2.18 The Evolution of the Vomeronasal System

M Halpern, State University of New York, Brooklyn, NY, USA

Glossary

accessory olfactory bulb	A forebrain structure that is the recipient of axons from the vomeronasal sensory epithelium.
amygdala	A structure in the basal forebrain composed of multiple nuclei receiving neural information from all sensory systems including the olfactory and vomeronasal systems.
basal cells	Undifferentiated cells that undergo mitosis and eventually develop into neurons or supporting cells.
bed nucleus of the accessory olfactory tract	Neurons embedded in and surrounding the accessory olfactory tract.
bed nucleus of the stria terminalis	A nucleus closely associated with the stria terminalis.
bipolar neurons	Neurons with a single dendrite and axon at opposite poles of the cell.
Bruce effect	Failure of implantation of fertilized ova following exposure of female mice to the odor of a strange male.
cation channel	A membrane pore that allows cations to move between the intracellular and the extracellular compartments or between different intracellular compartments.
cilia	Organelles composed of extensions of the plasma membrane containing doublets of parallel microtubules.
cloaca	A posteriorly located cavity used for evacuation of intestinal and urinary wastes and for genital system activity.
cribriform plate	The bony base of the skull through which the olfactory nerve fibers pass from the nasal cavity to the brain.
decapeptide	A peptide composed of 10 amino acids.
diacylglycerol (DAG)	A second-messenger molecule that stimulates the activity of protein kinase C.
diverticulum	A pouch or sac branching from a hollow tubular or sac-like organ.
external plexiform layer	A lamina in the main and accessory olfactory bulbs just internal to the glomerular layer.
flehmen	A behavior characteristically displayed by ungulates to facilitate odorant access to the vomeronasal organ. It includes head extension, upper lip retraction, baring of the gums, and frequently opening of the mouth.
glomerular layer	A lamina in the main and accessory olfactory bulbs in which the axons of bipolar cells terminate on the dendrites of mitral and tufted cells and processes of periglomerular cells.
G-protein	A regulatory protein that binds GTP (guanosine 5′-triphosphate).
G-protein-coupled receptor	A member of the family of membrane proteins that are bound to and interact with G-proteins.
granule cell layer	A lamina in the main and accessory olfactory bulbs that contains the axonless granule cells.

head bobbing A behavior exhibited by guinea pigs in which the snout is moved forward and back across a stimulus to allow the stimulus access to the vomeronasal organ.

inositol trisphosphate (IP_3) A second-messenger molecule used in signal transduction.

internal plexiform layer A lamina in the main and accessory olfactory bulbs between the mitral cell layer and the granule cell layer.

ligand An extracellular substance that binds to cellular receptors.

main olfactory bulb A forebrain structure that is the recipient of axons from the olfactory sensory epithelium.

methyl ketones Molecules with methyl and ketone groups.

microvilli Small hair-like protuberances from epithelial cells.

microvillar cells Cells whose apical surfaces contain microvilli.

mitral cell layer A lamina in the main and accessory olfactory bulbs containing the cell bodies of mitral cells, the major projection neurons of the bulbs.

murine Relating to members of the rodent family Muridae, e.g., rats and mice.

neurogenesis The process of formation of neural tissue.

nucleus sphericus A subdivision of the amygdala of squamate reptiles that is the major recipient of direct input from the accessory olfactory bulb.

nuzzling A behavior that delivers substances to the vomeronasal organ of opossums. It consists of forward rubbing motions with the ventral aspect of the snout interspersed with rapid snout tapping motions on a substrate containing a vomeronasal stimulus.

olfactostriatum A nucleus in the basal forebrain of snakes that receives major vomeronasal input from the nucleus sphericus.

periglomerular cells Neurons in the main and accessory olfactory bulbs that are located in the glomerular layer and whose axons and dendrites enter glomeruli, providing a basis for interaction among different glomeruli.

pheromone A chemical substance secreted by one animal and responded to by another animal of the same species.

phospholipase C An enzyme that catalyzes hydrolysis of phosphatidyl choline to produce choline phosphate and 1,2-diacylglycerol (DAG).

primer pheromone A pheromone that has an endocrinological effect on other members of the same species.

pseudostratified sensory epithelium A sensory epithelium that appears to be layered, but which contains cells that extend from its apical surface to its basal lamina.

receptor cells Cells that receive and respond to external stimuli.

releaser pheromone A pheromone to which another animal of the same species responds rapidly.

respiratory epithelium Nonsensory epithelium lining the nasal cavity (and other respiratory structures).

signal transduction A process by which a cell converts one type of signal to another, e.g., a chemical stimulus into an electrical signal.

sirenids Aquatic mammals of the order Sirenia, e.g., manatee and the dugong.

sodefrin A female-attracting pheromone secreted by an abdominal gland of male newts.

supporting cells Cells in a sensory epithelium that are not receptor cells or involved in cell turnover, but act in a supporting function, e.g., removing toxic substances.

Vandenbergh effect Acceleration of puberty in female mice exposed to odors of male mice.

vomeronasal amygdala The portion of the amygdala that receives direct projections from the accessory olfactory bulb.

vomeronasal organ A sensory structure, located in close relationship to the nasal and oral cavities, that contains receptor cells that respond to chemicals, usually those produced by other animals.

Whitten effect Synchronization of estrus in female rodents exposed to the odor of a male.

The vomeronasal system is a sensory system specialized for the detection of naturally occurring chemicals, typically emitted by one animal and responded to by another animal. The system is present, as a separate entity, in virtually all terrestrial vertebrates at some time during development. Among nonmammalian vertebrates, a functional vomeronasal system is present in most terrestrial and aquatic amphibians and reptiles (see Evolution of the Amphibian Nervous System, Evolution of the Nervous System in Reptiles). It appears to be absent in crocodilians and birds, and, although precursors may be present, there is no separate vomeronasal system in fishes. Most mammals possess a vomeronasal organ although it is absent in many bats, most aquatic mammals, and Old World monkeys (see The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates).

2.18.1 Composition and Structure of the Vomeronasal System

In all vertebrates possessing a vomeronasal system, it is composed of a peripherally located vomeronasal organ, an accessory olfactory bulb, and forebrain structures that receive input from the accessory olfactory bulb. These forebrain structures typically contain neurons whose axons project to the hypothalamus and variably to other brain structures as well.

2.18.1.1 Vomeronasal Organ

The vomeronasal organ consists of a pseudostratified sensory epithelium that lines a lumen through which stimulating chemicals gain access to the dendritic processes of receptor cells. These receptor cells are bipolar neurons with a single dendrite terminating on the luminal surface of the organ and a single axon that projects to the accessory olfactory bulb. With few exceptions, the dendritic terminals of vomeronasal receptor cells are covered with microvillar extensions, in contrast to the ciliated dendritic knobs typical of most main olfactory system bipolar neurons (see Evolution of Vertebrate Olfactory Subsystems).

In addition to the receptor cells of the vomeronasal organ, supporting cells and basal cells are present in its sensory epithelium. In those species in which it has been studied, it is clear that the basal cells are a reservoir of undifferentiated cells that periodically undergo mitosis and differentiate into receptor cells and, perhaps, supporting cells. The receptor cells migrate through the epithelium, vertically, from base to apex in snakes (and probably in other nonmammalian species, as well), to become mature receptor cells. Eventually, these receptor cells become senescent, die, and are extruded from the epithelium. The role of the supporting cells is currently unknown.

In mammals, neurogenesis in the vomeronasal organ occurs as well; however, the process of movement of newly formed neurons, i.e., from base to apex or from margins to center, varies among different species (see Neuronal Migration).

The location, shape, and isolation (from the main olfactory chamber) of the vomeronasal organ in the different nonmammalian vertebrate species vary considerably. In amphibia, the vomeronasal organ is variably separated from the olfactory epithelium either by a short segment of respiratory epithelium or in a separate chamber lateral, medial, or ventromedial to the main chamber of the nasal cavity. In urodeles (salamanders) (Figure 1) and apodans (caecilians), the vomeronasal epithelium lines a diverticulum ventrolateral to the main nasal cavity, whereas in sirenids and anurans (frogs and toads) (Figure 2), the vomeronasal epithelium develops as a ventromedial diverticulum of the main nasal cavity. In turtles, the vomeronasal epithelium is reported to be a ventral extension of the olfactory epithelium and is isolated from the latter by respiratory epithelium. In squamate reptiles, the vomeronasal organ is completely separate from the nasal cavity, being located just dorsal to the hard palate and within the ventral-most portion of the nasal septum. It is dome-shaped and its nonsensory epithelium lines a ventral cartilaginous invagination, called the mushroom body.

The mammalian vomeronasal organ contains at least two subsets of receptor cells: those expressing $G_{i2\alpha}$ and those expressing $G_{o\alpha}$. The $G_{i2\alpha}$-expressing cells are located in more apical portions of the

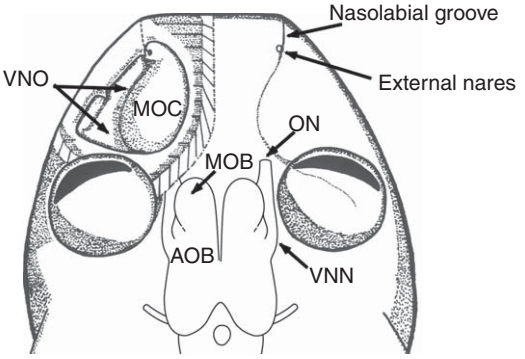

Figure 1 Drawing of the head and brain of a plethodontid salamander illustrating the position of the main olfactory chamber (MOC), vomeronasal organ (VNO), main olfactory bulb (MOB), and accessory olfactory bulb (AOB). The olfactory nerve (ON) and vomeronasal nerve (VNN) terminate in the MOB and AOB, respectively. Figure provided by Dr. Ellen Dawley.

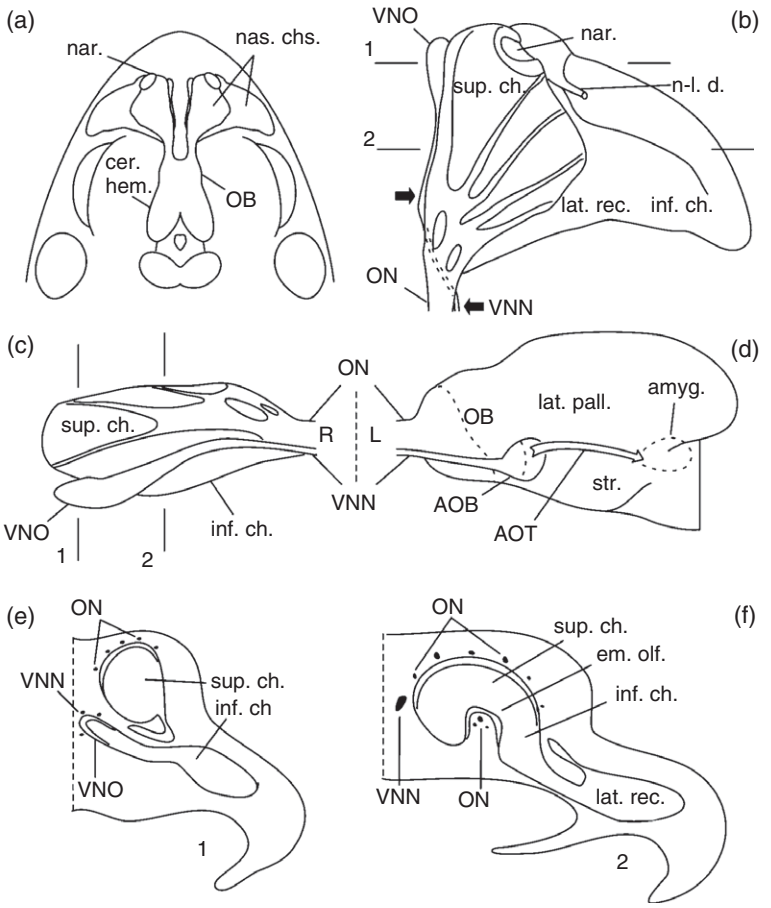

Figure 2 a, Outline of the nasal chambers and brain of a Ranid frog superimposed onto an outline of the head as seen from above. b, Dorsal aspect of the right nasal chambers. The vomeronasal organ is located in the medial recess of the inferior chamber and gives rise to the vomeronasal (accessory olfactory) nerve. The dorsal division of the main olfactory nerve is derived from multiple fascicles arising in the sensory epithelium in the roof of the superior chamber. On approaching the cranial cavity, the vomeronasal nerve (block arrows) winds across the ventral side of the ON to lie along its ventrolateral aspect before terminating in the ipsilateral accessory olfactory bulb (as in (d)). c, Medial aspect of the right nasal chambers showing the location of the vomeronasal organ and the initial course of the vomeronasal nerve. d, Lateral aspect of the left cerebral hemisphere. In this view, the left vomeronasal nerve is shown implanting into the left accessory olfactory bulb, which lies on the ventrolateral aspect of the main olfactory bulb. The MOB projects via the lateral olfactory tract (not shown) to the lateral pallium of the hemisphere, and the accessory olfactory bulb projects via the accessory olfactory tract to a distinct subdivision of the amygdala. e and f, Cross sections of the nasal chambers taken at level 1 (for (e)) and level 2 (for (f)) as indicated in (b) and (c). Part of the main olfactory epithelium is located in the inferior chamber on the dome-shaped olfactory eminence. This structure gives rise to the smaller, ventral division of the main olfactory nerve. The dorsal and ventral divisions coalesce to form a single nerve bundle as they approach the cranial cavity and join with the vomeronasal nerve. amyg., amygdala; AOB, accessory olfactory bulb; AOT, accessory olfactory tract; cer. hem., cerebral hemispheres; em. olf., eminentia olfactoria; inf. ch., inferior (nasal) chamber; lat. pall., lateral pallium; lat. rec., lateral recess (of the inferior nasal chamber); nar., nares; nas. chs., nasal chambers; n-l. d., nasolachrymal duct; OB, (main) olfactory bulb; ON, (main) olfactory nerve; str., striatum; sup. ch., superior (nasal) chamber; VNN, vomeronasal nerve; VNO, vomeronasal organ. Figure provided by Dr. Frank Scalia.

epithelium and those expressing $G_{o\alpha}$ are located closer to the basal lamina. Two families of G-protein-coupled receptor genes, V1R and V2R, have been described. Bipolar neurons expressing the V1R gene products are coextensive with $G_{i2\alpha}$-expressing cells and bipolar neurons expressing the V2R gene products are coextensive with $G_{o\alpha}$-expressing cells. Each subset of cells sends its axons to separate targets in the accessory olfactory bulb.

The lumen of the vomeronasal organ may open to the external environment through a duct into the oral cavity, as in squamate reptiles, through a groove onto the upper lip, as in plethodontid salamanders, or into the nasal cavity, as in frogs and turtles. The nature of access to the external environment is predictive of the behavioral adaptation used to deliver odorants to the vomeronasal epithelium. Thus, for example, snakes and lizards deliver odorants to the vomeronasal organ by means of tongue extensions out of the

mouth and retractions back into the mouth (tongue flicking). The exact mechanism by which the odorants are transferred from the tongue to the vomeronasal ducts is currently unknown. In plethodontid salamanders, odorants gain access to the vomeronasal organ by a head-tapping behavior that delivers the odorants to the base of the nasolabial grooves along the upper lip. The odorants then pass along the grooves to the vomeronasal epithelium, located in the lateral aspect of the nasal cavity.

In mammals, the vomeronasal organ may open into the mouth, into the nasal cavity, or into the nasopalatine duct that runs between the mouth and the nasal cavity. A variety of adaptations for delivery of odorants to the vomeronasal organ have been reported, including head bobbing in guinea pigs, flehmen and licking in a variety of mammals, and nuzzling in opossums. The autonomic nervous system, via a vomeronasal pump, has been demonstrated to control access and egress of substances to and from the rodent vomeronasal organ.

2.18.1.1.1 Signal transduction in vomeronasal receptor cells Among nonmammalian vertebrates, it is only in garter snakes that the mechanism of transduction of chemical signal to neural signal in the vomeronasal organ has been systematically investigated. Using known ligands for vomeronasal function derived from earthworms, it is now understood that the ligands bind to G-protein-coupled receptors on the luminal surface of vomeronasal bipolar neurons, initiating a cascade of events that include the activation of phospholipase C, leading to an increase in intracellular inositol trisphosphate (IP_3). The increase in IP_3 leads to a release of Ca^{2+} from intracellular stores and to an influx of Ca^{2+} from the extracellular compartment. The increase in intracellular Ca^{2+} leads to calcium-induced calcium release from ryanodine-sensitive stores. The intracellular calcium levels return to prestimulus levels through the action of a Na^{+}/Ca^{2+} exchanger. The exact mechanism by which this intracellular cascade results in a change in the membrane voltage of vomeronasal receptor cells is currently unknown.

The signal transduction pathway of the vomeronasal organ of mice appears to differ from that of snakes in important ways. Ligand binding to the G-protein-coupled receptors (V1R, V2R) initiates a cascade of events that results in the production of diacylglycerol (DAG). DAG activates a calcium-permeable cation channel in the distal portion of vomeronasal receptor dendrites, initiating a sensory current that is the basis of the receptor potentials recorded following ligand binding to vomeronasal sensory neurons. A principal subunit of this cation channel is encoded by the *TRPC2* gene, which has been shown to be involved in signal transduction to pheromonal stimuli in the vomeronasal organ of mice. The activity of diacylglycerol kinase terminates DAG signaling.

2.18.1.1.2 Primary vomeronasal pathway In salamanders (Figure 1), the axons of vomeronasal receptor cells do not aggregate, but follow the lateral edge of the olfactory nerve to the accessory olfactory bulb. In frogs, the fibers that make up the vomeronasal nerves are initially found medial to the olfactory nerve and wrap around the latter to obtain a ventral position prior to entering the cranial cavity (Figure 2).

In reptiles, the axons of vomeronasal receptor cells coalesce to form the vomeronasal nerves that travel along the nasal septum to penetrate the cribriform plate and terminate in the glomerular layer of the accessory olfactory bulb (Figures 3 and 4).

In mammals, the vomeronasal nerve coalesces posterior to the vomeronasal organ, travels along the nasal septum, enters the cranial cavity, usually medial to the main olfactory bulb, and terminates in the glomerular layer of the accessory olfactory bulb.

2.18.1.2 Accessory Olfactory Bulb

The accessory olfactory bulb is the only known site of terminations of axons of vomeronasal receptor cell axons. The bulb is a laminated structure located in the rostral telencephalon. Its relationship to the main olfactory bulb, the termination site for main olfactory receptor cell axons, is variable. In salamanders and frogs, the accessory olfactory bulb is located caudo-lateral to the main olfactory bulb; in snakes, it is caudal to the main bulb, and in turtles, it is dorso-posterior to the main bulb. In mammals, the accessory olfactory bulb is usually dorsal to the most caudal portion of the main olfactory bulb.

The size of the accessory olfactory bulb relative to the main olfactory bulb also varies, being close to two and a half times larger than the main bulb in snakes, of variable size in lizards, and smaller than the main bulb in amphibians. In virtually all mammals, the accessory olfactory bulb is a fraction of the size of the main olfactory bulb.

Similar layers are present in the accessory olfactory bulb of most vertebrates studied, although some layers may be severely reduced or absent. The most external layer is the nerve layer, which is composed of the axons of bipolar neurons whose cell bodies form the receptor cell layer of the vomeronasal sensory epithelium. These axons terminate in the glomerular layer, which is located just internal to the nerve layer. External plexiform, mitral

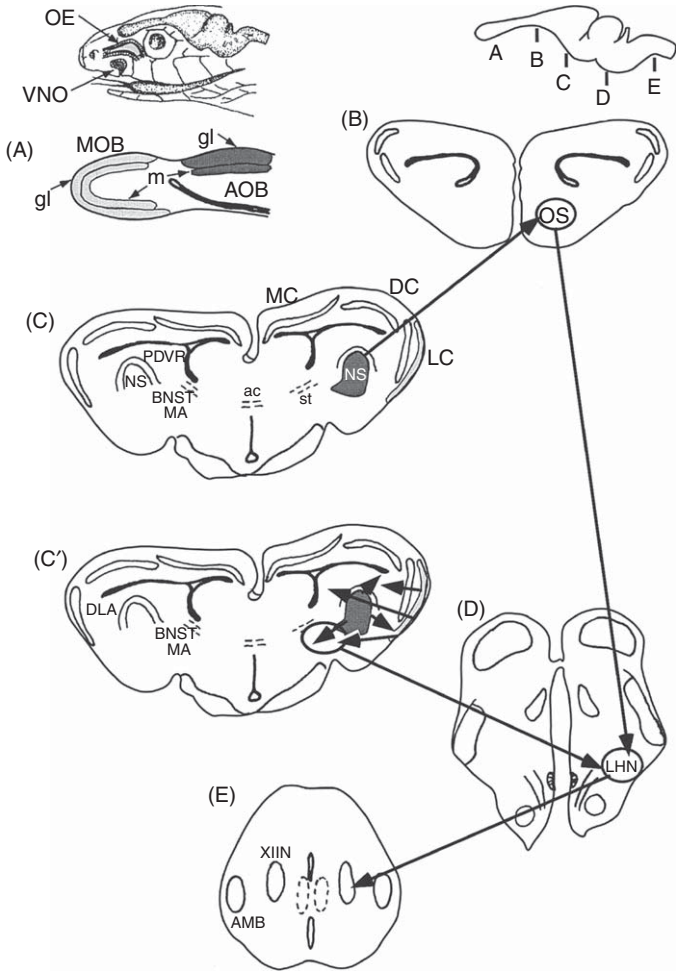

Figure 3 Top left: Drawing of snake head with vomeronasal organ (VNO), nasal cavity with olfactory epithelium (OE), and brain depicted as if the head were transparent. Top right: Drawing of brain as seen from the side, indicating the location of sections A through E. (A) Parasagittal depiction of main (MOB) and accessory (AOB) olfactory bulbs. Glomerular (gl) and mitral (m) cell layers are identified. B–E, Drawings of coronal sections through the rostral telencephalon, midcaudal telencephalon, dimesencephalic border, and hindbrain, respectively. The projections from the MOB, indicated in light gray, are primarily to the lateral cortex (LC). The projections from the AOB (dark gray shading) are primarily to the nucleus sphericus (NS) and medial amygdala (MA). The NS projects to the MA, which, in turn, projects to the lateral posterior hypothalamic nucleus (LHN), which sends its projections to the hypoglossal nucleus (XIIN), the source of efferents to the tongue musculature. Paralleling this pathway is one from the NS to the olfactostriatum (OS), which also projects to the LHN. The NS, in addition to its connections to the OS, projects to the dorsolateral amygdaloid nucleus (DLA) and LC; the LC projects to the MA and DLA. ac, anterior commissure; AMB, nucleus ambiguous; BNST, bed nucleus of the stria terminalis; DC, dorsal cortex; MC, medial cortex; st, stria terminalis; PDVR, posterior dorsal ventricular ridge. Figure provided by Dr. Alino Martínez-Marcos.

(mitral/tufted) cell, internal plexiform, and granule cell layers follow from external to internal layers. The principal dendrites of mitral/tufted cells project into the glomeruli of the glomerular layer, making synaptic contact with the axonal terminals of receptor cells. Periglomerular cells, located around the glomeruli, project dendrites and axons into the glomeruli. Short axon cells, located in the plexiform layers, make local connections; the axonless granule cells make dendro-dentritic contact with the lateral dendrites of the mitral/tufted cells. The primary dendrites of mitral/tufted cells may contact multiple glomeruli, unlike the situation in the mammalian main olfactory bulb. The mitral/tufted cells are the only projection neurons of the accessory olfactory bulb, sending their axons out of the bulb to contact a variable number of targets in the telencephalon.

2.18.1.3 Telencephalic Targets of the Accessory Olfactory Bulb

The major targets of mitral cell axons are nuclei of the amygdala (see Evolution of the Amygdala in Vertebrates). In nonmammalian vertebrates, these

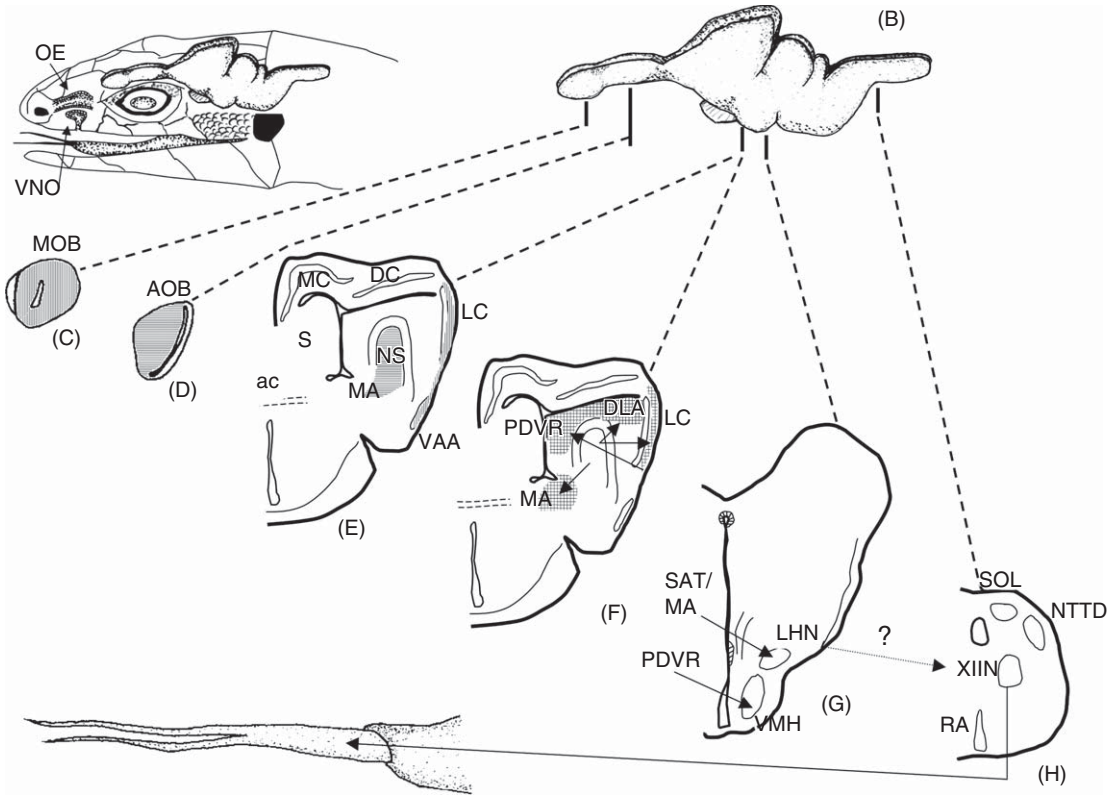

Figure 4 Vomeronasal system of the lizard, *Podarcis hispanica*. The vomeronasal organ (VNO) and olfactory epithelium (OE) are depicted *in situ* in the diagram at the top left. The brain, removed from the skull, is depicted at the top right (B) and the location of the coronal sections illustrated below are indicated with solid vertical lines. Projections from the main olfactory bulb (MOB) are indicated with vertical hatching, and projections from the accessory olfactory bulb (AOB) are indicated with horizontal hatching in section E. The primary projection of the MOB is to the lateral cortex (LC) and ventral anterior amygdala (VAA), whereas the major projection from the AOB is to the nucleus sphericus (NS) and the medial amygdaloid nucleus (MA). Further projections from the LC extend to the posterior dorsal ventricular ridge (PDVR). The nucleus sphericus projects to the dorsolateral amygdaloid nucleus (DLA), LC, and MA. The PDVR projects to the ventromedial hypothalamic nucleus (VMH) and the striatoamygdaloid transition area (SAT) and the MA projects to the lateral posterior hypothalamic nucleus (LHN). There is some unpublished evidence that LHN projects to the hypoglossal nerve nucleus (XIIN), which would control the tongue musculature. DC, dorsal cortex; MC, medial cortex; RA, raphe nuclei; S, septal nuclei. See Novejarque *et al.* (2004) for a discussion of SAT. Figure provided by Dr. Enrique Lanuza.

projections have been most extensively examined in frogs and snakes (see Evolution of the Amphibian Nervous System, Evolution of the Nervous System in Reptiles). In the frog, *Rana pipiens*, the accessory olfactory bulb projects, via the accessory olfactory tract, to the ipsilateral medial and cortical amygdaloid nuclei, with a fascicle continuing past these nuclei to cross the midline in the anterior commissure and terminate in the contralateral amygdala. In salamanders, the projection from the accessory olfactory bulb is also to the vomeronasal amygdala.

In snakes, the accessory olfactory bulb projects to the nucleus sphericus (a hypertrophied portion of the amygdala), the medial amygdala, and the nucleus of the accessory olfactory tract. The nucleus sphericus, in turn, projects to the lateral posterior hypothalamic nucleus and the olfactostriatum, a telencephalic structure. The neurons in the lateral posterior hypothalamic nucleus project their axons to the nucleus of the hypoglossal nerve, thus completing a circuit that is the anatomical substrate for vomeronasally induced tongue flicking (Figure 3).

In lizards, the accessory olfactory bulb projects to the nucleus sphericus, the bed nucleus of the accessory olfactory tract, the central and ventromedial amygdaloid nuclei, and the bed nucleus of the stria terminalis. In turn, the vomeronasal amygdala projects to the hypothalamus (Figure 4).

Early studies on the projections of the olfactory bulb in turtles assumed that there was no vomeronasal organ or accessory olfactory bulb; therefore, separate projections from the main and accessory olfactory bulb were not investigated. Therefore, at present, we do not know the targets of the accessory olfactory bulb in turtles.

