the preoperative level.

Survival rates In papers with short- to medium-term follow-up the survival rates range from 67.7 to 98.7% with an overall mean of 87.6 % survival at 5 years (Table 34.1).^{49,73–75,77–80,82–93} Similar results have been published in a recent meta-analysis by Haddad et al.³⁰ In 2007, results from the Norwegian, Swedish, and New Zealand registers were published. Norwegian results showed 5-year survival of 89% and 10-year survival of 76%.⁸⁴ Swedish results

^aFive of the studies included used two separate prostheses in their study; they were considered separately in the interest of more thorough interpretation. This gives a total of 25 entries for this table.

(Copyright © 2011 by the American Orthopaedic Foot and Ankle Society, Inc., originally published in Foot & Ankle International, 30(10):946 and reproduced here with permission.)

showed 5-year survival of 78%,⁸¹ but the results for the three surgeons who performed the majority of TAAs averaged 86%. New Zealand data reflected 5-year survival rate of 86%.⁸⁶ What is clear from the outcome data is that survival rates vary among different institutions, and that increased surgeon experience is associated with better outcomes.

Predictors of outcome Level IV and III evidence supports that TAA outcomes are not significantly influenced by the underlying cause of ankle degeneration.

In a 1998 level III long-term study, Kofoed found only slight differences in outcomes between patients with OA and those with RA, with no differences in TAA survival.⁷² Similar findings were reported by Anderson in 2003 from a level IV study⁷⁵ and Valderrabano in 2004 in a level IV series,⁹³ although Valderrabano found that the revision rate was higher in patients with post-traumatic OA.⁹³ Neither

the Norwegian register⁸⁴ nor the Swedish register⁸⁵ found any significant influence, except for a nonsignificant tendency found in the Swedish register for TAA in the post-traumatic group to have a slightly lower survival rate.

Age at surgery is controversial. In a long-term level III study, Kofoed found that TAA outcomes were equal in patients of all ages,⁹⁶ with similar level IV evidence by Valderrabano at 4 years follow-up.⁹³ The Norwegian register showed no significant influence.⁸⁴ However, a level IV study by Spirit showed that at 3 years follow-up younger age negatively influenced reoperation rates,⁹¹ and the Swedish register showed that lower age at index surgery implied increased risk of revision.⁸⁵

Level of postoperative activity is not strictly related to age. In 2009, Naal's level IV series showed no association between increased postoperative physical activity levels and the appearance of periprosthetic radiolucencies at 3.7 years after TAA.⁹⁷

Figure 34.6 (a) Preoperative varus ankle deformity. (b) Postoperative position with total ankle arthroplasty.

Gender has no significant influence on TAA outcome, according to both Norwegian⁸⁴ and Swedish registers.⁸⁵

Preoperative coronal plane ankle deformity (Figure 34.6) is another controversial topic. In their 2003 level IV series, Wood and Deakin⁷⁴ found that postoperative edge loading of the polyethylene bearing was more common in those with preoperative varus or valgus greater than 15°. In 2009, Wood further found that preoperative coronal plane deformity showed a significant effect on survivorship at 54 months, with the likelihood of revision being directly proportional to the size of the preoperative deformity. However, in 2009 Hobson's level III study found no significant difference in complications or outcomes between neutral ankles and those with preoperative deformity up to 30°,⁹⁸ and this has been supported by findings by Kim in a level III study.⁹⁹ Further research in this area may clarify what factors have produced the differences in outcomes, and what the safe recommendations are.

Supplementary procedures performed concurrently with TAA are common, including calcaneal osteotomy, subtalar/talonavicular fusion, ligament reconstruction, and tendon transfer. In Schuberth's level IV series,⁷³ concomitant procedures were not associated with an increased incidence of complications compared to TAA alone.

Radiographic findings Radiographic appearances have not yet found to be related to clinical findings.⁸⁹ However, many authors believe that it is simply a reflection of the short follow-up periods of TAA studies.

Periarticular heterotopic new bone formation is common. Two recent level IV papers from different major centers have interpreted its significance differently. Valderrabano⁹³ believed it to be responsible for decreased range of motion,

while Wood and Deakin⁷⁴ found that heterotopic new bone was not associated with a poor result.

Periprosthetic lucent lines are frequently found in uncemented TAA, but the fact that they are always seen within 2 years and are mostly nonprogressive suggest that they are not caused by polyethylene particle wear.⁸⁹ Progression of lucent areas, in contrast, is more indicative of prosthetic loosening.^{79,89} Polyethylene wear also occurs in TAA and can eventually also produce the classical expansile osteolysis recognized in hip and knee replacements.^{74,79,93}

Implant migration has been seen in some TAA series.^{89,92} Knecht⁷⁹ suggested that migration of 5 mm or 5° or more places a patient at higher risk of implant failure.

Scoring systems vs. patient satisfaction The majority of scoring systems used in the literature are based on pain, general mobility, and range of motion at the ankle joint. A significant improvement in the pain scales is a near universal finding; however, some persistent pain is common (level IV).^{89,93} Postoperative range of motion following TAA will be roughly equivalent to the preoperative level, even at mid- to long-term follow-up.^{74,75,89} It is fairly common to find that patient satisfaction remains high with TAA, independent of whether the scoring systems produce satisfactory or unsatisfactory results.^{79,89,92,93,100} This incongruence suggests that current outcome scores are not capturing the benefits of TAA as perceived by the patients.

Recommendation

- Patients can expect substantial improvement in pain following TAA, although range of motion is often the same. Survival rates range from 67.7 to 98.7% with an overall mean of 87.6 % survival at 5 years [overall quality: low to fair]

Question 5: What are the main complications of TAA?

Case clarification

Complications of TAA have the potential to consume many months and possibly require salvage surgery.

Relevance

Earlier design generations of the total ankle replacement were plagued with problems.

Current opinion

The belief that TAA is associated with high complication rates is held by many surgeons, who remain wary of the procedure because of its technical difficulty.

Finding the evidence

- PubMed, using search terms: “ankle,” together with “osteoarthritis” OR “arthrosis” OR “arthroplasty” OR “replacement.” Limits included: “English language” AND “humans”
- The reference lists of all eligible papers were also cross-referenced for further studies which did not come up on the original PubMed search.

Quality of the evidence

Most studies provide level IV evidence, with some level III work.

Findings

It has been well documented that a surgeon will experience an early high complication rate associated with TAA but this reduces with experience.^{73,74,85,101} In 2006 Schuberth published the perioperative complication rate of the first 50 consecutive total ankle replacements performed by a single surgeon.⁷³ There was a 38% rate of intraoperative malleolar fractures, 24% occurrence of some degree of component malalignment, 18% incidence of minor wound healing disturbances that resolved with local wound care, and a 2% rate of major wound complications requiring flap coverage. Early component revision was required in 16%. Each of these complications, other than wound complications, decreased with surgeon experience. In 2008, Lee documented the difference in complication rates between the first 25 TAA cases and the second 25 cases performed at a single hospital.¹⁰¹ In the first 25 cases, the complication rate was 60%, including a 16% incidence of intraoperative malleolar fractures. In the second 25 cases, the complication rate was 20%, and the malleolar fracture rate was 4%. Saltzman¹⁰² has confirmed the importance of increased collective surgical experience and suggested that overall outcomes can be expected to improve in future studies.

Recently an evidence-based classification system for complications in TAA has been proposed that classifies

complications according to their potential to cause failure of the prosthesis (defined as removal of implants).¹⁰³ Twenty studies identified under specific inclusion criteria revealed nine main complications of TAA. Deep infection, aseptic loosening, and implant failure were classified as “high-grade” complications since they were shown to result in failure greater than 50% of the time. Technical error, subsidence, and postoperative bone fracture were classified as “medium-grade,” resulting in failure less than 50% of the time. Intraoperative bone fractures and wound healing problems were classified as “low-grade,” resulting in failure less than 50% of the time.

Level IV evidence supports that supplementary extra-articular realignment procedures performed concomitantly with TAA are not associated with an increased incidence of complications.

Recommendation

- There is a well-described learning curve with TAA, and in the early stages a surgeon can experience 20–60% complication rates. However, many complications do not pose a threat to the longevity of the prosthesis itself, and a classification of complication impact has therefore been developed [overall quality: very low to low]

Question 6: Does TAA protect the subtalar joint complex from accelerated degeneration?

Case clarification

Patients hope to retain ankle and hindfoot motion following TAA.

Relevance

This is an important consideration, as it remains one of the main goals a surgeon hopes to achieve when performing TAA.

Current opinion

Interest in TAA developed as a way to treat ankle arthritis in RA while avoiding subsequent overload of adjacent hindfoot joints.

Finding the evidence

- PubMed, using search terms: “ankle,” together with “osteoarthritis” OR “arthrosis” OR “arthroplasty” OR “replacement.” Limits included: “English language” AND “humans”
- The reference lists of all eligible papers were also cross-referenced for further studies which did not come up on the original PubMed search

Quality of the evidence

There is level III evidence to support that patients do not go on to develop hindfoot OA following TAA.

Findings

Degeneration of ipsilateral hindfoot joints has been sought on follow-up radiographic study. Kofoed,⁷² in his long-term level III study, found that none of the patients with OA went on to develop subtalar arthrosis following arthroplasty, with similar results published by Valderrabano.⁹³

Recommendation

- Level III evidence supports that TAA prevents hindfoot degeneration in later years [overall quality: fair]

Question 7: Are there any direct comparisons of ankle arthrodesis vs. TAA in the literature?

Case clarification

Patients are interested in which procedure is more likely to succeed in their particular circumstance, and direct comparative studies are helpful in providing information.

Relevance

The deficiencies in historical studies looking at either ankle arthrodesis or TAA do not allow easy comparisons of results.

Current opinion

Opinions are divided on the matter, and the choice of procedure remains controversial in many cases.

Finding the evidence

- PubMed, using search terms: “ankle,” together with “osteoarthritis” OR “arthrosis”, AND “fusion” OR “arthrodesis,” AND “arthroplasty” OR “replacement.” Limits included: “English language” and “humans”
- The reference list of all eligible papers was also cross-referenced for further studies which did not come up on the original PubMed search

Quality of the evidence

The authors identified one short-term level II study, one level III meta-analysis, and one level IV paper.

Findings

Only three papers using modern surgical methods have directly compared the outcomes of ankle arthrodesis and TAA,^{30,70,102} and only one of these studies compared overall clinical outcomes.

In 2009, Saltzman¹⁰² published a prospective multicenter level II trial comparing ankle arthrodesis and TAA. By 24 months, ankles treated with TAA had better function and equivalent pain relief compared to ankles treated with fusion. Operative time, blood loss, and length of hospital stay were the same for both. Rates of secondary major surgeries were the same for both. The study

concluded that using modern implants and surgical techniques, superior overall patient success has been shown in the TAA group. The major weakness of this study, however, lies in the 2 year follow-up period, which is very short.

In 2007, SooHoo published a level III meta-analysis comparing reoperation rates between 4705 ankle arthrodesis and 480 TAA cases, based on their review of the California hospital database from 1995 to 2004.⁷⁰ Patients treated with ankle arthrodesis had a higher requirement for subtalar fusion at 5 years postoperatively than did those treated with ankle replacement. TAA had an increased risk of device-related infection and of having a major revision procedure.

The 2007 level IV publication by Haddad³⁰ compared the results of meta-analysis of TAA publications against meta-analysis of ankle arthrodesis publications. Patient satisfaction with their outcome in the TAA group was 78% and in the ankle arthrodesis group was 73%. The 5-year TAA survival was 78% and 10-year survival 77%. The TAA revision rate was 7%, mainly due to loosening and subsidence. The overall revision rate for ankle fusions was 9% with a non-union rate of 10%.

Recommendation

- Level II, III, and IV evidence supports that TAA and ankle arthrodesis provide equivalent results in the short term [overall quality: low to good]

Question 8: Does TAA result in more normal gait compared to ankle arthrodesis?

Case clarification

Patients undergoing arthroplasty hope to avoid a postoperative limp.

Relevance

For TAA to truly offer the patient an advantage over ankle arthrodesis, it must allow for enough motion to normalize gait.

Finding the evidence

- PubMed, using search terms “ankle,” together with “osteoarthritis” OR “arthrosis”, “fusion” OR “arthrodesis”, “arthroplasty” OR “replacement”, “gait” OR “limp.” Limits included “English language” and “humans”
- The reference list of all eligible papers was also cross-referenced for further studies which did not come up on the original PubMed search

Quality of the evidence

Good-quality Level II and III studies have been performed separately for each procedure as well as combined in the same study in order to compare the effect on gait.

Findings

Gait analysis after ankle arthrodesis Level III evidence in several gait analysis reports indicates abnormal gait patterns following ankle arthrodesis. Decreased stride length, reduced walking velocity, and reduced hindfoot motion are consistent findings after ankle arthrodesis.^{11,15,71,104,105} Compensatory sagittal motion in the midfoot occurs following ankle arthrodesis, giving a relatively “normal” appearance to gait.^{11,46,71} Decreased anterior tibial tilt and early heel-off at the end of stance phase has also been demonstrated in patients after arthrodesis.⁷¹ During normal gait, the tibia moves forward on the foot during midstance. This movement is due to dorsiflexion of the ankle joint. With an arthrodesed ankle, forward progression of the tibia is reduced but not eliminated, and is mediated by the compensatory midtarsal dorsi/plantarflexion. As this midtarsal compensation is incomplete, early heel-off occurs following arthrodesis. Beyaert et al.⁷¹ were able to demonstrate that this early heel-off results in the ground reaction force normally centered close to the metatarsal heads to be shifted posteriorly to the region of the midfoot during early heel-off. The authors conclude that this provides evidence for increased pathologic stresses applied to the midfoot after arthrodesis.⁷¹ Beyaert et al. and others also demonstrated that the abnormal gait patterns and altered foot dynamics in ankle arthrodesis are most evident when walking barefoot, are exacerbated when walking at speed, and are improved with shoe wear (especially with an elevated heel).^{11,71,104}

The effect of ankle arthrodesis on the ipsilateral hip (decreased hip flexion) and knee (early knee extension in late stance) is minimal unless the ankle is fused in equinus, where upon genu recurvatum, knee external rotation with increased stress on the medial collateral ligament can occur.¹¹ A level II gait analysis study on patients with RA treated with ankle and hindfoot fusions demonstrated significant improvements in both kinematics and kinetics of ipsilateral hip and knee joints.¹⁰⁶

Gait analysis after TAA Several gait analysis studies have been performed following patients with more recent TAA designs.^{95,107,108} Dyrby’s¹⁰⁷ and Valderrabano’s¹⁰⁸ level II studies and Doets’⁹⁵ level III study all support improvement of muscle function during walking, with near-normal gait pattern in terms of kinematics of the knee, ankle, and foot. Ground reactive forces at midstance were improved, but patients continued to demonstrate decreased vertical peak pressures during the terminal stance phase.⁹⁵ The improved dorsiflexion during the stance phase may help decrease the abnormal shear forces to the subtalar joint complex, thereby decreasing the incidence of progressive ipsilateral hindfoot arthritis.

Direct gait analysis comparisons between ankle arthrodesis and TAA Piriou’s 2008 level III paper¹⁰⁹ compared gait analysis after ankle arthrodesis and TAA. Neither procedure restored normal movement or walking speed. Ankle arthrodesis resulted in a faster gait with longer step length, although the timing of gait demonstrated greater asymmetry. The TAA group had greater movement at the ankle, a symmetrical timing of gait, and restored ground reaction force pattern.

Recommendation

- There is level II evidence indicating abnormal pressures through the midfoot⁷¹ and level III evidence indicating compensatory midfoot sagittal motion following ankle arthrodesis.^{11,46,71} Compared to arthrodesis, level II/III evidence demonstrates TAA improves gait analysis parameters towards normality, although normal gait kinetics or kinematics are not restored.^{95,107–109}

Summary of recommendations

Analysis of the evidence presented in this chapter suggests the possibility of equivalence in the outcomes of ankle arthrodesis and TAA procedures, with both yielding satisfactory outcomes. Long-term studies of ankle arthrodesis suggest persistent alterations in gait and high incidence of ipsilateral hindfoot joint OA, with pain and poor function. The improvement in gait mechanics following TAA may help decrease this.

Conclusions

The most common cause of ankle arthritis is trauma, followed by inflammatory arthropathies and structural deformity.¹¹⁰ The ankle joint is resilient to the process of aging, and primary OA is rare. Level I and II evidence shows that endstage ankle arthritis is as debilitating as endstage hip arthritis.^{111,112}

Any evaluation of ankle arthrodesis needs to be done in the light of the improving results with current TAA. Prospective long-term outcome studies comparing the two are needed. Future studies on ankle arthrodesis will hopefully report on ankles fused in optimum positions and utilize validated outcome measures. Only then will valid answers be provided with regard to the effect of ankle arthrodesis on adjacent hindfoot joints, its impact on functional outcomes, and ultimately how ankle arthrodesis measures up to current TAA.

Even in the hands of well-trained and experienced surgeons, results of TAA are still likely inferior to hip arthroplasty. Further improvement in prosthesis design, surgical technique, and clarification of the indications are required.

The long-term results of most new arthroplasty designs are unknown.

At present, TAA is a valuable and equivalent alternative to ankle arthrodesis, but it is not yet known if it will in future fully replace ankle arthrodesis.

In conclusion it is clear that both ankle arthrodesis and TAA may be assigned a grade B recommendation (fair evidence, level II or III studies with consistent findings) for the surgical treatment of endstage ankle arthritis. However, clearly more well-designed level I randomized controlled trials documenting patient preoperative characteristics and postoperative outcomes are needed to assist in making recommendations on which procedure is superior.

Fusion vs. Arthroplasty in the Treatment of 1st MTP Arthritis

Jeffrey G.M. Tan¹, Gilbert Yee,² and Johnny T.C. Lau¹

¹University of Toronto, Toronto, ON, Canada

²The Scarborough Hospital, Scarborough, ON, Canada

Case scenario

A 51 year old woman was seen in the clinic with pain and stiffness in her left hallux metatarsophalangeal (MTP) joint and limited walking distance. On examination, she has flexion of 0–20° and limited dorsiflexion of 0–10° in the MTP joint with pain on movement. Standing radiographs revealed dorsal osteophytes, severe decrease in joint space, and subchondral sclerosis in the MTP joint (grade III hallux rigidus). She had failed conservative therapy with podiatry-prescribed shoes, steroid injections, and analgesia.

Openmirrors.com
She was keen for surgical intervention, after suffering the symptoms for several years. Being an active individual who did weekly ballroom dancing and regular jogging, she requested an outcome that would allow her to continue her current lifestyle after the surgery. Looking at the clinical picture and radiographic findings, you presented two options of surgical treatment to this particular patient: fusion (arthrodesis) vs. arthroplasty.

You started a lengthy discussion with the patient on the indications and “pros and cons” of the above options. She is especially perturbed about the idea of “fusion” of the joint, which she perceived as being functionally limited, and seemed anxious about getting back to wearing high heels, ballroom dancing, tennis, and jogging after the procedure.

She seemed to be inclined towards the option of implant replacement arthroplasty and was trying to extrapolate the excellent results of hip and knee replacements to that in the forefoot. Her initial impression is that arthroplasty seemed to “fit in” more with her lifestyle and she asked you for advice on the long-term survival results of big toe implants.

Introduction

The hallux MTP joint can be affected by a number of conditions causing arthritis, commonly degenerative arthritis (described as hallux rigidus), rheumatological conditions, crystal deposition arthropathies (such as gouty arthritis), and neuropathic arthropathy as well as post-traumatic arthritis. This chapter focuses on the management options of endstage hallux rigidus, which is the most common form of arthritis affecting the great toe MTP joint.

The grading of hallux rigidus

In 1988, Hattrup and Johnson¹ described the following radiographic classification system:

- Grade 1: mild changes with a maintained joint space and minimal spurring
- Grade 2: Moderate changes, joint space narrowing, bony proliferation of the metatarsal head, and phalanx and subchondral sclerosis or cysts
- Grade 3: Severe changes with significant joint space narrowing, extensive bony proliferation, and loose bodies or a dorsal ossicle

Relevant anatomy

Degenerative arthritis or hallux rigidus of the great toe is the next common affliction of the MTP joint after hallux valgus. Hallux rigidus is the *most common* arthritis in the foot, with an incidence of 1 in 40 in persons aged 50 and above.^{2,3} Women are more commonly affected than men in

all age groups. The condition is more prevalent in North America and Europe than in Asia.

Many surgical options have been described such as arthrodesis, excisional arthroplasty, osteotomy, implant arthroplasty, cheilectomy, and interpositional arthroplasty. Despite the frequency of hallux rigidus, there remains some degree of controversy about its surgical treatment.

The 1st MTP joint consists of the articulation between the metatarsal head, proximal phalanx, and metatarsos-sesamoid articulation. The plantar aspect of the metatarsal head has an undulating surface with the intersesamoid ridge and respective grooves on either side for articulation with the sesamoids. The range of motion of the 1st MTP joint is greatest in the sagittal plane and consists of approximately 30° of plantar flexion to 90° of dorsiflexion.⁴

In hallux rigidus, there is a decreased total arc of motion with relatively normal plantar flexion and markedly decreased dorsiflexion secondary to mechanical block by dorsal osteophytes and scarring of plantar structures. A small degree of transverse motion in the medial and lateral direction also occurs in the sagittal range of motion, but this transverse motion has a 50% reduction in hallux rigidus, and is thought to be due to contracture of the collateral ligaments and joint capsule.⁴

Stability of the 1st MTP joint in turns leads to stability of the medial column of the foot. Approximately 40–60% of body weight passes through the 1st MTP joint and great toe during normal gait.⁵ During athletic activities like jogging and running, these forces can approach two to three times body weight.

Importance of the problem

The two main surgical procedures for the more advanced arthritis of the 1st MTP joint are arthrodesis or arthroplasty. There is still much debate between surgeons on the differing opinions on methods of surgical treatment for this condition.

Over the last decade, several designs of great toe MTP implant options are becoming widely available in the market and various trials have been conducted and published, mostly in small sample studies. The long-term results of these newer metal-on-polyethylene and metal resurfacing implants remain to be seen.

Surgical decision depends on the age of the patient, functional level and demand, comorbidities, and competency of the soft tissue restraint.

Top five questions

Therapy

1. What are the optimal techniques available for the fusion of the 1st MTP joint?

2. Does 1st MTP arthrodesis or arthroplasty effect a change in gait?

3. What are the effect of Keller's arthroplasty and interpositional arthroplasty on the treatment of 1st MTP arthritis?

4. What is the relative effect of arthrodesis vs. implant arthroplasty on the patient's satisfaction and complication rate?

Prognosis

5. What is the current survival analysis on the implants used in arthroplasty?

Question 1: What are the optimal techniques available for the fusion of the 1st MTP joint?

Relevance

There are multiple techniques to achieve optimal fusion of the 1st MTP joint. Good bone preparation and a reliable and stable fixation construct with good position of the joint is crucial to achieve satisfactory result in arthrodesis of the 1st MTP joint.

Current opinion

Arthrodesis is an accepted surgical option for advanced-stage osteoarthritis of the 1st MTP joint, as it is a reliable and predictable procedure with consistently favorable long-term results.⁶ The more common methods of preparation and fixation include conical reaming with a combination of lag screws and low profile dorsal plating.

Finding the evidence

- Cochrane Database, with search terms "MTP arthrodesis," "MTP fusion," "hallux arthrodesis," "MTP arthrodesis versus arthroplasty" or "hallux arthrodesis versus arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: "MTP arthrodesis," "MTP fusion," "hallux arthrodesis," "MTP arthrodesis versus arthroplasty," or "hallux arthrodesis versus arthroplasty"

Quality of the evidence

Level I

- 1 randomized trials

Level II

- 2 prospective comparative studies

Level IV

- 6 retrospective case series

Findings

Various methods of preparation of the bone ends and fixation of the fusion site have been described in the literature.

Methods of preparation includes conical reamers,⁷ ball and socket reamers,⁸ peg and cone preparation,⁹ and flat planar cuts of the metatarsal heads and phalangeal base, denuding the joint surfaces of cartilage and inserting small drill holes into subchondral bones.

Methods of fixation include cross screws, Kirschner wires, wire loops, external compression devices, Steinman pins, staples, and compression plating as well as a lag screw and plate combination.⁹⁻¹³ Fusion rates of 90–100%^{7-9,11,13} have been reported (Table 35.1). Several authors noted that the majority of nonunions were asymptomatic and did not necessarily serve as a predictor of poor outcome.^{7,13-15}

Complications of 1st MTP arthrodesis include shortening of the first ray, malunion, nonunion, transfer metatarsalgia, infection, and prominent implants. The average load across a fused MTP joint could reach approximately 172N.¹⁶

A crucial aspect of arthrodesis of the 1st MTP joint and maintenance of the biomechanics of the first ray requires minimal shortening and correct anatomical positioning of the fused joint.

Various biomechanical and clinical studies demonstrated that a dorsal plate with an oblique compression lag screw gave the most biomechanical stability after the bone ends were prepared by machined conical reaming, followed by conical reaming with either dorsal plating or interfragmentary screws alone.¹⁷⁻²⁰ Memory staples or Kirschner wires, in turn, were weaker than the compression screw fixation or dorsal plate fixation.²¹

Effect on shortening The effect of arthrodesis of the 1st MTP joint results in shortening. Two studies investigate the effect of shortening of the first ray on the biomechanics of the foot. Jung et al.²² showed that a decrease in the length of the first ray by 5–10mm can cause significant plantar pressure changes which can lead to metatarsalgia of the second ray ($p < 0.016$) in 12 pairs of cadaver feet.

A study²³ with six paired cadaver feet comparing the effect of two fusion techniques between flat bone cut and machined conical reamer preparation found that there was no statistically significant difference ($p = 0.44$) in the

Table 35.1 Summary of fusion rates of 1st MTP arthrodesis using various methods of joint preparation and internal fixation

Series (year)	N	Preparation method	Fixation method	Position of fusion	Postoperative regime	Fusion rate (%)
O'Doherty ¹⁵ (1990)	50	Debridement of cartilage and subchondral bone	20 gauge cerclage wire loop and Kirschner wire	–	Weight bear in cast slipper at 2 weeks Cast removed at 6 weeks	56.0
Gibson ²⁷ (2005)	38	Debridement of cartilage and subchondral bone	20 gauge cerclage wire loop and 2mm crossed Kirschner wire	10 DF	Partial weightbear in fiberglass cast after surgery	100.0 (6 delayed unions with final union at 12 months)
Brodsky ²⁹ (2005)	60	Curettage and rongeur to exposed cancellous surface	Parallel 3.5 mm cortical screws	10–25 DF 5–10 valgus	Postop shoes for 8 weeks Non-weightbear for the first 4 weeks	100.0
Hyer ¹⁹ (2008) comparative study	14 31	Simple curettage and rongeur to remove cartilage Subchondral bone drilled and "rose petalled" As above	2 crossed 4.0mm cannulated screws or 2.7 mm Herbert type cannulated screws 5-hole low profile titanium plate	0 valgus or varus As above	Partial weight bear with postop shoes after surgery As above	92.9 90.3
Goucher ⁹ (2006)	53	Dome-shaped power reamers	Dorsal titanium plate with a cross lag screw	10–15 DF 10 valgus	Postop shoe for 12 weeks Weight bear on heel and lateral border of foot	92.0
Coughlin ¹¹ (1994)	58	Cup- or cone-shaped reamers	Vitallium low profile dorsal plate	20–30 DF 15–20 valgus	Postop shoe with weight bear on heel and lateral aspect of foot Cast used if patient is unreliable	98.0

DF, dorsiflexion with respect to metatarsal shaft; N, sample size.

postprocedure lengths of the first ray between the two techniques. The authors concluded that neither of the techniques is likely to lead to transfer metatarsalgia as the length of shortening is similar.

Recommendation

- There is no consensus on the optimal method of preparation and fixation. In most studies, a combination of a lag screw with dorsal plating, followed by lag screws or dorsal plating alone, gives better biomechanical stability. A fusion rate of 90–100% is expected.

Question 2: Does 1st MTP arthrodesis or arthroplasty effect a change in gait?

Relevance

Surgeons may have some reservation about fusing the 1st MTP joint as this takes away a functional range of movement and causes gait cycle changes. There is also concern about weakness in push-off and developing arthritis in the interphalangeal joint.

Current opinion

Arthrodesis eliminates painful motion at the MTP joint, gives stability to the medial column of the foot but effects in a decrease of push-off power at toe-off.

Quality of the evidence

Level II

- 3 prospective comparative study

Level III

- 1 retrospective case control studies

Level IV

- 2 retrospective case series

Findings

Two studies comparing the effects of arthrodesis vs. Keller's arthroplasty and demonstrated that arthrodesis re-establishes the normal weightbearing pattern of the forefoot and redistributes more weight through the medial ray when the 1st MTP joint is fused.^{24,25} This results from a stabilization of the medial column when pain is eliminated although motion is lost in the MTP joint. After arthrodesis, the big toe bore weight in 80% compared with 40% after Keller's operation.²⁴

Three prospective studies showed inconsistent evidence with regards to plantar pressures under the hallux and push-off power. Two of the studies^{26,27} showed increased pressure under the first metatarsal ($p = 0.01$ and $p = 0.16$ respectively), while one study²⁸ suggested postoperative improvement in stability of the foot after arthrodesis. There is no consensus on the effect of push-off power.

Functional limitation In a functional evaluation of MTP arthrodesis (level IV study) by Brodsky et al.,²⁹ patients retained good function and were able to return to athletic activities such as jogging, golfing, hiking, and tennis. Good outcome and function was achieved when the fused joint is well positioned. More prospective studies would be needed to validate these observations as these data would be useful as a reference to counsel patients preoperatively regarding the functional outcome after arthrodesis.

Recommendation

- There is inconsistent evidence in prospective studies (level II) regarding plantar pressures and push-off power after arthrodesis or arthroplasty. However, a properly positioned and fused stable 1st MTP joint redistributes loads back to the first ray and medial column and provides stability during gait.

Question 3: What are the effects of Keller's resection arthroplasty and interpositional arthroplasty on the treatment of 1st MTP arthritis?

Relevance

Keller's arthroplasty has been performed since 1904 and involved a resection of the base of the proximal phalanx. Its indication has extended beyond the use in hallux valgus to hallux rigidus and has been a popular procedure for many decades. Since Keller's first description of the procedure, there has been several modification of the technique by using soft tissue interposition with an aim to improve stability and function as well as to reduce pain.

Current opinion

Keller's procedure is a resection arthroplasty that decompresses the joint at the expense of stability. Common complications include transfer metatarsalgia, claw toe, cock-up deformity, and hallux weakness. For this reason, the Keller's resection arthroplasty has been used for low-demand and elderly patients.^{6,15}

Interposition arthroplasty provides an alternative for treatment of endstage 1st MTP arthritis in a low-demand patient with pain relief and preservation of motion. There are inconsistent results, techniques and lack of comparison studies, and some authors consider it a salvage procedure.

Finding the evidence

- Cochrane Database, with search terms: "MTP excision arthroplasty," "MTP resection arthroplasty," "hallux resection arthroplasty," "Keller arthroplasty," or "MTP interpositional arthroplasty"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries and sensitivity search/ systematic reviews: "MTP

excision arthroplasty," "hallux resection arthroplasty," "Keller arthroplasty," "MTP interpositional arthroplasty," or "hallux interpositional arthroplasty"

Quality of the evidence

Level II

- 1 prospective comparative study

Level III

- 1 retrospective case control studies

Level IV

- 9 retrospective case series

Findings

Keller's arthroplasty In 1904, Keller³⁰ described a technique involving resection of the base of the proximal phalanx for treatment of hallux valgus with associated OA of the 1st MTP joint. This procedure has since been adapted for treatment of hallux rigidus as well. Following that, other level IV studies with Keller's procedure reported good satisfaction with pain relief.^{31,32} However complications such as transfer metatarsalgia and postoperative cock-up deformity were common.

In a randomized trial, O'Doherty et al.¹⁵ published the results comparing 50 arthrodeses and 60 Keller's arthroplasty in older patients (average age 60.5 years) with a minimum follow-up period of 2 years. Both groups gave a similar degree of patient satisfaction and symptom relief. No significant difference was noted in terms of the incidence of postoperative transfer metatarsalgia or cock-up deformity ($p > 0.01$).

The above study had limitations as the method of arthrodesis using cerclage wire loops and Kirschner wires contributed to the high incidence of nonunion (44%) and malrotation of the hallux. Although the authors had suggested that Keller's arthroplasty is the better operation in older and lower-demand patients, it was felt that the arthrodesis could have been optimized with more rigid fixation to improve the fusion rate.

Interpositional arthroplasty Interpositional arthroplasty combines a resection arthroplasty of the proximal phalanx and cheilectomy with the insertion of a biological tissue or spacer into the joint so as to avoid some of the problems associated with an isolated resection arthroplasty.

Various tissues including the extensor hallucis brevis (EHB), joint capsule, and plantaris and gracilis tendons have been utilized as the interpositional graft.^{33,34} This procedure requires less bone resection and maintains joint stability and range of motion. Soft tissue tension plays an important aspect in this procedure.

Complications from this procedure are common; they include transfer metatarsalgia, floppy hallux, stiffness,

short hallux, first toe weakness, and, less commonly, osteonecrosis of the metatarsal head.³⁴

Hamilton et al.³³ treated 37 feet with advanced-stage hallux rigidus using EHB tendon interposition over a 10 year period, and yielded satisfactory results in term of American Orthopaedic Foot and Ankle Score (AOFAS), improved dorsiflexion, and patient satisfaction. No weakness, transfer metatarsalgia, or metatarsal callosities were reported.

Subsequent investigators could not reproduce the results of Hamilton et al. in terms of satisfaction and complication rates. There is also a decrease in sample size in subsequent studies, variation in techniques and nonuniformity in patient selection and outcome measures.³⁴⁻³⁸ One study comparing EHB interpositional arthroplasty with Keller arthroplasty (level III) found no significant difference in terms of AOFAS, patient satisfaction, range of motion, and clinical and radiological outcome.³⁹

Recommendations

- Given the favorable results from level II and level IV studies, there is fair evidence to support the use of Keller's resection arthroplasty for the treatment of hallux rigidus in older and low-demand patients. Patient selection is important and the possibility of cock-up deformity and transfer metatarsalgia must be considered [overall quality: moderate]
- Considering the level of evidence (level III and IV), sample sizes of study, and differences in methods of outcome analysis and patient selection, there is insufficient evidence to recommend interpositional arthroplasty for the treatment of advanced arthritis of the 1st MTP joint [overall quality: low]

Question 4: What is the relative effect of arthrodesis vs. implant arthroplasty on the patient's satisfaction and revision rate?

Relevance

Arthrodesis is an accepted surgical option for advanced-stage osteoarthritis of the 1st MTP joint. Arthroplasty maintains range of motion of the 1st MTP joint and provides pain relief but the issue of longevity remains. Silastic implants have been used widely in the past but unfortunately late complications of silicone particulate synovitis and failure were a concern.

Current opinion

Most surgeons uses arthrodesis for the surgical treatment of endstage arthritis of the 1st MTP joint as it is a reliable and predictable procedure (gold standard) with consistently favorable long-term results.^{6,19}

Finding the evidence

- Cochrane Database, with search terms "MTP arthrodesis," "hallux arthrodesis," "MTP arthrodesis versus arthroplasty" or "hallux arthrodesis versus arthroplasty"

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews and sensitivity search using keywords: "MTP arthrodesis," "hallux arthrodesis," "MTP arthrodesis versus arthroplasty" or "hallux arthrodesis versus arthroplasty"

Quality of the evidence

Level II

- 1 randomized trial with methodological limitations

Level III

- 1 retrospective case control study

Level IV

- 4 retrospective case series

Findings

Arthrodesis provides pain relief and stability of the MTP joint at the expense of loss of motion. Besides hallux rigidus, it is also indicated for rheumatoid arthritis, hallux valgus or hallux varus with degenerative arthritis, and as a salvage procedure for failed implant arthroplasty or failed Keller's operation. Arthrodesis is generally preferred for young and active patients.

Two studies (level II and level III evidence) have compared arthrodesis with an implant arthroplasty of the 1st MTP joint. In these studies, arthrodesis demonstrated equivalent or superior results with fewer complications.

Gibson et al.²⁷ reported the results of a randomized controlled trial involving 38 cases of arthrodesis and 39 cases of arthroplasty for treatment of arthritis of the 1st MTP joint. The arthrodesis technique involves cerclage wire and a Kirschner cross wire. The replacement studied is an unconstrained joint with a polyethylene insert. However, there was a protocol deviation within 18 months of the trial: 5 of the first 30 patients were found to have radiographic signs of loosening and the protocol was then revised to cement the phalangeal component in the remaining 9 patients.

At 24 months, pain was more significantly improved in the arthrodesis group ($p = 0.01$). Six of the 39 implants had to be removed because of phalangeal component loosening. All the 38 arthrodeses united. The cost ratio was 2:1 in favor of arthrodesis. Arthroplasty has more complication rates in terms of revision surgery.

Raikin et al.⁴⁰ compared the long-term outcome of a metallic hemiarthroplasty of the proximal phalanx base (Biopro, Port Huron, MI) with arthrodesis for advanced arthritis of the 1st MTP joint.

The results of 21 hemiarthroplasties with a mean follow-up of 79 months were compared with 27 arthrodeses with a mean follow-up of 30 months. All arthrodeses united and 2 required hardware removal. Five (24%) of the hemiarthroplasties failed; most failures occurred within the first 2

years after surgery. The patients who underwent arthrodesis had significantly higher satisfaction rates ($p < 0.01$), higher AOFAS scores ($p = 0.006$), lower VAS scores ($p = 0.021$), and lower incidences of plantar callosities ($p = 0.041$). The authors concluded that arthrodesis was more predictable for alleviating symptoms and restoring function in patients with severe hallux rigidus. The study had limitations, as one surgeon performed the arthrodesis between 1999 and 2000, and another surgeon performed the arthroplasty after year 2000.

Incidence of interphalangeal joint arthritis after arthrodesis The reported incidence of developing osteoarthritis in the interphalangeal joint after 1st MTP joint arthrodesis varies from 10% to 15% (level IV studies), with most of the degenerative changes being usually asymptomatic.⁴¹⁻⁴³

Recommendations

- The favorable results reported in these level II and III studies constitute fair evidence to support the use of arthrodesis over arthroplasty for the treatment of advanced-stage osteoarthritis of the 1st MTP [overall quality: moderate]

Question 5: What is the current survival analysis on the implants used in arthroplasty?

Relevance

Over the last decade, newer generation implants have been developed with clinical trials under way for surgical replacement of the MTP joint. A search of the literature revealed various options of hemiarthroplasty resurfacing prostheses and total replacement prostheses, some of which are still undergoing clinical trials.

Current opinion

The newer prostheses for the big toe MTP joint currently in use have limited short-term results, and long-term outcomes remains to be seen. MTP resurfacing or total joint replacement provides an alternative in a selected group of patients who desire preservation of joint motion, function, and symptom relief.

Finding the evidence

- Cochrane Database, with search terms "survival analysis," "survivorship," "MTP arthrodesis versus arthroplasty," "long term survival"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews and sensitivity search using keywords: "survival analysis," "survivorship," "MTP arthrodesis versus arthroplasty," "long term survival"

Quality of the evidence

Level II

- 1 randomized trials with methodological limitations

Table 35.2 Results of hemiarthroplasty of the 1st MTP joint

Series (year)	Implant	N	Follow-up ^a (years) (range)	Age (range)	Complications
Konkel ⁵⁸ (2006)	Futura Hemi- Toe	13	8 (7.2–8.9)	59 (42–77)	11 radiographic sign of loosening 6 recurrent osteophytes 1 transfer metatarsalgia
Sorbie ⁵⁹ (2008)	cobalt chrome Trihedron	19	5.7 (2.8–6.0)	53 (35–70)	1 loss of alignment due to pre-existing hallux valgus (requiring further surgery)
Raikin ⁴⁰ (2007)	Biopro	21	6.6 (5.7–7.1)	59.7 (39–70)	5 failures (1 required revision and 4 required arthrodesis) . Additional 8 had radiographic cut-out of stem through plantar cortex
Giza ⁵⁶ (2005)	Biopro (preliminary results)	103	(0.5–4) (preliminary results)	60.7 (55–80)	17 cases underwent MUA at 3 months for postoperative stiffness
Townley ⁵⁷ (1994)	Biopro	279	(0.67–33)	54.4 (22–91)	13 failures (11 in patients with HV and RA), of which 12 required revision surgeries

HV, hallux valgus; MUA, manipulation under anesthesia; N, sample size; RA, rheumatoid arthritis.

^a Mean follow-up.

Level III

- 2 retrospective case control studies

Level IV

- 16 retrospective case series

Findings

There is sparse data in the literature regarding survivorship analysis of the implants used in arthroplasty of the MTP joint.

Silastic implants for the great toe of the Swanson design⁴⁴ have been used since 1967, albeit with high failure rates.^{45,46} Radiographic loosening and fragmentation coupled with silicone granulomatous disease, synovitis, and lymphadenitis were common complications on long-term outcomes.^{47–51} Salvage of failed silastic implants with poor bone stock was a challenging surgical problem.^{45,52}

It is beyond the scope of this chapter to assess the different types of big toe MTP implants used today. In brief, they can be divided into hemiarthroplasty resurfacing, and total joint replacement metal-on-polyethylene implants (usually nonconstrained). The majority of hemiarthroplasty implants involve resurfacing the proximal phalanx, which does not address the cartilage damage or degeneration on the metatarsal head. Some form of debridement, cheilectomy of the dorsal osteophytes on the metatarsals, and soft tissue release is required.^{53,54} A minority of the hemiarthroplasty implants involve resurfacing of the metatarsal head.⁵⁵ The Biopro implant (Biopro Inc, Port Huron, MI) has the most extensively published data and long-term results for its clinical use.^{40,53,56,57} A Kaplan–Meier analysis of a hemiar-

throplasty population using Biopro has an implant failure rate of 23.8% at 18 months postoperatively.⁴⁰

Results of the hemiarthroplasty and total replacement trials are summarized in Table 35.2 and 35.3 respectively. There is no published trial comparing the outcome between hemiarthroplasty and total joint replacement.

Implant cut-out, loosening, recurrent osteophytes with impingement, and metatarsalgia are reported complications with the hemiarthroplasties.^{39,52,54–56,58,59} Many of the total toe implants suffer from loosening and early failure requiring revision in short to medium-term results,^{27,60–63} with complications such as implant subluxation, subsidence, periprosthetic fracture, postoperative stiffness, infection, and transfer metatarsalgia.

Most of the published studies are mid-term (3–5 years) results with small sample sizes. There is a lack of large randomized multicenter trials, survivorship analysis, and long-term results. In addition, it is difficult to standardize the studies (level III and IV evidence) because of the many available implant types with different design rationale and surgical techniques. The study groups consisted of a vast distribution of patients with hallux valgus, hallux rigidus, inflammatory arthritis, and those undergoing revision surgery, all with different types of outcome measures. More data is needed for the salvage options for failure of the newer implants.

Recommendations

- Taking into consideration the above known common complications and long-term durability of silicone implants, there is insufficient evidence to recommend silastic/silicone implants for the treatment of 1st MTP arthritis [overall quality: high]

Table 35.3 Results of the 1st MTP total joint arthroplasty trials

Series (year)	Implant	N	Follow-up (years) (range)	Age (range)	Complications
Kundert ⁶² (2005)	Toefit-Plus (hemi- & total- modularity)	14	4 (3.0–5.3)	–	3 cases require revision before 3 years
Pulavarti ⁶³ (2005)	Bio-Action Great Toe	36	3.9 (3.0–5.8)	57 (38–72)	3 persistent pain (2 cases required revision at 2.5 years to arthrodesis or excision arthroplasty) 12 implant subsidence at 3 years
Gibson ²⁷ (2005)	Biomet Total Toe System	39	2.0 (2.0)	55.5 (34–69)	6 implants with phalangeal component loosening were revised before 2 years
Fuhrmann ⁶¹ (2005)	ReFlexion	43	3.3 (2.1–4.8)	–	4 cases with persistent pain were revised to arthrodesis at average 2.2 years Radiographic signs of loosening in 14 implants

N, sample size.

^aMean follow-up.

- Except for the study by Townley, the use of hemiarthroplasty in the management of 1st MTP arthritis is supported by poor quality evidence [overall quality: low]
- Given these conflicting results in multiple studies with different implants, there is weak and inconsistent evidence to support total joint arthroplasty as a standard procedure for advanced arthritis of the 1st MTP joint [overall quality: low]

Summary of recommendations

- There is no consensus on the optimal method of preparation and fixation. In most studies, a combination of a lag screw with dorsal plating, followed by lag screws or dorsal plating alone, gives better biomechanical stability. A fusion rate of 90–100% is expected.
- The consistently favorable results in many level II and IV studies constitute fair evidence to support the use of arthrodesis for the surgical treatment of advanced-stage arthritis of the 1st MTP joint
- Keller resection arthroplasty can be considered for advanced-stage of arthritis in elderly patients with low physical demand. However, complications such as cock-up deformity, weakness, and lateral metatarsalgia may develop for this procedure
- There is insufficient evidence to recommend interpositional arthroplasty as a standard treatment for end stage arthritis of the 1st MTP joint
- Though the evidence comparing arthrodesis with arthroplasty is rather weak with certain limitations, arthrodesis provides a predictable and reliable treatment for pain relief

- Given the inconsistent results, small sample size and quality of evidence, there is insufficient evidence to support total joint arthroplasty in the treatment of 1st MTP arthritis
- The use of hemiarthroplasty for resurfacing of the proximal phalanx in the management of 1st MTP arthritis is supported by poor quality evidence
- There is paucity of survivor analysis on the longevity of various implants including total prosthetic arthroplasty and hemiarthroplasty. Further long-term prospective trials are needed to investigate the long-term effects of these implants
- Taking into consideration the above known common complications and long-term durability of silicone implants, there is insufficient evidence to recommend silastic/silicone implants for the treatment of 1st MTP arthritis

Conclusions

- The evidence in the literature supports arthrodesis as a standard treatment for 1st MTP arthritis with successful fusion rates of 90–100%. In comparative trials with implant arthroplasty, arthrodesis provides superior and durable results as well as more reliable and predictable treatment for symptom relief
- There is also fair evidence to support Keller's resection arthroplasty for a selected group of elderly patients with low functional demand
- At present, there is insufficient evidence to support the use of total joint arthroplasty and interpositional arthro-

plasty. The use of hemiarthroplasty for the proximal phalanx is weakly supported.

Charcot–Marie–Tooth Disease and the Treatment of the Cavo-Varus Foot

David N. Townshend and Alastair S.E. Younger

University of British Columbia, Vancouver, BC, Canada

Case scenario

A 35 year old man presents with recurrent ankle instability and overload of the lateral border of his foot. This has worsened over the last few years. He is otherwise fit and well. His father had a similar problem, with a similar foot shape. On examination he has a bilateral high arches and varus heels with callosities under the lateral borders of his feet. He has some clawing of the toes.

Charcot–Marie–Tooth disease and cavo-varus foot deformity

Cavo-varus foot deformity results from an imbalance of muscle forces. Charcot–Marie–Tooth disease (CMT) is a hereditary motor sensory neuropathy (HSMN) and is a common cause of cavo-varus deformity. Cavo-varus foot may also be caused by cerebral palsy, cerebral injury (stroke), anterior horn cell disease (polio, spinal root injury), talar neck injury, and residual clubfoot.¹ CMT as a clinical entity was described in 1886 by Jean-Martin Charcot and Pierre Marie in France, and Howard Henry Tooth in England. It has since become apparent that the condition is a result of many different genetic mutations which result in phenotypically similar deformities. More than 30 different gene defects have been identified in relation to CMT. More recently it has been recognized that the heterogeneity of this disease precludes a standard treatment “recipe” approach to managing individual patients.²

Limitations of outcome studies

The variation in phenotypic expression of this disease group makes evaluation of prior studies difficult, as the preoperative deformities are often not outlined. The major-

ity of the literature represents level V or expert opinion only and there are no more than level IV studies to guide operative management. Many series do not differentiate progressive from nonprogressive etiologies of the cavo-varus foot, further complicating interpretation of outcome data. Description of the anatomic deformity and the procedures required to correct this will be required in future studies.

Relevant anatomy

CMT is a progressive disease characterized by muscle imbalance. The tibialis anterior and peroneus brevis are often weak, with relative preservation of tibialis posterior, peroneus longus, and extensor hallucis longus. The posterior compartment is usually spared until late in the disease. Foot intrinsics are often weak, resulting in claw toes.

Importance of the problem

The true incidence of CMT and its impact on society is unknown. Many patients will live with milder forms of the disease without ever presenting to a physician. Cavo-varus deformity may present with ankle instability, metatarsalgia, stress fracture, degenerative joint pain, and/or difficulties with shoe wear. A Google search for “Charcot Marie Tooth” gives 297,000 hits, which compares with 731,000 for hip fracture.

Top four questions

1. Is there any evidence for orthotics in the management of the foot deformity in CMT?
2. Should the patient be referred for physiotherapy?

Table 36.1 Outcomes of orthotic interventions

Author	Year	Patients (n)	CMT	Intervention	Outcome	Level
Bean et al. ⁴	2001	1	1	AFO		IV
Refshauge et al. ³	2006	14	14	Night splints	No improvement with night splints	IV
Vinci and Gargiulo ⁵	2008	25	25	AFOs	Poor compliance with AFO	IV
Burns et al. ⁶	2006	154	Unknown	Custom orthoses	Custom orthoses improved pain and function	I

AFO, ankle-foot orthosis.

3. When is the best time to recommend reconstructive surgery?

4. What are the outcomes from surgical reconstruction of the cavo-varus foot in a patient with CMT?

Question 1: Is there any evidence for orthotics in the management of the foot deformity in CMT?

Relevance

Abnormal distribution of pressure leading to pain, foot drop, and ankle instability can all be managed with an orthotic shoe insert or brace. Orthoses are the first line of management for many foot and ankle disorders, but custom orthoses can be expensive.

Current opinion

Patients should try orthoses before proceeding to surgery. CMT is a neurogenic, progressive disorder and as such early surgery may prevent or slow secondary joint degeneration.

Finding the evidence

- Cochrane Database with search term “(Charcot Marie Tooth OR Pes Cavus OR Cavo-varus)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND orthotics
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords (“Charcot Marie Tooth” OR “Pes Cavus” OR “Cavo-varus”) AND orthotics

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 randomized trial with methodological limitations
- 3 systematic reviews/meta-analyses (of no more than level II studies)

Findings

The most comprehensive study looking solely at patients with CMT was a (level II) randomized controlled trial (RCT) of night splints but with only 14 patients.³ Wearing night splints was not found to improve dorsiflexion strength or range of motion. Two further (level IV) studies found that optimizing CMT patients’ ankle-foot orthosis (AFO) prescription improved physiological performance and perceived exertion,⁴ but compliance with AFOs in CMT patients is poor.⁵

In a good-quality (Level I) RCT of 154 symptomatic cavus feet (9 with CMT) Burns et al. found significant improvement in pain, function, and distribution of plantar pressure with custom orthotics vs. sham insoles.⁶ Nine of these patients had CMT. The results of orthotic interventions are summarized in Table 36.1.

Recommendations

- There is insufficient evidence to support the use of orthotics specifically in CMT [overall quality: low]
- There is, however, strong evidence to support the use of custom-made orthotics in the symptomatic cavus foot [overall quality: high]

Question 2: Should the patient be referred for physiotherapy?

Relevance

Lateral ligament instability and/or foot drop, disorders which conventionally are referred for physiotherapy, can be manifestations of CMT.

Current opinion

Depending on the degree of symptoms a course of physiotherapy may be beneficial. In the presence of progressive motor and sensory deficits, strengthening and proprioceptive training are less likely to be of benefit.²

Finding the evidence

- Cochrane Database with search term “(Charcot Marie Tooth OR Pes Cavus OR Cavo-varus)”

Table 36.2 Outcomes of physiotherapy interventions

Author	Year	Patients (n)	CMT	Intervention	Outcome	Level
Lindeman ⁷	1995	62	29	Strength training	Moderate benefit	II
Chetlin et al. ⁸	2004	40	40	Resistance training ± creatine	No benefit from creatine	II
Chetlin et al. ⁹	2004	20	20	Resistance training	Moderate benefit	IV
El Mhandi et al. ¹⁰	2008	8	8	Interval training	Moderate benefit	IV

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND physiotherapy
- PubMed sensitivity search using keywords: (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND physiotherapy

Quality of the evidence

Level II

- 1 randomized trial with methodological limitations
- 1 prospective comparative study
- 3 systematic reviews/meta-analyses (of no more than level II studies)

Findings

In one RCT of poor quality with small numbers (level II), a moderate increase in strength and leg-related functional performance was demonstrated with strength training in patients with HSMN.⁷ A prospective comparative study (level II) of resistance training with and without creatine supplementation showed no additional benefit.⁸ Two small case series (level IV) also showed that resistance training⁹ and interval training exercise¹⁰ could improve functional performance and subjective perception of pain and fatigue. Outcomes of physiotherapy interventions are summarized in Table 36.2.

Recommendation

- In light of the poor quality of the level II studies, only a limited recommendation can be given for physiotherapy-directed exercise in CMT [overall quality: moderate]

Question 3: When is the best time to recommend reconstructive surgery?

Relevance

CMT is a progressive disorder. Benefits of surgery must be weighed against risks; in general, flexible deformities are more easily corrected than late, fixed deformity.

Current opinion

Some surgeons believe that tendon surgery should be performed early to prevent progression of deformity.¹

Finding the evidence

- Cochrane Database with search term “(Charcot Marie Tooth OR Pes Cavus OR Cavo-varus)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND physiotherapy
- PubMed sensitivity search using keywords : (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND physiotherapy

Quality of evidence

Level IV

- 1 observational study
- 1 case-control study

Findings

There is no evidence to guide timing of surgical intervention. One observational study demonstrated a reduction in muscle strength and sensory function over a 2 year period in patients with CMT type 1A.¹¹ Another case-control study demonstrated an increase in physical disability over 5 years but, interestingly, a similar deterioration in muscle strength compared to a control group.¹²

Recommendation

- No recommendation can be made for early surgical intervention due to insufficient evidence [overall quality; low]

Question 4: What are the outcomes from surgical reconstruction of the cavo-varus foot in a patient with CMT?

Case clarification

The patient may have failed the nonoperative interventions described above and/or you believe that early surgical intervention is warranted.

Relevance

CMT is a progressive disorder characterized by muscle imbalance. The goals of surgical reconstruction are to rebalance the foot, to reduce pain, and to maintain a plantigrade, shoeable foot. Traditionally this was performed with a

triple arthrodesis but the poor long-term results, particularly in the adolescent population, have directed attention towards more joint-sparing procedures.

Finding the evidence

- Cochrane Database with search term “(Charcot Marie Tooth OR Pes Cavus OR Cavo-varus)”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND surgery
- PubMed sensitivity search using keywords : (“Charcot Marie Tooth” OR “Pes Cavus” OR cavo-varus) AND surgery

Quality of the evidence

A number of scientific articles have been written on the surgical management of CMT but no more than level IV evidence is available and most of the literature is expert opinion. This reflects the complex nature and heterogeneity of the disease.

Findings

Surgeries can be broadly classified into soft tissue procedures, osteotomies, and fusions. These procedures will, however, usually be combined.

In one of the longest case series (level IV), Ward et al.¹³ reviewed 41 feet in 25 consecutive patients with CMT who underwent an “algorithmic” approach to reconstruction of their cavo-varus feet at an average of 26.1 years of age. This included a dorsiflexion osteotomy of the 1st metatarsal, transfer of the peroneus longus to the peroneus brevis, plantar fascia release, transfer of the extensor hallucis longus to the neck of the 1st metatarsal, and in selected cases transfer of the tibialis anterior tendon to the lateral cuneiform. Although 11 patients required subsequent procedures, no patients required a triple arthrodesis and reoperation rates and rates of degenerative changes were lower than reports following triple arthrodesis.

Soft tissue surgery Frequently described soft tissue procedures include gastrosoleus lengthening, plantar fascia release, and tendon transfers. One of the few series (level IV) of soft tissue procedure only was described by Roper and Tibrewal.¹⁴ Surgery included tendo achilles (TA) lengthening, tibialis anterior transfer, Jones transfer, plantar fascia release, and Girdlestone Taylor transfer for claw toes. Follow-up was to an average of 14 years with a “good” outcome reported in all 10 patients. No patients had required a triple fusion. Tynan and Klenerman¹⁵ described a case series (level IV) of isolated Jones transfers in 28 feet with pes cavus of varying etiology. The procedures were successful for clawing but not first ray overload and the authors recommended adjunctive procedures.