The projections of the accessory olfactory bulb in mammals follow a pattern that is similar to, albeit more complex than, that in other vertebrates,

projecting primarily to amygdaloid targets that in turn project to discrete portions of the preoptic area and hypothalamus.

2.18.2 Functions of the Vomeronasal System

The best documented functions of the vomeronasal system are those related to pheromone detection and its role in reproductive behavior. Among the nonmammalian vertebrates, most information on the role of the vomeronasal system in behavior comes from snakes, although information about the role of the vomeronasal system in foraging and pheromone detection in lizards and amphibians has also become available.

A female-attracting pheromone, a decapeptide, from the abdominal gland of the cloaca of the male red-bellied newt, *Cynops pyrrhogaster*, sodefrin, has been identified, isolated, purified, sequenced, and synthesized. Sodefrin elicits marked physiological responses when applied to the vomeronasal epithelium of female newts. In other amphibian species, pheromones that increase female receptivity and attract females have also been isolated and purified, and a female-attracting aquatic sex pheromone from the parotid and rostral glands of the male magnificent tree frog, *Litoria splendida*, has also been identified. However, it has not yet been established that these latter pheromones act through stimulation of the vomeronasal system.

The vomeronasal system of snakes is involved in prey detection and response to pheromones. Garter snakes with their vomeronasal nerves severed are unable to follow prey trails and eventually stop eating earthworm prey. Garter snakes also employ the vomeronasal system for finding conspecifics for the purpose of aggregation and to respond appropriately to female pheromones. The female garter snake (*Thamnophis sirtalis parietalis*) produces a series of nonvolatile saturated and monounsaturated long-chain methyl ketones that attract male garter snakes and induce stereotypical courtship behaviors. Although the role of the vomeronasal system in response to this pheromone has not been directly tested, the fact that male garter snakes without a functional vomeronasal system fail to respond to females secreting this pheromone is supportive of this idea.

To date, the only known functions of the mammalian vomeronasal system are related to the response to conspecific chemical signals, pheromones. These pheromones may function to modify behavior immediately (signaling pheromones) or to modify activity of the hypothalamic/pituitary axis (primer pheromones). Many of the murine pheromone effects (the Bruce effect, Whitten effect, Vandenbergh effect, etc.) are mediated by primer pheromone stimulation of the vomeronasal system. Responses of mammals to signaling pheromones frequently lead to mounting and copulation, aggressive, parental, and/or marking behaviors. Not all responses to pheromones are mediated by the vomeronasal system; some are mediated by the olfactory system. For example, individual recognition in some species is not mediated by the vomeronasal system, although some neurons in the mouse vomeronasal organ respond to major histocompatibility complex peptides. In addition, not all vomeronasal ligands are pheromones.

2.18.3 Origins of the Vomeronasal System

The vomeronasal system is not a universal feature of vertebrates. The system is absent in most aquatic species, i.e., teleost fish, crocodilians, and cetaceans (whales and dolphins). Birds, some bats, and Old World primates also lack a vomeronasal system (see The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates). Whether humans possess a functional vomeronasal system is, at present, controversial.

The olfactory epithelium of some fish contains both ciliated and microvillar receptor cells, the latter being reminiscent of vomeronasal receptor cells. Fish live in an aquatic environment and the vomeronasal organ of terrestrial vertebrates is known to be fluid filled and to respond to nonvolatile odors, frequently in a liquid state. Therefore, it is not unreasonable to believe that the vomeronasal system might have evolved from the fish olfactory system, as vertebrates moved to a terrestrial environment.

One study suggests that the microvillar cells of the olfactory epithelium of fishes may be precursors to vomeronasal receptor cells. The microvillar cells of goldfish express G-proteins ($G_{o\alpha}$, $G_{i\text{-}3\alpha}$, and G_q) and receptor genes that are expressed in mammalian vomeronasal receptor neurons, but not in olfactory receptor neurons. The microvillar cells are distinct in these properties compared to the ciliated receptor cells, as well as in their location, separate from the ciliated olfactory receptor neurons, suggesting that segregated populations of receptor cells may have been present prior to the evolution of tetrapods and the segregation of olfactory and vomeronasal epithelia into distinct chambers (see Evolution of Vertebrate Olfactory Subsystems).

It is clear from research on fully aquatic amphibian species, e.g., aquatic salamanders, that some of these animals possess well-developed vomeronasal organs.

Since the vomeronasal system is generally present in tetrapods, appears to have originated in early amphibians, is present in amphibian larvae, and is well developed in aquatic amphibians, the proposition that the appearance of this system in evolutionary history was an adaptation to terrestrial life appears untenable. The presence of the vomeronasal system in most tetrapods and its absence in some species, e.g., arboreal lizards, birds, Old World monkeys, and some aquatic mammals, suggests that this system was lost in the past history of some species.

2.19 Electric Fish, Electric Organ Discharges, and Electroreception

T H Bullock[†], University of California at San Diego, La Jolla, CA, USA

Glossary

ampullary organ	A type of electroreceptor sensitive to low frequencies (under 20 Hz).
electric fish	Fish that have evolved electric organs. As these fish are dispersed in phylogenetically diverse groups, they have evolved independently a number of times.
EOD	The electric organ discharge.
JAR	The jamming avoidance response. When two weakly electric fish with similar frequencies of electric organ discharge meet, their electrolocation systems jam each other, impairing their ability to electrolocate. To avoid this jamming, they shift their EOD frequencies away from each other.
tuberous receptors	A type of electroreceptor sensitive in the range of hundreds of hertz, but not below 30 Hz.

2.19.1 Introduction

Conventional wisdom may be well justified in claiming that brain evolution is led to a large degree by the modalities of the senses. Species with good vision or a well-developed auditory system, olfaction, or proprioception show this in the size and degree of elaboration of the brain. This article provides another example from a group of fishes possessing an unfamiliar sense modality: electroreception. This is an abbreviated account of these systems, stressing their evolution, which shows both radiation in direction of special adaptations and parallelism in independent development of the same trait in two or more phylogenetic lines. Among taxa (animal groups) that exhibit reception of feeble electric currents, a first-order dichotomy exists between certain families of fishes, amphibians, and one mammal whose electroreception is used in a passive mode – processing currents from sources external to the receiver, whether animate or inanimate – whereby the sense organs filter and map extraneous electric fields. Other species use the system in an active form, involving an electric organ that generates pulses (efference) of current under central control, and an array of specialized sense organs that detect the animal's own field and central (brain) circuits that analyze this afference with respect to its spatial and temporal structure. In addition to discussing each of these topics, we will briefly mention the behavioral uses, ontogeny, evolution, and special aspects.

A species of catfish common in African freshwaters that can deliver a strong jolt as well as a Mediterranean species of ray that was called torpedo, presumably because it can induce torpor, were known to the ancients. Very soon after 1492, South American electric eels were brought back to Europe and their high-voltage discharges became familiar. They figured in classical experiments and controversies about animal electricity in the eighteenth century, reviewed by Brazier (1984). Not until the 1940s was it realized that many smaller relatives of the electric eel, common in neotropical freshwaters, also discharge electric organs, although feebly, usually peaking at a few millivolts measured on the skin, out of water, in one or a few millisecond pulses, several times every second, continuously night and day. Studies of the mechanisms of production, control, and use of the strongly electric discharges (EODs) were already well along when the weakly electric fish and the continuous train of weak discharges night and day by the powerful eel added questions of reception, brain analysis, use,

[†] Deceased.

function, development, and evolution. These rapidly expanding fields of research have been reviewed in two books: Bullock and Heiligenberg (1986), updated in Bullock *et al.* (2005). The following is a condensed and selective summary.

2.19.2 Electric Organs

Specialized for generating either low current, high voltage or high current, low voltage, pulses are from modified muscle cells or from branched nerve endings. Electric organ cells (electrocytes) maintain a standing electromagnetic field (EMF) between inside and outside by ion pumps, like ordinary cells. They can be discharged by brief depolarizing signals from the synchronized electromotor nerve cells in the spinal cord, under brain control. In some species, motor nerve endings by one of several arrangements first depolarize one face of the electrocytes and then the other, while the faces are anatomically patterned to add their pulses either many in series (e.g., high-voltage electric eel) or many in parallel (e.g., high-current torpedo).

Diversity is also conspicuous in the temporal pattern of EODs. Some species are called pulse fish because the EODs iterate at a low and irregular repetition rate (intervals several to many times the duration of the single pulse). Others are wave fish because the intervals are brief and regular (equal to or little longer than discharge duration), reaching regularities higher than any other known biological rhythms. Each discharge is commanded by a special brain nucleus that receives and integrates multiple inputs and is usually relayed through one or more synapses in the brainstem and again in the spinal cord, besides the last junction between efferent axon and electrocyte. The regularity of the EODs can be controlled by the brain and routinely shows a coefficient of variation (standard deviation divided by mean interval) smaller than 0.1% of the mean (i.e., SD < 1 μs). It is not yet clear what situations or states of the brain are associated with higher or lower regularity or what selective advantage such extremely low variation confers. Presumably, it lies in the domain of detecting or assessing objects that distort the instantaneous electric field of the EOD, the signal analyzed by the electroreceptive system to detect and evaluate objects, whether obstacles or passageways. Electric organs must have been invented independently at least several times, perhaps as many as seven times in various taxa of elasmobranchs and teleosts. Intermediate or early stages in the evolution of electric organs are not clear, but one suggestion is the apparently well-synchronized muscle action potentials of respiratory movements in lampreys (Kleerekoper and Sibakin, 1956).

2.19.3 The Electroreceptor System

The electroreceptor system begins with an array of many primary sensory neurons in small, widely dispersed sense organs sending afferent axons to the brain via the lateral line nerves. Two broad classes are: (1) ampullary receptors, which act as low-pass filters, insensitive to stimulus components above approximately 20 Hz. Some taxa are excited by one polarity, e.g., current entering the skin and inhibited by the other polarity. Other taxa are the opposite. (2) Tuberous receptors are high-pass filters, sensitive in the range of hundreds of hertz but not below about 30 Hz. Some of these respond by increasing the probability of firing nerve impulses as the stimulus is increased in amplitude (probability coders or P units). Others respond by shortening the latency of the single nerve impulse that follows each brief stimulus (phase coders or T units). Each fish typically has all three kinds of receptors – ampullary, T units, and P units – sometimes answering to only one kind of stimulus: social, passive, extraneous, or active distortion of its own EOD by an object of higher or lower conductance than the surrounding milieu.

2.19.4 Central Electrosensory Circuits

Centers, nuclei, and pathways processing the input from electroreceptor are found in each brain segment from medulla, midbrain, diencephalon, and cerebellum to the forebrain, hypothalamus, basal ganglia, and cerebral pallium plus the spinal cord, *in toto* a massive system. Many of these are known either from physiological responses to quasinormal electric stimuli or from pathway-tracing dyes injected into known cell groups to reveal the destination of their axons or to visualize the cells of origin of the fibers that took up the dye. Details can be found in the books cited and the original papers referenced in those chapters.

A landmark in neuroethology, the science that seeks to explain behavior in terms of neural structure and function, is the jamming avoidance response (JAR), a simple behavior observed in wave species when two or more individuals are within range of each other and have EOD frequencies close to each other. Unless there is a large difference in size, each fish will quite reliably shift its EOD frequency in the direction to increase the difference in frequency, interpreted as an avoidance

of being mutually jammed. This behavior means that each fish is solving the problem of recognizing which part of the mixed electric fields in the water comes from its own EOD and which part is from other fish. Ingenious experiments by Heiligenberg (1991) showed that they do not utilize information in the brain that commands each EOD train but depend on analysis of the sensory feedback. Certain cells in a particular layer of the tectal cortex are excited when the amplitude-sensitive P afferents are increasing their firing frequency in response to the rising phase of the beat cycle caused by the mixing of two or more EODs of different frequencies. Other cells are excited by the afferents from T units when their phase of firing is retarded during the delay part of the phase cycle that accompanies the beat cycle. Still other units are inhibited when the rising limb of the P cycle is in phase with the falling limb of the T cycle, and these exert the modulatory influence upon the pacemaker nucleus that we see as the JAR of EOD rates. Each of these cell types is in a small, localized population whose anatomy and connections in and out are known through at least 14 orders from the primary afferent neuron.

2.19.5 Ontogenetic Development

The multiple types of electroreceptors are all derived from lateral line receptors, which are endowments of all fishes, plus aquatic amphibians mediating mechanical senses associated with relative movement of animal and water in a low frequency range, 0.1–100 Hz, commonly called water flow and vibration, overlapping with acoustic reception via the inner ear and eighth cranial nerve. The sense cells in both mechanoreceptors and electroreceptors are members of a large class of sensory cells called hair cells, although some of the electric sense cells have lost their ciliary hairs. We do not know the crucial features that evolved to alter the adequate stimulus from the mechanical event to an electrical one, but the change in sensitivity was many orders of magnitude and, in each class of electroreceptor, was tuned to a best frequency that could be many octaves apart. The ontogenetic development in the young animal begins, as for lateral line sense organs in clusters of neuroblasts, in the head, called lateral line placodes that send their outgrowing central axonal processes into the brain by one of several cranial nerves, mostly the trigeminal. Their peripheral axons grow into the lateral line nerves to a species-characteristic, quite wide distribution over the skin of the developing non-nervous parts of the eventual sense organs. These non-nervous parts plus the sensory hair cells detect and transduce the stimulus event into physiological signals that can conduct along the axons. They depend on the nerve growing in from the distant neuron to steer, trigger, and control the placement, orientation, tuning, and sensitivity that develops (see Evolution of the Nervous System in Fishes).

2.19.6 Evolution

Electric organs are known in some species of skates (rajoid elasmobranchs) and electric rays (torpinoids), without clear indication whether there was only one or more than one independent invention. The EOD of skates is weak and episodic, probably mainly functioning in communication between members of the same species, for example, in reproductive behavior. The EOD of torpedo is high in current but low in voltage and, whatever else it does, certainly contributes to catching prey fish by disorienting their swimming. Electric organs are known in a number of bony fish, including several species and presumably all families of catfishes (Siluriformes), including one with a strong EOD (*Malapterurus*), the others being weak, presumably social communicating systems. Probably all of the New World knife fishes (Gymnotiformes), which includes the classical, high-voltage, low-current electric eel (*Electrophorus*), all species of the African order of Mormyriformes (elephant nose and many others). One family of stargazers (Astroscopidae) has EODs of very moderate strength and quite unknown function. It seems likely that evolution has discovered how to make and make use of electric organs at least five times, independently and possibly more, an outstanding case of parallel evolution, possibly exceeded, however, by the number of plesiomorphic features independently invented for electroreception. Diversity on the motor side includes a variety of forms of innervation of the electrocytes in mormyrids, where these cells have stalks that in some species penetrate the flat disk-like electrocyte and receive motor nerve endings at a circumscribed part of the stalk. Studies of the mitochondrial DNA sequencing of many species permit conclusions about which form of innervation was primitive and which was derived and agree very well with phylogeny based on anatomical characteristics (Alves-Gomes and Hopkins, 1997). With such high sensitivity, it becomes difficult to guess what the world must look like to such an animal, especially what the sources of noise might be, that interfere with detection of significant signals or limit resolution. One such factor must be lightning, since it has been shown to cause millisecond pulses in natural water bodies, up to hundreds of

kilometers distant (Hopkins, 1973), overlapping in duration and forming the EOD pulses of many species of weakly electric fish. As in the case of the JAR, it may well be that brain processing which compares the afference from different parts of the body surface enables the fish to distinguish such far field sources from the reafference of its own EOD. The fish are demonstrably able to use high-frequency-dependent small differences in impedance but it is still not known just what discriminations these fish make, based on complex impedance, for example, among aquatic plants.

A speculation of possible interest in ethology is that there might be patterns of texture in the electrochemical fields close to the bottom or to objects past which water is flowing that electrosensitive fish can detect and characterize as useful signs of the features of the solid surfaces. One class of experiments has shown that such fish detect or compute the plane of an invisible (transparent plastic) bottom in order to maintain a preferred tilt or angle between the fish's vertical axis and the plane of the substratum (the ventral substrate response akin to the dorsal light reaction) (Meyer *et al.*, 1976).

For many years, there was no special reason to believe that there must be a novel modality for electrosense, but when it was discovered that many species have a very-low-voltage EOD and convincingly when Machin and Lissmann (1960) demonstrated that one of these feeble electric fish can learn to distinguish objects such as two porous ceramic filters one containing a 6 mm diameter glass rod and the other a 4 mm rod, invisible through the walls of the filter and hence differing only in electrical impedance, via the active ongoing EOD and sense organs that measure the local strength of the electrical field at different parts of the fish's body surface. The relevant signals are therefore in gradients of hundredths of a microvolt per centimeter (Machin and Lissmann, 1960). Even higher sensitivity has been measured, repeatedly, by directly applied electrical pulses in the seawater around some skates and sharks, via their passive electrical receptors; $0.005\ \mu V\,cm^{-1}$ at the peak of a 1 Hz wave can elicit feeding or orienting behavior (Kalmijn, 1982, 2000). Differences between species can be large: one factor being the salinity of the normal habitat. Freshwater forms are generally much less sensitive than seawater animals, which is perhaps correlated with the greater attenuation of available signals in the high conductance of seawater.

Electrosensory receptors have evolved in, presumably, all elasmobranchs, including the truly freshwater rays, as well as in the sister group of the Holocephala (rat fish and chimaeras) and in one group of the agnathans (cyclostomes), the lampreys or petromyzontids, but not in the hagfishes (myxinoids), which are otherwise more advanced in brain differentiation. Thus, electroreception contributes to the argument that these two subdivisions of the cyclostomes are unrelated except through remote common ancestors.

The only analogue of an electric organ discharge in lampreys is the synchronized muscle action potential accompanying each cycle of respiratory movements, and one report would suggest that the lamprey uses this synchronized potential as a form of active electroreception (Kleerekoper and Sibakin, 1956). Most elasmobranchs lack any analogue of an EOD, as far as we know, but they might well detect distortions of their own standing electric fields due to DC fields from the skin, gills, and mucous membranes, like everything living in a conducting medium. The same questions are open for other groups that possess electroreception but which lack electric organs. This includes the holocephalans, some aquatic salamanders (apodan urodeles), and most of the large and diverse superorder of siluriform teleosts (catfish and others). Perhaps the best evidence of animals apparently anticipating earthquakes is that of Hatai and Abe (1932) on catfish in Japan. Several recent discoveries have enlarged the list of catfish that have small electric organs or produce EODs now and then at intervals of many hours, requiring special techniques to capture the episodes for analysis (Baron 1994; Baron *et al.*, 1994, 2003).

At one stage, it seemed that having the central and peripheral specializations for electroreception must be a characteristic of the order and would be found in all families of those orders. An exception has turned up (Notopteridae of the Osteoglossiformes), where one suborder (Xenomystinae) has and another (Notopterinae) lacks the electrosense. Also puzzling are the stargazers *Astroscopus* and *Uranoscopus* (Baron and Mikhailenko, 1976). These live buried in the sand with only the eyes and lips showing, ready to inhale prey fish by suddenly opening the mouth; hence, like the long interval catfish, above, they have EODs episodically (when a moving shadow coincides with a tap on the wall of the container, simulating a passing fish; Pickens and McFarland, 1964), but seem to lack electroreception (by the usually reliable test of evoked potentials in the midbrain tectum). The EOD is doubtfully strong enough to disorient a passing prey and doubtfully early enough to give sensory guidance to prey catching.

Since the two orders display an active electrosense (using their own EODs) – the Gymnotiformes and the Mormyriformes are not closely related and many sister groups have no electric sense – it seems probable that their systems have been independently invented in evolution. The gymnotiforms are close to the siluriforms and might have shared a common ancestral invention. Just possibly the xenomystine knife fishes inherited an invention of the mormyriforms since they both belong to the osteoglossiforms. As few as two parallel inventions within the teleosts can be argued with parallelisms remarkable in their detail. Outside the teleosts, conceivably one single invention has left its mark in the elasmobranch form of ampullary sense organs and central pathways, in the petromyzontiforms through the elasmobranchs and the chondrostei (sturgeons and paddlefish), dipnoans (lungfish), crossopterygians and brachiopterygians, to the apodan urodele amphibians. Too little, if any behavioral research has been done on most of these groups to advance learning on what use they make of the sensory system as a passive sense.

Exceptions are the elasmobranchs and the paddle fish. In the former, elegant behavioral physiology (Kalmijn, 1973, 1982, 2000) has shown under quasinatural conditions that it is used for navigation relative to the earth's magnetic field due to currents induced either by the translation of the animal in ocean currents or to self-movement of the animal relative to the surrounding water as well as to find food fish buried in the sand. Note that each of these requires that the medium around the animal be a good conductor. In young paddle fish (*Polyodon*, Acipenseriformes, Chondrostei; Wilkens *et al.*, 1997), it has been convincingly shown that the electric sense guides prey capture even when the prey are small planktonic crustaceans about a millimeter long (*Daphnia*), evoking accurately directed capture of single individuals.

In a remarkable case of parallel evolution (see The Evolution of The Evolution of Parallel Visual Pathways in the Brains of Primates), electroreception is also present in monotreme mammals, both the spiny anteater, *Echidna*, and the duck-billed platypus, *Ornithorhynchus*. The latter is semiaquatic and feeds under water in the ponds and streams of New Guinea and Australia. It is not clear as yet just which of their live prey are located by this sense or how. But they respond to pulses or sustained currents a fraction of a millivolt per centimeter with saccades of the head suggestive of foveation and have thousands of sense organs reminiscent of teleost ampullary organs on the bill in parasagittal stripes. Side-to-side head swaying probably enhances sensitivity by creating a succession of ON and OFF stimuli, which also should aid in localizing the sources of the field and in measuring the distance. Between the stripes are arrays of push-rod mechanoreceptors that project to the same somatosensory cortex as the electroreceptors. Units there are bimodal, responding to both bill modalities and facilitating certain temporal input features. The system shows that somatosensory cortex can involve significant distance reception.

Echidnas are mainly terrestrial but feed in moist soil on living prey that doubtless provide ample electrical fields to home in upon, including earthworms firing their giant fibers. A few mucous gland electroreceptors on the tip of the snout have higher thresholds than those of the platypus. No electrosensory behavior has been documented but a moist snout making a liquid junction has been proposed to aid in finding insects (Gregory *et al.*, 1989).

Patently, many of these topics are still very fluid and will disclose new discoveries with further investigation.

2.20 Evolution of Taste

T E Finger, University of Colorado Medical School, Aurora, CO, USA

Glossary

amphid A paired chemosensory organ at the anterior end of nematodes including *Caenorhabditis elegans*. The amphid is innervated by 11 chemosensory neurons and one associated thermosensory neuron.

auxiliary cells Nonsensory cells of invertebrate sensilla. This class of cells includes socket cells, sheath cells, tormogen cells, and thecogen cells.

Ecdysozoa One of two major groups of the protostome division of the animal kingdom (cf. Lophotrochozoa). Members of this group, including arthropods and nematodes, possess an outer cuticle rather than an internal skeleton.

ecto-ATPase An enzyme that breaks down extracellular ATP. The ecto-ATPases can be divided into several molecular families.

inner labial sensillum One of eight chemosensory organs around the mouth (stoma) of nematodes. This organ contains only two sensory cells only one of which has free access to the external surface of the worm.

labellum A fleshy ovoid pad at the end of the probiscus of a fly used as a taste organ. The labellum houses numerous taste and tactile sensilla.

labrum A chemosensory organ in flies situated at the anterior end of the oral cavity.

Lophotrochozoa One of two major groups of the protostome divisions of the animal kingdom (cf. Ecdysozoa). Members of this group, including annelids and mollusks, share common developmental forms although the adults appear quite diverse.

Merkel cell A specialized epithelial cell found in vertebrates which participates in mechanoreception. Upon stimulation, Merkel cells release serotonin and ATP to activate a closely associated sensory nerve fiber.

Merkel-like basal cell A basal cell of nonmammalian taste buds named because of their similarity with epithelial Merkel cells in terms of structure and neurotransmitter contents.

Schreiner organ A presumed epithelial chemosensory organ of hagfish. This multicellular end organ is superficially similar, but not homologous, to taste buds. Unlike taste buds, Schreiner organs can be innervated by any epithelial nerve.

sensillum A sensory organ of invertebrates in which the sensory cells extend a hair-like process out of the cuticle.

sheath cells The inner non-neuronal cell of a sensory end organ of invertebrates, especially *C. elegans*, closely surrounding the sensory neurons.

socket cells The outer non-neuronal cell of an invertebrate sensory organ.

solitary chemoreceptor cell (SCC)	Scattered specialized chemosensory cells in the epidermis of aquatic vertebrates also found in the gut and airways of terrestrial vertebrates.
T1R	A family of mammalian taste receptors that includes three members which heterodimerize to form either sweet or umami receptors.
T2R	A large family of mammalian taste receptors that form bitter-sensitive taste receptor molecules.
taste cell	An elongate specialized epithelial cell of vertebrate taste buds.
thecogen cell	The inner auxiliary (nonsensory) cell of a sensillum, cf. sheath cell.
tormogen cell	The outer auxiliary (nonsensory) cell of a sensillum, cf. socket cell.

2.20.1 Introduction

We humans recognize taste as sensation arising from the oral cavity and indicating information about the chemical quality of potential foodstuffs. The sense of taste uniquely arises from the specialized sensory end organs for this system: taste buds. In humans, taste sensations are only those that we describe as salty, sweet, sour, bitter, and 'umami' (the taste of glutamate). All other oral sensations, for example, the coolness of mint, the smoothness of fats or the hotness of pepper, arise from the general cutaneous innervation of the epithelium and should not be considered to be 'taste'. So, for humans and other vertebrates, 'taste' is a system defined by the sensory end organs mediating the sensibility. For humans, and by extension, other vertebrates, taste can be defined by the use of taste buds in the context of food selection.

When examining the evolution of the sense of taste, we are met with several difficulties. First, how can the sense of taste be defined for organisms lacking taste buds and, second, is the sense of taste evolutionarily conserved across species, and if so, across what range of species? This second question leads directly to the issue of where and at what point in phylogeny did taste buds evolve, and what tissues they may have evolved from. I will consider each of these points in the following sections leading to the conclusion that taste is a well-defined sense only in vertebrates, where taste buds are a clearly recognizable feature. Related chemical senses in other taxa may have arisen independently and are not 'taste' other than by having an analogous function.

2.20.1.1 What is Taste?

For humans and other vertebrates, taste is a sensory system that starts with taste buds as the specialized sensory end organ and deals with information concerning the chemical composition of food in contact with mouthparts. Primarily, the sense of taste is used across taxa to distinguish the edible from the inedible (Glendinning *et al.*, 2000). The important features in the above definition are that taste is a chemical sense associated with mouthparts and utilized in control of feeding. Note that the definition says nothing about the medium conveying the stimulus (e.g., air vs. water), nor does it include any description of molecular features or transduction mechanisms – neither is a defining feature of the taste system. For the vertebrate clade, taste is defined by the sensory end organ; for invertebrates, this definition fails since taste buds exist only in vertebrates.

Single-cell organisms may show positive chemotaxis toward a food source by following a concentration gradient of an attractive substance (Van Houten, 2000). Although this behavior shares some aspects of taste-mediated behaviors in more complex organisms, it is not taste. Single-cell organisms have no oral cavity and have no specialized sensory end organs. To include the positive chemotaxis of single-cell organisms under the rubric of 'taste' would necessitate extending the abilities of taste and smell to plants which exhibit positive and negative growth in response to chemical signals in the environment (Filleur *et al.*, 2005).

A more difficult situation arises when examining the invertebrates. Complex invertebrates such as crustaceans and mollusks (Ache, 1987) have specialized chemoreceptors associated with well-defined mouth parts. These chemoreceptive end organs are not homologous to taste buds although they share several features with taste buds, for example, multicellular aggregates specialized for the detection of a limited variety of chemical substances. The presence of such specialized chemoreceptor organs on mouthparts certainly makes these end organs similar to taste buds in terms of function and behavior; yet, are they taste? The difficulty in drawing a conclusion about this depends on the context in which one wishes to use the comparison. For example, if one wishes to compare the behavior of a fly with that of a rat, then referring to the feeding-related perioral chemosensors of these animals as 'taste' has some utility. However, calling both of these systems 'taste' is misleading when considering the detailed molecular or cellular features of the sensory end organs, that is, the labellar sensillae of a fly are

entirely different from the taste bud of a rat. The sensory cells in flies are bipolar neurons extending an axon into the central nervous system (CNS); the sensory cells of taste buds are axonless, modified epithelial cells that synapse onto the peripheral process of a cranial nerve ganglion cell. These systems are analogous, but clearly not derived from a common ancestral condition, that is, they are not homologous.

Even for vertebrates, including humans, the word 'taste' is confounded by common usage meaning sensations arising from the mouth. Conversationally, we use the word 'taste' to include many aspects of flavor other than salty, sweet, sour, bitter, and umami. The confusion arises because of the nasopharynx connecting our oral and nasal cavities. Vapors from food in the oral cavity pass retronasally through the nasopharynx to reach the olfactory epithelium. Thus, food in our mouth stimulates not only taste buds, but also chemoreceptors of the olfactory and trigeminal systems. A further confusion is that, even among vertebrates, taste buds are not always confined to the oral cavity. Catfish, for example, have plentiful taste buds scattered across the body surface, being especially densely distributed on the barbels and leading edges of the fins. Despite their location, these oddly situated taste buds are innervated by a gustatory nerve (facial N.) and are used in the context of finding foods (Bardach *et al.*, 1967).