Osteotomies Where a CMT foot demonstrates a combination of fixed and flexible deformity, osteotomies may be employed to supplement soft tissue correction.

Kucukkaya et al.¹⁶ reported a case series (level IV) of pes cavus including two feet with CMT treated with V-osteotomy and Ilizarov method. Of nine feet treated, eight achieved a painless, plantigrade foot but follow-up was only to average 9 months. Sammarco and Taylor¹⁷ reported on 21 feet in 15 patients treated with calcaneal osteotomy and one or more metatarsal osteotomies; 15 patients had CMT. These authors advocated an adjunctive plantar fascia release.

Fusions More literature is available documenting triple arthrodesis than any other single intervention for CMT, although there are still no more than level IV studies to guide practice and outcome measures are also inconsistent between the studies.

Wetmore and Drennan¹⁸ reported a series of 16 patients with CMT, average age 15 years, with a total of 30 triple arthrodesis. Average length of follow-up was 21 years. Of 30 feet, 2 were excellent, 5 good, 9 fair, and 14 poor; 23 feet had evidence of ankle and/or midfoot arthritis and 6 had required ankle arthrodesis. Wukich and Bowen¹⁹ reported a series of 22 patients reviewed at average of 12.4 years with 88% good or excellent results and 86% satisfied; 24% had ankle arthritis and 62% rest of foot arthritis on radiographs, and 15% had talo-navicular pseudarthroses. Mann and Hsu²⁰ reported on 12 feet in 10 adolescent patients with CMT with an average follow-up 7.7 years. Only 5 feet were plantigrade and asymptomatic and radiographically fused; 3 had asymptomatic pseudarthroses. The authors comment that achieving plantigrade foot is most important.

In the single largest and longest review of triple fusions, Saltzman et al.²¹ reported on 67 feet in 57 patients of whom 6 had CMT. With an average follow-up 44 years, 78% had residual deformity, 28% were good, 69% fair and 3% poor at final follow-up. All had radiographic arthritis at ankle and midfoot. Note that in this series, soft tissue procedures were performed as necessary. Outcomes of surgical interventions are summarized in Table 36.3.

Recommendations

- No more than level IV evidence exists for any surgical intervention; only a limited recommendation can therefore be given for an appropriate combination of soft tissue and bony procedures [overall quality: low]
- More evidence is available for triple arthrodesis, but the relatively poor long-term outcomes of surgery performed in adolescents should be noted [overall quality: low]

Mann and Hsu ²⁰	1992	10 (12 feet)	10	Triple arthrodesis	Non-plantigrade foot poorer outcome	IV
Santavirta et al. ²²	1993	15 (26 feet)	15	Various fusions	Mean 14yrs, 4 excellent, 15 good, 4 fair, 3 poor	IV
Saltzman et al. ²¹	1999	57 (67 feet)	6	Triple arthrodesis	Mean 44yrs, 19 good, 46 fair, 17 poor	IV
Kucukkaya et al. ¹⁶	2002	9	2	Ilizarov frame	Mean 9 months, 8 satisfactory	IV
Ward et al. ¹³	2008	21 (45 feet)	21	Combined approach	Mean 26yrs, 31 feet no further surgery	IV

Summary of recommendations

- There is insufficient evidence to support the use of orthotics specifically in CMT, but strong evidence to support the use of custom-made orthotics in the symptomatic cavus foot.
- There is fair evidence for physiotherapy-directed exercise in CMT.
- There is insufficient evidence to guide timing of surgical intervention.
- No more than Level IV evidence exists for any surgical intervention.
- There is poor evidence to guide selection of appropriate combination of soft tissue and bony procedures.
- There is poor evidence for triple arthrodesis. The relatively poor long-term outcomes of surgery performed in adolescents should be noted.

Conclusion

The cavo-varus foot deformity resulting from CMT represents a challenging problem. The relative heterogeneity of the problem makes evaluation of the literature difficult. A thorough knowledge of the disease process and resulting deformities is essential to guide the surgeon in selecting appropriate soft tissue and bony procedures. Future outcome studies should include details of the specific deformities and the procedures used to address them.

Acromioclavicular Joint

Bill Ristovski and Michael D. McKee

St. Michael's Hospital and University of Toronto, Toronto, ON, Canada

Case scenario

A 23 year old man comes to the Emergency Department after being tackled during a football game and injuring his left shoulder. He has swelling and deformity at the distal end of his clavicle. His upper extremity is neurovascularly intact. It is an isolated injury.

Relevant anatomy

The lateral end of the clavicle and the acromion meet to form the acromioclavicular (AC) joint. The capsule resists mainly anterior and posterior motion while the vertical checkrein is the coracoclavicular (CC) ligament complex. Increasing disruption of these anatomic structures usually results in higher-grade injuries.

AC joint injuries are typically classified into six grades:

- I AC joint strain
- II AC joint subluxated and the CC ligaments are intact
- III AC joint dislocated and the CC ligaments are disrupted
- IV AC joint superiorly and posteriorly dislocated
- V AC joint dislocated with 100–300% separation
- VI AC joint dislocated and inferiorly displaced under the coracoid

Importance of the problem

A Google search for “AC joint separation” returns over 7,000,000 hits. This high hit rate correlates with how common AC joint injuries are, and the various treatments that have been put forward for such injuries. The AC joint remains one of few major joints in the body where dislocation is often accepted without intervention.

Top five questions

Diagnosis

1. Is there a role for MRI rather than standard radiographs in the diagnosis of AC joint injuries?

Therapy

2. What is the optimal nonoperative treatment of an AC joint injury?
3. What type of AC joint injuries should be considered for operative intervention?
4. What is the best operative repair for an AC joint injury?

Prognosis

5. What is the outcome of acute repair vs. delayed reconstruction of an AC joint injury?

Question 1: Is there a role for MRI rather than standard radiographs in the diagnosis of AC joint injuries?

Case clarification

Most AC injuries can be accurately graded using plain radiographs (Figure 37.1). However, this is not always the case and some injuries may be graded incorrectly due to their benign appearance on radiographs secondary to changes in the positioning of the upper extremity, angle of the radiograph beam, or position of the patient. The role of MRI in assessing the extent of injury is brought up by the patient.

Relevance

The classification of AC joint injuries is important as it aids decision-making for potential treatments. Most surgeons

Figure 37.1 Radiograph demonstrating a left grade V AC joint dislocation from the patient in our case scenario.

treat types I and II AC joint injuries nonoperatively. Types IV–VI usually require operative stabilization secondary to their displacement, instability, and associated soft tissue damage. The current debate centers on the optimal management of type III AC joint injuries. Typically, type III injuries have AC joint capsule disruption as well as tearing of the CC ligaments or, rarely, fracture of the coracoid process. Hence the role of MRI is being investigated to define injury severity and perhaps aid in accuracy of classification and improve treatment.

Current opinion

Most orthopedic surgeons would treat type III AC joint injuries nonoperatively.

Finding the evidence

- Cochrane Database, with search term “acromioclavicular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search: “acromioclavicular joint”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) randomized controlled trials: “acromioclavicular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) comparative study: “acromioclavicular”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) Meta-analysis: “acromioclavicular”
- Repeat searches with “acromioclavicular dislocation” and “acromioclavicular injury”
- Repeat searches with “acromioclavicular AND nonoperative”
- Repeat searches with “acromioclavicular AND chronic OR delay”

Quality of the evidence

- Level IV

Findings

The most commonly accepted classification of AC joint injuries by Rockwood is based on the radiographic appear-

ance of the distal clavicle relative to the acromion and coracoid process. The grades essentially escalate with increasing soft tissue disruption about the AC joint. With little disruption of soft tissues (grades I and II) nonoperative treatment is preferred. With significant soft tissue damage (grades IV–VI) most surgeons favor operative treatment in order to reduce and restore stability to the AC joint. Grade III injuries have intermediate soft tissue disruption, with tearing of the AC joint capsule along with the coracoclavicular ligaments. Unfortunately, as in many classification systems, inter- and intraobserver reliability is such that absolute concordance of classification is not possible. In addition, occasionally, patient positioning, support of the extremity, or X-ray beam angle can cause more serious separations of the AC joint to be misdiagnosed. To avoid this, many authors have suggested stress or weighted radiographs of the AC joint, which would in theory separate the acromion from the clavicle allowing the full extent of the AC joint injury to be documented. Bossart et al. evaluated the efficacy of weighted films and found that only 4% of weighted films unmasked a more severe injury (level III).¹ In some instances weighted films made the injury less severe secondary to the uninjured contralateral side, increasing its coracoclavicular distance under stress or muscular contraction secondary to weighted limbs reducing the clavicle separation on the injured side. Their conclusion was that weighted films were not necessary for AC joint injuries. This, combined with the pain the patient endures to obtain these radiographs, as well as the greater radiation exposure, has made stress films less popular in recent times.

With stress films losing popularity, attention has turned to other imaging modalities such as MRI. However, no comparative data exists in sufficient quantity to judge radiographic appearances of AC joint injuries with MRI and correlate this with classifications of the injuries. It is evident that MRI has the ability to demonstrate injury to the AC joint and evaluate the integrity of the coracoclavicular ligaments (level IV).^{2,3} This has allowed some authors to use MRI results to classify AC joint injuries on the basis of Rockwood’s classification. However, the sensitivity and specificity of injury detection and accuracy of classification via MRI compared to radiograph remains to be determined, and indications for MRI in this setting remain controversial.

Recommendation

Most patients can be reliably diagnosed and classification of their AC joint injury can be determined by an accurate focused history and physical examination along with standardized radiographs including AP, axillary, and upshot (Zanca) view where the arm is resting at the side, without use of a sling. Typically grade I, as well as grades IV–VI, can be reliably distinguished on radiographs. In the rare circumstances where a patient’s treatment might be altered because clinical and radiographic findings are equivocal,

MRI will give the physician and patient more information on the integrity of the AC joint soft tissues restraints. How this additional information factors into the ultimate outcome following such injuries has yet to be determined.

- There is insufficient evidence to recommend use of MRI imaging for AC joint injuries. [overall quality: low]

Question 2: What is the optimal nonoperative treatment of an AC separation?

Case clarification

Once an AC joint separation is diagnosed and classified the clinician and patient must decide on operative vs. nonoperative treatment. If nonoperative treatment is decided upon, what form of nonoperative treatment leads to the best outcome?

Relevance

The majority of patients with an AC joint injury will benefit from nonoperative treatment. Taping, bracing/splinting, simple sling, and casting have all had proponents and opponents over time. The issue remains if one method has been able to show benefits when compared to alternate treatments.

Current opinion

Most orthopedic surgeons use a simple sling as their preferred nonoperative management of AC joint injuries.

Finding the evidence

- See Question 1

Quality of the evidence

- Level III

Findings

AC joint separations have been recognized at least since the time of Hippocrates. Many nonoperative treatments have been proposed, with variable success. Lazcano et al. divided nonoperative treatments into three groups: (1) adhesive dressings, (2) various harnesses and braces, or (3) hanging-type casts (suspension casts).⁴ Some authors have reported success with various devices, achieving healing in the reduced position (level IV).⁵ However, there has been little in the way of direct comparative studies looking at simple sling vs. other more elaborate splints/braces that effectively elevate the arm and acromion and/or depress the clavicle dynamically. In one study operative vs. nonoperative treatment was studied. The nonoperative treatment arm consisted of simple sling, a Kenny–Howard splint (a combination of straps that are designed to elevate the acromion while depressing the clavicle) and casting/taping. Overall the authors felt that the Kenny–Howard splint was superior in reducing the AC joint separation radiographically. However, only 1 in 10 patients ended

with an anatomic reduction of the joint vs. 0 out of 43 patients with simple sling treatment (level III).⁶

Overall, there appears to be evidence that it is possible to reduce an AC joint and maintain this position with various splinting techniques. However, these devices are often elaborate, must be positioned correctly, can be painful to wear, and have questionable patient compliance. The combination of these factors has likely negated the potential benefits that can be demonstrated by such splints.

Recommendation

- Although there are reports that can demonstrate reduction of displaced AC joint with splints, there is insufficient evidence to support the use of a reduction splint vs. simple sling for the nonoperative treatment of AC joint injuries [overall quality: low]

Question 3: What type of AC joint injuries should be considered for operative intervention?

Case clarification

Our patient presents after an isolated, closed injury to the AC joint. He is neurovascularly intact and otherwise healthy with no comorbidities. The patient inquires about surgical treatment vs. nonoperative treatment of this injury.

Relevance

The patient's understanding of the result of nonoperative treatment of their injury vs. the expected risks and benefits of operative intervention forms the basis of treatment decisions. With AC joint injuries the goals of operative intervention are restoration of preinjury anatomy, restoration of preinjury strength and function, and restoration of shoulder appearance.

Current opinion

Most orthopedic surgeons would treat grade I and II AC joint injuries nonoperatively and grade IV–VI AC joint injuries operatively with their preferred technique. Grade III injuries receive variable treatment, with mixed opinion on whether operative treatment is warranted or not.

Finding the evidence

- See Question 1

Quality of the evidence

Level II

- 2 meta-analyses
- 3 randomized controlled trials (RCTs)

Findings

Most of the literature detailing the treatment of severe AC joint injuries (grade IV–VI) is based on expert opinion.

Openmirrors.com

Most authors recommend operative treatment based on their experience of patient outcome following such injuries. Authors have noted deformity, shoulder weakness, loss of shoulder motion, and pain. Unfortunately, there is a paucity of objective data on these injuries. Intuitively, increasing soft tissue damage with increasing grades of AC joint injury would lead to greater functional deficits and pain. Particularly poor outcome has been noted when the clavicle tears through the deltotrapezial fascia and remains directly subcutaneous. Lying subcutaneous makes the clavicle deformity more prominent, and lack of muscular attachments contributes to ongoing shoulder dysfunction.

Three RCTs focusing on AC dislocations were identified. Bannister et al. completed two of these trials (level II).^{7,8} Patients were randomized to nonoperative treatment vs. surgical treatment, which consisted of removal of the AC joint meniscus and screw fixation of the clavicle to the coracoid, as well as repair of the anterior deltoid if torn. Hardware was removed 6 weeks after surgery. Patients were ranked as excellent or not excellent in one study or perfect, excellent, good, or fair in another study. Overall, in both studies the authors felt that nonoperative treatment was favorable as patients returned to full activity sooner with avoidance of surgical complications. However, in severely displaced AC joints (defined as >2cm above the acromion), operative fixation was deemed to give more favorable results.

Larsen et al. completed a randomized study on dislocated AC joints comparing nonoperative treatment to operative treatment which consisted of removal of the AC joint meniscus, reduction and transarticular pinning of the AC joint with Kirschner wires (K-wires), and repair of the CC ligaments and any associated muscle damage (level II).⁹ Wires were removed 5–12 weeks after surgery. Points were assigned to patients based on their strength (gauged by spring weights), motion, and subjective pain. Their conclusion was that nonoperative treatment was superior because of the lack of complications seen in the operative group including pin breakage/migration, infection, loss of reduction, and prolonged rehabilitation vs. nonoperative treatment. Outcomes were not significantly different.

Systematic reviews on grade III AC joint injuries have come to the conclusion that operative treatment is not warranted as it shows no difference compared to nonoperative treatment (typically with a sling) and exposes patients to increased risk of complications (level II).^{10,11} From the data that is available no appreciable difference in range of motion, pain control, or ultimate shoulder strength was found.

These studies and meta-analyses unfortunately contain flaws that render the conclusions questionable. Many of the authors subjectively felt that their studies were underpowered and that younger patients with greater demands on

their shoulder (athletes, laborers who perform overhead activities, etc.) actually did better with surgery.^{7,9} In addition, these studies employed fixation techniques/procedures that are inferior to modern techniques. Fixation devices including hook plates, autograft/allograft fixation, or combinations of fixation techniques are felt to be superior (level IV).^{12–17} A recent retrospective comparative study by Gsettner et al. showed a statistically significant higher Constant score achieved by patients in the operative fixation group via hook plate compared to the nonoperative group in patients with a Rockwood grade III AC joint injury (level III).¹⁸ Such studies and author inferences combined with presumed better operative techniques have added to the debate on the optimal treatment of grade III AC joint injuries.

Recommendation

There is mounting level III/IV evidence that modern operative techniques can result in improved outcomes compared to Bosworth screw or K-wire fixation of grade III AC joint injuries. Higher-quality randomized clinical trials with validated outcome measures and objective testing will be required to elucidate whether the benefits of improved surgical intervention outweigh the potential risks of surgery for such injuries.

- There is insufficient evidence to recommend surgical intervention for grade III AC joint injuries. [overall quality: low]

Question 4: What is the best operative repair for an AC joint injury?

Case clarification

This patient has a widely displaced grade V AC joint injury. He is a young active man with no other comorbidities. The injury is closed and isolated and his upper extremity is neurovascularly intact. The recommendation for operative intervention is made.

Relevance

In high-grade (IV–VI) AC joint injuries most surgeons agree that operative intervention is warranted. Many techniques have been reported with variable success. The ideal repair would achieve and maintain an anatomic reduction, and promote healing in such a way as to preserve the physiological motion demonstrated by the AC joint.

Current opinion

Opinion is divergent on the best operative intervention for AC joint injuries

Finding the evidence

- See Question 1

Findings

No RCTs or meta-analyses exist in the literature comparing fixation techniques for AC joint dislocations. Previous RCTs looking at nonoperative vs. operative treatment for grade III AC joint injuries have demonstrated that clavicular-coracoid screw fixation alone or transfixation of the AC joint via K-wires is not superior to nonoperative treatment (level II).^{7-9,19,20} Bannister et al. felt that widely displaced AC joint injuries did have superior results with clavicular-coracoid screw fixation alone.

Many other procedures have been described, including both intra-articular and extra-articular procedures. Authors have reported using various fixation devices, coracoclavicular slings (either biologic or synthetic), coracoacromial ligament transfer to the distal end of the clavicle, or dynamic transfers of the conjoint tendon/coracoid process (level IV).^{12,14-18,21-25} Comparison is extremely difficult, with multiple different techniques and implants being employed on various grades of injuries. In addition, these case series are typically small and combine acute and chronic injuries.

Recommendation

Our preferred method of treatment involves the use of a hook plate (Figure 37.2), which we have found to provide stable fixation and adequate reduction for these types of injuries. A disadvantage of this technique is the need for subsequent reoperation for removal in most cases. Although many authors have been able to show good results with K-wire fixation, we would not employ this technique secondary to the rare but potentially devastating complications of K-wire migration to vital organs, especially when other alternative modes of fixation are available that avoid such major complications (level IV).²⁶⁻³⁰ The patient in our case scenario elected to undergo operative fixation of his AC joint injury via open reduction and internal fixation with a hook plate.

- There is insufficient data to recommend one type of operative repair over another for dislocated AC joints.

Question 5: What is the outcome of acute repair vs. delayed reconstruction of an AC joint injury?

Case clarification

The patient's radiograph reveals a grade V separation of the AC joint. Surgery is offered to the patient. The patient inquires about waiting to see if the injury is symptomatic and if so can surgery be completed then.

Relevance

Prediction of which patients will be symptomatic following a particular grade of injury is extremely difficult. A patient's ultimate outcome is influenced by their injury, age, handedness, functional demand, expectations, etc. A reasonable question is whether delayed reconstruction is as effective as acute operative intervention.

Current opinion

Most orthopedic surgeons feel that delayed reconstruction of AC joint injuries has inferior results compared to acute repair in comparable injuries.

Finding the evidence

- See Question 1

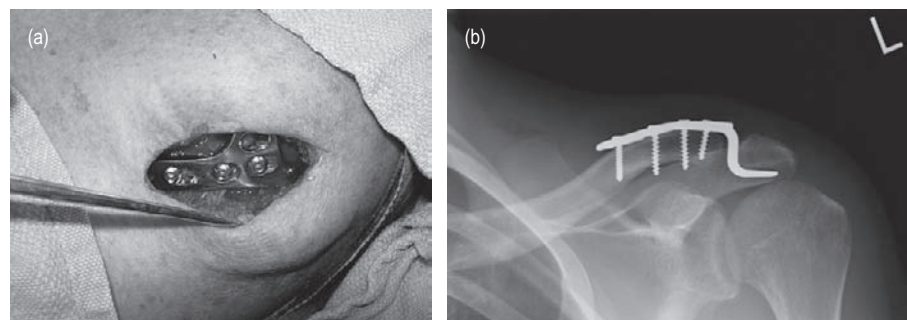

Quality of the evidence

- Level III

Findings

No RCTs or meta-analyses exist on this topic. Many authors have been able to show improved outcomes following reconstruction of chronic AC joint dislocations in case series but have not compared their results to acute reconstruction (level IV).^{16,21,24,31,32} Rolf et al. looked retrospectively at a total of 49 patients, 20 with delayed repair of their AC joint injury and 29 with acute repair. Acute repair consisted of reduction of the AC joint with PDS coracoclavicular sling and repair of the AC joint ligaments with

Figure 37.2 (a) Intraoperative photograph of a clavicular hook plate in situ. (b) Postoperative radiograph demonstrating a reduced AC joint held by a hook plate. Note the hook portion of the plate resting in the subacromial space, resisting the superior displacement of the clavicle.

temporary K-wire transfixation. Delayed reconstruction consisted of distal clavicular excision with transfer of the coracoacromial ligament to the distal clavicle and augmentation with PDS coracoclavicular sling. Overall, a significant nine point difference in Constant scores was demonstrated, favoring acute repair (level III).¹³

Recommendation

- Early level III evidence supports that patients with acute reconstruction ultimately have marginally better outcomes [overall quality: low]

Summary of recommendations

- There is insufficient evidence to recommend use of MRI imaging for AC joint injuries. Most patients can be reliably diagnosed and classification of their AC joint injury can be determined by an accurate focused history and physical examination along with standardized radiographs including AP, axillary, and 20° upshot (Zanca) view.
- Although there are reports that demonstrate reduction of displaced AC joint with specialized splints, there is insufficient evidence to support the use of a reduction splint vs. simple sling for the nonoperative treatment of AC joint separation.
- There is insufficient high quality evidence to recommend surgical intervention for grade III AC joint injuries in general.
- There is insufficient data to recommend one type of operative repair over another for dislocated AC joints.
- Early level III evidence supports that patients with acute repair ultimately have marginally better outcomes, compared with delayed reconstruction of AC joint injuries.

Conclusion

The literature on the treatment of AC joint injuries has been extremely varied. Conventional opinion dictates primary repair is indicated for higher-grade (IV–VI) injuries. Careful injury classification and patient selection is critical to successful operative treatment. RCTs are in progress to better delineate which patients would benefit with operative treatment and which techniques can optimize the ultimate function and satisfaction of patients.

Bill Ristevski and Michael D. McKee

University of Toronto and St. Michael's Hospital, Toronto, ON, Canada

Case scenario

A 30 year old man who is left-hand dominant and currently employed as a carpenter presents with intense pain in his shoulder after falling off of his mountain bike. On examination his left shoulder is deformed, appearing shortened and "ptotic." It is a closed injury and his left upper extremity is neurovascularly intact (Figure 38.1).

Relevant anatomy

The etymology of clavicle is from the Latin *clavicula* meaning "tendril, small key, rod, or bolt." Appropriately this relatively thin, double-curved bony "rod" struts the shoulder from the axial skeleton and was deemed to demonstrate "key-like" motion with shoulder movement.

According to the *Arbeitsgemeinschaft für Osteosynthesefragen/Orthopaedic Trauma Association (AO/OTA)* classification (Figure 38.2), clavicular injuries are typically divided into medial, shaft, and distal fractures. Shaft fractures may be simple, wedge, or complex.

Importance of the problem

Clavicle fractures represent approximately 2.6% of all fractures.¹ The majority can be treated successfully by nonoperative techniques. Historically, orthopedic dogma based on large studies using clavicular union as the ultimate successful endpoint, molded surgical belief in such a way that operative intervention was deemed unnecessary and dangerous.

Recently, other outcomes such as patient satisfaction, shoulder strength/endurance, time to recovery, and shoulder appearance have come to the fore. Modern studies have demonstrated functional deficiencies and higher nonunion rates with displaced clavicle fractures compared to previous reports. In some patients there is evidence many of these issues, and resultant disabilities, can be improved by acute operative intervention.

Many patients attempt to weigh fact and opinion from an increasingly massive amount of information that is directed toward them. A Google search for "collarbone fracture" yields 970,000 hits. With expanding treatment options for clavicle fractures, orthopedic surgeons together with their patients must decide on appropriate treatment.

Top five questions

Therapy

1. What is the optimal nonoperative treatment of a closed midshaft clavicle fracture?
2. What factors are associated with poor outcomes following nonoperative treatment of displaced clavicle fractures?
3. What is the optimal treatment of a displaced midshaft clavicle fracture?
4. What is the best operative technique for a clavicle fracture: intramedullary pin or plate?

Prognosis

5. What are the results of acute repair vs. delayed reconstruction secondary to nonunion or malunion for clavicle fractures?

Figure 38.1 Radiograph of a 30 year old man who fell off his mountain bike and sustained a midshaft clavicle fracture. Displacement and shortening is evident.

Question 1: What is the optimal nonoperative treatment of a closed midshaft clavicle fracture?

Case clarification

The patient's radiograph reveals a displaced midshaft clavicle fracture. Many surgeons would now offer operative treatment for such an injury. However, this patient is strongly against surgery. Two nonoperative options are offered: a figure-of-eight bandage or a simple sling.

Relevance

Obtaining and maintaining reduction for clavicle fractures via closed reduction techniques has eluded practitioners of medicine, despite literally hundreds of immobilization devices since the advent of bandaging fractures. The two nonoperative treatment methods that are most popular are figure-of-eight immobilization (believed to help control shoulder position to aid in the reduction of the fracture) or a simple sling.

Current opinion

Current opinion suggests that the majority of surgeons use a simple sling for the nonoperative treatment of a midshaft clavicle fracture.

Finding the evidence

- Cochrane Database, with search term "clavicle fracture"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) systematic reviews: "clavicle"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) randomized controlled trials: "clavicle"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical trial: "clavicle AND fracture, clavicle AND malunion, clavicle AND nonunion"
- American Academy of Orthopedic Surgeons, proceedings of the 2003–2008 annual meetings.
- MEDLINE OVID clavicle and fracture and plate limited to comparative study

Quality of the evidence

Level II

- 1 meta-analysis
- 2 randomized trials with methodologic limitation

Findings

Meta-analysis of the current evidence does not allow definitive conclusions on which intervention is better (level II).² Two trials were included in the meta-analysis, one by Andersen et al. in 1987 and the other by Hoofwick et al. in 1988 (level II).^{3,4} Both trials were underpowered, with the total number of participants being 234. Data pooling was not possible because of the different and/or unvalidated outcome measures used by the authors.

Pain, union, and function Between the two treatment groups both authors reported no difference in union, malunion, or shoulder function with the use of a sling or figure-of-eight bandage. Andersen reported 9/34 patients were dissatisfied with figure-of-eight treatment vs. 2/27 for sling treatment.³ Some of the reasons for this were secondary to the figure-of-eight bandage causing pain, difficulty sleeping, edema, and paresthesias of the arm.

Pain as measured by a visual analogue scale in the Hoofwijk study was better at 15 days in the group treated by sling vs. figure-of-eight bandage, (mean difference 0.80, 95% CI 0.34–1.26; visual analogue scale, 0 (no pain) to 10 (worst pain)).²

Recommendation

In adult patients with closed midshaft clavicle fractures:

- Sling immobilization is as effective as figure-of-eight bandage, with superior patient tolerance [overall quality: moderate]

Question 2: What factors are associated with poor outcomes following nonoperative treatment of displaced clavicle fractures?

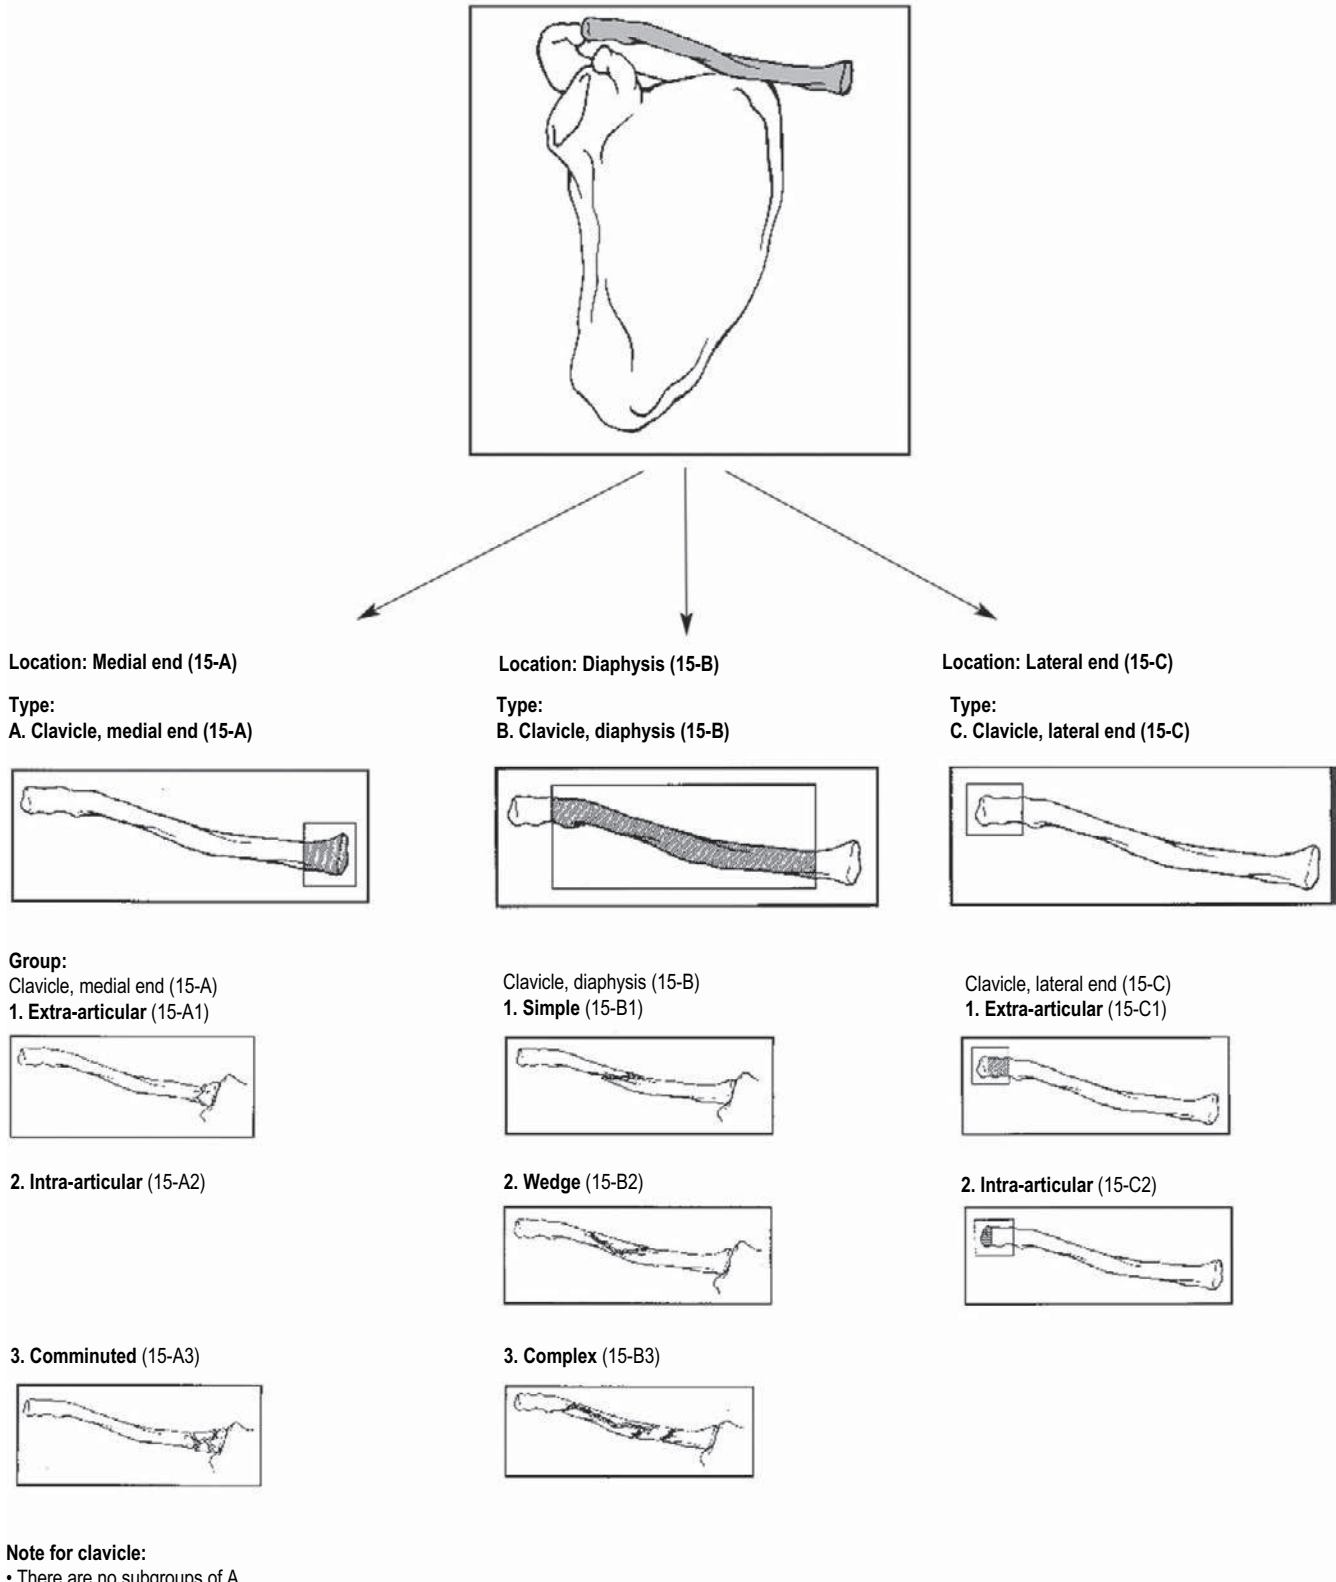

Case clarification

This young man has a displaced, shortened, midshaft clavicle fracture with minimal comminution. Clinically his scapula is malpositioned with prominence of the medial border and inferior tip. The natural history of this particular injury vs. an undisplaced clavicle fracture is discussed with the patient.

Relevance

Neer and Rowe independently reported on 2236 and 566 clavicle fractures and observed nonunion rates of 0.13% and 0.8% respectively.^{5,6} This helped support the overwhelming notion that these injuries were best treated nonoperatively.

BONE: CLAVICLE (15)

Note for clavicle:
 • There are no subgroups of A.

Figure 38.2 The OTA classification of clavicle fractures.

More recent literature, contrary to previous reports, demonstrated a subset of patients with permanent disability following the non-operative treatment of a clavicle fracture. This prompted further investigations to elucidate the potential negative sequelae of clavicle fractures and how to avoid them.

Current opinion

Most orthopedic surgeons recognize that a subset of patients with clavicle fractures will go on to have sustained pain and/or functional impairment.

Finding the evidence

- See Question 1

Quality of the evidence

Level I

- 1 systematic review
- 2 prospective prognostic studies

Findings

Most patients with a clavicle fracture will heal uneventfully via nonoperative treatment and most will have a satisfactory functional outcome with subjectively acceptable shoulder appearance. A minority of patients will have ongoing sequelae from a clavicle fracture.

In their 1997 study Hill et al. identified a subset of patients who had persistent symptoms and shoulder complaints following clavicle fracture. Patients with a completely displaced middle third clavicle fracture had a 15% nonunion rate and 31% expressed dissatisfaction with their ultimate outcome (level II).⁷

In 2005 Zlowodzki et al. performed a systematic review of the literature focusing on papers on clavicle fractures published from 1975 to 2005. A total of 22 studies were deemed acceptable, reporting on a total of 2144 fractures. Of these 1145 were treated nonoperatively with a resultant nonunion rate of 5.9%. Subset analysis identified 159 displaced fractures, whose nonunion rate was 15.1%, consistent with Hill's earlier findings (level I).⁸

Encompassed within this systematic review were important prospective observational cohort studies that provided insight into factors that are associated with negative outcomes after clavicle fracture. Robinson's study employing multivariate analysis found increasing fracture displacement, comminution, advancing age, and female gender all to be independent predictors of nonunion in shaft fractures (level I).⁹ Nowak et al. also found that displacement, comminution, and older age were predictors for sequelae (pain and deformity) following clavicle fracture (level I).¹⁰ Other authors have found association of long-term symptoms to be related to the degree of shortening. Patients with overall shortening of the clavicle by more than 15–20mm had increasingly prominent symptoms.^{7,8,11–15}

Recommendation

Increased risks for having ongoing symptoms or nonunion after clavicle fracture include no cortical contact at fracture site (amount of displacement), comminution, excessive shortening (>20mm), advancing age, and female gender.

- If risk factors are present, a more objective prognostication of potential negative outcomes can be offered to the patient and treatment alternatives considered [overall quality: high]

Question 3: What is the optimal treatment of a displaced midshaft clavicle fracture?

Case clarification

This patient is a healthy, active young man whose job entails heavy lifting, repetitive motions, and overhead activity. His radiograph shows a widely displaced and shortened clavicle. On physical exam he has shoulder "ptosis" and a prominent medial border of his scapula (a form of scapular winging). The risks and benefits of two options are discussed with the patient: reduction with internal fixation vs. nonoperative management.

Relevance

A logical sequence of investigational questions can be temporally mapped in the literature, leading to a renewed interest in operative treatments for clavicle fractures. First, compelling evidence from patient-based studies showed that nonoperative management of displaced clavicle fractures in young patients have poor outcomes following specific types of clavicle fractures. Second, investigations directed at categorizing patient or fracture types identified an at-risk population for poor outcome. Third, studies objectively demonstrated functional deficits following nonoperative treatment of displaced clavicle fractures. Fourth, studies investigating the use of acute operative fixation to potentially improve outcomes for patients at risk of long-term sequelae were performed. Debate continues with regard to which patients would benefit from acute fixation of clavicle fractures. Mitigation of overtreatment secondary to poor patient selection for operative stabilization is critical to avoid unnecessary risk exposure for patients.

Current opinion

Most surgeons acknowledge a benefit from acute operative fixation of widely displaced midshaft clavicle fractures in young healthy adults.

Finding the evidence

- See Question 1

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 systematic review
- 3 randomized trials

Findings

In a systematic review, Zlowodzki et al. on behalf of the Evidence-Based Orthopaedic Trauma Working Group reported on 2144 clavicle fractures. Plated fractures (N = 635) had a nonunion rate of 2.5% vs. 5.9% for nonoperative treatment (relative nonunion risk for nonoperative treatment, 2.4 (95% CI 1.4–4), and a relative risk reduction for plating of 57% (95% CI 27–75%; $p = 0.001$). (level II).⁸

When subset analysis of displaced fractures was reviewed, 460 plated fractures had an ultimate nonunion rate of 2.2% vs. 15.1% for nonoperatively treated displaced fractures. Therefore, the relative nonunion risk for nonoperative treatment was 6.9 (95% CI 3.4–14.2), with a relative risk reduction for plating of 86% (95% CI 71–93%); $p < 0.001$). Intramedullary pin fixation of the clavicle showed a similar improvement in nonunion rates vs. nonoperative treatment (level II).⁸

In 2007 The Canadian Orthopaedic Trauma Society (COTS) published their results from a multicenter prospective randomized controlled trial (RCT) of plate fixation vs. nonoperative treatment for displaced midshaft clavicle fractures. Outcomes included analysis of the Constant shoulder score, Disability of the Arm, Shoulder and Hand (DASH) score, radiographs, and standard clinical follow-up for duration of 1 year. The operative arm of the study had patients that demonstrated statistically significant differences including a shorter time to union (16.4 vs. 28.4 weeks), improved Constant and DASH scores, as well as being more satisfied with their outcomes and appearance (level I).¹⁶ The operative group had Constant and DASH scores that were improved by approximately 10 points, a difference that has been shown to be clinically relevant.^{17,18}

Complications for the operative group were 37% vs. 63% for nonoperative treatment. The operative group's complications included hardware irritation (with some patient requests for removal), transient brachial plexus irritations, and wound complications (4.8%). The nonoperative group had complications predominated by nonunion, malunion (requiring corrective surgery), and transient brachial plexus irritation. The only statistically significant difference in complications was a lower incidence of symptomatic malunion and nonunion in the operative group (level I).¹⁶

RCTs by both Smith and Smekal noted excellent results following operative fixation of displaced midshaft clavicle fractures (level II).^{19,20} Smekal et al., looked at operative fixation via elastic stable intramedullary nailing of fully displaced clavicle fractures vs. nonoperative treatment. A total of 60 patients were enrolled in the study. A significant difference was found in favor of the operative group in terms of the DASH score (first 18 weeks postoperatively) and the Constant score up until 2 years (Figure 38.3). In the nonoperative group 3 patients (10%) had a nonunion vs. 0 in the operative group, with 7 patients in the operative group having medial nail protrusion and 2 implant failures

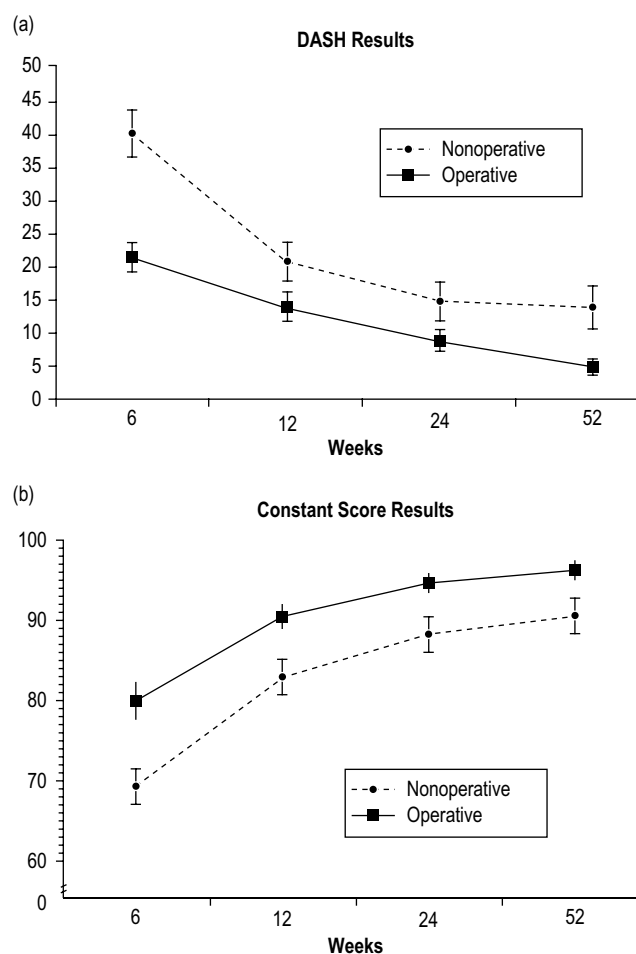

Figure 38.3 (a) Graphical DASH results, plate fixation group vs. nonoperative group for acutely displaced clavicle fractures. The DASH is a disability score with a “perfect” upper extremity achieving a score of 0. The operative group scores are significantly improved (lower DASH score) at every follow-up time point. (b) Graphical Constant score results, plate fixation group vs. nonoperative group for acutely displaced clavicle fractures. The operative group scores are significantly improved at every follow-up time point ($p = 0.01$). (Adapted from Canadian Orthopaedic Trauma Society. Nonoperative Treatment compared with plate fixation of displaced midshaft clavicle fractures. A multicenter, randomized clinical trial. *J Bone Joint Surg(A)* 89:1–10, 2007. Reprinted with permission of the Journal of Bone and Joint Surgery. www.jbjs.org)

requiring revision surgery after repeat trauma. Overall, Smekal noted operatively treated patients returned to daily activities quicker, and had a higher degree of satisfaction. Smith et al. found similar results in their prospective randomized study,²⁰ where 12 out of 35 patients in the nonoperative group developed a nonunion, whereas all 30 patients treated with plate fixation went on to unite ($p = 0.001$). There was a 30% rate of hardware removal in their study.

Recently, Judd et al. published a prospective randomized trial looking at nonoperative treatment vs. operative treat-

ment employing a modified Hagie pin for displaced midshaft clavicle fractures (level II).²¹ No significant difference in outcome was identified at 1 year after the interventions, except the operative group had a higher amount of complications particularly related to hardware prominence.

Recommendation

- Young active individuals who are low risk for general anesthetic and have a completely displaced clavicle fracture demonstrate a functional benefit and overall higher satisfaction level with operative vs. nonoperative treatment. A discussion with such patients should be had outlining the relative risks of operative fixation vs. nonoperative treatment [overall quality: moderate]

Question 4: What is the best operative technique for a clavicle fracture: intramedullary pin or plate?

Case clarification

This young adult man has a displaced, shortened clavicle fracture with minimal comminution and clinically malaligned scapula. After patient counseling a decision to proceed with operative treatment is made (Figure 38.4). Two options are offered: intramedullary pinning vs. plate fixation.

Relevance

Early studies of clavicle fixation demonstrated that small plates and/or cerclage wires for clavicle fractures were inadequate and would commonly lead to catastrophic failure or nonunion.^{5,6} This certainly added to the impetus to avoid operating on clavicle injuries. In addition, the clavicle poses other difficulties in terms of operative treatment. It is a superficially located, irregularly shaped bone

in close proximity to neurovascular structures. Depending on the position of the arm the clavicle undergoes motion, which alternates the topography of compressive, tensile, and rotation forces on the bone. This provides an extremely challenging stress on implants used for fixation. Although many methods of internal fixation exist, two general categories have been popular: intramedullary fixation and plate fixation.

Current opinion

Plate fixation for clavicle fractures provides increased stability and more reliable results for maintenance of reduction vs. intramedullary devices.

Finding the evidence

- See Question 1

Quality of the evidence

Level I

- 1 randomized trial

Level II

- 1 systematic reviews/meta-analyses
- 4 randomized trials

Findings

RCTs have shown benefits in terms of union rates, avoidance of malunion, and quicker return to baseline function with internal fixation vs. nonoperative treatment for displaced midshaft clavicle fractures (level I/II).^{16,20} Other studies employing intramedullary fixation have demonstrated mixed results, some comparable to plate fixation (level II)¹⁹ with other studies showing no benefit of intramedullary fixation (level II/III).^{21,22} Some authors have suggested that the benefit of intramedullary stabilization of clavicle fractures is negated by the complications—mainly hardware migration, infections, and loss of reduction associated with this type of hardware (level II/III).^{21,22}

There has been only one RCT directly comparing intramedullary pinning vs. plate fixation, by Lee et al. (level II).²³ The difference between Knowles pins and plate fixation was investigated in elderly patients. Overall, the authors felt Knowles pins were superior, secondary to a smaller incision and decreased pain rate. No difference in healing time, shoulder scores, or union was observed. However, interpretation of this data is difficult as this study focused on elderly patients with lower functional demands. In addition, some patients had cerclage wire in addition to implantation of the Knowles pin or plate fixation, which included the use of reconstruction plates, tubular plates (which are suboptimal in higher-demand patients), or dynamic compression plates.

Recommendation

Most of the complications with intramedullary devices are centered on hardware migration (skin protrusion/hardware

Figure 38.4 The patient in the above case scenario elected to have operative treatment. This radiograph was obtained during follow-up and demonstrates fixation with a precontoured clavicle plate.

irritation), loss of reduction, and infection vs. hardware prominence and potential for more wound complications/infections with the larger incision needed for plating. More studies are necessary to determine if the potential advantage of smaller incisions with intramedullary fixation can outweigh the risks of losing fracture reduction via shortening or rotation, problems associated with any unlocked intramedullary device.

- There is insufficient evidence to determine if plating or intramedullary fixation provides a superior outcome for displaced midshaft clavicle fractures [overall quality: insufficient]

Question 5: What are the results of acute repair vs. delayed reconstruction secondary to nonunion or malunion for clavicle fractures?

Case clarification

This young adult has a completely displaced midshaft clavicle fracture, with a clinically obvious shoulder deformity. The expected benefits of acute fixation are discussed vs. the potential benefits of delayed reconstruction of a nonunion or malunion.

Relevance

Improper healing of a clavicle fracture can be problematic. However, a proportion of patients with significant malunions and to lesser degree nonunions of their clavicle may be asymptomatic. This suggests that a possible treatment approach would be delayed reconstruction of a symptomatic malunion or nonunion vs. acute fixation.

Current opinion

Most orthopedic surgeons recognize that acute fixation of displaced clavicle fractures provides a better functional outcome than reconstructive procedures.

Finding the evidence

- See Question 1

Quality of the evidence

- Level III

Findings

There is limited information available comparing delayed reconstruction of clavicle fracture malunion and nonunions to acute fixation. Potter et al. found that patients with delayed reconstruction had a significant difference in their Constant scores, with the acute fixation group scoring on average 6 points higher than the group who underwent delayed reconstruction (level III).^{14,24} Patients with delayed reconstruction also had significantly poorer endurance strength of their shoulders.

Other studies have demonstrated improved Constant and/or DASH scores with delayed reconstructions but unfortunately did not have an acute clavicle fixation group to compare with (level IV).^{14,15,25-27}

Answering such questions by the scientific method is difficult, as a delayed reconstruction implies bias; patients who underwent nonoperative treatment and are displeased with their outcome. This may select a subgroup of patients with intrinsically poor results.

Recommendation

Debate continues as to how significant the differences of acute fixation are relative to delayed reconstruction. This should be discussed with the patient and overall suitability ascertained by the patients' age, expectations, timeline to return to activities, occupation/recreational activities, comorbidities, operative suitability, level of risk aversion, and possible need for reoperation secondary to complication or for hardware removal.

- There is no level I evidence to suggest that acute fixation of a displaced midshaft clavicle fracture provides superior outcome compared with delayed reconstruction. What evidence is available supports a marginally improved Constant shoulder score and improved endurance strength with acute fixation. In isolation this information should not be used to make a decision between nonoperative vs. operative treatment, but can be relayed to patients to allow a complete discussion of such injuries [overall quality: low]

Summary of recommendations

- In adult patients with a closed midshaft clavicle fracture, sling immobilization is as effective as a figure-of-eight bandage with superior patient satisfaction. Our recommendation is nonoperative treatment with a sling
- Prognostic factors for poor outcome following a clavicle fracture include:
 - No cortical contact at fracture site (amount of displacement)
 - Comminution
 - Excessive shortening (>20 mm)
 - Advancing age
 - Female gender
- Young active individuals who are low risk for anesthetic and have a completely displaced midshaft clavicle fracture demonstrate a functional benefit and overall higher satisfaction level with operative vs. nonoperative treatment
- There is insufficient evidence to determine if plates or intramedullary fixation provides a superior outcome for

displaced midshaft clavicle fractures treated operatively. Complications of intramedullary nailing include hardware migration with subsequent loss of reduction, and hardware irritation. Hardware prominence and wound complications are more common with plating. In general, results appear to be more consistent with plating

- There is no level I evidence to suggest that acute fixation of a displaced midshaft clavicle fracture provides superior outcome compared with delayed reconstruction. What evidence is available supports an improved Constant shoulder score and activity endurance with acute fixation

Conclusion

The treatment of clavicle fractures has changed dramatically over the last two decades, with high-quality prospective and randomized trials supporting primary operative fixation of completely displaced clavicle fractures in select patients.

Scapula

Peter A. Cole and Lisa K. Schroder

University of Minnesota–Regions Hospital, Saint Paul, MN, USA

Case scenario

History and physical examination

A 28 year old snowboarder crashed into a tree. He was dazed at the scene, had labored respirations, and was carried off via stretcher and airlifted to a level I trauma center.

A trauma workup revealed a Glasgow Coma Score of 13 in a mildly disoriented man who complained of severe shoulder, chest, and back pain.

History revealed that he was a right-handed warehouse stockman who was otherwise healthy. Physical examination revealed left-sided facial lacerations and an abrasion over a tender mass at the acromion. He had a strong grip and intact sensation of C5–T1, but an inability to forward elevate or externally rotate the shoulder.

Radiography

A chest radiograph revealed four consecutive left-sided rib fractures and a pneumothorax, prompting dedicated shoulder radiographs. A fracture of the scapula in the region of the glenoid neck in addition to a displaced acromioclavicular (AC) joint was diagnosed (Figure 39.1). Moderate displacement at the lateral scapula border, and a glenopolar angle (GPA) of 63° as seen on the anteroposterior (AP) view, with an angular deformity of 21° measured on the scapula Y radiograph, prompted a CT scan (Figure 39.2).

On 3-D CT, the patient had 20° of angulation, 150% translation and 0.5cm of displacement of the lateral border. Fracture lines propagated into the spinoglenoid notch, and out the scapular spine, and vertebral border. A 2-D CT revealed no intra-articular involvement, but significant displacement at the base of the coracoid, and a retroverted glenoid neck of 11° (Figure 39.2C).

Relevant anatomy

Often, the “neck” of the scapula is referred to as the anatomy just proximal to the glenoid extending up to the coracoid, though some refer to a fracture of the neck as one which remains lateral to the acromion base. Others refer to the neck as simply involving the high lateral border. The coracoid and acromion processes are vulnerable to fracture because of their narrow stalks, though variation in fracture patterns of these scapular extensions is wide, as evidenced by the mapping of these injuries (level IV).¹ On the other hand, fracture patterns involving the scapula neck and body are quite consistent, as reported by Armitage et al. (level IV),² and emanate from just inferior to the glenoid and out the vertebral border at the base of the spine in over two thirds of cases. The spinoglenoid notch is involved in about 20% of cases (Figure 39.3). The best opportunities for fixation are at the glenoid neck and lateral border, though the spine of the scapula and the vertebral border are also used, but provide lesser purchase.

Neurovascular structures at risk during typical posterior surgical approaches include the suprascapular neurovascular bundle, which must be protected from iatrogenic harm. The circumflex scapular artery, a mean 5.6 cm (range 4.5–7.0) from the spinoglenoid notch must also be protected or coagulated (Figure 39.4A,B).³

Importance of the problem

Scapula fractures account for approximately 1% of all fractures, about the same percentage as calcaneus fractures and exceeding that of talus fractures. Therefore, this injury is quite relevant, particularly for trauma centers, where such injuries are filtered with regularity.

Figure 39.1 Radiographic series of the shoulder of a 28 year old man involved in a snowboarding accident: (a) AP radiograph shows a comminuted glenoid neck fracture with significant displacement. The glenopolar angle is 63°, different from the normal range of 30–45°. (b) Trans-scapular Y radiograph views shows angulation of 21°. Note that the fracture is translated about 150%. This radiograph also reveals a coracoid fracture and acromioclavicular dislocation. (c) Axillary radiographic view helps evaluate location of the shoulder and the displaced coracoid.

Figure 39.2 3-DCT reconstruction of the patient allows better visualization of the fracture pattern and assists in measurements for preoperative planning: (a) The AP radiographic view shows a comminuted glenoid neck fracture with an associated displaced coracoid. (b) Scapula Y reveals dislocation of the acromioclavicular joint. This patient has a triple disruption of the superior shoulder suspensory complex. (c) The 2-D CT demonstrates glenoid retroversion of 11°.

Eighteen muscles insert on, originate from, or traverse the scapula. This bone provides interplay between the clavicle, humerus, and thoracic cage, as well as providing the conduit for the suprascapular nerve and protection of the brachial plexus. A displaced scapula fracture therefore has a number of clinical implications.

Displacement of the glenoid relative to the lateral border, anteversion of the glenohumeral joint with the proximal scapular fragment, and the tendency for gravity to rotate the glenoid caudad, all manifest in displacements that adversely

affect shoulder biomechanics.⁴ If the scapula heals in the typical malunited position, multiple muscles are shortened, the rotator cuff and deltoid yield a shearing rather than compressive force on the glenohumeral joint, and the arc of motion of the glenohumeral joint is shifted, compromising forward elevation, abduction, and external rotation.

Concomitant injuries to the shoulder girdle also need to be taken into consideration during treatment, particularly in the context of the superior shoulder suspensory complex (SSSC) described by Goss (level V).⁵ Massive thoracic injury

Figure 39.3 (a) A study of 90 3-D CT scans of surgically treated scapula fractures demonstrated that 20 (22%) involved the spinoglenoid notch. (b) 3-D CT scan showing a typical fracture pattern involving the spinoglenoid notch.

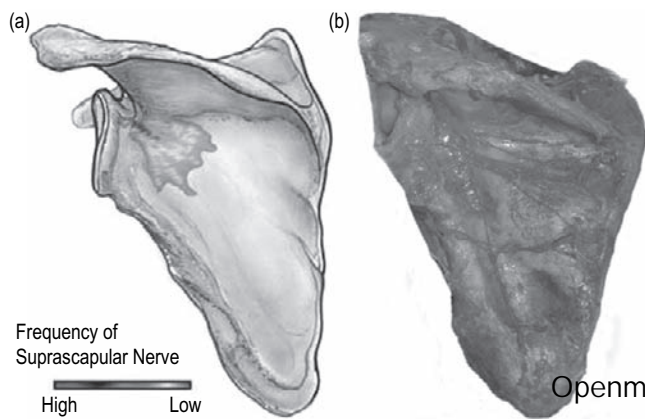

Figure 39.4 (a) Precise radial coordinate measurements of the suprascapular nerve were made on 24 cadaveric scapulae to create a frequency distribution of the suprascapular nerve. (b) Posterior view of a cadaveric scapula after removal of infraspinatus showing the suprascapular nerve at the base of the acromion before it branches to innervate infraspinatus and teres minor muscles.

from the force vector hitting the superior or lateral shoulder may also result in many consecutive segmental rib fractures. Ultimately, treatment decisions will be influenced by these factors as well as patient functional demands, age, activity level, handedness, and occupation. Not unlike other fractures, the well-stabilized shoulder girdle will yield more immediate patient comfort and effective rehabilitation.

Top seven questions

Diagnosis

1. What should the appropriate preoperative workup include?
2. What displacements are important to measure in deciding which cases should be considered for surgery?

Therapy

3. What are the implications for treating patients nonoperatively?
4. What are the indications for open reduction and internal fixation (ORIF)?
5. What approach should be utilized for ORIF?
6. How should an operative or nonoperative patient be rehabilitated?

Prognosis and harm

7. What is known about outcomes and complications of ORIF?

Finding the evidence

Study identification followed the following steps (April 2010 search date):

- Cochrane Database, with search term “scapula OR glenoid AND fracture” in Title, Abstract or Keywords in Cochrane Database of Systematic Reviews
 - 1 hit, not relevant
- PubMed (www.ncbi.nlm.nih.gov/PubMed/) clinical queries search/ systematic reviews: ((scapula* [ti] OR glenoid* [ti] AND fracture* [ti] NOT rim* [ti])) AND systematic[sb]
 - 2 hits, both relevant
- PubMed-MEDLINE (www.ncbi.nlm.nih.gov/PubMed/) -sensitivity search using keywords “scapula* [ti] OR glenoid* [ti] AND fracture* [ti]”
 - 295 hits

Question 1: What should the appropriate preoperative workup include?

Case clarification

Our patient had injuries which required prioritization over the scapula (massive facial lacerations, a painful neck, and

a pneumothorax). The obvious recognition of a scapula fracture on the chest radiograph led to shoulder films, and then, on the basis of the displacement, to a dedicated CT scan.

The scapula fracture was complex and displaced at the spinoglenoid notch, a pattern which is associated with suprascapular nerve lesions. The pattern of displacement was atypical because the glenoid was actually tilted superior (glenopolar angle (GPA) 63°) and it was retroverted (11°) rather than anteverted. Postoperative electromyography (EMG) and nerve conduction study revealed that he had a complete lesion of the suprascapular nerve, also witnessed at the time of surgery.

Relevance and current opinion

A history should include the patient's job description and recreational activities. The shoulder can compensate adequately in lower-functioning individuals; therefore, not every displaced scapula fracture requires surgery. A physical examination should include whether or not abrasions exist over the shoulder, palpation of the acromioclavicular and sternoclavicular joints, and a neurovascular examination of the extremity. When the patient can be upright, they must be examined disrobed to appreciate shoulder drooping, which is bothersome in severe cases.

Shoulder radiographs yield the detail necessary to determine whether or not there is displacement of a fracture. If on the radiographs, there is displacement of a fracture greater than 1 cm, a 3-D CT should be obtained to specifically measure displacement and angulation. In nondisplaced fractures in which nonoperative treatment has been selected, weekly follow-up films over 2 weeks should be obtained due to the risk of displacement (level IV).⁶

Often, scapula fractures are delayed in referral or workup, either because of missed injury, or treatment of other bodily injuries, or the time it takes to refer to an appropriate medical center (level IV).⁷ In cases when such delay is greater than 2 weeks, an EMG and nerve conduction study should be performed because this injury has a high association with nerve injuries (level V).⁸ This information is helpful for preoperative planning and prognostication. A 2-D CT scan is useful when there is intra-articular involvement to determine step, gap, and number of fragments.

Recommendations

- If radiographs show displacement of a fracture greater than 1 cm, a 3-D CT should be obtained to specifically measure displacement and angulation
- In nondisplaced fractures in which nonoperative treatment has been selected, weekly follow-up films over 2 weeks should be obtained due to the risk of displacement
- When referral is delayed longer than 2 weeks, an EMG and nerve conduction study should be performed because scapula fracture has a high association with nerve injuries

Question 2: What displacements are important to measure in deciding which cases should be considered for surgery?

Case clarification

Our patient had multiple indications for surgery, as is commonly the case: a displaced "triple lesion", (acromioclavicular joint, coracoid, and neck) and an excessive GPA. The patient also had dramatic translational deformity of the lateral border (150%) indicating a very unstable injury. He was a young manual laborer who would depend on maximum upper extremity function for his livelihood.

Relevance and current opinion

Medialization, angulation, GPA, and intra-articular step-off should be measured. Medialization is often misunderstood: it represents the displacement at the fractured lateral border, or the position of the proximal relative to the distal main fragments. This definition is most relevant because it defines the relationships of muscles acting on or across the scapula and glenohumeral joint. Angulation refers to the angle measured between the lateral borders on the scapula Y view. GPA measures the inferior rotation of the glenoid (on its proximal fragment) relative to the body as measured off an AP image. A 3-D CT scan is vital for accuracy since this modality allows for the perfect rotation of the images to get an accurate "AP and Y view."

Question 3: What are the implications for treating patients nonoperatively?

Case clarification

With this constellation of fractures and displacement, our patient would have fared very poorly, particularly in the first months after injury. With a floating shoulder and all the displacement and rib fractures, he would have required immobilization for at least 3 weeks, coming out very stiff and requiring months of therapy just to get to a plateau in function. He would have lost the internal rotation that his retroverted neck would have measured and the extension that his GPA side-to-side difference was, and he would have been weakened as a result of changing the Blick's curve of all the shoulder muscles. He would have had a high risk for a painful coracoid nonunion, and impingement from an acromion which was tilted into the subacromial space from downward rotation.

Relevance and current opinion

Though nonoperative treatment of double lesions of the SSSC have been shown to result in good or excellent outcomes, it is likely that such series reflected minimally displaced injuries since almost no malunions were reported (all level IV; Table 39.1).⁹⁻¹² Nonoperative series to date have not stratified data based on measured displacement, and rigorous outcome assessment of strength, motion, and function are lacking in

Table 39.1 Current evidence in floating shoulder fractures

Author	Level of evidence No. of patients No. followed/total (% follow-up)	Summary
Therapy		
Herscovici et al. (1992)	IV 2 Nonop/7 Op/2 LTF 9/11 (82%)	The authors reviewed 9 patients having double lesion injuries and recommended the use of anteroposterior radiographs of the clavicle and scapula, and trans-scapular Y views. Internal fixation of the clavicle should be performed as soon as possible to prevent malunion of the scapular neck fracture
Leung and Lam (1993)	IV 15 Operative 15/15 (100%)	The authors found that operative treatment for ipsilateral fractures of the scapular neck and the clavicle is safe and that functional recovery is predictably good with most patients regaining normal function of the shoulder soon after injury. With fixation of both fractures, postoperative rehabilitation is greatly facilitated
Rikli et al. (1995)	IV 12 Operative 12/12 (100%)	The authors found that in an unstable shoulder girdle, the therapeutic goal can be reached with ORIF of the clavicle alone. The fracture of the scapular neck is usually reduced indirectly and sufficiently stable for functional after treatment. ORIF of the scapula is therefore, only necessary in displaced intra-articular fractures
Oh et al. (2002)	IV 3 Nonop/10 Op 13/13 (100%)	The authors found that surgical treatment for double disruption of the SSSC is a good option, allowing for early rehabilitation and giving good functional results
Prognosis		
Ramos et al. (1997)	IV 16 Nonoperative 13/16 (81%)	The authors found that after a mean follow-up of 7.5 years, the functional results were good or excellent in 13 patients. They propose that successful nonoperative treatment was due to intense physical therapy, and to the fact that most clavicular and scapular fractures do not require formal reduction for healing, and even vicious callus is well tolerated by most patients
Edwards et al. (2000)	IV 36 Nonoperative 20/36 (56%)	The authors concluded that many floating shoulder injuries are not as unstable as was previously thought and do not require operative fixation. None of the functional assessments utilized identified poor outcomes and thus, it is difficult to identify factors that might predict which fractures will do well with non operative treatment and which will have a better result with surgery
Egol et al. (2001)	IV 12 Nonop/7 Op/4 LTF 19/23 (83%)	The authors concluded that good results may be seen both with and without operative treatment, and therefore do not universally recommend operative treatment for double disruption of the superior shoulder suspensory complex. Treatment must be individualized for each patient
Van Noort et al. (2001)	IV 31 Nonop/4 Op/11 LTF 35/46 (76%)	The authors conclude that ipsilateral fractures of the neck of the scapula and of the clavicle is not inherently unstable and, in the absence of caudal dislocation of the glenoid, conservative treatment gives a good functional outcome
Hashiguchi and Ito (2003)	IV 5 Operative 5/5 (100%)	The authors conclude that for a patient with a floating shoulder, it is important to determine the severity of fracture displacement accurately and the presence or absence of coracoclavicular ligament rupture radiographically. On the basis of those factors, an appropriate treatment for both fractures that may lead to a satisfactory clinical outcome can be determined
Labler et al. (2004)	IV 8 Nonop/9 Op 17/17 (100%)	The authors concluded that nondisplaced or less displaced floating shoulders are expected to give good results after nonoperative treatment and recommend operative treatment in cases of displacement of scapular neck fracture of more than 25 mm and/or reduction of the glenopolar angle less than 30° as an indirect sign for ruptured associated ligaments

those series (all level IV; Table 39.1).^{9–13} Furthermore, other authors have reported patients with malunion which eventuated in poor outcomes, indicating that not all malunions are benign (all level IV).^{14–16} One study demonstrated increased pain and dysfunction and/or decreased motion in almost half of patients who were malunited.¹²

Question 4: What are the indications for ORIF?

Case clarification

By almost anyone's criteria, our patient warranted surgical intervention on the basis of a highly displaced double (triple) lesion, a displaced coracoid and acromion, and an angulated glenoid neck.

Relevance and current opinion

There are multiple opinions on the degree of displacement or angular deformity which warrant ORIF. These have included articular injuries displaced by 4–10 mm (all level IV),^{7,17–19} fractures with lateral border displacement (“medialization”) of 10–20 mm (all level IV),^{7,16,17,20} angular deformity of 25–45°,^{7,16,17,20} and a GPA of less than 20° (all level IV).^{14,15} Some authors feel that excessive translation and version of the proximal relative to the distal fragment should be considered a relative indication for surgery (level IV, V respectively).^{6,21} Though there is no “high-level” evidence to date, deductive reasoning would lead us to believe that some degree of displacement and angular deformity will yield an adverse clinical result. If the clinician believes that function and form are interdependent, then malunion results in compensation, and by definition, compensation costs something. Experts differ as to what amount and type of displacement warrants intervention, but there is growing consensus, given the positive surgical results on record, that operative correction of displaced scapula fractures is beneficial for a subset of patients.

Recommendation

- There is growing consensus that operative correction of displaced scapula fractures is beneficial for a subset of patients

Question 5: What approach should be utilized for ORIF?

Case clarification

Our patient had a staged posterior and anterior approach to his shoulder. The surgeon began with the posterior approach to reduce and fix the neck and body of the scapula. During this approach, the suprascapular nerve was found trapped in the fracture and partially lacerated. Decompression from the callus was required, with reattachment of a torn branch. The patient was in a lateral slightly forward position for this part of the procedure. Now there was a stable base on to which the coracoid could be fixed from anterior.

An anterior approach from a beach chair position was used to address both the coracoid and the acromioclavicular (AC) dislocation. A single incision was drafted from medial to lateral along the distal clavicle to within a centimeter of the AC joint, and then caudad over the coracoid down along the superior limb of the deltopectoral approach. The AC joint relocation and fixation was necessary to effect the reduction of the coracoid, since the coracoid was attached to the displaced clavicle via the coracoclavicular ligaments.

Relevance and current opinion

Fractures of the scapula neck and body should be addressed through a posterior approach. There have been a number of modifications to the posterior Judet approach,²² which are variations on the theme of more or less invasiveness (level IV and V).^{17,23,24} Either the entire rotator cuff (and deltoid) can be mobilized from the vertebral border to the lateral border on the neurovascular pedicle, or muscular intervals between the infraspinatus and teres minor can be utilized to spare the muscles of detachment from their origins. Such an interval allows good access to the articular surface (level IV).²⁴ A straight posterior approach to the glenoid neck can be used for fractures isolated to the posterior glenoid or those lateral to the acromial base. The only glenoid fractures associated with the scapula body which should be addressed from anterior rather than posterior are those involving the superior coronal half extending into the superior fossa, usually inferior to the coracoid. Sometimes the coracoid itself is detached at the base in these variants.

Most articular fractures, however, are best accessed through a deltopectoral approach, as the version of the glenoid allows for better visualization from anterior, either through an arthrotomy or through a fracture interval. A transaxillary approach has also been described for inferior glenoid fractures in the frontal plane (level V).²⁵

Recommendation

- Fractures of the scapula neck and body should be addressed through a posterior approach. Most articular fractures, however, are best accessed through a deltopectoral approach, and a transaxillary approach has also been described for inferior glenoid fractures in the frontal plane

Question 6: How should an operative or nonoperative patient be rehabilitated?

Case clarification

Our patient began full passive range of motion as his symptoms allowed the day after surgery. He was taught how to use pulleys, the help of his spouse, and the use of his opposite hand, pushing himself to discomfort. The second month consisted of full active range of motion. The third month consisted of a strength program beginning with 3–5 lb (1.5–2.5 kg) weights and working up to no

restrictions after 3 months. In the fourth month, endurance activities were promoted, swimming when possible, with an attempt to return to normality.

Relevance and current opinion

One of the goals of surgery is to achieve stability, which means that the fixation can withstand physiologic motion. Intraoperatively, the patient should be taken through a range of motion to prove such stability has been accomplished. Often, the patient is well ahead of the schedule detailed for our patient, as the resolution of pain after ORIF is rather rapid. To our knowledge, different rehabilitation regimens have not been studied or compared after scapula fractures.

The only caveat for physical therapy and rehabilitation in nonoperated scapula fractures is that the patient requires a period of immobilization due to the instability of the fragments. Not only are they too painful for a few weeks to begin motion, but there is a risk of further displacement if motion ensues too early.⁶ This period of immobilization is not benign, as extrinsic adhesions establish, and must be overcome.

Question 7: What is known about outcomes and complications of ORIF?

Case clarification

At seven months after surgery, the patient's Disability of Arm Shoulder and Hand Index (DASH score) was 4.2, indicating a good outcome, based on normative data from uninjured populations.²⁶ The patient's active forward flexion was 135° and external rotation with the arm at his side was 18° (normal side 145°, 55° respectively). His strength measured with a handheld dynamometer, was 9 lb (4 kg) of force relative to the opposite side of 35 lb (16 kg) for forward flexion, and 13 lb (6 kg) of force relative to the opposite side of 36 lb (16 kg) for external rotation. The patient claimed to have no pain, and was eager to get back on his snowboard for the upcoming season. These results, though not perfect, represent a significant improvement over his 3 months measures, which still reflected the incomplete but significant injury to the suprascapular and axillary nerve.

Relevance and current opinion

The literature is replete with many retrospective series of operative intra-articular (Table 39.2) and extra-articular

Table 39.2 Current evidence in exclusive articular glenoid fractures

Author	Level of evidence No. of patients No. followed/total (% follow-up)	Summary
Openmirrors.com		
Therapy		
Kavanagh et al. (1993)	IV 10 Operative 9/10 (90%)	The authors concluded the posterior operative approach described allowed excellent visualization of both intra-articular and extra-articular components of the fractures and that open reduction and internal fixation should be seriously considered for patients who have this type of injury and wish to remain active
Leung et al. (1993)	IV 14 Operative 14/14 (100%)	The authors concluded that operative treatment is indicated in displaced intra-articular fractures of the glenoid. This report shows that the operation is safe and the result is good. Special attention must be paid to prevent and treat the complications resulting from the common association of chest injuries in these patients
Mayo et al. (1998)	IV 31 Operative 27/31 (87%)	The authors reported that this series documents the assertion that these difficult and unusual injuries can be successfully treated surgically in most cases. Perfect joint reduction is the goal and can be achieved in a high percentage of cases. Complications are uncommon and the poor outcomes usually are not related to glenohumeral arthritis. Rather, they are most often the result of associated injuries or poor rehabilitative effort
Adam (2002)	IV 10 Operative 10/10 (100%)	The authors found that displaced intra-articular fractures are managed better by operative than by nonoperative treatment. Functional end result and avoidance of post traumatic instability or degenerative joint changes after surgery for these markedly displaced intra-articular fractures demand experience and a thorough knowledge of anatomical approaches, and a strict postoperative rehabilitation program
Schandelmaier et al. (2002)	IV 22 Operative 22/22 (100%)	The authors conclude that open reduction and fixation can give good results for patients with displacement of the glenoid fossa. Additional factors such as polytrauma, brachial plexus injury, and the general condition of the patient should be taken into consideration. The Ideberg classification is useful when planning surgical approach
Nork et al. (2008)	IV 17 Operative 17/17 (100%)	The authors conclude that in the surgical treatment of displaced type IV, V, and VI intra-articular fractures of the glenoid, the ease and accuracy of anatomic articular reduction is improved by initially addressing the medial fracture displacement. Use of the modified surgical approach allows for medial fracture reduction, reconstitution of the overall scapular morphology, and subsequent articular reduction using the infraspinatus-teres minor interval

(Table 39.3) fractures, demonstrating good and excellent outcomes with very low complication rates, including almost no reports of a nonunion, and less than 2% infection rate in over 300 operated patients in the literature (level IV).^{27,28} Several authors note that the rare poor results were associated with brachial plexus or neurological lesions,¹⁹ much like the patient described in this chapter.

Recommendation

- A 2-D CT scan is useful when there is intra-articular involvement to determine step, gap, and number of fragments

Summary of recommendations

- If radiographs show displacement of a fracture greater than 1cm, a 3-D CT should be obtained to specifically measure displacement and angulation

- In nondisplaced fractures in which nonoperative treatment has been selected, weekly follow-up films over 2 weeks should be obtained due to the risk of displacement
- When referral is delayed longer than 2 weeks, an EMG and nerve conduction study should be performed because scapula fracture has a high association with nerve injuries
- A 2-D CT scan is useful when there is intra-articular involvement to determine step, gap, and number of fragments
- There is growing consensus that operative correction of displaced scapula fractures is beneficial for patients having displaced articular injuries, fractures with substantial lateral border displacement, angular deformity or a GPA of less than 20°
- Fractures of the scapula neck and body should be addressed through a posterior approach. Most articular fractures, however, are best accessed through a deltopectoral approach, and a transaxillary approach has also been described for inferior glenoid fractures in the frontal plane

Table 39.3 Current evidence in scapular neck and body fractures (± articular involvement)

Author	Level of evidence No. of patients No. followed/total (% follow-up)	Summary
Therapy		
Wilber and Evans (1977)	IV 38 Nonop/2 Op 6/40 (15%)	The authors concluded that fractures of the scapular body, neck or spine can be treated conservatively and good clinical results can be anticipated. Fractures involving the acromion, glenoid, or coracoid processes should be treated by immobilization in abduction for 6 weeks, with early active abduction exercises to prevent the contractures that commonly result after these fractures. Open reduction is rarely necessary
Armstrong and Van der Spuy (1984)	IV 62 Nonoperative 52/62 (84%)	The authors concluded that the combination of a fracture of the scapula and the underlying 1st rib appear to be a particularly severe injury. Good results can be obtained with conservative therapy in fractures of the body, spine, coracoid and acromion. Less favorable results follow fractures of the neck and glenoid. In young and fit patients open reduction may be indicated in fractures of the neck and glenoid
Bauer et al. (1995)	IV 25 Operative 20/25 (80%)	Depending on age, activity, and general condition of the patient, ORIF is recommended in: grossly displaced fractures of the acromion and coracoid process; displaced fractures of the anatomical neck; unstable fractures of the surgical neck; displaced fractures of the glenoid fossa. The authors recommend early operative treatment for these types of fractures in order to achieve good results
Khallaf et al. (2006)	IV 5 Nonop/14 Op	The authors found that ORIF of grossly displaced scapular neck fractures can restore the normal biomechanics of both glenohumeral and scapulothoracic joints and allow favorable clinical outcome
Herrera et al. (2009)	IV 22 Operative 16/22 (73%)	The purpose of this retrospective study was to examine the safety and efficacy of delayed operative management of displaced fractures of the scapula and to describe early functional outcomes. The authors found that their results suggest that safe surgery can be accomplished and good outcomes achieved even with late presentation and surgery
Jones et al. (2009)	IV 37 Operative 37/37 (100%)	The authors found that the modified Judet approach allows for excellent scapular and glenoid fracture visualization and reduction while preserving rotator cuff function. Minifragment fixation along the lateral scapular border provides excellent plate position and fracture stability

Table 39.3 (Continued)

Author	Level of evidence No. of patients No. followed/total (% follow-up)	Summary
Prognosis		
Hardegger et al. (1984)	IV 37 Operative 33/37 (89%)	Two groups of scapular fractures can be distinguished: those which will probably heal without long-term complications, and those liable to cause significant disability. The first group includes most fractures of the scapular body, and also those fractures of the scapular neck and apophyses (coracoid, acromion, scapular spine) which have minimal displacement. The second group is composed of glenoid fracture-dislocations, unstable fractures of the scapular neck and significantly displaced apophyseal fractures
Ada and Miller (1991)	IV 113 Nonop/8 Op 32/121** (26%)	There is a high incidence of significant associated injuries with scapular fractures. Displaced scapular neck and comminuted spine fractures present major long-term and immediate problems, such as dysfunction of the rotator cuff and pain. The majority can be treated non operatively, but indications for surgical management should be extended to include some types of displaced scapular neck and spine fractures, as well as intra-articular injuries
Nordqvist and Pettersson (1992)	IV 129 Nonoperative 84/129 (65%)	The authors' results indicate that patients with persisting shoulder deformity and persisting symptoms often sustained a more serious trauma. The treatment of concomitant injuries was sometimes given a higher priority. In some cases with displaced fractures of the scapula, initial open surgical procedures could perhaps have improved the long-term result
Romero et al. (2001)	IV 16 Nonop/ 3 Op	Pain, reduced activities of daily living, and abduction weakness at follow-up were significantly more common among patients with severe rotational malalignment of the glenoid neck (GPA < 20°) than among patients with no or mild glenoid malunion. The simple measurement of GPA may yield useful prognostic information
Bozkurt et al. (2005)	IV 18 Nonoperative	The authors report that in the determination of the degree of dysfunction, decreased GPA has proven more reliable evidence than the fracture type. Patient age and associated injuries were also found as effective determinants of the functional outcome
Pace et al. (2005)	IV 12 Nonoperative 9/12 (75%)	The authors found that the majority of glenoid neck fractures treated nonoperatively have some activity-related pain, which in turn seems to be associated with glenoid neck malunion
van Noort and van Kampen (2005)	IV 23 Nonop/1 Op 13/24 (54%)	The authors found that nonoperative treatment of a surgical neck fracture of the scapula in the absence of an ipsilateral shoulder injury and associated permanent neurological impairment leads to a good to excellent functional outcome, with or without significant translational displacement
Schofer et al. (2009)	IV 137 Nonop/7 Op 50/137 pts (37%)	The purpose of this study was to determine the long-term prognoses for nonoperatively treated fractures of the scapula. The authors found that after conservative treatment, scapular fractures heal with a good functional result despite measureable restrictions
Diagnosis		
McGinnis and Denton (1989)	IV 39 Nonoperative	Patients with a fractured scapula should be thoroughly examined for associated injuries. The scapula fracture should not be neglected due to the associated injuries. Even if the scapula fracture is an isolated injury, the patient should be admitted to a hospital with a follow-up chest radiograph to rule out the late development of pneumothorax, hemothorax, or pulmonary contusion. 73% of the patients in this series had excellent or good results
McAdams et al. (2002)	IV 20	The authors found that scapular neck fracture displacement, angulation, and anatomic classification showed moderate interobserver reliability by plain films but were not enhanced by 2-D CT. 2-D CT may be useful in selected cases in which intra-articular extension is noted on plain films

Acknowledgments

The authors would like to acknowledge Dr. Erich Gauger for his support in preparing this manuscript. In addition, we wish to thank Synthes, Inc. for the research grant funding which supports the research of the Scapula Institute at the University of Minnesota Regions Hospital.

Post-Traumatic Avascular Necrosis of the Proximal Humerus

Ilia Elkinson and Darren S. Drosdoweck

St Joseph's Health Care, London, ON, Canada

Case scenario

A 60 year old woman presented to clinic complaining of activity-related pain and stiffness of the shoulder joint. Two years ago she fell over and sustained a fracture of the proximal humerus. She was treated at a different institution with a locking proximal humeral plate and screw fixation. The metalware was removed 9 months ago. Clinical examination revealed a healed scar from the previous anterior deltopectoral approach to the shoulder. She has 100° of active forward elevation, 60° of scapular abduction, 25° of external rotation, and limited internal rotation. Open mirrors on the buttocks.

Relevant anatomy

Gerber et al. performed an anatomical perfusion study of the arterial vascularization of the humeral head.¹ They found that the humeral head was consistently perfused by the anterolateral ascending branch of the anterior circumflex humeral artery, known as the arcuate artery.

In 1993 Brooks performed an experimental cadaver perfusion study looking at the effects of simulated four-part fracture on the vascularity of the proximal humerus.² A simulated four-part fracture interrupted the perfusion of the humeral head in all specimens.

Importance of the problem

Codman in 1934 discussed the importance of the soft tissue attachments in fractures of the proximal end of the humerus.³ Neer in 1963 and Baux in 1969 reported on cases

of aseptic osteonecrosis after displaced fractures of the humeral neck.^{4,5}

In 1970, Neer introduced the “four-part” classification system of proximal humerus fractures.^{6,7} Fracture pattern was linked to prognosis and the development of osteonecrosis of the humeral head.

Reported incidence of avascular necrosis (AVN) following a three-part fracture was found to be between 3% and 21%. Four-part fractures have been associated with much higher rates of AVN, with reported incidence between 21% and 75%. Table 40.1 summarizes reported incidence of AVN following a four-part fracture of the proximal humerus.⁷⁻¹⁶

The most commonly used classification of AVN in the humeral head is that of Cruess, who modified the Ficat and Arlet classification system of AVN in the femoral head.¹⁷⁻²⁰ There are five stages of AVN, according to radiographic appearance ranging from stage I to stage V. (Figure 40.1)

Top four questions

Diagnosis

1. What is the natural history of post-traumatic AVN in the humeral head, and the relationship between extent of the disease at presentation and prognosis?

Management and prognosis

2. What are the nonarthroplasty treatment options in managing post-traumatic AVN of the humeral head?

3. What are the indications for arthroplasty in post-traumatic AVN, and what type of arthroplasty should we recommend?

4. What are the rates of revision in arthroplasty for post-traumatic AVN?

Question 1: What is the natural history of post-traumatic AVN of the humeral head, and the relationship between extent of the disease at presentation and prognosis?

Case clarification

The patient's plain radiographs revealed a partially collapsed humeral head with no evidence of glenoid involvement. We diagnosed this patient with stage IV AVN of the humeral head.

Cruess stage IV denotes progression to subchondral humeral head collapse and fragmentation, without glenoid involvement.

Relevance

Knowledge of the natural history will determine the most appropriate type of treatment and will have important implications for outcome and function.

Table 40.1 Incidence of avascular necrosis following four-part fractures

Author (year)	Number	%
Neer (1970)	6/13	46
Lee and Hansen (1981)	4/19	21
Sturzenegger, Fornaro and Jacob (1982)	5/14	36
Leysbon (1984)	6/8	75
Marti, Lim and Jolles (1987)	6/13	46
Jacob et al. (1991)	5/19	26
Schai (1995)	10/13	77
Wijgman et al. (2002)	8/9	88
Gerber, Werner and Vienne (2004)	7/18	39
Solberg et al. (2009)	6/15	40

Current opinion

Post-traumatic AVN is associated with significant patient morbidity.

Finding the evidence

- Cochrane Database, with search term "osteonecrosis humeral head," "avascular necrosis humeral head"
- PubMed: search using keywords: "avascular necrosis humeral head" OR "osteonecrosis humeral head" AND "post-traumatic"

Quality of the evidence

Level IV

- 4 retrospective case series

Findings

There is a small number of retrospective case series on the natural history of post-traumatic AVN. Basamania et al. reported on the long-term outcome of post-traumatic vs. atraumatic AVN in 55 shoulders.²¹ They found 41% of patients with atraumatic AVN responded well to nonoperative treatment but 100% of patients with post-traumatic AVN required surgical intervention.

Bigliani in 1991 reported that AVN in this subgroup of patients invariably leads to a stiff and painful shoulder.²² Gerber in 1998 reported on the clinical outcomes of post-traumatic AVN of the shoulder in 25 patients with partial or complete head collapse over a 15 year period.⁸ The global shoulder function was poor, with a Constant score of 46, which corresponded to a functional shoulder value of 51% of a matched normal control group.

Hattrup and Cofield in 1999 reported their results in a large cohort of 200 shoulders in 151 patients with AVN.²³ The need for arthroplasty was examined in the context of disease extent, staging at presentation and diagnosis. In

Figure 40.1 Stages of progression from pre-collapse lesion to late stage disease and humeral head collapse in the avascular necrosis of the humeral head: Stage I: No radiographic evidence of osteonecrosis. The humeral head appears normal, with no sclerosis, and sphericity is maintained. Stage II: Signs of mottled sclerosis appear, but the curvature of the humeral head remains intact. Stage III: A crescent sign is indicative of subchondral fracturing; humeral head loses its sphericity. Stage IV: progression to collapse of the subchondral bone. Stage V: there are degenerative changes in the glenoid fossa. (©1997 American Academy of Orthopaedic Surgeons. Reprinted from the Journal of the American Academy of Orthopaedic Surgeons, Volume 5(6), pp. 339–346 with permission.)

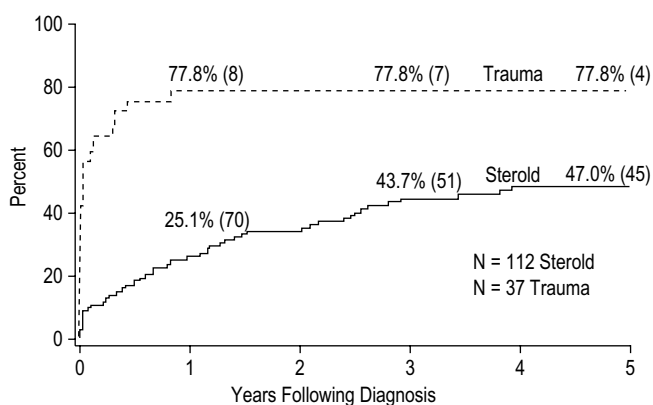

Figure 40.2 Diagnosis of avascular necrosis and shoulder arthroplasty over time. Kaplan–Meier survivorship analysis. Percentage is cumulative incidence of replacement. Number in parenthesis is number of patients remaining at risk at each time point. (Reprinted from Journal of Shoulder and Elbow Surgery, 8,Hattrup SJ, Cofield RH, Osteonecrosis of the humeral head: Relationship of disease stage, extent, and cause to natural history, 559–564, 1999, with permission from Elsevier.)

this study 112 (56%) had a previous history of corticosteroid use, followed by 37 patients (18.5%) who had post-traumatic AVN. Among the 97 shoulders that had undergone arthroplasty, the average time to surgery was 0.9 years. The range was between 1 day and 11.9 years.

Shoulders in the post-traumatic group did considerably worse. By 3 years after initial diagnosis, 77.8% with post-traumatic AVN required surgery vs. 43.7% with a history of corticosteroid use ($p < 0.001$) (Figure 40.2).

Extent of involvement and the stage at presentation were directly related to the need for further surgery. With the Kaplan–Meier survivorship analysis at 3 years from diagnosis, the authors reported that 42% of shoulders with stage II disease and 29.3% with stage III disease required surgery. The difference was not statistically significant ($p < 0.465$). However, 55% with stage IV and 79% with stage V disease had required shoulder arthroplasty within 3 years from presentation (Figure 40.3). The overall difference in the need for arthroplasty was statistically significant ($p < 0.001$) between stages II vs. III vs. IV vs. V.

Recommendations

- Patients with post-traumatic AVN tend to require surgery more often than patients with atraumatic AVN [overall quality: very low]
- At 3 years after initial diagnosis, up to 78% of patients with post-traumatic AVN need shoulder arthroplasty [overall quality: very low]
- Up to 30% of patients in stage III disease and up to 80% in stage IV disease at presentation required arthroplasty [overall quality: very low]
- Similarly, at 3 years, more patients with greater extent of humeral head involvement required arthroplasty [overall quality: very low]

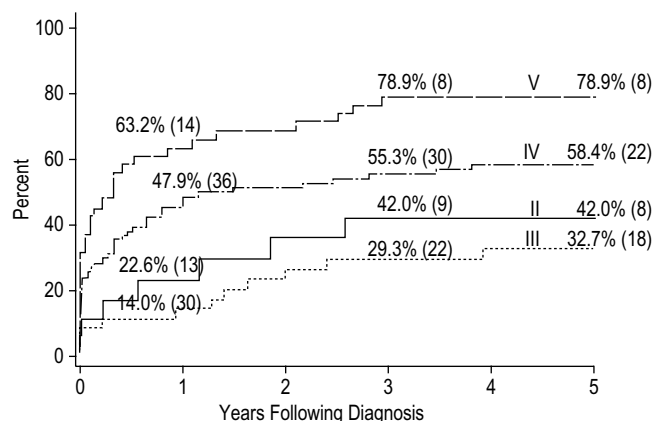

Figure 40.3 Disease stage and shoulder arthroplasty over time. With the Kaplan–Meier survivorship analysis method, need for shoulder arthroplasty is shown for stage of disease at presentation. Percentage is cumulative incidence. Number in parenthesis is number of patients remaining are risk at each time point. (Reprinted from Journal of Shoulder and Elbow Surgery, 8,Hattrup SJ, Cofield RH, Osteonecrosis of the humeral head: Relationship of disease stage, extent, and cause to natural history, 559–564, 1999, with permission from Elsevier.)

Question 2: What are the nonarthroplasty treatment options in managing post-traumatic AVN of the humeral head?

Case clarification

This patient has stage IV disease and has painful restriction of shoulder motion. She has difficulty with most activities of daily living. We propose that this patient should be treated with prosthetic replacement. The patient would like to know if there are any other alternatives to prosthetic replacement of the shoulder.

Relevance

The treating surgeon has to be familiar with all treatment modalities, which also include nonarthroplasty options.

Current opinion

Nonarthroplasty treatments can be considered in the management of early stage disease.

Table 40.2 Results of core decompression in avascular necrosis

Author (year)	Mean follow-up (months)	No. of shoulders with AVN post trauma	No. of shoulders with atraumatic AVN	Successful outcomes			
				Stage I	Stage II	Stage III	Stage IV
Dines (2007)	7	0	3	—	1 (100%)	—	—
Chapman (2004)	—	0	1	1 (100%)	—	—	—
LaPorte (1998)	120	3	60	15/16 (94%)	15/17 (88%)	16/23 (70%)	1/7 (14%)
Mont (1993)	67.2	5	25	6/6 (100%)	8/8 (100%)	7/10 (70%)	1/6 (16%)

Findings

Nonsurgical management of post-traumatic AVN must include range of motion and muscle strengthening exercises to maintain glenohumeral joint function and prevent disuse-related stiffness. These measures are thought to be more successful in the shoulder joint than in the hip.

Bisphosphonates represent the most clinically relevant class of antiresorptive drugs available. There are no published reports on the use of bisphosphonates in post-traumatic AVN of the humeral head.

Arthroscopic debridement as a minimally invasive treatment modality of AVN was first described by Johnson in 1986.²⁴ Arthroscopy allows direct visualization of the entire humeral head, hence it may aid diagnosis and staging of AVN. Surgical debridement of osteochondral flaps and removal of loose intra-articular bodies has been shown to alleviate mechanical symptoms.^{25,26}

Hungerford (1979), followed by Ficat (1985), first reported on the use of core decompression in the shoulder.^{27,28} Mont (1993) reported his results in a retrospective review of 20 patients (30 shoulders) at a mean follow-up of 5.6 years (range 2–14 years).²⁹ Their technique involved using a 6–10-mm trephine to perform an open core decompression. Of the 30 shoulders, 22 (73%) had good or excellent results and did not require shoulder arthroplasty. All 14 patients (100%) with stage I and II disease avoided further surgery and 7 of 10 (70%) with radiographic stage III disease also had good and excellent results. The remaining 6 patients in stage IV disease progressed to require shoulder arthroplasty, although progression was delayed in 4 of those 6 patients by up to 5 years.

LaPorte and Mont (1998) expanded their earlier study to include 63 shoulders in 43 patients with 2–20 year follow-up (mean 10 years).³⁰ Successful outcome was observed in 15 of 16 (94%) patients with stage I disease and 15 of 17 (88%) with stage II disease. Of the patients in stage III, 16 of 23 (70%) had good and excellent results and only 1 of 7 (14%) patients with stage IV disease did not require arthroplasty.

Harreld et al. reported on the use of the percutaneous small diameter technique with a 3.2 mm Steinmann pin in 15

patients (26 shoulders).³¹ At a mean follow-up of 32 months no patient had progressed to shoulder arthroplasty.

A new arthroscopic-assisted technique of core decompression was described by Chapman et al. (2004). A similar technique was also reported by Dines et al. (2007).^{32,33} Table 40.2 summarizes current studies on core decompression for AVN.^{29,30,32,33}

Recommendations

- Currently there is no data concerning safety or efficacy of bisphosphonates for cases specific to the shoulder [overall quality: very low]
- Core decompression should be considered for stages i, ii and iii [overall quality: very low]

Question 3: What are the indications for arthroplasty in post-traumatic AVN, and what type of arthroplasty should we recommend?

Case clarification

We would recommend prosthetic replacement for this patient. The arthroplasty options include resurfacing arthroplasty, humeral head replacement (hemiarthroplasty), and total shoulder arthroplasty.

Relevance

Arthroplasty in the setting of post-traumatic AVN presents multiple challenges which include dealing with deformity, contracted soft tissues and cuff pathology.

Current opinion

Patients with stage IV disease should be considered for hemiarthroplasty while those with stage V disease will be candidates for a total shoulder arthroplasty.

Finding evidence

- Cochrane Database, with search term “osteonecrosis humeral head,” “avascular necrosis humeral head”
- PubMed: sensitivity search using keywords: “avascular necrosis humeral head” OR “osteonecrosis humeral head” AND “post-traumatic,” “shoulder arthroplasty,” “shoulder resurfacing,” “surface replacement arthroplasty”

Quality of the evidence

Level II

- 2 prospective cohort studies

Level IV

- 14 case series

Findings

Hemiarthroplasty and total shoulder arthroplasty data

Arthroplasty was reserved for management of advanced AVN of the humeral head. Indications for arthroplasty included failure of nonoperative treatment, progression of AVN to head collapse with advanced arthritis (Cruess stages IV and V) despite core decompression, or arthroscopy. Neer as early as 1955 reported his results of arthroplasty in 3 patients with AVN.³⁴

- Cruess stage IV: humeral head collapse, glenoid not involved
- Cruess stage V: head collapse with glenoid degenerative changes²

Information on outcomes of shoulder arthroplasty in post-traumatic AVN was provided in 11 published studies (N = 325). There were 10 retrospective case series and 1 prospective cohort treatment study by Orfaly et al.³⁵⁻⁴³ Studies of arthroplasty for atraumatic AVN were not included in this review. Table 40.3 summarizes results of arthroplasty for post-traumatic AVN of the humeral head.

Our review found that there was a high degree of variability in data reporting in the literature. Reported sample sizes tended to vary greatly (N = 3 patients in a study by Dines⁴³ and N = 137 in the largest retrospective case series

Table 40.3 Published results of arthroplasty for post-traumatic avascular necrosis of the humeral head

Study	No. of shoulders	HHR vs. TSA vs. reverse	Follow-up (mo)	Improved or satisfactory Result (%)	No or slight pain (%)	Normalized Constant score	Mean ASES score	Mean active elevation and external rotation (°)	Complications (%)	Revisions

by Boileau³⁸). The mean follow-up was 54 months (range 19–107 months).

All reviewed literature demonstrated the ability of arthroplasty to improve shoulder function, pain, and range of motion. Satisfactory or improved results were reported to occur in between 64% of cases (study by Mansat et al.,³⁹ N = 7 shoulders) and more recently 95% (study by Tauber et al.,³⁶ N = 38 shoulders).

Between 70% and 95% reported no or slight pain postoperatively. Constant scores and ASES (American Shoulder and Elbow Surgeons score) improved, but four earlier studies did not use these outcome measures in their results.

- Constant score (Constant–Murley Shoulder Outcome Score): This 100 point scoring system consists of four variables: pain, daily activities, motion, and strength. Subjective assessment includes pain (15 points), activities of daily living (20 points); objective assessment includes range of motion (40 points) and strength (25 points). Higher score indicates better-functioning shoulder.⁴⁴
- ASES (American Shoulder and Elbow Surgeons score): A 100 point system based on pain and function. 50 points are assigned based on the pain indicated on a visual analog scale (VAS), and 50 points are given based on the ability to perform 10 activities of daily living.⁴⁵

The longest published follow-up was reported recently by Tauber et al. (mean 96 months, range 60–156 months).³⁶ Constant scores improved overall from 27 points preoperatively (range 11–59 points) to 57 points at follow-up (range 6–95 points). The overall range of motion improved substantially in all planes. Active forward elevation increased from mean 66° preoperatively (range 10–120°) to mean 120° at follow-up (range, 10–180°), $p < 0.01$. External rotation improved significantly from 15° preoperatively (range 5–50°) to 39° at follow-up (range 0–80°), $p < 0.01$.

The only prospective cohort treatment study was by Orfaly et al. (N = 9/21 shoulders with post-traumatic AVN). Significant overall improvement was observed. The mean pain level measured by VAS was 45 points preoperatively to 17 points at follow-up ($p < 0.01$). Active forward elevation increased from 87° to 114° (statistically not significant, p -value not provided). External rotation improved from a mean of -7° (range -45° to -35°) to a mean of 34° (range -10° to 60°), $p < 0.001$.

Visual analog scale (VAS): A 100-point score was used for pain and function. A score of 0 indicated no pain, and 100 meant a constant, severe pain. For the functional assessment, a score of 0 indicated comfortable use of shoulder for all activities, and 100 indicated an inability to perform any of the normal tasks.

Functional scores at follow-up improved from a mean score of 57 points to 14 points at follow-up, $p < 0.001$. When comparing outcomes between the atraumatic and post-traumatic groups, there was no statistically significant difference at follow-up.³⁷

Hattrup and Cofield in 2000 retrospectively reviewed a large cohort of 88 arthroplasties which included 42 shoulders with atraumatic AVN and 46 shoulders with post-traumatic AVN.⁴² In contrast to the previous report, they found statistically significant difference in ASES scores between the two groups. The mean ASES score was 69 in the atraumatic group, compared to 55 in the post-traumatic group ($p < 0.017$). Shoulder motion in every direction at follow-up also showed significantly better results in the atraumatic group ($p > 0.003$).

Resurfacing arthroplasty data Surface replacement was considered when nonarthroplasty treatments failed and there was sufficient bone stock for implant fixation (up to 70% of the head).

The literature on the use of surface replacement for post-traumatic AVN was limited to four reports: one prospective cohort study (N = 6/12 shoulders) and three retrospective series (N = 23).

In 2001, Levy and Copeland reported results from 94 patients with a mean follow-up 81.6 months (range 60–120 months).⁴⁶ There were 4 patients with AVN (etiology was not specified). For the AVN group, Constant scores improved from 11 to 74 points, active forward elevation improved from 63° to 133°, and external rotation improved from -3° to 81° ($p < 0.001$). There was 1 revision to a TSA at 21 months due to an acute fracture.

In 2009, Raiss et al. reported on 17 shoulders with atraumatic (n = 9) and post-traumatic (n = 8) AVN.⁴⁷ On average, the necrotic area occupied 18.6% of the humeral head (range 8.9–30.9%). All of the final outcome measures were significantly better in the atraumatic group. The mean final Constant score was 69.8 in the atraumatic group (SD 12.6, range 52–81) vs. 52.4 in the post-traumatic group (SD 18.1, range 27–83), $p < 0.05$. Significant postoperative differences were also found for shoulder abduction and power ($p < 0.05$), with higher scores in the atraumatic group.

There were 2 published studies of partial resurfacing for AVN. Scalise et al. (2007) reported short-term multicenter results in 62 patients, which included 8 patients with AVN (etiology was not specified).⁴⁸ Uribe et al. (2009) published a prospective cohort treatment study of partial resurfacing in 12 shoulders, including 6 patients with post-traumatic AVN.⁴⁹ At an average follow-up of 30 months (range 21–57 months), there was no statistically significant difference between the atraumatic and post-traumatic groups.

Recommendation

- Shoulder hemiarthroplasty is indicated in humeral head collapse in stage IV disease [overall quality: very low]
- Total shoulder arthroplasty is reserved for patients with glenoid involvement as seen in stage V [overall quality: very low]
- There are no long-term evidence for resurfacing arthroplasty for post-traumatic AVN [overall quality: very low]

Question 4: What are the rates of revision in arthroplasty for post-traumatic AVN?**Case clarification**

The patient has consented to undergo shoulder hemiarthroplasty. She would like to know more about the possibility of requiring further revision surgery.

Relevance

Revision arthroplasty in the post-traumatic AVN setting poses great challenges. Failure of hemiarthroplasty due to glenoid wear is a major reason for revision to a total arthroplasty.

Current opinion

Outcomes of arthroplasty in the post-traumatic and atraumatic groups are similar.

Finding the evidence

- Cochrane Database, with search terms “osteonecrosis humeral head,” “avascular necrosis humeral head”
- PubMed: sensitivity search using the following keywords: “avascular necrosis humeral head” OR “osteonecrosis humeral head” AND “post-traumatic,” “shoulder arthroplasty,” “shoulder resurfacing,” “surface replacement arthroplasty”

Quality of the evidence

Level II

- 2 prospective cohort studies

Level IV

- 14 case series

Findings

As there were a limited number of studies and data reporting was variable, it was difficult to evaluate revision rates for post-traumatic AVN. We found that most studies did not expand on the etiology of their revision cases. The largest retrospective case series was reported by Boileau and colleagues in 2006.³⁸ Their revision rate for post-traumatic AVN was 11% (15/137). Tauber et al. reported a revision rate of 5% (2/38 shoulders).³⁶ No hemiarthroplasties had to be revised to a total shoulder replacement.

Most available revision data comes from the studies of atraumatic AVN. Five studies with longer follow-up of up to 12 years showed glenoid involvement as a major reason for conversion of humeral head replacement to a total shoulder arthroplasty.^{20,37,42,50,51} Revision rates ranged from 6% in two reports with mean follow-up to 12 years, to 20% in an earlier study of 5 patients by Cruess.

Recommendation

- Current evidence lacks specific information of the rate of revision of arthroplasty in the setting of post-traumatic AVN [overall quality: very low]

Summary of recommendations

- Patients with post-traumatic AVN tend to require surgery more often than patients with atraumatic AVN
- At 3 years after initial diagnosis, up to 78% of patients with post-traumatic AVN need shoulder arthroplasty
- Up to 30% of patients in stage III disease and up to 80% in stage IV disease at presentation required arthroplasty
- Similarly, at 3 years, more patients with greater extent of humeral head involvement required arthroplasty
- Currently there is no data concerning safety or efficacy of bisphosphonates for cases specific to the shoulder
- Core decompression should be considered for stages I, II, and III
- Shoulder hemiarthroplasty is indicated in humeral head collapse in stage IV disease
- Total shoulder arthroplasty is reserved for patients with glenoid involvement as seen in stage V
- There is no long-term evidence for resurfacing arthroplasty for post-traumatic AVN
- Current evidence lacks specific information of the rate of revision of arthroplasty in the setting of post-traumatic AVN

Conclusion

Post-traumatic AVN of the humeral head is associated with displaced fractures of the proximal humerus. Three- and four-part fractures have been shown to result in AVN in 21–75% of patients. Studies of the natural history of this disease demonstrated rapid progression to surgical treatment, which included core decompression and arthroplasty. The stage at presentation and extent of the lesion were directly associated with disease progression and need for arthroplasty. Currently there is no evidence on safety and efficacy of bisphosphonate treatment in post-traumatic AVN of the shoulder. Core decompression and arthroscopic debridement may be considered for stages I–III disease.

Hemiarthroplasty should be reserved for stage IV disease and total shoulder replacement for stage V disease. There is no long-term data on the resurfacing arthroplasty for post-traumatic AVN.

Proximal Humerus Fractures

Job N. Doornberg¹ and David Ring²

¹Orthotrauma Research Center Amsterdam, Academic Medical Center Amsterdam, and St. Lucas Andreas Hospital, Amsterdam, The Netherlands

²Harvard Medical School and Massachusetts General Hospital, Boston, MA, USA

Case scenario

A 69 year old woman presents to the emergency department after a slip and fall at home. She is an avid golfer and does not take any medication. On examination, she has pain, swelling, and ecchymosis of her right dominant shoulder and arm and a normal neurovascular examination. Radiographs reveal a fracture of the proximal humerus.

Relevant anatomy

Fractures of the proximal humerus may be (1) avulsion fractures of the tuberosities; (2) stable impacted fractures of the surgical or anatomical neck; (3) displaced fractures; or (4) fractures associated with dislocation of the glenohumeral joint. Neer¹ suggested classification according to four parts as follows: (1) the articular segment or anatomical neck, (2) the greater tuberosity, (3) the lesser tuberosity, and (4) the shaft or surgical neck. To be considered a separate part, a fragment has to be at least 1 cm displaced or 45° angulated.

Importance of the problem

Proximal humeral fractures occur largely in older men and women in a 30:70 ratio,² usually after a simple fall.³ Proximal humerus fractures are among the most common fractures associated with osteoporosis, accounting for 18% of osteoporotic fractures in postmenopausal women and 43% of osteoporotic fractures in patients older than 75 years.⁴ Most fractures of the proximal humerus are minimally displaced, stable, and associated with limited functional impairment

after nonoperative treatment.^{3,5} Displaced fractures that heal with malunion or are treated with arthroplasty can be associated with severe shoulder impairment.⁶

Top five questions

Diagnosis

1. Is there a role for CT scan in the classification and management of fractures of the proximal humerus?

Therapy

2. When should patients with minimally displaced fractures of the proximal humerus start exercises to regain motion?

3. What are the indications for operative vs. nonoperative treatment of displaced proximal humerus fractures?

4. When treated operatively, what is the best treatment for displaced three- and four-part fractures and fracture-dislocations of the proximal humerus: arthroplasty or open reduction and internal fixation (ORIF)?

Prognosis

5. Which factors predict outcome after a proximal humeral fracture in an elderly patient?

Question 1: Is there a role for CT scan in the classification and management of fractures of the proximal humerus?

Case clarification

The patient's radiographs are reviewed at a morning fracture conference. The surgeons present at the conference

disagree whether the amount of displacement merits consideration of operative treatment. They also debate whether CT will help guide management and lead to an improved outcome.

Relevance

Surgeons and patients hope that more detailed imaging will help improve management and outcome.

Current opinion

Surgeons debate whether CT helps to characterize complex fractures or facilitates preoperative planning.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “proximal humerus fracture” AND “imaging”
- Bibliography of eligible articles
- It is recommended to include only the most recent studies in decision-making, as CT imaging protocols have become significantly more advanced over the last few years.

Quality of the evidence

Level II

- 2 diagnostic test accuracy/observer reliability studies with methodological limitations^{7,8}

Findings

Conventional radiographs vs. 2-D and 3-D CT imaging One prospective diagnostic study⁷ (44 consecutive cases, all fracture types included, 3 independent observers) with methodological limitations (no gold standard, no power calculation) showed a significantly better assessment ($p < 0.05$) of relevant structures (tuberosities, the glenoid and humeral head) using a four-grade scoring system (1, excellent; 2, good; 3, fair; 4, inadequate) based on CT diagnostics than conventional radiographs (AP view, scapular Y views and axillary views) independently of fracture severity (i.e. two-, three-, or four-part fractures) (level II).

An intra- and interobserver study⁸ using kappa statistics (40 consecutive patients, 4 independent observers) with methodological limitations (no gold standard, no power calculation, retrospective design) showed a significantly ($p < 0.001$) improved interobserver reliability from ‘moderate’ for radiographs ($\kappa = 0.42$) and 2-D CT ($\kappa = 0.56$), to ‘good’ for the Neer classification system ($\kappa = 0.76$). Intraobserver reliability improved ($p < 0.001$) from ‘moderate’ for conventional radiographs ($\kappa = 0.48$) and 2-D CT ($\kappa = 0.63$), to ‘excellent’ for the Neer classification ($\kappa = 0.84$) (level II).

Recommendations

- CT imaging improves the reliability of classification of proximal humerus fractures [overall quality: moderate]

- 3-D CT improves the reliability of classification over 2-D CT [overall quality: low]
- It is not known whether more reliable classification leads to more accurate classification or improved outcomes

Question 2: When should patients with minimally displaced fractures of the proximal humerus start exercises to regain motion?

Case clarification

The fracture is stable with limited displacement and the patient and surgeon elect nonoperative treatment. The patient wants to know she should begin exercises to regain motion.

Relevance

Immediate initiation of exercises might result in better final shoulder motion and function but could also interfere with healing.

Current opinion

There is debate between early (within 1 week) or late (3 weeks or more, once healing is established) initiation of exercises after a proximal humerus fracture.

Finding the evidence

- Cochrane Database, with search term “humerus fracture”.

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “humerus fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “proximal humeral fracture,” as well as “proximal humerus fracture” AND “treatment”
- Bibliography of eligible articles

Quality of the evidence

Level I

- 1 multicenter randomized controlled trial (RCT)⁹

Level II

- 2 systematic reviews/meta-analyses (of level II RCTs)^{10,11}
- 4 randomized trials with methodological limitations^{12–15}

Findings

Shoulder function (Constant score) Two prospective RCTs^{12,13} (160 patients) with methodological limitations (possible bias; allocation concealment unclear, some blinding outcome assessors, blinding patients impossible, inclusion/exclusion criteria not (clearly) defined) showed that early mobilization within one week resulted in significantly better Constant shoulder scores at 12 weeks¹² for impacted (stable) proximal humeral fractures (weighted mean difference 9.9, 95% CI 2.1–17.7, $p < 0.05$) and 16 weeks¹³ for non- and minimally displaced two-part fractures (mean difference 16.0, 95% CI 7.1–24.9, $p < 0.001$). There were no significant differences 6 months¹² (mean difference 6.1, 95%

CI -0.2 – 12.4 , $p = 0.06$) and 1 year¹³ (mean difference 7.0, 95% CI -3.4 – 17.4 , $p = 0.19$) after fracture (level II).

General health status (Short Form-36) One prospective RCT¹³ (86 patients) showed that early mobilization within 1 week for patients with non- and minimally displaced proximal humerus fractures resulted in significantly better health-related quality of life scores at 16 weeks in two dimensions of the SF-36 (role limitation physical: mean difference 22.2, 95% CI 3.8–40.6; pain: mean difference 12.1, 95% CI 3.2–20.9). There were no statistically significant differences between the two treatment groups in the other six dimensions (e.g., physical functioning) of SF-36, nor in any of the eight dimensions at 1 year (level II).