2.20.2 Taste in Invertebrates

As mentioned above, taste, when applied to invertebrates, is not as clearly defined as for vertebrates. Following the definition above, I will consider the sensory end organs used by different invertebrates in detecting nutritive substances and toxins in potential food items. By definition, the sensory end organs for taste must be associated with mouthparts or other appendages used in feeding. However, in many segmentally organized invertebrates, similar end organs often occur on mouthparts and legs. This may, in part, be due to the fact that mouthparts and legs are serial homologues in many segmented invertebrates. Even in nonsegmented invertebrates, for example, octopus, apparent taste end organs occur on the legs as well as mouthparts. In these cases, the anatomical distinctions are blurred and one must rely more on the context in which the end organ is used to define the system. By analogy to vertebrates, for invertebrates, we can then extend the definition of taste to include contact, or near-range (i.e., high-threshold) chemoreceptors used in a feeding context and which are similar to the chemoreceptors of the mouthparts.

The invertebrate clade includes relatively primitive, radially symmetric groups, for example, Cnidaria and Porifera, and the Bilateria including the Protostomes (Holland, 2000). While the more basal group of animals clearly respond to a variety of chemicals (presumably via specialized chemoreceptors), it is difficult to draw distinctions between various modes of chemoreception. Also, comparatively little is known about the nature of chemosensory cells in these basal forms.

The Protostomes fall into two large groups: Ecdysozoa (including nematodes and arthropods) and Lophotrochozoa (including flatworms, annelids, and mollusks; Holland, 2000). In both groups, taste as a feeding-related sense, can be distinguished from other well-developed chemosensory modalities. This article will describe aspects of the 'taste' systems in representatives of each of these major groups; it is not meant to be a comprehensive review.

2.20.2.1 Ecdysozoa

Many Ecdysozoa have a relatively impermeable cuticle covering the outside of the body. Hence, exteroceptive end organs including chemoreceptors must have sensory processes extending beyond the cuticle or else have openings in the cuticle to permit access to the external stimuli. Sensory end organs of this clade have a common general structure in which the cell bodies of the sensory neurons lie beneath the surface cuticle and extend dendrites to reach through or near the cuticle. The apical dendrites of the sensory cells are usually associated with one or more non-neuronal accessory cells designated by a variety of names, for example, sheath, socket, auxiliary, tormogen, and thecogen cells.

The overall organizational scheme of taste-like sensory organs in Ecdysozoa is similar in many respects to vertebrate taste systems. Yet, any similarity must be attributed to convergence rather than common origin. In both major groups, each taste organ comprises a variety of sensory cells 'tuned' to different chemical stimuli. That is, although each end organ responds to many different chemical cues, the individual sensory cells within the end organ are tuned fairly narrowly. In the Ecdysozoa, each receptor cell responds either to appetitive or to aversive substances, but never both. This dichotomy is reflected in the nonoverlapping central connectivity of the receptor cells and the behaviors driven by their stimulation (Wang *et al.*, 2004).

2.20.2.1.1 Nematodes Chemoreceptor cells and their molecular receptors are well studied in *Caenorhabditis elegans*. Unfortunately, the literature in this field is confounded by the tendency to refer to chemoresponses to water-soluble compounds as 'taste' while chemoresponses to volatiles is termed 'olfaction' although the same end organ (amphid chemoreceptors) is used to mediate both responses. As discussed above, the separation of taste and smell according to chemical nature of the stimulus is not generally useful (e.g., compare taste and olfaction in catfish). The well-studied chemoreceptor of the nematode *C. elegans* consists of paired amphid organs each innervated by 12 neurons (Figure 1; Ward *et al.*, 1975). Of these, 11 are chemosensory, the other being thermoceptive (Bargmann and Mori, 1997). Eight of the chemosensory neurons (ADF, ADL, ASE, ASG, ASH, ASI, ASJ, ASK) extend dendrites through the amphid pore in the cuticle to be in fairly direct contact

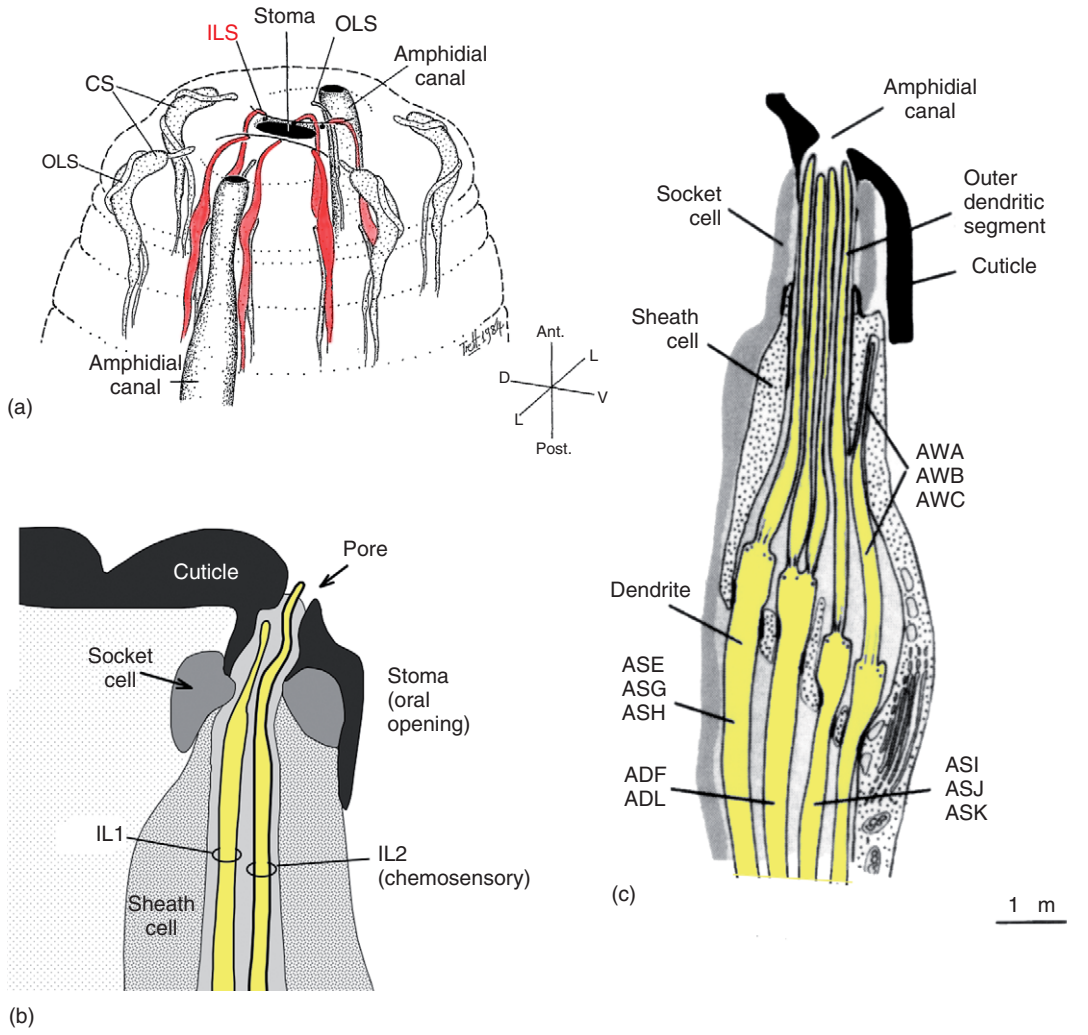

Figure 1 Chemoreceptor organs on the head of nematodes. a, Diagram showing the location of the head sensilla of *Pratylenchus* sp. CS, cephalic sensillum; ILS, inner labial sensillum; OLS, outer labial sensillum. b, Diagram of an inner labial sensillum (rendered in red in panel a). IL2, whose dendritic tip is exposed to the outside milieu, is a chemosensory neuron while IL1, whose tip is not exposed, is reported to be mechanosensory. c, The amphid contains numerous chemosensory neurons which detect either soluble (ASE, ASG, ASH, ADF, ADL, ASI, ASJ, ASK) or volatile (AWA, AWB, AWC) substances. It is not clear whether the amphid chemoreceptors should be considered 'taste' according to the definition in this chapter since stimulation of these receptor cells results in chemotaxis rather than feeding. a, Reproduced from Trett, M. W. and Perry, R. N. 1985. Functional and evolutionary implications of the anterior sensory anatomy of species of root-lesion nematode (genus *Pratylenchus*). *Revue Nematol.* 8(4), 341–355, with permission from IRD. b, Drawing based on Ward, S., Thomson, N., White, J. G., and Brenner, S. 1975. Electron microscopical reconstruction of the anterior sensory anatomy of the nematode *Caenorhabditis elegans*. *J. Comp. Neurol.* 160(3), 313–337. c, Reproduced from Cell biology of olfactory epithelium. In: Neurobiology of Taste & Smell; Farbman, A.; *eds.* T. E. Finger, W. L. Silver, and D. Restrepo; Copyright © 2000, Wiley. Reprinted with permission of John Wiley & Sons, Inc.

with the environment. These cells respond to water-soluble substances. Three other amphid chemosensory neurons (AWA, AWB, AWC) have dendrites extending near the amphid pore, but are encapsulated by the 'sheath' or 'wing' cell and thus do not have direct contact with the environment. The AWA, AWB, and AWC cells respond to volatile substances, presumably those capable of diffusing through or being transported across the sheath cell. The commonly studied chemotaxic behaviors are driven almost entirely by these amphid chemoreceptors (Bargmann and Mori, 1997). As described above, the nematode chemotaxic behaviors are commonly divided into 'taste' and 'smell' according to the nature of the chemical stimulus (water soluble or volatile, respectively). I suggest that all behaviors mediated by the amphids should more properly be considered 'smell' since none of the measured behaviors is concerned with palatability of a suspected food object. Rather the amphid drives locomotor behaviors, just as the olfactory sense in vertebrates drives approach/avoidance locomotor responses.

Nematodes, including *C. elegans*, have a set of lesser-known chemoreceptors, the inner labial neurons, which are situated more within the oral cavity and appear likely to mediate taste-like behaviors (Tabish *et al.*, 1995). Yet, little is known of the function or responses of these perioral presumed chemoreceptors. Trett and Perry (1985) suggest, on the basis of structure, that the IL2 neuron of inner labial sensilla serve as contact chemoreceptors (just as taste buds have been described) but this speculation has yet to be confirmed by functional or behavioral studies. Nematodes studied to date possess six radially symmetric paired inner labial sensilla with cuticular openings facing the inner side of the rostral end of the oral cavity in many species (see Figure 1). Each sensillum is innervated by two neurons (IL1 and IL2) one of which (IL2) extends a process to reach the outer environment; the other sensory dendrite terminates just below the surface beneath the opening in the cuticle (Ward *et al.*, 1975). In parasitic species, however, the inner labial sensilla may be purely mechanosensory in that their sensory processes do not have access to the surface (Fine *et al.*, 1997) but this arrangement would not preclude detection of volatile substances like the AWA, AWB, and AWC amphid neurons.

2.20.2.1.2 Arthropods Arthropods, including insects, arachnids, and crustaceans, rely on chemosensory sensilla to detect chemicals in the environment. The best-characterized system is that of the fruit fly *Drosophila* (see Figure 2) but other arthropods appear to have receptors of similar ilk. Chemosensory sensilla are present not only on the mouthparts but also on the wing margins, tarsi (feet) and some other appendages likely to contact potential foodstuffs (e.g., Dethier, 1962). The chemosensory sensilla in the perioral region and upper alimentary canal apparently mediate feeding behavior and therefore fit into the definition of a sense of taste. The chemosensory sensilla on the other appendages are structurally and molecularly similar to the oral ones and are usually used in the context of food detection. So it is not reasonable to exclude these from the taste system merely because of their location on the body. The end organ structure is right and the behavioral context is right. Including the tarsal chemoreceptors as part of the taste system is analogous to including the taste buds on the barbels and body of fishes in their taste system. In the case of the external taste buds of fishes, they are clearly part of the taste system (based on the end organ structure, innervation, and behavioral context). By analogy, we should then accept the tarsal chemoreceptors of arthropods as being part of the taste system. A similar argument can be made for the chemoreceptors on the wing margins, although their behavioral context is less well studied. In contrast, the chemosensory sensilla of other body parts, for example, antenna or ovipositor, should not be included in the taste system, regardless of expression of common receptor molecules, since they are used in other behavioral contexts, for example, navigation or egg-laying.

The basic structure of the chemosensory sensilla is similar whether the end organ be on a mouthpart, wing, or leg. These end organs contain one mechanoreceptor cell and several (2–4), physiologically distinct chemosensory cells with an apical process (outer dendritic segment) extending into the sensilla proper which is a thin, hair-like protrusion of the cuticle (Shanbhag *et al.*, 2001). One or more pores lies at the apex of the sensilla thereby permitting substances in the outside medium to come into contact with the fluid (sensillum lymph) filling the space around the dendrites within the sensillum. Potential tastants must then traverse the fluid-filled space to activate receptors on the dendrites of the sensory cells. As is typical of invertebrate sensory cells, each receptor cell of the chemosensory sensilla contributes an axon to the peripheral nerves which then enter the CNS. In addition, there are numerous taste 'pegs', which are smaller sensory sensilla that protrude little from the surface of the epithelium and which bear only one chemosensory cell along with a mechanosensory cell (Shanbhag *et al.*, 2001).

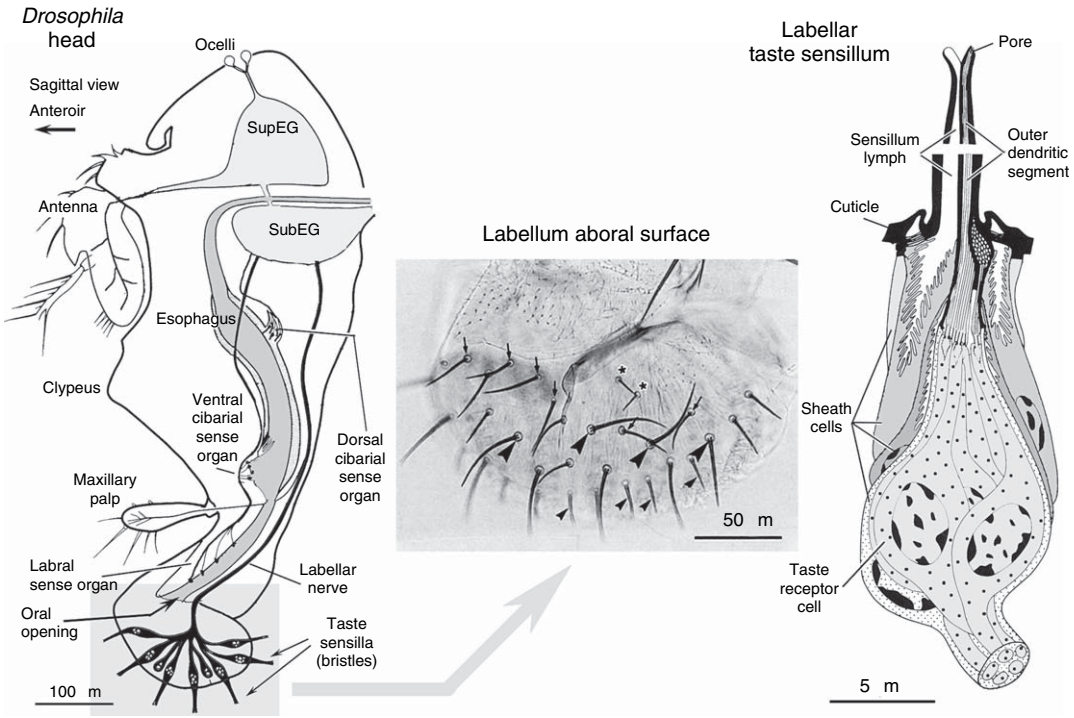

Figure 2 Taste receptors on the fly *Drosophila*. Left: Drawing of a sagittal section through the head of the fly showing the location of the major taste organs: labellum, labral sense organ, and cibarial sense organs. Center: Labial palp whole-mount preparation showing the aboral surface of left palp. Anterior is left and dorsal top. Sensilla marked with stars are purely mechanosensory and the remaining are taste bristles. Taste sensilla are divided into three sub-types: short (small arrowheads), intermediate (arrows), and large (large arrowheads). Only some sensilla of each sub-type are marked. Right: drawing of a single sensillum showing the receptor and auxiliary cells. Center panel, reproduced from *Cell Tissue Res.*, vol. 304(3), 2001, pp. 423–437, Gustatory Organs of *Drosophila melanogaster* : Fine Structure and expression of the putative odorant-binding protein PBPRP2, Shanbhag, S. R., Park, S. K., Pikielny, C. W., and Steinbrecht, R. A., figure 1b, with kind permission of Springer Science and Business Media. Left and right panels, reproduced from cell biology of taste epithelium. In: Neurobiology of Taste & Smell; Finger, T. E. and Simon, S. A.; *eds.* T. E. Finger, W. L. Silver, and D. Restrepo; Copyright © 2000, Wiley, and modified from the original work of Singh (1997). Reprinted with permission of John Wiley & Sons, Inc.

In *Drosophila*, chemosensory sensilla are especially dense on the labellum and to a lesser extent on the labrum, which sits at the entrance to the oral cavity. Intraoral chemosensory sensilla are also present in the cibarial sense organs. Both the intraoral and oral chemosensory end organs form nerves that terminate within the subesophageal ganglion, in contradistinction to the olfactory (antennal) receptors that project to the antennal lobes of the supraesophageal ganglion.

The labellar chemosensory sensilla are divisible into three morphological types according to the length of the sensillum: short (s-type), intermediate (i-type), and long (l-type) (Shanbhag *et al.*, 2001). The i-type sensilla possess only two chemosensory cells, whereas the s- and l-types have four chemosensory cells. The chemosensory cells fall into four broad functional classes according to chemoresponsiveness. The w-cells respond to water, s-cells respond to sugars, L1-cells respond to low concentrations of salt, and L2-cells to high concentrations of salt and to various bitter substances. But this formulation may be overly simple (e.g., see Hiroi *et al.*, 2002). The two chemosensory cells of the i-type sensilla consist of one cell with L2-type responses (bitter, high salt) and the other cell with a combination of S and L1 properties (Hiroi *et al.*, 2004). Water-responsive units are present only in the s-type and l-type sensilla. In summary, the sensory cells of *Drosophila* gustatory sensilla fall into one of two groups according to the behavior elicited by their activation: one group (e.g., s-units, w-units, and L1-units) drives appetitive behaviors under the right motivational conditions, while the other group (L2-units responsive to high salt and bitter substances) drives aversive behaviors.

The dichotomy in driven behaviors of the different types of receptor cells coupled with the presence of an axon extending directly from the receptor cell to the CNS, permits direct assessment of the pattern of projection into the brain of these functionally different types of receptor cells (Inoshita and

Tanimura, 2006; Wang *et al.*, 2004). Gustatory information in the CNS of *Drosophila* is organized first, according to gustatory end organ, and second, according to driven behaviors – appetitive or aversive. Thus, the taste sensilla on the labellum project to a different part of the subesophageal ganglion than do the taste organs within the oral cavity proper (Stocker and Schorderet, 1981; Wang *et al.*, 2004). Within the subesophageal ganglion, bitter-responsive cells (L2-type) map dorsomedial to the sugar-responsive (L1-type) neurons. Water-responsive receptor cells also project to the lateral neuropil of the subesophageal ganglion, perhaps overlapping or slightly lateral to the sugar-responsive group (Inoshita and Tanimura, 2006).

Some interesting similarities exist between the insect and mammalian gustatory systems. First, the gustatory end organs comprise multiple sensory cells exhibiting a limited range of chemoresponsiveness. That is, each end organ responds to a spectrum of tastants, although each sensory cell within that end organ is more limited. Second, the fundamental organizational plan in the CNS is one of organotopy, that is, each part of the body is represented in a unique part of the CNS, suggesting that the location of a chemical cue is key to gustatory-mediated behavior. Finally, within each organ-specific zone of the CNS, quality may be encoded by position within the somatotopically delineated field of neuropil. Just as different areas of neuropil are implicated in appetitive versus aversive cues in the subesophageal ganglion of the fly, different areas of neuropil appear activated by different tastants in the gustatory centers of mammals (Harrer and Travers, 1996; Sugita and Shiba, 2005).

2.20.2.2 Lophotrochozoa

2.20.2.2.1 Annelids The annelids, as represented by earthworms and leeches, have widespread chemoreceptors scattered across their body surface, but a set of these, associated with the lips (labia) control feeding behavior (Elliott, 1987). These are relatively poorly characterized, except for the labial chemoreceptors of leech which were studied both anatomically and physiologically by Elliot (1986, 1987).

The medicinal leech, *Hirudo medicinalis*, will initiate a full sequence of feeding behavior in response to human blood or plasma whether presented at room or body temperature (Elliott, 1986). The essential components of blood appear to be NaCl and arginine, which together provoke the full feeding behavior. The sensory region crucial to this behavior is the dorsal lip whose ablation results in loss of the feeding sequence in response to chemical stimulation. Likewise, in *Haemopsis marmorata*, a carnivorous leech that eats and trails earthworms, ablation of the dorsal lip abolishes their ability to track earthworm trails (Simon and Barnes, 1996).

The dorsal lips of leeches contain large and small sensilla containing unique ciliated sensory cells. As is typical of invertebrates, the sensory cells are bipolar neurons with a centrally directed axon and a dendritic process that extends to the surface of the epithelium. The sensory cells are grouped together into sensilla of two different sizes. The approximately 150 larger sensilla are arrayed ~125 μm apart in a band across the dorsal lip. Each sensillum forms a raised papilla of ~35 μm in diameter with an apical opening of ~20 μm through which extend the cilia of the underlying sensory cells (Elliott, 1987). Each sensillum contains multiple sensory cells, but the number is not specified. The 250 small lip sensilla are 8–10 μm in diameter and lie along the edges of the stripe of large sensilla. The smaller sensilla which sit flush to the surface of the surrounding epithelium can be recognized by the collection of cilia protruding from the surface. Since each sensory cell possesses a small number of cilia, a small sensillum is likely to comprise a dozen or so sensory cells (Elliott, 1987).

The nerves formed by the axons of the sensory cells assemble mostly into the dorsal cephalic nerves (Perruccio and Kleinhaus, 1996) to reach the cerebral ganglia. Stimulation of the lip region with either NaCl or arginine evokes robust neural activity (Li *et al.*, 2001). Interestingly, simultaneous stimulation with quinine or denatonium, both of which are feeding deterrents in these animals, reduces peripheral afferent activity. These findings suggest that feeding deterrents may act, at least in part, by inhibiting the neural response to appetitive cues (Li *et al.*, 2001).

2.20.2.2.2 Mollusks The taste-related chemoreceptors of mollusks have been characterized in both gastropods and cephalopods. In gastropods, as typified by *Aplysia*, feeding-related chemoreceptors are present on the lips and anterior tentacles (Jahan-Parwar, 1972). Likewise, cephalopods, especially well studied in octopus, have chemoreceptors on the tentacles as well as in the perioral region. Those associated with the suckers on the tentacles were well described in an elegant series of papers by Graziadei (Graziadei, 1964a, 1964b, 1965; Graziadei and Gagne, 1976) following studies by Emery (1975a, 1975b) on ciliated sensory cells (assumed to be chemoreceptors) on the lips of

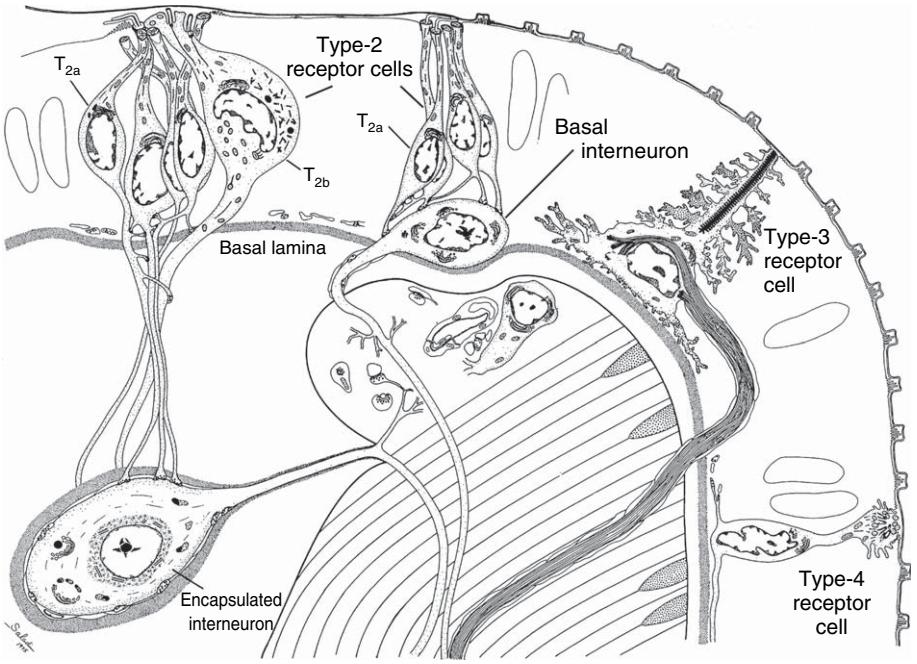

Figure 3 Diagram of sensory neurons in the rim of a sucker on the arm of an octopus. Based on structural considerations, type-2 receptors are likely to be chemoreceptors as are the type-4 cells which look similar to olfactory receptor cells in squid. Type-3 cells appear to be mechanoreceptors. The clusters of type-2 cells superficially resemble vertebrate taste buds, but obvious structural differences exist. The occasional contacts between some type-2 cells and basal interneurons is reminiscent of the relationship between elongate taste cells and Merkel-like basal cells in nonmammalian vertebrates. Reproduced from 'Sensory innervation in the rim of the octopus sucker', *J. Morphol.*; Graziadei, P. P. and Gagne, H. T.; Copyright © 1976, Wiley-Liss. Reprinted with permission of Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc.

squid and octopus. A brief summary of Graziadei's findings follows, but the reader should refer to the original papers for a complete description of the sensory apparatus of the tentacles.

Sensilla of the mollusks are similar in many ways to the sensilla of leeches. The sensory cells are bipolar neurons with an apical dendrite that extends to the surface of the epithelium, and a basal axonal process that contributes to nerves coursing to the CNS. The likely chemoreceptors of the sucker are elongate epithelial cells (termed type-2 cells by Graziadei and Gagne, 1976) which are collected into small 'apical clusters' (5–10 cells), superficially similar to taste buds in vertebrates (see Figure 3). The most common form of sensory cell in the apical cluster is a narrow elongate cell (type 2a of Graziadei and Gagne) which extends a small number (e.g., 3–8) cilia above the surface of the surrounding epithelium. The apical clusters may contain a second elongate cell type (type 2b) which is larger than the 2a cells and has somewhat different cytological features. The apical clusters also may be associated with a horizontally oriented 'basal interneuron' lying between the apical cluster and the basal lamina of the epithelium. These basal interneurons as well as 'encapsulated' interneurons apparently receive synaptic contacts from the type-2 cells of the apical cluster. The situation is reminiscent of the organization of taste buds in bony fishes where the elongate sensory cells synapse onto a Merkel-like basal cell (see below). Of course, the tentacle sensilla of octopus are not homologous to taste buds in vertebrates, hence similarities in organization must be due to convergence rather than phyletic continuity.

2.20.3 Taste in Vertebrates and Chordates

Taste buds are recognizable throughout the vertebrate lineage – from lampreys to teleosts to mammals. Although structural details can be quite varied across species, taste buds retain a host of key features that distinguish them from other end organs. The common features of taste buds include: (1) aggregates of specialized epithelial cells including both receptor and supporting cells (since the cells are epithelial, they have a limited life span and are continuously replaced through out the life span of the animal); (2) more than one type of sensory cell reaching the epithelial surface via an

opening (taste pore) in the surrounding epithelial covering; and (3) sensory (afferent) innervation from facial, glossopharyngeal, or vagus nerves which project to the viscerosensory column of the medulla. Taste buds in diverse vertebrates share other features but it is unclear whether such features are necessary as defining features, or are rather elements in common to a subset of vertebrates. Such common features include: (1) a cell type capable of concentrating and releasing serotonin (Kim and Roper, 1995; Nada and Hirata, 1977); (2) one or more cells that manifest a neuron-like phenotype (e.g., expressing NCAM: Nelson and Finger, 1993; Smith *et al.*, 1993), neuron-specific enolase (NSE) (Toyoshima *et al.*, 1991; Yoshie *et al.*, 1989), or neural differentiation markers such as Mash-1 (Kusakabe *et al.*, 2002); and (3) strong ecto-ATPase activity (Iwayama and Nada, 1967; Barry, 1992) perhaps because ATP is a requisite neurotransmitter in this system (Finger *et al.*, 2005).

2.20.3.1 Epithelial Chemoreceptors in Chordates

The chordate lineage includes the invertebrate cephalochordates (e.g., *Amphioxus*) and craniates. The craniates can be subdivided into two groups: (1) hagfish and their relatives, and (2) true vertebrates, including both agnathan (lamprey) and gnathostome lineages. All extant vertebrates, from lampreys to amniotes, have clearly recognizable taste buds innervated by branches of the facial (CN VII), glossopharyngeal (CN IX), or vagus (CN X) nerves. The cells of taste buds are modified epithelial cells and, unlike most invertebrate receptors, do not possess an axon or any process extending below the basal lamina. While taste buds are clear in all vertebrates, the evolutionary origins of these end organs is obscure.