Pain One prospective controlled trial of patients with impacted proximal humeral fractures¹² (64 patients) reported significantly less pain in patients that started pendulum exercises immediately compared to those who were immobilized for 1 month as measured on a 100 mm visual analog scale (VAS) pain score at 3 months (mean difference 15.7, 95% CI 0.52–30.9, $p < 0.05$), but not at 6 weeks (mean difference 3.6, 95% CI -13.6 – 20.8 , $p = 0.68$) or 6 months (mean difference -0.20 , 95% CI -14.4 to 14.0, $p = 0.98$) (level II).

Recommendation

Limited evidence suggests that for patients with non- and minimally displaced two-part fractures and impacted fractures of the proximal humerus:

- Early initiation of exercises does not affect impairment or disability 6 months or more after fracture of the proximal humerus [overall quality: moderate]
- No risk of nonunion was seen with early initiation of exercises [overall quality: moderate]
- The decision regarding when to start exercises can be left to the preferences of patient and surgeon

Question 3: What are the indications for operative vs. nonoperative treatment of displaced proximal humerus fractures?

Case clarification

The fracture is unstable with displacement and the patient and surgeon have to decide between operative and nonoperative treatment.

Relevance

The indications for operative treatment are incompletely defined.

Current opinion

The decision regarding optimal treatment is based on the preferences of patient and surgeon.

Finding the evidence

- Cochrane Database, with search term “humerus fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews: “humerus fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “proximal humeral fracture,” as well as “proximal humerus fracture” AND “treatment”
- Bibliography of eligible articles

Quality of the evidence

Level I

- 1 multicenter randomized controlled trial^{19,16}

Level II

- 3 systematic reviews/meta-analyses (of level II studies)^{10,17}
- 3 randomized trials^{18–20}

Findings

Shoulder function Three prospective controlled trials^{18–20} (103 patients) with serious methodological limitations (possible bias; unclear allocation concealment, unable to blind patients and caregivers, outcome assessors not blinded, >25% loss to follow-up) randomized patients to nonoperative treatment; vs. arthroplasty with a Neer prosthesis for displaced fractures (32 patients),²⁰ vs. transcutaneous reduction and external fixation for displaced two-, three-, and four-part fractures (31 patients),¹⁸ and vs. tension-band osteosynthesis for three- or four-part proximal humerus fractures (40 elderly patients, mean age 74 years).¹⁹ Two studies^{18,19} using standardized outcome instruments found no statistically significant differences in Constant²¹ (mean difference 5.0, 95% CI -7.5 to 17.5, $p = 0.43$)¹⁹ or Neer¹ scores (RR = 2.2, 95% CI 0.74–6.54, $p = 0.16$) (level II).¹⁸ One study²⁰ did not use standardized outcome instruments, but reported significantly more patients who were dependent in activities of daily living (RR = 4.5, 95% CI 1.2–17.4, $p = 0.03$) and significantly more patients with constant pain (RR = 4.8, 95% CI 1.2–18.47, $p = 0.02$) in the nonoperative treatment group as compared with the group treated with a Neer prosthesis (level II).

Complications There were no differences in major complications,^{18–20} deep infections (RR = 0.27, 95% CI 0.1–1.6, $p = 0.15$) nonunion (RR = 4.0, 95% CI 0.5–30.3, $p = 0.18$) osteonecrosis (RR = 1.06, 95% CI 0.2–5.5, $p = 0.95$) or refractures (RR = 1.06, 95% CI 0.7–14.1, $p = 1.00$) (level II).

Recommendations

There is insufficient evidence to determine if operative treatment will produce consistently better outcomes for displaced proximal humerus fractures than nonoperative treatment.

- Although fewer patients in the operative treatment groups had unsatisfactory ratings of function, with current

small sample sizes there is no significant difference in shoulder scores [overall quality: very low]

- Operative treatment is associated with nonsignificantly more complications [overall quality: very low]

Question 4: What is the best operative treatment for displaced three- and four-part fractures and fracture-dislocations of the proximal humerus: arthroplasty or ORIF?

Case clarification

Radiographs and 2-D and 3-D CT show a complex four-part fracture of the proximal humerus. Patient and surgeon elect operative treatment. Which type of operative intervention is preferred?

Relevance

Difficulties associated with loss of fixation, nonunion, malunion, and osteonecrosis make prosthetic arthroplasty an appealing treatment option, but function after arthroplasty has been poor and prostheses gradually loosen, particularly in active patients.

Current opinion

There is a lack of consensus regarding the optimal operative treatment strategy.

Finding the evidence

- Cochrane Database, with search term “humerus fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): clinical queries search/systematic reviews: “humerus fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “proximal humeral fracture,” as well as “proximal humerus fracture” AND “arthroplasty”
- Bibliography of eligible articles

Quality of the evidence

Level I

- 1 multicenter randomized controlled trial⁹

Level II

- 3 systematic reviews/meta-analyses (of level II RCTs)^{10,17,22}
- 1 randomized trial with methodologic limitations²³

Findings

Tension-band wiring vs. arthroplasty One RCT²³ (30 patients) with methodological limitations (unclear allocation concealment, unable to blind caregivers, patients not blinded, outcome assessors not blinded, >25% loss to follow-up) showed no difference in shoulder function as measured with the Constant score (minus power component) between patients with four-part proximal humerus fractures treated with tension-band wiring vs. arthroplasty (49 vs. 48 points).

Patients in the arthroplasty group had significantly fewer subsequent surgeries within 1 year (RR = 0.09, 95% CI 0.01–1.5, $p < 0.05$), but no difference in implant removal (RR = 0.1, 95% CI, 0.01–1.9, $p = 0.13$) or pain (RR = 0.5, 95% CI 0.05–4.6, $p = 0.54$) (level II).

Recommendation

- There is insufficient evidence from randomized trials to determine the preferred (operative) intervention in patients with displaced four-part fractures of the proximal humerus.

Question 5: Which factors predict outcome after a proximal humeral fracture in an elderly patient?

Case clarification

The patient loves to swim and wonders whether this will be possible.

Relevance

Patients and surgeons often make decisions based on prognosis.

Current opinion

A growing body of evidence suggests that pain is a stronger correlate with disability than impairment at many anatomical sites. Even pathophysiological changes such as osteonecrosis do not seem to affect outcome as much as one might imagine.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “proximal humeral fracture,” “proximal humerus fracture” AND “prognostic factors” as well as “proximal humerus fracture” AND “outcome”
- Bibliography of eligible articles

Quality of the evidence

Level II

- 1 prospective case series²⁴

Level III

- 1 systematic review (of level III) studies²⁵
- 2 retrospective case series²⁶

Findings

Predictors of humeral head ischemia One prospective study²⁴ evaluated predictors of fracture-induced ischemia in a consecutive series of 100 proximal humerus fractures in 98 patients (mean age 60 years). Fifty-five heads were considered ischemic and 45 perfused according to a definition of borehole bleeding and pulsatile Doppler signal. Less than 8mm of metaphyseal extension remaining attached to the

head ($p < 0.0001$; PPV = 0.77, NPV = 1), disruption of the medial hinge (displacement of the shaft) greater than 2 mm ($p < 0.0001$; PPV = 0.83, NPV = 0.75) and anatomical neck fractures ($p < 0.0001$; PPV = 0.71, NPV = 0.68) were good predictors of ischemia. Four-part fractures (PPV = 0.74, NPV = 0.61), more than 45° of angular displacement of the head (PPV = 0.79, NPV = 0.55), more than 10 mm displacement of the tuberosities (PPV = 0.63, NPV = 0.58), glenohumeral dislocation (PPV = 0.6, NPV = 0.46), head-split components (PPV = 0.61, NPV = 0.46) and three-part fractures (PPV = 0.43, NPV = 0.34) were moderate and poor predictors of ischemia (level II).

Internal fixation and avascular necrosis A systematic review²⁵ of 12 studies with 791 patients treated with locking plates of two-, three-, and four-part fractures reported an incidence of avascular necrosis of 7.9%.

One retrospective study²⁶ of a consecutive series of 34 two-, three-, and four-part fractures found a significant difference in function as measured with the Constant shoulder score between patients with and without complete or partial avascular necrosis (66 point vs. 81 points; $p < 0.0005$) (level III).

Prognostic factors after arthroplasty One retrospective study²⁷ investigated prognostic factors on the outcome of arthroplasty in a consecutive series of 38 patients (mean age 58 years) with 2 Neer type III, 15 type IV, and 15 fracture-dislocations of the proximal humerus. Ninety-seven percent had no or mild pain. Patients treated within 14 days ($r = 0.60$; $p = 0.005$) and patients with superior radiological parameters describing the position of the greater tuberosity relative to the humeral head (humeral offset; $p = 0.002$) and humeral head height ($r = -0.57$; $p = 0.002$) had significantly better outcome according to the Constant shoulder score (level III).

Recommendation

There is insufficient evidence from prospective case studies to identify predictors of outcome in patients with complex fractures of the proximal humerus. The following trends were noted:

- Patients with proximal humeral fractures with the following radiographic characteristics are more likely to develop avascular necrosis: less than 8 mm of metaphyseal extension remaining attached to the head, disruption of the medial hinge (displacement of the shaft) greater than 2 mm and anatomical neck fractures [overall quality: moderate]
- 7.9% of patients with complex two-, three-, and four-part fractures develop avascular necrosis [overall quality: very low]
- Patients with avascular necrosis have significantly impaired shoulder function [overall quality: very low]

Summary of recommendations

- CT imaging improves the reliability of fracture classification over radiographs alone, but there is no evidence that CT improves outcome
- 3-D CT improves the reliability of classification over 2-D CT
- Although fewer patients in the operative treatment groups had unsatisfactory ratings of function, with current small sample sizes there is no significant difference in shoulder scores
- Operative treatment is associated with nonsignificantly more complications
- For patients with non- and minimally displaced two-part fractures and impacted fractures of the proximal humerus, early mobilization and physical therapy results in less pain and faster and better recovery without compromising long-term outcome
- In patients with displaced four-part fractures of the proximal humerus, there is no difference in shoulder function between arthroplasty and tension-band wiring, but patients treated with arthroplasty had significantly fewer subsequent procedures and arthroplasty nonsignificantly reduces pain compared to tension-band wiring
- Patients with proximal humeral fractures with the following radiographic characteristics are more likely to develop avascular necrosis: less than 8 mm of metaphyseal extension remaining attached to the head, disruption of the medial hinge (displacement of the shaft) greater than 2 mm and anatomical neck fractures
- 7.9% of patients with complex two-, three-, and four-part fractures develop avascular necrosis
- Patients with avascular necrosis have significantly impaired shoulder function

Conclusion

There is insufficient evidence from randomized trials to determine the optimal intervention in patients with proximal humeral fractures.

Humeral Shaft Fractures

Amy Hoang-Kim¹, Jörg Goldhahn², and David J. Hak³

¹St. Michael's Hospital, University of Toronto, Toronto, ON, Canada

²Schulthess Clinic, Zurich, Switzerland

³Denver Health, University of Colorado, Denver, CO, USA

Case scenario

A 35 year old man is brought to the Emergency Department following a motor vehicle accident. He is complaining of right arm pain. He has an obvious deformity of his right upper arm, which appears to be his only orthopedic injury.

Relevant anatomy

Surgical approaches to the humerus must take into account the neurovascular anatomy of the brachium (Figure 42.1). Proximally, the circumflex humeral vessels and the axillary nerve divide the humerus at the surgical neck. Distally, the radial and ulnar nerves cross the intermuscular septae to leave the posterior compartment between the brachioradialis and brachialis muscles. Innervation is provided by branches of the radial nerve which passes through the lateral intermuscular septum to innervate the lateral third of the brachialis. The medial two thirds of the brachialis muscle and the remainder of the anterior compartment are innervated by the musculocutaneous nerve.

Importance of the problem

Fractures of the humeral shaft account for 1–5% of all fractures.^{1,2} Over 66,000 humeral shaft fractures occur annually in the United States and account for over 363,000 days in the hospital.³ Google Scholar returns 17,100 hits for “humeral shaft fractures” proving the topic to be much discussed, and the body of unfiltered literature contains conflicting opinions.

Top five questions

Therapy

1. What is the optimal nonoperative approach in patients with humeral shaft fractures?
2. What is the relative effect of plate fixation vs. intramedullary nailing in the management of displaced or comminuted humeral shaft fractures?
3. What is the approach for radial nerve injury when the nerve is out vs. when the nerve is initially in, but goes out following closed reduction or fracture manipulation?
4. What predictors of plate fixation failure indicate use of a locking plate vs. a nonlocking plate?

Harm

5. What are the complications associated with plate/screw fixation of humeral shaft fractures?

Finding the evidence

A search was conducted of the literature published from 1950 to June 2009 using the following computer databases: Cochrane Database of Systematic Reviews, CINAHL, Embase, OVID MEDLINE and experts in the field.

1. Exp humeral fractures/ or (exp fractures, bone/ and ((exp humerus/ or humeral.mp.))
2. (humer\$ adj1 fracture\$.mp.
3. 1 or 2
4. Exp diaphysis/ or diaphys\$.mp.
5. Shaft\$.mp. or shaft\$.tw.
6. 3 and (4 or 5)

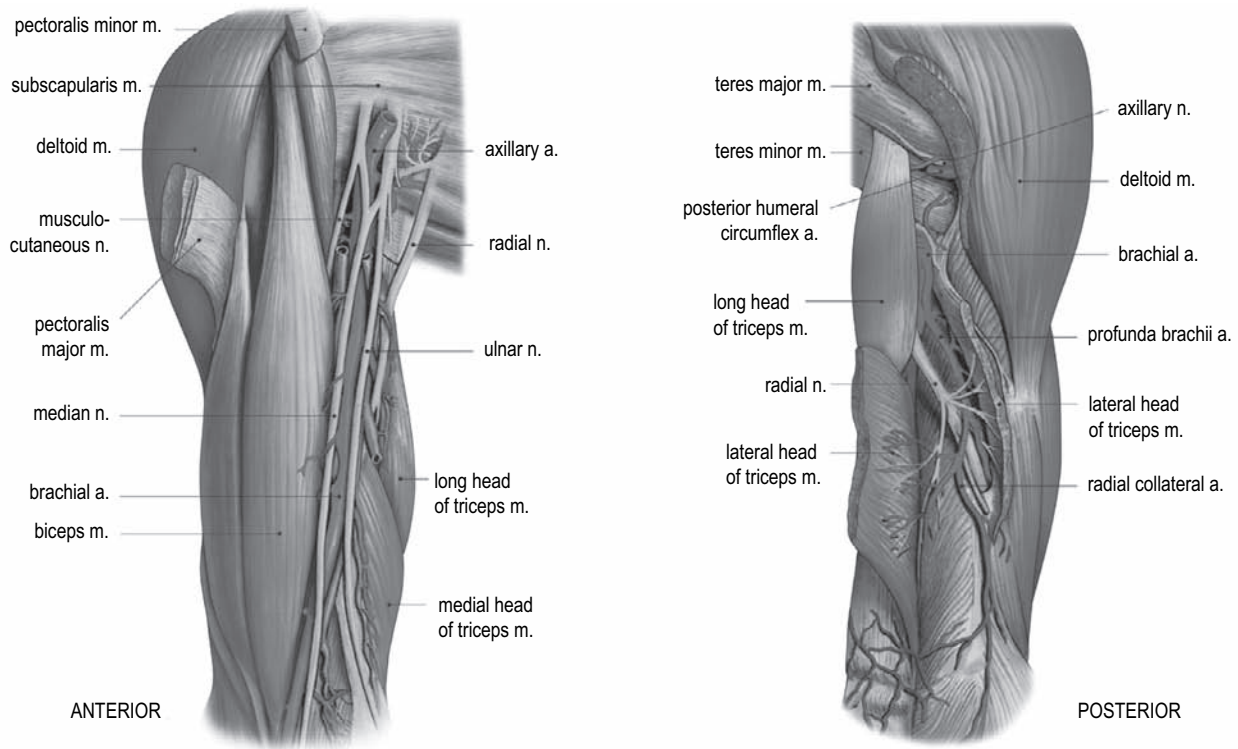

Figure 42.1 Anatomy and innervation of the humerus.

- Cochrane Database of systematic reviews, with text words "humeral fracture" (fracture or fractures) or ('humerus' and 'fracture') + diaphysis or shaft.
- PubMed: "humerus" + 'fracture' or 'humeral fracture' + ('shaft' or diaphysis)
- CINAHL, exp humeral fractures + ('shaft' or 'diaphysis' or 'long')
- EMBASE exp Humeral fractures or (exp humerus + exp fracture) + diaphysis

Question 1: What is the optimal nonoperative approach in patients with humeral shaft fractures?

Case clarification

The patient's neurological examination is normal. His arm is splinted in the Emergency Department. He follows up a week later with an orthopedic surgeon who places him in a humeral fracture brace. The patient returns to his orthopedic surgeon 2 weeks after placement of the humeral fracture brace. Radiographs are obtained, and to the patient they appear to show that his bone is quite crooked. He expresses concerns to his orthopedic surgeon that the fracture is not properly aligned.

Relevance of the question

Nonoperative modalities include hanging cast, functional bracing, and plaster U splint. Residual deformity may

influence active and passive range of motion as well as the function of the adjacent joints. However, the high degree of freedom provided by the shoulder joint may overcompensate deformities of the humeral shaft resulting from a misaligned humeral fracture.

Current opinion

Humeral shaft fractures can be effectively treated by functional fracture-bracing as developed by Sarmiento.

Quality of the evidence

Level I

- 1 systematic review

Findings

Union rates Following an initial 2 week period of immobilization in a plaster cast, functional bracing is indicated provided that the patient is compliant. Nonunion rates, associated with fracture pattern, are 12.8% for spiral, 4.9% for oblique, 8.9% for transverse, and 2.2% for comminuted and segmental fractures.⁴

Angulation and shortening Angulation of less than 10° is reported with an acceptable 2cm shortening of the fracture.⁴ Even slight residual angulation when managing a spiral or comminuted fracture does not produce a clinically significant deformity at this level.

Table 42.1 Summary of evidence of trials reporting health status and region-specific scores for functional bracing in patients following humeral fracture

Author (year)	Intervention	No. of patients for functional outcome (%), loss to follow-up	Level of evidence, patient characteristics	Final follow-up (months)	Health status	Region-specific scores	No. of patients recovered (%)
Ekholm et al. (2006)	Functional brace	49 (78), 1	Level III N = 43 patients healed fracture after nonoperative treatment N = 6 patients healed fracture after operative treatment	26.4	SF-36 lower results compared to Swedish reference population. Bodily pain was the exception	Better SMFA scores for nonoperative treatment than surgical intervention	21 (49) nonoperative vs. 0 (0) surgically treated (p < 0.05)
Rosenberg et al. (2006)	Functional brace	15 (100), 0	Level V n = 9 midshaft fractures n = 3 proximal third fractures n = 3 distal third fractures	30	NR	Constant score significantly lower in injured limb vs. normal contralateral side (p < 0.001) Oxford shoulder score of 34 (range 17–54) in injured extremities vs. contralateral side	6 (40)

NR, not reported.

Functional outcome Two studies (N = 64 patients) reported worse region-specific scores; one of them reported lower health status (Table 42.1).

Recommendations

- Functional bracing follows an initial 2 week period of immobilization in a plaster splint [overall quality: moderate]
- Angulation up to 10° can be tolerated and shortening should not exceed 2cm [overall quality: moderate]

Question 2: What is the relative effect of plate fixation vs. intramedullary nailing in the management of displaced or comminuted humeral shaft fractures?

Case clarification

Follow-up radiographs show persistent distraction at the fracture site, suggesting the possibility of soft tissue interposition, an indication for operative treatment. The surgeon discusses two surgical fixation options with the patient: plate fixation or intramedullary nail (IMN) fixation.

Relevance of the question

Surgical intervention using both open reduction and internal fixation (ORIF) with plate and screws, or IMN and external fixation has specific indications (Table 42.2). Two

Table 42.2 Some indications for operative treatment of humeral shaft fractures

Inability to obtain and maintain an acceptable closed reduction: common examples include: obesity, segmental fractures, patients requiring prolonged recumbency
Floating elbow (ipsilateral forearm fracture)
Multiply injured patients
Open fractures
Vascular injury
Pathologic fractures
Spinal cord injury
Brachial plexus injury
Bilateral humeral shaft fractures
Progressive or new onset nerve palsy
Patients noncompliant for bracing

Table 42.3 Characteristics of randomized controlled trials comparing intramedullary nailing to plate fixation

Author (year)	Study design	Sample	Fracture type	IMN intervention	DCP intervention	Outcomes	Follow-up months (%)	Level of evidence
Changulani (2007) ¹⁴	RCT	N = 47 patients Male: 87% Female: 13% Age: 37 years (24–51)	Comprehensive classification type A, B, and C	Antegrade nail: n = 23	n = 24	Infection, nonunion, implant failure, iatrogenic nerve injury	6–33 (96)	II
Chapman (2000) ⁶	RCT	N = 84 Male: 62% Female: 38% Age: 34 years (18–83)	Closed and open type I, II, IIIA, IIIB, and IIIC	Antegrade nail: n = 38	n = 46	Infection, malunion, nonunion, iatrogenic nerve injury, elbow and shoulder pain, elbow and shoulder ROM, hardware removal	13 (4–48) NR	II

Rodriguez-Merchan (1995) ¹⁵	RCT	N = 40 Male: 78% Female: 22% Age: 46 years (20–65)	Closed transverse fractures	Flexible nail : n = 20	n = 20	Infection, nonunion, implant failure, elbow and shoulder ROM, pain, disability	18.5 (12–50) NR	II

Openmirrors.com

IMN, intramedullary nail; RCT, randomized controlled trial; ROM, range of motion.

indications for ORIF are a coexisting injury to the brachial artery that requires arterial repair and a progressive loss of radial nerve function.

Current opinion

ORIF with compression plate fixation has the advantage of accurate fracture reduction, but has disadvantages of additional soft tissue and periosteal stripping, infection, and potential risk of radial nerve injury. Biomechanical studies show increased initial stability when an IMN is inserted antegrade for proximal fractures and retrograde for distal fractures.⁵

Quality of the evidence

Level I

- 1 systematic review/meta-analysis

Level II

- 4 studies

Findings

Impairment Three studies demonstrated overall more shoulder pain and reduced shoulder range of motion with IMN (Table 42.3). Chapman et al. reported 93% healing in

those patients treated with plate fixation and 87% with IMN at 16 weeks.⁶ In the plate fixation group, a significant decrease in elbow range of motion was seen especially for distal third diaphyseal fractures ($p = 0.003$).

Shoulder pain following antegrade vs. retrograde nail insertion ranges from 16% to 37%, and can be reduced by carefully splitting, retracting and repairing the rotator cuff.^{7,8} Cheng et al. (RCT; level II) reported similar fracture healing rate and time to healing did not differ significantly between retrograde and antegrade IMN.⁹ Active range of motion exercises should be started in the early postoperative period, 4–7 days after surgery. Crutch ambulation is possible if the fixation is stable and will axially load the fracture site, aiding union.⁵

Disability McCormack (RCT; level II) and Gregory et al. (meta-analysis; level II), found no significant differences in the function of the shoulder and elbow between groups.^{7,10} McCormack used the American Shoulder and Elbow Surgeons score (ASES) for 16 activities involving the shoulder and elbow movement ($p = 0.713$). In the randomized trial by Cheng, the authors sustain a better average Neer shoulder score for the antegrade group than the retrograde

IMN (90.8 ± 6.5 vs. 93.5 ± 4.6 , respectively, $p = 0.03$, 95% CI -3.53 to 0.33). There were no significant differences in the Mayo elbow performance score between the two nail insertion groups ($p = 0.16$, 95% CI -0.62 to 3.62).

The American Shoulder and Elbow Surgeons (ASES) shoulder scale contains both a patient-derived subjective assessment and a physician-derived objective assessment. It was published in 1994 by the Research Committee of the American Shoulder and Elbow Surgeons. The subjective patient self-report section consists of two equally weighted domains, pain and function, and has been widely used for outcomes assessment in patients with shoulder instability, rotator cuff disease, and glenohumeral arthritis. Pain is recorded on an ordinal scale, ranging from 0 to 10, and accounts for 50% of the overall ASES score. Function accounts for the other 50% of the overall score and is divided into ten questions.

Recommendations

- Plate fixation and IMN can result in similar healing patterns at 16 weeks [overall quality: moderate]
- Antegrade and retrograde IMN can be inserted using either an antegrade or a retrograde approach [overall quality: low]
- IMN is associated with more shoulder pain and reduced range of motion. Both IMN and compression plating can achieve similar functional results [overall quality: low]

Question 3: What is the recovery rate of radial nerve injury when the nerve is out vs. the nerve is initially in, but goes out following closed reduction or fracture manipulation?

Case clarification

Scenario 1: When the patient initially presents to the Emergency Department, physical examination reveals that he is unable to actively extend his wrist or fingers. This deficit persists following closed reduction and splint placement. Scenario 2: On initial presentation to the Emergency Department, the patient's physical examination shows intact motor function. He undergoes closed reduction and application of a splint. Following the reduction physical examination, indicates an inability to actively extend his wrist or fingers.

Relevance of the question

When radial nerve palsy develops following fracture manipulation, many surgeons have advocated radial nerve exploration because this scenario suggests that the radial nerve might be trapped within the fracture.

Current opinion

A survey of current practice among trauma surgeons in England showed that surgeons still differ in the ways of

managing radial nerve palsy associated with humeral fractures, with a slightly higher percentage of surgeons preferring conservative treatment.¹¹

Quality of the evidence

Level II

- 2 studies

Findings

Recovery rate Shao et al. reported that a spiral fracture pattern of the distal humerus with associated nerve palsy is not an absolute indication for radial nerve exploration and showed no significant difference in the rate of recovery between primary (88.6%) and secondary nerve palsies (93.1%).¹² A limited period of waiting also had no effect on the final recovery. Eleven studies ($n = 98$ patients) showed that the mean delay to first exploration was 4.3 months (range 1–15). In 101 cases treated expectantly at first, the mean spontaneous recovery onset time was 7.3 weeks, which may indicate the minimum waiting time before exploration.

The rationale for this type of injury is not to be indicated for open reduction unless it constitutes an increase in radial nerve deficit. It is reported that nerve fibers will regenerate in 3 months' time. When recovery in this time period has failed, appropriate tendon transfers can improve irreparable nerve damage. Because irrigation and debridement is required for open fractures, it is reasonable to explore the nerve at this same operation. Shao et al. did not identify a significant difference in the spontaneous recovery of radial nerve palsies in open vs. closed fractures.¹²

Recommendation

- Exploration is at 4–6 months if there is no resolution following a primary radial nerve palsy [overall quality: low]
- In patients with indications for earlier operative fixation, exploration of the nerve should be at the time of internal fixation [overall quality: low]
- Primary and secondary nerve palsies show no difference in recovery rate [overall quality: moderate]

Question 4: What predictors of plate fixation failure indicate use of a locking plate vs. a nonlocking plate?

Case clarification

Following discussion with his surgeon regarding surgical treatment options, the patient elects to undergo open reduction and plate fixation. In planning for the surgical procedure, the surgeon wonders whether he should request a traditional nonlocking plate or a more expensive locking plate.

Table 42.4 Summary of the biomechanical evidence for locking screw/plate fixation in cadaveric humeral shaft fractures

Author (year)	Study design	Intervention	Outcomes	Results
Simon (1999)	Biomechanical cadaver study	6 pairs of cadaveric humeri from elderly individuals with 10-hole broad DCP plate on one side and a DCP plate augmented with Schuhlis at each screw hole on contralateral side placed in cortical bone	Axial loading, torsion, and four-point bending, (AP, LM)	Locked construct showed a consistent ability to sustain larger rotational displacements and loads prior to failure by spiral fracture. No significant differences for the stiffness values in the testing modalities prior to or after cycling.
Jazrawi (2000)	Biomechanical cadaver study	6 pairs of Schuhl locking nuts with standard screws and cement augmented screws for fixation in humeral shaft fractures with osteoporosis	Axial compression, 4-point bending, torsion	Cement augmented screws showed no significant difference in fixation stability in all loading modes before and after cycling. The Schuhl locking nuts and cement augmented screws had significantly greater fixation stability than the standard screws before and after cycling in torsional loading.
Korner (2004)	Biomechanical cadaver study	10 matched pairs of humeri with two standard configurations of double-plate osteosynthesis with either conventional reconstruction plates or locking compression plates. Each plate was fixed with 3 bicortical screws in the proximal fragment and 3 monocortical screws in the distal fragment.	Stiffness testing (AP bending) torsion and axial compression loading. Failure patterns under cyclic loading and strength testing	Primary stiffness in AP bending and torsional loading is significantly increased using LCP in a 90° configuration ($P < 0.05$) as compared with dorsally applied plates.
O'Toole (2008)	Biomechanical cadaver and synthetic humeri study	10-hole 3.5 mm LCP with either locking or nonlocking bicortical screws in cadaveric elderly matched pairs ($n = 12$) and synthetic bones ($n = 6$).	Stiffness testing and failure testing	No difference between axial stiffness before and after cyclic loading for the plates ($p = 0.94$). No difference in ultimate failure force ($p = 0.87$).

AP, anteroposterior; DCP, dynamic compression plate; LCP, locking compression plate; LM, lateral medial.

Relevance of the question

Locking plates provide a new mechanical paradigm for the fixation of fractures; they do not rely on compression of the plate to the bone to maintain their rigidity.

Current opinion

The use of the locking plate, which has a higher energy to failure, may compensate for loss of screw purchase typical in osteoporotic bone.

Quality of the evidence

Level V

- 3 studies

Findings

Union rates Ring and coinvestigators suggest that a better alternative, if it is anticipated that standard screws will not

function adequately, is to use Schuhl nuts to transform each screw into a fixed-angle device.¹³

Biomechanical results Most biomechanical data support the use of locked screws (Table 42.4).

Recommendation

- Biomechanical data shows potential benefits in using locked screw configurations in the plating of osteoporosis humeral fractures [overall quality: moderate]

Question 5: What are the complications associated with plate/screw fixation of humeral shaft fractures?

Case clarification

In completing the informed consent the surgeon reviews the potential risks involved in the planned surgical fixation.

Relevance of the question

Potential complications will influence decision-making either for or against surgical management. It will also affect patient compliance and expectation.

Current opinion

Although all studies of humeral shaft fractures report specific complications, there is no general consensus on how to report them. This further challenges the comparison or pooling of different studies.

Quality of the evidence*Level I*

- 2 systematic reviews/meta-analyses

Level II

- 4 studies

Findings

Reoperation McCormack's results (RCT, level II) demonstrate that for every three patients treated with plating as opposed to treatment with an IMN, one reoperation could be avoided.⁷ Chapman (RCT, level II) reported no difference, with 13% of patients having reoperations for IMN compared with 9% in the plating group.⁶ Changulani (RCT, level II) favors IMN over plating (RR 1.44, 95% CI 0.47, 4.44).¹⁴ A recent updated review by Heineman et al. (2010) indicates potential confounding in the analysis conducted in 2006, since Rodriguez-Merchan included 19 patients treated with retrograde flexible nails.¹⁵⁻¹⁷ However, there was a strong trend in favoring plates over IMN for risk of reoperation.^{16,17}

Nonunion Nonunion ranges from 5% to 13% for IMN compared with 4-13% for plating.^{6,7,14} In the three studies by Chapman, McCormack, and Changulani et al., when pooled, IMN and plating result in similar percentages of patients with nonunion (RR 1.1, 95% CI 0.4, 3.1).

Mean time to union Mean time to union was 6.3-9.8 weeks in the IMN group compared with 8.9-10.4 weeks in the plating group. McCormack reported no difference in time to union between IMN (9.8 weeks) and plating (10.4 weeks), $p = 0.664$,⁶ while Changulani showed a significant difference in mean time to union, 6.3 weeks in the IMN group compared with 8.9 weeks in the plating group ($p < 0.001$).¹⁴ The union rate was similar in both groups as reported in the meta-analyses.^{16,17}

Infection Infection rates range from 0% to 5% for IMN compared to 0-21% for plating. Chapman and McCormack show a decreased infection risk for IMN compared with plating;^{6,7} however, the difference was not significant in the

Changulani study, although infectious complications were higher in the plate fixation group (20.8% vs. 4.7%; RR 0.21, 95% CI 0.03, 1.7) where RR was calculable.¹⁴ While individual studies have shown a higher infection rate with plate fixation, meta-analyses results indicates that there are no significant differences between the two treatments.^{16,17}

Iatrogenic nerve injury Rates for nerve injury range from 4% to 15% for IMN compared with 0-4% for plating.^{6,7,14} Chapman and McCormack report a higher rate of nerve injury with IMN,^{6,7} although, when the data are pooled, the difference between IMN and plating is not significant (RR 3.4, 95% CI 0.7, 16).

Recommendations

- There was an increase in risk of reoperation with IMN, which was significant when data were pooled across studies [overall quality: moderate]
- Evidence from three RCTs with rigid nails suggests that treatment of acute humeral shaft fractures with IMN compared with dynamic compression plating leads to comparable results with respect to rates of nonunion, infection, and iatrogenic nerve injury [overall quality: moderate]
- A more recent meta-analysis performed which also included a subsequently published RCT¹⁸ suggests that the risk of a complication is lower with plate fixation compared to IMN

Summary of recommendations

- Functional fracture-bracing can be used following an initial 2 week period of immobilization in a plaster splint
- Angulation up to 10° can be tolerated and shortening should not exceed 2 cm
- Plate fixation and IMN can result in similar healing patterns at 16 weeks
- Antegrade and retrograde IMN can be inserted using either an antegrade or a retrograde approach
- IMN is associated with more shoulder pain and reduced range of motion. Both IMN and compression plating can achieve similar functional results
- IMN result in higher rates of reoperation and no differences between rates of nonunion, infection, or iatrogenic nerve injury when compared to compression plating
- Antegrade IMN has lower rate of nonunion and intra-operative complications
- Exploration is at 4-6 months if there is no resolution following a primary radial nerve palsy
- In patients with indications for earlier operative fixation, exploration of the nerve should be at the time of internal fixation

- Primary and secondary nerve palsies show no difference in recovery rate
- Biomechanical data shows potential benefits in using locked screw configurations in the plating of osteoporosis humeral fractures
- There was an increase in risk of reoperation with IMN, which was significant when data were pooled across studies
- Evidence from three RCTs with rigid nails suggests that treatment of acute humeral shaft fractures with IMN compared with dynamic compression plating leads to comparable results with respect to rates of nonunion, infection, and iatrogenic nerve injury
- A more recent meta-analysis performed which also included a subsequently published RCT suggests that the risk of a complication is lower with plate fixation compared to IMN

Conclusion

Evidence suggests comparable results between IMN and compression plating with respect to rates of nonunion, infection, and iatrogenic nerve injury. IMN patients have an increased risk of reoperation, with conflicting evidence concerning the mean time to union.

Distal Humerus Fractures

Aaron Nauth and Emil H. Schemitsch

St. Michael's Hospital, University of Toronto, Toronto, ON, Canada

Case scenario

An 86 year old female patient, who lives independently, presents to the Emergency Department after a fall from standing height on her right arm. She is complaining of pain in her right elbow. There are no open wounds and her limb is neurovascularly intact.

Relevant anatomy

Distal humerus fractures involve the supracondylar region of the humerus with or without extension to the articular surface. They are most commonly classified according to the OTA/AO classification system (Figure 43.1). In this classification system "A" designates an extra-articular fracture, "B" designates a partial articular fracture, and "C" indicates an intra-articular fracture in which the articular surface is completely dissociated from the shaft of the humerus. These three types are further subdivided using the numbers 1–3 to indicate increasing degrees of comminution.

Importance of the problem

Distal humerus fractures occur in adults with an estimated incidence of 5.7 per 100,000 per year, based on a United Kingdom study in 2003.¹ The authors reported a distribution of 38.7% type A fractures, 24.1% type B fractures, and 37.2% type C fractures based on the OTA/AO classification. These injuries occur in a bimodal distribution with an early peak in males aged 12–19 years who sustain a sport-

ing or motor vehicle accident, and a second peak in elderly women with osteoporotic bone who sustain a simple fall from standing height.

In a Finnish study based on the National Health Registry, the authors reported a threefold increase in the incidence of distal humerus fractures in women aged 60 years and older over their study period (11 per 100,000 in 1975 to 30 per 100,000 in 1995).² The authors concluded that the incidence of distal humerus fractures in elderly women is increasing rapidly and predicted an annual incidence of 52 per 100,000 in 2030.

These data indicate that although fractures of the distal humerus are rare, their incidence is increasing significantly. The dramatic increases reported in elderly female patients with potentially osteoporotic bone is of particular note, suggesting that fixation strategies for osteoporotic bone and possible joint replacement techniques, as well the management of osteoporotic disease itself, will play important roles in the future management of these injuries.

Top six questions

Diagnosis

1. What is the value of preoperative CT scanning in the assessment of distal humerus fractures?

Therapy

2. What is the optimal surgical approach for the fixation of distal humerus fractures?

3. What is the optimal fixation strategy for distal humerus fractures?

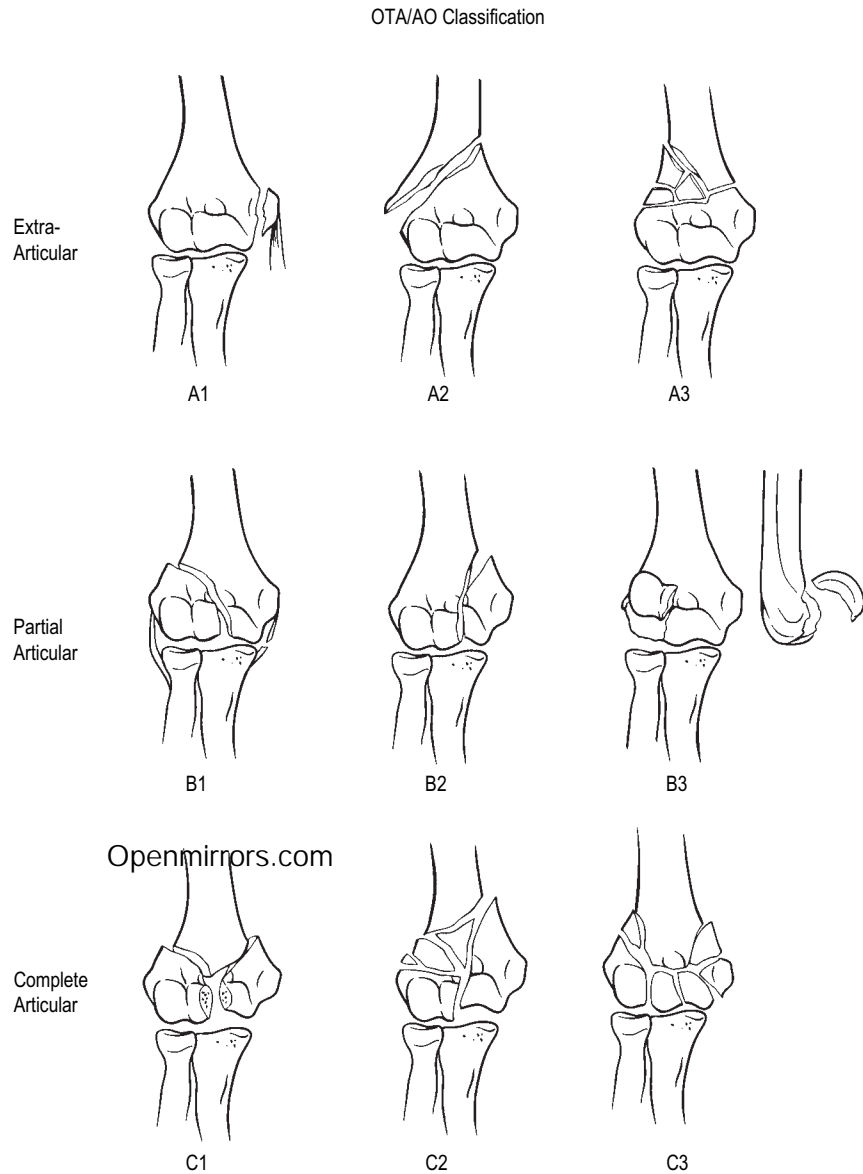

Figure 43.1 OTA/AO Classification of distal humerus fractures.

4. What is the evidence for transposition of the ulnar nerve?
5. Should heterotopic ossification prophylaxis be used following surgical fixation of distal humerus fractures?
6. What is the evidence for open reduction and internal fixation (ORIF) vs. total elbow arthroplasty (TEA) in elderly patients?

Finding the evidence

- Cochrane Database with search term “distal humerus fracture”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews: “distal humerus fracture”

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “distal humerus” AND “fractures” as well as “distal humerus” AND “imaging,” “internal fixation,” “non-operative,” “surgical approach,” “locking plates,” “ulnar nerve,” “heterotopic ossification,” “elbow arthroplasty”

- Manual search of AO Traumatline Database (<http://www.aofoundation.org>)

This search strategy was used for all of the questions discussed in this chapter.

Figure 43.2 Radiographs of an 86 year old female patient with a displaced intra-articular distal humerus fracture (OTA/AO Type C3).

Question 1: What is the value of preoperative CT scanning in the assessment of distal humerus fractures?

Case clarification

Radiographs are obtained of the patient's right elbow (Figure 43.2). They show a displaced C3 type distal humerus fracture with significant comminution. You consider the value of obtaining a CT scan for preoperative planning.

Relevance

Distal humerus fractures can be difficult to characterize and classify on the basis of plain radiographs. CT scanning is a readily available modality that has been shown to influence treatment decisions in multiple other articular fractures.^{3,4}

Current opinion

Most surgeons feel that CT scanning is useful for preoperative planning in distal humerus fractures that involve the articular surface, especially if articular comminution is evident on plain films.

Quality of the evidence

Level III

- 1 study⁵

Level IV

- 4 studies⁶⁻⁹

Findings

A single level III study compared the use of 3-D CT reconstructions to the use of 2-D CT and radiographs for the classification of distal humerus fractures and treatment decision-making.⁵ The authors reported increased interob-

server and intraobserver reliability for fracture classification with the use of 3-D CT, as well as increased intraobserver reliability for treatment decisions. The remainder of the literature consists of level IV case series that incorporated the use of CT, primarily for the evaluation of coronal shear type fractures of the distal humerus.

Recommendation

- CT scanning can be useful for improved reliability of fracture classification and guiding treatment decisions in the management of distal humerus fractures, particularly in the setting of articular comminution [overall quality: low]

Question 2: What is the optimal surgical approach for the fixation of distal humerus fractures?

Relevance

Numerous surgical approaches have been described for the fixation of distal humerus fractures. With the exception of approach strategies for coronal shear fractures, all of these involve a posterior skin incision with various strategies of working through, or around, the triceps. Described approaches include the triceps-splitting, olecranon osteotomy, triceps-reflecting (Bryan-Morrey), triceps-reflecting anconeus pedicle (TRAP), and paratricipital approaches.

Current opinion

Surgeon opinion regarding the optimal surgical approach to distal humerus fractures is widely divergent.

Quality of the evidence

Level III

- 4 studies¹⁰⁻¹³

Level IV

- 10 studies¹⁴⁻²³

Findings

Four level III studies retrospectively compared the triceps split approach and the olecranon osteotomy approach for the fixation of distal humerus fractures. Three of these studies showed no statistically significant differences between the approaches with regards to either objective elbow strength, range of motion, or functional outcome (n = 62 patients).^{10,11,13} One of these studies found an increased rate of reoperation with the olecranon osteotomy approach due to the need for olecranon hardware removal in 27% of patients.¹¹ Other level IV series of patients treated with olecranon osteotomy have reported rates of hardware removal ranging from 6% to 30% and nonunion of the olecranon osteotomy in 0-9% of patients.¹⁴⁻¹⁸ One level III study compared the two approaches for the fixation of

open distal humerus fractures and found better functional outcomes and a trend towards improved range of motion in the triceps split group (n = 26 patients).¹² The authors hypothesized that this effect was due to the fact that open fractures had a large tear in the triceps that was easily incorporated into the triceps-splitting approach. Multiple level IV studies have reported satisfactory results using the olecranon osteotomy,¹⁴⁻¹⁸ triceps-splitting,¹⁹ triceps-reflecting,^{20,21} and paratricipital^{22,23} approaches.

Recommendations

- The use of a triceps-splitting approach may lead to equivalent functional outcomes and a decreased need for reoperation when compared to an olecranon osteotomy [overall quality: low]
- A triceps-splitting approach is preferred over olecranon osteotomy for the treatment of open fractures of the distal humerus [overall quality: moderate]

Question 3: What is the optimal fixation strategy for distal humerus fractures?

Relevance

Since the introduction of Arbeitsgemeinschaft für Osteosynthesefragen (AO) techniques involving dual column plating for the fixation of distal humerus fractures in the 1970s, significant improvements in surgical outcomes have been observed. However, controversy remains regarding the position/orientation of plate fixation.

Locking plates have been shown to provide improved fixation in osteoporotic bone and improved outcomes when used in other periarticular fractures.²⁴⁻²⁶ The use of locking plates in distal humerus fractures remains controversial at present and the indications for their use in this setting are unclear.

Current opinion

Most surgeons agree that dual plate fixation is indicated for most distal humerus fractures; however, controversy exists with regard to plate configuration, with some authors recommending perpendicular plating and others recommending parallel plate fixation. Opinion among surgeons regarding the use of locking plates in the management of distal humerus fractures is highly divergent.

Quality of the evidence

Level II

- 1 study²⁷

Level III

- 2 studies^{28,29}

Level IV

- 20 studies³⁰⁻⁴⁹

Findings

Two level III studies retrospectively compared operative fixation with dual plates vs. minimal fixation with Kirschner (K)-wires or screws (n = 97 patients).^{28,29} Both studies reported significantly improved functional outcomes following plate fixation. One study showed an almost three times higher risk of a poor outcome with the use of K-wires/screws vs. plate fixation (RR = 2.8, 95% CI 1.5-5.1).²⁹

One level II study compared parallel plating to perpendicular plating in a prospective randomized fashion (n = 35 patients).²⁷ Although no statistically significant differences were found between the two treatment groups, there were two nonunions in the perpendicular plating group vs. no nonunions in the parallel plating group. This study may not have been sufficiently powered to detect a clinically significant difference in union rates. Multiple level IV series have reported satisfactory results with perpendicular plating techniques³⁰⁻³⁴ and parallel plating techniques.³⁵⁻⁴⁰

Several biomechanical studies have demonstrated that parallel plate configurations at 180° to each other are biomechanically superior to perpendicular plates when a gap model is used to simulate fracture comminution.⁴³⁻⁴⁵

Two clinical level IV studies have reported on the results of locked plating of distal humerus fractures (n = 52 patients).^{46,47} Pooled analysis showed good/excellent results in 79% of patients, with only a single case of implant failure.

Biomechanical studies have shown somewhat improved fixation of locking plates in models of osteoporotic or comminuted distal humerus fractures.^{43,48,49}

Recommendations

- Plate fixation is favored over screw/K-wire fixation for distal humerus fractures in adults [overall quality: moderate]
- All distal humerus fractures involving both columns should be treated with dual plate fixation in either a perpendicular or parallel configuration [overall quality: moderate]
- In severely comminuted or osteoporotic fractures, a parallel plate configuration, with plates on both columns at 180° to each other, should be considered [overall quality: low]
- There is currently insufficient evidence to recommend for or against the use of locking plates in distal humerus fractures [overall quality: very low]

Question 4: What is the evidence for transposition of the ulnar nerve?

Relevance

Distal humerus fractures are often complicated by injury to the ulnar nerve either due to the original injury or as a

result of surgical intervention. Controversy exists regarding the management of the ulnar nerve during surgical intervention, with some authors recommending routine anterior transposition and others recommending in-situ decompression alone.

Current opinion

Management of the ulnar nerve during the fixation of distal humerus fractures is controversial, with advocates both for and against routine anterior transposition of the ulnar nerve.

Quality of the evidence

Level II

- 1 study⁵⁰

Level IV

- 7 studies^{17,27,37,40,50-52}

Findings

A single level II study randomized patients with a distal humerus fracture and preoperative ulnar nerve symptoms to either anterior subcutaneous transposition or in situ decompression (n = 29 patients).⁵⁰ The results showed significantly improved outcomes in the transposed group, with complete nerve recovery in 12/15 transposed patients vs. 8/14 patients treated with decompression alone (p < 0.05).

Several level IV studies have reported rates of ulnar neuropathy from 0% to 12.5% with routine anterior subcutaneous transposition in patients whose ulnar nerves were normal preoperatively.^{17,27,37,40,50,51} Another level IV study reported on the 12–30 year follow-up of patients who had surgical treatment of a distal humerus fracture with no transposition of the ulnar nerve.⁵² Of the 30 patients evaluated, only one had symptoms of ulnar nerve dysfunction at the time of final follow-up.

Recommendations

- Anterior transposition of the ulnar nerve should be performed during the fixation of distal humerus fractures in all patients who exhibit preoperative ulnar nerve symptoms [overall quality: low]
- There is insufficient evidence to recommend for or against transposition of the ulnar nerve in patients with a distal humerus fracture who present with a normal neurological exam preoperatively [overall quality: very low]

Question 5: Should heterotopic ossification prophylaxis be used following surgical fixation of distal humerus fractures?

Relevance

Heterotopic ossification (HO) can cause significant limitations in range of motion and functional outcome when it

occurs following operative intervention for distal humerus fractures.

Current opinion

Opinion among surgeons regarding the indications for HO prophylaxis following operative fixation of a distal humerus fracture is mixed, with some surgeons favoring routine prophylaxis and others recommending the selective use of prophylaxis in high risk patients.

Quality of the evidence

Level III

- 1 study¹⁷

Level IV

- 8 studies^{27,36,37,40,53-56}

Findings

One level III study retrospectively reviewed the incidence of HO in two groups of operatively treated distal humerus fractures: one in which prophylaxis was not used, and another group which received routine prophylaxis in the form of 6 weeks of indomethacin (n = 23 patients).¹⁷ Forty-two percent of the patients without prophylaxis developed HO, whereas only 18% of the patients who received indomethacin developed HO. The difference between the groups was not significant, although the study was likely underpowered to detect a clinically significant difference in the occurrence of HO based on the number of patients evaluated.

Results of modern series of operative fixation of distal humerus fractures which have not used routine HO prophylaxis have reported rates of clinically significant HO from 0% to 21%.^{36,37,40,53-55} Pooled analysis of the data from these studies demonstrates an overall 8.6% rate of clinically symptomatic HO when routine prophylaxis is not used (n = 239 patients). Two recent level IV studies have reported on routine prophylaxis against HO in a series of distal humerus fractures treated operatively. One study used an initial dose of radiation therapy on postoperative day 1, followed by 2 weeks of indomethacin.²⁷ The authors reported a rate of clinically symptomatic HO of 2.9%, with a nonunion rate of 5.7% (n = 35 patients). The other study used 6 weeks of celecoxib (Celebrex) for routine prophylaxis and reported a 3.1% rate of clinically symptomatic HO (n = 32 patients).⁵⁶ No nonunions occurred in that study.

Risk factors that have been reported in the literature to significantly increase the risk of development of HO in association with a distal humerus fracture include central nervous system injury,⁵⁷ delay in surgical intervention,⁵⁵ surgery prior to definitive fixation,⁴⁰ and open fractures.⁴⁰

Recommendations

- There is insufficient evidence to recommend for or against routine prophylaxis against HO following opera-

tive fixation of distal humerus fractures [overall quality: very low]

- Prophylaxis should be considered in patients at particularly high risk for the development of HO, such as patients with associated injuries to the central nervous system, delays in surgical intervention, surgical procedures prior to definitive fixation, and open fractures [overall quality: low]
- There is insufficient evidence to recommend a specific regimen for HO prophylaxis in distal humerus fractures (3–6 weeks of a nonsteroidal anti-inflammatory (NSAID) medication, such as indomethacin or celecoxib, is a reasonable option) [overall quality: very low]

Question 6: What is the evidence for ORIF vs. TEA in elderly patients?

Case clarification

Given your patient's advanced age, low demand, the osteopenic appearance of her bones on radiographs, and the significant articular comminution of her fracture, you elect to perform a primary TEA (Figure 43.3).

Relevance

Distal humerus fractures with comminution of the articular surface can be difficult to manage, even in young patients with excellent bone quality. In elderly patients with poor bone quality and significant articular comminution, this challenge increases exponentially, and surgical outcomes have historically been poor in these patients. This has prompted many authors to investigate, and more recently advocate, the use of acute TEA in the management of distal humerus fractures in elderly patients.

Current opinion

Many surgeons feel that elderly patients with a distal humerus fracture that involves significant comminution of

the articular surface can be treated effectively with a constrained TEA.

Quality of the evidence

Level II

- 1 study⁵⁸

Level III

- 5 studies^{59–62}

Findings

A prospective, randomized, multicenter study (level II evidence) compared ORIF vs. TEA for displaced, intra-articular fractures of the distal humerus (OTA/AO type C) in patients over the age of 65 years ($n = 40$ patients).⁵⁸ The authors reported better functional outcomes in the TEA group vs. the ORIF group at 2 year follow-up. In addition there was a 25% rate of intraoperative conversion to TEA in the ORIF group due to extensive comminution and inability to achieve stable fixation.

Three level III studies compared ORIF vs. TEA, in a retrospective manner, in elderly patients with intra-articular distal humerus fractures ($n = 256$).^{59,60,63} Pooled analysis of the results suggests that TEA results in a higher proportion of patients experiencing a good/excellent functional outcome (89% in TEA vs. 76% in ORIF, $p = 0.036$). Complication rates did not differ significantly between the two groups.

One level III study retrospectively compared the outcome of acute TEA for distal humerus fractures vs. delayed TEA following failed ORIF or conservative treatment ($n = 32$ patients).⁶¹ The authors reported a high rate of good/excellent functional outcomes (82%) with no significant differences between the two treatment groups. However, the results showed trends towards increased rates of infection, nerve injury, and implant failure in the delayed treatment group, and the study was likely underpowered to detect clinically significant differences in the rates of these complications between groups.

A final level III study performed a systematic review of level IV studies assessing ORIF or TEA for distal humerus fractures in elderly patients published prior to 2003.⁶² Based on the eight studies identified, the authors reported equivalent outcomes between the two groups at less than 4 years follow-up ($n = 134$ patients).

Recommendation

- In elderly patients (>65 years) with displaced, intra-articular distal humerus fractures not amenable to stable internal fixation, acute TEA is preferred [overall quality: moderate]

Figure 43.3 Postoperative radiographs of the same patient treated with an acute total elbow arthroplasty.

Summary of recommendations

- CT scanning can be useful for improved reliability of fracture classification and guiding treatment decisions in

the management of distal humerus fractures, particularly in the setting of articular comminution

- The use of a triceps-splitting approach may lead to equivalent functional outcomes and a decreased need for reoperation when compared to an olecranon osteotomy
- A triceps-splitting approach is preferred over olecranon osteotomy for the treatment of open fractures of the distal humerus
- Plate fixation is favored over screw/K-wire fixation for distal humerus fractures in adults
- All distal humerus fractures involving both columns should be treated with dual plate fixation in either a perpendicular or parallel configuration
- In severely comminuted or osteoporotic fractures, a parallel plate configuration with plates on both columns at 180° to each other should be considered
- There is currently insufficient evidence to recommend for or against the use of locking plates in distal humerus fractures
- Anterior transposition of the ulnar nerve should be performed during the fixation of distal humerus fractures in all patients who exhibit preoperative ulnar nerve symptoms
- There is insufficient evidence to recommend for or against transposition of the ulnar nerve in patients with a distal humerus fracture who present with a normal neurological examination preoperatively
- There is insufficient evidence to recommend for or against routine prophylaxis against HO following operative fixation of distal humerus fractures
- Prophylaxis should be considered in patients at particularly high risk for the development of HO, such as patients with associated injuries to the central nervous system, delays in surgical intervention, surgical procedures prior to definitive fixation, and open fractures
- There is insufficient evidence to recommend a specific regimen for HO prophylaxis in distal humerus fractures (3–6 weeks of an NSAID medication, such as indomethacin or celecoxib, is a reasonable option)
- In elderly patients (>65 years) with displaced, intra-articular distal humerus fractures not amenable to stable internal fixation, acute TEA is preferred

Fracture-Dislocations of the Elbow

Reyhan A. Chaudhary, Maurice Tompack, and J. Whitcomb Pollock

University of Ottawa, Ottawa, ON, Canada

Case scenarios

Case 1

A 35 year old man presents to the Emergency Department after a downhill skiing injury. He is an otherwise healthy, right hand dominant, high school physical education teacher. On examination he has medial and lateral tenderness, swelling, and ecchymosis of his left elbow. Neurovascular examination is normal. Radiographs demonstrate a fracture-dislocation of the elbow (Figure 44.1).