Sensory cells in nearly all invertebrates are primary sensory neurons, also called type I receptors, complete with both a sensory dendrite extending to the epithelial surface and an axon connecting to the CNS (see above). The amphioxus has many such epithelial sensory cells including type I cells of Lacalli (Lacalli and Hou, 1999). But secondary sensory neurons first make a substantial appearance in this group of organisms. The epithelial secondary sensory cells of *Amphioxus* (type II receptors; Holland and Yu, 2002) extend immotile cilia to the epithelial surface. These cilia contain numerous microtubules (Lacalli and Hou, 1999) rather than the more standard 9+2 arrangement for cilia. The apical morphology of the type II receptors is striking in that a ruff or collar of microvilli surround a central elongate cilium (Figure 4). This feature is commensurate with a chemosensory rather than mechanosensory function. The type II epithelial receptors extend two or three basal processes a short distance within the epithelium to synapse onto neural processes (Lacalli and Hou, 1999).

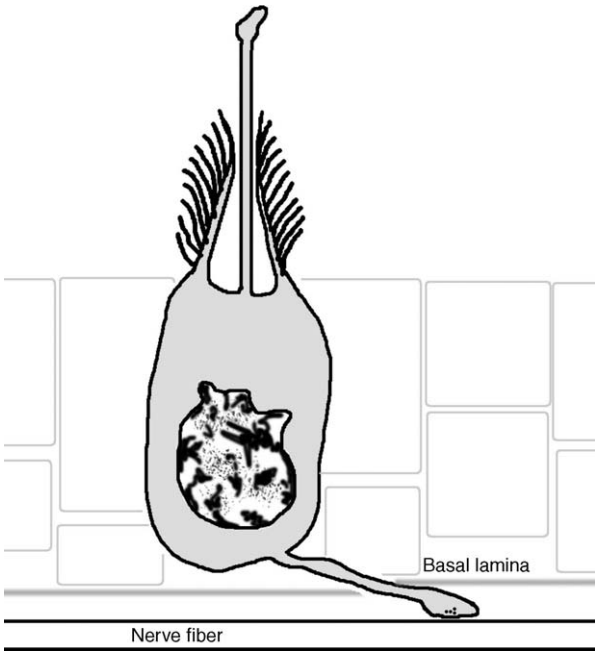

Figure 4 Schematic drawing of a type II sensory cell from *Amphioxus*. These receptor cells bear a long central cilium surrounded by a ruffle of microvilli. The numerous microvilli, which serve to expand the surface area of the cell, coupled with the lack of a 9+2 microtubule arrangement in the cilium are consonant with a chemosensory function. These sensory cells often extend a short process, sometimes through the basal lamina, to synapse on nearby nerve fibers. Based on descriptions and figures in Lacalli, T. C. and Hou, S. 1999. A re-examination of the epithelial sensory cells of amphioxus. *Acta Zool.* 80, 125–134.

2.20.3.2 Solitary Chemoreceptor Cells and Schreiner Organs

All craniates, including hagfishes, possess solitary chemoreceptor cells (SCCs) scattered within the epithelium of the gut, respiratory tract and even across the body surface (Whitear, 1992; Finger, 1997; Sbarbati and Osculati, 2003). SCCs resemble the type II sensory cells of amphioxus as well as the individual cells of taste buds in terms of being elongate, columnar epithelial cells which synapse onto cranial nerve sensory processes. The SCCs differ from taste buds in that they can be innervated by any cutaneous or visceral nerve. For example, SCCs scattered across the surface of the body of fishes are innervated by the local cutaneous nerve – either

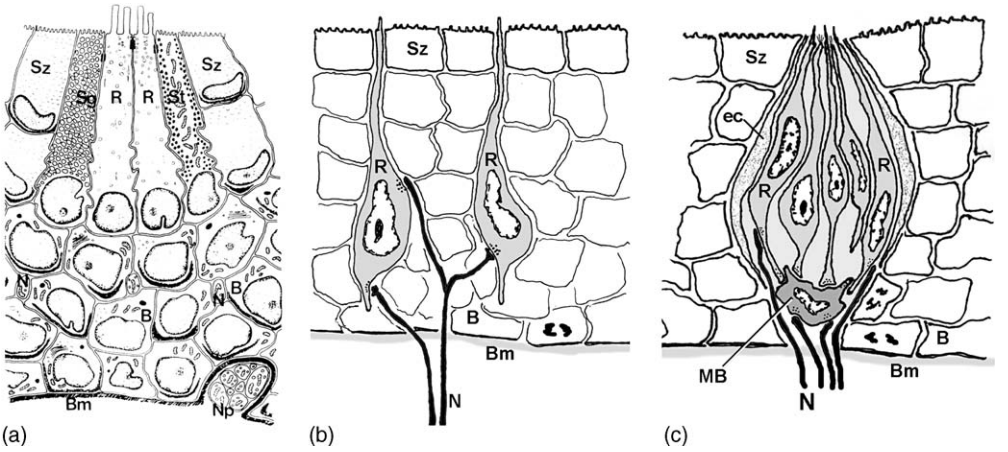

Figure 5 Schematic drawing comparing a Schreiner organ in a hagfish (a), with SCCs (b), and a taste bud in a typical teleost fish (c). In (a), the receptor cells (R) do not extend to the basal lamina and are flanked by various supporting or secretory cells. Part b is a schematic diagram of SCCs in a typical teleost. The SCCs are isolated in the epithelium appearing without associated supporting or secretory cells. Part c is a schematic diagram of a taste bud from a typical teleost. Multiple types of receptor cells are surrounded by flattened edge cells. The receptor cells reach nearly to the basal lamina where they form synapses with both nerve processes and Merkel-like basal cells. B, basal cell; Bm, basal lamina (basement membrane); ec, edge cell; MB, Merkel-like basal cell; N, nerve fiber; Np, nerve plexus; R, receptor cell; Sz, mucous cell; Sg, glandular supporting cell; St, type II supporting cell. a, Reproduced from Georgieva, V., Patzner, R., and Adam, H. 1979. Scripta* 8, 61–67, with permission from Blackwell Publishing.

spinal or trigeminal according to location. In contrast, taste buds on the body are innervated by a recurrent branch of the facial nerve, not by the local spinal nerve (Herrick, 1901). Hence, taste buds always have a unique relationship with the cranial nerves associated with epibranchial placodes (Northcutt and Barlow, 1998).

Hagfish (chordates, but perhaps not vertebrates) lack taste buds as defined above, although they do possess Schreiner organs, which are multicellular aggregates of presumed chemoreceptor cells. These may simply be aggregations of SCCs, but the cells of the Schreiner organ are not identical to SCCs. Schreiner organs also have several features similar to taste buds, but do not share all of the features of taste buds, for example, Schreiner organs do not span the full thickness of the epithelium and do not possess three cytologically distinct cell types. The relationship between Schreiner organs, SCCs, and taste buds remains enigmatic (see Braun, 1998, for a nice discussion of this issue).

The ultrastructure of the Schreiner organs has been described by Georgieva *et al.* (1979), who found there to be one type of sensory cell (type I) replete with microvilli, a likely supporting cell and an associated secretory cell similar to mucus cells elsewhere in the epithelium (see Figures 5 and 6). The sensory cells of Schreiner organs appear identical to the SCCs in the same species. Further ultrastructural studies are necessary in order to determine the degree of similarity between the Schreiner organ cell types and those of taste buds. For example, the supporting cells (type II cells) of Schreiner organs are similar to type I (glial-like) cells of taste buds in that they wrap around the sensory cells. Our preliminary data indicate that Schreiner organs are not associated with high levels of ecto-ATPase, which is a key feature of the type

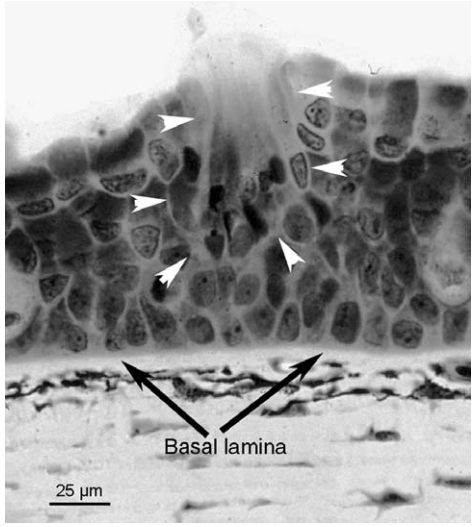

Figure 6 Photomicrograph of a Schreiner organ for the hagfish, *Eptatretus*. Note that the sensory organ (arrowheads) lies well above the basal lamina. Photomicrograph courtesy of Dr. C. Braun, Hunter College, New York, NY, USA.

I (glial-like) cells of vertebrate taste buds in which ATP serves as a neurotransmitter (Finger *et al.*, 2005; Kirino *et al.*, 2006). Thus, Schreiner organs and tastes buds are further distinguished in terms of utilizing different neurotransmitter systems.

Whatever the similarities of Schreiner organs and taste buds, it is noteworthy that SCCs themselves and taste buds share several features. Both comprise modified epithelial cells that undergo continuous replacement during the life of the animal. In the catfish, *Ictalurus punctatus*, the SCCs and taste buds react similarly to the PHA-E lectin (*Phaseolus vulgaris* agglutinin) which reacts with the arginine-binding taste receptor protein (Finger *et al.*, 1996). Thus, in these fish, it appears that SCCs and taste buds may utilize a common receptor mechanism. Similarly, in mammals, nasal and gut SCCs, like taste buds, express T2R (bitter) and T1R receptors and their associated downstream signaling components (Finger *et al.*, 2003; Sbarbati and Osculati, 2003). Thus, in both teleosts and mammals, SCCs and taste buds may utilize common receptor mechanisms. Nonetheless, differences do exist. Whereas SCCs form clear synapses with nerve fibers, the cells of taste buds that share biochemical features with SCCs (type II cells – see Section 2.20.4.3.1.(*ii*)) do not. Further studies are needed to understand the evolutionary relationships between these cutaneous chemoreceptor systems.

2.20.4 Taste Buds in Vertebrates

In this article, I present an overview of some of the different appearances of taste buds, but this is not meant to be comprehensive. An excellent comparative view of taste buds can be found in the work of Reutter and Witt (1993).

The structure of taste buds varies considerably across vertebrates (see Figure 7) but several consistent features emerge when comparing across species, as described above. These include: (1) aggregates of 50–150 specialized epithelial cells including both receptor cells and glial-like supporting cells, (2) multiple types of elongate cells reaching an opening in the epithelial surface, and (3) innervation by one of the three gustatory nerves: facial, glossopharyngeal, or vagus. Categorization of cell types within taste buds is complicated by the fact that taste buds consist not only of different functional types of cells, but also cells of different ages within each functional class. Taste buds are surrounded by specialized epithelial cells, 'edge', 'marginal', or ciliated cells (in frog), which form the outer boundary of the taste bud proper. In addition, all taste buds are closely associated with proliferative basal cells which divide to replace the aging and apoptotic cells of the taste bud. The literature on the types of cells in taste buds is extensive and complex (reviewed in Yee *et al.*, 2001). Rather than reviewing the vagaries of this literature, I will present a summary of our current understanding of the organization and structure of taste buds.

Some groups, such as frogs, have distinctive apomorphic characteristics, where taste buds take on a broad cylindrical form of large taste 'disks' spanning 100 μm. Most vertebrates have more compact taste buds organized in an onion-like configuration with an apical pore only tens of micra across. These more compact taste buds, found in all vertebrate groups, have two different plans of organization, typified in the descriptions below as the nonmammalian and mammalian schemes (the situation in birds is not clear). Whether these differences in morphology are more related to phylogeny or to habitat is unknown.

Historically, elongate taste cells in taste buds have been categorized according to their propensity to stain with acidophilic dyes or degree of osmiophilia in preparations for electron microscopy. This has led to descriptions of cells as being either 'light' or 'dark' but these descriptors may vary according to preparatory technique and particular stain utilized. Some authors have extended this classification system to imply function, characterizing the elongate taste cells as being 'sustentacular' (or 'supporting') versus 'sensory' ('receptor') cells. More careful ultrastructural analysis leads to a characterization according to structural features such as size and shape of apical specialization, presence of distinctive granules, or size and shape of the nucleus. Nonetheless, the mixed nomenclature remains in the current literature.

2.20.4.1 Taste Buds in Nonmammalian Vertebrates

Taste buds in these aquatic forms have been described in many teleosts, a few elasmobranchs, and urodeles (reviewed in Reutter and Witt, 1993) as well as in a lamprey, where the end organs have been called 'terminal buds' (Baatrup, 1983). The detailed structure of taste buds can vary substantially between species, or even within a species, between taste buds situated in different locations, for example, oral compared to extraoral (Reutter and Witt, 1993). Nonetheless, a common organizational plan can be abstracted.

2.20.4.1.1 Cell types Taste buds in this group are distinguished by containing not only elongate

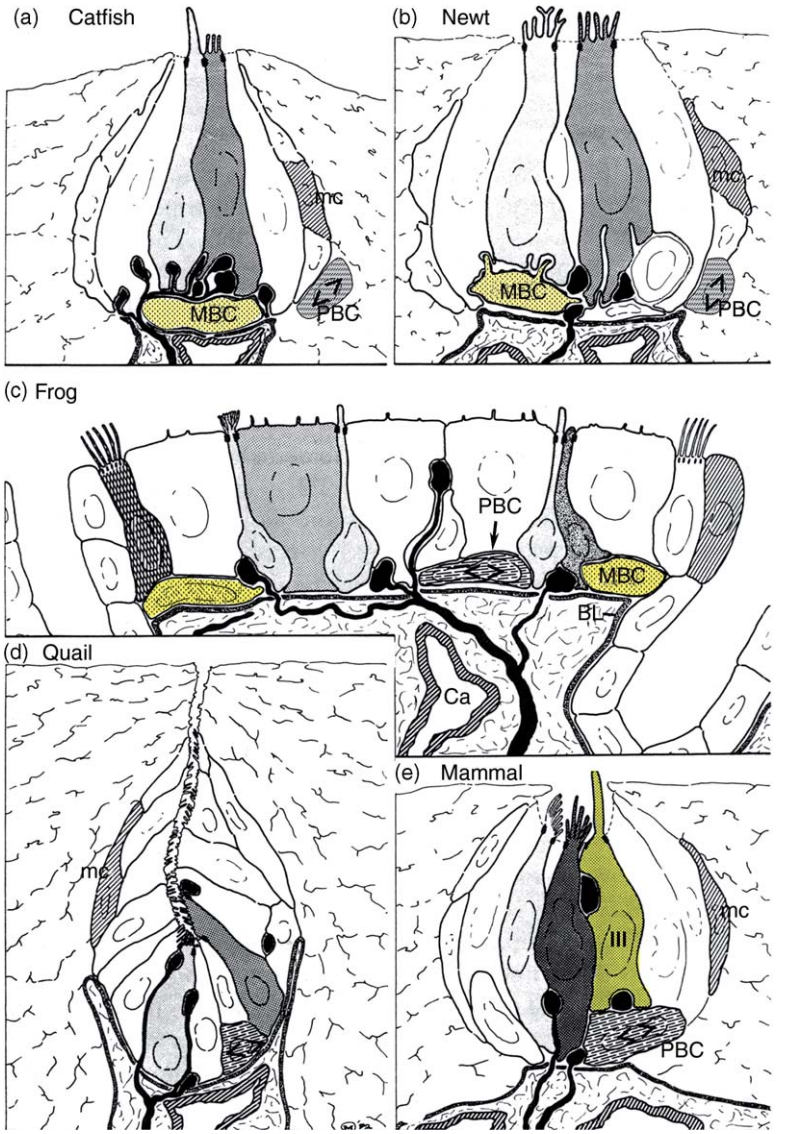

Figure 7 Schematic drawings of taste buds from various vertebrates. The area over which receptor cells gain access to taste substances (receptor area) is relatively broad in aquatic species, but narrows to a 'taste pore' in mammals and birds. Taste buds in all species contain different types of elongate cells indicated by the varied shading. Also, in all species, taste buds are bounded by specialized epithelial cells termed 'edge' cells or 'marginal' cells (mc). In all species, taste buds contain a serotonergic cell type – Merkel-like basal cells (MBCs) in nonmammalian forms, and type III taste cells (III) in mammals. All taste buds are also associated with a population of proliferative basal cells (PBCs) which undergo continuing cell division to replace the taste bud cells throughout the life span of the animal. BL, basal lamina; Ca, capillary. Copyright © 1993; From 'Morphology of vertebrate taste organs and their nerve supply'. In: Mechanisms of Taste Transduction by Reutter, K. and Witt, M.; *eds.* S. A. Simon and S. D. Roper. Reproduced by permission of Routledge/Taylor & Francis Group, LLC.

(columnar) spindle-shaped cells, but also a small number (e.g., five) of nonproliferative, 'Merkel-like' basal cells, lying in the lower half of the taste bud and which do not extend to the apical surface of the epithelium. Like cutaneous Merkel cells, the Merkel-like basal cells of taste buds concentrate biogenic amines including serotonin and are immunoreactive for NSE (Reutter and Witt, 1993). Also, like cutaneous Merkel cells, the Merkel-like cells of taste buds extend numerous spine-like processes from their cell body to form synapses on nerve fibers as well as on the elongate taste cells in the taste bud. It is likely that these Merkel-like basal cells, like cutaneous Merkel cells, serve as mechanoreceptors or perhaps in the taste bud, as integrative elements (Ewald and Roper, 1994). It is unfortunate that these Merkel-like basal cells are sometimes referred to simply as 'basal cells' in that this causes confusion with the proliferative basal cells associated with taste buds of both aquatic and terrestrial species.

The nonmammalian type of taste bud also possesses several types of elongate modified epithelial cells that extend an apical process into the region of the taste pore. In aquatic forms, including fishes and aquatic amphibians, the apex of the taste bud is a substantial opening – 10–20 μm or larger – in the surrounding epithelium through which extend the apices of the elongate taste cells (Figure 8). This opening in the epithelium is much larger than the equivalent 'taste pore' present in mammals or birds. Whether this difference in the size of the taste pore is characteristic of the clade of vertebrates (e.g., poikilothermic vs. homothermic) or of the habitat (aquatic–terrestrial) is unclear.

Elongate cells in fish and amphibia usually are characterized as being 'light' or 'dark'. These two descriptors are undoubtedly inadequate to fully characterize all of the different types of elongate cells present in these taste buds. The light cells are spindle-shaped cells with a single, large apical microvillous extending into the taste pore. Light cells extend short branches from their base to synapse with the Merkel-like basal cells and with nerve fibers. Dark taste cells are irregular in cross-sectional form and may envelop or extend interdigitating processes between the light cells (Reutter and Witt, 1993). At its apex, a dark cell extends numerous (10–25) small microvilli into the taste pore. Although dark cells apparently form synaptic contacts with the Merkel-like basal cells, they rarely do so with nerve fibers. In *Necturus*, light cells constitute only ~25% of the elongate cells within the taste bud, the remainder being dark cells. Taste buds in fish and *Necturus* also contain a less common, third cell type with a brush-like or bushy microvillous apex.

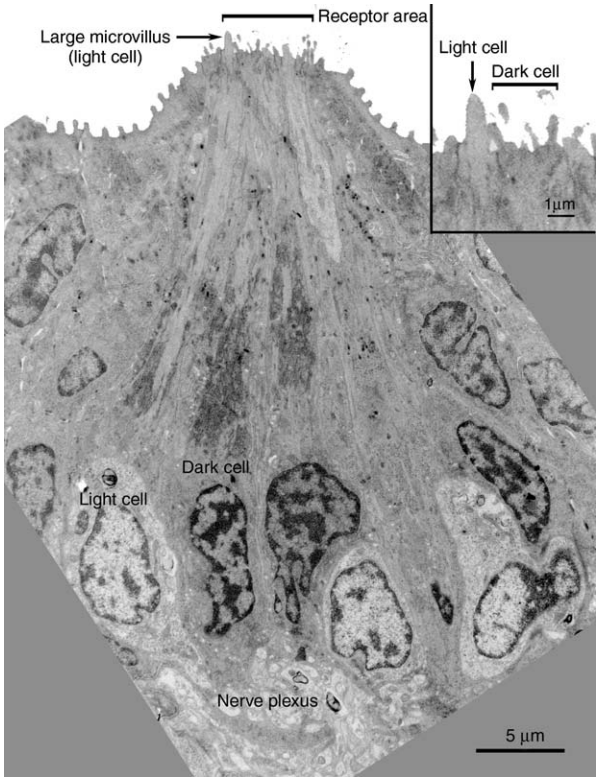

Figure 8 Electron micrograph of a taste bud from a zebra fish. Even at this low magnification, the different sizes of microvilli within the receptor area (taste pore) are evident. The large microvillus belongs to a 'light cell' while the smaller microvilli originate from a 'dark cell'. Inset (upper right) shows an enlargement of the receptor area. Courtesy of Dr. Anne Hansen, University of Colorado.

2.20.4.1.2 Proliferative cells In nonmammalian vertebrates, the taste bud is closely associated with a small number (e.g., 5) of proliferative basal or marginal cells that apparently generate daughter cells which enter into the taste bud and differentiate into the various mature cell types. These proliferative cells do not sit directly below the taste bud, where the Merkel-like basal cells reside, but rather around the basal circumference of the bud (Raderman-Little, 1979).

2.20.4.2 The Specialized Taste Organ of Frogs

The taste organs of frogs, called 'taste disks' are highly derived compared to other anamniote vertebrates (Osculati and Sbarbati, 1995) although many commonalities can be observed. In frogs, the apical opening is an expansive disk over 100 μm in diameter (see Figure 8). The taste disk is surrounded by specialized, ciliated cells. Inside this ring is a floor largely consisting of short, broad mucous cells each surrounded by the apical processes of 'wing' cells, thought to be supporting cells (Figure 9). The elongate taste (sensory) cells have their nucleus situated deeper in the taste disk than the wing and mucous cells, but extend a thin apical process to the surface of the taste organ. These cells are divided into two forms: type II cells and type III cells. Although type II cells have substantial contacts with basally situated axons, no obvious synaptic junctions occur. This situation appears similar to the type II taste cells of mammals (see below). The type III cells of the frog taste disk do exhibit clear synaptic contacts with nerve and are similar in that respect to type III cells of mammals. Glial-like sustentacular cells embrace and separate the different cells and nerve fibers in the lower half of the taste disk. This relationship is similar to the type I cells in mammalian taste buds. In addition, frogs have serotonergic Merkel-like basal cells characteristic of

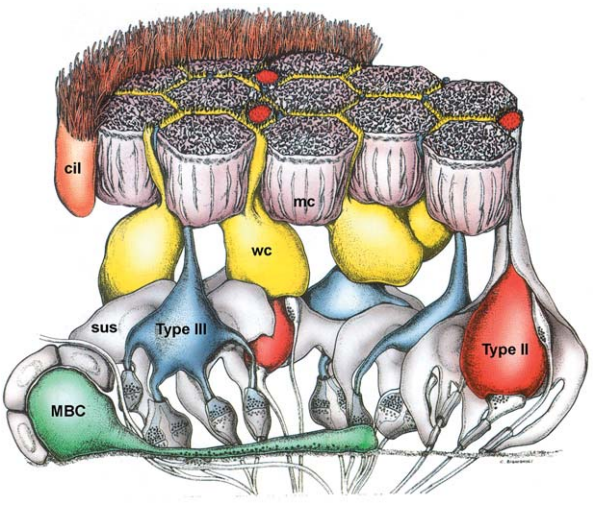

Figure 9 Drawing of the principal cell types of a frog taste disk. Ciliated cells (cil) surround the receptor surface of the taste organ. The superficial third of the organ is occupied by mucus (mc) and wing cells (wc), which are probably involved in maintenance of the mucus layer covering the taste disk. In the middle layer of the disk lie the cell bodies of the elongate receptor (type II and type III) cells which extend an apical process penetrating the surface layer. Both type II and type III cells contact afferent nerve fibers, although distinct synaptic complexes occur only between the type III cells and the nerve fibers. Sustentacular (sus = type Ic) cells wrap the other cell types and nerve fibers. Finally, MBCs lie in the deepest portion of the taste disk. Reproduced from Osculati, F. and Sbarbati, A. 1995. The frog taste disc: A prototype of the vertebrate gustatory organ. *Prog. Neurobiol.* (*Oxford*) 46(4), 351–399, with permission from Elsevier.

nonmammalian taste buds. The presence of both these Merkel-like basal cells and the type III sensory cells suggests that the transition from a nonmammalian type of taste bud to a mammalian type of taste bud is not simply the migration and transformation of the Merkel-like basal cells to an elongate morphology.

2.20.4.3 Mammalian Taste Buds

Taste buds in amniotes differ from anamniote taste buds in two respects. First, the taste pore is considerably narrower (~10 μm or less). Whether this is attributable to a drier, terrestrial lifestyle, or to phylogenetic factors is unclear. Second, mammalian taste buds lack the Merkel-like basal cell characteristic of nonmammalian taste buds. The taste buds of mammals do, however, possess a type of elongate cell which, like the Merkel-like basal cells, concentrates serotonin and forms distinctive synapses with the afferent nerve fibers. This has led many authors to speculate that the serotonin-containing elongate cells of amniote taste buds are homologous, if not functionally equivalent, to the Merkel-like basal cells (e.g., Ewald and Roper, 1994; see Evolution of Gustation).

2.20.4.3.1 Taste cells Taste buds in mammals comprise three distinct morphological types of elongate cells (type I, II, and III taste cells). These are defined according to ultrastructural criteria following the original descriptions of taste cells in rabbit foliate papillae by Murray (1986). Although the different types of taste cells are fairly distinct in rabbit foliate papillae, the morphological distinctions are less clear in other species. This has led to a great deal of confusion in the literature as to the equivalencies and distinctions between taste cell types in various mammals, especially rats and mice. In reviewing past literature on this subject, it is important to keep in mind that one author's 'type II' cell may not be the same as another author's cell of the same name. To further complicate matters, some authors have retained the older light microscopic terms: dark cell and light cell (originally based on staining properties of aniline dyes). The light–dark cell descriptors are only loosely equivalent to the morphological types as defined by electron microscopy. That is, type I cells nearly always have an electron dense cytoplasm and thus are called dark cells. Unfortunately, type III cells are more variable in staining characteristics and have been grouped by various authors into the category of 'light cell', 'dark cell', or 'intermediate cell', thereby seriously confusing the literature. With the advent of immunocytochemistry, it is possible to recognize the three distinct cytological and functional classes as originally defined by Murray.

2.20.4.3.1.(i) Type I taste cell The type I taste cells constitute over 50% of the total cells within a mature taste bud. As described by Murray and others, this cell often wraps around other taste cell types and nerve fibers. The cytoplasm is electron dense and stains heavily with acidophilic dyes, giving the cell a dark appearance in both light and electron microscopy. The nucleus is elongate with an irregular, indented nuclear membrane and substantial amounts of heterochromatin along the inner leaflet. These cells usually contain large apical granules ~100 nm in diameter and extend long, slender microvilli into the taste pore.

In many ways, the type I cells are similar to glia of the CNS. They express GLAST, a glial glutamate transporter (Lawton *et al.*, 2000) and NTPDase2, an astrocytic ecto-ATPase (Bartel *et al.*, 2006; Wink *et al.*, 2006). The processes of type I cells insinuate themselves between the other cell types and often cover a point of contact between other taste cells

and nerve fibers, just as astrocyte processes embrace synapses in the CNS. Since ATP is a crucial neurotransmitter between taste cells and the afferent nerve fibers (Finger *et al.*, 2005), these type I cell processes may serve to restrict cross-talk between cells within the taste bud by diffusion of ATP away from points of functional contact between taste cells and nerve fibers.

2.20.4.3.1.(ii) Type II taste cell Type II cells represent ~25–30% of the cells in each taste bud and are responsible for transduction of many tastants. These cells are elongate, spindle-shaped cells with short and thick apical microvilli. The cell is typified by a large, round, clear nucleus, and pale cytoplasm (Figure 10a). Type II cells express the bevy of receptor and second-messenger proteins implicated in transduction of bitter, sweet, or umami stimuli. These include the known T1R and T2R families of taste receptors, gustducin (G-protein), PLCβ2, and IP3R3 (Yang *et al.*, 2000b; Miyoshi *et al.*, 2001; Kusakabe *et al.*, 2002; Clapp *et al.*, 2004). Thus, type II cells mediate detection of these classes of tastants. Curiously, although type II cells closely contact afferent nerve fibers within taste buds (e.g., Kinnamon *et al.*, 1985; Yang *et al.*, 2000a), synapses between these elements are rare. Rather, subsurface cisternae appear at points of contact between afferent fibers and type II cells (Clapp *et al.*, 2004).

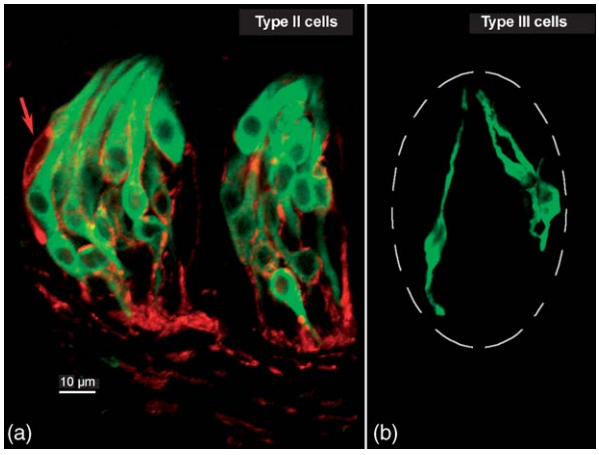

Figure 10 Fluorescence micrographs of immunocytochemically reacted taste buds of the circumvallate papilla from rodents. a, Reactivity for the inositol-trisphosphate receptor 3 (IP3R3) in a rat circumvallate papilla shows the morphology of typical type II taste receptor cells: broad, triangular cell body with a prominent, large, round nucleus. This section is also reacted for synaptobrevin revealing the numerous afferent nerve fibers and a rare taste cell (arrow), most likely a type III taste cell near the edge of the taste bud. b, A taste bud in the circumvallate papilla of a mouse, reacted for serotonin to reveal a population of type III taste cells. Note that they are more slender and less regular in shape than the type II cells illustrated in the left-hand panel. The approximate boundary of the taste bud is indicated by the dashed line. a, Photo courtesy of Drs. J. C. Kinnamon and R. Yang, Denver University, Denver, CO, USA.

Each type II taste cell is specified for detection of one class of taste substance and, therefore, expresses only one class of taste receptor, although multiple members of a class may be expressed in a single taste cell (Chandrashekar *et al.*, 2000; Zhang *et al.*, 2003). For example, a taste cell that expresses one member of the T2R family of receptors (for detecting bitter substances) will express several members of this same family (Adler *et al.*, 2000). Since each receptor molecule is responsive to only a small set of bitter substances, by expressing multiple members of the T2R family, a taste cell then exhibits broader responsiveness to many different bitter compounds. Whether type II cells also are the transduction elements for detection of sour and salty stimuli is unclear. At least some evidence implicates type III cells in these processes.

2.20.4.3.1.(iii) Type III taste cell The type III cell is relatively scarce in taste buds, comprising only 10–15% of the total population. Type III cells are sometimes called 'intermediate cells' since they share features with both type I and type II cells. What distinguishes type III cells from the others is the presence of well-formed synapses from the taste cells onto the afferent nerve fibers. Type III cells also exhibit some distinctive histochemical features which can be used to distinguish them from the other cell types. A subset of type III cells concentrates biogenic amines, including serotonin (Figure 10a). This property has led to their being likened to the Merkel-like basal cells of anamniote vertebrates (see the discussion above).

Type III taste cells are narrow, spindle-shaped cells that extend a single, thick apical process into the taste pore. Their nuclei are more elongate than those of type II cells and exhibit some degree of indentation. The cytoplasm is variable in staining density, ranging from light to dark. These features then are intermediate between the type I and II cells and have led some authors to consider type III cells to be a stage in the maturation of type II cells or to combine these cells into a single class (e.g., Delay *et al.*, 1986; Pumplin *et al.*, 1997). Recent studies suggest that type II and type III cells may arise from a common lineage (Finger, 2005; Kusakabe *et al.*, 2002; Miura *et al.*, 2005).

The function of type III cells is not established, but two possibilities are clear. First, the type III cells, being the only taste cells with prominent synapses, may serve as the only output cells of the taste bud,

receiving input from the transducing, type II taste cells and integrating this information before transmitting a signal to the afferent nerve fibers (Roper, 1992). The other possibility is that both type II and type III cells transmit information to nerve fibers, but that type II cells do so using a mechanism that does not require a conventional-looking synapse. Since type III cells exhibit voltage-gated ion channels (Medler *et al.*, 2003) and such cells respond to acidification (Richter *et al.*, 2003), then it is likely that type III cells are capable of directly transducing sour information and also passing this along the nerve fibers.

2.20.4.3.1.(iv) Other cells In addition to the three elongate types of taste cells described above, the taste buds of mammals, like those of nonmammalian vertebrates, are associated with proliferative basal cells and edge or marginal cells. Indirect evidence indicates that the taste bud progenitor cells of the basal epithelium are different than the basal cells of the general epithelium. When gustatory nerves are directed to grow into lingual epithelium that does not normally produce taste buds, the taste buds do not form despite the abundance of gustatory nerve fibers (Krimm *et al.*, 2001). The fact that taste nerves are unable to induce taste buds in anything but taste epithelium suggests that the epithelial cells in taste-bud bearing regions have a special capacity to generate these end organs. Conversely, when taste epithelia are innervated only by nongustatory nerves, then production of taste buds is limited at best (Farbman, 1971). Together, these studies indicate that basal cells of taste epithelia have a unique capacity to produce taste buds under the influence of gustatory innervation.

2.20.5 Detection and Representation of Different Tastes

The taste systems in vertebrates have the ability to respond to a variety of stimuli according to the habitat and nutritional needs of the organism. These taste stimuli are varied in chemical properties, including size, charge, hydrophobicity, and pH. Despite the diverse array of vertebrates and habitats, the taste system has a remarkable consistency in the types of compounds it can respond to. This may be due to the fact that many substances, for example, plant alkaloids, are toxic to most vertebrates and therefore all vertebrates require a food monitoring system capable of detecting potential toxins in the food supply. Conversely, different vertebrates have different nutritional needs and drives, so somewhat more divergence exists in terms of what substances can drive appetitive behaviors. Looking across all organisms, the taste system serves two primary functions: avoiding toxins and driving ingestion for nutritive substances. This means that the responses of the taste system should vary according to the diet of the particular organism. For example, the taste system of carnivores should not be driven by sugars, whereas the taste system of herbivores should be highly responsive to sugar. In contrast, most species should respond to amino acids.

Different cells in taste buds respond optimally to different taste qualities. It is interesting to note that this principle of cellular coding also occurs in taste organs of invertebrates. Since taste buds and 'taste' organs of invertebrates are not homologous, this property of encoding taste information should be viewed as convergent rather than evolutionarily conserved. Indeed, the chemosensory cells of the invertebrates seem more organized according to the behaviors they induce rather than the nature of the chemical stimulus detected. For example, a single chemosensory cell (ASE) in the amphid of *C. elegans* may respond to cAMP, biotin, and lysine despite their diverse chemical structures. But all of these substances are attractants. So, stimulation of the ASE cell will produce attraction. The taste systems in more complex organisms, for example, flies, fish, or mammals, have more complexity. Several substances may drive ingestion, but may be detected by different receptor cells. For example, both alanine and arginine drive appetitive behavior in catfish, but these amino acids appear to be detected by different receptors expressed in different taste cells (Finger *et al.*, 1996). Similarly, different taste cells in mice express receptors for glutamate and sweeteners although both drive food intake (Zhang *et al.*, 2003).

2.20.6 Evolution of Taste Preference and Taste Receptors

In order for a species to adapt to a new habitat or feeding strategy, the spectrum of substances to which its taste organs respond must change. For example, for terrestrial animals, especially those with a purely vegetarian diet, sodium is a crucial nutrient. Salt-deprived amniotes have a drive to seek out and ingest salt (Schulkin, 1991). Their taste system carries unique information about the sodium content of potential foodstuffs and detection of the sodium is regulated in part by

circulating hormones that alter the sensitivity of the sodium-detecting channels of the taste buds (Herness, 1992; Lin *et al.*, 1999). Yet, sodium is not a crucial nutrient for aquatic anamniotes, so their taste systems are not particularly responsive to sodium content of food (Caprio *et al.*, 1993). Thus, the responsiveness of taste buds had to change when vertebrates made the transition from water to land. In frogs, the entire epithelium is sensitive to sodium levels, perhaps via the same ion channel (AsNaC) used in sodium detection in many mammals (Nagai *et al.*, 1999). Thus transduction of sodium by taste may have evolved from a general epithelial property of regulated sodium transport.

The receptors for tastes can be ion channels themselves (as in the case of sodium (salty) or protons (sour), may be ligand-gated ion channels (e.g., for arginine-detection in catfish; Brand *et al.*, 1991), or can be G-protein-coupled receptors (Brand *et al.*, 1991; Adler *et al.*, 2000; Chandrashekar *et al.*, 2000; Zhang *et al.*, 2003; Ishimaru *et al.*, 2005). The G-protein-coupled receptors, T1R and T2R families, are phylogenetically old since family members have been identified in fish as well as in mammals. Yet in mammals, some of these receptors respond to sweeteners whereas in fish, sweeteners are not effective taste stimuli. Accordingly, evolutionary change of the receptor molecules is likely to correspond to evolutionary changes in the spectrum of substances to which the taste system can respond. This can be seen in the evolution of felines which are insensitive to sugars and other sweeteners unlike other carnivores. The taste system of basal carnivores most likely responds well to sweet substances since many contemporary carnivores, for example, dogs and bears, are strongly attracted to sweets, whereas cats are not (Li *et al.*, 2005). One of the genes encoding the sweet taste receptor is nonfunctional in cats, thereby rendering them insensitive to sugar and other sweeteners. Thus, a simple mutation in a single taste receptor gene is capable of altering the diet of a species.

Acknowledgments

This article is dedicated to the memory of Theodore H. Bullock, whose boundless enthusiasm and insights served as an inspiration to us all. The author thanks Drs. Anne Hansen and Linda Barlow for their comments and improvements on various drafts of this work. This work was supported by NIH Grants to T. Finger and D. Restrepo.

2.21 Shared Features of the Auditory System of Birds and Mammals

C E Carr and D Soares, University of Maryland, College Park, MD, USA

Glossary

interaural time difference — Birds and mammals use the interaural time difference (ITD) for localization in the horizontal plane. When sound comes from one side of the body, it reaches one ear before the other, which creates an ITD. These ITDs depend upon head size, and in some cases on an interaural canal. In general, animals with large heads have larger time differences available to them.

phase-locking — The auditory system uses phase-locked spikes to encode the timing or phase of the auditory signal. Phase-locked neurons fire spikes at or near particular phase angles of sinusoidal waveform. Physiological experiments measure this spike phase with respect to the stimulus period. Spike phase is plotted in a period histogram, and is used to calculate the statistic vector strength (r). Each spike defines a vector of unit length with a measured phase angle. The vectors characterizing the spikes are plotted on a unit circle and the mean vector calculated. The length of the mean vector provides a measure of the degree of synchronization.

2.21.1 Introduction

Grothe *et al.* (2005) have pointed out that we cannot construct a comprehensive description of the evolution of the vertebrate central auditory system because we do not know what the common ancestors of terrestrial vertebrates could hear or how their ears worked. It seems likely, however, that tympanic ears have evolved independently in synapsids, lepidosauromorph diapsids, archosaurs, turtles, and amphibians (Clack, 1997). These new ears could convey responses to both vibration and airborne sound to brainstem auditory neurons, leading to the parallel evolution of the central targets of the auditory nerve. Further developments in ancestral mammals, such as moveable ears and multiple ossicles, may have had additional reorganizing effects (see Epigenetic Responses to a Changing Periphery – Wagging the Dog). In this review we will argue that the elaborated central auditory systems in the different clades of recent land vertebrates have evolved in parallel.

With the transition to airborne sound, selection might be expected to improve the auditory system's ability to encode the more rapid changes associated with higher frequency sounds. For example, precise encoding of temporal information at best frequencies above 1–2 kHz is biophysically demanding (see Koppl, 1997), but also has direct behavioral

relevance for sound localization and communication (Hafter and Trahiotis, 1997; Heffner and Heffner, 1992) and should be selected for.

We will discuss the appearance of similar physiological and morphological adaptations for encoding both time and level information in the auditory brainstem of birds and mammals, and draw two major conclusions. First, the similarities among the brainstem circuits that encode sound in birds and mammals appear to be the result of parallel evolution. Second, the existence of these similar circuits allows us to identify algorithms shared by the auditory system of birds and mammals, and to argue that these are suited to extracting the stimulus variables relevant for auditory coding; thus, studies of evolution can inform computational neurobiology. For further discussion of this topic, the reader is directed to recent reviews including Grothe *et al*. (2005) and Carr and Soares (2002).

Animals with tympanic ears should experience similar constraints in detecting sounds. The essential features of auditory coding are very similar in birds and mammals. Understanding the evolutionary and developmental events behind the similar form and function of temporal coding cells in birds and mammals will require a detailed knowledge of multiple species under study, and of their phylogenetic relationships. This requires a deliberate concentration upon comparative neurobiology, and the differences among animals (see Relevance of Understanding Brain Evolution). In this review we compare similar coding strategies in the auditory systems of a few species of birds and mammals in order to identify shared features (Section 2.21.2). We then examine the special case of temporal coding in birds and mammals, and use these comparative studies to argue that natural selection has produced suitable solutions to the problems of temporal coding (Sections 2.21.3 and 2.21.4).

2.21.2 Encoding Sound: Similar Strategies in Birds and Mammals

Both birds and mammals use similar strategies to encode various aspects of the auditory scene. In fact, all animals may use similar auditory codes (Fay, 1988; Manley, 2005). Vertebrate auditory systems exhibit a similar basic Bauplan, in which the auditory nerve enters the hindbrain and bifurcates to contact different subdivisions of the cochlear nucleus (Ryugo and Parks, 2003). The cochlear nuclei give rise to different connections within the lower auditory system, including projections to groups of neurons in the superior olive and the lateral lemniscus before these pathways reunite at the level of the auditory midbrain. Despite these large-scale similarities, the details of the connections and cell types show substantial diversity between the major vertebrate clades (reviews in Cant, 1992; Carr and Code, 2000; McCormick, 1999).

In both birds and mammals, the cochlear nuclei encode parallel ascending streams of auditory information. In birds, the auditory nerve projects to nucleus magnocellularis and nucleus angularis in the pattern described for the bird and reptile morphotype. The nucleus magnocellularis is the origin of a neural pathway that encodes timing information, while a parallel pathway for encoding sound level originates with nucleus angularis (Takahashi and Konishi, 1988a). In mammals, auditory nerve afferents send an ascending branch to the anterior ventral cochlear nucleus and a descending branch to both the posterior ventral cochlear nucleus and the new dorsal cochlear nucleus. This division may also support parallel encoding of sound level and time, although evidence for this simple division is not strong. Instead, it appears that the cells in the mammalian cochlear nucleus form many parallel ascending streams (Cant and Benson, 2003; see the discussion below). In both birds and mammals, the auditory nerve forms different types of terminals onto different cell types in the cochlear nucleus (Ryugo and Parks, 2003). Endbulbs of Held terminals are formed on bushy cells (see Section 2.21.3), and bouton-like terminals on the other cell types in the cochlear nuclei. The auditory nerve appears to use glutamate as a transmitter, often with the postsynaptic cell expressing 'fast' AMPA type glutamate receptors that can mediate precise temporal coding (Parks, 2000).

The avian and mammalian cochlear nuclei both contain heterogeneous cell populations, and exhibit similar responses to sound (Koppl and Carr, 2003; Soares *et al*., 2002; for review of the mammalian cochlear nuclei, see Romand and Avan, 1997; Cant and Benson, 2003). We do not know if these similar features evolved as a response to selective pressures to encode airborne sound. There are two reasons why similarities might be due to parallel evolution. First, true tympanic ears arose independently in birds and mammals (Clack, 1997). These peripheral changes would have had different reorganizing effects upon the ancestral population of brainstem auditory neurons. Second, the cell types of the avian and mammalian cochlear nuclei are similar but not identical. We describe the similarities and differences between birds and mammals in this section. A satisfactory study will, however, require detailed analyses of the development, morphology and

physiology of cell types in the cochlear nucleus in all amniote groups, including turtles, basal lizards, and crocodilians.

2.21.2.1 Organization of the Cochlear Nuclei in Mammals and Birds

It has been historically difficult to compare the mammalian and avian cochlear nuclei. To do so in this article, we will first describe the cochlear nuclei in mammals and birds, then discuss their similarities and differences. The mammalian cochlear nuclear complex is divided into dorsal and ventral nuclei that contain separate, well-defined populations of cells. The large projection cells are distinguished on the basis of morphology, projections, and physiological responses to sound (Cant and Benson, 2003; Rhode and Greenberg, 1992; Rouiller, 1997; Young, 1998). The anterior part of the ventral cochlear nucleus contains bushy cells that respond in a primary or auditory nerve-like fashion to the auditory stimulus. The posterior part of the ventral cochlear nucleus contains octopus cells that respond to onsets or stimulus transients and two classes of multipolar neurons that respond principally with 'chopper' firing patterns.

Bushy cells receive endbulb inputs from the auditory nerve and exhibit accurate temporal coding. There are two forms of bushy cells, spherical and globular. Spherical cells dominate the anterior ventral cochlear nucleus, respond to lower best frequencies and project to the medial superior olive, which is sensitive to interaural time differences (ITDs). Globular bushy cells by comparison sometimes chop or exhibit onset responses to the stimulus, respond to higher frequencies, and project to the lateral superior olive and the medial nucleus of the trapezoid body. These projections may mediate detection of interaural level differences. Octopus cells in the posterior ventral cochlear nucleus are multipolar, with thick dendrites that extend across the nerve root (Oertel *et al*., 2000). This morphology enables them to integrate auditory nerve inputs across a range of frequencies. Octopus cells encode the time structure of stimuli with great precision and exhibit onset responses to tonal stimuli. Onsets play an important role in theories of speech perception, and segregation and grouping of sound sources (Bregman, 1990). Cochlear root neurons send widespread projections to areas of the reticular formation involved in startle reflexes and autonomic functions. Type I multipolar cells may encode complex features of natural stimuli and send excitatory projections directly to the inferior colliculus. Type II multipolar cells send inhibitory projections to the contralateral cochlear nuclei (Cant and Benson, 2003).

The dorsal cochlear nucleus (DCN) appears for the first time in mammals, perhaps associated with the development of high-frequency hearing and motile external ears. DCN cells exhibit wide variety of response types, with one theory of function relating to echo suppression. The DCN is composed of a cerebellar-like circuit in the superficial layers, with projection cells in the deep layers that receive auditory nerve inputs (Young, 1998). The granule cells in the superficial layers receive sensory input that may convey information about head and ear position. The deep portion of the DCN contains fusiform and giant cells. Fusiform cells exhibit complex (Type IV) frequency-tuning curves, with small areas of excitation at best frequency and at the edges of the response curves. Type IV responses appear well suited to detecting the notches in sound level created by the pinna that provide cues for locating sound in elevation (May, 2000). Fusiform cell responses may mediate localization of sounds based on spectral cues and send direct excitatory projections to the inferior colliculus. Giant cells in the DCN also project directly to the inferior colliculus; some of them may convey inhibitory inputs to the contralateral cochlear nucleus as well (Cant and Benson, 2003).

In birds the auditory nerve projects to two cochlear nuclei, the nucleus magnocellularis and the nucleus angularis (Carr and Code, 2000). The nucleus magnocellularis principal cells dominate all but the low best-frequency region of the nucleus, and project to the nucleus laminaris, which is sensitive to ITDs. The nucleus angularis contains 4–5 cell types that project to the superior olive, to the lemniscal nuclei, and to the central nucleus of the auditory midbrain. The parallel ascending projections of angularis and laminaris may or may not overlap with one another, and probably do overlap in the primitive condition.

The mammalian bushy cells are very similar to the avian magnocellular neurons (see Sections 2.21.3 and 2.21.4) and originally nucleus angularis was thought to be similar to the mammalian DCN (Boord, 1969; Sachs and Sinnott, 1978; Sachs and Young, 1980). Closer examination has, however, shown that there are no deep morphological correspondences between nucleus angularis (NA) and the DCN (Soares and Carr, 2001) although there are physiological similarities. Both nuclei contain a cell type that exhibits type IV (complex nonmonotonic) physiological responses (Koppl and Carr, 2003; Sachs and Sinnott, 1978; for review of DCN see Young *et al*., 1988). Parsimony would suggest that

the type IV responses observed in the redwing blackbird by Sachs and Sinnot and in the barn owl by Koppl and Carr may have emerged in parallel with similar responses in mammalian DCN. The DCN appears to be a unique feature of the mammalian auditory system. Furthermore, unlike the case with the NA, the DCN shares many common features with the cerebellum, including unique cell types and cortical circuitry (Berrebi *et al*., 1990; Oertel and Young, 2004; Wright and Ryugo, 1996).

2.21.2.2 Morphology of Cell Types in Birds and Mammals

The morphological characteristics of neurons contribute to the input–output functions of neural circuits. We suggest that similar rules of dendritic organization apply to the cochlear nuclei of both mammals and birds. Furthermore, examination of similar cell types in birds and mammals may reveal shared computational strategies.

Neurons of the rat ventral cochlear nucleus that project to the DCN have been divided into two main groups: radiate and planar (Doucet and Ryugo, 1997). Radiate neurons have long dendrites perpendicular to isofrequency contours and are sensitive to a broad range of frequencies. Planar neurons, on the other hand, have dendrites that are confined to an isofrequency plane, therefore more sensitive to a narrow range of frequencies.

At a first approximation, the avian NA has an organization similar to that seen in the rat ventral cochlear nucleus. In both the barn owl (Soares and Carr, 2001) and the chicken (Fukui and Ohmori, 2003; Soares *et al*., 2002), NA contains several major morphological classes of neurons. In the barn owl, these are classified as planar, radiate, vertical, and stubby. Planar neurons are confined to an isofrequency band, whereas radiate neurons have dendrites that could extend across an isofrequency band. Vertical cells have long dendrites oriented perpendicularly to isofrequency bands. Stubby cells are confined to an isofrequency band because of their short dendrites. Representatives of all cell classes can be found throughout NA of the chicken (Fukui and Ohmori, 2003; Soares *et al*., 2002). Thus, a similar pattern of organization appears to have evolved in parallel in the cochlear nuclei of both birds and mammals, in which one population (planar, stubby, and bushy) remains within an isofrequency band, another (radiate) extends across the isofrequency axis, and a third (vertical, marginal, and octopus) has a dendritic orientation orthogonal to the isofrequency axis.

Although there are shared morphological characteristics among individual neurons of both clades, other organizational rules differ. First, there are many cell types within the mammalian ventral cochlear nucleus that are not included in Doucet and Ryugo's classification scheme, principally bushy cells, octopus cells, and small cell types (for reviews, see Cant and Benson, 2003). Bushy cells appear to be similar to nucleus magnocellularis (NM) neurons, but there are no obvious morphological counterparts to octopus cells in the avian cochlear nuclei. This is significant because both octopus cells and cells in NA respond to sound with onset responses (Sullivan, 1985; Warchol and Dallos, 1990). Nevertheless, Golgi analyses of barn owl NA neurons and intracellular labeling of cells in chicken NA have not revealed cells with the characteristic octopus cell morphology – thick dendrites that extend across the incoming auditory nerve inputs (Soares and Carr, 2001; Soares *et al*., 2002). Thus, it appears that the evolution may not necessarily have produced identical solutions for encoding onset of sounds. Second, the majority of NA cells are stubby neurons that have no obvious counterpart within the multipolar cell types of the mammalian ventral cochlear nucleus. Instead, they most closely resemble NM neurons and bushy cells. Third, small cells rarely appear in NA (Soares and Carr, 2001), and it seems that they are not as various or numerous in NA as in the mammalian cochlear nucleus. Finally, the avian cochlear nuclei have neither the granule cell layer that characterizes mammalian cochlear nucleus, nor a DCN.

2.21.2.3 Intracellular Physiological Responses of Cochlear Nucleus Neurons in Birds and Mammals

Descriptions of neural circuitry are based on both dendritic morphology and physiological characteristics. Descriptions of both *in vivo* and *in vitro* responses complement the morphological studies, and responses of cochlear nucleus neurons in brain slices from both birds (chicken) and mammals (rat, mouse) can be compared.

There appear to be no direct one-to-one physiological correspondences between neurons in birds and mammals, with the exception of neurons that are specialized for temporal coding, such as mammalian bushy cells and avian magnocellular neurons. Even these very similar responses may have evolved in parallel: the suite of features that distinguish temporal coding neurons in auditory nuclei, including the nuclei of the lateral lemniscus (Wu, 1999a), is also found in temporal coding

neurons in electric fish (Carr, 1986; Rashid *et al.*, 2001). One cannot therefore use shared features to argue for homology among cochlear nucleus neurons in birds and mammals. Instead, shared features may be used to identify common computational strategies.

Avian NM neurons and NA stubby neurons respond with only one spike when depolarized. The responses of NA stubby neurons are similar to those of both bushy and octopus cells in the mammalian VCN (Golding *et al.*, 1999; Manis and Marx, 1991; Wu and Oertel, 1984). These mammalian cell types exhibit the depolarization-activated, dendrotoxin-sensitive, low-threshold K^+ conductance that is activated at rest (see Section 2.21.2; Manis and Marx, 1991; Bal and Oertel, 2000; Brew and Forsythe, 1995). A similar dendrotoxin-sensitive conductance underlies the responses of NA one spike neurons (Fukui and Ohmori, 2003), NM and nucleus laminaris (NL) neurons (Rathouz and Trussell, 1998; Reyes *et al.*, 1994, 1996) and the irregularly firing principal cells of the tangential nucleus (Gamkrelidze *et al.*, 1998, 2000). These biophysical similarities suggest that stubby neurons, like bushy, octopus, NM and NL neurons, may mediate accurate transmission of temporal information.

There are additional shared physiological characteristics between the cochlear nuclei of both groups. Despite the multiplicity of cochlear nucleus cell types, auditory nerve synapse kinetics are similar in all. In avian NA, spontaneous excitatory post synaptic current (EPSC) receptor kinetics are the same for all cell types (MacLeod and Carr, 2005). This is also the case for bushy, T-stellate, tuberculoventral and octopus cells in the mammalian VCN (Gardner *et al.*, 1999). Other NA cell types share biophysical features with mammalian VCN neurons (Soares and Carr, 2001).

2.21.2.4 Ascending Lemniscal Projections

Avian and mammalian cochlear nuclei both share ascending lemniscal projections, but these differ in many respects (Figure 1). The greatest difference may be the comparative lack of descending projections in birds when compared with mammals (Carr and Code, 2000).

In birds and crocodilians, the NA projects to the superior olive, the contralateral posterior portion of the dorsal nucleus of the lateral lemniscus (Figure 1a; Takahashi and Konishi, 1988a; Wild *et al.*, 2001) and the inferior colliculus (Conlee and Parks, 1986; Yang *et al.*, 1999). The posterior division of the dorsal nucleus of the lateral lemniscus is the first site of binaural interactions in the intensity pathway of the barn owl and is where sensitivity to interaural level differences first appears (Manley *et al.*, 1988; Moiseff and Konishi, 1983). The pathways encoding ITDs and interaural level differences ultimately converge in the external nucleus of the inferior colliculus, where neurons are selective for combination of interaural time and level differences (Figure 1a, for review, see Konishi, 2000). The projections of the mammalian cochlear nucleus are more elaborate than those in birds (Figure 1b; for reviews see Cant and Benson, 2003; Cant and Hyson, 1992; Romand and Avan, 1997).

2.21.3 Encoding Temporal Information

Auditory nerve fibers encode temporal information by phase-locking to the waveform of the acoustic stimulus, and preserve this temporal information in projections to NM and NA. Three lines of evidence show that accurate temporal coding is important for sound localization. First, measurements of the vector strength of the auditory nerve signal, calculated from the variability in the timing of spikes with respect to the phase of the acoustic stimulus, show an improvement in high frequency phase-locking in the owl as compared to other animals by an octave or more (Koppl, 1997). Second, models of coincidence detection perform better when the vector strength of the inputs improves (Colburn *et al.*, 1990; Simon *et al.*, 1999). Third, inactivation of NM neurons with lidocaine removes sensitivity to ITDs from the responses of midbrain space-mapped neurons (Takahashi *et al.*, 1984).

We will review the features associated with preserving temporal cues up to the point where ITDs are detected. There are several shared features of temporal coding circuits in the auditory systems of birds and mammals. These include high-quality inputs, presynaptic specializations to make neurotransmitter release precise, and postsynaptic specializations, including specific glutamate receptors, potassium conductances, and characteristic neuronal morphology. These features have been reviewed in Oertel (1999), Trussell (1999), and Carr and Friedman (1999).