Case 2

A 20 year old man presents to the Emergency Department after falling while climbing a 10 foot (3m) fence. He is an otherwise healthy active construction worker. On examination, he has tenderness, swelling and ecchymosis of his left elbow and a normal neurovascular examination. Radiographs reveal a fracture-dislocation of the elbow (Figure 44.2).

Importance of the problem

The incidence of elbow dislocations is approximately 6 in every 100,000 persons during their lifetime¹ and it is the second most commonly dislocated joint in the adult upper limb.² Dislocations constitute 10–25% of all injuries to the elbow³ and occur at a median age of 30 years.⁴ These injuries range from simple dislocation with ligamentous and musculotendinous damage to complex fracture-dislocations.

Relevant anatomy

The primary role of the elbow is to position and support the hand in space.^{5,6} Stability is derived from highly congruent joint surfaces and capsuloligamentous and musculotendinous soft tissue restraints.⁷ The elbow joint consists of three bony articulations: the ulnohumeral, radiocapitellar, and proximal radioulnar (PRUJ) joints.

Stability has both dynamic and static contributions. All muscles crossing the elbow joint contribute to dynamic stability. Static constraints consist of the ulnohumeral and radiocapitellar bony articulations, the medial collateral ligament (MCL), lateral collateral ligament (LCL), and the capsule. The primary stabilizers of the elbow joint are the coronoid, MCL, and LCL.^{2,8,9} The secondary constraints consist of the capsule, the radiocapitellar articulation, and the common extensor and flexor origins.^{2,8–10} The radial head is also a secondary valgus stabilizer⁸ while the coronoid is the primary stabilizer to varus stress^{11,12} and an important stabilizer to axial, posteromedial, and posterolateral rotatory forces.^{9,10,13}

The MCL originates from the anterior inferior base of the medial epicondyle^{13,14} and consists of three distinct bundles: anterior, posterior, and transverse.^{2,14} The anterior bundle, which inserts on to the sublime tubercle of the coronoid, is considered the most important ligamentous stabilizer to valgus stress, posteromedial instability, and internal rotation of the ulna.^{2,15–17}

The LCL consists of the lateral ulnar collateral ligament (LUCL), the radial collateral ligament (RCL), the annular ligament (AL), and the variably present accessory lateral collateral ligament.² The AL wraps around the radial head and neck and inserts on to the anterior and posterior

Figure 44.1 Case 1, preoperative AP and lateral radiograph of left elbow.

Figure 44.2 Case 2, preoperative radiographs of left elbow: (a) oblique, (b) lateral, (c) AP.

margins of the lesser sigmoid notch of the ulna.^{2,15} The RCL and LUCL both originate from the lateral epicondyle.^{2,15} The RCL blends with AL and LUCL inserts on to the crista supinatoris of the proximal ulna.^{2,18} The LCL is the primary soft tissue stabilizer to varus or posterolateral stress at the elbow.^{2,11,12,15–20}

Classification and mechanism of injury

Elbow dislocations have traditionally been classified based on the final resting position of the radius and ulna relative to the distal humerus.^{12,21} Dislocations are reported as anterior, divergent, posterior, posterolateral, posteromedial, and pure lateral. This classification provides very little information as to the treatment or prognosis.

O'Driscoll has described the “ring of instability” or the progressive disruption of the LUCL, the capsule, and finally the medial ulnar collateral ligament.²¹ O'Driscoll's classification consists of three stages (see box).

O'Driscoll's classification of elbow subluxation and dislocation

- *Stage 1* involves the disruption of the LUCL
- In *stage 2* the continued force disrupts the remaining lateral ligaments, and the anterior and posterior capsule
- *Stage 3* can involve partial disruption of the MCL (3a) or complete disruption of the MCL (3b).
- *Complete dislocation* is the last of three sequential stages of elbow instability

Figure 44.3 O'Driscoll's classification of coronoid fractures.

This chapter focuses on complex elbow dislocations, which by definition have associated fractures. Approximately 2–15% of patients with elbow dislocation have associated coronoid fractures.^{2,22} Traditionally coronoid fractures were classified according to the height of the coronoid involved.²³ O'Driscoll has recently classified coronoid fractures to include fractures in the sagittal plane (fractures of the anteromedial facet).²⁴ Type 1 is a tip fracture, type 2 is an anteromedial facet fracture and type 3 is a fracture through the base. Type 2 fractures are further subdivided based on anatomical location: subtype I involves the rim of the anteromedial facet; subtype II includes the rim and tip; and subtype III involves the rim and the sublime tubercle which provides attachment for the anterior bundle of the MCL²⁴ (Figure 44.3). Disruption of the LCL and posterior bundle of the MCL are often associated with these injuries.²⁴

Top seven questions

Diagnosis

1. What methods can be used to avoid missing the diagnosis of an anteromedial coronoid (AMC) fracture?

Therapy

2. What is the role for nonoperative vs. operative treatment of complex fracture-dislocations of the elbow?
3. When is operative fixation necessary and what the fixation methods are available for AMC fracture management?
4. In the surgical treatment of terrible triad injuries, is it necessary to address and repair the MCL?
5. When faced with a fractured radial head in the setting of a terrible triad elbow injury, is it better to perform open

reduction and internal fixation (ORIF) of the fractured radial head or radial head arthroplasty?

Prognosis

6. What complications are associated with operative and nonoperative treatment of AMC fractures?
7. What functional outcomes are reported for the operative treatment of terrible triad elbow injuries?

Question 1: What methods can be used to avoid missing the diagnosis of an AMC fracture?

Case 1 clarification

An orthopedic surgeon reviews the preoperative orthogonal elbow radiographs provided (see Figure 44.1) and diagnoses a coronoid fracture. The surgeon classifies this as being a type 2 coronoid fracture according to O'Driscoll's classification system²⁴ (see Figure 44.3) and wonders if it represents a subtype III involving the rim and sublime tubercle. Will a CT scan aid in the proper classification and affect treatment of this fracture?

Case 2 clarification

An orthopedic surgeon reviews the preoperative orthogonal elbow radiographs provided (see Figure 44.2) and diagnoses a terrible triad variant injury. The coronoid fracture is complex and is thought to include a large coronal fracture with extension into the anteromedial facet and possibly the sublime tubercle. The radial head fracture is thought to include at least three main fracture fragments. Will a CT scan aid in the proper classification and subsequent treatment choice for this injury?

Figure 44.4 Case 2, preoperative CT scan of left elbow: sagittal and coronal cuts.

Relevance

Will more detailed cross-sectional elbow imaging improve treatment and prognosis of this injury? (See Figures 44.4 and 44.5 for CT scan images of case 2.)

Current opinion

Surgeons use CT to better characterize complex elbow fractures to facilitate preoperative planning.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords “terrible triad” AND “imaging,” “coronoid fracture” AND “imaging,” and “radial head fracture” AND “imaging”
- Bibliography of eligible articles

It is recommended to include only the most recent studies in decision-making, as CT imaging protocols have become significantly more advanced over the last few years.

Quality of the evidence

Level III There are limited studies investigating the interobserver/intraobserver agreement between elbow radiographs vs. elbow CT scan on the classification, diagnosis, and treatment of coronoid fractures. However, most experts would agree that a CT scan better evaluates the osseous pattern of complex elbow fractures.

A prospective diagnostic study²⁵ tested the hypothesis that three-dimensional (3-D) CT reconstructions improve interobserver agreement on the classification and treatment of coronoid fractures when compared to 2-D CT using kappa multirater measure statistics. Twenty-nine orthopedic surgeons evaluated 10 coronoid fractures on 2 occasions, first with radiographs and 2-dimensional CT and then with radiographs and 3-DCT, separated by a minimum of 2 weeks.²⁵ Three-dimensional CT improved interobserver agreement in Regan and Morrey’s classification²³ ($\kappa_{3-D} = 0.51$ vs. $\kappa_{2-D} = 0.40$; $p < 0.001$) and O’Driscoll et al.’s classifications²⁴ ($\kappa_{3-D} = 0.48$ vs. $\kappa_{2-D} = 0.42$; $p = 0.009$).²⁵

Figure 44.5 Case 2, preoperative 3-D CT reconstructions of left elbow.

There were trends toward better reliability for 3-D reconstruction in recognition of coronoid tip fractures ($\kappa_{3-D} = 0.19$, $\kappa_{2-D} = 0.03$; $p = 0.268$), comminution ($\kappa_{3-D} = 0.41$ vs. $\kappa_{2-D} = 0.29$; $p = 0.133$), and impacted fragments ($\kappa_{3-D} = 0.39$ vs. $\kappa_{2-D} = 0.27$; $p = 0.094$), and in surgeons' opinions on the need for something other than screw and/or plate fixation ($\kappa_{3-D} = 0.31$ vs. $\kappa_{2-D} = 0.15$; $p = 0.138$).²⁵ Interobserver agreement on treatment approach was better with 2-D CT ($\kappa_{3-D} = 0.27$, $\kappa_{2-D} = 0.32$; $p = 0.015$).²⁵

Level IV: expert opinion radiology Doornberg et al.¹⁸ investigated the interobserver/intraobserver agreement of the coronoid fracture fragment height using elbow CT scan on the classification of coronoid fractures in terrible triad injuries. They examined 3-D CT scans in 13 patients with a terrible triad injury. There were 10 men and 3 women with an average age of 50 years (range 25–73 years). Power analysis indicated that a total sample size of 13 elbows would provide 80% power to detect differences of 1.0mm with respect to intraobserver and interobserver reliability.¹⁸ Pearson correlations for intraobserver agreement were $r = 0.95$ and $r = 0.97$ for coronoid height and $r = 0.94$ and $r = 0.99$ for fracture fragment height. For interobserver reliability the correlation was $r = 0.94$ for coronoid height and $r = 0.94$ for coronoid fracture fragment height (all $p < 0.001$).¹⁸ The total height of the coronoid process of the ulna averaged 19mm (range 12–25mm). The average height of the coronoid fracture fragment was 7mm (range 3–12mm). This corresponds to an average of 35% of the total height of the coronoid process (range 19%–59%).¹⁸

In terms of the coronoid fracture component of a terrible triad injury, the prospective diagnostic study highlighted in Question 1 on AMC fractures is relevant.²⁵

Guillon et al.²⁶ quantitatively measured the surface 3-D topography of radial head fractures with CT combined with computer analysis software. They analyzed 46 patients with radial head fractures and found that their technique could better qualify the extent of radial head fractures. No interobserver/intraobserver agreement was conducted in this study, nor was the technique compared to traditional elbow radiograph or CT interpretation.

Haapamaki et al.²⁷ hypothesized that CT of elbow fractures would improve fracture identification and fracture site of origin compared to plain radiographs. A total of 65 fractures and 3 main fracture types were established: 16 (25%) ulnar coronoid process fractures, 13 (20%) radial head fractures, and 12 (18%) humeral supracondylar fractures.²⁷ CT of the elbow revealed 13 occult fractures in the elbow joint compared to primary radiography.²⁷ In four patients (7%) a displaced fracture fragment was detected in primary radiography, but the origin of the fragment was unclear.²⁷ In all four cases, CT revealed the origin of the fragment.²⁷

Recommendations

- CT imaging improves the reliability of classification of coronoid fractures [overall quality: moderate]
- 3-D CT improves the reliability of classification over 2-D CT [overall quality: moderate]
- 3-D CT may improve the reliability of classifying radial head fractures [overall quality: low]

- Radiography remains the primary imaging modality in elbow trauma, but in complex fracture patterns CT is a recommended complementary radiographic examination [overall quality: moderate]
- It is not yet known whether more reliable classification leads to more accurate classification, affects surgical management, or improves outcomes.

Question 2: What is the role for nonoperative vs. operative treatment of complex fracture-dislocations of the elbow?

Cases 1 and 2 clarification

In both cases the AMC fracture is displaced. What fractures influences the decision between operative vs. nonoperative treatment.

Relevance

The indications for operative treatment for AMC and terrible triad injuries are incompletely defined.

Current opinion

The decision regarding optimal treatment, indications, and type of surgical fixation is unknown and based on expert opinion.

- Bibliography of eligible articles

Quality of the evidence

Level III and IV Dornberg and Ring reported a retrospective case series of 18 consecutive patients with AMC fractures;²⁸ 15 patients were treated operatively and 3 were treated nonoperatively. At 26 months mean follow-up, all patients (11) with anatomical secure fixation of the AMC achieved good to excellent elbow function. In contrast, all six patients with malalignment of their AMC facets developed early post-traumatic arthrosis and had only a fair or poor result according to the system of Broberg and Morrey.²⁸ Finally, seven of nine patients with limited treatment of the coronoid fracture had problems with elbow stability.²⁸

Pollock et al. biomechanically tested the stability of 10 cadaver elbows under varus and valgus gravitational

loading with simulated AMC fractures (subtypes I, II, and III).¹⁰ They demonstrated that the size of the anteromedial facet fracture and the presence of a concomitant LCL injury appear to be important determinants of the need for ORIF. In the varus position, the kinematics of 2.5mm subtype I fractures with the LCL repaired were similar to those of the intact elbow. However, 5mm fractures demonstrated a mean of $6.2 \pm 4.5^\circ$ of internal rotation compared with a mean of $3.3 \pm 3.1^\circ$ of external rotation in the intact elbow ($p < 0.05$). In the varus position, subtype II 2.5mm fractures with the LCL repaired demonstrated increased internal rotation (mean $7.0 \pm 4.5^\circ$; $p < 0.005$). Subtype II 5mm fractures demonstrated instability in both the varus and valgus positions ($p < 0.05$). Subtype III fractures with the LCL repaired were unstable in all three testing positions ($p < 0.05$). This study suggests that the size of the coronoid fracture fragment affects elbow kinematics, particularly with varus stress. The study demonstrated that even small AMC fractures affect elbow kinematics. The authors suggested that internal fixation of AMC facet fractures larger than 2.5mm should be considered and that LCL repair alone should not be expected to restore kinematics in the majority of patients with this injury. Only small O'Driscoll type 2 (subtype I) fractures, with an intact MCL, can be treated with isolated LCL repair with a strict rehabilitation protocol.

A retrospective cohort study investigated the effect of delayed operative treatment (initial period of nonoperative treatment) on elbow function of patients with a terrible triad injuries.²⁹ Acute terrible triad patients (18) who had surgery an average of 6 days after injury were compared with patients who had delayed operative treatment (14) an average of 7 weeks after injury. The authors concluded that stability and strength were restored with both acute and subacute treatment, but earlier treatment is more straightforward and is associated with a better flexion arc (116° in the acute cohort and 93° in the subacute cohort).²⁹ Broberg and Morrey scores were comparable between cohorts (90 vs. 87 points).²⁹

Finally, a study by Ring et al.³⁰ looked at 11 patients with a terrible triad injury who were evaluated after a minimum of 2 years. None of these patients had surgery on their coronoid fractures. The radial head fracture component of this injury was repaired in five patients, the radial head was resected in four, and the LCL was repaired in only three patients. All 11 patients returned for clinical examination, functional evaluation, and radiographs. Seven elbows redislocated in a splint after manipulative reduction.³⁰ Five, including all four treated with resection of the radial head, redislocated after operative treatment. At the time of final follow-up, three patients were considered to have a failure of the initial treatment. One of them had recurrent instability, which was treated with a total elbow arthroplasty after multiple unsuccessful operations; one had severe arthrosis

and instability resembling neuropathic arthropathy; and one had an elbow flexion contracture and proximal radioulnar synostosis requiring reconstructive surgery.³⁰ The remaining eight patients, who were evaluated at an average of 7 years after injury, had an average of 92° (range 40–130°) of ulnohumeral motion and 126° (range 40–170°) of forearm rotation. The average Broberg and Morrey functional score was 76 points (range 34–98 points), with two results rated as excellent, two as good, three as fair, and one as poor.³⁰ Overall, the result of treatment was rated as unsatisfactory for 7 of the 11 patients. All four patients with a satisfactory result had retained the radial head, and two had undergone repair of the LCL. Of the 10 patients who did not go on to have a total elbow arthroplasty, 7 had radiographic signs of advanced ulnohumeral arthropathy.³⁰ Ulnohumeral arthropathy was less severe in those patients who had internal fixation of their radial head rather than surgical excision.³⁰

Recommendations

There is evidence to suggest that operative treatment will produce consistently better outcomes for displaced AMC fractures than nonoperative treatment. Further clinical studies are needed to determine patient outcomes following operative treatment and the effectiveness of internal fixation of these fractures.

There is a general lack of evidence with regards to nonoperative treatment of terrible triad injuries. This lack of literature partially reflects the fact that these elbow injuries have significant instability requiring surgical management.

- A biomechanical study suggests that nonoperative treatment of a displaced coronoid fracture fragment larger than 2.5mm will affect elbow kinematics [overall quality: moderate]
- Nonoperative treatment of terrible triad elbow fracture-dislocations can be attempted in minimally displaced, well-aligned fractures; however, parameters for this choice of treatment need to be further ironed out [overall quality: low]
- The results of early surgical treatment of terrible triad elbow injuries are superior to delayed. However, delayed fixation can still achieve good results [overall quality: moderate]
- Failure to repair the coronoid and/or the LCL may result in unsatisfactory patient outcomes following operative treatment for this injury [overall quality: low]

Question 3: When is operative fixation necessary and what fixation methods are available for AMC fracture management?

Case clarification

Radiographs and 2-D and 3D-CT show a type 2 subtype III AMC fracture in case 1 (see Figure 44.1) and a complex transolecranon type 2 subtype III coronoid fracture involv-

ing the rim, tip, and sublime tubercle in case 2 (see Figures 44.4 and 44.5). Should these patients undergo surgical management? Furthermore, if surgery is performed, what type of internal fixation is optimal for these fractures?

Relevance

Difficulties associated with loss of fixation, nonunion, malunion can potentially lead to poor functional outcomes such as elbow arthropathy.

Current opinion

There is a lack of consensus regarding the optimal internal fixation: sutures, Kirschner wires, screws, or buttress plate fixation have all been suggested.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews, using search term: "coronoid fracture"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords "coronoid fracture," as well as "coronoid fracture" AND "internal fixation" or "operative treatment"
- Bibliography of eligible articles

Quality of the evidence

Level IV—biomechanical study Although not specific to AMC fractures, a biomechanical study by Moon et al. compared the stability of coronoid fractures internally fixated with a 2.7mm cortical screw inserted in the anteroposterior (AP) direction with the stability of a screw inserted in the posteroanterior (PA) direction.³¹ They examined 11 pairs of fresh-frozen cadaveric ulnas and simulated a type II coronal coronoid fracture in these elbows via an osteotomy. This study found that PA screw placement yielded greater strength and stiffness of fixation than AP placement. The mean load to failure was 184N in the PA screw group and 131 N in the AP screw group ($p < 0.05$).³¹ The mean stiffness was 106N/mm with PA screws and 76N/mm with AP screws ($p < 0.05$).³¹ These differences were statistically significant despite the fact that the screw insertion torque was similar in the PA screw (0.27Nm) and the AP screw (0.25 Nm) ($p = 0.2$).³¹

Recommendation

There is insufficient clinical evidence from the literature to determine the preferred (operative) intervention in patients with AMC fractures. Biomechanical studies suggest that a PA screw is preferred to an AP screw when screw fixation is used for coronal fractures of the coronoid. There are no studies comparing the fixation options for AMC fracture subtypes which could include sutures, screws, Kirschner wires, plate, or combinations depending on the size and fracture pattern.

• Regardless of fixation used, biomechanical studies suggest that repair of the LCL is critical with this type of injury and ORIF should be performed when the size of the anteromedial facet fracture is greater than 2.5 mm.¹⁰

Question 4: In the surgical treatment of terrible triad injuries, is it necessary to address and repair the MCL?

Case 2 clarification

Radiographs and 2-D and 3D-CT demonstrate a variant terrible triad fracture-dislocation injury to the elbow. Both the patient and surgeon elect operative treatment. When should the MCL ligament be repaired?

Relevance

Surgeons must decide when MCL repair is necessary to provide adequate stability to allow early postoperative mobilization

Current opinion

There is a lack of consensus regarding when a torn MCL should be repaired in the setting of a terrible triad injury. Some surgeons believe that the MCL should be addressed if the elbow still demonstrates instability following surgery to the radial head, coronoid, and LCL.³²

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews, using search term: "terrible triad"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords "terrible triad," "terrible triad" AND "medial collateral ligament," "terrible triad" AND "MCL," "elbow fracture-dislocation" AND "medial collateral ligament," as well as "elbow fracture-dislocation" AND "MCL"
- Bibliography of eligible articles

Quality of the evidence

Level III Forthman et al.³³ reviewed the functional outcomes obtained after not repairing the MCL of 34 patients who had suffered an elbow dislocation with an intra-articular fracture. They hypothesized that it was unnecessary to repair the MCL if a patient's fracture and LCL were properly repaired. Of the 34 patients included in this study, 22 had a terrible triad injury. After a mean follow-up of 32 months, the authors noted that one patient with a terrible triad injury had postoperative instability related to non-compliance. Patients with terrible triad injuries had an average of 117° of ulnohumeral motion and 137° forearm rotation.³³ Seventeen of 22 patients (77%) had good or excellent results.³³

A second study, by Jeong et al.,³⁴ retrospectively evaluated the functional outcomes following surgical treatment of terrible triad injuries, where all damaged medial structures were repaired. They found that concentric elbow stability was restored in all 13 patients with a mean follow-up of 25 months.³⁴ The flexion-extension arc of the elbow averaged 128° and forearm rotation averaged 134.6°.³⁴ The mean Mayo Elbow Performance Score was 95 points (range 85–100), which corresponded to 10 excellent results and 3 good results.³⁴

Finally, a biomechanical study by Pollock et al.³⁵ evaluated the role of type II coronoid fracture fixation and collateral ligament repair in complex elbow fracture/dislocations. They submitted six fresh-frozen cadaver arms to passive varus and valgus and simulated active vertical motion. Varus/valgus angle and internal/external rotation were measured with the coronoid intact, with 50% removed, and after ORIF. Testing was performed with the collateral ligaments detached and repaired.³⁵ The results of this study showed that the vertical stability of the elbows were normal when both the collateral ligaments were repaired, regardless of the state of the coronoid. Elbow kinematics were altered with a repaired LCL, incompetent MCL, and type II coronoid fractures ($p < 0.05$).³⁵ On the basis of these results, the authors suggested that repair of type II coronoid fractures and injured collateral ligaments should be performed whenever possible.³⁵

Recommendations

For the terrible triad injury:

- It appears that MCL repair is not always necessary to obtain elbow stability in this injury pattern. Clinical studies with longer follow-up are required [overall quality: low-moderate]
- Good elbow functional outcomes can be obtained whether or not the MCL is repaired in the surgical management of this injury. Specific rehabilitation protocols should be followed and further clinical studies with longer follow-up are required [overall quality: moderate]
- If instability persists, after repair of the radial head, coronoid and LCL, repair of the MCL should be considered.

Question 5: When faced with a fractured radial head in the setting of a terrible triad elbow injury, is it better to perform ORIF of the fractured radial head or radial head arthroplasty?

Case 2 clarification

Radiographs and 2-D and 3-D CT show a three-fragment radial head fracture associated with this terrible triad variant elbow injury. The patient and surgeon elect operative treatment. Should the surgeon perform ORIF or radial head arthroplasty?

Relevance

Difficulties associated with loss of fixation, nonunion, and malunion following ORIF of radial head fractures associated with terrible triad elbow injuries can potentially lead to poor functional outcomes. Similarly, radial head arthroplasty is not without its own set of postoperative problems and complications.

Current opinion

There is a lack of consensus regarding the optimal treatment of radial head fractures in the setting of a terrible triad elbow injury. Most authors would agree that a stable radial head (native or arthroplasty) is required to obtain stability.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/ systematic reviews, using searchterm: "terrible triad"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords "terrible triad," "terrible triad" AND "radial head fractures," "terrible triad" AND "Mason fractures," "elbow fracture-dislocation" AND "radial head fractures," as well as "elbow fracture-dislocation" AND "Mason fractures"
- Bibliography of eligible articles

Quality of the evidence

Level III Winter et al.³⁶ followed 13 consecutive terrible triad patients treated with radial head arthroplasty. At 25 months, all elbows were stable and 84% of the patients were satisfied with an average elbow flexion of 131° (range 110–140°),

average elbow extension of -11° (range -30 to 0°), average pronation of 72° (range 40 – 80°), and average supination of 70° (range 50 – 80°).³⁶ The grip strength averaged 75% of that of the noninjured side (range 50–105%).³⁶

Recommendation

There is insufficient clinical evidence to determine the preferred (operative) intervention in patients with radial head fractures in the setting of terrible triad elbow injuries. Patients with this injury pattern can do well functionally with ORIF or arthroplasty of their radial head. Isolated Mason type II radial head fractures can do well with conservative management when there is 2–5 mm of fracture displacement.³⁷ There is also evidence suggesting that Mason Type-III fractures with four or more fragments function poorly following ORIF and may benefit from radial head arthroplasty at the initial surgical sitting.³⁸

Question 6: What complications are associated with operative and nonoperative treatment of AMC fractures?**Cases 1 and 2 clarification**

The patient and surgeon elect operative treatment. ORIF is performed through a posterior incision and deep Taylor approach. The LCL was repaired in both patients. Radiographs illustrate the internal fixation used (see Figures 44.6 for postoperative radiographs of case 1, and Figures 44.7 and 44.8 for postoperative radiographs of case 2). What are the potential complications?

The patient in case 2 goes on to complain of hardware prominence and elbow stiffness at 6 months postoperatively. He undergoes hardware removal and open release

Openmirrors.com

Figure 44.6 Case 1, postoperative radiographs of left elbow following ORIF of the AMC and the radial head and LCL repair.

Figure 44.7 Case 2, immediate postoperative radiographs of the left elbow (following ORIF of the left elbow).

Figure 44.8 Case 2, postoperative radiographs of the left elbow taken at the 3 month postoperative follow-up patient visit.

of their elbow contracture (see Figure 44.9 for 9 month postoperative radiographs).

Relevance

Complications can impair a patient's postoperative recovery and can potentially worsen functional outcome following surgery.

Current opinion

Postoperative complications following AMC fracture fixation can include, but are not limited to, infection, bleeding, malunion, nonunion, symptomatic hardware, failure of

fixation, nerve injury, arthrosis, elbow contracture, and heterotopic ossification.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/) clinical queries search/systematic reviews, using search term: "coronoid fracture"
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) sensitivity search using keywords "coronoid fracture," "coronoid fracture" AND "complication," and "anteromedial coronoid" AND "complication"
- Bibliography of eligible articles

Quality of the evidence

Level III: therapeutic Many studies in the literature can be found highlighting the long-term complications from both operative and nonoperative treatment of elbow dislocations with and without coronoid fractures. Despite this abundant literature, there is a lack of data on complications relating specifically to AMC fractures.

The study highlighted in Question 3 includes some data on complications related to AMC fractures. This case series examined 18 consecutive patients with AMC fractures,²⁸ 15 of whom were treated operatively and 3 were treated nonoperatively. At 26 months mean follow-up, Dornberg and Ring reported good to excellent elbow function in all patients (11) when anatomic secure fixation of AMC was achieved. These authors also reported on six patients who had malalignment of their AMC facets, because either their anteromedial facet fracture was not specifically treated (four patients) or because there was loss of anatomic fracture fixation (two patients). All six of these patients had development of arthrosis due to varus posteromedial subluxation of their elbow and had a fair or poor result according to the system of Broberg and Morrey.²⁸

Figure 44.9 Case 2, postoperative radiographs of the left elbow taken 9 months after the initial surgery. These radiographs were taken postoperatively following a second surgery where a partial hardware removal was performed as well as an open soft tissue contracture release.

Recommendation

There is insufficient clinical evidence from the literature on AMC fractures to highlight the complications associated with the treatment of this injury. Complications can be extrapolated from the literature on other complex elbow fracture-dislocations. Common complications following treatment for terrible triad injuries include infection, malunion, nonunion, elbow instability, elbow stiffness, heterotopic ossification, hardware-related problems, and ulnar neuropathy.^{21,32,33,39,40} Pugh et al. quoted a 24% complication rate using a standardized surgical protocol to treat 34 terrible triad elbow injuries with a mean follow-up of 34 months.⁴¹

Question 7: What functional outcomes are reported for the operative treatment of terrible triad elbow injuries?

Case 2 clarification

The patient and surgeon elect operative treatment. Radiographs illustrate the internal fixation used (see Figures 44.7 and 44.8). What functional outcomes can we expect following operative treatment of terrible triad elbow fracture-dislocations?

Relevance

The type of operative treatment for terrible triad injuries is influenced by patient outcomes.

Current opinion

Many surgeons advocate specific surgical protocols or algorithms to treat these complex elbow fracture-dislocations.

Quality of the evidence

Level III and level IV Ring et al.³⁰ evaluated 11 patients with a terrible triad injuries after a minimum of 2 years. None of these patients underwent fixation of their coronoid fractures. The radial head fracture was repaired in five patients, and the radial head was resected in four; the LCL was repaired in only three patients. All 11 patients returned for follow-up clinical examination, functional evaluation, and radiographs. Of the 11 patients with follow-up, 7 elbows redislocated.³⁰ Five, including all four treated with resection of the radial head, redislocated after operative treatment. At final follow-up, three patients were considered to have a failure of the initial treatment. One of them had recurrent instability, which was treated with a total elbow arthroplasty after multiple unsuccessful operations; one had severe arthrosis and instability resembling neuropathic arthropathy; and one had an elbow flexion contracture and proximal radioulnar synostosis requiring reconstructive surgery.³⁰ The remaining eight patients, who were evaluated at an average of 7 years after injury, had an average of 92° (range 40–130°) of ulnohumeral motion and 126° (range 40–170°) of forearm rotation.³⁰ The average Broberg

and Morrey functional score was 76 points (range 34–98 points), with two results rated as excellent, two as good, three as fair, and one as poor.³⁰ Overall, the result of treatment was rated as unsatisfactory for 7 of the 11 patients.³⁰ All four patients with a satisfactory result had retained the radial head, and two had undergone repair of the LCL. Seven patients had radiographic signs of advanced ulnohumeral arthrosis.³⁰ Ulnohumeral arthrosis was less severe in those patients who had internal fixation of their radial head rather than surgical excision.³⁰

Pugh et al.⁴¹ reviewed the results of an operative treatment algorithm performed in 36 consecutive patients with a terrible triad elbow injury. Mean follow-up was 34 months. They found a flexion-extension arc of $112 \pm 11^\circ$ and forearm rotation averaging $136 \pm 16^\circ$. The mean Mayo Elbow Performance Score was 88 points (range 45–100 points), which corresponded to 15 excellent results, 13 good results, 7 fair results, and 1 poor result.⁴¹ Concentric stability was restored to 34 elbows.⁴¹ Approximately 25% of patients had a complication following surgery. Eight patients had complications requiring a reoperation: two had a synostosis; one, recurrent instability; four, hardware removal and elbow release; and one, a wound infection.⁴¹

Zeiders et al.⁴² reported on 32 patients who underwent operative treatment for their terrible triad injury. All patients had repair of the coronoid-brachialis complex.⁴² The radial head was noted to be intact in six elbows. The radial head was successfully reconstructed in 7 of 13 cases in which reconstruction was attempted, and it was replaced in 19 cases.⁴² A lateral repair alone was performed in 18 cases, a medial repair was performed in 2 cases, and a combined medial and lateral repair was performed in 12 cases.⁴² Twenty-one elbows required protection in a hinged external fixator. After a mean follow-up of 3 years, all 32 elbows had a functional arc of motion from 30° to 130° .⁴² The mean extension loss was 12° (range 0 – 20°), the mean flexion loss was 14° (range 0 – 20°), and a full range of motion was exhibited by three patients.⁴² The average DASH score was 23 (range 19–28).⁴² Three patients developed heterotopic ossification as a complication.

Another study by Chemama et al.⁴³ reported on 23 terrible triad injuries in 22 patients. ORIF of the radial head was performed in 13 cases and arthroplasty in 4 cases. The coronoid fracture was treated with ORIF in 10 cases. All torn ligaments were repaired which included 19 LCL repairs and 6 MCL repairs.⁴³ Of these 22 patients, 13 patients (14 elbows) had a mean follow-up of 63 months.⁴³ All patients had a stable elbow joint and 90% of patients reported mild or no elbow pain. The arc of extension-flexion ranged from 18° to 127° , while the average pronation-supination arc was 134° .⁴³ The mean Mayo Elbow Performance Score was 87. Only one patient developed symptomatic osteoarthritis at 8 years.⁴³

Chen et al.⁴⁴ retrospectively evaluated the functional outcomes of operative management of terrible triad injuries in 10 patients with a mean follow-up of 24.9 months. These authors used a similar surgical approach. They fixed the coronoid and radial head and repaired the anterior capsule and LCL. Repair of the MCL along with a mobile-hinged external fixation was used in three patients. Elbow range of motion was measured at 6 months. The mean flexion-extension arc was 106.5° (range 85 – 130°), and the mean pronation-supination arc was 138° (range 100 – 160°).⁴⁴ The Hospital for Special Surgery Total Elbow Scoring System was excellent in four cases, good in four cases, and fair in two cases.⁴⁴ Complications included one radial nerve injury, six patients who developed heterotopic ossification, and one patient who developed radiographic signs of subluxation.⁴⁴

Finally, Xun et al. retrospectively evaluated the functional outcomes after operative management of terrible triad injuries in 9 patients with a mean follow-up of 31 ± 6 months.⁴⁵ These authors used a similar surgical approach to that of previous authors. The coronoid and radial head were fixed, and the LCL and anterior capsule were repaired. If there was residual valgus instability the MCL was repaired. At 3 months follow-up, the mean flexion and extension arch was $(102 \pm 3)^\circ$ (range 80 – 110°), and the mean pronation and supination arch of the forearm was $(135 \pm 6)^\circ$ (range 100 – 150°).⁴⁵ According to the Mayo Elbow Scoring System, the results were excellent in five cases, good in three cases, and fair in one case. Complications included heterotopic ossification in three patients.⁴⁵

Recommendation

- There is insufficient clinical evidence from the literature to state that a specific surgical protocol is better than another. However, there is sufficient evidence to suggest that a systematic approach to the operative treatment of terrible triad injuries is important and obtains good functional results [overall quality: moderate]

Summary of recommendations

- It is not yet known whether more reliable classification leads to more accurate classification, affects surgical management, or improves outcomes
- CT imaging improves the reliability of classification of coronoid fractures
- 3-D CT improves the reliability of classification over 2-D CT and may improve the reliability of classifying radial head fractures
- Radiography remains the primary imaging modality in elbow trauma, but in complex fracture patterns CT is a recommended complementary radiographic examination
- Biomechanical studies suggest that nonoperative treatment of a displaced coronoid fracture fragment larger than 2.5 mm will affect elbow kinematics

- Nonoperative treatment of terrible triad elbow fracture-dislocations can be attempted in minimally displaced, well-aligned fractures; however, parameters for this choice of treatment need to be further ironed out
- The results of early surgical treatment of terrible triad elbow injuries are superior to delayed. However, delayed fixation can still achieve good results
- Failure to repair the coronoid and/or the LCL may result in unsatisfactory patient outcomes following operative treatment for this injury
- Repair of the LCL is critical with this type of injury and ORIF should be performed when the size of the anteromedial facet fracture is greater than 2.5 mm
- It appears that MCL repair is not always necessary to obtain elbow stability in terrible triad injury. Clinical studies with longer follow-up are required
- Good elbow functional outcomes can be obtained whether or not the MCL is repaired in the surgical management of terrible triad injury. Specific rehabilitation protocols should be followed and further clinical studies with longer follow-up are required
- If instability persists, after repair of the radial head, coronoid and LCL, repair of the MCL should be considered
- Common complications following treatment for terrible triad injuries include infection, malunion, nonunion, elbow instability, elbow stiffness, heterotopic ossification, hardware-related problems, and ulnar neuropathy
- A systematic approach to the operative treatment of terrible triad injuries is important and obtains good functional results

Radial Head Fractures

Andrea S. Bauer and David Ring

Massachusetts General Hospital, Boston, MA, USA

Case scenario

A 36-year-old woman is brought to the Emergency Department with elbow pain after a fall onto her outstretched left hand while skating. On examination, her range of elbow motion is limited due to pain, and she has tenderness over the radial head.

Relevant anatomy

Radial head fractures were classified as types I-III by Mason (see box).¹ Broberg and Morrey made the following modifications: (1) they added fractures of the radial neck; (2) defined “marginal” as less than 30% of the articular surface area; and (3) defined displacement as 2mm step or gap of the articular surface.²

Mason’s classification of radial head fractures

- Type I: nondisplaced or small marginal fractures
- Type II: displaced articular fractures involving part of the radial head
- Type III: displaced articular fractures of the entire radial head

Top five questions

Diagnosis

1. What is the role of aspiration/injection of the elbow joint in the initial evaluation of radial head fractures?

Therapy

2. What is the role of operative vs. nonoperative treatment of displaced isolated partial radial head fractures (modified Mason II)?
3. For unstable or displaced fractures of the radial head that are part of a complex injury, what is the evidence for open reduction and internal fixation (ORIF) vs. prosthetic replacement vs. excision?
4. Is there any role for arthroscopy in radial head fractures?

Prognosis

5. What can a patient with an isolated radial head fracture expect in the long term?

Finding the evidence

- Cochrane Database, with search term “radius fracture”
- PubMed, with search term “radial head fracture”
- Above, limited to systematic reviews
- OVID, with search term “radial head fracture” and “aspiration” or “injection”

Question 1: What is the role of aspiration/injection of the elbow joint in the initial evaluation of radial head fractures?

Case clarification

The patient’s radiographs reveal a nondisplaced radial head fracture (Mason type I). She is unwilling to flex and

extend her elbow more than a few degrees because of pain, and she cannot fully supinate her arm.

Relevance

The bleeding associated with fractures of the radial head can be quite painful. The inhibition of elbow motion associated with this pain might delay recovery or lead to greater loss of motion. With displaced fractures, one needs to know if the fracture blocks forearm rotation. Aspiration of the hemarthrosis, with or without local anesthesia, can help distinguish such a block from inability to rotate due to pain.

Quality of the evidence

Level I

- 1 meta-analysis
- 3 randomized trials

Findings

A meta-analysis was published in 1999 based on two randomized trials examining the role of aspiration in radial head fractures (level I).³ In one study, 80 patients with radial head fractures were randomized to aspiration and injection of bupivacaine with initiation of exercises or exercises alone (level I).⁴ There was improved comfort with immediate range of motion (ROM) in 92% of patients who underwent the aspiration and injection, but no difference in ROM. In the second study, 28 patients with modified Mason type I and II fractures were randomized to aspiration of the hemarthrosis vs. no aspiration. (level I).⁵ The authors noted better pain relief and ROM in the aspiration group immediately and at 3 and 6 month evaluation. The meta-analysis concluded that the evidence for aspiration of a traumatic elbow effusion is insufficient to recommend it as a routine procedure.

A third randomized trial, not included in the above meta-analysis, randomized 40 patients with Mason I radial head fractures to aspiration alone vs. aspiration with intra-articular injection of bupivacaine (level I).⁶ The authors found no difference in ROM or pain relief between the two groups at all time points examined from 1 day to 1 year.

Recommendations

For Mason I fractures of the radial head:

- Aspiration of the hematoma of the elbow joint might aid in pain relief in the acute setting [overall quality: moderate]
- There is insufficient evidence to determine whether joint aspiration and/or injection can improve the final elbow motion
- It is unclear whether injection of local anesthetic provides any benefit over joint aspiration alone

We did not identify any studies that examined the role of injection of local anesthetic to facilitate diagnosis of a

block to motion by a fracture fragment in the acute setting. Given the documented pain relief with aspiration of the hemarthrosis in the acute setting, it is likely this will aid in a more comfortable examination of forearm motion. Whether this is superior to simply waiting a few days and reexamining the patient when they are more comfortable and whether assessment of a "block to forearm rotation" in any form leads to more accurate diagnosis or decision-making regarding treatment requires further study.

Question 2: What is the role of operative vs. nonoperative treatment of displaced isolated partial radial head fractures (modified Mason II)?

Case clarification

The patient's radiographs reveal an isolated, displaced (2mm step in the articular surface) partial articular radial head fracture. What evidence exists to inform the decision between operative and nonoperative treatment?

Relevance

There is substantial debate about the best method for treating these fractures. Operative treatment is straightforward and associated with good results, but also has complications. Nonoperative treatment of isolated displaced partial articular fractures of the radial head has been associated with very good recovery in most series.

Quality of the evidence

Level II

- 1 systematic review

Findings

There is one systematic review to date examining conservative treatment vs. surgical intervention for radial head fractures (level II).⁷ In this review, the authors found a maximum of level II evidence. A total of 28 studies were included; 14 studies involving 519 patients examined either pain or Broberg-Morrey outcomes in patients who underwent various surgical treatments for Mason II fractures. These same outcomes were also measured in 7 studies involving 430 patients who were treated nonoperatively for Mason II fractures. In these studies 52% of patients treated nonoperatively demonstrated good to excellent Broberg scores compared with 88% of patients who underwent surgery. Additionally, residual pain was reported in 42% of the patients treated without surgery vs. 32% of the patients who underwent operative treatment. However, the study designs and outcome measures were quite heterogeneous, preventing meaningful pooling of the results. The authors state that no conclusions can be drawn regarding the optimal management of Mason II fractures.

Recommendations

No level I studies have been completed concerning operative vs. nonoperative management of Mason II radial head fractures. The heterogeneity of existing evidence prevents meaningful conclusions regarding treatment decisions

- It may be that operative treatment of Mason II fractures is more likely to yield improved Broberg scores and less residual pain, but further study is warranted [overall quality: low]

Question 3: For unstable or displaced fractures of the radial head that are part of a complex injury, what is the evidence for ORIF vs. excision with or without prosthetic replacement?

Case clarification

The patient had a concomitant elbow dislocation that was reduced. Her radiographs reveal a displaced articular fracture involving the entire radial head (modified Mason III). You plan to treat her operatively.

Relevance

Treatment of complex radial head fractures remains controversial. Fractures that were once treated with excision are now often treated with ORIF or prosthetic replacement.

Quality of the evidence*Level II*

- 1 randomized controlled trial

Level III

- 3 retrospective comparative studies

Findings

Our review of the literature identified one randomized controlled trial evaluating ORIF vs. prosthetic replacement of the radial head for modified Mason type III fractures (level II).⁸ Fourteen patients were randomized to radial head replacement, while 8 patients received ORIF, and patients were followed for an average of 16 and 14 months, respectively. The authors found good to excellent results in 92% of the patients treated with radial head replacement, compared to 12.5% of patients treated with ORIF. Despite the small numbers, the magnitude of this difference was enough to achieve statistical significance ($p = 0.0004$). The authors conclude that type III fractures are better treated with radial head replacement.

Three nonrandomized comparative studies have examined ORIF vs. excision of the radial head in the treatment of modified Mason III fractures. The first evaluated 28 patients who were treated surgically for comminuted fractures of the radial head (a combination of modified Mason

III and IV—meaning associated with a dislocation—fractures) (level III).⁹ The 15 patients treated prior to 1996 received radial head excisions, while the 13 patients treated in 1996 and after underwent ORIF of the radial head. Nine of the patients who underwent ORIF later underwent plate removal. At final evaluation between 2 and 4 years after surgery, the authors noted significant improvements in visual analog scale (VAS) pain score, elbow extension, and strength in extension and supination in the group treated with ORIF vs. those treated with radial head excision. They also noted significantly improved functional scores (Broberg–Morrey and ASES) for those patients treated with ORIF.

The second study examined 20 patients at an average of 44 months following either radial head excision or ORIF for Mason II and III fractures of the radial head (level III).¹⁰ On follow-up radiographs, signs of arthrosis were present in 90% of patients who had undergone capitellectomy and 20% of those who had undergone ORIF.

Lastly, Lindenhovius and colleagues examined 28 patients with modified Mason III fractures, 15 of whom were treated with radial head excision and 13 of whom who underwent ORIF of the radial head (level III).¹¹ At an average of 17 years follow-up, the authors noted that 8 patients in the excision cohort had developed arthrosis, compared with only 2 patients in the osteosynthesis group.

Openmirrors.com **Recommendation**

- Limited retrospective data suggest that among patients with Mason III fractures, those with associated dislocations in particular, excision of the radial head leads to greater arthrosis and worse function when compared to ORIF [overall quality: low]
- Limited retrospective and prospective data also support prosthetic replacement over ORIF for complex, displaced fractures of the entire head of the radius (Mason III). [overall quality: moderate]

Question 4: Is there any role for arthroscopy in the treatment of radial head fractures?

Case clarification

The patient has an isolated minimally displaced fracture of the radial head (Mason II), and has decided on operative treatment. She asks about a minimally invasive approach with arthroscopy that she read about on the internet.

Relevance

The indications for elbow arthroscopy are expanding to include elbow trauma.

Quality of the evidence*Level IV*

- 3 retrospective case series

Findings

Only three case series exist examining the role of elbow arthroscopy in the acute treatment of radial head fractures. A total of 23 patients are reviewed in these studies. The first study examined 3 patients with radial head fractures but does not describe specific outcomes (level IV).¹²

The second study described percutaneous fixation of 6 radial head fractures: 3 Mason type II, 2 Mason type III, and 1 Mason type IV (level IV).¹³ The authors cite a satisfactory functional outcome in the short term (6–18 month follow-up).

Lastly, Michels and colleagues reviewed 14 Mason II radial head fractures treated with arthroscopic percutaneous reduction and fixation (level IV).¹⁴ At an average 5 year follow-up, the authors reported 3 good and 11 excellent Mayo elbow scores.

Recommendations

- In our opinion, only the Broberg–Morrey Mason type II fracture is suitable for arthroscopic-assisted fixation [overall quality: very low]

Given that these fractures can do very well with nonoperative treatment, as well as the fact that an open procedure is done through a 3–4cm incision in most patients, the value of arthroscopy will need to be demonstrated in high-quality level I trials before we will change our practice.

Question 5: What can a patient with an isolated radial head fracture expect in the long term?**Case clarification**

One patient has a simple Mason II fracture of the radial head, while another has an unstable modified Mason III fracture. These are young, active patients who question how these fractures will affect them in the future.

Relevance

In the acute setting, patients often question what limitations, if any, they will have in the future due to their injury, and how this may relate to treatment options. While patients can often recover quite well after simple fractures of the radial head, modified Mason III fractures can be complex, “elbow-changing” injuries.

Quality of the evidence

Level IV

- 8 retrospective case series

Findings

In 2005, Herbertsson and colleagues examined 32 patients treated nonoperatively for displaced Mason I fractures at an average 21 years of follow-up (level IV).¹⁵ Twenty-nine

of the patients had no complaints at final follow-up, while 3 of them had occasional elbow pain. The authors found an increased prevalence of degenerative changes on radiographs in the formerly injured elbow, but found that in general displaced Mason I fractures can be successfully managed nonoperatively.

In 2006, the same group published a 19-year follow-up of 49 patients with modified Mason II fractures treated nonoperatively (level IV).¹⁶ All patients had sustained two-fragment fractures with between 2mm and 5mm of articular displacement. Six patients underwent delayed radial head excision. At final follow-up, 40 of the patients had no complaints, 8 had occasional elbow pain, and 1 had daily pain. On average, there was a slight decrease in flexion, extension, and supination noted compared with the contralateral side, as well as a slightly higher prevalence of radiographic evidence of arthrosis. The authors concluded that the long-term outcome of type II fractures treated nonoperatively is favorable.

More recently, a long-term evaluation of Mason II fractures treated operatively has been published (level IV).¹⁷ Sixteen patients were evaluated at an average of 22 years after ORIF using either screws alone or a plate and screws. Complications after surgery included 2 infections, 1 transient posterior interosseous nerve palsy, and 2 screws of excessive length that restricted elbow motion. Fourteen of the 16 patients underwent surgery for hardware removal. The authors noted a decreased ROM at final follow-up, with an average flexion arc of 129° and an average forearm rotation of 166°. They conclude that there is no appreciable advantage of operative intervention in the treatment of Mason II fractures of the radial head.

Five studies were found examining long-term results of Mason III fractures. One of these, by Herbertsson and colleagues, involves 100 patients with Mason II and III fractures followed for an average of 19 years (level IV).¹⁸ Seventy-eight patients were treated nonoperatively and 22 operatively. Ten of the 100 patients underwent a secondary procedure—delayed radial head resection in 9 patients and an ulnar neurolysis in one patient. At final follow-up, most patients had no complaints, 21 had occasional pain, and 2 had daily pain. ROM testing demonstrated only slight deficits in flexion and extension. There was a higher incidence of radiographic arthrosis on the injured side vs. the uninjured side.

A long-term review of acute excision for Mason III fractures was published in 1998 (level IV).¹⁹ This study reviewed 18 patients treated with radial head excision for Mason III fractures at a minimum of 16-year follow-up, and another 3 patients at 6–12 year follow-up. One patient had a poor outcome on the Broberg–Morrey scale, with pain with daily activities and a 25° loss of supination. On radiographic review, there were 12 patients with proximal migration of the radius from 1–3mm, 11 patients with degenerative

changes at the elbow, and 7 patients with periarticular ossification. The authors conclude that radial head resection is a good option for Mason III fractures, provided the medial collateral ligament is intact.

A long-term review of radial head replacement for radial head fractures was published in 2001 (level IV).²⁰ The authors reviewed 20 patients who had undergone acute radial head replacement for radial head fractures with associated instability (Mason IV). Using the Mayo elbow performance score, they found 12 patients had excellent results, 4 good, 2 fair, and 2 poor. No patients had recurrent instability. The authors conclude that radial head replacement should be considered for the unreconstructable radial head fracture with associated instability.

Lastly, Esser and colleagues examined 26 patients at an average follow-up of 7 years after radial head ORIF (level IV).²¹ There were 11 patients with Mason II fractures, 9 with Mason III fractures, and 6 with Mason IV fractures. Using the Broberg–Morrey score, the authors found that all patients with type II and III fractures had good to excellent results, whereas 2 patients with type IV fractures had poor results. These 2 patients underwent delayed radial head excision with improved pain and ROM.

Recommendations

- In the long term, patients with a Mason I fracture of the radial head can expect minimal functional difficulties with possible radiographic evidence of arthrosis. [overall Quality: Low]
- Patients with a modified Mason II fracture can expect some limitation of ROM with the possibility of persistent pain and dysfunction whether treated operatively or non-operatively [overall quality: low]
- Operative intervention brings with it the risk of complications, along with the possibility of a second operation for hardware removal [overall quality: low]
- There is insufficient data to recommend any one method of treatment for unstable fractures of the radial head
- Radiographic evidence of arthrosis does not seem to correlate with patients' pain or loss of motion [overall quality: very low]

Summary of recommendations

- Aspiration of the hematoma of the elbow joint might aid in pain relief in the acute setting
- There is insufficient evidence to determine whether joint aspiration and/or injection can improve the final elbow motion
- It is unclear whether injection of local anesthetic provides any benefit over joint aspiration alone
- It may be that operative treatment of Mason II fractures is more likely to yield improved Broberg scores and less residual pain, but further study is warranted

- Limited retrospective data suggest that among patients with Mason III fractures, those with associated dislocations in particular, excision of the radial head leads to greater arthrosis and worse function when compared to ORIF
- Limited retrospective and prospective data also support prosthetic replacement over ORIF for complex, displaced fractures of the entire head of the radius (Mason III)
- In our opinion, only the Broberg–Morrey Mason type II fracture is suitable for arthroscopic-assisted fixation
- In the long term, patients with a Mason I fracture of the radial head can expect minimal functional difficulties with possible radiographic evidence of arthrosis
- Patients with a Mason II fracture can expect some limitation of ROM with the possibility of persistent pain and dysfunction whether treated operatively or nonoperatively
- Operative intervention brings with it the risk of complications, along with the possibility of a second operation for hardware removal
- There is insufficient data to recommend any one method of treatment for unstable fractures of the radial head
- Radiographic evidence of arthrosis does not seem to correlate with patients' pain or loss of motion

Conclusion

Most of the data available regarding the management of radial head fractures consists of retrospective case series, making meaningful conclusions difficult. With regards to stable fractures of the radial head, including Broberg and Morrey modified Mason I and II fractures, it is certainly not clear that operative intervention provides any benefit over nonoperative treatment. With regard to modified Mason III fractures, operative intervention does offer some advantages, but the value of ORIF vs. radial head excision or replacement is still uncertain. For fractures associated with instability of the elbow, radial head replacement does seem to offer improved stability. Certainly, further investigation and high-quality comparative studies are needed to further elucidate the answers to these questions.

46

Monteggia Fracture-Dislocations

Bryce T. Gillespie and Jesse B. Jupiter

Massachusetts General Hospital, Boston, MA, USA

Case scenarios

Case 1

A 35 year old male carpenter comes to the Emergency Department after falling 6 feet (1.8m) off of a ladder and landing on his outstretched right arm. He complains of right elbow and forearm pain. Examination demonstrates elbow tenderness and point tenderness with angular deformity at the proximal-third ulna border. Radiographs demonstrate an anteriorly angulated proximal-third ulnar shaft fracture and an anterior dislocation of the radial head (Figure 46.1).

Case 2

A 70 year old woman comes to the Emergency Department after tripping inside her home and landing on her outstretched left arm. She notes left elbow and forearm pain and deformity. Examination demonstrates a bony prominence at the posterolateral aspect of the elbow and deformity along the proximal ulna. Radiographs demonstrate a posteriorly angulated metaphyseal ulna fracture and a posteriorly dislocated radial head that is fractured (Figure 46.2).

Top four questions

Diagnosis

1. What methods can be used to avoid missing the diagnosis of Monteggia fracture-dislocation?

Therapy

2. Is there a role for nonplate fixation (i.e., intramedullary fixation or tension band wire fixation) of ulnar shaft fractures in Monteggia fracture-dislocations?

3. What should be done for a radial head/neck fracture in a Monteggia fracture-dislocation?

Prognosis

4. What are the complications associated with operative treatment of Monteggia fracture-dislocations?

Question 1: What methods can be used to avoid missing the diagnosis of Monteggia fracture-dislocation?

Case clarification

Radiographs in Case 1 clearly show the ulna fracture, but the radial head dislocation may be a subtle finding.

Relevance

Missing the diagnosis of an acute Monteggia fracture-dislocation can cause inappropriate and incomplete treatment leading to long-term functional deficits, including arthrosis and restricted range of motion (ROM). Chronic Monteggia fracture-dislocations may require more extensive surgical intervention. If dislocated more than 4 weeks, the radial head would likely need to be resected at the time of realignment of the ulna.

Current opinion

The correct diagnosis can usually be made by close review of elbow, forearm, and wrist radiographs, paying close attention to the congruency of the radiocapitellar joint.

Quality of the evidence

Level IV

- 4 retrospective case-series¹⁻⁴
- 1 case report⁵

Findings

Speed and Boyd recognized the importance of a high index of suspicion and complete radiographs to diagnose this injury. A radial head dislocation should be suspected with any ulna fracture not accompanied by a radius fracture. They state that elbow radiographs should always be done for ulna fractures, and that "failure to do so may lead to a grave error in diagnosis and to permanent disability."¹

All proximal-third ulna shaft fractures should be presumed to be associated with a radial head dislocation until

proven that the radiocapitellar joint is stable. A single radiograph showing a congruent radiocapitellar joint may be deceiving. Kadakia et al. reported a missed Monteggia fracture in which static films showed a located radiocapitellar joint with a proximal ulna fracture. The patient continued to have pain and subsequent radiographic examination under anesthesia showed easily dislocatable radiocapitellar and proximal radioulnar joints. Maintaining a high index of suspicion led to the correct diagnosis.⁵

Giustra et al. found that three of five Monteggia fracture-dislocations (one adult and two pediatric) were initially misdiagnosed. Reasons for misdiagnosis included the rarity of the injury, difficult physical examination, no dedicated elbow radiographs, and midshaft, rather than proximal, ulna fractures.²

A line drawn along the axis of the radial shaft at the elbow should intersect the capitellum on all views with any amount of elbow flexion or extension.³ Imaging of the contralateral, uninjured elbow in pediatric elbow trauma has not been shown to improve diagnostic accuracy,⁴ which may also be true in adult cases.