2.21.3.1 Precise Synaptic Transmission

The task of accurately representing the stimulus phase becomes more difficult with increasing stimulus frequency (Hill *et al.*, 1989). This is because the absolute temporal precision required for phase-locking to high frequencies is greater than that needed for low frequencies, that is, the same

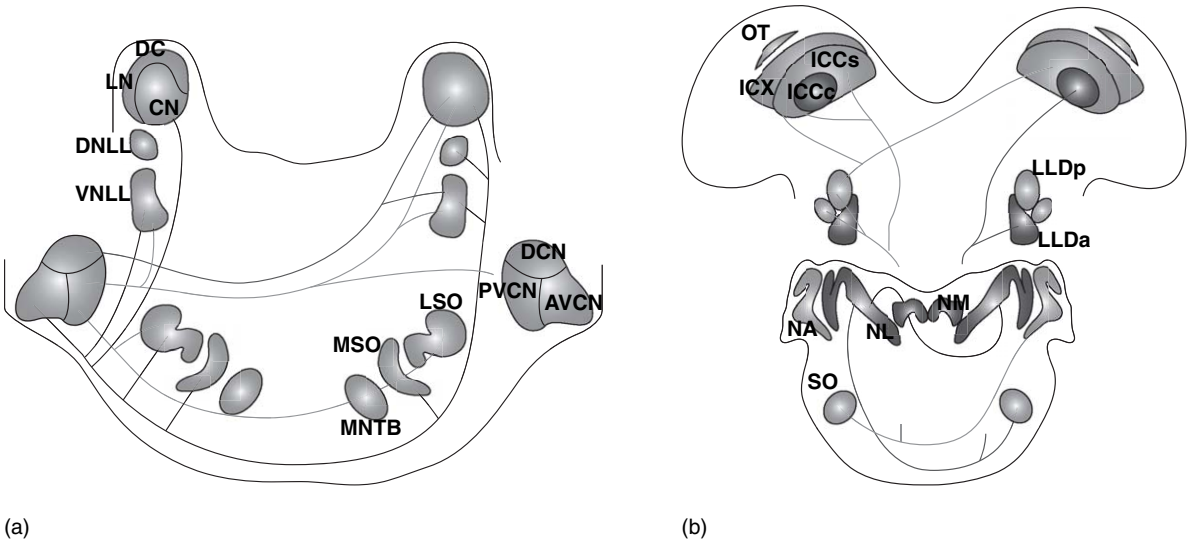

Figure 1 Schematic showing the connections in the mammalian and avian auditory brainstem. a, Mammals: the auditory nerve bifurcates to give rise to an ascending and a descending branch. The ascending branch innervates the AVCN, and the descending branch innervates first the PVCN and then the DCN. The projections of the cochlear nuclei are denoted as different lines (AVCN – dark lines, PVCN – light lines, and DCN – dotted lines). The cochlear nuclei send ascending projections to the olivary and periolivary nuclei, which include the MNTB, MSO, and LSO. The IC in mammals is subdivided into a central nucleus, an external cortex, and a dorsal cortex. Stellate cells from VCN and fusiform and giant cells from DCN project to the contralateral central nucleus of the IC giving rise to banded inputs. The central nucleus receives bilateral input from LSO and a mostly ispilateral input from MSO, also forming banded, tonotopically organized projections. It also receives projections from the nuclei of the lateral lemniscus (DNLL and VNLL). b, Birds: in barn owls, separation into time and sound level pathways (dark lines and light lines, respectively) begins with the cochlear nuclei. Eighth nerve afferents divide to innervate both the level-coding NA and the time-coding NM. NM projects bilaterally to NL, which in turn projects to superior olive, nucleus of the lateral lemniscus, and to the central nucleus of the inferior colliculus. The superior olive projects back to NA, NM, and NL (projections are not drawn). In birds, the IC is subdivided into two principal subnuclei, the external nucleus (ICX) and the more medially located central nucleus (ICC). a, Reproduced from Sound Source Localization, 2005. Development of sound localization, Kubke, M. F. and Carr, C. E. (*eds.* A. N. Popper and R. R. Fay), Springer. With kind permission of Springer Science and Business Media. b, Reproduced from Kubke, M. F., Gauger, B., Basu, L., Wagner, H., and Carr, C. E. 1999. Development of calretinin immunoreactivity in the brainstem auditory nuclei of the barn owl (*Tyto alba*). *J. Comp. Neurol.* 415, 189–203.

variation in temporal jitter of spikes translates to greater variation in phase for high frequencies. Hill *et al*. (1989) estimated phase-locking in the auditory fibers of the pigeon in terms of the commonly used synchronicity index (vector strength) as well as by measuring temporal dispersion. Vector strength of phase-locking decreases for frequencies above 1 kHz. Temporal dispersion, however, also decreases with frequency, indicating enhanced temporal synchrony as frequency increased (Koppl, 1997). The upper frequency limit of phase-locking therefore appears to depend upon the ability of hair cells to phase-lock and upon an irreducible jitter in the timing of spikes. It is about 8–9 kHz for barn owls, and between 4 and 6 kHz for most other birds and mammals studied (Koppl, 1997).

Endbulb or caliciform synapses mediate the transmission of phase-locked spikes. These synapses form a fenestrated cup that envelopes most or part of the cell body, and contains large numbers of active zones (Nicol and Walmsley, 2002). The invasion of the presynaptic spike into the calyx leads to the synchronous release of quanta at these sites, endowing the synapse with a high safety factor (Sabatini and Regehr, 1999). Studies of endbulbs in both the avian NM and the medial nucleus of the trapezoid body (MNTB) have shown that the invading presynaptic spike is extremely narrow (Turecek and Trussell, 2001), probably due to rapid repolarization mediated by specific potassium conductances. Calcium influx into the presynaptic terminal is also brief and occurs only during the falling phase of the presynaptic spike (Turecek and Trussell, 2001). Because the spike is narrow, its downstroke occurs quickly, as does calcium influx, reducing the synaptic delay. The brief period of calcium influx produces a confined and phasic period of neurotransmitter release, increasing the temporal precision of transmission across the synapse (Brenowitz and Trussell, 2001b).

Endbulb terminals may have emerged as an adaptation for accurate transmission of phase

information for frequencies above ~500 Hz, perhaps also associated with the development of hearing in land vertebrates. Large endbulb-like terminals have been found in all amniote groups examined. There are no data on turtles, but in the alligator lizard the auditory nerve forms both large somatic terminals and smaller boutons in NM (Szpir *et al*., 1990). In crocodilian NM, the rostral high best frequency NM neurons receive endbulb-like projections, while lower best frequency NM neurons receive bouton terminals (Soares, unpublished). Large endbulb terminals are found in both birds and mammals (Ryugo and Sento, 1991), and may be developed in parallel in archosaurs and mammals to mediate accurate transmission of temporal information at higher sound frequencies (Carr and Soares, 2002). Evidence for the parallel evolution of endbulbs in birds and mammals comes from studies of their development, which follows different trajectories (Rubel and Fritzsch, 2002), and from studies of transmitter release modulation (Trussell, 2002).

Support for the hypothesis that endbulbs evolved to facilitate transmission of high best frequency phase-locking comes from comparisons of low and high best frequency regions of NM. Endbulb terminals do not appear to be essential for transmission of phase-locked spikes at low frequencies, because they are not found in low best frequency regions. The very low best frequency cells of the NM receive large bouton terminals from the auditory nerve and phase-lock to frequencies below ~1 kHz (Koppl, 1997), while in crocodilian NM, only the rostral high best frequency NM neurons receive endbulb-like projections (Soares, unpublished).

2.21.3.2 Glutamate Receptors

Activation of AMPA type glutamate receptors at endbulb synapses generates brief, large synaptic currents that are suited to the transfer of temporally precise information from pre- to postsynaptic cell (Raman and Trussell, 1995; Zhang and Trussell, 1994). The brevity of EPSCs in these neurons depends not only on the time course of release but also on the specific properties of the postsynaptic receptors. AMPA receptors are made up of glutamate receptor subunit (GluR) splice variants, and the GluR3 and 4_{flop} isoforms found in auditory neurons have fast kinetics and rapid desensitization rates, such that the duration of miniature EPSCs in auditory neurons are among the shortest recorded for any neuron (Gardner *et al*., 1999; Trussell, 1999). These rapid kinetics are due to a characteristic 'auditory' pattern of expression (Parks, 2000). In the chicken NM, where a homogeneous population of neurons makes mRNA analysis possible, the relative abundance of the four AMPA receptor subunits reveal very low levels of GluR2, and higher levels of the 'fast' flop splice variants of GluR3 and 4 (Parks, 2000; Ravindranathan *et al*., 1996a). Similar splice variants characterize mammalian bushy cells (Gardner *et al*., 2001). Further support for the role of GluR4 has emerged from developmental studies. AMPA receptor-mediated EPSCs in NM and MNTB become faster in decay time as animals mature (Brenowitz and Trussell, 2001a; Joshi *et al*., 2004; Koike-Tani *et al*., 2005). In parallel with the increase in kinetics, GluR4 flop increases from P7 to P14 and changes little thereafter (Koike-Tani *et al*., 2005).

2.21.3.3 Potassium Conductances

Although brief EPSCs underlie the precisely timed responses of neurons that phase-lock to the auditory stimulus, the intrinsic electrical properties of these neurons also shape the synaptic response as well as the temporal firing pattern. Two K^+ conductances are important for phase-locked responses in auditory neurons: a low-threshold conductance and a high-threshold conductance (Brew and Forsythe, 1995; Manis and Marx, 1991; Rathouz and Trussell, 1998; Reyes *et al*., 1994; Wang and Kaczmarek, 1998).

The low-threshold conductance activates at potentials near rest and is largely responsible for the outward rectification and nonlinear current–voltage relationship around the resting potential seen in a number of auditory neurons (for review, see Oertel, 1999). Activation of the low-threshold conductance leads to a short active time constant so that the effects of excitation are brief and do not summate in time (Wu and Oertel, 1984). Only large excitatory post synaptic potentials (EPSPs) reaching threshold before significant activation of the low-threshold conductance would produce spikes with short latencies, whereas small EPSPs that depolarize the membrane more slowly would allow time for low threshold conductance activation to shunt the synaptic current and prevent spike generation and thus long latency spikes. Blocking the low-threshold conductance elicits multiple spiking in response to depolarizing current injection (Manis and Marx, 1991; Rathouz and Trussell, 1998) or synaptic activation (Brew and Forsythe, 1995). The K^+ channels underlying this conductance appear to be composed of Kv1.1 and Kv1.2 subunits. Both subunits are

expressed in auditory neurons, although the subcellular distribution is unknown (Grigg *et al*., 2000). In NM, neurons express Kv1.1 potassium channel mRNA and protein, in a gradient that is highest in the high-BF region of NM (Fukui and Ohmori, 2004; Lu *et al*., 2004).

The high-threshold conductance is characterized by an activation threshold around –20 mV and by fast kinetics (Brew and Forsythe, 1995; Rathouz and Trussell, 1998; Wang and Kaczmarek, 1998). These features of the high-threshold conductance result in fast spike repolarization and a large but brief afterhyperpolarization without influencing input resistance, threshold, or spike rise time. Thus, the high-threshold conductance can keep spikes brief without affecting spike generation. In addition, the high-threshold conductance minimizes Na^+ channel inactivation, allowing cells to reach firing threshold sooner and thereby facilitating high-frequency firing. In the MNTB, blockade of this conductance diminishes the ability to follow high-frequency stimuli in the range of 300–400 Hz, but has little effect on responses to low-frequency (< 200 Hz) stimulation (Wang and Kaczmarek, 1998). Also in MNTB, elimination of the Kv3.1 gene in mice results in the loss of a high-threshold component of potassium current and failure of the neurons to follow high-frequency stimulation (Macica *et al*., 2003).

Similar potassium conductances characterize other time-coding cells. There are numerous examples, many discussed in Oertel's (1999) review. In addition to the NM and mammalian MNTB neurons discussed above, the coincidence detectors in the avian NL and mammalian medial superior olive also express similar conductances and respond with temporal precision to the auditory stimulus (see the discussion below). The reasons for temporal precision are clear for the circuit that detects ITDs. There are also other aspects of the auditory stimulus that require temporal precision. In particular, the mammalian cochlear nucleus octopus cells form the origin of a circuit that encode timing of events, especially broadband transients. Octopus cells produce the briefest, most sharply timed synaptic responses in mouse cochlear nucleus (Golding *et al*., 1995). Octopus cells are characterized by both a large low-threshold conductance and a high-threshold conductance (Bal and Oertel, 2000). Type II cells in the ventral nucleus of the lateral lemniscus produce sharply timed responses and receive endbulb input from octopus cells (Wu, 1999b). Thus, selection for temporal accuracy may in each case drive expression of conductances that improve neuronal performance and behavioral accuracy.

2.21.3.4 Large Neurons

Selective pressure for temporal accuracy at the synapse, particularly for high-frequency inputs, may have driven the evolution of larger cell size. Larger somata and axons are less vulnerable to noise caused by stray currents, since their low input resistance keeps the influence of voltage fluctuations to a minimum. Many of the known time-coding pathways include large cells (Carr and Amagai, 1996). Enlarged size must be accompanied by an increase in synaptic current. Fast, large synaptic currents minimize the influence of ambient voltage fluctuations on the timing of spikes. Reducing the electrotonic distance between the synapse and the site of integration can enhance these effects. This occurs in electric fish neurons that encode the phase of the electric organ signal and in the cells of the nucleus magnocellularis and the nucleus laminaris in birds (Jhaveri and Morest, 1982; Smith and Rubel, 1979; Carr and Boudreau, 1993) and in electric fish (Kawasaki and Guo, 1996). In the mammalian auditory system, both bushy and MNTB neurons are large, and characterized by calciform synapses and large brief synaptic currents (see Cant and Benson, 2003).

2.21.4 Coincidence Detection and Coding of ITDs

Behavioral experiments have shown that most animals use ITDs to localize sound (Fay, 1988). These time differences depend upon head size, and in some cases also upon an interaural canal. In general, animals with large heads have larger time differences available to them. Thus, animals with smaller heads have to achieve much greater resolution of binaural time differences than a large animal in order to obtain the same degree of accuracy. For example, barn owls and humans have very similar abilities to localize sound, since psychophysical studies have shown that human subjects are able to localize a frontal tone with an accuracy of about 2°, while owls have a best accuracy of 3° (Bala and Takahashi, 2000; Middlebrooks and Green, 1991). The human discrimination task is easier than the barn owl's because the human head is larger, but both humans and barn owls are extremely accurate. Heffner and Heffner (1992) have suggested that a major selective pressure on localization comes when animals with narrow fields of best visual acuity such as a fovea use accurate sound localization to direct their gaze. Animals with smaller heads or animals that do not look directly at a sound source tend to have poor localization ability.

How good is an ability to discriminate targets 3° apart? Given the barn owl's head size, 1.5° separation is equivalent to an ITD of about 3 μs (Moiseff and Konishi, 1981). Discrimination of these microsecond ITDs requires accurate transduction and processing of the original stimulus, followed by detection of ITDs. The preferred model for detecting temporal disparities was first proposed by Jeffress with his place theory (Figure 2; Jeffress, 1948). The model circuit is composed of two elements, delay lines, and coincidence detectors. The delay lines are created by varying axonal path lengths, and the coincidence detectors are neurons that respond maximally when they receive simultaneous inputs, that is, when the time difference is exactly compensated for by the delay introduced by the inputs. The Jeffress model explains not only how ITDs are measured but also how they are encoded. The circuit contains an array of coincidence detectors receiving input from afferent axons serving as delay lines. Because of its position in the array, each neuron responds only to sound coming from a particular direction, and thus the anatomical place of the neuron encodes the location of the sound. These neurons compute a new variable, time difference, and in the process, transform the time code into a place code. The selectivity of all higher-order auditory neurons to time difference derives from the 'labeled-line' output of the place map (Carr, 1993; Joris *et al*., 1998; Konishi, 2003).

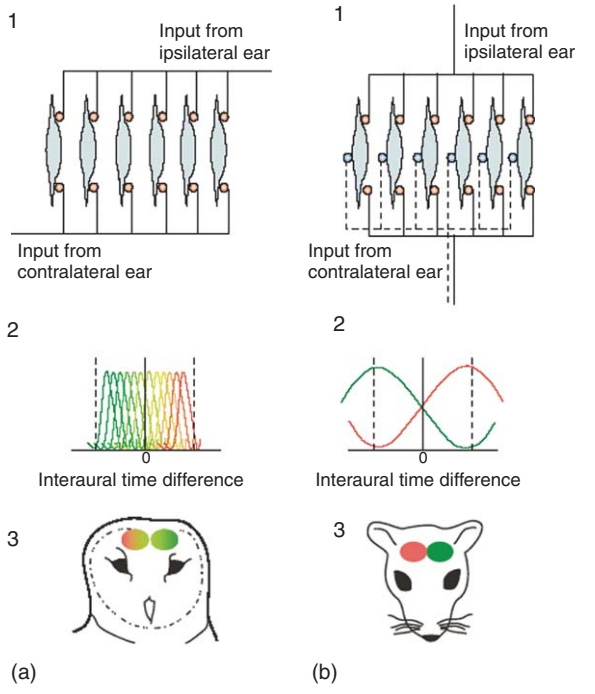

Figure 2 ITD coding strategies in birds and mammals. a, In birds, ITD detection depends upon a circuit composed of coincidence detectors and delay lines. (1) Each neuron in NL acts as a coincidence detector and fires maximally when inputs from the two sides arrive simultaneously. This occurs when the interaural phase differences are compensated for by an equal and opposite delay in the delay line inputs. (2) In the barn owl coincidence detector neurons are sharply tuned for ITDs relative to the width of the head (dotted lines). The lateral position of a sound source is read out as the position within the array that is maximally active. The different ITD tuning of single neurons is indicated by different colors. (3) Neurons in each brain hemisphere are tuned to different lateral positions in contralateral space. b, In mammals, the model of ITD-sensitive neurons does not depend on a map of ITDs created by delay line inputs. (1) In the gerbil, Grothe (2003) proposed that without inhibitory inputs, axonal conduction delays are distributed around zero ITD. The addition of glycinergic input from the contralateral ear (dotted lines) would shift the peaks of ITD functions toward longer ITDs. (2) The distribution of peak responses is positioned beyond the physiological range (dotted lines), centered on 45° interaural phase difference with respect to neural tuning for sound frequency. The sensitive slope of the broadly tuned functions is positioned within the physiological range. (3) The relative activation of the two brain hemispheres could provide a code of lateral position (McAlpine *et al*., 2001). Reproduced from McAlpine, D. and Grothe, B. 2003. Sound localization and delay lines – do mammals fit the model? *Trends Neurosci.* 26, 347–350, with permission from Elsevier.

2.21.4.1 Delay Line – Coincidence Detection Circuits in Birds

The avian circuit conforms to the requirements of the Jeffress model, in that the axons from NM act as delay lines to create maps of ITD, and NL neurons act as coincidence detectors (see discussion below; Figure 2). Recent evidence from small mammals, however, suggests that the Jeffress model does not completely explain how ITDs are encoded in the mammalian auditory brainstem (McAlpine and Grothe, 2003). There are many shared features of ITD coding circuits in birds and mammals; principally, both encode the phase of the auditory stimulus, and both encode ITD, but there are significant differences between the two clades. We will therefore discuss birds, then mammals, and finally compare the coding strategies employed in each group.

In birds, the projections from NM to NL act as delay lines to create maps of ITDs, and NL neurons act as coincidence detectors (Figure 2a). NL neurons phase-lock to both monaural and binaural stimuli but respond maximally when phase-locked spikes from each side arrive simultaneously, that is, when the difference in the conduction delays compensates for the ITD (Carr and Konishi, 1990; Overholt *et al*., 1992; Pena *et al*., 1996). Within the birds, the details of delay line circuit organization vary. In the chicken, NL is composed of a monolayer of

bipolar neurons that receive input from ipsi- and contralateral cochlear nucleus onto their dorsal and ventral dendrites, respectively (Rubel and Parks, 1975). These dendrites increase in length with decreasing best frequency. Evidence from brain slices suggests that only the projection from the contralateral cochlear nucleus acts as a delay line, while inputs from the ipsilateral cochlear nucleus arrive simultaneously at all neurons (Overholt *et al*., 1992). This pattern of inputs creates a single map of ITD in any tonotopic band in the mediolateral dimension of NL (Figure 2a; Overholt *et al*., 1992).

The barn owl is capable of great accuracy in detecting time differences, and its auditory system is hypertrophied in comparison to the chicken (Kubke *et al*., 2004). The nucleus laminaris is both much larger and reorganized when compared to the plesiomorphic condition exemplified by the chicken (Kubke *et al*., 2002, 2004). Magnocellular axons from both cochlear nuclei act as delay lines (Carr and Konishi, 1988). They convey the phase of the auditory stimulus to NL such that axons from the ipsilateral NM enter NL from the dorsal side, while axons from the contralateral NM enter from the ventral side. Recordings from these interdigitating ipsilateral and contralateral axons show regular changes in delay with depth in NL (Carr and Konishi, 1990). Thus, these afferents interdigitate to innervate dorsoventral arrays of neurons in NL in a sequential fashion, and produce multiple representations of ITD within the nucleus. Despite the differences in organization of NL in owls and chickens, ITDs are detected by neurons that act as coincidence detectors in both species (Joseph and Hyson, 1993; Kubke *et al*., 2002; Pena *et al*., 1996; Sullivan and Konishi, 1984).

A consistent feature of both avian and mammalian coincidence detectors is that they share physiological features with NM neurons and mammalian bushy cells (see Section 2.21.03.3). Coincidence detectors exhibit specific K^+ conductances that lead to a single or few well-timed spikes in response to a depolarizing stimulus *in vitro* (Kuba *et al*., 2002; Reyes *et al*., 1996; Smith, 1995). The low-threshold conductance channels should decrease the effective membrane time constant, that is, the average membrane time constant for a cell receiving and processing *in vivo* rates of EPSPs, which will be much shorter than the passive membrane time constant (Gerstner *et al*., 1996; Grau-Serrat *et al*., 2003; Softky, 1994). These fast conductances may be critical to coincidence detection, and current models suggest that fast membrane time constants are instrumental in keeping the firing rate near zero when the inputs are completely out of phase, and in allowing nonzero firing rate when the inputs are monaural.

2.21.4.2 ITD Detection Circuits in Mammals

The mammalian superior olive (MSO) contains neurons that receive excitatory input from the cochlear nucleus, and act as coincidence detectors to encode ITD (Goldberg and Brown, 1969; Yin and Chan, 1990). Despite this similarity with NL, the two structures may not be homologous, and their similarities may have emerged from the constraints of encoding ITD (Grothe, 2003). The reasons for assuming that the two nuclei are not homologous are both anatomical and physiological. First, the MSO is located in the ventral brainstem and forms part of the mammalian superior olivary complex, while the NL is dorsal and closely associated with NM. Thus, the embryological origins of the two structures may not be the same. Second, although MSO neurons act as coincidence detectors, it is not clear if their cochlear nucleus inputs act as delay lines to form maps of ITD. Anatomical data from the cat suggest that contralateral, but not ipsilateral inputs, could act as delay lines (Beckius *et al*., 1999), but there is as yet no unambiguous physiological evidence for a map formed by the incoming axons. Finally, the MSO receives fast, well-timed inhibitory inputs from the medial and lateral nucleus of the trapezoid body (Cant and Hyson, 1992; Grothe, 2003). These inhibitory inputs may enhance coincidence detection in several ways. Inhibition may produce a somatic shunt during coincidence detection to decrease the membrane time constant (Brughera *et al*., 1996). Inhibition may also modify the neural code for ITD. In the Mongolian gerbil, a small mammal with low-frequency hearing, precisely timed glycine-controlled inhibition in the MSO shifts the ITD curve so that the greatest change in firing rate falls within the physiologically relevant range of ITDs (Brand *et al*., 2002).

Inhibitory inputs are also found in the avian NL, but they are more diffuse, and appear to decrease excitability through a gain-control mechanism, rather than being phase-locked (Funabiki *et al*., 1998; Monsivais *et al*., 2000; Pena *et al*., 1996; Yang *et al*., 1999). Avian superior olivary neurons receive projections from the NA and NL and provide a GABAergic feedback projection to NM, NA, and NL (Lachica *et al*., 1994; Takahashi and Konishi, 1988b). This olivary input appears to provide tonic inhibition (Monsivais *et al*., 2000; Yang

et al., 1999), in contrast to the inhibitory projections in the mammalian MSO. It appears that the GABAergic input in birds maintains the coincidence detector in the optimal range of operation (Funabiki *et al.*, 1998). *In vivo* recordings from the barn owl support this interpretation (Pena *et al.*, 1996; Takahashi and Konishi, 2002).

The differences in how birds and mammals encode ITDs goes beyond differences in the neural circuit for ITD detection to the deeper issue of how ITDs are coded in the brain. Recent evidence from gerbils indicates that ITDs are not represented by maximal discharges of a few neurons, but rather by the relative activity in both MSOs. It has been proposed that this activity is regulated by inhibition, not delay-lines, and that there is no requirement for a map of azimuthal space in the MSO (Figure 2b; reviews in Grothe, 2003; McAlpine and Grothe, 2003). These observations, together with the lack of evidence for maps of ITD in the mammalian inferior colliculus, have been used to support the hypothesis that the neuronal representation of auditory space differs in birds and mammals, indicating again a parallel evolution of spatial hearing.

2.21.4.3 Models of Coincidence Detection and Dendritic Structure

In both birds and mammals, coincidence detectors are bitufted neurons with inputs from each ear segregated on separate sets of dendrites (Figure 3). Modeling studies suggest this dendritic separation improves coincidence detection (Agmon-Snir *et al.*, 1998; Grau-Serrat *et al.*, 2003). The dendritic separation may allow each dendrite to act as a current sink for inputs on the other dendrite, thus decreasing the amount of current to the soma when inputs arrive only on one side. This effect might be boosted by the presence of a low-threshold K^+ conductance similar to that found in NM and bushy neurons so that out-of-phase inputs are subtractively inhibited (Grau-Serrat *et al.*, 2003). With only monaural input, the low-threshold K^+ conductance in the opposite dendrite is somewhat activated, producing a mild current sink. When, however, there are recent EPSPs in the opposite dendrite due to out-of-phase inputs, the low-threshold K^+ conductance is strongly activated and acts as a large current sink suppressing spike initiation. Thus, the model predicts the experimental finding (Carr and Konishi, 1990; Goldberg and Brown, 1969; Yin and Chan, 1990) that the monaural firing rate, while lower that the binaural in-phase rate, is higher than the binaural out-of-phase rate. The benefits conveyed by the neuronal structure of the coincidence detectors further supports the idea that the evolution of coincidence detectors in the bird NL and mammalian MSO may have occurred in parallel (Carr and Soares, 2002).

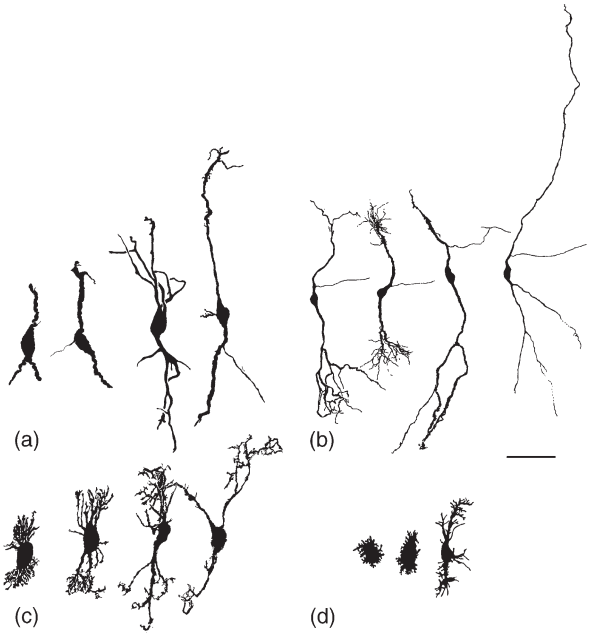

Figure 3 Coincidence detectors share bitufted morphology. a, Alligator NL neurons labeled with Golgi technique, from presumed high to low best frequency regions of NL (left to right; Soares, unpublished). b, Chicken NL neurons labeled with Golgi technique, from high to low best frequency regions of NL (Jhaveri and Morest, 1982). c, Guinea pig MSO neurons (Smith, 1995). d, Barn owl NL labeled with Golgi technique (Carr and Boudreau, 1993). Dendritic length increases from left to right except in the principal cells of the medial superior olive from the guinea pig, where a frequency gradient is not apparent (Smith, 1995). The bipolar architecture and the segregation of the inputs arriving from both ears are common to both mammalian and avian coincidence detectors. In the barn owl, coincidence detectors have lost this bipolar organization, except in low best frequency regions where their short dendrites radiate around the cell body. Reproduced from Carr, C. E. and Soares, D. 2002. Evolutionary convergence and shared computational principles in the auditory system. *Brain Behav. Evol.* 59, 294–311, with permission from Karger, Basel.

2.21.5 Summary and Conclusions

The cochlear nuclei of birds and mammals share similar features, including heterogeneous cell populations, and similar responses to sound. These shared characteristics may represent similar responses to selective pressures to encode the features of airborne sound. The principal reason for arguing that the similarities in the cochlear nuclei of birds and mammals may be due to similar

selective pressures, and not homology, is that the ancestors of birds and mammals separately developed true tympanic ears (Clack, 1997). A second reason is that close comparisons of bird and mammal cochlear nuclei reveal many differences. A third is that the observed similarity in the morphology and physiology of cochlear neurons is a plausible outcome of parallel evolution, because neurons in both birds and mammals experience similar constraints in detecting sound. Thus, although a common population of brainstem auditory neurons existed in the tetrapod ancestor, distinct evolutionary forces may have acted on these two groups allowing for the emergence of different ears and in turn, dissimilar organization in the brainstem.

Comparisons of temporal coding reveal shared computational principles. When compared with a simple integrate-and-fire unit, the auditory neurons that phase-lock, detect coincidences, and encode temporal patterns all exhibit a suite of physiological and morphological adaptations that suit them for their task. The core features of auditory coding are very similar in birds and mammals (and probably in other animals as well). Comparative studies of temporal coding can therefore add to the discussion of whether neuronal function follows form. A case can be made for this in time-coding neurons of the auditory brainstem of birds and mammals, and for phase-coding neurons in weakly electric fish (Kawasaki and Guo, 1998).

If there are computational advantages to particular neuronal architectures, similar forms should be expected. For example, we argue that the bitufted structure of coincidence detector neurons in birds and mammals is computationally advantageous. Therefore, morphological similarities might not support homology, but rather similar computational demands, and we can argue that the neurons of nucleus laminaris and MSO may have converged upon their similar form (Carr and Soares, 2002). In another example, it appears that large somatic terminals on NM or bushy cells are an ancestral feature of amniote auditory nerve. A shared pressure to encode higher-frequency sounds may have driven the parallel appearance of complex endbulbs in archosaurs and mammals.

Finally, phenotypically different neurons can produce similar computations. Neurons may differ in the expression and/or distribution of their ionic channels and still behave similarly. Thus, there may be numerous acceptable ways to carry out a particular computation. These may be revealed by comparative studies.