Recommendations

- Maintain high index of suspicion for Monteggia fracture-dislocation with any fracture of the ulna [overall quality: very low]
- Include elbow radiographs of ulna fractures to evaluate for radiocapitellar joint dislocation [overall quality: very low]

Question 2: Is there a role for nonplate fixation (i.e., intramedullary fixation or tension band wire fixation) of ulnar shaft fractures in Monteggia fracture-dislocations?

Case clarification

The ulna fracture in Cases 1 and 2 could theoretically be addressed with intramedullary (IM) fixation instead of plate fixation.

Relevance

IM fixation has been used elsewhere in the body to provide fracture stabilization, but less commonly with adult Monteggia fracture-dislocations. An IM pin is often used to maintain reduction of the ulna fracture in pediatric Monteggia fracture-dislocations. A tension band wire (TBW) or IM screw fixation is commonly used to fix simple olecranon fractures in adults, but this method of fixation is not thought to be stable enough for adult Monteggia fracture-dislocations.

Current opinion

IM or TBW fixation of the ulna fracture in adult Monteggia fracture-dislocations does not provide sufficient stability to

ensure maintained reduction of the fracture and radiocapitellar joint during healing, therefore plate fixation is the predominant treatment choice.

Finding the evidence

- PubMed and OVID, search terms “Monteggia” AND “fracture” with limits: “Humans” AND “All Adults: 19+ years” AND “English language”
- Cochrane Database, search term “fracture” AND “Monteggia” OR “ulna.” One result that addressed ulna shaft fractures, but excluded Monteggia fracture-dislocations and only compared plate fixation vs. nonoperative treatment.⁶
- Manual review of cited references from identified articles.

Quality of the evidence

Level IV

- 8 retrospective case series⁷⁻¹⁴

Findings

TBW and IM screw fixation has been used for olecranon fractures, but these methods do not provide enough stability for ulna fractures when there are additional injuries, as seen in Monteggia fracture-dislocations.¹¹

In their review of posterior (Bado type II) Monteggia fracture-dislocations, Jupiter et al. conclude that this fracture pattern is not amenable to nonplate fixation. Due to the direction of the injury, the ulnar shaft fracture is predisposed to further flexion deformity leading to redislocation of the radiocapitellar joint. They recommend fixation only with a contoured plate applied to the dorsal cortex of the proximal ulna to act as a tension band plate and assure anatomic reduction.⁸

Four of 16 adult Monteggia fracture-dislocations in one series were treated with Rush pin fixation; two required reoperation for nonunion. More recent cases were treated with plate fixation, and this is their recommended method.⁷

Only four of 38 adult Bado type II injuries in a series of 48 Monteggia fracture-dislocations were treated with nonplate fixation (3 TBW and 1 IM pin); 1 of the 3 TBW constructs required revision to a contoured dorsal plate to obtain fracture union. The fourth patient had the IM pin removed at 6 months, but the fracture healed with recurrent flexion deformity.⁹

Six patients in a series of 10 proximal ulna atrophic nonunions had initial operative treatment of Bado type II Monteggia fracture-dislocations. Three had initial plate fixation, 2 had TBW, and 1 had IM screw fixation; all required revision fixation with a contoured dorsal plate.¹⁰

In another series of 12 patients with proximal ulna nonunions, 7 had operative treatment of Bado types I and II Monteggia fracture-dislocations; 4 had initial plate fixation,

2 had Rush nail fixation, and 1 had TBW. All fractures healed after plate and cortical strut fixation.¹⁴

Eleven of 37 adult patients with Bado type II Monteggia fracture-dislocations were treated with TBW fixation in one series. The remaining 26 with Bado type II and the 7 with Bado types I, III, and IV injuries had plate fixation. Due to the selection bias of less comminuted fractures being fixed with TBW, the authors could not correlate fixation method and functional outcome. They suggest that a contoured plate along the dorsal cortex should be used to stabilize the ulna fracture.¹³

Muckley et al. have reported the use of IM nailing in 2 patients with ulnar shaft nonunion following plate fixation. Both fractures healed with near normal elbow ROM. They suggest this technique when concerned about the soft tissue envelope causing further complications with revision plating.¹²

Recommendations

- TBW fixation may be effective for certain isolated proximal ulna fractures, but the construct may not be strong enough to resist the additional instability seen with Monteggia fracture-dislocations [overall quality: low]
- IM pins are commonly used for pediatric Monteggia fracture-dislocations, but likely do not provide sufficient stability in adults. IM nails could be an option for revision fixation of nonunions [overall quality: very low]

Question 3: What should be done for a radial head/neck fracture in a Monteggia fracture-dislocation?

Case clarification

Case 2 represents a posterior Monteggia fracture-dislocation with an associated radial head fracture. In addition to fixation of the ulna fracture and reduction of the radiocapitellar joint, what should be done for the radial head fracture?

Relevance

Debate continues about the appropriate treatment of radial head fractures, especially when associated with another injury. The modified Mason classification system of radial head fractures is often utilized to help guide treatment.¹⁵

Treatment decisions can affect outcomes by impacting elbow stability, ROM, or arthrosis.

Current opinion

The radial head fracture in a Monteggia fracture-dislocation often requires intervention. The goal is elbow stability and functional ROM, often necessitating internal fixation or prosthetic replacement.

Finding the evidence

See Question 2.

Quality of the evidence*Level IV*

- 4 retrospective case series^{9,13,16,17}

Findings

In one case series, 10 of 14 adults with Bado type II Monteggia fracture-dislocations sustained radial head fractures. Two were Mason type I (treated nonoperatively), 5 were Mason type II, and 3 were Mason type III (treated with primary excision). The type II radial head fractures either had partial excision or open reduction and internal fixation (ORIF). These five patients had similar elbow flexion/extension (120/20° vs. 117/25°), but those who had ORIF had less forearm pronation/supination (60/53° vs. 35/30°). The Mason type III radial head fractures were all excised and had even more limited elbow ROM (flexion/extension of 95/12° and pronation/supination of 42/10°). No patients had prosthetic replacement. Overall, radial head fractures were more common in Bado type II than type I injuries (71% vs. 30%), and those patients with radial head fractures had poorer motion and functional results.¹⁶

Twenty-six of 38 adult Bado type II Monteggia fracture-dislocations had associated radial head fractures in another series. Of the 7 Mason type II fractures, 3 were treated nonoperatively, 2 had partial excision, and 2 had ORIF. Only 1 of the 19 Mason type III fractures was treated nonoperatively, 8 had ORIF and 10 had excision with 2 being replaced with silicone prostheses. Six of the 8 Mason type III fractures that had ORIF went on to have complications, including restricted ROM, secondary head excision, or migrated hardware. All patients with Bado type II injuries that had unsatisfactory results had associated radial head fractures. Ten of the 12 patients who had radial head excision without prosthetic replacement had satisfactory results.⁹

Egol et al. reviewed 20 Monteggia fracture-dislocations with radial head/neck fractures. Twelve were treated nonoperatively, 3 had ORIF, 1 was excised, and 4 had titanium prosthetic replacements. Two more patients later underwent radial head replacement for persistent instability. The Broberg–Morrey scores trended towards better functional outcome if no surgery was done for the radial head fracture. Compared to other studies, these authors concluded that radial head fractures caused restricted ROM and resulted in poorer functional outcome.¹⁷

In a case series of 47 adult Monteggia fracture-dislocations, 16 had concurrent radial head fractures (13 of which were Bado type II injuries). All 7 Mason type II and 5 of 9 Mason type III radial head fractures were treated with ORIF. The other 4 Mason type III fractures were treated with primary excision and no prosthetic replacement. Two patients required revision ORIF for loss of initial fracture reduction. Radial head fractures were correlated

with a “poor” Broberg–Morrey score, but no difference in scores could be determined between the ORIF and excision groups.¹³

Recommendations

- If the radial head fracture can be managed nonoperatively, this treatment method may improve long-term outcome [overall quality: very low]
- No recommendations were made regarding radial head excision alone vs. prosthetic replacement, but the goal of overall forearm stability should be considered when making this decision [overall quality: very low]

Question 4: What are the complications associated with operative treatment of Monteggia fracture-dislocations?**Case clarification**

The injuries in Cases 1 and 2 and the subsequent operative intervention can be associated with complications and long-term sequelae affecting functional outcome.

Relevance

Some complications of Monteggia fracture-dislocations may be unavoidable sequelae of the injury, but careful surgical technique can help reduce their morbidity.

Current opinion

Early identification and appropriate surgical reduction and fixation of Monteggia fracture-dislocations can enhance outcomes.

Finding the evidence

See Question 2.

Quality of the evidence*Level IV*

- 9 retrospective case series^{7,9,13,16–21}

Findings

Two studies reported overall complication rates of 43% and 39% for adult Monteggia fracture-dislocations.^{18,20} Table 46.1 highlights the difficulties associated with treating these complex injuries.

Ring et al. had 3 malunions in 48 patients and Reynders et al. noted 4 in 67 patients.^{9,18} The nonunion rates in other studies (7.4–18.8% with average of 12%) included longstanding nonunions and early fixation failures that necessitated intervention.^{7,13,16–21}

Incomplete reduction of the radiocapitellar joint or unstable fixation of the ulnar shaft fracture can result in persistent subluxation or dislocation. Four of 7 instances of dislocation in one series were due to non-anatomic ulna fracture fixation.¹⁸ Overall rates were 5.6–10.4% (average 8%).^{18–20}

Table 46.1 Rates of complications for operative treatment of Monteggia fracture-dislocations

Complication	Average rate (%)	No. of patients	No. of studies	References
Overall rate	41	51/121	2	Reynders 1996, Llusa 2002
Malunion	6	7/115	2	Reynders 1996, Ring 1998
Nonunion/failure of fixation	12	32/278	8	Ovesen 1990, Reynders 1996, Simpson 1996, Givon 1997, Llusa 2002, Egol 2005, Strauss 2006, Konrad 2007
Radiocapitellar joint instability	8	12/148	3	Givon 1996, Reynders 1996, Llusa 2002
HO	14	19/134	4	Reynders 1996, Simpson 1996, Egol 2005, Strauss 2006
PRUJ synostosis	7	15/216	4	Reynders 1996, Ring 1998, Llusa 2002, Konrad 2007
Radiographic osteoarthritic changes	38	58/154	5	Ovesen 1996, Ring 1998, Egol 2005, Strauss 2006, Konrad 2007
Postoperative infection	3	5/195	4	Ovesen 1996, Ring 1998, Egol 2005, Strauss 2006, Konrad 2007

HO, heterotopic ossification; PRUJ, proximal radioulnar joint.

Heterotopic ossification (HO) and synostosis of the proximal radioulnar joint (PRUJ) can have significant adverse effect on functional results. High-energy injuries and patients with head trauma appear more likely to develop HO.²⁰ Four case series reported their rates of HO ranging from 8.7% to 35% (average 14%).^{16–18,21} The highest rate was seen in a review of 20 patients with Monteggia fracture-dislocations who had concurrent radial head fractures.¹⁷ The average rate of PRUJ synostosis was 7% (range 4.3–8.9%).^{9,13,18,20} Reynders et al. reported that 6 of their 67 patients had PRUJ synostosis and that 4 of these 6 patients had undergone open annular ligament reconstruction. Therefore they recommended against doing this procedure.¹⁸

Five studies reported long-term radiographic osteoarthritic changes.^{7,9,13,17,21} Rates ranged from 6.3% to 70% (average 38%). Most were mild changes, but at least five patients had severe arthrosis.

Postoperative infection rates were reported in four studies.^{13,18–20} Overall 5 of 195 patients had infections. The average rate was 3% (range 1.5–4.3%).

Only two studies present follow-up ROM values based upon Bado type of Monteggia fracture-dislocation. Ring et al.'s study of 48 patients included Bado types I–IV and the other study only had 24 patients with types I and II.^{9,16} With these limited numbers, it is difficult to draw conclusions, but Bado types II and IV appear to have the most loss of motion (Table 46.2).

Table 46.2 Postoperative range of motion by Bado type of Monteggia fracture-dislocation

Bado type	No. of patients	Average flexion/extension arc (°)	Average pronation/supination arc (°)
I	17	117	142
II	52	110	122
III	1	120	120
IV	2	108	110

References: Simpson 1996, Ring 1998.

Recommendation

- These results can help an orthopedic surgeon educate a patient about the potentially poor outcomes associated with Monteggia fracture-dislocations and the risks of operative treatment of these injuries [overall quality: low]

Summary of recommendations

- Maintain high index of suspicion for Monteggia fracture-dislocation with any fracture of the ulna
- Include elbow radiographs of ulna fractures to evaluate for radiocapitellar joint dislocation
- TBW fixation may be effective for certain isolated proximal ulna fractures, but the construct may not be strong

enough to resist the additional instability seen with Monteggia fracture-dislocations

- IM pins are commonly used for pediatric Monteggia fracture-dislocations, but likely do not provide sufficient stability in adults. IM nails could be an option for revision fixation of nonunions
- If the radial head fracture can be managed nonoperatively, this treatment method may improve long-term outcome
- No recommendations were made regarding radial head excision alone vs. prosthetic replacement, but the goal of overall forearm stability should be considered when making this decision
- These results can help an orthopedic surgeon educate a patient about the potentially poor outcomes associated with Monteggia fracture-dislocations and the risks of operative treatment of these injuries

Conclusions

Monteggia fracture-dislocations represent significant injuries to the upper extremity with potentially serious functional loss. Prompt recognition and appropriate treatment can help restore function.

Ulnar fractures in Monteggia fracture-dislocations require rigid fixation to allow bone and soft tissue healing while maintaining alignment of the fracture(s) and reduction of the radiocapitellar joint. This is best accomplished with application of a contoured, stout plate along the dorsal border of the proximal ulna. This position allows for orthogonal screw fixation proximally and displaces very little muscle. Alignment of the ulna fracture usually results in reduction of the radial head dislocation, so open reduction of the radiocapitellar joint can, and should, be avoided. Dorsal plate application also has a biomechanical advantage of resisting elbow flexion forces. Newer plate technology, such as precontoured olecranon plates, has yet to be compared to other plates with regard to Monteggia fracture-dislocations.

47

Olecranon Fractures

Bryce T. Gillespie and Jesse B. Jupiter

Massachusetts General Hospital, Boston, MA, USA

Case scenarios

Case 1

A 28 year old male motorcyclist comes to the Emergency Department complaining of right elbow pain following a collision. Examination demonstrates tenderness with a palpable defect over the proximal ulna. He has no active elbow extension. Imaging studies demonstrate a displaced, comminuted olecranon fracture (Figure 47.1).

Case 2

A 75 year old woman comes to the Emergency Department complaining of left elbow pain after slipping on the ice and landing on her outstretched left arm. Examination demonstrates tenderness at the posterior elbow. She cannot actively extend her elbow. Imaging studies demonstrate a displaced, transverse, proximal olecranon fracture (Figure 47.2).

Top five questions

Diagnosis

1. What is the role of cross-sectional imaging in determining treatment method of olecranon fractures?

Treatment

2. When can fragment excision and triceps advancement be used to treat olecranon fractures?
3. Can either K-wire tension band fixation (TBF) or dorsal plating be used to treat simple or minimally comminuted olecranon fractures?

Prognosis

4. Does treatment method affect the functional outcomes of operatively treated olecranon fractures?
5. What are the complications associated with operative treatment of olecranon fractures?

Question 1: What is the role of cross-sectional imaging in determining treatment method of olecranon fractures?

Case clarification

The fractures in Cases 1 and 2 can be identified with radiographs, but would cross-sectional imaging affect treatment decisions?

Relevance

Cross-sectional imaging of the olecranon fracture in Case 1 may give further information regarding the comminution and injury to the articular surface. This may affect the planned techniques of surgical fixation. Additional imaging of the fracture in Case 2 may reveal what portion of the articular surface is involved and the overall quality of this elderly patient's bone. This may guide treatment to internal fixation or fragment excision and triceps advancement.

Current opinion

Complex intra-articular fractures benefit from cross-sectional imaging for preoperative planning. Olecranon fractures with comminution or associated injuries, vs. simple fracture patterns, are more likely to undergo this additional imaging.

Finding the evidence

- PubMed and OVID, search terms "olecranon" AND "fracture" with limits: "Humans" AND "All Adults: 19+ years" AND "English language"

Figure 47.1 Lateral elbow radiograph for Case 1.

Figure 47.2 Lateral elbow radiograph for Case 2.

- Cochrane Database, search term “fracture” AND “olecranon” OR “ulna”
 - One result that addressed ulna shaft fractures, but not olecranon fractures¹
- Manual review of cited references from identified articles

Quality of the evidence

Level IV

- 1 retrospective case-series²

Findings

No studies have systematically evaluated the role of cross-sectional imaging for evaluation and treatment planning of

olecranon fractures. Several studies have demonstrated that 2-D and 3-D CT scans can improve reliability and/or accuracy of fracture characterization and influence treatment decisions for other intra-articular upper extremity fractures.³⁻⁶

One case series of 20 adult patients evaluated the role of MRI in detecting occult fractures in patients with acute elbow trauma and an elbow effusion seen on radiographs, but no visible fracture. Fifteen of the patients were found to have an occult fracture, but only one of these was an olecranon fracture: the remainder had radial head (13) or lateral epicondyle (1) fractures. There was no change in treatment plan based upon the MRI results.²

Recommendation

- Consider cross-sectional imaging (CT scan) for complex olecranon fractures to assist with selecting appropriate treatment modality, however, this recommendation requires investigation [overall quality: very low]

Question 2: When can fragment excision and triceps advancement be used to treat olecranon fractures?

Case clarification

The fracture in Case 2 may be amenable to fragment excision and triceps advancement, but it could also be addressed with internal fixation.

Relevance

As internal fixation methods and hardware technology have improved, more fractures are being addressed with surgical reduction and stabilization. This includes olecranon fractures that may previously have been addressed with fragment excision.

Current opinion

Fragment excision and triceps advancement is usually now reserved for elderly patients with low functional demands and olecranon fractures with small proximal fragments. Otherwise, internal fracture fixation is the predominant treatment method.

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 6 retrospective case series⁷⁻¹²

Findings

Since the 1940s, fragment excision and triceps advancement has been considered a viable treatment option for olecranon fractures, especially for comminuted fractures that cannot be easily repaired.⁷⁻⁹

Instability is a valid concern when removing a portion of the olecranon, but excision is thought to produce a durable result when less than 75% of the joint surface is removed and there are no concurrent injuries to the coronoïd, radial head, or collateral ligaments.

Despite range of motion results that did not differ between 4 patients treated with excision and 34 patients treated with internal fixation, Rettig et al. still recommended excision only when internal fixation is not possible.¹⁰

Gartsman et al. reported the largest series (53 patients) treated with primary excision.¹¹ Excision was used for all severely comminuted and small avulsion fractures and half of the two-part fractures. Fifteen patients who had fractures excised that were less than 50% of the joint surface were evaluated with long-term follow-up (average 3.6 years). They achieved approximately 70% of the isometric and isokinetic elbow extensor strength as compared to the uninjured side and these results were similar to the patients treated with fracture fixation.

Nonoperative treatment has also been suggested for elderly patients. One series of 12 patients aged 73–90 were treated with cast immobilization. Despite 9 patients having pseudarthrosis, 11 patients reported excellent satisfaction with their treatment result.¹²

Recommendation

- Fragment excision and triceps advancement can be considered for fractures involving up to 50% (and possibly up to 75%) of the articular surface with the expectation of similar postoperative elbow strength compared to fracture fixation [overall quality: low]
- Associated injuries may lead to instability with fragment excision, therefore this method may be best reserved for those isolated, severely comminuted fractures that are not amenable to fixation [overall quality: very low]

Question 3: Can either K-wire TBF or dorsal plating be used to treat simple or minimally comminuted olecranon fractures?

Case clarification

The fracture in Case 1 may be too comminuted for K-wire TBF, but fractures with minimal comminution or those where the fragments can be lagged together prior to K-wire fixation may be amenable to either treatment method.

Relevance

K-wire TBF was originally used for almost all olecranon fractures, but this method may fail with excessive fracture comminution. New technology has made dorsal plating a more common treatment method.

Current opinion

TBF remains an acceptable and predictable treatment for simple or minimally comminuted olecranon fractures.

Plate fixation is required for more complex multifragmented fractures.

Finding the evidence

See Question 1.

Quality of the evidence

Level II

- 1 randomized trial with methodological limitations¹³

Findings

Forty-one isolated olecranon fractures, 19 treated with K-wire TBF and 22 treated with one-third tubular plate fixation, were followed for an average of 7 months in the only prospective, randomized trial comparing these treatment options.¹³ These results were evaluated in aggregate, so the results of minimally comminuted fractures could not be independently assessed (Table 47.1).

Forty-two percent of the tension band group had painful hardware vs. only 5% in the plate fixation group. There was no difference in range of motion; loss of extension averaged 7–10°.

Ten fractures treated with TBF lost reduction, including 5 that initially had perfect reduction, while only 1 fracture treated with plate fixation lost reduction. Eighty-six percent of the plate fixation group had initial reduction with less than 1 mm step-off, while only 63% of the TBF group

Table 47.1 K-wire tension band fixation vs plate fixation for olecranon fractures

	K-wire tension band fixation (19 patients)	One-third tubular plate fixation (22 patients)
Postoperative infection	16% (3 pts)	5% (1 pt)
Nonunion	5% (1 pt)	0% (0 pt)
Heterotopic ossification	5% (1 pt)	0% (0 pt)
Painful hardware	42% (8 pts)	5% (1 pt)
Average loss of extension	10°	7°
Initial reduction <1 mm step-off or gap	63% (12 pts)	86% (19 pts)
Healed reduction >2 mm step-off or gap	84% (16 pts)	9% (2)
Lost reduction	53% (10 pts)	5% (1 pt)
Operative time	94.5 min (75–120 min)	120 min (85–150 min)

Reference: Hume 1992.

Table 47.2 Functional outcomes for K-wire tension band fixation and plate fixation of olecranon fractures

Study/fixation	No. of patients	Average follow-up	Flexion-extension ROM or arc	Pronation-supination ROM or arc	Avg. MEPI score	Good or excellent MEPI score ^a	Avg. DASH score	Radiographic osteoarthritic changes
K-wire tension band wire fixation								
Rommens 2004	95 total 58 at follow-up	36 months	Extension Loss >20°: 10% (6 pts)	Flexion Loss >20°: 9% (5 pts)				32% (19 pts)
Villanueva 2006	37	48 months	7–131°		88	86% (32 pts)	18	27% (10 pts)
Chalidis 2008	62	8.2 years				86% (53 pts)		48% (30 pts)
Plate fixation								
Bailey 2001	25	34 months	8.5–128.5°	76.7–67.2°	89	92% (23 pts)	10	8% (2 pts)
Anderson 2007	32 total 24 at follow-up	2.2 years	120°	158°	89	92% (22 pts)	25	
Buijze 2009	16	24 months	13–136°	74–71°	93	94% (15 pts)	13	44% (7 pts)

^aMEPI Score greater than 74.

achieved this level of initial reduction. Sixteen patients had step-off or gapping of greater than 2mm following TBF, while only 2 had this following plate fixation.

The authors suggest that plate fixation offers better initial reduction and better maintenance of reduction with fewer complications than TBF.

Recommendation

- For all fracture types, plate fixation was shown to provide equal or better initial reduction with less loss of reduction than did K-wire TBF [overall quality: low]

Question 4: Does treatment method affect the functional outcomes of operatively treated olecranon fractures?

Case clarification

The patient characteristics and functional demands are different in Cases 1 and 2. This may alter choice of treatment method and give varying functional outcomes.

Relevance

Most olecranon fractures require surgical treatment to restore elbow function. A consensus on appropriate treatment for the varying injury patterns could yield improved outcomes.

Current opinion

Stable fracture fixation with restoration of anatomy is the goal of operative treatment of olecranon fractures. Distinct

from treatment method, this is the most important determinant of functional outcomes.

Finding the evidence

See Question 1.

Quality of the evidence

Level IV

- 6 retrospective case series^{14–19}

Findings

Villanueva et al. reported on 37 patients who underwent fixation of olecranon fractures with a K-wire tension band and had average follow-up of 4 years.¹⁴ The worst extension loss was 25°. The average Mayo Elbow Performance Index (MEPI) score was 88.²⁰ The average Disabilities of the Arm, Shoulder, and Hand (DASH) score was 18. Seventy-eight percent had scores of less than 30, indicating that most patients had mild disability (Table 47.2).

Sixty-two patients who had TBF of isolated olecranon fractures were evaluated at a minimum of 6 years after surgery.¹⁵ Eighty-six percent had good or excellent MEPI scores, although 48% had some evidence of degenerative changes on radiographs.

A majority of the 95 patients (81%) included in Rommens et al.'s study had TBF of olecranon fractures, but only 58 were available for follow-up at an average of 36 months after surgery.¹⁶ Twenty-one percent had no loss of extension, while 53% had no loss of flexion. Arthritis was 3.4

times more common in those fractures that had suboptimal initial osteosynthesis.

Bailey et al. reported on 25 patients who underwent fixation of olecranon fractures with various plates.¹⁷ They reported no difference in elbow motion as compared to the uninjured elbow except for supination being limited to 67° on average, as compared to 76°. The average DASH score was 10, equivalent to almost normal function.

Twenty-four of 32 patients who had fracture fixation with congruent plates underwent follow-up on average 2.2 years after surgery.¹⁸ The average flexion contracture was 13.5°, but four patients had contractures of more than 30°.

Buijze and Kloen reported on 16 patients who had fixation of comminuted olecranon fractures with a 3.5mm locking compression plate.¹⁹ Seven patients had radiographic osteoarthritis by at least 12 months postoperative follow-up.

Recommendations

- Both treatment methods seem to provide functional elbow range of motion [overall quality: very low]
- On average, 92% (58/65) of the patients who had plate fixation had good or excellent MEPI scores, while 86% (85/99) of those with TBF had similar results.^{14,15,17-19} This suggests some improved function following plate fixation of olecranon fractures [overall quality: low]

Question 5: What are the complications associated with operative treatment of olecranon fractures?

Case clarification

The injuries in Cases 1 and 2 and the subsequent operative intervention can be associated with complications and long-term sequelae affecting functional outcome.

Relevance

Some complications of olecranon fracture fixation may be unavoidable sequelae of the injury, but careful surgical technique can help reduce their morbidity.

Current opinion

Appropriate surgical reduction and fixation of olecranon fractures can enhance outdoor outcomes and limit the morbidities associated with this injury.

Finding the evidence

See Question 1.

Quality of the evidence

Level II

- 1 randomized trial with methodological limitations¹³

Level IV

- 19 retrospective case series^{13-19,21-32}

Findings

Overall complication rates of up to 85% have been reported for surgical treatment of olecranon fractures.²¹ Higher rates are more commonly associated with K-wire TBF and usually related to prominent hardware (Table 47.3).

Rates of hardware removal are quite variable but indicate that both constructs are susceptible to becoming symptomatic. The average rate of hardware removal for tension band constructs is 57% (range 27–85%), while for plate fixation it is 20% (range 0–56%).^{15,17-19,21-29}

Painful hardware, that may or may not have required removal, was separately reported in seven case series. In their randomized study, Hume and Wiss reported painful hardware for 42% of patients who had TBF and only 5% who had plate fixation.¹³ Three other tension band case series had painful hardware rates of 28–75%.^{21,25,28} Three case series of plate fixation had rates of 0–56% (average 19%).^{18,19,29} All of the symptomatic plates were subsequently removed.

Mullett et al. compared two configurations of K-wires in TBF constructs. Forty-five patients had K-wires placed longitudinally into the ulnar intramedullary canal and 35 had transcortical K-wires that pierced the anterior cortex of the ulna distal to the coronoid. Three of the intramedullary wires and only one of the transcortical wires backed out. Therefore they recommended placing transcortical K-wires to improve construct stability and decrease back-out rates.²⁷

Postoperative infection rates were comparable for TBF and plate fixation at 4% (range 0–11%) and 5% (0–15%), respectively.^{13,15,18,19,21-23,25-27,32}

Nonunion rates, on average, were equal for both TBF and plate fixation at 2%, ranges were 0–5% and 0–6%, respectively.^{13-19,21,23,26,27,29}

Velkes et al. presented two patients with proximal radioulnar joint (PRUJ) synostosis following K-wire TBF of olecranon fractures.³⁰ Matthews et al. highlighted the risk of transcortical K-wires or screws approaching or engaging the radius after passing through the anterior ulna. They indicated that starting the K-wires more lateral on the tip of the olecranon and aiming them more ulnar (down the shaft of the ulna) can help prevent this complication.³¹ Two case series of TBF noted heterotopic ossification (HO) in 9 of 78 patients.^{14,17} Two of 25 patients who had plate fixation developed HO but did not have any block to motion.¹⁷

Irregularities at the articular surface can be secondary to initial malreduction or loss of initial reduction. One series of 34 patients treated with TBF reported 10 malreduced fractures and they found malreduced fractures were more likely to further displace later than those that were initially well reduced.²² Nine of 54 patients (17%) treated with TBF in two other case series had some loss of reduction.^{21,22} This rate was far lower than that reported by Hume and Wiss,

Table 47.3 Rates of complications for operative treatment of olecranon fractures

Complication	Average rate	No. of patients	No. of studies	References
K-wire tension band fixation				
Overall rate	66%	106/160	4	Macko 1985, Jensen 1986, Wolfgang 1987, Romero 2000
Hardware removal	57%	262/456	10	Holdsworth 1984, Macko 1985, Jensen 1986, Helm 1987, Wolfgang 1987, Finsen 2000, Mullett 2000, Romero 2000, Villanueva 2006, Chalidis 2008
Painful hardware	41%	50/122	4	Holdsworth 1984, Macko 1985, Hume 1992, Finsen 2000
Postoperative infection	4%	16/368	8	Holdsworth 1984, Macko 1985, Helm 1987, Wolfgang 1987, Hume 1992, Mullett 2000, Romero 2000, Chalidis 2008
Malunion	2%	2/108	2	Romero 2000, Chalidis 2008
Nonunion	2%	6/362	8	Macko 1985, Wolfgang 1987, Hume 1992, Mullett 2000, Romero 2000, Rommens 2004, Villanueva 2006, Chalidis 2008
Heterotopic ossification	12%	9/78	2	Bailey 2001, Villanueva 2006
Plate fixation				
Overall rate	0%	0/14	1	Tejwani 2002
Hardware removal	20%	17/86	4	Bailey 2001, Tejwani 2002, Anderson 2007, Buijze 2009
Painful hardware	15%	13/84	4	Hume 1992, Tejwani 2002, Anderson 2007, Buijze 2009
Postoperative infection	5%	4/83	4	Hume 1992, Simpson 1996, Anderson 2007, Buijze 2009
Nonunion	2%	2/109	5	Hume 1992, Bailey 2001, Tejwani 2002, Anderson 2007, Buijze 2009
Heterotopic ossification	8%	2/25	1	Bailey 2001

who found 10 of 19 patients with TBF lost reduction, including five patients who had initially perfect reduction. Comparatively, only 1 of 22 patients in their study treated with plate fixation lost reduction and 19 of the 22 had initially anatomic reductions.¹³

Recommendationw

- Placing K-wire tension band hardware deep to the triceps tendon and having the K-wires engage the anterior ulnar cortex may reduce symptomatic hardware, hardware removal, and fracture displacement rates [overall quality: very low]
- Plate fixation may overall have fewer complications, but the plate can still be prominent and require subsequent removal [overall quality: very low]

Summary of recommendations

- Consider cross-sectional imaging (CT scan) for complex olecranon fractures to assist with selecting appropriate

treatment modality, however, this recommendation requires investigation

- Fragment excision and triceps advancement can be considered for fractures involving up to 50% (and possibly up to 75%) of the articular surface with the expectation of similar postoperative elbow strength compared to fracture fixation
- Associated injuries may lead to instability with fragment excision, therefore this method may be best reserved for those severely comminuted fractures that are not amenable to fixation
- For all fracture types, plate fixation was shown to provide equal or better initial reduction with less loss of reduction than did K-wire TBF
- Both K-wire TBF and plate fixation seem to provide functional elbow range of motion
- On average, 92% (58/65) of the patients who had plate fixation had good or excellent MEPI scores, while 86% (85/99) of those with TBF had similar results.^{14,15,17-19} This suggests some improved function following plate fixation of olecranon fractures

- Placing K-wire tension band hardware deep to the triceps tendon and having the K-wires engage the anterior ulnar cortex may reduce symptomatic hardware, hardware removal, and fracture displacement rates
- Plate fixation may overall have fewer complications, but the plate can still be prominent and require subsequent removal

Conclusions

Displaced olecranon fractures require operative intervention. Patient and fracture characteristics can influence treatment choices that include fragment excision and triceps advancement, K-wire TBF, and plate fixation.

K-wire TBF has long been the treatment for most fractures. Done well, this construct can still be used for many fractures, but newer plate technology may continue to expand the use of plates to stabilize olecranon fractures. Plate fixation may slightly improve functional outcome and decrease the overall number of complications.

Forearm Fractures, Including Galeazzi Fractures

S. John Ham, Matthijs R. Krijnen, and Rudolf W. Poolman

Onze Lieve Vrouwe Gasthuis, Amsterdam, The Netherlands

Case scenarios

Case 1

A 40 year old plumber was cycling and fell on his right dominant forearm. He was taken to the local Emergency Department by his wife. Physical examination revealed an abnormal position of the forearm without neurologic deficit and normal arterial pulsations. Radiographs showed a comminuted, dislocated fracture of the distal diaphyseal part of the radius. An isolated radius fracture was diagnosed. The fracture of the radius was treated with open reduction and plate fixation. The patient was allowed to move the arm functionally without weightbearing.

Case 2

A 25 year old man presented at the Emergency Department after being involved in a fight in a local bar. Besides several bruises, he complained of pain at the midulnar region of the left, nondominant forearm. Radiographs revealed an isolated ulnar shaft fracture, with only slight (10%) dislocation. Treatment advise was cast immobilization, starting with 3 weeks long-arm cast, followed by short-arm cast.

Relevant anatomy

The ulna is a relatively straight bone. The radius, however, has a gentle lateral bowing that influences the rotational capacity of the forearm. Distally, the radius and ulna articulate in a complex relationship, held together by the dorsal and volar ligaments and the triangular fibrocartilage complex (TFCC). The interosseous membrane plays an

important role in normal forearm function and in providing stability to ulnar shaft fractures. The unique anatomy provides the possibility of supination and pronation of the forearm, which are important movements in the usual activities of daily living.

Importance of the problem

The reconstruction of the anatomy of the bones and soft tissue of the forearm, including the distal radioulnar joint (DRUJ) and TFCC is important in achieving maximum functional outcome.

Four types of fractures can be considered: isolated fractures of the radius, isolated fractures of the ulna, diaphyseal fractures of both bones of the forearm, and Galeazzi fracture-dislocation.

Isolated fractures of the radial diaphysis without an ulna fracture are relatively rare. The majority of these fractures is unstable and require open reduction and internal fixation (ORIF).¹ Restoring the radial bowing is of importance to achieve restoration of rotational capacity of the forearm. A Galeazzi injury must be ruled out by thorough evaluation of the DRUJ.

Diaphyseal fractures of the ulna, also called *nightstick fractures*, are usually the result of a direct blow. The central diaphyseal fractures can often be managed with a cast or functional brace.² More than 50% displacement and/or 10° of angulation are considered unstable, necessitating ORIF.²⁻⁴ Fractures of the proximal and distal third are more likely to require ORIF because of displacement.^{4,5} The advantage of anatomic reduction and accelerated rehabilitation may be an argument to consider ORIF as the treatment of choice.

Displacement is standard following diaphyseal fractures of both forearms. Anatomic reduction and internal fixation of the forearm fractures are mandatory for restoration of function and now form the standard treatment regimen.^{1,6} This is supported by the good results of rigid plate fixation in many studies. Bone grafting of the fractures is considered in selected cases, especially in complex forearm fractures.^{1,6-8} Plate removal is often advised, but the complication rate might be considerable.

Galeazzi fractures account for 6–7% of all adult forearm diaphyseal fractures.^{9,10} The fracture is located at the middle to distal third of the radius and associated with dislocation and/or instability of the DRUJ. It is also called the *fracture of necessity*, which refers to its unstable nature and the need for ORIF of the radial fracture to achieve a satisfactory functional outcome in adults.¹¹⁻¹³ Persistent instability of the DRUJ leads to an unfavorable result, therefore a thorough examination of the DRUJ should always be conducted. Treatment of DRUJ lesions depends on the amount of instability.

Top six questions

Diagnosis

1. How accurate is radiological examination in the diagnosis of DRUJ involvement in radial shaft fractures/Galeazzi type fracture-dislocation? Is the location of the radial fracture a prognostic factor for DRUJ instability?

Therapy

2. What is the relative effect of ORIF vs. nonsurgical treatment, ORIF vs. ORIF, and nonsurgical vs. nonsurgical treatment in isolated ulnar shaft fractures?
3. Does bone grafting influence the union rate in comminuted diaphyseal fractures of the radius and/or ulna?

Prognosis

4. What is the influence of the timing of surgery due to delayed diagnosis in relation to the time of injury on functional outcome and complications in patients with Galeazzi type fractures?
5. Is there evidence that surgical reconstruction or temporary transfixion of the DRUJ prevents decrease in range of motion of the forearm and degenerative disease of the DRUJ in Galeazzi type fractures?

Harm

6. How long after surgery for forearm fracture is plate removal a safe procedure in terms of postoperative refractures or other complications?

Question 1: How accurate is radiological examination in the diagnosis of DRUJ involvement in radial shaft fractures/Galeazzi type fracture-dislocation? Is the location of the radial fracture a prognostic factor for DRUJ instability?

Case clarification

Case 1 During the rehabilitation period, the patient noticed a popping sensation in his wrist during pro- and supination leading to a reduction in strength when using a screwdriver or pliers. A second opinion confirmed an unstable DRUJ at physical examination. In a secondary procedure, the DRUJ was stabilized and the patient recovered uneventfully, with only slightly limited pro- and supination at the final follow-up. Nevertheless, working with a screwdriver had improved after the second procedure.

Although the radiographs revealed a fracture of the distal part of the radial diaphysis, the surgeon overlooked an injury to the DRUJ.

Relevance

Distal radioulnar instability may not be obvious on radiographs and therefore missed. It is important that radiographic features suggestive of disruption of the DRUJ are recognized. This would also facilitate planning of surgery. Furthermore, DRUJ instability has to be addressed appropriately, whereas in the absence of this injury, immediate postoperative mobilization might be possible.

Current opinion

The correct diagnosis can usually be made by meticulous review of forearm and wrist radiographs paying close attention to the congruency of the DRUJ.⁹

Finding the evidence

- Cochrane Database: No reviews available
- PubMed, using search terms: "Galeazzi fracture AND distal radioulnar joint and radiograph and prognosis" as well as "Galeazzi fracture AND distal radioulnar joint AND radiograph*"

Quality of the evidence

Level IV

- 2 case series

Findings

Rettig and Raskin suggested distinguishing isolated radius fractures with and without DRUJ involvement on the basis of fracture location.¹⁴ Fractures more than 7.5 cm from the midarticular surface of the distal radius were likely to be stable. Only 1 of 18 fractures in this location had intraoperative DRUJ instability after ORIF of the radial shaft

fracture. In contrast, 12 of 22 fractures within 7.5 cm were associated with intraoperative DRUJ instability.

Ring et al. stated that the location of the fracture alone may not be sufficient to be certain that the DRUJ is stable.¹⁵ In their series fractures of the distal third of the radius were associated with DRUJ injury in 5 of 8 patients, whereas more proximal fractures of the radius were associated with DRUJ injury in only 4 of 28 patients. Injury of the DRUJ was defined in this latter study as more than 5 mm of ulnar-positive variance on radiographs taken before any manipulative or surgical reduction. This was based on biomechanical studies that have suggested that this amount of displacement indicates injury to all of the soft tissue stabilizers of the DRUJ.

Both studies relied on retrospective data, and no formal evaluation of the DRUJ was performed. Furthermore, in the studies of Ring et al. the method of quantitatively measuring dislocation might have over- or underestimated the rate of true dislocation.

Recommendations

- Fractures of the distal third of the radius are often associated with DRUJ instability [overall quality: very low]
- DRUJ instability is best evaluated, both radiographically and physically by manipulation during surgery after stabilization of the radial fracture [overall quality: very low]
- A proximally located isolated radial fracture does not rule out traumatic DRUJ instability [overall quality: very low]

Question 2: What is the relative effect of ORIF vs. nonsurgical treatment, ORIF vs. ORIF, and nonsurgical vs. nonsurgical treatment in isolated ulnar shaft fractures?

Case clarification

Case 2 Treatment advice was cast immobilization, starting with 3 weeks long-arm cast, followed by short-arm cast. However, the patient decided that he wanted surgical stabilization so he could resume his work as a self-employed carpenter much earlier.

Relevance

Although isolated ulnar shaft fractures are relatively rare, the choice of treatment is the basis for patient satisfaction, functional results, and return to work.

Current opinion

If the displacement is less than 50% of the width of the bone and the angulation less than 10°, no closed reduction or manipulation is needed and the fracture can be treated by cast immobilization or functional bracing. Unstable fractures are treated with ORIF using compression plating.

Finding the evidence

- Cochrane Database: one Cochrane study reviewed in 2009.
- PubMed, using the search term: "isolated fractures AND ulnar shaft"

Quality of the evidence

Level II

- 3 randomized trials with methodologic limitations

Level III

- 1 case control study/retrospective comparative study

Level IV

- 3 case series

Findings

The Cochrane review included three level II trials.¹⁶⁻¹⁹ A fourth trial in the Cochrane review was not found in PubMed using the above search term.²⁰ The objective of the Cochrane study was to assess the effects of various forms of treatment for isolated fractures of the ulnar shaft in adults. Randomized or quasi-randomized trials of conservative and surgical treatment in adults were selected. The 4 selected trials involved a total of 237 participants. All trials were methodologically flawed and potentially biased. Three trials tested conservative treatment interventions. One trial compared short-arm functional braces with long-arm plaster casts; there was no significant difference in the time it took for fracture union.¹⁷ Patient satisfaction and return to work during treatment were significantly better in the bracing group. The other two trials, both quasi-randomized, had three treatment groups. One trial compared Ace Wrap elastic bandage vs. short-arm plaster cast vs. long-arm plaster cast.¹⁸ The large loss to follow-up in this trial made any data analysis tentative. The need for replacement of the Ace Wrap by other methods due to pain indicated a serious problem with this intervention. The other trial which compared immediate mobilization vs. short-arm plaster cast vs. long-arm plaster cast for minimally displaced fractures, found no significant difference in outcome between these three interventions.¹⁹ The fourth trial, which compared two types of plates for surgical fixation, found no significant differences in functional or anatomical outcomes nor complications between the two groups.²⁰

The study of Goel et al. was excluded from the Cochrane review.²¹ In this prospective trial, 89 people with 90 isolated ulna fractures were treated with either a cast (45) or an elastic crepe bandage support with early mobilization (45). It was not clear how the groups were derived and only 60 people were followed up. Average time to union was 10.8 weeks in the first group (28 fractures) and 7.8 weeks in the

second (32 fractures). Nonunion was only reported after 2 fractures in the first group.

Finally, in three papers the results of two different treatment regimens were reported without randomization or the initial intention of comparison. Pollock et al. evaluated 71 isolated ulnar fractures: the first 12 were treated with long-arm plaster cast, and the remaining 59 without a cast or with a cast or splint for no longer than 2 weeks followed by mobilization as tolerated.²² The average healing time in the first group was 10.5 weeks, with a nonunion rate of 8%, and in the second group 6.7 weeks with no nonunions. Szabo and Skinner treated 18 patients by immediate ORIF, and 28 closed.⁵ One open fracture in the first group became infected and resulted in nonunion, whereas in the second group 7 failed to unite. Boussouga et al. treated patients with either open reduction and plate fixation or closed intramedullary pinning.²³ The results were comparable, although more nonunions and complications occurred after open intervention.

Recommendation

- Based on the present literature no conclusive recommendation is possible. [overall quality: very low]

Question 3: Does bone grafting influence the union rate in comminuted diaphyseal fractures of the radius and ulna?

Openmirrors.com

Case clarification

Case 1 Did the fracture require acute bone grafting in addition to ORIF?

Relevance

Does acute bone grafting of diaphyseal forearm fractures decrease the incidence of nonunion and reduce the time to union?

Current opinion

In the past, there have been controversies over the use of bone graft in comminuted fractures of the forearm. Currently, most authors agree that acute bone grafting is not necessary, with the exception of severe comminution.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed, using the search terms: "diaphyseal forearm fractures AND acute bone grafting" and "diaphyseal forearm fractures AND bone grafting"

Quality of the evidence

Level IV

- 6 case series

Findings

Anderson et al. reviewed 330 diaphyseal forearm fractures treated with ORIF.⁶ Autogenic iliac crest bone was used in 90 fractures in which one third of the shaft circumference was comminuted. The union rate for the severely comminuted fractures treated with bone graft was 98%, which was comparable to the union rate for fractures with less or no comminution treated without bone grafts. Chapman et al. reviewed 129 forearm fractures of the shaft treated with compression plating, of which 68 cases involved bone grafting.⁸ They routinely bone grafted open and comminuted fractures. The union rate for the comminuted and/or open fractures treated with bone graft was 99%, which was not significantly different from the union rate for the closed, noncomminuted fractures treated without bone graft. Both series did not specially evaluate the results of the comminuted fractures treated without bone graft.

The recommendation to bone graft fractures with comminution involving more than one third the diameter of the bone has been widely quoted, but also questioned. No data have been presented in support of this recommendation.

Wright et al. retrospectively reviewed 198 diaphyseal forearm fractures.²⁴ Although no strict criteria were used for bone grafting, the attending surgeon was more likely to use bone graft for comminuted fractures that were open. The union rate for comminuted fractures treated without bone graft was 98%, whereas the rate for comminuted fractures treated with bone graft was only 83%. They found no significant difference between the union rate for comminuted fractures that they treated without bone graft and the union rates for comminuted fractures that Anderson's and Chapman's groups treated with bone graft. They concluded that routine bone grafting of comminuted forearm shaft fractures was not indicated.

Wei et al. compared the results of the comminuted diaphyseal forearm fractures treated with and without bone grafting in a contemporaneous set of subjects derived from the same patient population.²⁵ Fifty-six fractures were followed for at least 1 year beyond clinical and radiological union. ORIF was done in all cases. All noncomminuted fractures were treated without bone graft. For the comminuted fractures, the decision to use bone graft was left to the discretion of the operating surgeon. Acute bone grafting of the diaphyseal forearm fractures did not affect the union rate or the time to union. Shortcomings of these studies included the mixture of various types and the inclusion of skeletally immature patients.

Ring et al. examined factors associated with nonunion in skeletally mature patients with diaphyseal fractures of both the radius and the ulna and comminution of at least one fracture treated with plates of adequate size and at least three screws on each side of the fracture.²⁶ Forty-one

patients were followed at a minimum of 12 months follow-up. Nonunion occurred in five patients (12%). The use of bone graft was not associated with a higher rate of union.

Mikek et al. compared the union rate and time to union in fractures with different extents of comminution.²⁷ All fractures (319 diaphyseal fractures of forearm bones in 214 consecutive patients) were treated with ORIF without the use of bone grafting. Fractures with bone loss greater than two thirds of the diameter of the diaphysis (5% of all fractures) had a significantly prolonged time to union; there was, however, no significant difference in the union rate between groups. They concluded that primary bone grafting of comminuted diaphyseal forearm fractures was not necessary in most cases.

Recommendations

- Standard bone grafting is not required in comminuted diaphyseal fractures during initial treatment [overall quality: very low]
- If bone grafting is used, its application should possible be reserved only for fractures with bone loss greater than two thirds of the diameter of the diaphysis [overall quality: very low]

Question 4: What is the influence of the timing of surgery due to delayed diagnosis in relation to the time of injury on functional outcome and complications in patients with Galeazzi type fractures? Is there a role for nonoperative management?

Case clarification

Case 1 A delay in DRUJ reconstruction may have contributed to suboptimal outcome.

Relevance

Galeazzi fractures are known to be underdiagnosed.¹¹ They may be mistaken for a simple radius fracture. What is the effect of an untreated or delayed treated DRUJ injury? Has there ever been a study published comparing ORIF with conservative treatment in adults?

Current opinion

In seemingly isolated radial fractures, DRUJ may be missed. Close attention to the DRUJ is warranted. The goal of surgical intervention should be relocation of the DRUJ with anatomic reduction of the radial fracture which is rigidly fixed.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed, using the search terms: "Galeazzi fracture* AND treatment," "Galeazzi fracture* AND conservative

treatment," and "Galeazzi fracture* AND delay in treatment"

Quality of the evidence

Level IV

- 3 case series

Findings

One level IV study addressed the issue of delay in surgery. Moore et al. retrospectively reviewed 34 patients with 36 closed Galeazzi fractures, who were treated using standard AO compression plates with 4–7 holes.⁹ Follow-up was 1.5–7 years (average 2.5 years). Loss of strength was not related to a delay in surgery for more than 10 days after injury; however, the delay had a significant influence on the final range of motion. Only 3 of 24 forearms that were operated on within 10 days had less than an excellent final range of motion, while 6 (50%) of the 12 forearms for which the operation was delayed beyond 10 days were rated good or fair. Delay in treatment was caused by various reasons, including abrasions near the fracture site and craniofacial and thoracoabdominal injuries. Of note, no statistical evaluation was performed in this paper.

Data on nonoperative management are sparse. Based on one retrospective case series, nonoperative treatment resulted in poor results in 16 out of 20 patients (80%).¹² Poor results after closed reduction were also reported by Reckling in contrast to the results of ORIF and immobilization of the forearm in full supination.¹³

Recommendations

- Anatomical fixation of the radius in Galeazzi fractures is a necessary condition to obtain DRUJ congruency [overall quality: very low]
- Surgical treatment of Galeazzi fractures should take place within 10 days after injury [overall quality: very low]

Question 5: Is there evidence that surgical reconstruction or temporary transfixion of the DRUJ prevents decrease in range of motion of the forearm and degenerative disease of the DRUJ in Galeazzi type fractures?

Case clarification

Case 1 Our patient had residual complaints located at the DRUJ even after surgical correction.

Relevance

DRUJ instability may lead to limitation in pro- and supination incapacitating forearm function. Restoring the congruency of the joint and the stability of the DRUJ could thus prevent a loss of forearm rotation.

Current opinion

If the DRUJ is reduced after ORIF of the radial fracture, cast immobilization with or without transfixion of the distal ulna to the distal radius can be performed. If the DRUJ is irreducible, open reduction should be performed with removal of interposed soft tissue and repair if necessary.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed, using the search terms: "Galeazzi fracture* AND treatment" and "Galeazzi fracture* AND distal radioulnar joint repair"

Quality of the evidence

Level IV

- 3 case series

Findings

In a retrospective case series including 24 patients (adults and children) with Galeazzi fractures, 15 (62.5%) were available for follow-up.²⁸ In 13 cases, the DRUJ had been immobilized by pinning with Kirschner (K) wires: at follow-up, 8 of these patients revealed limited pro- or supination. In the other 5 patients, as well as in 10 cases with stable DRUJ, no decrease in range of motion was found. The authors concluded that ORIF is a requisite for healing of the radius fracture. Open reduction of the DRUJ is only indicated when soft tissue interposition prevents exact reposition. To prevent K-wire failure, postoperative cast immobilization was indicated after this procedure. Because of the retrospective nature of the study it was not definitely clear if K-wire fixation was superior to immobilization.

Two papers reported of DRUJ function after ORIF. Strehle and Gerber reviewed 19 patients after an average of 83 months.²⁹ They found that anatomic fracture reduction was mandatory for functional results. Open revisions, repair of the TFCC, and immobilization of the wrist were not necessary if anatomic reduction of the joint was obtained by indirect means such as ORIF of the radius.

Mestdagh et al. also reported that additional percutaneous Kirschner pinning across the ulna and the radius in order to avoid redislocation did not seem to be necessary.³⁰ They stressed the importance of maintaining the reduction of the DRUJ in a plaster cast for 4–6 weeks, since persistent ulnar head displacements always resulted in a lack of pronation of more than 25°.

No comparative study surgical fixation of the DRUJ after reduction vs. plaster immobilization after reduction addressed the issue of degenerative disease of the DRUJ after Galeazzi fracture-dislocation.

Recommendations

- The DRUJ must be radiographically visualized and manually tested during surgery after ORIF of the radial fracture

to assess joint congruency and residual instability [overall quality: very low]

- If ORIF of the radial fracture leads to anatomic reduction of the DRUJ cast immobilization is sufficient and additional Kirschner wire fixation is not necessary [overall quality: very low]

Question 6: How long after surgery for forearm fracture is plate removal a safe procedure in terms of postoperative complications, especially refracture?**Case clarification**

Case 1 The treating surgeon recommended plate removal after 18 months. The patient, however, is not fully convinced about the necessity for this procedure.

Relevance

Plates used for stabilization of forearm fractures can give rise to complaints, which might be a reason for removal. However, asymptomatic plates are also often removed despite the risk of complications, including refracture and injury of the superficial branch of the radial nerve.^{8,31,32}

Current opinion

Because of the substantial risk of refracture and injury, especially to the superficial branch of the radial nerve, elective plate removal is not indicated in asymptomatic patients.

Finding the evidence

- Cochrane Database: no reviews available
- PubMed, using the search terms "diaphyseal forearm fracture AND plate removal and complications," "forearm fracture AND plate removal AND complications," "forearm fracture AND plate removal," "forearm fracture AND plate removal AND refracture"

Quality of the evidence

Level IV

- 8 case series

Findings

Hidaka and Gustilo reported 7 refractures 2–42 weeks after removal of 32 plates in 23 patients (radius 14, ulna 18).³³ Six of these fractures were located in the radius. The interval between plate application and removal had ranged from 8 to 62 months. Average cast immobilization had been 6 weeks. The authors concluded that plates should not be removed before 12 months. Chapman suggested that use of the 4.5mm system contributed to the high incidence of refracture in this series.⁸

Deluca et al. found refracture in 7 of the 37 patients who had a total of 62 diaphyseal plates removed from the forearm.³⁴ Six of the 7 refractures were after an original

fracture of both bones. The interval between removal of plates and refracture ranged from 42 to 121 days. Only one patient had had adequate compression of the original fracture, the other six did not. In retrospect, radiolucency at the site of the original fracture was seen in most patients when the plate was removed.

Rosson and Shearer reported refracture after plate and screw removal in 4 of 51 adults after minimal trauma.³⁵ According to the authors, refracture was significantly more common among those patients having plates removed within 12 months compared with those in whom plates stayed in longer. The authors stated that the incidence of refracture should be minimal using the 3.5mm plating system.

Langkamer and Ackroyd studied 55 patients who had undergone elective removal of 44 radius and 37 ulna plates.³⁶ Plate removal took place at 5–84 months (average 23.7 months) after insertion. Refracture occurred in 2 patients through the previous fracture site; plate removal had taken place in those patients 9 months (4.5mm rigid plates had been used) and 24 months after initial repair, respectively. In both, no protection or restricted activities had been prescribed. The total complication rate was 40%, with more complications occurring when junior surgeons performed the surgery. It was recommended by the authors that forearm plates should be removed only if there were significant symptoms.

Rumball and Finnegan retrospectively reviewed all patients undergoing forearm plate removal during a 5.5 year period.³⁷ There were 4 refractures in 63 patients, an incidence of 6%. Factors that appeared to influence the refracture rate were degree of initial displacement and comminution, physical characteristics of the plate, early removal, and lack of postremoval protection.

Labosky et al. reported 80 plates removed from the radius and/or ulna in 51 patients.³⁸ Removal of plates was elective in 37 patients and for clinical reasons in 14. The average time from insertion to removal was 13.6 months (range 4.4–36 months). Only one refracture occurred in one patient whose plate was taken out 6 months after surgery. According to the authors, leaving a plate in cannot be considered a benign decision considering the persistent chance for refracture and the potential complications from prolonged exposure to metal corrosion complexes and metal ions.

Beaupré and Csongradi reported a retrospective examination of 401 patients with 459 plates removed after forearm fracture.³⁹ These data were collected from seven studies in the literature. Various types of plates had been used, and 37 refractures had occurred in 29 patients. The refracture risk was significantly greater for the narrow large-fragment DCP system than with either the small-fragment DCP system or the one third tubular system.

Chia et al. (1996) found in a retrospective review of 82 patients with 128 diaphyseal fractures operated at a single

institution that 97.5% had no complications after implant removal.⁴⁰ Two patients sustained a refracture at the site of the original fracture within 6 months after plate removal, which could be treated successfully by cast immobilization. Twenty patients experienced minor complications ranging from mild superficial wound infection to nerve injury.