Glossary

accessory optic system Group of nuclei in the ventral tegmentum that receive retinal projections through the basal optic root and are involved in the regulation of eye movements.

advanced More recently derived from ancestral stock.

amniotes Turtles, diapsid reptiles (lizards, snakes, crocodiles) and birds, mammals. They are characterized by an amnion, a membrane surrounding the embryo, and an amniotic fluid.

anterior dorsal ventricular ridge Part of the pallium in reptiles and birds that primarily receives sensory projections from dorsal thalamic sensory nuclei, noticeably from the relay (rotundal nucleus) in the tectofugal visual subsystem.

AOS Accessory optic system.

dendritic field Area occupied by all branches of neuronal dendrites.

derived characters Certain newly acquired features that can be found in a particular taxon as a result of adaptive specialization, and not traced in ancestral forms.

DLA Anterior dorsolateral complex, the group of retinorecipient nuclei in the dorsal thalamus of birds (the relay in the thalamofugal visual subsystem), comparable to mammalian GLd.

DLL DLA lateral subdivision.

GABA γ-aminobutyric acid, an inhibitory neurotransmitter.

GLd Dorsal lateral geniculate nucleus, the retinorecipient nucleus in the dorsal thalamus of reptiles and mammals (the relay in the thalamofugal visual subsystem).

GLv Ventral lateral geniculate nucleus, the retinorecipient nucleus in the ventral thalamus of amniotes.

Gt Nucleus griseus tectalis, the retinorecipient nucleus in the pretectum of reptiles and birds.

homology Common character observed in a monophyletic taxon; this character can be traced back to a common ancestor.

IGL	Intergeniculate leaflet, the retinorecipient nucleus in the ventral thalamus of amniotes.
immunoreactivity	Visualization of neuroactive substances using the antigen–antibody reaction.
interneuron	Local-circuit neuron intercalated between a primary sensory neuron and a projection neuron.
Lm	Nucleus lentiformis mesencephali, the retinorecipient nucleus in the pretectum of reptiles and birds.
Lp/Pulv	Lateral posterior nucleus/pulvinar, the nuclei in the dorsal thalamus of mammals (the relay in the tectofugal visual subsystem).
nBOR	Nucleus of the basal optic root, the retinorecipient nucleus in the ventral tegmentum of reptiles and birds belonging to the AOS.
neuropil	Region devoid of projection neuron cell bodies but containing dendrites and nerve fibers, in which most synaptic contacts occur.
NOL	Nucleus olivaris, the retinorecipient nucleus in the pretectum of mammals.
NOT	The nucleus of the optic tract, the retinorecipient nucleus in the pretectum of mammals.
NPP	Nucleus pretectalis posterior, the retinorecipient nucleus in the pretectum of mammals.
phylogeny	Evolutionary development of a taxon or taxa.
plesiomorphy (plesiomorphic characters)	Primitive characters inherited from ancestral stock and remaining unchanged during phylogeny.
primitive characters	Any feature that can be traced early in the phylogeny and conserved in advanced (or recent) lineage.
Ptv	Nucleus pretectalis ventralis, the nonretinorecipient nucleus in the pretectum of reptiles.
retinotopic organization	Representation of the retinal spatial organization in the visual structures of the brain.
Rot	Nucleus rotundus, the nonretinorecipient nucleus in the dorsal thalamus of reptiles and birds (the relay in the tectofugal visual subsystem).
saccades	Rapid eye movements that allow repositioning of the eyes to fix a new object entering the visual field.
SC	Superior colliculus, the retinorecipient mesencephalic roof of mammals (equivalent to the optic tectum of reptiles and birds).
SGC	Stratum griseum centrale, the central cellular layer of the optic tectum and SC.
SGFS	Stratum griseum et fibrosum superficiale, the superficial cellular and fiber layer of reptilian and avian optic tectum.
SGP	Stratum griseum periventriculare, the periventricular cellular layer of the optic tectum and SC.
SGS	Stratum griseum superficiale, the superficial cellular layer of the mammalian SC.
SO	Stratum opticum, the optic fiber layer of the optic tectum and SC.
visuomotor behavior	Motor reaction elicited by the movements of images across the retina of an animal.
X, Y, and W Cells	Morphologically and functionally different retinal ganglion cells of mammals.

2.22.1 Introduction

Visual information reaches the cortex of the brain of amniote vertebrates by way of several pathways. The retina projects directly to a thalamic nucleus (the GLd of reptiles and mammals, or the anterior dorsolateral complex (DLA) of birds), from which projections arise to the reptilian lateral dorsal cortex, the avian Wulst, or the mammalian striate cortex. This retinothalamotelencephalic pathway is generally referred to as the thalamofugal visual subsystem. In addition, the retina projects to the optic tectum (or its mammalian homologue, the SC), from which projections arise to the thalamic nucleus rotundus (Rot) of reptiles and birds, or to the mammalian complex formed by the lateral posterior nucleus and the pulvinar (Lp/Pulv), these in turn projecting to the anterior dorsal ventricular ridge of reptiles, the ectostriatum of birds, and the extrastriate cortex of mammals, to form a tectofugal visual subsystem.

These two pathways are not, however, independent. Projections from the optic tectum or the mammalian SC to the GLd have been described in all amniote groups (see below); this tectogeniculate pathway is complemented by a second, pretectofugal series of projections arising in some of the pretectal nuclei and also terminating in the GLd.

In the pages that follow, we propose analyzing in detail the anatomical organization of the tectogeniculate and pretectogeniculate pathways in different groups of amniotes, and attempting to specify their main evolutionary tendencies during the phylogeny of this vertebrate group (see The Evolution of Visual Cortex and Visual Systems, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, Visual Cortex of Turtles, Evolution of Color Vision and Visual Pigments in Invertebrates).

2.22.2 The Tectogeniculate Pathway

The optic tectum (or mammalian SC) is one of the most phylogenetically conservative structures of the vertebrate visual system. Its projection to the GLd has been described in many reptilian species (Ulinski *et al.*, 1992; Reiner, 1994; Butler and Hodos, 1996; ten Donkelaar, 1997; Martínez-Marcos *et al.*, 1998; Belekhova *et al.*, 2003; Kenigfest *et al.*, 2004). In birds, the principal optic nucleus of the dorsal thalamus, the DLA, is generally considered as the homologue of the GLd (Watanabe, 1987; Miceli *et al.*, 1990; Wu and Karten, 1998), and receives projections from the optic tectum (Watanabe, 1987; Wild, 1989; Sugita *et al.*, 1996). In mammals, a colliculogeniculate projection has been described in many species (for review, see Harting *et al.*, 1991).

In all amniotes, the tecto/collicular projection to the GLd is ipsilateral and is considerably sparser than that to the dorsal thalamic relay of the tectofugal visual subsystem (the Rot or the mammalian Lp/Pulv complex), and to the ventral lateral geniculate nucleus (GLv) and intergeniculate leaflet (IGL).

2.22.2.1 Location of the Tectogeniculate Projection Neurons

The optic tectum/SC of amniotes varies considerably in its degree of differentiation, although three main cellular layers can be consistently distinguished: the periventricular stratum griseum periventriculare (SGP), the stratum griseum centrale (SGC), and the stratum griseum et fibrosum superficiale (SGFS) of reptiles and birds or the mammalian stratum griseum superficiale (SGS).

Among the reptiles, the highest degree of tectal differentiation is observed in the dracomorph lizards, in which the tectogeniculate projection neurons are located almost exclusively in the retinorecipient SGFS, those neurons projecting to the Rot lying in the nonretinorecipient SGC. In contrast, in lacertomorph lizards, turtles, and snakes, the tectal layers are less well differentiated, and tectogeniculate projection neurons are found in all three layers but preferentially in the SGFS; the neurons projecting to the Rot are found in the SGC and to some extent in the SGP.

In birds, which have a highly differentiated optic tectum, the tectogeniculate neurons are located, as in dracomorph lizards, exclusively in the SGFS (Wild, 1989), while the tectorotundal neurons are virtually exclusively observed in the SGC, with an insignificant proportion being located in the SGFS (Karten *et al.*, 1997; Hellmann and Güntürkün, 2001).

The colliculogeniculate projection of all mammalian species arises from neurons situated in the most dorsal sublayer of the superficial collicular layer (Harting *et al.*, 1991), well separated from those neurons of the ventral sublayer of the SGS and upper layer of the stratum opticum (SO) which project to the Lp/Pulv complex (Major *et al.*, 2000). In the tree shrew and bush baby, different tectal cells project to separate layers of the GLd (Diamond *et al.*, 1991; Lachica and Casagrande, 1993).

Since the phylogeny of the amniote visual system shows a progressive migration of neurons from deep to superficial tectal layers, Northcutt (1984) and Reiner (1994) have speculated that the location of the projection neurons in different tectal layers may reflect the pattern of neuronal migration from the periventricular to the superficial regions of the tectum. Turtles and lacertomorph lizards on the one hand, and birds on the other, may be considered as the two extremes of organization of tectothalamic projections in nonmammalian amniotes, with a completion of the outward migration of projection neurons being observed in mammals.

2.22.2.2 Morphology of the Tectogeniculate Projection Neurons

Information concerning the morphology of the tectogeniculate projection neurons in reptiles is somewhat scarce. In turtles, most of these neurons, located in the SGFS, are small, fusiform, and vertically oriented; their apical dendrites extend into the optic fiber layer (SO) and have relatively narrow fields of terminal arborization. The tectogeniculate projection neurons in the other tectal layers (SGC and SGP) share these morphological features; their long ascending dendrites also give rise to narrow fields of arborization in the most superficial retinorecipient layer of the tectum. Another population of projection neurons, situated in the deep nonretinorecipient sublayer of the SGFS, has been described in turtles; these give rise to moderately wide dendritic fields in the most superficial layers of the SGFS.

In lacertilian lizards (Martínez-Marcos *et al.*, 1998), two types of tectogeniculate projection

neurons have been described: (1) small, radially oriented neurons located in the SGFS and SGP, similar to those described in turtles, and which project to the neuropil of the GLd; and (2) large, multipolar neurons located in the SGC which project to the GLd cell plate.

In birds, also, the tectogeniculate projection arises from neurons morphologically similar to those described in turtles, with narrow fields of terminal arborization. Reiner (1994) considers the projection cells of turtles and birds as a homologous population of neurons which only differ by their location in a radial gradient of migration during development.

The vast majority of the colliculogeniculate projection neurons of mammals resemble those of reptiles and birds; they are small, fusiform, radially oriented cells with small, well-defined receptive fields. In rodents, these neurons receive an input from the W ganglion cells of the contralateral retina, or, in the case of primates and cats, an additional input from the Y cells of the ipsilateral retina. In the cat, two additional populations of polygonal projection neurons have been described; these receive a predominantly corticofugal afferent supply with little or no retinal input (Harting *et al.*, 1991).

2.22.2.3 Location of the Tectal Projections in the GLd: Light and Electron Microscopic Data

In reptiles, several retinorecipient nuclei, with a variety of morphological features, comprise the complex of the GLd (Rainey and Ulinski, 1986; Repérant *et al.*, 1992; Butler and Hodos, 1996). The retinal projections to these nuclei have been described in considerable detail, but the extraretinal afferent supply is less well documented. In turtles, lacertilian lizards, and some snakes, tectofugal terminals have been described in both the cell plate and neuropil of the nucleus (Reiner, 1994; Martínez-Marcos *et al.*, 1998; Belekhova *et al.*, 2003). In turtles, the tectofugal projections to the GLd are denser in the inner neuropil and cell plate; in these regions, the type I and III retinal terminals are also located. In the outer neuropil of the GLd, in which type II retinal terminals are mainly located, tectal projections are virtually absent (for a discussion of the three types of retinal terminals, see Sjöström and Ulinski, 1985). The tectal projections to the turtle GLd overlap the corticogeniculate projections (Kenigfest *et al.*, 1998, 2004).

In birds, several subnuclei of the DLA receive tectal projections; these predominate in the lateral subdivision of the complex (DLL; Watanabe, 1987; Wild, 1989; Sugita *et al.*, 1996) which also receives projections from the Wulst (Watanabe, 1987). The available data are too scanty to support any speculations as to possible homologies between the subcomponents of the avian DLA and the different layers of the mammalian GLd.

In the majority of mammalian species, the tectogeniculate projection is visuotopically organized, and innervates the small-celled regions of the GLd that contain neurons receiving input from W retinal ganglion cells and projecting to layers 1–3 of the striate cortex. In some species (Diamond *et al.*, 1991; Lachica and Casagrande, 1993), these may be resolved into two distinct pathways arising from distinct populations of collicular neurons which project to different small-celled layers of the GLd that have different targets in the striate cortex. This degree of specification of the colliculogeniculate projections is higher than that of the tectogeniculate projections in nonmammalian amniotes.

Few ultrastructural studies of the tectogeniculate projections have been carried out, and are limited to turtles (Kenigfest *et al.*, 2004) and mammals (Feig and Harting, 1994). In both groups, they comprise γ-aminobutyric acid (GABA)-immunonegative, small-axon terminals, containing rounded synaptic vesicles, which establish asymmetrical synaptic contacts. In turtles, these contacts are made with dendrites of relay cells, mainly in the cell plate and inner neuropil, regions which are also the main targets of cortical terminals. In monkeys, the colliculogeniculate terminals generally form synapses with small dendrites of W-type relay cells in the koniocellular layers of the GLd.

2.22.3 The Pretectogeniculate Pathway

The pretectal region of the amniote brain is generally a highly conservative region of the diencephalomesencephalic junction containing several retinorecipient and nonretinorecipient nuclei with ill-defined contours. Almost all pretectal nuclei have tight reciprocal connections with the optic tectum and the nuclei of the accessory optic system (AOS). The pretectal projection to the GLd has been demonstrated in all amniotes, but only recently in turtles (Kenigfest *et al.*, 2000, 2004). In reptiles, birds, and mammals, the pretectogeniculate projection is ipsilateral and considerably weaker than the pretectogeniculate projection to the Rot or the mammalian Lp/Pulv complex, or to the ventral thalamic GLv and IGL.

2.22.3.1 Location of the Pretectogeniculate Projection Neurons

Among reptiles, the pretectogeniculate pathway has only been described in turtles (Kenigfest *et al.*, 2000, 2004). The chelonian GLd receives a weak ipsilateral

pretectal projection arising from neurons of the retinorecipient nucleus lentiformis mesencephali (Lm) and nucleus griseus tectalis (Gt), as well as cells of the nonretinorecipient nucleus pretectalis ventralis (Ptv), which is a source of a major input to the Rot (Kenigfest *et al.*, 2000). Those pretectal nuclei projecting to the GLd also have reciprocal projections with the optic tectum, GLv, and the nucleus of the basal optic root (nBOR) of the AOS (Fite, 1985; Fan *et al.*, 1995; Weber *et al.*, 2003) and with visual telencephalic areas (Kenigfest *et al.*, 2000).

In birds, the pretectogeniculate pathway also arises from the retinorecipient Lm and Gt (Wild, 1989; Wylie *et al.*, 1998); as in turtles, this pathway is weaker than the pretectorotundal pathway arising from the complex of nonretinorecipient pretectal nuclei (Kenigfest *et al.*, 2000). The avian Lm also receives afferents from the visual Wulst, and has reciprocal connections with the optic tectum and nBOR (Wylie *et al.*, 1998). The main difference between reptiles and birds is that the pretectal nuclei of birds are considerably better differentiated than in turtles, indicating that the pretectogeniculate and pretectorotundal pathways are less well separated in turtles than in birds.

In mammals, the pretectal region has undergone a remarkable reorganization during the course of evolution. As a result, the mammalian pretectum shows considerable interspecific variation; it consists of numerous retinorecipient and nonretinorecipient nuclei, whose homology with avian or reptilian pretectal nuclei is not always obvious. The pretectal projection to the mammalian GLd arises mainly from three retinorecipient nuclei: (1) the nucleus of the optic tract (NOT); (2) the nucleus pretectalis posterior (NPP); and, to a lesser extent, (3) from the nucleus olivaris (NOL); the mammalian NOT/NPP may be considered as possible homologues of the reptilian and avian Lm. The same three mammalian pretectal nuclei give rise to projections to the Lp/Pulv complex, which arise from different cell populations than those to the GLd. As in reptiles and birds, the retinorecipient nuclei of the mammalian pretectum have reciprocal connections with the SC, the terminal nuclei of the AOS, and the visual cortical areas (see Simpson *et al.*, 1988, for review).

2.22.3.2 Morphology and Neurochemical Properties of the Pretectogeniculate Projection Neurons

In turtles, the neurons of the Lm and Gt which project to the GLd are relatively small, round or fusiform in shape, with long, profusely branching dendrites. The neurons of the Ptv, which vary in both shape and size, are larger than the projection neurons of the Lm and Gt. The extensive dendritic branches of the Ptv projection neurons remain confined within the boundaries of the nucleus. The vast majority of neurons in all three pretectal nuclei are GABA-immunoreactive, thus giving rise to GABAergic projections to the GLd and Rot (Kenigfest *et al.*, 2000).

In birds, as in turtles, the neurons of the Lm that project to the DLA are small in size, whereas those pretectal neurons projecting to the Rot are larger. The pretectothalamic projection neurons are GABA-immunoreactive and thus have an inhibitory influence on the DLA and Rot (Kenigfest *et al.*, 2000).

In mammals, both the pretectogeniculate and pretectopulvinar projection neurons vary in size and shape. All the pretectal nuclei are well endowed with GABA-immunoreactive cells that project in different proportions to the GLd and Lp/Pulv complex (Cucchiaro *et al.*, 1991, 1993; Reimann and Schmidt, 1996). Because of the heterogeneity of the size and shape of pretectal projection neurons in mammals, it is difficult to compare the morphologies of cells projecting to the GLd and Lp/Pulv across mammalian species. However, it is apparently the case that the neurons of the NPP and NOT that project to the Lp/Pulv complex appear to be generally small in size, whereas those projecting to the GLd appear to be larger (Kubota *et al.*, 1988; Cucchiaro *et al.*, 1991; Reimann and Schmidt, 1996); the contrary is true for reptiles and birds.

2.22.3.3 Location of the Pretectal Projections in the GLd: Light and Electron Microscopic Findings

The location of pretectal terminals in the reptilian GLd and avian DLA is similar to that of the tectogeniculate projections. Both pathways terminate in zones that receive predominantly corticofugal projections and considerably fewer retinal projections (Wild, 1989; Wylie *et al.*, 1998; Kenigfest *et al.*, 2000, 2004).

In turtles, some recent findings (Kenigfest *et al.*, 2004) have shown that, under the electron microscope, the pretectal terminals are more numerous in those regions of the GLd (cell plate and inner neuropil) that receive tectal and cortical afferents than in the outer neuropil, which is the major target of retinal projections. The pretectal terminals contain pleomorphic synaptic vesicles, are GABA-immunoreactive and establish both symmetric and asymmetric synaptic contacts, almost exclusively with the dendrites of geniculocortical projection neurons, and to a very small extent with the dendrites of GABAergic interneurons. The principal influence of the GABAergic pretectogeniculate

projections upon the geniculocortical neurons of the turtle is thus inhibitory.

In birds, no ultrastructural studies of the pretectogeniculate projections appear to have been carried out.

In mammals, the pretectogeniculate projection arising from the retinorecipient NOT is retinotopically organized, while the less dense projections from the NPP and NOL are not (Kubota *et al.*, 1988). While a GABAergic, inhibitory pretectogeniculate projection exists in all studied mammalian species, and their location within the GLd differs from that of the corticogeniculate terminals, the laminar location of the former shows remarkable interspecific variation. In the majority of mammalian species, these terminals are located in the parvo- and/or magnocellular layers of the GLd which contain X- and Y-type cells involved respectively in detailed object vision or motion detection and which project to layer 4 of the striate cortex; they are much less evident in the small-celled layers containing W-type neurons (Cucchiaro *et al.*, 1993; Feig and Harting, 1994; Uhlrich and Manning, 1995; Büttner-Ennever *et al.*, 1996). The pretectogeniculate terminals contain flattened or pleomorphic synaptic vesicles, and make symmetrical synaptic contacts (Cucchiaro *et al.*, 1993; Feig and Harting, 1994; Wang *et al.*, 2002). In the monkey, the majority of the pretectogeniculate GABAergic terminals establish contacts with the geniculocortical projection neurons, in both the retinorecipient and corticorecipient zones (Feig and Harting, 1994). On the other hand, in the cat (Cucchiaro *et al.*, 1993; Wang *et al.*, 2002), the postsynaptic target of the pretectogeniculate terminals is exclusively the dendrites of GABAergic interneurons. Thus, the main influence of the pretectal input to the GLd is, in the cat, the disinhibition of relay neurons by means of inhibition of interneurons, while in the monkey the greater part of the pretectal input directly inhibits the relay cells.

In general, in mammals, the pretectogeniculate pathway is both more heterogeneous and more widely distributed within the GLd than the colliculogeniculate pathway.

2.22.4 Functional Considerations

In reptiles, birds, and mammals, the tectum and pretectum, together with the AOS, are involved in the organization of visuomotor behavior. These structures contain directionally sensitive neurons, and have multiple descending projections to premotor and motor centers of the hindbrain responsible for eye and head movements (Jassik-Gerschenfeld and Hardy, 1984; Fite, 1985; McKenna and Wallman, 1985; Fan *et al.*, 1995). Although little functional information is available concerning the tecto- and pretectogeniculate pathways in non-mammalian amniotes, the purely morphological and neurochemical data indicate strongly that they may well be involved in the modulation of the sensitivity of geniculocortical projection neurons during visuomotor behavior. Wylie *et al.* (1998) have suggested that, in birds, the pretectal and AOS input to the visual thalamofugal subsystem may be involved in perception of the three-dimensional layout of the environment, distinguishing object motion from self-motion, and in spatial cognition.

In mammals, the function of the two pathways and their role in visuomotor activity are more obvious. Neurophysiological data show that the stimulation or suppression of activity in the SC modifies visually driven activity in both the GLd and visual cortex (Molotchnikoff *et al.*, 1986; Xue *et al.*, 1994).

The colliculogeniculate pathway, which arises in the superficial collicular layer, interacts with direct projections from the W-type retinal ganglion cells which provide information about slowly moving objects in the visual field. The integrated information is then passed to the striate cortex and combined with information from the magno- (Y-type) and parvo- (X-type) geniculocortical projection neurons. Some authors have suggested that the colliculogeniculocortical pathway is involved in selective visual attention (Harting *et al.*, 1991; Lachica and Casagrande, 1993).

Another pathway from the superficial collicular layers to the intermediate and deep premotor layers has been suggested in the involvement of visually guided orienting movements (Helms *et al.*, 2004). During saccadic eye movements, for which the SC is responsible, a suppression of activity in the magnocellular pathway, and to a lesser extent in the parvocellular pathway, of the GLd occurs; this is followed by a facilitation of activity in the GLd after the fixation of a new visual image upon the retina (Ramcharan *et al.*, 2001; Reppas *et al.*, 2002). The modulatory effect of saccades on the activity of the geniculocortical projection neurons can be exercised by both excitatory and inhibitory inputs from both cortical areas and subcortical or brainstem tectorecipient centers.

In contrast to the collicular neurons, the mammalian pretectal neurons involved in saccadic eye movements project directly to the GLd and modify the activity of the geniculocortical projection

neurons after a saccade. The most extensive studies of this process have been carried out in the cat (Cucchiaro *et al.*, 1991, 1993; Uhlrich and Manning, 1995; Schmidt, 1996; Wang *et al.*, 2002); the activity of geniculocortical relay cells, blocked by a saccade, is restored by inhibition of the inhibitory interneurons of the GLd by the GABAergic pretectal afferents. In primates, the influence of the pretectum on the activity of the GLd is somewhat more complicated, involving as it does both the direct inhibition and indirect disinhibition of the geniculate relay cells (Feig and Harting, 1994).

2.22.5 Conclusions

While tectal and pretectal inputs to the GLd appear to exist in all amniote groups, it would be somewhat premature to suggest that they exercise an identical function in each; nevertheless, the similarities in the morphological and neurochemical features of these pathways suggest that they exert a similar function in the processing of visual information by the thalamofugal subsystem. In all amniotes, the two pathways provide the opportunity for the integration of visual signals and visuomotor activity at an early stage of visual information processing. Both pathways are less elaborate than the massive tectal and pretectal inputs to the dorsal thalamic relay of the tectofugal visual subsystem and to other thalamic centers directly related to visuomotor activity.

The fundamental plan of morphological and neurochemical organization of these pathways, shared by all amniotes, indicates strongly that they may have a common origin in ancestral forms of this group.

During the course of evolution of the amniotes, the progressive segregation and specialization both between and within the tecto- and pretectogeniculate pathways have proceeded in parallel with the laminar and nuclear differentiation both of their sources in the tectum and pretectum, and of their targets in the GLd. Recent mammals, especially those with well-developed binocular vision, show a clear heterogeneous composition of both pathways that is only indicated in reptiles and some birds.

2.23 Evolution of Myelinated Nervous Systems

B I Roots, University of Toronto, Toronto, ON, Canada
R M Gould, University of Illinois at Chicago, Chicago, IL, USA

Glossary

desmosome	Specialized adherens junction between neighboring cells.
myelin internode	A myelin sheath that defines the region between two nodes of Ranvier or a node of Ranvier and the initial segment or distal region where myelin sheaths terminate.
myelin sheath	Found in both vertebrate and invertebrate nervous systems, they are multilayered membranes that surround large-caliber axons and facilitate saltatory conduction.
nodes of Ranvier	Axonal membrane where sodium channels are concentrated. These are seen as segmented interruptions in the myelin sheaths.
oligodendrocyte (OL)	Central nervous system glial cell that produces myelin sheaths around one or more (upwards of 40) internodes.
Schwann cell	Derived from the neural crest, this cell either produces single myelinated nerves in the peripheral nervous system or establishes nonmyelinating relationships with one to multiple small-caliber peripheral nerve axons. The cells bordering the squid giant axon are often referred to as Schwann cells. As cells in the peripheral nervous system that associate with axons, this definition may apply.

2.23.1 Introduction

Associations between glial cells and large-caliber axons are common features among invertebrate and vertebrate nervous systems examined (Schweigreiter *et al.*, 2006). At one extreme are squid giant axons, which reach 1 mm or more in diameter and 10–20 cm in length in widely dispersed species. Tens of thousands of glial cells associate with each giant axon (Villegas and Villegas, 1984; Brown and Abbott, 1993). Another well-studied animal model, the sea lamprey, has many, if not all, of its larger-caliber axons surrounded by glial cells (Bertolini, 1964; Merrick *et al.*, 1995). The reasons why glial cells first appeared in ancient nervous systems, why they began to associate selectively with larger axons, remain a mystery. Clearly, they not only contribute to efficiency of nerve impulse propagation by preventing/reducing cross-talk, they also provide structural support and nutrition for the axons and other larger neurites with which they associate.

The largeness of squid giant axons allows investigators to separate axoplasm from the axolemmal membrane and surrounding glial cells by simple extrusion (Brown and Lasek, 1990). This feature led investigators to discover that glial cells transfer a subset of newly synthesized proteins to giant axons (Gainer *et al.*, 1977; Lasek *et al.*, 1977; Sheller *et al.*, 1995). It seems reasonable that similar mechanisms exist in other large-caliber axons for, although protein transfer was not measured directly, a transfer of glial-derived proteins and other molecules is thought to underlie the long-term survival of these axons following their separation from neuronal soma (Hoy *et al.*, 1967; Bittner, 1991). Although efforts to understand better the multifaceted nature of interactions between neurons and glial cells are ongoing (Kretzschmar and Pflugfelder, 2002; Oland and Tolbert, 2003; Edenfeld *et al.*, 2005; Sattelle and Buckingham, 2006), our focus is on the specific interactions that result in the formation of myelinated axons.

High-resistance myelin sheaths covering nearly the entire surface of large-caliber vertebrate axons are crucial to saltatory conduction, a process that brings both unprecedented efficiency and speed to axon signaling and allows the unmatched

complexity of modern-day vertebrate nervous systems. Whereas many invertebrate and all vertebrate nervous systems (except cyclostomes) evolved the ability to form myelinated axons, both structural and biochemical evidence (see below) suggests that myelination originated independently several times in invertebrates and only once in vertebrates (Waehneldt, 1990). Furthermore, whereas the strategies used to make the vertebrate myelinated nervous system are being ever more clearly understood, strategies underlying invertebrate glial cell myelination are totally unknown and form the variety of structural features expressed (see below), probably quite varied (see Compensatory Innervation in Development and Evolution, Basic Nervous System Types: One or Many?, Origin and Evolution of the First Nervous System, Adult Neurogenesis and Neuronal Regeneration in the Teleost Fish Brain: Implications for the Evolution of a Primitive Vertebrate Trait).