Recommendations

- Elective removal of forearm plate is contraindicated and should only be considered if there is pain or another symptom resulting from hardware irritation to the soft tissues [overall quality: very low]
- If plate removal is considered, It should be delayed for at least 12–18 months after the initial fixation [overall quality: very low]
- The use of large screws (>3.5mm) in forearm fractures should be avoided [overall quality: very low]

Summary of recommendations

- Fractures of the distal third of the radius are often associated with DRUJ instability
- DRUJ instability is best evaluated, both radiographically and physically by manipulation during surgery after stabilization of the radial fracture
- A proximal located isolated radial fracture does not rule out traumatic DRUJ instability
- Based on the present literature there is no conclusive recommendation possible for the most optimal treatment method in isolated ulnar fractures
- Standard bone grafting is not required in comminuted diaphyseal fractures during initial treatment
- If bone grafting is used, its application should possible be reserved only for fractures with bone loss greater than two thirds of the diameter of the diaphysis
- Anatomical fixation of the radius in Galeazzi fractures is a necessary condition to obtain DRUJ congruency
- Surgical treatment of Galeazzi fractures should take place within 10 days after injury
- The DRUJ must be radiographically visualized and manually tested during surgery after ORIF of the radial fracture to assess joint congruency and residual instability
- If ORIF of the radial fracture leads to anatomic reduction of the DRUJ cast immobilization is sufficient and additional K-wire fixation is not necessary
- Elective removal of forearm plate is contraindicated and should only be considered if there is pain or another symptom resulting from hardware irritation to the soft tissues
- If plate removal is considered, It should be delayed for at least 12–18 months after the initial fixation
- The use of large screws (>3.5mm) in forearm fractures should be avoided

Conclusions

Fractures of the forearm can be divided into four groups. Isolated radial fractures (1) and fractures of both bones of the forearm (2) are routinely treated by ORIF. Acute bone grafting in comminuted fractures is not necessary in most cases. Most isolated fractures of the ulnar diaphysis (3) can be treated with immobilization in a cast or functional brace. Galeazzi fracture-dislocations (4) must be recognized and treated with stable internal fixation of the radial fracture to ensure DRUJ congruency and anatomic alignment. Thorough evaluation of the DRUJ should be performed in every isolated radial fracture, regardless of the fracture location. Temporary fixation of the DRUJ with K-wires can be of use to maintain the reduction, but there is no evidence that this should be performed in all cases. Open reduction of the DRUJ is indicated only in irreducible dislocations.

Distal Radius Fractures

Boris A. Zelle¹ and Michael Zlowodzki²

¹University of Texas Health Science Center at San Antonio, San Antonio, TX, USA

²University of Minnesota, Minneapolis, MN, USA

Case scenario

A 65 year old woman presents to the Emergency Department after a fall on to her outstretched right hand. She noticed immediate onset of wrist pain and swelling.

Relevant anatomy

In the radiographic evaluation of distal radius fractures, different anatomic parameters serve as guidelines for quantifying the amount of displacement (Table 49.1).¹

Openmirrors.com

Importance of the problem

Distal radius fractures usually result from low-energy trauma and occur more frequently in women than in men.^{2,3} Along with spine and hip fractures, distal radius fractures are the most common osteoporosis-related fractures in the elderly patient.⁴ The lifetime risk of sustaining a distal radius fracture at the age of 50 years has been estimated to be 2% for white men and 15% for white women.⁵ It has been suggested that fractures that heal with a significant intra-articular step-off appear are at risk for developing post-traumatic osteoarthritis.⁶

Top eight questions

1. Initial splinting: long-arm vs. short-arm?
2. External fixation vs. cast?
3. Bridging vs. nonbridging external fixation?
4. Kapandji vs. across-fracture pinning?

5. Injectable calcium phosphate bone cement?
6. Volar plating vs. external fixation?
7. Volar plating vs. dorsal plating?
8. Arthroscopic vs. fluoroscopic reduction?

Question 1: Initial splinting: long-arm vs. short-arm?

Case clarification

Closed reduction and splinting is performed in the Emergency Department. The healthcare staff ask if immobilization should be done with a short-arm or long-arm splint.

Relevance

Long-arm splints limit supination/pronation of the forearm and limit flexion/extension of the elbow. However, they are more uncomfortable than short-arm splints, and may result in soft tissue compromise at the elbow.

Current opinion

Sugar-tong splints should be used in the acute setting to protect against pronation/supination and flexion/extension.

Finding the evidence

Articles that were not in the English language were excluded. Data from abstracts and book chapters were not included.

Quality of the evidence

Level II

- 3 randomized clinical trials (RCT) with limitations

Level II

- 1 systematic review of cohort studies with worrisome heterogeneity

Findings

A Cochrane review included eight trials comparing above-elbow vs. below-elbow splinting of distal radius fractures.⁵ Most data was retrieved from meeting abstracts and articles from the non-English literature. The authors did not identify any evidence to support recommendations for above-elbow vs. below-elbow splinting of distal radius fractures.

We identified three clinical trials comparing above-elbow vs. below-elbow splinting (Table 49.2).^{7–9} These trials were heterogeneous with regard to splinting methods used and

Table 49.3 Functional, clinical, and anatomical outcomes of external fixation vs. casting

	N	Events		Relative risk (95% CI)
		Ex fix	Cast	
Nonexcellent functional outcome	321	134/256	166/265	0.82 (0.71–0.95)
Pin-track infections	846	69/444	1/402	12.02 (5.07–28.49)
Osteomyelitis	332	1/182	0/150	2.47 (0.10–59.70)
Reflex sympathetic dystrophy	731	25/384	17/347	1.31 (0.74–2.32)
Redisplacement resulting in secondary treatment	694	7/356	51/338	0.17 (0.09–0.32)

CI, confidence interval; Ex fix, external fixator.

reporting of outcomes. There was no pooling of data. Significant differences in loss of reduction between long-arm and short-arm constructs were not recorded in any of these studies. Bong et al. reported improved comfort in the short-arm group at the 1 week follow-up as measured by the DASH score.⁷

Recommendations

- Short-arm splints do not increase the risk of secondary displacement in distal radius fractures [overall quality: low]
- Short-arm splints seem better tolerated by patients [overall quality: low]

Question 2: External fixation vs. cast?

Case clarification

Three days later, the patient returns to the office for follow-up. The fracture is well splinted and reduced, but she remains at risk for secondary displacement. The option of external fixation is discussed.

Relevance

Maintaining a good reduction is important in the treatment of displaced distal radius fractures.

Current opinion

External fixation may provide improved stabilization and may be associated with a decreased risk of secondary displacement.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 1 systematic review of 15 randomized and pseudo-RCTs

Findings

In a Cochrane review¹ of 15 trials with 1022 patients, external fixation and casting of dorsally displaced distal radius fractures were compared (Table 49.3). External fixation resulted in a significantly reduced risk of fracture displacement. A significantly higher portion of patients undergoing external fixation achieved excellent functional grading. However, a sensitivity analysis showed that this finding was not robust. External fixation was associated with a significantly higher risk of minor complications, such as pin-site infections. The risk of serious complications, such as reflex sympathetic dystrophy (RSD), was not significantly different.

Recommendations

- External fixation reduces the risk of redisplacement of dorsally displaced radius fractures compared with casting [overall quality: high]
- External fixation may result in a better functional outcome [overall quality: low]
- External fixation is associated with an increased risk of pin-track complications [overall quality: high]

Question 3: Bridging vs. nonbridging external fixation?

Case clarification

Different external fixation techniques are discussed with the patient.

Relevance

Both bridging and nonbridging external fixation have been described.

Current opinion

Bridging external fixation is widely used in the treatment of distal radius fractures.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 4 RCTs (Table 49.4)¹⁰⁻¹³

Findings

Only 1 study found significantly better final outcomes in the nonbridging group for volar tilt, grip strength, and wrist flexion.¹³ Krishnan et al.¹¹ recorded significantly better wrist flexion at 6 and 52 weeks in the bridging group. Krukhaug et al.¹² reported significantly better wrist flexion in the bridging group at 6 weeks with no difference at 52 weeks.

Recommendations

- Nonbridging external fixation of distal radius fractures does not result in improved outcomes as compared with bridging external fixation [overall quality: moderate]

Question 4: Kapandji vs. across-fracture pinning?

Case clarification

The option of percutaneous pinning is discussed with the patient.

Relevance

In most percutaneous pinning techniques, the wires are placed across the fracture site. In Kapandji pinning, the wires are inserted intrafocally into the fracture gap to buttress the distal fragment.

Current opinion

Both techniques are similarly effective.

Finding the evidence

See Question 1. Trials reporting on percutaneous pinning in conjunction with other fixation methods, such as external fixation, were not included.

Quality of the evidence

Level I

- 1 RCT

Level II

- 1 RCT with methodological limitations

Findings

Two trials were identified (Table 49.5).^{14,15} Lenoble et al.¹⁴ reported a higher incidence of local nerve injury and RSD in the Kapandji group. Strohm et al.¹⁵ reported significantly

better functional outcomes in the Kapandji group as measured by a nonvalidated scoring system. Pooling of data was not feasible. The outcomes of these studies are potentially biased by the different postoperative protocols (earlier mobilization in the Kapandji groups).

Recommendations

- Kapandji and across-fracture pinning result in similar functional, anatomical, and clinical outcomes [overall quality: low]

Question 5: Injectable calcium phosphate bone cement?

Case clarification

The radiographs show overall poor bone stock and significant metaphyseal comminution. The use of injectable synthetic bone cement is discussed with the patient.

Relevance

Injectable synthetic bone cements appear to be an attractive option in the treatment of metaphyseal fractures.

Current opinion

The use of injectable calcium phosphate cements improves outcomes.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 1 systematic review of 6 RCTs (subgroup analysis on distal radius fractures)

Findings

A recently published meta-analysis included six RCTs on the use of injectable calcium phosphate bone cement in the treatment of distal radius fractures (Table 49.6).¹⁶ No significant difference between patients treated with and without injectable calcium phosphate bone cement was identified for functional and anatomical outcomes. Given the significant study heterogeneity, the results from this pooled analysis must be considered with caution. The use of injectable calcium phosphate bone cement was associated with a decreased risk of infection with a relative risk reduction of 85% (95% CI 58–85%, $p < 0.0001$). All infections were related to external fixator pins or Kirschner (K)-wires.

Recommendations

- The use of injectable calcium phosphate bone cement in the treatment of distal radius fractures decreases the risk of infection [overall quality: moderate]

Table 49.4 Final outcomes: bridging vs. nonbridging external fixation

	Atroshi et al. ¹⁰	Krishnan et al. ¹¹	Krukhaug et al. ¹²	McQueen et al. ¹³

Table 49.5 Outcomes of Kapandji vs. across-fracture pinning

	Lenoble et al. ¹⁴	Strohm et al. ¹⁵
N Total	96	81
N Kapandji vs. across-fracture pinning	54 vs. 42	40 vs. 41
Level of evidence	II	I
Treatment Kapandji pinning	2 intrafocal k-wires, immediate mobilization, pin removal after 45 days	2 intrafocal k-wires plus one trans-styloid wire, 6 weeks of volar splint, PT started at 3 weeks, pin removal at 6 weeks
Treatment across-fracture pinning	2 trans-styloid k-wires, 45 days of short-arm cast, pin removal after 45 days	2 trans-styloid k-wires, 6 weeks of forearm cast, pin removal at 6 weeks
Follow-up	24 months	Median 10 months (range 6–20 months)
Pain at final FUP Kapandji vs. across-fracture pinning	7.6 vs. 6.9 (VAS 0–100) (NS)	Not recorded
Grip strength Kapandji vs. across-fracture pinning	84% vs. 83% of uninjured side at 12 months (NS)	Not recorded
Pinch strength Kapandji vs. across-fracture pinning	89% vs. 87% of uninjured side at 12 months (NS)	Not recorded
Functional outcome at final FUP Kapandji vs. across-fracture pinning	No functional outcome score recorded	Modified Martini score (0–38) Median: 34 vs. 28 (significant)
Final anatomical outcome Kapandji vs. across-fracture pinning	Similar anatomical long-term outcomes illustrated on graphs, no raw data provided	Not recorded
SBRN injuries Kapandji vs. across-fracture pinning	8/54 vs. 3/42	Not recorded
Nerve irritation Kapandji vs. across-fracture pinning	Not recorded	5/40 vs. 7/41
RSD Kapandji vs. across-fracture pinning	8/54 vs. 3/42	1/40 vs. 1/41
Superficial pin-site infection Kapandji vs. across-fracture pinning	1/54 vs. 3/42	0/40 vs. 0/41
Wire migration Kapandji vs. across-fracture pinning	0/54 vs. 0/42	3/40 vs. 5/41

NS, not significant; PT, physical therapy; RSD, reflex sympathetic dystrophy; SBRN, superficial branch radial nerve; VAS, visual analog scale.

Table 49.6 Outcomes in patients treated with and without injectable calcium phosphate bone cement

Outcome	N	No. of events calcium phosphate cement vs. control group	Point estimate (95% CI) (P value)	Tests for heterogeneity (P value, I ²)
Grip strength (mean % of uninjured side) at 1 year	494	N/A	WMD = 5.95 (-6.39 to 18.29) (p = 0.34)	<0.01, 94%
ROM flexion (mean % of uninjured side) at 1 year	456	N/A	WMD = 2.11 (-10.9 to 15.13) (p = 0.75)	<0.01, 94%
ROM supination (mean % of uninjured side) at 1 year	456	N/A	WMD = 3.18 (-7.8 to 14.16) (p = 0.57)	<0.01, 96%
Mean loss of radial inclination at 1 year	456	N/A	WMD = -4.04 (-11.78 to 3.7) (p = 0.31)	<0.01, 98%
Mean loss of dorsal angulation at 1 year	492	N/A	WMD = -2.75 (-7.45 to 1.9) (p = 0.25)	0.03, 79%
Infections	375	4/187 vs. 27/188	RR = 0.15 (0.15-0.42) (p < 0.0001)	N/A (only 2 trials)

N/A, not applicable; ROM, range of motion; WMD, weighted mean difference.

- The use of calcium phosphate bone cement does not result in improved functional or anatomical outcomes [overall quality: moderate]

Question 6: Plating vs. external fixation?

Case clarification

Articular involvement is noticed on the radiographs. More invasive options are discussed with the patient.

Relevance

Intra-articular step-off appears to be a significant predictor for the development of post-traumatic osteoarthritis.⁶

Current opinion

Multiple plating systems for distal radius fractures have become available and have reduced the use of external fixation constructs in many centers.

Finding the evidence

See Question 1. Studies comparing external fixation vs. open reduction and internal fixation (ORIF) were identified.

Quality of the evidence

Level I

- 4 RCTs

Level II

- 2 RCTs with methodological limitations

Findings

Six RCTs compared external fixation vs. ORIF (Table 49.7).¹⁷⁻²² Various external fixation and ORIF techniques were used. Given the heterogeneity of these studies, pooling of data was not possible. Leung et al.²⁰ recorded significantly better functional outcomes in the plating group. Kreder et al.¹⁹ recorded a faster functional recovery in the external fixation group, but no difference at final follow-up. Wei et al.²¹ recorded a better restoration of radial inclination and radial length with the use of radial column plates. One trial comparing external fixation vs. dorsal plating was terminated because of the high complication rate in the dorsal plating group.¹⁸

Recommendations

- ORIF does not result in better functional and anatomic outcomes than external fixation [overall quality: moderate]

Question 7: Volar plating vs. dorsal plating?

Case clarification

The option of volar vs. dorsal plating is discussed with the patient.

Relevance

Most dorsally displaced fractures are amenable to volar or dorsal plating.

Table 49.7 External fixation vs. plating

	Egol et al. ¹⁷	Grewal et al. ¹⁸	Kreder et al. ¹⁹	Leung et al. ²⁰	Wei et al. ²¹	Xu et al. ²²

Remarks	—	Study terminated because of high complication rate in dorsal plating group	1. 8 patients crossed over from external to fixation to plate group to achieve reduction 2. Authors observed faster recovery in external fixation group		Radial plate group achieved significantly higher radial length and radial inclination than external fixation and volar plate group	

BG, bone graft; CTS, carpal tunnel syndrome; DRUJ, distal radioulnar joint; HWR, hardware removal; NS, not significant; RSD, reflex sympathetic dystrophy; SBRN, superficial branch of radial nerve.

^aLower score means better outcome.

^bNot specified.

Current opinion

Dorsal plating allows for a better reduction of displaced dorsal fragments, but is associated with a high risk of tendinitis.

Finding the evidence

See Question 1.

Quality of the evidence

Level I

- 1 RCT

Findings

One RCT evaluated the outcomes of 30 patients with intra-articular distal radius fracture undergoing volar vs. dorsal plating.²³ The volar plating group achieved significantly

better outcomes for grip strength, range of motion, and the Gartland–Werley score at 6 months follow-up (Table 49.8). Radiographic outcomes were similar in both groups.

Recommendations

- Volar plating of distal radius fractures results in superior functional short-term outcomes [overall quality: moderate]

Question 8: Arthroscopic vs. fluoroscopic reduction?

Case clarification

The plan is to proceed with external fixation and percutaneous pinning. The option of arthroscopic vs. fluoroscopic reduction is discussed.

Table 49.8 Outcomes of volar vs. dorsal plating

N	Volar plate	Dorsal plate	P
	15	15	
Gartland–Werley score ^a	1.73 ± 1.1	4.9 ± 2.1	<0.01
Grip strength % of uninjured side	95 ± 11	65 ± 15	<0.01
Pain VAS 0–10	1.2 ± 0.8	3.1 ± 1.5	>0.05
ROM			
Total arc flexion/extension (°)	115 ± 23	68 ± 17	<0.01
Total arc supination/pronation (°)	151 ± 16	130 ± 18	0.002
Radiographic outcomes			
Radial inclination (°)	21	24	0.061
Volar tilt (°)	6	10	0.145
Complications	1 RSD 0 secondary displacements 1 painful scar	2 RSD 2 secondary displacements 3 painful scars	

ROM, range of motion; RSD, reflex sympathetic dystrophy; VAS, visual analog scale.

^aLower score means better outcome.

Relevance

Wrist arthroscopy offers the potential benefit of direct visualization of intra-articular step-offs and allows for treatment of associated intra-articular soft tissue injuries.

Current opinion

Despite its potential benefits, wrist arthroscopy is rarely used in the treatment of distal radius fractures.

Finding the evidence

See Question 1. Studies comparing arthroscopic vs. fluoroscopic reduction in patients undergoing external fixation and percutaneous pinning were identified.

Quality of the evidence

Level I

- 1 RCT

Level II

- 1 prospective cohort study:

Findings

Two trials were identified.^{24,25} Arthroscopically assisted reduction appeared to be associated with significantly better functional outcomes, range of motion, and articular reduction (Table 49.9). Both studies recorded that wrist arthroscopy detected a relatively high incidence of intra-articular soft tissue injuries that were addressed during the index procedure.

Recommendations

- In patients undergoing external fixation and percutaneous pinning, arthroscopically assisted reduction results in better functional and anatomic outcomes than fluoroscopic reduction alone [overall quality: moderate]

Summary of recommendations

- Short-arm splints do not increase the risk of secondary displacement in distal radius fractures
- Short-arm splints seem better tolerated by patients
- External fixation reduces the risk of redisplacement compared with casting, but is associated with increased risk of pin-site infection
- Nonbridging external fixation does not result in better outcomes than bridging external fixation
- Kapandji and across-fracture pinning result in similar functional, anatomical, and clinical outcomes
- The use of injectable calcium phosphate bone cement in the treatment of distal radius fractures decreases the risk of infection
- The use of calcium phosphate bone cement does not result in improved functional or anatomical outcomes
- ORIF does not result in better outcomes than external fixation
- Volar plating fractures results in better functional short-term outcomes than dorsal plating
- In patients undergoing external fixation and percutaneous pinning, arthroscopically assisted reduction results in

Table 49.9 Arthroscopic vs. fluoroscopic reduction

	Ruch et al. ²⁴	Varitimidis et al. ²⁵

BG, bone graft; FUP, follow-up; LT, luno-triquetral; NS, not significant; RSD, reflex sympathetic dystrophy; SL, scapholunate; TFCC, triangular fibrocartilage complex.

^aLower score means better outcome.

Openmirrors.com

better functional and anatomic outcomes than fluoroscopic reduction alone

Conclusions

Numerous reports on the treatment of distal radius fractures have been published. However, only few recommendations for the management of distal radius fractures are supported by high-level evidence.

Perilunate Dislocations

Geert A. Buijze¹, Job N. Doornberg¹, and David Ring²

¹Orthopaedic Research Center Amsterdam, Academic Medical Center, Amsterdam, The Netherlands

²Harvard Medical School, Boston, MA, USA

Case scenario

A 30 year old man presents to the Emergency Department after a high-energy motorcycle collision. His only injury is to his right (dominant) wrist, which is painful, swollen, and deformed. Radiographs reveal a dorsal perilunate dislocation of the wrist. The neurovascular examination is unremarkable.

Relevant anatomy

The wrist tends to dislocate around the lunate, leaving the radiolunate relationship relatively spared. The ligaments and bones around the lunate are injured, hence the term perilunate injury. There are two types of injuries: so-called *lesser arc injuries* in which the ligament attachment of the lunate are injured and *greater arc injuries* which involve one or more fractures of surrounding carpal bones instead of a ligament injury (Figure 50.1). According to the system of Mayfield et al.,¹ perilunate injuries follow a four-stage mechanism of progressive instability from radial to ulnar (Figure 50.2; see box). In reverse perilunate injuries the mechanism is opposite, from ulnar to radial.

Four-stage mechanism of perilunate injuries

- Stage 1: scapholunate dissociation
- Stage 2: capitulunate dissociation
- Stage 3: lunotriquetral dissociation
- Stage 4: lunate dislocation

Importance of the problem

Perilunate injuries cause permanent wrist impairment and midcarpal arthrosis with effective treatment and global wrist arthrosis necessitating wrist arthrodesis with ineffective treatment.

Top seven questions

Openmirrors.com

Diagnosis

1. Is there a role for CT, MRI, or arthroscopy in the diagnosis of perilunate wrist dislocations?
2. What is the relative prevalence of greater and lesser arc injuries and reverse perilunate injuries?

Therapy

3. How often is manipulative reduction successful?
4. What is the optimal timing of definitive surgery?
5. What is the preferred operative exposure in perilunate injuries?
6. What is the preferred type of temporary fixation of the carpus: screws or Kirschner (K-) wires?

Prognosis

7. What are the most important factors to predict impairment and disability after perilunate dislocations?

Figure 50.1 Patterns of greater arc and lesser arc injuries.

Figure 50.2 Mayfield's four stages of perilunate instability and dislocation.

Question 1: Is there a role for CT, MRI, or arthroscopy in the diagnosis of perilunate wrist dislocations?

Case clarification

Lateral and posteroanterior radiographs suggest a lesser arc perilunate injury without major fracture, but the anatomy is distorted and there are some bone fragments of unclear source.

Relevance

Perilunate dislocations are usually treated with open reduction and it is not clear that CT scanning or MRI helps with preparation or understanding of the injury beyond that gained with open visualization of the injury.

Current opinion

The role of more sophisticated imaging is debated.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "perilunate injur* OR carpal dislocation" AND "imaging"
- Bibliography of eligible articles
- Articles that were not in the English language were excluded.

It is recommended to include only the most recent studies in decision-making, as CT and MRI imaging protocols have become significantly more advanced over the last few years.

Quality of the evidence

Level IV

- 1 case series²

Level V

- 1 expert opinion³

Findings

Despite the fact that posteroanterior and lateral radiographs are almost always sufficient to diagnose carpal dislocations, up to 25% of these injuries are missed at presentation, as shown by Herzberg et al. (level IV).² Advanced imaging is not required, but according to Kaewlai et al. (level V) CT with multiplanar and volumetric reformation can be a useful technique to demonstrate the complexity and extent of fractures and dislocations.³ There are no methodological studies comparing plain radiographs to CT imaging, MRI, or diagnostic arthroscopy for carpal dislocations.

Recommendation

- Advanced imaging is not necessary for diagnosis of perilunate dislocations among experts, but 2-D and 3-D CT

might be helpful to nonspecialists and can occasionally assist in evaluating complexity [overall quality: very low]

Question 2: What is the relative prevalence of greater and lesser arc injuries and reverse perilunate injuries?

Relevance

Greater and lesser arc injuries are managed differently and may have different prognoses.

Current opinion

Greater arc injuries are commonly believed to be less frequent than lesser arc injuries.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “carpal” AND “fracture* OR injur*” AND “epidemiology OR prevalence”
- Bibliography of eligible articles

Quality of the evidence

Level III

- 1 epidemiologic study⁴

Level IV

- 2 case series^{2,5}

Findings

A study by van der Molen et al. (level III), which assessed the epidemiology of functionally disabling carpal injuries (resulting in at least 6 weeks of time off work) in a 4 year period in the Netherlands, found that carpal fracture-dislocation represented 5.4% of all carpal injuries.⁴ The fracture-dislocations consisted of lesser arc injuries (2.1%), greater arc injuries (3%), and radiocarpal dislocations (0.4%). In Dunn’s (level IV) series of 40 carpal fracture-dislocations over a 16-year period in one center in the United States, there were 12 lesser arc injuries (30%), 13 greater arc injuries (33%), 6 (15%) radiocarpal dislocations, 5 carpometacarpal dislocations (13%), and 4 dislocations of carpals other than the lunate (10%).⁵ In the largest multicenter study reported by Herzberg et al. (level IV), greater arc injuries were twice as frequent as lesser arc injuries.²

Recommendation

- Greater arc injuries are more common than lesser arc injuries.

Question 3: How often is manipulative reduction successful?

Relevance

Immediate successful reduction can limit the potential for median nerve dysfunction and allow for delay of definitive repair.

Current opinion

Closed reduction is often possible within a day of injury, but becomes more difficult with progressive delay.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “perilunate injur* OR carpal dislocation” AND “treatment”
- Bibliography of eligible articles

Quality of the evidence

Level IV

- 1 case series⁶

Level V

- 1 case report⁷
- 1 expert opinion⁸

Findings

In the study reported by Adkison et al. (level IV) manipulative reduction was successful in 37 of 55 (67%) patients.⁶ Fifty-nine percent of the wrists lost alignment during the first 6 weeks of treatment despite cast immobilization. Closed treatment alone was only successful 27% of the time. The likelihood of success decreases rapidly within a few days after injury.^{7,8}

Recommendations

- Manipulative reduction is mostly successful in the acute setting and mostly unsuccessful if not performed within the first few days [overall quality: low]
- Closed reduction can only be maintained for a short period with cast immobilization [overall quality: low]

Question 4: What is the optimal timing of definitive surgery?

Relevance

Some consider these injuries emergencies.

Current opinion

If closed reduction can be achieved, surgery can be delayed for up to a week after injury.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “perilunate injur* OR carpal dislocation” AND “treatment”
- Bibliography of eligible articles

Quality of the evidence

Level III

- 1 case-control studies¹⁰

Level IV

- 2 case series^{2,9}

Level V

- 3 expert opinions¹¹⁻¹³

Findings

Weir (level IV) showed that if treatment is delayed by more than 2 weeks, functional outcome is expected to be worse.⁹ In the largest retrospective series reported by Herzberg et al. (level IV), delay in treatment of more than 7 days showed near-significantly worse results ($p = 0.07$) compared to treatment within 7 days.² Delay in treatment of more than 45 days showed significantly worse results ($p < 0.05$). However, not all patients in that series underwent surgery.

In a study by Komurcu et al. (level III) comparing the outcome of early vs. delayed treatment in 12 patients with greater arc injuries, there was a significant difference in clinical and radiological outcome in favor of early treatment¹⁰.

Most surgeons suggest surgery between 3 and 5 days after injury for dislocations that can be manipulatively reduced.¹¹⁻¹³

Recommendation

- The optimal timing of definitive surgery for a manipulatively reducible dislocation is within a week after injury [overall quality: moderate].

Question 5: What is the preferred operative exposure in perilunate injuries?

Relevance

There is controversy regarding the optimal surgical approach.

Current opinion

Approaches may be either arthroscopic-assisted percutaneous or open using a dorsal, volar, or combined exposure.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "perilunate injur*" OR carpal dislocation" AND "treatment"
- Bibliography of eligible articles

Quality of the evidence

Level IV

- 8 case series^{2,14-20}

Level V

- 3 expert opinions^{13,18,21}

Findings

There are no direct comparative studies between the different operative approaches for perilunate injuries. All three open exposures (dorsal, volar, and combined) can lead to satisfactory outcome.^{2,15-20} A long-term outcome study reported by Forli et al. (level IV) of 18 greater and lesser arc injuries including all three open exposures did not show a correlation between outcome and approach.¹⁷ Volar and dorsal approaches each have advantages and drawbacks. Herzberg (level V) reports that a combined volar and dorsal approach improves exposure, but increases the possibility of postoperative fibrosis and stiffness.¹³ An arthroscopically assisted percutaneous approach can be a promising alternative in less severe cases, but to date only three patients with good outcomes have been reported by Park and Ahn (level V).²¹ Moreover, one series from Wong and Ip (level IV) using a minimally invasive percutaneous approach showed good results in 21 greater arc injuries.¹⁴ There is no evidence to determine the best methods for reduction (open or closed), ligament repair or reattachment, or immobilization. Percutaneous reduction and fixation without direct ligament repair is appealing, but the little data published on this technique suggest that it is inferior to open techniques.

Recommendation

- The surgical approach should be based on the surgeon's preference and individualized for the patient [overall quality: low].

Question 6: What is the preferred type of temporary fixation of the carpus: screws or K-wires?

Relevance

Temporary screws may reduce the likelihood of skin problems or infection and may allow earlier mobilization.

Current opinion

Most surgeons use K-wires to hold the carpus reduced while the ligaments heal.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords "perilunate injur*" OR carpal dislocation" AND "treatment"
- Bibliography of eligible articles

Quality of the evidence

Level III

- 1 case-control study²²

Level V

- 1 expert opinion²³

Findings

Herbert (level V) suggested using temporary screws between the scaphoid and lunate and between the lunate and the triquetrum as an alternative to K-wire fixation.²³ In the study by Souer and colleagues (level III) comparing the two treatment methods in 18 patients there were no significant differences in radiographic and functional outcomes.²² Although none of the outcomes were significant, there was a trend favoring screw fixation in some of the outcomes. The average flexion–extension arc was slightly higher (87° vs. 73°) and the prevalence of midcarpal arthritis was lower (29% vs. 71%) in the screw fixation group. There were 2 pin infections in the K-wire cohort and the only pin in the screw fixation cohort (used to address ulnocarpal translocation) also became infected, with 2 patients having wrist sepsis.

Recommendation

- There results of treatment with temporary screws and temporary K-wires are comparable [overall quality: moderate]

Question 7: What are the most important factors to predict impairment and disability after perilunate dislocations?

Relevance

Despite optimal management most patients with perilunate injuries experience persistent impairment and disability.

Current opinion

The most important factors predicting impairment and disability are delay in treatment, open injuries, and persistent carpal malalignment.

Finding the evidence

- PubMed (www.ncbi.nlm.nih.gov/pubmed/): sensitivity search using keywords “perilunate injur* OR carpal dislocation” AND “outcome OR prognosis”
- Bibliography of eligible articles

Quality of the evidence

Level IV

- 6 case series^{2,9,16,17,19,24}

Findings

In the series of 166 perilunate injuries by Herzberg et al. (level IV), the factors significantly influencing the clinical results consisted of open injury and delay in treatment of more than 45 days, whereas the anatomical type of injury (greater vs. lesser arc) had no significant influence.² Delay in treatment of more than 2 weeks was associated with

poor results in a series of five late reductions, reported by Weir (level IV).⁹ In two case series, additional osteochondral fractures of the head of the capitate were associated with poorer results.^{19,24} In the series of 18 perilunate injuries with the longest follow-up (minimum of 10 years) reported by Forli (level IV), the presence of radiological arthritis and static carpal instability did not cause reduced function.¹⁷ These findings are consistent with the findings of Weir et al.⁹ and Hildebrand et al. (level IV).¹⁶ The latter series of 23 perilunate injuries also investigated differences in outcome between lesser and greater arc injuries and found no significant differences in any of the clinical outcome measurements. The only significant difference was that lesser arc injuries had a significantly larger revised carpal height ratio.

Recommendations

- The most important factors predicting impairment and disability are delay in treatment, open injury, and osteochondral fracture of the capitate head [overall quality: low]
- Clinical outcomes are often substantially better than radiographic outcomes [overall quality: low]

Summary of recommendations

- Advanced imaging is not necessary for diagnosis of perilunate dislocations among experts, but 2-D and 3-D CT might be helpful to nonspecialists and can occasionally assist in evaluating of complexity
- Greater arc injuries are more common than lesser arc injuries
- Manipulative reduction is mostly successful in the acute setting and mostly unsuccessful if not performed within the first few days
- Closed reduction can only be maintained for a short period with cast immobilization
- The optimal timing of definitive surgery for a manipulatively reducible dislocation is within a week after injury
- The surgical approach should be based on the surgeon's preference and individualized for the patient
- There results of treatment with temporary screws and temporary K-wires are comparable
- The most important factors predicting impairment and disability are delay in treatment, open injury, and osteochondral fracture of the capitate head
- Clinical outcomes are often substantially better than radiographic outcomes

Conclusions

Because of the low prevalence of perilunate dislocations, there is a paucity of high-quality evidence regarding its

diagnosis, treatment, and prognosis. The best available evidence on these injuries consists of retrospective comparative studies. Therefore, all recommendations in this chapter are of moderate to very low quality and thus need to be interpreted with caution.

Carpal Fractures

Bertrand H. Perey¹, Anne-Marie Bedard², and Fay Leung³

¹University of British Columbia, Port Moody, BC, Canada

²Laval University, Centre Hospitalier Universitaire de Quebec, Quebec, QC, Canada

³University of British Columbia, Vancouver, BC, Canada

Case scenario

A 30 year old laborer fell from his truck and landed on his right arm with the wrist in dorsiflexion. He presented to the Emergency Department with pain and swelling of the right wrist, at the anatomical snuffbox. Range of motion of the wrist is limited by pain. Radiographs were taken (Figure 51.1).

Relevant anatomy

The scaphoid is anatomically divided into three sections: proximal pole, waist, and distal pole. The scaphoid is largely covered with articular cartilage, and receives its blood supply primarily from the artery to the dorsal ridge of the scaphoid, a branch of the radial artery. Approximately 75% of the scaphoid, including the proximal pole, is supplied by retrograde flow from this artery. The vascularity of the proximal pole is tenuous as it depends entirely on this intraosseous blood supply. The distal pole receives abundant blood supply directly from the palmar superficial branch of the radial artery.

Scaphoid fractures are described by location (proximal, waist, or distal) and by stability (stable and unstable). An unstable scaphoid fracture is defined as greater than 1 mm of displacement on any radiological views, or greater than 15° of lunocapitate angulation, or greater than 45° scapholunate angulation on the lateral view.

The intrascaphoid angle, evaluated on a sagittal CT scan cut (Figure 51.2) is formed by the junction of two lines

perpendicular to the diameter of the proximal and distal pole. The normal intrascaphoid angle is 24°.

Importance of the problem

The scaphoid is the most commonly fractured carpal bone, and accounts for approximately 60% of carpal fractures and 11% of all hand fractures. Most fractures occur in young men, many of whom are manual workers. These patients are particularly disabled when prolonged immobilization is required to achieve union.

Untreated scaphoid fractures may go on to mal- or nonunion, leading to abnormal carpal kinematics and subsequent wrist osteoarthritis (Figure 51.3), underlining the need for early diagnosis and vigilant care of an acute scaphoid injury.

Top seven questions

Diagnosis

1. What diagnostic modality should be used in the process of diagnosing, evaluating, and following a scaphoid fracture?

Treatment

2. What is the recommended treatment for an acute undisplaced fracture of the waist of the scaphoid?
3. When treating an undisplaced fracture of the scaphoid conservatively, what is the ideal method of casting?

Figure 51.1 PA in ulnar deviation (a), lateral (b) and scaphoid (c) view of the right scaphoid.

Figure 51.2 Intrascaphoid angle measured at 62° on CT scan. It is formed by the junction of two lines perpendicular to the diameter of the proximal and distal pole. Normal is 24°.

4. When treating an undisplaced scaphoid fracture with internal fixation, what is the ideal surgical technique?
5. What is the ideal treatment when faced with a delayed diagnosis of an undisplaced fracture of the scaphoid?
6. What is the ideal treatment for displaced fracture of the waist of the scaphoid?
7. What is the ideal treatment for an undisplaced proximal pole fracture?

Question 1: What diagnostic modality should be used in the process of diagnosing, evaluating and following a scaphoid fracture?

Case clarification

The patient’s radiographs are initially negative. You are planning to immobilize the patient in a cast and reassess him in 2 weeks with repeat radiographs (Figure 51.4), but you wonder if an immediate bone scan, CT scan, or MRI would be more appropriate.

Relevance

A missed scaphoid fracture can have adverse outcomes. It is generally accepted that a delay in diagnosis and treatment of scaphoid fractures can lead to nonunion or malunion resulting in symptomatic osteonecrosis, carpal collapse, or secondary osteoarthritis.

Current opinion

Patients presenting with a clinically suspected scaphoid fracture, but negative initial radiographs, are treated with temporary cast immobilization for 10–14 days before a second set of radiographs is performed.

Finding the evidence

- Cochrane Database, with search term “scaphoid fracture”, 1985 to present.

Quality of the evidence

Level I

- 28 diagnostic studies
- 1 therapeutic randomized controlled trial (RCT)

Figure 51.3 (a) Nonunion at the junction of the waist/proximal pole (b) Stage 1 scaphoid nonunion advanced collapse following a proximal pole fracture (c) Stage 3 scaphoid nonunion advanced collapse.

Figure 51.4 (a) Pronated oblique view of the same patient in Figure 51.1. Following the injury, there was a doubt about a waist fracture. (b) A radiograph taken 10 days later reveals more clearly the waist fracture.

Level IV

- 1 case series

Findings

Sensitivity and negative predictive value of initial radiographs

The negative predictive value (NPV) of initial radiographs varies greatly between studies. While a randomized control trial showed a sensitivity and NPV of 93% and 98.9% respectively (Table 51.1 and Table 51.2),¹ Table 51.3 shows a range between 63% and 93%. To compensate for this variation, patients with clinically suspected acute scaphoid fractures but negative initial radiographs are typically treated with 2 weeks of cast immobilization followed by repeated examination and radiographic studies. This leads

to unnecessary immobilization of probably over 75% of these patients, with the socioeconomic impact of loss of productivity, time off work, and the inappropriate use of healthcare resources.

Is immobilization necessary while waiting for the second series of radiographs? The absence of immobilization would improve the function of the patient and decrease the associated costs while waiting for the final diagnosis. However, this alternative must not compromise the outcome of being safe for fractures missed initially.

An RCT conducted by Sjolín et al.¹ studied 108 patients with a clinical suspicion of scaphoid fracture but negative

**Figure 51.5** Coronal Fat Sat T2 MRI confirming a suspected proximal pole fracture of the scaphoid.

initial radiographs and randomized them to treatment with either a supportive bandage or a dorsal plaster cast. Four patients proved to have incomplete waist fractures and three to have avulsions from the tuberosity. No complete fractures were seen. The average sick leave was 14 days for those in a cast and 4 days for those in a bandage, a difference that represented a significant loss of productivity. The authors concluded that occult fractures on initial radiographs are likely to be very stable, and they may be treated with a supportive bandage while awaiting definitive diagnosis.

Another argument against immediate immobilization comes from a level IV case series²² that studied the consequences of a delay in cast treatment and the development of nonunion in 285 fractures of the scaphoid. No increase in the time to union or in the incidence of nonunion was found following a delay of immobilization of less than 4 weeks. However, when the delay exceeded 4 weeks, some fractures had healing complications.

Other diagnostic modalities and their utility in avoiding significant, unnecessary immobilization time Bone scan is sensitive but not specific for diagnosing scaphoid fractures. Sensitivity has been evaluated at approximately 95%, while specificity is around 70%. Moreover, it usually requires a delay of 72 hours following the injury before the test can be performed. Currently, MRI is thought to have sensitivity and a specificity approaching 100% (Figure 51.5).

Five level I diagnostic studies compare MRI to bone scan.^{6,7,11,23} In 2005, the pooled results of four of these

studies²⁴ showed that MRI is at least as sensitive as bone scan for diagnosing scaphoid fractures, but it has superior specificity. MRI also allows for earlier diagnosis, and the ability to detect associated soft tissue injuries. According to Thorpe et al.,⁷ costs would be similar between the two options.

More recently, a new comparative diagnostic study evaluated 100 consecutive patients with suspected scaphoid fractures and negative radiographs.²⁵ Among the 20 cases with a proven scaphoid fracture, there were 4 false-negative cases with MRI, and 8 false-positive cases with bone scan. The authors could not confirm the superiority of MRI over bone scintigraphy and criticized the previous 4 studies for using different imaging sequences and protocols, variable timing to MRI, and small sample sizes.

Brooks¹⁹ investigated the cost-effectiveness of MRI by randomizing 28 patients with a suspected scaphoid fracture to either MRI or immobilization with radiographs at 10–14 days. MRI reduced the days unnecessarily spent in a cast (3 days vs. 10 days, $p < 0.006$) and the use of health-care resources. The total expenditure in the two groups was similar (MRI group = \$594 (Australian), control group = \$428, $p = 0.19$), owing to the direct cost of MRI. Costs from productivity loss and income loss secondary to immobilization were not included in the calculation; however, if considered, this may have swayed the conclusion in favor of MRI.

Dorsay²⁶ constructed a cost-effectiveness model based on a review of the literature pooling data on the NPV of initial radiographs (similar to Table 51.3). They found that 75% patients will be needlessly immobilized, as the diagnostic process will conclude the absence of scaphoid fracture. Their cost analysis, which did not include productivity losses, suggested that initial MRI is nearly equivalent to repeated radiographs.

CT scan can also identify occult fractures (Figure 51.6) but is more useful in defining the fracture pattern and the angular deformity.²⁷ It is not as sensitive, specific, or accurate as MRI for identifying acute occult fractures.²⁸

Two level I diagnostic studies have looked at the results of ultrasound^{29,30} and found a sensitivity of 78%, a specificity of 89%, a PPV of 88% and a NPV of 80%. This is inferior to MRI or bone scan, and only slightly better than radiographs.

Recommendations

- An initial normal radiograph cannot accurately guarantee absence of a scaphoid fracture: it is therefore recommended to proceed with further imaging, either acutely or 2 weeks later [overall quality: high]
- MRI is the study of choice to diagnose occult scaphoid fracture in the acute setting and has the advantage of avoiding unnecessary immobilization. There is good evidence to support its cost-effectiveness. The availability of

Figure 51.6 CT scan of the same patient as in Figure 51.1. CT can identify occult fracture but is more useful in assessing fracture displacement and angulation.

this modality may limit its application [overall quality: high]

- A second set of radiograph at 2 weeks is an appropriate diagnostic tool but leads to unnecessary immobilization of the majority of patients. However, there is good evidence to support that immobilization of the wrist in a cast is not necessary in the interval before the new images [overall quality: high]

Question 2: What is the recommended treatment for an acute undisplaced fracture of the waist of the scaphoid?

Case clarification

The patient's radiographs were repeated 2 weeks after the injury and now reveal an undisplaced fracture of the waist of the scaphoid (Figure 51.7). He works as a laborer and will not be able to work with a cast. He asks you about alternative options.

Relevance

Conservative treatment of undisplaced fractures by plaster cast immobilization has been reported in case series to be successful in approximately 95% of patients.^{30–32} However, some have questioned the reliability of plain radiographs in diagnosing union, suggesting that reported union rates may be falsely elevated.³³ Meanwhile, many case series have shown the union rate with percutaneous technique to be close to 100%. Moreover, acute scaphoid fractures

Figure 51.7 (a) AP, (b) pronated oblique and (c) scaphoid view of an undisplaced scaphoid fracture.

mainly affect young working individuals for whom immobilization is associated with costs related not only to medical treatment but also to work disability. The superiority of percutaneous treatment over cast treatment for undisplaced fractures of the scaphoid is as yet unproven.

Current opinion

Currently, the majority of acute undisplaced scaphoid fractures are treated conservatively with a cast.

- 1 economic and decision analysis

Level II

- 1 RCT with methodologic limitations

Level III

- 1 retrospective comparative study

Level IV

- 2 case series

Findings

Nine RCTs have evaluated cast treatment vs. surgical fixation for undisplaced acute scaphoid fractures.³⁴⁻⁴² Table 51.4 summarizes the findings in each study. Derived from these randomized studies, the following observations can be drawn.

Range of motion and grip strength No negative long-term effect of cast immobilization with respect to joint stiffness and decreased grip strength was observed.

Functional scores At final follow-up, no study showed a significant difference in subjective functional scoring

Rate of union Only one study used CT scan to assess union.⁴² In the remaining studies, the determination of healing was made using radiographs only, which may give an inaccurate diagnosis of union.³³ With the information available, the rate of union between conservative and surgical treatment is not different. Only Dias et al. found a difference between the two groups, but their definition of nonunion may have been too inclusive, as 5/10 nonunions diagnosed at 12 weeks eventually healed without further intervention.

Time to union For the same reason, assessment of time to union was suboptimal, and the time to union was not reported in every study. In the study by Aurora et al., the only study to include the use of CT scan, a significant difference was found in the time to union in favor of the percutaneous technique. However, the data is insufficient to conclude any advantage of the percutaneous technique over conservative treatment.

Time off work Vinnars et al. evaluated the subgroup of occupationally active individuals in an RCT³⁴ and published their observations in a cost-effectiveness trial.³⁵ The median time of absence from work was 74 days in the cast group and 39 days in the surgery group, but this difference was not significant ($p = 0.32$). In the subgroup of manual workers, there was a significantly longer period of absence from work in those undergoing closed treatment than those treated surgically (100 vs. 61 days, $p = 0.03$). Saeden et al. similarly reported that manual laborers remained on sick

^ap = 0.32. But when assessed separately, patients with manual work had significantly longer time off work than the nonmanual employees/self-employed: 84 days vs. 16, statistically significant, p < 0.001.

^b2 in the nonsurgical group.

^cStatistically significant, p < 0.001

^dThe original article describes 5 distal fractures, 2 proximal fractures, 10 fractures with mild displacement (amount not specified), 7 fractures with DISI and 22 fractures with comminution.

^eStatistically significant, p < 0.001. Nonunion was assessed at 12 weeks. One fracture healed with continued cast treatment, whereas 4 fractures were considered healed at the time of surgery for nonunion. This leaves 5 real nonunions. Moreover, of these 10 apparent nonunions in the cast group, 5 occurred among the 11 patients with comminution.

^fStatistically significant, p < 0.01

^gStatistically significant, p = 0.002. The difference was significant for patients with blue-collar occupation, but not for patients with a white-collar occupation.

^hStatistically significant, p = 0.0003.

ⁱStatistically significant, p = 0.0001, but the trial was performed on U.S. Navy personnel who are not allowed to return to work with a cast.

^jStatistically significant, p < 0.02, but ROM recorded at 16 weeks, just after cast removal.

^kStatistically significant, p < 0.05. Only study using CT scan to assess union.

leave for a mean period of 7 weeks in the operated group and for 18 weeks in the conservative group (p < 0.001), whereas no significant difference was found in patients with sedentary occupations. McQueen et al. and Aurora et al. both found significantly longer periods off work in the

conservative group. They did not evaluate for a difference between manual and sedentary workers. The difference found by Bond et al. can be questioned, as the trial was performed on U.S. Navy staff, who were not permitted to return to work with a cast.

Time spent off work with surgery is significantly shorter for manual workers, with lack of a clear advantage for sedentary workers. The definition of manual worker should probably be revised to encompass any individual for whom the unencumbered hand is necessary to accomplish his/her work (e.g., a surgeon or a pianist).

Cost-effectiveness There are three cost-effectiveness comparisons between the conservative and the surgical treatment of undisplaced scaphoid fractures. Two are included in the therapeutic RCTs mentioned earlier,³⁵ and one is a decision analytic model.⁴³ Aurora et al. found significant differences in the immobilization time and the time absent from work between the conservative and the surgical groups. The hospital costs were significantly higher in operated patients because of the direct cost of the surgery. The work disability costs were significantly less in operated patients (€200 vs. €1453, $p < 0.01$). When all costs were calculated, operative treatment (€2097) was less expensive than conservative treatment (€2363 Euros) but this was not statistically significant ($p > 0.05$).

As mentioned earlier, Vinnars et al. found a significant difference in time off work in manual workers treated surgically, with no such difference found in sedentary workers/self-employed group. Hospital-related costs were always higher in the operated group than in the cast group ($p < 0.01$) due to the direct cost of surgery. In the sedentary and self-employed workers, work disability costs were minimal, making the surgical option clearly not cost-effective for these patients. In the manual workers group, the work disability costs were numerically higher in the cast group than in the surgical group, but this did not reach statistical significance. The costs related to surgery were offset by lower work disability costs, with the final total costs being not significantly different to the cast treatment.

Davis et al.⁴³ designed a decision analytic model based on quality of life measures and cost differences between surgery and casting. They concluded that open reduction and internal fixation (ORIF) offers greater quality-adjusted life years and is more cost-effective than casting because less productivity is lost.

Complications Complications are variably reported, accounting for the difference in rate of complications between studies. Table 51.5 reports the complications encountered among the RCTs cited earlier. These studies all used a volar approach, either open or percutaneous.

Scaphotrapezial osteoarthritis Vinnars et al. found a significant increase in the prevalence of osteoarthritis in the scaphotrapezial joint of their surgical group ($p = 0,005$). No difference in the rate of osteoarthritis was found between those treated with a volar mini-incision (3/11), compared to an open approach (8/28). Subjective outcomes of pa-

tients diagnosed with scaphotrapezial osteoarthritis (STT OA) did not differ from the remaining patients.

Saeden et al. similarly reported 14/23 cases of STT OA in the surgical group, compared to 4/16 in the conservative group, as diagnosed by CT 12 years after internal fixation of scaphoid fractures. Again, these findings did not affect clinical outcome.

Recommendations

- The surgical treatment of an undisplaced scaphoid fracture does not lead to improved range of motion, grip strength, or functional outcome at final follow-up [overall quality: high]
- The rate of union and the time to union are not improved by surgical treatment of an undisplaced fracture, as assessed by radiographs. Studies with CT scan assessment of union are mandatory in the future [overall quality: moderate]
- The time off work is significantly shorter when treating a manual worker surgically, but this does not appear to be true for sedentary workers. Consequently, surgery is more cost-effective in patients who are involved in work, sports, or lifestyles incompatible with long-term immobilization [overall quality: high]
- In those where immobilization does not alter daily function, cast immobilization remains the standard treatment since patients are not subject to the attendant risks associated with surgery [overall quality: high]

Question 3: When treating an undisplaced fracture of the scaphoid conservatively, what is the ideal method of casting?

Case clarification

The patient radiographs reveal an undisplaced fracture of the waist of scaphoid (see Figure 51.7). After discussing the nonsurgical and surgical options with the patient, you decide to treat him conservatively.

Relevance

Many casting options are suggested in the literature. The ideal casting method should be one that protects the fracture fragments from moving while providing maximum function to the patient.

Current opinion

Short-arm thumb spica cast remains the most widely accepted treatment of undisplaced scaphoid fracture.

Finding the evidence

- Cochrane Database, with search term “scaphoid fracture”, 1985 to present.

Quality of the evidence

Level I

Level II

- 1 prospective comparative study

Level III

- 2 retrospective comparative study

Level IV

- 1 case series

Findings

Long-arm vs. short-arm cast One RCT⁴⁴ studied the results of a long-arm vs. a short-arm cast immobilization for acute undisplaced fracture of the scaphoid. Proximal, middle, distal third, and tuberosity fractures were included. This study showed significantly shorter time to union in the long-arm group (9.5 vs. 12.5 weeks, $p < 0.05$), and higher rate of non-unions and delayed unions (p value not mentioned). Union was assessed using plain radiographs only, which brings into question the validity of the results.³³ Nevertheless, this

study remains the only level I paper addressing the long-arm vs. short-arm cast issue.

One level II prospective comparative study⁴⁵ failed to show any difference in the time to union between the two methods of casting. Level III^{46,47} and level IV³⁰ studies show conflicting results, and no conclusion can be drawn in favor of either of the two methods.

Many biomechanical comparative studies have been conducted, again showing conflicting results.⁴⁸⁻⁵¹ A cadaveric study⁵² used CT scan to evaluate amount of fracture displacement during pronation between unprotected scaphoids and scaphoids immobilized in below-elbow thumb spica cast. Long-arm casting was not tested. Less than 1mm of displacement was judged to be acceptable. The total magnitude of motion from pronation to supination averaged 0.2mm in the specimens immobilized with a below-elbow thumb spica cast, suggesting that a short-arm cast would be appropriate in preventing motion at the fracture site.

Table 51.6 Union rate according to type of casting, at 6 months postinjury

Cast	Definitely united		Probably united		Nonunion	
	N	%	N	%	N	%
Thumb spica	111	78	18	12	14	10
Colles	114	77	19	13	15	10

NB: no p value provided in the article.

Lawton et al.⁵³ compared the forearm rotation allowed by a long-arm thumb spica cast vs. an epicondylar bearing (Munster) thumb spica cast on healthy individuals with no fracture. The authors suggested that the Munster cast could still limit enough forearm rotation to avoid healing complications while allowing more elbow flexion/extension than a long-arm cast; however, the clinical advantages of this type of casting have not been demonstrated.

Inclusion of the thumb One RCT⁵⁴ showed that immobilization with a thumb spica cast is no more likely to achieve union than immobilization of the wrist alone with a Colles type of cast (Table 51.6).

Furthermore, Karantana et al.,⁵⁵ in another level I trial, compared the effect of the two types of casts on hand function in 20 healthy volunteers. Both casts prolonged the time taken to complete the hand function test compared to controls, but the thumb spica cast group took significantly longer than the group in the Colles cast (thumb spica cast = 48.2 seconds, Colles cast = 58.5 seconds, no p value provided) to complete the test.

Position of immobilization of the wrist In the 1950s and 1960s, authors advocated numerous wrist positions, with the goal of reducing displaced fractures and maintaining the reduction in a cast. In the only level I RCT addressing this issue, Hambridge et al.⁵⁶ showed that wrist position does not influence rate of union (union rate 89%, $p = 0.46$) but does influence function. At 6 months, the patients with a Colles cast in 20° of flexion had significantly greater restriction in extension than those immobilized with 20° of extension (61° vs. 73° of dorsiflexion, $p < 0.01$). Flexion, radial deviation, and ulnar deviation were not impaired by any type of immobilization.

Recommendations

- The evidence is not strong enough to support the use of a long-arm cast in the treatment of an undisplaced scaphoid fracture [overall quality: moderate]
- Inclusion of the thumb in the cast is not critical for scaphoid fracture healing [overall quality: high]

Table 51.7 Advantages and disadvantages of the volar and dorsal open approaches

Advantages	Disadvantages
Volar	
Preservation of main blood supply	Violation of radiocarpal ligaments
Better access to middle and distal third fractures	Poor access to proximal pole
Easier correction of humpback deformity	Central placement of screw more difficult ^a
Dorsal	
Preservation of radiocarpal ligaments	Risk for dorsal branch of radial artery
Better access to proximal pole	Poor access to distal third
Central placement of screw easier	Difficult correction of humpback deformity
Less tourniquet time	

^aSee discussion in the section on percutaneous technique.

Question 4: When treating an undisplaced scaphoid fracture with internal fixation, what is the ideal surgical technique?

Case clarification

The patient's radiograph reveals an undisplaced fracture of the waist of scaphoid (Figure 51.7). After discussing the nonsurgical and surgical options with the patient, you decide to treat him surgically.

Relevance

When planning the surgery, the specialist must decide between an open or percutaneous technique. Each technique can further be accomplished with a volar or a dorsal approach. The surgeon must know the advantages and possible concerns/complications of each strategy.

Current opinion

The majority of surgeons prefer to use the percutaneous volar retrograde technique when treating an undisplaced fracture of the scaphoid.

Finding the evidence

- Cochrane Database, with search term "scaphoid fracture", 1985 to present.

Quality of the evidence

Level I

- 5 RCTs

Level III

- 4 retrospective comparative studies

Level IV

- 5 case series

Findings

Open approach The majority of case series discussing ORIF of scaphoid fractures have used a volar approach, which avoids disruption of the dorsal branch of the radial artery. However, violating the volar radiocarpal ligaments may subsequently create carpal instability. The dorsal approach for scaphoid fracture fixation has also been described.^{57,58}

Table 51.7 summarizes the advantages and disadvantages of the volar and dorsal open approaches.

There are two retrospective level III studies comparing the open volar and dorsal approaches. Polsky et al.⁵⁹ studied 26 patients with scaphoid fractures treated with a cannulated screw. Sixteen patients underwent a dorsal approach and 10 patients a volar approach. There was no difference in the rate of union between the two approaches (dorsal 81%, volar 80%, *p* value not reported). No significant differences were noted between the groups for range of motion, grip strength or pain level (*p* > 0.08). There was a significantly shorter tourniquet time with the dorsal approach (*p* = 0.047), explained by easier exposure with dorsal approach, with no risk of violating the radiocarpal ligaments and easier targeting of the central axis of the scaphoid (see later discussion on percutaneous approaches).

Garcia-Elias et al.⁶⁰ compared the volar approach to the dorsal approach in cases of scaphoid nonunions treated with inlay bone grafting and found a similar union rate (around 80%). The volar approach resulted in a significant increase in the scapholunate angle (*p* < 0.001) and in the lunocapitate angle (*p* < 0.05). Surgical division of the palmar radiocarpal ligaments was thought to be responsible for these findings.

To our knowledge, there is no randomized study comparing the open volar and dorsal approaches in cases involving only acute scaphoid fractures.

Percutaneous vs. open approaches There is no study directly comparing percutaneous and open approaches. It is generally accepted that the percutaneous approach reduces the surgical morbidity associated with an open procedure.

Indications for percutaneous technique are listed in Table 51.8.

Positioning of the screw Trumble et al.⁶¹ showed decreased time to fracture union (*p* < 0.05) in open scaphoid fixation with screws located more centrally in the proximal fragment. This was true with the use of either a cannulated or noncannulated screw, but significantly more cannulated

Table 51.8 Indications for the use of a percutaneous technique

Indications	Contraindications
Nondisplaced fracture ^a	Irreducible fracture
Displaced reducible fracture	Nonunion with severe sclerosis
Proximal pole fracture	Nonunion with bone loss >1 mm
Fracture with delayed presentation	Presence of humpback deformity
Fracture with fibrous union	Pseudarthrosis
Nonunion with minimal sclerosis, bone loss <1 mm ^b	AVN of proximal pole
Presence of associated fractures, if scaphoid fracture meet the above criteria	

^aIf surgical treatment chosen.

^bNo angulation present. Consider percutaneous curettage and bone grafting.

screws were placed centrally (17/18 in the cannulated group, 7/16 in the noncannulated group, *p* < 0.01).

Trumble further stressed the importance of central screw placement after conducting a comparative biomechanical study between centrally and eccentrically placed screws.⁶² This study confirmed that screws placed centrally in the proximal fragment are stronger, with greater stiffness (43%, *p* < 0.01) and increased load to displacement (113%, *p* < 0.01) and provide more secure fixation and lower risk of screw migration or fracture at the screw–bone interface.

Choice of screw Trumble's work suggests that the type of screw is not as important as its central positioning. The use of cannulated systems greatly facilitates central placement of the screw. Surgeons also favor the use of headless designs, which allow the screw to be fully buried in the bone and prevent erosion on adjacent structures. In a biomechanical comparative study, the Herbert–Whipple and the standard Acutrak were not different in their ability to resist cyclical bending load.⁶³

Volar vs. dorsal percutaneous approach The volar percutaneous technique is the most commonly used (Figure 51.8). Extension and ulnar deviation of the wrist during the procedure facilitates maintenance of fracture reduction and introduction of the screw. It is more difficult to place the screw centrally with this approach, first because the surgeon cannot rely on the ring sign under fluoroscopy to target the central scaphoid axis, and, secondly, the volar lip of the trapezium limits the ability to enter the scaphoid in a

Figure 51.8 Retrograde volar percutaneous technique. (a) and (b): insertion of the KW in a retrograde fashion, through the trapezium in order to achieve central placement of the screw. (c) insertion of the screw. (d) and (e): final result.

central position unless a transtrapezial technique is used.⁶⁴ Finally, with the volar approach, there is concern about injury to the superficial branch of the radial artery or to the scaphotrapezial joint.

With the dorsal approach, the position of flexion and pronation of the wrist under fluoroscopy makes the proximal pole of the scaphoid look like a circle (ring sign). This facilitates placement of the Kirschner (K)-wire into the center of the circle. It is imperative, but technically challenging, to maintain this position throughout the surgery to prevent the K-wire from bending or breaking. There is also a risk of fracture displacement with this position. While avoiding the scaphotrapezial joint, the dorsal approach raises concerns about violating the radiocarpal joint, as well as injuring the extensor tendons.

The only situation where there is a clear advantage of a given approach is in the case of a proximal pole fracture, where the dorsal/proximal approach is more effective in securely fixing and compressing the small proximal fragment.⁶⁵ Proximal pole fractures are discussed under Question 7.

The two approaches have been directly compared in only one level III retrospective study published in 2009.⁶⁶ The two approaches were similar for all outcomes measures, namely pain, range of motion, grip strength, and Mayo wrist score. No statistically significant difference regarding union rate could be detected between the two groups ($p = 0.683$). The same authors also evaluated the effect of dorsal vs. volar approach on screw placement. While the dorsal approach appeared to allow for a more perpendicular placement of the screw relative to the fracture line ($p < 0.05$), and screw placement more parallel to the long axis of the scaphoid in the semipronated oblique view only ($p = 0.019$), there was no difference in union rate between the dorsal and volar groups. A cadaveric comparison of the two approaches also observed that the dorsal approach allows for a more central placement of the screw, but in the distal third only ($p = 0.045$).⁶⁷ While previous studies have insisted on central placement of the screw in the proximal fragment,^{61,62} it remains unclear whether a more central placement in the distal pole only translates into improved clinical outcome.

As mentioned earlier in Question 2, a lack of standardization in complication reporting makes comparison of complication rates across studies difficult. Complication rates ranging from 0% to 30% have been reported in series using a volar percutaneous approach. The majority are case series but among them figure also the controlled trials of Dias et al.,^{37,38} Bond et al.,⁴⁰ Adolfsson et al.,⁴¹ and Arora et al.⁴² (see Question 2, section on complications). Complications reported for the dorsal percutaneous techniques are derived from five case series⁶⁷⁻⁷¹ and range from 0% to 29%. Each approach brings different concerns, but generally, no approach is superior in terms of rate of complications.

The special concern about scaphotrapezial osteoarthritis with the volar percutaneous approach was discussed in Question 2.

Recommendations

- For an undisplaced fracture of the scaphoid, a percutaneous technique reduces the surgical risks compared to an open approach and is therefore the technique of choice [overall quality: moderate]
- Both the antegrade and retrograde percutaneous techniques can be used: the surgeon has to learn the technical aspects and inherent risks associated with each approach [overall quality: moderate]
- Central placement of the screw in the scaphoid is critical, as it tends to increase the rate of union and decrease the time to union [overall quality: high]
- Scaphotrapezial changes are common in patients treated with the retrograde technique, but long-term outcomes are the same in these patients [overall quality: high]

Question 5: What is the ideal treatment when faced with a delayed diagnosis of an undisplaced fracture of the scaphoid?

Case clarification

The patient presents 5 weeks after injury to his wrist. Radiographs show an undisplaced scaphoid waist fracture.

Relevance

Scaphoid fractures can escape early detection because the initial symptoms can be minimal, and the clinical and radiographic signs can be subtle. Many authors suggest that any fracture that presents more than 4 weeks from injury is at high risk of nonunion.

Current opinion

When there is a delay in diagnosis, most scaphoid fractures should be treated operatively.

Finding the evidence

- Cochrane Database from 1980 to 2009, with search terms "scaphoid," "carpal," and "delay"

- MEDLINE (OVIDSp) search from 1980 to 2009 identifying population (adult), with keywords "scaphoid," "fracture," and "delay"
- The above searches were supported by additional cross-referencing of the bibliographies of eligible published reports

Quality of the evidence

Level IV

- 3 case series

Findings

Russe⁷² reported 27 cases of delayed presentation of scaphoid fractures (range 3 weeks to 3 years). All fractures eventually achieved union with cast treatment, but the duration of immobilization was considerable.

Eddleland et al.³² reported that the rate of nonunion was 73.3% (11/15) when immobilization was initiated between 4 weeks and 1 year, and 96.3% (26/27) when it was initiated at more than 1 year. They concluded that a delay in treatment of more than 4 weeks from injury is highly predictive for the development of scaphoid nonunion.

Finally, another retrospective review of 285 scaphoid fractures demonstrated that, while the incidence of nonunion was negligible if treatment was initiated within 0–28 days of injury, the frequency of nonunion significantly increased with a delay in treatment of greater than 4 weeks (p < 0.001).²² The frequency of nonunion increased incrementally with length of treatment delay (p < 0.02). Of the fractures that eventually healed, a treatment delay of more than 4 weeks was associated with a significantly increased time to union (p < 0.001).

Recommendation

- Delay in treatment exceeding 4 weeks from time of injury is associated with high risk of nonunion or delayed union, and therefore surgical intervention is warranted [overall quality: low]

Question 6: What is the ideal treatment for a displaced fracture of the waist of the scaphoid?

Case clarification

The patient elected to be treated with a cast, and returns 1 week after his original injury. He has been noncompliant with the cast, and has removed it. While mountain biking, he sustained a fall on to the affected hand. The new radiographs are as shown in Figure 51.9.

Relevance

It is assumed that a displaced fracture has greater disruption of the blood supply, as well as more fracture instability, leading to a higher risk of nonunion. The generally accepted criteria for displacement in scaphoid fractures are provided

Figure 51.9 AP and lateral radiographs of a displaced scaphoid fracture. Note the increased lunocapitate and scapholunate angles, implying scaphoid shortening and angulation.

by Cooney et al.,³⁰ who defined a displaced or unstable fracture as greater than 1 mm offset on the AP radiograph or oblique views, or a lunocapitate angle greater than 15° or scapholunate angle greater than 45° on lateral radiograph.

Current opinion

Displaced scaphoid fractures treated conservatively are associated with an unacceptable risk of nonunion or malunion, and thus surgical treatment, by either an open or percutaneous technique, is generally preferred.

Finding the evidence

- Cochrane Database of systematic reviews, from 1980 to 2009, with search terms “scaphoid,” “carpal,” “displaced”

- Surgical treatment of displaced scaphoid fractures: 11 case series
- Postoperative immobilization: 1 meta-analysis of level IV evidence
- Bone graft: 8 case series

Findings

Cast immobilization Several studies have described delayed union or nonunion associated with cast treatment for dis-

placed scaphoid fractures.^{30,32,73,74} However these studies are case series that often consist of heterogeneous groups of acute and chronic fractures of varying morphology, and they assess the outcome of different types of treatments, either conservative or surgical. Despite the limitations of these studies, the available literature uniformly suggests that cast immobilization is associated with increased healing time, and a higher risk of nonunion. The reported success rates following surgical treatment of displaced scaphoid fractures are high, precluding further studies comparing nonsurgical and surgical treatment strategies.

Surgical treatment Many surgical techniques have been described for the treatment of displaced scaphoid fractures, demonstrating union rates of 88–100%.^{58,67–69,75–84} The choice of approach has been discussed in Question 4. Most case series describe treatment with the volar approach, using a variety of fixation techniques.^{75–79} Two prospective case series reported on the outcome of an open dorsal approach for displaced fractures.^{58,80} The authors both reported a 100% union rate, with low complication rate.

The use of percutaneous fixation techniques is becoming increasingly favorable, even for displaced fracture. Union rates have varied from 89% to 100% union with arthroscopically assisted techniques.^{67–69,81–84}

Arthroscopy has been used both to evaluate fracture reduction and to identify associated injuries not apparent on imaging.^{67–69,82–84} One study of 15 patients treated with arthroscopically assisted reduction and percutaneous fixation found that 73% of displaced fractures were associated with injury to adjacent structures.⁸³ Thirteen percent had scapholunate ligament injury, 26.7% lunotriquetral ligament injury, 40% chondral injury to the capitate or lunate,

33% radiolunate or radioscapuloulate ligament injury, and 33% triangular fibrocartilage complex (TFCC) tear.

While the available literature of varying fixation techniques consistently demonstrates high rates of union for displaced scaphoid fractures, these studies are limited to retrospective case series. There are no clinical trials comparing open and percutaneous fixation techniques, and the addition of arthroscopy has not been shown to yield better functional outcome.

Postoperative immobilization There are no studies directly evaluating the postoperative protocol following surgical treatment of acute scaphoid fractures. Most authors use a thumb spica splint for approximately 1–2 weeks. The splint is then removed, range of motion is initiated, and a removable splint is worn for 3 months. When fixation of the fracture is deemed to be tenuous or for fractures of the proximal pole, authors advocate a 4–6 week course of cast immobilization.^{81,82,85}

A recent meta-analysis on scaphoid nonunions reviewed data from 36 case series, and found a union rate of 74% regardless of immobilization in a pooled sample of 500 patients.⁸⁶ The authors concluded that there is no compelling necessity for postoperative cast immobilization when fixation with a screw is stable.

Bone graft The need for bone graft in the setting of acute scaphoid fracture is not well addressed in the literature. A biomechanical study comparing various screw types showed that loss of volar cortex of the scaphoid greatly decreased the quality of fixation provided by screws.⁶³ In clinical studies describing an open approach to scaphoid fractures, cancellous or corticocancellous graft has been used in the presence of fracture comminution and bone loss.^{76,77,79} With the advent of percutaneous reduction and fixation techniques, most studies have not described the use of bone graft.^{67,81,83,84} Most recently, Slade et al.⁸² suggested that scaphoid fractures and nonunions with significant gaps require bone grafting. However, in his retrospective review of 126 acute fractures treated with arthroscopically assisted dorsal percutaneous fixation, no bone graft was required acutely.

Recommendations

In patients with a displaced scaphoid fracture, evidence suggests:

- Nonoperative treatment is associated with a high risk of nonunion or malunion [overall quality: low]
- Operative management, using open dorsal or volar approach for fracture reduction and fixation or reduction and percutaneous fixation, is associated with high rate of fracture union [overall quality: low]
- When stable fixation is achieved, postoperative immobilization is unnecessary [overall quality: very low]

- There is no evidence to support use of bone graft for the treatment of acute scaphoid fractures [overall quality: low]

Question 7: What is the ideal treatment for an undisplaced proximal pole fracture?

Case clarification

The patient presents with an undisplaced proximal pole fracture (see Figure 51.10). He would like to know his treatment options.

Relevance

Cadaveric studies have indicated a tenuous blood supply to the proximal pole of the scaphoid. Fractures to this area therefore require longer fracture healing time, and present higher risk of nonunion.^{87,88}

Current opinion

Because of the presumed risk of delayed union and nonunion of fractures of the proximal pole, many surgeons favor early operative intervention for acute proximal pole fractures, using a dorsal approach (Figure 51.11).

Finding the evidence

- Cochrane Database of systematic reviews from 1980 to 2009, with search terms “scaphoid,” “carpal,” and “proximal pole”
- MEDLINE (OVIDSp) search from 1980 to 2009, identifying population (adult), with keywords “scaphoid,” “fracture,” and “proximal pole”
- The above searches were supported by additional cross-referencing of the bibliographies of eligible published reports

Quality of the evidence

Level IV

- Nonoperative management of proximal pole fractures: 5 case series
- Surgical management of proximal pole fractures: 4 case series

Findings

Nonoperative management The available data is derived from level IV cases series only.^{22,54,72,89} They suggest that nonoperatively treated proximal pole fractures are at risk for developing non- or delayed union. All these studies involve small numbers and do not include statistical analysis comparing healing time of proximal pole fractures to waist fractures. Furthermore, evaluation of healing was performed using radiographs, which may not represent a reliable measure of fracture union.

Surgical treatment Although there have not been any studies comparing volar vs. dorsal approach for proximal

Figure 51.10 AP and pronated oblique view of proximal pole scaphoid fracture

Figure 51.11 The same patient treated with a dorsal mini-open incision and antegrade screw.

scaphoid fractures, the dorsal approach is favored as it allows for easier exposure of the fracture site and maximizes fracture stability.^{67,90}

There are no RCTs or comparative trials evaluating surgical treatment of proximal pole fractures. The only focused series of acute proximal pole fractures treated surgically is reported by Rettig et al.⁹¹ Seventeen proximal pole fractures were treated within 15 days using a dorsal approach with a Herbert screw inserted in a retrograde fashion. Thirteen of these fractures were comminuted and were bone grafted. At an average follow-up of 37 weeks, the authors reported 100% of fractures achieved union as evaluated by CT, and no complications were encountered.

The literature on surgical treatment of proximal pole fracture is thus mainly derived from series where waist fractures, proximal pole fractures, and distal pole fractures are pooled together.^{67,77,82,83} The high variability among those studies precludes any conclusion specific to proximal pole fracture.

Recommendations

- Nonoperative management of proximal pole scaphoid fractures is associated with a high risk of delayed union or

nonunion. Surgical management is preferred [overall quality: low]

- The dorsal approach is preferred for surgical stabilization of proximal pole fractures [overall quality: very low]

Summary of recommendations

- An initial normal radiograph cannot accurately predict the absence of a scaphoid fracture: it is therefore recommended to proceed with further imaging, either acutely or 2 weeks later

- MRI is the study of choice to diagnose occult scaphoid fracture in the acute setting and has the advantage of avoiding unnecessary immobilization. There is good evidence to support its cost-effectiveness. The availability of this modality may limit its application

- A second set of radiographs at 2 weeks is an appropriate diagnostic tool but leads to unnecessary immobilization of the majority of patients. However, there is good evidence to support that immobilization of the wrist in a cast is not necessary in the interval before the new images

- The surgical treatment of an undisplaced scaphoid fracture does not lead to improved range of motion, grip strength or functional outcome at final follow-up
- The rate of union and the time to union are not improved by surgical treatment of an undisplaced fracture, but studies with CT scan assessment of union are mandatory in future
- The time off work is significantly shorter when treating a manual worker surgically, but this does not appear to be true for sedentary workers. Consequently, surgery is cost-effective and more beneficial to patients who are involved in work, sports or lifestyles incompatible with long-term immobilization
- In those where immobilization does not alter daily function, cast immobilization remains the standard treatment since patients are not subject to the attendant risks associated with surgery
- The evidence is not strong enough to support the use of a long-arm cast in the treatment of an undisplaced scaphoid fracture
- Inclusion of the thumb in the cast is not critical for scaphoid fracture healing
- For an undisplaced fracture of the scaphoid, a percutaneous technique reduces the surgical risks compared to an open approach and is therefore the technique of choice
- Both the antegrade and retrograde percutaneous technique can be used: there are technical aspects and inherent risks associated with each approach
- Central placement of the screw in the scaphoid is critical, as it tends to increase the rate of union and decrease the time to union
- Scaphotrapezial arthritic changes are common in patients treated with the retrograde technique, but long-term outcomes are the same as in patients without scaphotrapezial changes
- Delay in treatment exceeding 4 weeks from time of injury is associated with high risk of nonunion or delayed union, and therefore surgical intervention is warranted
- Nonoperative treatment of displaced scaphoid fractures is associated with a high risk of nonunion or malunion
- Operative management of displaced scaphoid fractures, using open dorsal or volar approach for fracture reduction and fixation or reduction and percutaneous fixation, is associated with high rate of fracture union
- When stable fixation is achieved, postoperative immobilization is unnecessary
- There is no evidence to support use of bone graft for the treatment of acute scaphoid fractures
- Nonoperative management of proximal pole scaphoid fractures is associated with a high risk of delayed union or nonunion. Surgical management is preferred
- The dorsal approach is preferred for surgical stabilization of proximal pole fractures

Brent Graham

Toronto Western Hospital, Toronto, ON, Canada

Case scenario

A 22 year old man is referred to the hand a clinic 3 days after having sustained an injury to the right hand as a result of an altercation. The patient came to the Emergency Department a few hours after the injury where radiographs were obtained showing the presence of a fracture involving the 5th metacarpal. The patient was immobilized in an ulnar gutter cast from the fingertips of the ring and small fingers to the proximal forearm without a prior reduction. This individual's health is entirely satisfactory. He is normally employed as a carpenter. The injured hand is the dominant limb.

The physical examination showed the presence of extensive edema and ecchymosis around the ulnar border of the hand and in the palm. The contour of the hand in this area was obscured by edema but it appeared that the prominence of the metacarpal head at the metacarpophalangeal joint of the small finger was decreased. There was an angular deformity of the distal diaphyseal area of the 5th metacarpal and this corresponded to the area of maximal tenderness to palpation. Movements of the digits were limited by voluntary guarding because of pain but the patient was capable of nearly full composite flexion with no indication of rotational deformity involving the small finger. The sensory and vascular condition of the hand was normal.

The radiographs obtained in the Emergency Department showed a fracture through the distal diaphyseal/metaphyseal junction of the 5th metacarpal with angulation of the distal fragment volarly by 50°. There was no

displacement of the distal fragment, which appeared to be impacted onto the proximal fragment. No judgment could be made of rotation of the distal fragment.

Relevant anatomy

Fractures of the metacarpal bones are among the most common of all fractures incurred by the hand and the 5th metacarpal is by far the most common metacarpal fractured. The bone is slightly curved volarly when viewed from the side. As a result, angular forces applied to the dorsal surface of the distal end of the bone result in a palmarly angulated fracture when the bending tolerance of the bone is exceeded. This is a frequent occurrence when the closed fist of an individual strikes a hard object.

Painless movement of the 5th ray at the metacarpophalangeal and interphalangeal joints is critical to the ability to generate a composite grasp of adequate strength. Restoration of this ability is the principle goal of treatment for fractures of the 5th metacarpal

Importance of the problem

The most common mechanism of injury is an altercation, and the typical patient is a man between the ages of 18 and 40. The demographic group most frequently affected by this injury is an important component of the workforce and because the injury is infrequently related to work, time away from activities—both work-related and recreational—is an important consideration.

Top five questions

1. What is optimal treatment for an angulated fracture of the 5th metacarpal that is not affected by rotation of the distal fragment?
2. How is rotational deformity at the fracture site most effectively established?
3. What is the long-term outcome of fractures of the 5th metacarpal? Is there a difference in long-term prognosis between cases treated surgically and those treated nonoperatively?
4. Is a supervised course of physical or occupational therapy usually required for the optimal treatment of fractures of the 5th metacarpal?
5. What is the optimal treatment for fractures at the base of the 1st metacarpal?

Question 1: What is optimal treatment for an angulated fracture of the 5th metacarpal that is not affected by rotation of the distal fragment?

Case clarification

The patient is a young man employed in a manual occupation. The injured hand is his dominant limb. There is moderate, clinically visible deformity at the fracture site, but the fragments themselves are stable.

Relevance

The patient should be treated with strategy that optimizes the functional outcome with as short a period of treatment as possible.

Current opinion

Nonoperative treatment, consisting of about 3 weeks of immobilization in a plaster cast, is associated with a rapid restoration of movement and strength despite substantial angulation at the fracture site. Treating the patient nonoperatively implicitly accepts the fracture deformity but obviates any of the risks associated with surgery, even though those are probably small. Later reconstruction, if required, is entirely feasible if nonoperative treatment fails to lead to a satisfactory outcome, but this is very rarely required.

Finding the evidence

- Cochrane Database, with search term “metacarpal fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/), with search terms: “metacarpal fractures” AND “treatment,” “metacarpal fractures” AND “surgical treatment,” and “metacarpal fractures” AND “outcome”

Quality of the evidence

There have been no level I studies evaluating treatment for metacarpal fractures. There has been a Cochrane review of the topic.

Findings

Despite the frequency with which this injury is encountered, little evidence exists in the literature supporting one method of treatment over another. In some measure this may be related to the fact that the condition is so common that anecdotal experience has been substantial and so the effort to accumulate actual evidence has not been made. An additional important factor is likely the difficulty in completing prospective studies, even those with a relatively short ascertainment period, in this young, mobile patient population. Added to this obstacle is the near universal experience that outcomes with this injury are generally excellent, hence the low priority given to studying the injury in detail.

One of the main controversies related to the treatment of fractures of the 5th metacarpal has been the indication for surgical intervention. The principle that has been promulgated in the literature by the advocates of surgical treatment has related to the extent of angulation of the distal fragment beyond which operative management should be considered. The concern is that, if left untreated, excessive angulation will subsequently lead to problems with hand function, although this conclusion has been based mostly on biomechanical rather than clinical observations. However, there has been wide variation in the threshold amount of angulation that should be considered excessive. In addition, the reliability of radiographic evaluation for fracture angulation has been found to be poor.¹ The relative roles of operative and nonoperative treatment for this injury therefore remain unclear.

A Cochrane review on the topic of nonoperative treatment for closed treatment of fractures in the 5th metacarpal found the quality of existing literature on the subject to be poor.² There were no studies that used a validated hand function measure as a primary outcome measure and the conclusions were based on a variety of secondary measures of outcome including pain after treatment, return to activities, cosmesis, and patient satisfaction.

The treatments that were compared were cast immobilization of the hand and wrist and a variety of “functional” treatments including bracing in the hand only, immobilization with taping or an elastic bandage in the hand, and complete freedom to move without any kind of immobilization. Most of the patients had an initial angulation at the fracture site of about 40°, and where this was measured in follow-up there was little or no change. In the early weeks after treatment, patients who were immobilized in a cast were less likely to report pain than were patients who were treated in a functional brace and, in turn, these patients

were less likely to report moderate pain than were those treated with bandaging alone. At 12 weeks of follow-up more than 90% of patients did not report pain regardless of the method of treatment. The prevalence of reporting severe pain was approximately the same in all groups for whom this symptom was evaluated: 5–7%. Mobility was greater in the early weeks after treatment in patients who were treated with the various forms of mobilization. At 3 months follow-up a small percentage of patients treated with cast immobilization had incomplete movement. Strength was also reduced in the first 6 weeks among patients treated with cast immobilization in comparison to those allowed mobility. No long-term data on this outcome was available. One study³ showed that a larger proportion of patients treated with functional bracing experienced an early return to work activities than did patients treated with “neighbor strapping.” Very small percentages of patients reported concerns about cosmesis, regardless of the treatment.

Where management of fractures of the 5th metacarpal is surgical, there is limited evidence in the literature to guide the selection of treatment. Winter et al.⁴ compared intramedullary fixation to transverse pin fixation in a small group of patients randomized to receive one or the other of the treatments. The indication for surgery in two thirds of the patients was a rotatory deformity. Patients who underwent intramedullary pinning had a slightly larger range of motion and grip strength at 3 months, although it was not clear whether the differences observed were clinically relevant. The study did not give any details about many of the important methodologic aspects of a randomized trial, including the process of randomization and blinding/masking of the evaluators.

A parallel case series comparing the same two procedures by Wong et al.⁵ did not find statistically significant differences on any of the radiologic parameters or measures of impairment between the two groups. The indication for surgery in these patients was rotation or angulation of more than 30°, but the proportion meeting each of these indications was not specified.

Recommendation

- There is no clear difference in the outcome of metacarpal fractures that have been treated operatively vs. those that have been treated nonoperatively [overall quality: very low]

Question 2: How is rotational deformity at the fracture site most effectively established?

Case clarification

Most clinical experts accept the idea that a rotary malunion leads to a substantial decrease in hand function because of scissoring of the fingers. As a result, the conventional wisdom has been for fractures with rotary instability to be treated with some kind of operative stabilization although

this idea has not been tested in a randomized trial, nor is it likely to be so evaluated in the future because of the degree to which this concept has become entrenched in clinical practice.

Relevance

Identifying the need for surgical intervention depends on the recognition of this kind of fracture deformity.

Current opinion

A carefully conducted physical examination should allow even small degrees of rotatory malalignment to be identified. This requires the patients to make a full, or nearly full, composite fist, which may not be practical for some patients because of pain.

Finding the evidence

- Cochrane Database, with search term: “metacarpal fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/), with search terms: “metacarpal fractures” AND “clinical evaluation” and “metacarpal fractures” AND “imaging”

Quality of the evidence

There have been no studies that compare various methods of establishing the presence of absence of rotatory malalignment after a metacarpal fracture.

Findings

One clear indication for the operative treatment of metacarpal fractures in general is the presence of rotational deformity at the fracture site. The reasons operative management for these injuries is favored are the inability to control the fragments and maintain a satisfactory reduction with nonoperative measures and the important functional problems that occur with a rotational malunion, mainly scissoring of the digits. This may impair both strength and dexterity.

The evaluation of metacarpal fractures for rotational deformity is primarily clinical. The reliability of imaging, including plain radiographs and more advanced axial imaging such as CT scanning, is insufficient. The observation of the digits in a position of extension at the metacarpophalangeal joints may not allow identification of important rotational displacement. This is more easily and reliably identified by the observation of the digits during active composite flexion. Although there may be pain at the fracture site during this maneuver, most patients can accomplish this sufficiently that a judgment of rotational deformity can be made.

Recommendation

- Rotatory malalignment of fractures in the 5th metacarpal can be established clinically. There is no evidence to support

the use of advanced imaging studies to assist in this evaluation. The topic has not been studied [overall quality: cannot assess]

Question 3: What is the long-term outcome of fractures of the 5th metacarpal? Is there a difference in long-term prognosis between cases treated surgically and those treated nonoperatively?

Case clarification

The patient is a 22 year old manual worker.

Relevance

Most of the patients who sustain fractures of the metacarpal are young men. In general this demographic group encompasses individuals who are active and who are frequently employed in manual occupations.

Current opinion

The long-term outcome of these injuries appears to be satisfactory. Even where there is substantial angulation at the fracture site, the impact on hand function seems to be very limited. While there may be measureable differences in some hand functions, in comparison to individuals matched for age, gender, and hand dominance, these do not appear to be clinically relevant. It is rare for patients to present for some kind of reconstruction after a malunion of a fracture of a single metacarpal.

Finding the evidence

- Cochrane Database, with search term “metacarpal fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/) with search terms: “metacarpal fractures” AND “treatment,” “metacarpal fractures” AND “surgical treatment,” and “metacarpal fractures” AND “outcome”

Quality of the evidence

There have been no level I studies evaluating treatment for metacarpal fractures. There has been a Cochrane review of the topic.

Findings

The Cochrane review on methods of nonoperative treatment² showed that pain control was satisfactory for a larger proportion of patients who were treated with cast immobilization than with all other forms of treatment. The long-term results with respect to what was termed “severe pain” were the same in all groups. Normal movement was reported to be restored at an earlier point after treatment with the methods that allowed mobilization as opposed to cast immobilization, although after pooling the data no statistically significant difference was identified for range of motion between any of the treatment groups.

There have been no prospective trials comparing nonoperative treatment to surgical management with any of the many available techniques. There has been one comparative case series⁶ that evaluated 258 patients with metacarpal fractures. Approximately 80% of these patients had been treated with brief cast immobilization without any attempt at reduction, while the remaining patients were treated with a variety of percutaneous and open fixation techniques. The follow-up time was not specified in the study but the authors demonstrated that on average there was no difference between the patients treated operatively and those treated nonoperatively for outcome measured with the DASH score, grip strength, or cosmetic appearance of the hand. This result was observed for fractures of the neck of the 5th metacarpal with angulation up to 50° and fractures of the metacarpal diaphysis with angulation up to 40°. This would represent the large majority of patients with this injury. In all cases the DASH score was very low (range 3–5), indicating that the overall disability regardless of fracture location, unresolved angulation, and method of treatment was extremely limited.

In addition to its retrospective nature and lack of random assignment of treatment, the main deficiency of this study was the small proportion of patients that were successfully located for follow-up, approximately 17% of a possible sample of over 1200 individuals. However, despite this shortcoming the findings are consistent with contemporary anecdotal experience and seem likely to be reliable.

Recommendation

- Either operative or nonoperative treatment for angulated fractures of the 5th metacarpal is acceptable management [overall quality: very low]

Question 4: Is a supervised course of physical or occupational therapy usually required for the optimal treatment of fractures of the 5th metacarpal?

Case clarification

The patient is a 22 year old manual worker.

Relevance

The focus for most young, active individuals will be on a rapid return to those normal activities that may be temporarily interrupted by treatment for a fracture of a metacarpal.

Current opinion

Most patients will not require a formal course of rehabilitation, especially if management has consisted of nonoperative treatment. A spontaneous restoration of mobility and strength is the usual expectation. If this fails to occur within 2–3 weeks after immobilization is discontinued,

introduction of a formal therapy program at that point will be as effective in maximizing the quality of the result as if this were immediately instituted.

Finding the evidence

- Cochrane Database, with search term: “metacarpal fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/), with search terms: “metacarpal fractures” AND “treatment,” “metacarpal fractures” AND “therapy,” “metacarpal fractures” AND “rehabilitation,” and “metacarpal fractures” AND “outcome”

Quality of the evidence

No level I studies have been reported, but a single well-performed systematic review has been published.

Findings

Feehan and Bassett⁷ reported a carefully conducted systematic review of the literature on the topic of early mobilization following extra-articular fractures in the hand. Their conclusions were based on a total of six quasi-randomized studies, all of which concerned treatment of metacarpal fractures. No level I studies were identified. The outcomes of interest concerned the two main contrasting issues around early mobilization, concern about fracture stability and loss of position vs. an advantage to early mobilization with respect to functional outcome. No adverse effects on fracture healing were identified. One study reported complications relating to adverse skin reactions in approximately 25% of patients treated with a removable brace, but the authors of this systematic review attributed this to the use of a commercial splint because two other studies, which utilized custom orthoses, did not report similar observations. All of the studies reported transient advantages to early mobilization with respect to restoration of motion and grip strength and in return to activities, but at final follow-up there were no differences, suggesting that there are no fundamental benefits or disadvantages to early mobilization beyond what might be considered convenience.

Recommendation

- Early mobilization of fractures of the 5th metacarpal is associated with more movement, greater strength, and an earlier return to activity at early follow-up. There is no clearly deleterious effect of early motion of fracture healing [overall quality: moderate]

Question 5: What is the optimal treatment for fractures at the base of the 1st metacarpal?

Case clarification

This patient suffered a fracture of the 5th metacarpal, which may be fundamentally distinct from a fracture of the 1st

(thumb) metacarpal because of the basic differences in overall hand function that are served by the small finger and by the thumb.

Relevance

In contrast to fractures involving the other metacarpals, fractures of the thumb metacarpal frequently involve the proximal articular surface and may be associated with subluxation of the trapeziometacarpal joint.

Current opinion

Even in cases where there is substantial deformity of the proximal articular surface of the 1st metacarpal, operative treatment is rarely required. This appears to be due to the fact the tolerance of the joint surface for moderate incongruity is high. Although there may be radiographic evidence of post-traumatic degenerative changes in the trapeziometacarpal joint, these seem to be only rarely associated with clinical complaints that require treatment.

Finding the evidence

- Cochrane Database, with search term: “metacarpal fracture”
- PubMed (www.ncbi.nlm.nih.gov/pubmed/), with search terms: “metacarpal fractures” AND “treatment,” “metacarpal fractures” AND “surgical treatment,” “metacarpal fractures” AND “outcome,” “Bennett’s fractures” AND “treatment,” “Bennett’s fracture” AND “surgical treatment,” and “Bennett’s fracture” AND “outcome”

Quality of the evidence

The only literature on the topic of treatment for intra-articular fractures of the first metacarpal consists of level IV and V studies that report small comparative case series.

Findings

Fractures of the thumb metacarpal most typically occur at the base of the bone and frequently involve the proximal articular surface of the bone and the trapeziometacarpal joint. Displacement is often considerable because the medial fragment is held in place by the volar beak ligament, the main stabilizer of the trapeziometacarpal joint, while the larger lateral fragment, which usually consists of the remainder of the metacarpal, is displaced by the abductor pollicis longus. Without a reduction there will be substantial articular incongruity and the concern is that this will lead to changes of osteoarthritis. This expectation is based on the usual outcome in other joints which are affected by intra-articular deformity after fractures; however, whether or not this principle applies to injuries to the base of the 1st metacarpal remains unclear. Osteoarthritis of the trapeziometacarpal joint is an extremely prevalent condition in most industrialized socie-

ties and yet evidence of a previous, unreduced fracture of the base of the 1st metacarpal is rarely observed in these cases. Conversely, patients in whom articular incongruity persists after a fracture of the base of the 1st metacarpal very infrequently present with arthritis-related pain in this area. As a result, the need for an anatomic reduction of these fractures is unknown but this is an important question because this goal usually cannot be met without operative treatment.

There have been no randomized trials comparing treatments for fractures of the base of the 1st metacarpal. All of the literature on this topic reports level IV and V evidence, and these studies report conflicting results following operative and nonoperative treatment. Cannon et al.⁸ followed a small series of patients at least 5 years after an intra-articular fracture of the 1st metacarpal. Almost 90% of the patients had been treated nonoperatively, and most of them did not report significant symptoms related to the thumb despite the presence of clinical and radiographic deformity.

Timmenga et al.⁹ evaluated a small series of patients treated with either open reduction and internal fixation (ORIF) or closed reduction and percutaneous pinning. Although radiographic changes of post-traumatic arthritis appeared to be related to the quality of the reduction, the results appeared to be satisfactory regardless of the method of stabilization or the quality of reduction.

The literature is bereft of any reliable evidence with which to guide treatment recommendations and so there is no consensus on the indications for operative treatment, especially with respect to the extent of articular displacement that should be considered as acceptable. The conflicting results reported in the literature suggest that any differences in outcome that might be associated with various treatments may be small.

Recommendation

- Fractures of the base of the first metacarpal may be treated either operatively or nonoperatively [overall quality: very low]

Summary of recommendations

- There is no clear difference in the outcome of metacarpal fractures that have been treated operatively vs. those that have been treated nonoperatively
- Either operative or nonoperative treatment for angulated fractures of the 5th metacarpal is acceptable management
- Rotatory malalignment of fractures in the 5th metacarpal can be established clinically. There is no evidence to support

the use of advanced imaging studies to assist in this evaluation. The topic has not been studied

- Early mobilization of fractures of the 5th metacarpal is associated with more movement, greater strength, and an earlier return to activity at early follow-up. There is no clearly deleterious effect of early motion of fracture healing
- Fractures of the base of the first metacarpal may be treated either operatively or nonoperatively

Conclusions

There are no clear guidelines for the treatment of most fractures of the metacarpals because there is a dearth of evidence on the subject. Satisfactory results appear to be associated with either operative or nonoperative treatment. Early mobilization either after operative or nonoperative treatment may lead to a restoration of function more quickly than a period of immobilization, but these early advantages do not necessarily result in better outcomes in the long-term.

Gregory J. Della Rocca, Brett D. Crist, and Yvonne M. Murtha

University of Missouri, Columbia, MO, USA

Case scenario

A 47 year-old otherwise healthy man is the restrained driver involved in a high-speed motor vehicle crash. He complains of left hip pain and is unable to bear weight. He is brought to the local Emergency Department for evaluation, which reveals an externally rotated, abducted, and extended left lower extremity. Neurovascular examination is normal, and no other injuries are noted.

Relevant anatomy

The hip joint represents the junction between the acetabulum and the femoral head. Stability is based upon bony architecture and soft tissue attachments. The acetabulum is recessed into the pelvis and surrounds the femoral head in a nearly hemispherical fashion, providing good inherent stability. Further stability is provided by the ligamentum teres, which takes its origin in the fossa acetabuli and inserts in the fovea centralis of the femoral head, as well as the acetabular labrum and the hip capsule.

Dislocation of the femoral head from the acetabulum can occur in isolation, or it can occur with associated fractures. Isolated dislocations of the native hip without fracture are unusual because of the high degree of constraint provided by the deep acetabular socket. Associated fractures can include acetabular fractures, femoral head fractures, or both. Soft tissues surrounding the hip, such as the acetabular labrum and the hip capsule, are almost invariably damaged during traumatic hip dislocation. Posterior dislocations are the most common dislocation type, although anterior dislocations also occur (Figure 53.1).

The blood supply to the femoral head is derived primarily from the medial femoral circumflex artery, which sends retinacular vessels into the posterior hip capsule. Further minor contributions to femoral head blood supply are provided by the lateral femoral circumflex artery and the artery of the ligamentum teres.

Importance of the problem

Traumatic hip dislocation in the young patient requires high amounts of energy, which often causes multiple injuries (level IV).^{1,2} Motor vehicle crashes are a prime example of injury mechanism causing hip dislocation (level IV).³ All of this can contribute to prolonged rehabilitation requirements. Complications of hip dislocation include osteoarthritis (OA) and osteonecrosis (ON). OA has been described in up to 25% of patients who sustained isolated traumatic hip dislocations without fracture (level IV).⁴ Acetabular fracture associated with hip dislocation increases the rate of OA substantially. ON has been described in up to 19% of patients following hip dislocation (level IV).^{5,6}

Costs associated with isolated traumatic hip dislocation have not been extensively analyzed. Short-term costs include those associated with hospitalization and rehabilitation, plus opportunity cost related to lost wages. Long-term costs include those associated with adverse long-term sequelae of hip dislocation, such as recurrent instability requiring repeat hospitalization or OA/ON which leads to further surgical procedures, rehabilitation, and lost wages.

A Google search for the term "hip dislocation" (without quotation marks) yields approximately 350,000 results. Much of this information is not peer-reviewed or based on scientific evidence.

Figure 53.1 Plain AP radiograph of a young man with an isolated anterior dislocation of the left hip.

Figure 53.2 Plain AP radiograph of a young man taken after closed reduction of an isolated traumatic anterior left hip dislocation. Note concentric reduction of the hip joint.

Finding the evidence

- Cochrane Database, with search term “hip dislocation”
- PubMed queries, with search terms “hip dislocation” AND XXX, with XXX representing “osteonecrosis AND reduction” or “osteonecrosis AND trauma,” “arthrosis AND reduction” or “arthrosis AND trauma,” “MRI,” or “arthroscopy”

Top four questions

1. What is the urgency of hip reduction after traumatic dislocation, as it relates to osteonecrosis of the femoral head?
2. What is the risk of arthrosis after traumatic hip dislocation?
3. Is CT or MRI indicated after reduction of a traumatic hip dislocation?
4. Is hip arthroscopy indicated after traumatic hip dislocation?

Question 1: What is the urgency of hip reduction after traumatic dislocation, as it relates to osteonecrosis of the femoral head?

Case clarification

The patient undergoes radiographic examination of the pelvis and left femur. An anterior dislocation of the left hip is noted, without apparent bony injury (Figure 53.1). Orthopedic consultation is requested, but is delayed due to arrival of other multiply injured patients in the Emergency Department at the same time. Once the orthopedic consult-

ant is prepared to perform reduction of the patient’s left hip, a further delay occurs while sedation is being prepared. Reduction of the patient’s left hip is accomplished without difficulty (Figure 53.2), approximately 6 hours after the motor vehicle crash.

Relevance

Delay in reduction is associated with prolonged patient discomfort and may be associated with increased risk of ON of the femoral head.

Current opinion

Rapid reduction of the dislocated hip is associated with improvements in patient comfort and therefore should be expedited. Early reduction of the dislocated hip may be associated with lower rates of ON.

Quality of the evidence

Studies were only included if definitive patient numbers and times of reduction of hip dislocation were available from the body of the manuscripts.

Level III

- 1 prospective cohort with methodologic limitations

Level IV

- 5 retrospective case series

Findings

Six studies were identified (a total of 554 hip dislocations and fracture-dislocations) in which correlations could be

Table 53.1 Percentages of patients developing osteonecrosis after isolated traumatic hip dislocation (without fracture of the ipsilateral acetabulum or femoral head), as it correlates with speed of reduction of hip (<6 hours from injury vs. >6 hours from injury)

Study	Total patients	Early reduction (<6 h)	Osteonecrosis	Late reduction (>6 h)	Osteonecrosis
Brav 1962 ⁹	262	204	36	58	33
Reigstad 1980 ⁷	56	43	2.0	13	1.0
Hougaard 1987 ⁴	100	83	4.0	17	9
Dreinhofer 1994 ⁶	35	35	3	0	0
Sahin 2003 ²	62	35	2.0	27	3.0
Onche 2008 ⁸	39	22	0	17	8
Totals		422	47	132	54
Percentage			11%		41%

made between timing of reduction and development of osteonecrosis, out of a total of 11 that suggested a positive correlation between delay in reduction and development of osteonecrosis (Table 53.1) (levels III and IV).^{2,4,6-9} The remaining studies did not provide direct data evidence for their suggestion that delayed reduction of hip dislocations is associated with development of ON. Early reduction was defined in some studies as less than 6 hours from injury, and in others as less than 12 hours from injury, creating heterogeneity of results which demands cautious interpretation. Early reduction was associated with an ON rate of 11%, while late reduction was associated with an ON rate of 41%. Early reduction was associated with a decreased risk of ON relative to delayed reduction (relative risk: 0.27).

Recommendation

- In adult patients with traumatic hip dislocations, rapid reduction of the dislocation is associated with a decreased rate of ON of the femoral head [overall quality: very low]

Question 2: What is the risk of arthrosis after traumatic hip dislocation?

Case clarification

The patient underwent uncomplicated closed reduction under conscious sedation approximately 6 hours after the motor vehicle crash. What is the likelihood that he will develop arthrosis of the hip, and is there a relationship to the time delay to reduction?

Relevance

Hip arthrosis may be a common sequela of hip dislocation.

Current opinion

Likelihood of future arthrosis is increased after hip dislocation, and may not be related to speed of reduction in the absence of ON.

Quality of the evidence

Studies were only included if the following could be elucidated: total number of patients with isolated dislocation (fracture-dislocations were excluded) and total number of patients developing arthrosis. Total follow-up times for studies were extremely variable.

Level IV

- 12 retrospective case series

Findings

Twelve studies were identified in which the number of patients sustaining an isolated hip dislocation (i.e., no fracture of the ipsilateral femoral head or acetabulum) was able to be discerned (584 patients) and the number of patients developing ipsilateral hip arthrosis was also able to be discerned (level IV).^{2-7,9-14} Other studies did not differentiate between isolated dislocations and fracture-dislocations in such a manner that patients with post-traumatic arthrosis could be delineated based upon type of initial injury. Arthrosis was noted in 109 of 584 hips, correlating with a rate of 18.7% (Table 53.2).

Recommendation

- Patients sustaining an isolated, traumatic dislocation of the hip may be advised that their risk of developing post-traumatic ipsilateral hip arthrosis is approximately 18.7%. Prevalence of hip arthrosis in the general population approximates 3.5% (level IV).¹⁵ This correlates with an increased risk of arthrosis related to isolated hip dislocation (relative risk: 5.33) [overall quality: very low]

Question 3: Is CT or MRI indicated after reduction of a traumatic hip dislocation?

Case clarification

The patient has undergone uncomplicated reduction of his hip dislocation under sedation in the Emergency

Table 53.2 Percentages of patients developing coxarthrosis after sustaining an isolated, traumatic hip dislocation (without fracture of the ipsilateral acetabulum or femoral head).

Study	Total patients	Arthrosis	Percentage

^aTwo different sets of values were given by the authors, one with early follow-up and one with late follow-up. There was significant loss to follow-up at the late time points. Only the late time points are included in this table.

Department. Postreduction plain radiographs reveal a concentric reduction of the hip joint. Is a CT scan or MRI necessary for full evaluation of the hip joint, in order to rule out interposed soft tissues or free chondral or osteochondral fragments?

Relevance

Reduction of an apparently isolated hip dislocation may entrap soft tissues, chondral fragments, or osseous fragments within the joint. Large fragments prevent a concentric reduction, which may be apparent on plain radiographs. Smaller fragments may not be seen on plain radiographs, and reduction may still appear concentric on plain radiographs.

Current opinion

Plain radiographs, after reduction of an apparently isolated hip dislocation (without associated acetabular or femoral head fracture), which reveal a concentric reduction of the hip joint are sufficient to guide further treatment of the hip dislocation patient.

Quality of the evidence

Studies were only included if the following could be elucidated: total number of patients with isolated dislocation (fracture-dislocations were excluded) and total number of patients undergoing CT or MR scanning.

Level IV

- 4 retrospective case series (CT)
- 3 retrospective case series (MRI)

Findings

Four studies were identified in which patients with isolated hip dislocations (without fracture and nonrecurrent) had undergone CT scans for further evaluation of a concentrically reduced joint (level IV).^{16–19} Other identified studies either were nonclinical, dealt purely with the pediatric population, described treatment of known fracture-dislocations, or did not describe findings quantitatively. A total of 226 hip dislocations with concentric reductions underwent CT imaging. No loose bodies were noted in any of these hip joints. Out of 199 hip dislocations imaged by CT scanning, femoral head impaction injuries were noted in 41. One study,¹⁸ describing 20 impaction injuries, reported surgical repair in 12 without reporting indications for such repair. The other study,¹⁷ describing 21 impaction injuries, reported an incidental finding of 18 posterior wall acetabular fractures not apparently noted on plain radiographs.

Only 3 studies were identified which detailed use of early MRI after isolated hip dislocation in the adult patient (40 hip dislocations) (level IV).^{20–22} One study, with MRI occurring within 5 weeks of injury, demonstrated intra-articular loose bodies in 4 and an entrapped ligamentum teres in 1 of 18 reduced dislocations without reference to concentricity of reduction on plain radiographs.²⁰ The other two studies demonstrated no loose bodies within the hip joints of 22 reduced dislocations. In one of these studies, a series of 9 football-associated dislocations demonstrated a triad of posterior lip fractures of the acetabulum, disruption of the ligamentum teres, and hemarthrosis in all patients.²² Of 14 patients undergoing serial MRI of reduced hip dislocations in the other study, 8 patients were noted to have abnormal marrow signals in the femoral head. Five of these were noted to resolve and 3 progressed to frank ON, questioning the significance of abnormal marrow signals and MRI acutely after reduction of hip dislocation.²¹

Recommendations

- CT scanning of patients with a concentric reduction after isolated hip dislocation is likely of little value in identifying potentially problematic loose intra-articular bodies [overall quality: very low]
- MRI of patients with a concentric reduction after isolated hip dislocation is unlikely to yield valuable early information, although it can delineate the spectrum of soft tissue injury. It is of uncertain prognostic significance [overall quality: very low]

Question 4: Is hip arthroscopy indicated after traumatic hip dislocation?

Case clarification

After uncomplicated reduction of the hip dislocation under sedation in the Emergency Department, a concentric hip

joint reduction is noted on plain radiographs. However, a small fragment of bone is noted within the fossa acetabuli. CT scan reveals the presence of a concentric hip reduction and a small osseous fragment within the fossa acetabuli that does not appear to be in contact with the femoral head. Should the patient be taken to the operating room for removal of the loose body and joint exploration for other loose bodies, utilizing an arthroscopic technique?

Relevance

Loose bodies that require removal may be present within the hip joint and not detectable after reduction of a traumatic hip dislocation, whether by plain radiographs, CT scans, or MRI.

Current opinion

Small osseous fragments within the fossa acetabuli do not mandate operative removal. Fragments noted to be incarcerated between the articular surfaces of the acetabulum and femoral head, or the presence of nonconcentric joint reduction, mandate operative exploration with removal and/or fixation.

Quality of the evidence

Studies were only included if the following could be elucidated: total number of patients with isolated dislocation (fracture-dislocations were excluded) and total number of patients undergoing arthroscopy. Other studies were included in the analysis if arthroscopy was utilized for known intra-articular pathology.

Level IV

- Arthroscopy without known loose bodies: 4 retrospective case series
- Arthroscopy for treatment of known loose bodies: 2 retrospective case series and 2 case reports

Findings

Four studies were identified in which the number of patients sustaining an isolated hip dislocation or fracture-dislocation underwent arthroscopy in the setting of normal postreduction imaging studies could be elucidated (44 patients) (level IV).²³⁻²⁶ and four further publications (two series, two case reports) reported on arthroscopy for retrieval of known intra-articular loose bodies after reduction of an isolated hip dislocation (20 patients) (level IV).²⁷⁻³⁰ Out of 44 cases of isolated hip dislocations and fracture-dislocations (Byrd and Jones²⁴ did not subdivide between these groups), 40 were found to have previously unrecognized articular pathology, including intra-articular loose bodies, labral tears, or chondral damage. In the 20 patients undergoing arthroscopy for removal of known intra-articular loose bodies, arthroscopic removal was successful.

Recommendation

- Patients sustaining an isolated, traumatic dislocation of the hip may have intra-articular pathology, such as loose bodies, labral tears, or articular chondral damage, which may not be evident on postreduction imaging, and which may be treated successfully with hip arthroscopy [overall quality: very low]

Summary of recommendations

- In adult patients with traumatic hip dislocations, rapid reduction of the dislocation is associated with a decreased rate of ON of the femoral head
- Patients sustaining an isolated, traumatic dislocation of the hip may be advised that they have an increased risk of developing post-traumatic ipsilateral hip arthrosis
- CT scanning of patients with a concentric reduction after isolated hip dislocation is likely of little value in identifying potentially problematic loose intra-articular bodies
- MRI of patients with a concentric reduction after isolated hip dislocation is unlikely to yield valuable early information, although it can delineate the spectrum of soft tissue injury. It is of uncertain prognostic significance
- Patients sustaining an isolated, traumatic dislocation of the hip may have intra-articular pathology, such as loose bodies, labral tears, or articular chondral damage, which may not be evident on postreduction imaging, and which may be treated successfully with hip arthroscopy

Conclusion

Patients sustaining a traumatic hip dislocation appear to have an increased risk of coxarthrosis as compared to the general population (18.7%, as compared to 3.5%). Patients also have a risk of ON, and this risk appears to be increased with delays in reduction (11% risk with early reduction, 41% risk with late reduction). Evidence supporting both of these statements is of low quality and primarily consists of retrospective case series. Only one study offering level III evidence was available which demonstrated a reduced risk of ON when reduction of the hip dislocation was undertaken expeditiously.

Case scenario

A 22 year old man is involved in a head-on motor vehicle collision. He presents complaining of left hip pain. On examination, the hip is held in a flexed, adducted, and internally rotated position.

Relevant anatomy

Originally described by Birkett in 1869,¹ femoral head fractures are relatively uncommon injuries. They typically occur as a result of a posterior dislocation of the hip, and may be associated with fractures of the acetabulum or femoral neck. Femoral head fractures were further classified by Pipkin in 1957 into four types (see box).²

Classification of femoral head fractures

- *Type I*: Dislocation with fracture of the femoral head caudad to the fovea
- *Type II*: Dislocation with fracture of the femoral head cephalad to the fovea
- *Type III*: Type I or type II injury associated with fracture of the femoral neck
- *Type IV*: Type I or type II injury associated with fracture of the acetabular rim

Fractures above the fovea (type II) involve the weight-bearing surface of the femoral head, whereas those below the fovea (type I) have less impact on force distribution. Only approximately 10% of hip dislocations are anterior,³ and these can be associated with impaction fractures of the femoral head, often with a poor outcome.⁴

The blood supply to the femoral head is quite precarious, and may be disrupted either by the traumatic dislocation itself, or the surgical approach to address the fracture.⁵ This may result in avascular necrosis (AVN) of the femoral head, leading to head collapse and early hip arthrosis.

Importance of the problem

Femoral head fractures are high-energy injuries, and often occur in a young, active population. They have been documented to occur in up to 7% of posterior hip dislocations.⁶ These articular injuries can lead to early post-traumatic arthrosis in many patients.⁷ Similarly, there is a significant risk of AVN of the femoral head as a result of the injury and its treatment. Both situations can lead to significant pain, disability, and an eventual need for total hip arthroplasty. These complications can have a significant impact on employment status and quality of life for the patient.

Despite the importance of these injuries, their relative rarity has resulted in little high-quality evidence in the published literature. Much of our treatment of femoral head fractures is based on level IV and level V evidence, which emphasizes the need for an evidence-based approach to this problem.

Top six questions

Therapy

1. Should I attempt a closed reduction?
2. Is there a role for nonoperative treatment?
3. Which surgical approach should I use?
4. Should the fragment be excised or repaired?

Prognosis

- 5. What complications should be anticipated?
- 6. What is the expected outcome?

Question 1: Should I attempt a closed reduction?

Case clarification

You begin to prepare for a conscious sedation and attempt at closed reduction in the Emergency Department. The nurse asks if this is safe, or if you should be proceeding directly to the operating room?

Current opinion

Emergent reduction of hip fracture-dislocations is routinely performed in the Emergency Department.

Relevance

While delay to reduction has been implicated in the development of AVN following hip dislocation, there are also risks associated with attempts at closed reduction.