2.23.2 Myelin Sheaths in Invertebrates

Despite a long history, of well over a century, that includes many descriptions of multilayered myelin-like sheaths that surround invertebrate axons/neurites, current focus on invertebrate myelination is sparse (Bullock, 2004; Pan *et al*., 2006). In contrast to prominence of myelinated axons in vertebrate nervous systems, generally the numbers of axons covered with multi-layered membranes in annelid and crustacean nervous systems are small. In striking contrast to an invariant nature of vertebrate myelinated axons, the nature of invertebrate myelin sheaths is highly variable. Some myelin sheaths, as in the crayfish, *Procambarus clarkii* (Cardone and Roots, 1991, 1996), are loosely wound, whereas others, e.g., the eyestalk of the crab, *Cancer irroratus* (McAlear *et al*., 1958) and earthworm, *Lumbricus terrestris* (Günther, 1973, 1976; Roots and Lane, 1983) are highly compacted, more like vertebrate myelin. Among the annelids, myelin-like wrappings have been reported in members of three oligochaete families, i.e., two species of Lumbricidae, *Eisenia foetida* (Hama, 1959) and *L. terrestris* (Coggeshall, 1965; Günther, 1973, 1976; Roots and Lane, 1983), one species of Lumbriculidae, *Lumbriculus variegatus* (Drewes and Brinkhurst, 1990), and one Tubificid, *Branchiura sowerbyi* (Zoran *et al*., 1988). Three families of polychaetes, Capitellidae, Spionidae, and Maldanidae (Nicol, 1958), have large axons covered with multilayered sheaths. Among crustacea, Malacostracan crustacea, several shrimps, prawns, crayfish, and crabs (Holmes, 1942; McAlear *et al*., 1958; Hama, 1966; Heuser and Doggenweiler, 1966; Kusano, 1966; Govind and Pearce, 1988; Cardone and Roots, 1991; Xu and Terakawa, 1999; Lenz *et al*., 2000; Weatherby *et al*., 2000) have axons covered with myelin-like sheaths.

Resemblances between oligochaete and vertebrate sheaths include spiral winding and sheath thicknesses that are correlated with axon caliber. In *E. foetida* sheath thickness ranges from two to 30 lamellae, whereas in *L. terrestris*, sheaths contain 60–200 lamellae. Also, interlamellar spacing can be highly variable. The sheath of the *L. terrestris* median giant fiber, in particular, contains a mix of tightly compacted membranes that resemble vertebrate myelin, and redundant loops formed where the sheath buckles and retains substantial quantities of cytoplasm between membranes. Stacks of desmosome-like structures run serially in register across some sheaths, attaching lamellae to each other (Figure 1). Although these structures resemble vertebrate desmosomes in electron micrographs, they differ in both their intramembranous organization, as revealed by freeze-fracture (Roots and Lane, 1983), and in their protein composition (Pereyra and Roots, 1988).

The sheaths found in crustaceans differ from those of annelids and vertebrates; they are concentric rather than spiral. Moreover, they come in two patterns. In the prawn *Palaemonetes vulgaris* (Heuser and Doggenweiler, 1966) and in shrimps, genus *Penaeus* (Xu and Terakawa, 1999), the concentric laminae join at a short seam reminiscent of vertebrate sheath mesaxons. The arrangement of seams is very regular with those of alternate laminae located on opposite sides of the axon. In the

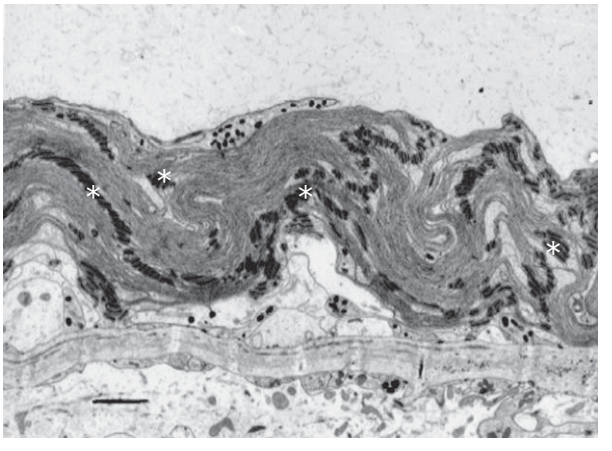

Figure 1 Myelin-like sheath in a longitudinal section of the median giant fiber of *Lumbricus terrestris* nerve cord. Note the desmosome-like structures (*) running in register across the sheath. Scale bar: 1 μm.

copepods *Undinula vulgaris*, *Neocalanus gracilis*, and *Euchaeta rimana*, the lamellae form complete circles and lack seams (Weatherby *et al.*, 2000). Another distinguishing feature of crustacean myelin is the location of glial cell nuclei, which are located in variable positions within the sheath (Heuser and Doggenweiler, 1966; Xu and Terakawa, 1999). The conditions whereby glial cell nuclei and perinuclear cytoplasm lie close to axons would tend to favor a potential metabolic transfer of glial proteins and other metabolites to axons.

The myelin-like sheath of the crab, *C. irroratus*, in particular, bears a striking resemblance to vertebrate myelin. Glial cell nuclei lie outside the sheaths, compaction is similar to that of vertebrate myelin, and structures resembling Schmidt–Lanterman incisures and nodes of Ranvier are present (McAlear *et al.*, 1958). At present it is unclear whether the sheath is spirally or concentrically wound.

As in annelids and vertebrates, in crustaceans myelin thickness correlates with axon caliber. Lamellar numbers vary from 1 or 2 up to 50. In copepods, interlamellar spacing varies between 3 and 30 nm while the compact intralamellar (fused membranes) space remains constant, around 18 nm in thickness (Weatherby *et al.*, 2000). In prawns, the interlamellar periodicity is more than 20 nm (Heuser and Doggenweiler, 1966), whereas in *Penaeus* shrimps it is 8 or 9 nm (Xu and Terakawa, 1999). Periodicity is species-dependent in both invertebrates and vertebrates (see following section; moreover, it is affected by tissue-processing methods (Kirschner and Blaurock, 1992; Roots, 1993). The periodicity of the fully compact myelin of *Penaeus setiferus*, determined by X-ray diffraction (probably the most accurate measurement), is 16 nm, a value similar to that in teleost peripheral myelin (Blaurock, 1986).

Interruptions, functionally comparable to vertebrate nodes of Ranvier, occur in both annelid and crustacean sheaths. In many decapod crustaceans (prawns, shrimps, and crabs), the nodes are strikingly similar to vertebrate nodes, both in terms of general morphology (Retzius, 1890; Holmes *et al.*, 1941; Holmes, 1942) and in the disposition of paranodal loops. As is the case in vertebrate loops (see below), these include structures that resemble septate desmosomes (McAlear *et al.*, 1958; Heuser and Doggenweiler, 1966). Internodal distances are generally shorter than in vertebrates (Holmes *et al.*, 1941). A more detailed comparison of crustacean and vertebrate nodes is available (Roots, 1984). Other shrimps, six species of the genus *Penaeus*, a number of copepods (Hsu and Terakawa, 1996; Xu and Terakawa, 1999; Weatherby *et al.*, 2000), and the earthworms *E. foetida* and *L. terrestris* (Hama, 1959; Günther, 1973, 1976) have completely different nodes. They have circular openings in the myelin sheath and are referred to as focal or fenestration nodes. In *L. terrestris*, there are two nodes of 10–15 μm diameter in each segment. In *Penaeus* shrimps, node diameter and internodal distance are both approximately proportional to fiber diameter. Node diameter varies between 5 and 50 μm and internodal distance from 3 to 12 mm (Xu and Terakawa, 1999). Another morphological feature, suggesting a novel mechanism of fast nerve conduction, occurs in shrimps of the genus *Penaeus*. A large gel-filled space is present between the axon and myelin sheath. This submyelinic space increases effective axon diameter and, as a consequence, conduction velocity. It is tightly sealed at the node regions, permitting saltatory conduction (Hsu and Terakawa, 1996; Xu and Terakawa, 1999).

Conduction velocity has been measured in only a few invertebrate nerves. In the median giant fiber of the earthworm *L. terrestris*, which is 90 μm in diameter, it is 30 m s^{-1} (Günther, 1976). In the shrimp, *Penaus japonicus*, it is 90–190 m s^{-1} in fibers 120 μm in diameter (Kusano, 1966; Kusano and LaVail, 1971). For comparison, a rat fiber of 4.5 μm diameter with a sheath of about 50% of its total diameter conducts at 59 m s^{-1}. Thus, vertebrate sheaths are far more effective in increasing conduction velocity. Reaction times for the escape responses of calanoid copepods have been measured (Lenz *et al.*, 2000). The fastest responses were recorded in myelinated species, the escape response being initiated 2–5 times more rapidly than in the nonmyelinated species. Myelin is found only in the more recently evolved copepod superfamilies, which also live in more diverse habitats. They not only live in neritic and deep-water environments but also in regions of the ocean where faster reaction times are essential for avoiding predators (Hayward and McGowan, 1979; Parks, 1986; Hays *et al.*, 1997; Lenz *et al.*, 2000). Thus, during the course of copepod evolution, the development of myelin has allowed them to occupy new habitats.

Very little is known about the distribution of sodium channels in invertebrate axons. Studies on the shrimp *P. japonicus* indicate that, as in vertebrates, sodium channels are concentrated at the nodes at a density of 530 channels μm^{-2} (Hsu and Terakawa, 1996; Xu and Terakawa, 1999). In the earthworm *L. terrestris*, sodium channels are also concentrated at the nodes (Günther, 1976; Roots, 1984, 1995b).

Information on the chemical compositions of different invertebrate myelin sheaths is limited.

Fortunately, techniques used to purify myelin membranes (based on size and density of the membrane) from vertebrates are adaptable to invertebrates (Pereyra and Roots, 1988; Waehneldt *et al.*, 1989). Analysis of lipid and protein compositions in annelid and crustacean myelin shows marked differences from vertebrate myelin (see below) and from one another. Birefringence studies of earthworm myelin showed the sheath to be qualitatively similar to that of frog sciatic nerve, with protein contributing 30–40% of the total birefringence and the rest attributed to lipids (Taylor, 1942). In the shrimp, *Penaus duorarum*, a strikingly high proportion of lipids is found in isolated myelin; the lipid-to-protein ratio is 15 : 1 (Okamura *et al.*, 1986b).

Galactolipids, major constituents of vertebrate myelin sheaths (Morell and Quarles, 1999) are not present in annelid or crustacean myelin. Instead, glucocerebroside in amounts equivalent to galactocerebroside in vertebrate myelin is present in crustacean, though not in earthworm, myelin. Sphingomyelin is absent from earthworm nerve cord and, although it is found in crayfish (*Cambarus clarki*) nerves, it is structurally quite different from vertebrate sphingomyelin (Komai *et al.*, 1973; Okamura *et al.*, 1986a). Thus, there is an evolutionary trend in which glucocerebrosides in protostomes are replaced by galactolipids in deuterostomes. Although deuterostomes also synthesize glucocerebroside (Tamai *et al.*, 1992), and do so under circumstances when galactolipid synthesis is blocked (Bosio *et al.*, 1998), evolutionary inclusion of galactosphingolipids in myelin (Roots, 1995a) may have occurred to foster lipid–lipid and lipid–protein interactions needed for node/paranode stabilization (Popko, 2000) and/or raft-dependent signaling involved in myelin assembly (Boggs and Wang, 2001).

The protein components of both annelid (earthworm *L. terrestris*) and crustacean (crayfish *P. clarkii* and pink shrimp *P. duorarum*) myelin are totally different from those of vertebrates. As in vertebrates, the protein pattern of earthworm myelin is relatively simple, with 80 and 42 kDa proteins predominating and 28–32 kDa proteins as minor components. The structure of these proteins is unknown and there is no cross-reactivity with antibodies to myelin proteins (see Section 2.23.4 for more information on these proteins), including myelin basic protein (MBP), proteolipid protein (PLP), myelin-associated glycoprotein (MAG), and 2′,3′-cyclic nucleotide 3′-phosphodiesterase (CNP) (Pereyra and Roots, 1988; Cardone and Roots, 1990). In the pink shrimp, four major proteins, 21.5, 40, 78, and 85 kDa, and four minor proteins, 36, 41.5, 43, and 50 kDa, are found in purified sheath membranes. None of these proteins show cross-reactivity with antibodies that recognize mammalian MBP or PLP or trout MBP, 36 K or protein zero (P_0) (Okamura *et al.*, 1986b; Waehneldt *et al.*, 1989). A monoclonal antibody generated to earthworm myelin-like membranes and showing cross-reactivity with 30–32 and 40 kDa proteins cross-reacts with 60–65, 42, and 40 kDa proteins in crayfish (*P. clarkii*) axon-ensheathing membranes (Cardone and Roots, 1996). Thus, earthworm and crayfish myelin membrane proteins have some antigenic epitopes in common.

The presence of a myelin sheath confers several advantages in invertebrate survival. The startle reactions of earthworms, escape responses of crayfish, shrimp, and copepods, and retraction of eyestalks in crabs are behaviors in which speed is of paramount importance (Bullock, 1984). Alternatively, faster conduction may be achieved by simply increasing axon diameter, as occurs in squid giant axons (see above). However, this alternative is evolutionarily less favorable. A more efficient means of increasing conduction speed and, therefore, the rapidity with which escape mechanisms take place is the development of myelin sheaths. The nodes of invertebrate nerve fibers serve to allow saltatory conduction in a similar fashion to vertebrate nodes of Ranvier. It should be noted that the points of emergence of small collaterals serve as nodes in both vertebrates (Roots, 1984) and the shrimps *Penaeus chinensis* and *P. japonicus* (Xu and Terakawa, 1999).

2.23.3 Morphological Features of Vertebrate Myelin

Myelination arose in the common gnathostome ancestor as cyclostomes; lamprey and hagfish totally lack myelin (Bullock *et al.*, 1984) and all gnathostomes examined have myelinated nervous systems that are structurally rather invariant, as descriptions for mammalian myelin (Peters *et al.*, 1991; Hildebrand and Mohseni, 2005) readily apply to nonmammalian myelin/myelination and vice versa (see below). Furthermore, the growing understanding of vertebrate myelination is nurtured by continued cross-fertilization, as studies with mammals and nonmammals are often interpreted interchangeably (Kagawa *et al.*, 2001; Lobsiger *et al.*, 2002; Jessen and Mirsky, 2004, 2005; Miller and Reynolds, 2004; Le *et al.*, 2005; Richardson *et al.*, 2006). Several reasons why nonmammals have been chosen for study are: (1) quail-chick

chimeras allow ready oligodendrocyte (OL) lineage tracing (Cameron-Curry and Le Douarin, 1995; Pringle *et al.*, 1998); (2) fishes and some amphibians have the ability to regenerate their central nervous system (CNS) (Sivron *et al.*, 1990; Diekmann *et al.*, 2005); (3) a general interest in comparative myelination (Jeserich and Rauen, 1990; Jeserich *et al.*, 1990; Jeserich and Stratmann, 1992; Gould *et al.*, 1995; Nguyen and Jeserich, 1998; Park *et al.*, 2005); (4) a growing interest in comparative genomics (Aparicio *et al.*, 2002; Gilchrist *et al.*, 2004; Venkatesh and Yap, 2005); and (5) use of high-throughput genetic screens in zebra fish (Rossant and Hopkins, 1992; Sprague *et al.*, 2003), that adapt to identifying proteins important for myelination (Lyons *et al.*, 2005).

The first electron microscopic studies showing the spiraling nature of peripheral nerve myelin formation were conducted with nonmammals, i.e., chick (Geren, 1954) and chameleon (Robertson, 1955) nerves. Subsequent electron microscope observations made on frog (Maturana, 1960) and toad (Stensaas and Stensaas, 1968) CNS sections show similar spiral wrapping of axons with elaborations of OL plasma membrane. More recently, antibody studies of PLP expression showed that frog OLs displayed identical structural appearances during development to mammalian OLs (Yoshida, 1997).

We readily realize the morphological conservation of CNS and peripheral nervous system (PNS) myelination among gnathostomes with comparisons of images from developing and mature mammalian and nonmammalian species (Figures 2–4). Clearly, at both light and electron microscopic levels, multiple features, including selection of large-caliber axons, loose followed by tight wrapping, and development of nodal and paranodal specializations appear indistinguishable between these evolutionarily divergent species. At the time myelination begins in ventral spinal cord and medial longitudinal fascicle of elasmobranches (4–5 cm spiny dogfish fetuses) and mammals (newborn rats: Schwab and Schnell, 1989), one can clearly see that initial appearances of OLs and early myelin wrapping are quite similar (Figure 2). In both cases, early OLs hover around the edge of the tissue (Figures 2a and 2b, *). At the electron microscopic level, similar appearances of OL nuclei with chromatin clumped along the nuclear envelop and large regions of perinuclear cytoplasm filled with mitochondria, Golgi, rough and smooth endoplasmic reticulum, and numerous microtubules characteristic of myelinating mammalian OLs (Figure 2d) are also characteristic of myelinating spiny dogfish OLs. As development progresses in spiny dogfish ventral funiculi, the numbers of large

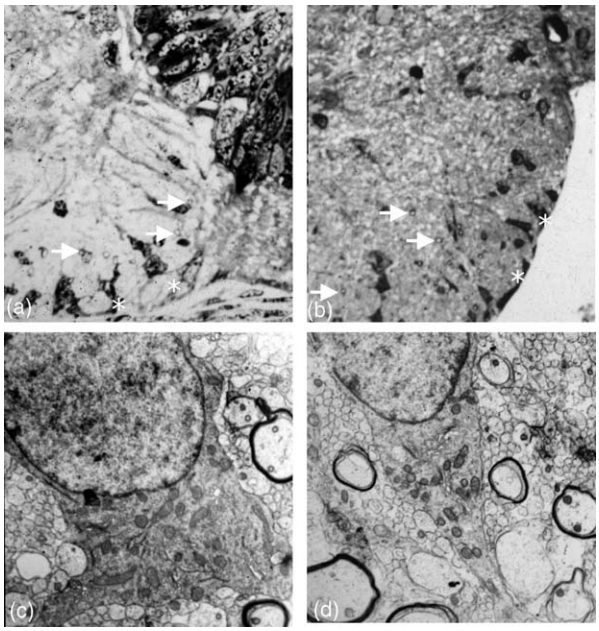

Figure 2 Transverse sections of developing ventral funiculi in spinal cords of spiny dogfish (left) and rat (right). a, From 4.5 cm spiny dogfish fetus showing the first appearances of OLs (small dark profiles lining the medial border) and initial ring-shaped myelin sheaths. b, From newborn rat pup showing similarly appearing early OLs (dark profiles) and beginning myelin sheaths. c, Electron micrograph from a 6 cm spiny dogfish fetus ventral spinal cord showing an OL (nucleus with clumped chromatin at upper left) and typical organelle-rich perinuclear cytoplasm with a few large-caliber axons in early stages of myelination. Many small unmyelinated axons also surround the OL. d, Electron micrograph from a P2 neonatal rat pup ventral spinal cord with a similar-appearing OL with surrounding large axons in early stages of myelination and clusters of many small-caliber unmyelinated axons. Arrows in (a) and (b) point to early myelin sheaths and asterisks (*) mark the tissue border. Adapted from Schweigreiter, R., Roots, B. I., Bandtlow, C. E., and Gould, R. M. 2006. Understanding myelination through studying its evolution. *Int. Rev. Neurobiol.* 73, 219–273, Elsevier.

myelinated fibers increase dramatically. When the fetus has more than doubled its size, large numbers of myelinated fibers and few OLs occupy a cross section of ventral cord (Figure 3a). Even though the ventricle seems filled with large-caliber myelinated fibers, there are still many very small fibers that are totally disregarded. At the electron microscopic level, these fibers are still bundled tightly together (Figure 3b). That these axons are eventually myelinated can be seen when a comparable region of ventral spinal cord is imaged in the adult spiny dogfish (Figure 3c). By this time, i.e., after several years, the entire funiculus is composed of myelinated fibers of widely different caliber. An evolutionary important lesson is that OLs show an absolute selectivity for those axons that are enlarging while

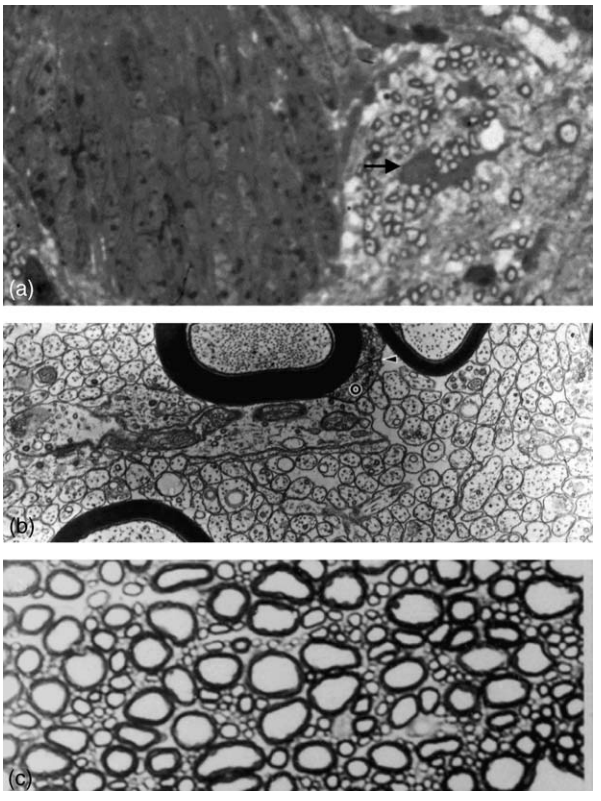

Figure 3 a, Transverse section from the ventral funiculus in the spinal cord of a 13 cm spiny dogfish, myelination. Now there are many myelinated fibers and a few OL profiles (arrow) per cross section. b, What is not appreciated is the very large number of small nonmyelinated fibers that are still present in the ventral spinal cord and can only be seen when viewed through the electron microscope. c, In the same region of the adult spiny dogfish spinal cord, axons of wide-ranging sizes are all myelinated.

disregarding small-caliber axons. Evidence is emerging as to signaling molecules important for this recognition (see following section).

As in the CNS, the Schwann cell-based PNS myelin is highly similar among vertebrates. Again, we will show examples from spiny dogfish to illustrate this point (Figure 4). We have followed the development of trigeminal nerve in spiny dogfish fetuses of 2–26 cm, the latter being the size at birth. In the smallest fetuses, bundles of axons are surrounded by an outer layer of immature Schwann cells, much like those seen in mice and rats (Figure 2; Jessen and Mirsky, 2005). When the fetuses reach 6 cm, nearly all the trigeminal axons are separated from all of their neighbors by Schwann cells (Figure 4A). A few have layers of noncompacted and compacted myelin (not shown). When the fetus reaches 13 cm in size, all of the axons are myelinated (Figure 4B). Myelin sheaths are related to Schwann cells in the same manner that has been described most frequently for the mammalian PNS (Peters *et al.*, 1991).

2.23.4 Biochemical and Molecular Features of Vertebrate Myelin Sheaths

Based on structural differences (high lipid content and large expanses of compact membrane layers), methods that separated mammalian brain and peripheral nerve myelin from other membranes were developed in the 1960s (Albers, 1981; Quarles *et al.*, 2005). Fortunately, these methods

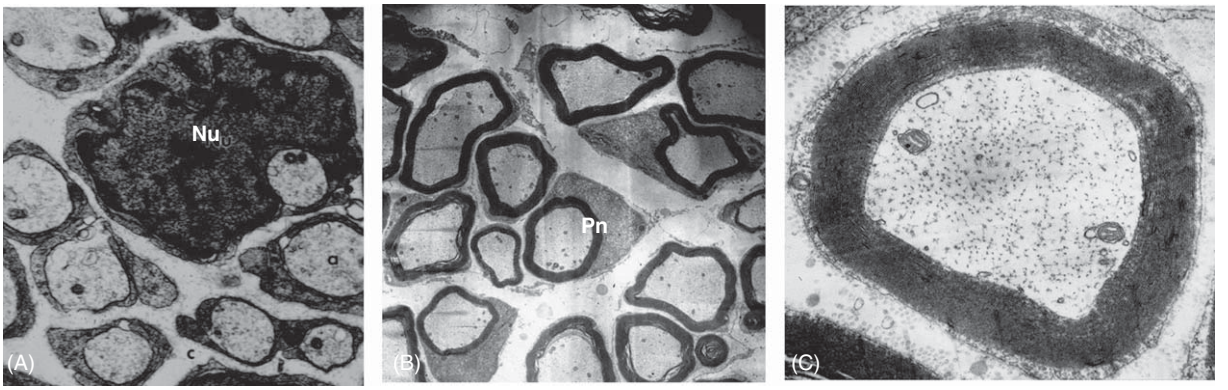

Figure 4 Transverse section of developing trigeminal nerve in spiny dogfish fetuses that were either 4.5 cm (A) or 22 cm (B and C). A, During early development, axons (a) reach a critical size (all axons in the field have reached this size) when they become separated from all neighboring axons and are covered by single Schwann cells segmentally arranged. A large nucleus (Nu) of one Schwann cell indicates that the section is taken at the point where the Schwann cell soma is found. Collagen-filled (c) extracellular space separates each individually ensheathed axon. B, At later developmental stages all larger trigeminal axons are myelinated with sheaths of thicknesses that relate to axon caliber. As at earlier times, axons sectioned near the center of the myelinating cell display nuclei and/or perinuclear (Pn) Schwann cell cytoplasm. C, At high magnification enrichment of neurofilaments and microtubules in the axon along with a few motochondria and smooth membranes are visible. A thin rim of organelle-filled Schwann cell cytoplasm surrounds compact myelin and a basal lamina covers the surface.

easily adapt to the isolation of myelin-like membranes from invertebrate neural tissues (see above) and from non-mammalian vertebrate neural tissues (Mehl and Halaris, 1970; Franz *et al.*, 1981; Waehneldt *et al.*, 1984). Analyses of myelin fractions from species representing each group of modern-day gnathostomes confirmed that, as in mammalian myelin preparations, they contain an abundance of lipids (70–80% of the isolated membrane fraction dry weight), including high portions of cholesterol, galactolipids, and ethanolamine plasmalogen (Bürgisser *et al.*, 1986; Kirschner and Blaurock, 1992), and a relatively simple protein profile (Waehneldt *et al.*, 1986a).

The major proteins in mammalian myelin, like those in invertebrate myelin, are of low molecular weight. In general antibodies recognizing mammalian myelin proteins recognize homologs in non-mammalian brain and nerve samples (Waehneldt *et al.*, 1986a). These studies revealed that all vertebrate myelin sheaths contain a dominant protein, either P_0 (one or two bands) or PLP (with a less abundant alternatively spliced variant, DM-20, absent only in amphibians; for review, see Waehneldt, 1990; Maisey, 1986). All peripheral nerve myelin, from elasmobranches to mammals, have P_0-based myelin sheaths. The difference between fish and tetrapods lies in CNS myelin. Cartilaginous and bony fishes express P_0, the same protein(s) they express in their PNS. In contrast, all tetrapod CNS myelin is PLP-based. This difference was first recognized through immunoblot comparisons of the proteins from fish and tetrapod myelin preparations (Franz *et al.*, 1981; Waehneldt *et al.*, 1985). This difference is apparent at the structural level as sheaths with P_0 have wider intraperiod lines, double in appearance. The difference is seen by both electron microscopy and X-ray diffraction (Kirschner *et al.*, 1984, 1989; Waehneldt *et al.*, 1984; Kirschner and Blaurock, 1992). Recent evidence that further supports the correlation of P_0 and wider intraperiod lines was obtained with transgenic mice with P_0 substituted for PLP (Yin *et al.*, 2006). A possible reason why the P_0-based CNS myelin of teleost and cartilaginous fishes evolved to PLP-based CNS myelin in amphibians and other tetrapods was recently suggested (Schweitzer *et al.*, 2006). Since the growth of the brain cases of tetrapods slows in adulthood, the tighter packing of a PLP-based CNS myelin would allow more myelin in a limited space.

Although PLP/DM-20 (fish do not have exon 3b, the PLP-specific exon; see below) and P_0 are co-expressed in amphibians (Takei and Uyemura, 1993; Yoshida and Colman, 1996) and teleost fishes (Schweitzer *et al.*, 2006), differences in intraperiod spacing (Kirschner and Blaurock, 1992) reflect the dominance of PLP in amphibian myelin and P_0 in fish myelin. P_0 is present at roughly 50% of total myelin protein, at least in mammalian PNS (Greenfield *et al.*, 1973), and additional information on properties of P_0 can be obtained in several reviews (Spiryda, 1998; Eichberg, 2002; Kirschner *et al.*, 2004). It is type I (single transmembrane) glycoprotein, a smallest member, which has a single immunoglobulin domain, of the immunoglobulin superfamily, and has HNK-1-reactive antigens in many species (Quarles, 2002). Other post-translational modifications include sulfation and fatty acylation. It is involved in adhesion at both the intraperiod and major dense lines (Kirschner *et al.*, 1996; Shapiro *et al.*, 1996). P_0 homologues were not detected in ascidians (Gould *et al.*, 2005), indicating that this protein likely evolved after the common gnathostome ancestor separated from the lineage leading to extant hemichordates.

PLP and DM-20 are tetraspan proteins of an ancient family, termed lipophilins (Gow, 1997; Hudson, 2004; Gould *et al.*, 2005; Schweitzer *et al.*, 2006), with both N- and C-terminal regions in the cytoplasm. Although PLP is restricted to tetrapod CNS myelin, DM-20-like proteins are present in teleost fish (Tohyama *et al.*, 1999, 2000; Brosamle and Halpern, 2002; Schweitzer *et al.*, 2006), elasmobranch (Kitagawa *et al.*, 1993; Sinoway *et al.*, 1994), and amphibians (Yoshida and Colman, 1996). The difference between PLP and DM-20 is a 35-amino-acid sequence (exon 3b), present in PLP, that lies in the cytoplasmic loop between the second and third transmembrane domain. There are two different proteins that resemble DM-20, called M6A and M6B. The latter proteins are expressed in neurons and probably to much lesser extents in glial cells (Yan *et al.*, 1996; Werner *et al.*, 2001). Homologues of these DM-20/M6a/M6b proteins have been identified in insects (Stecca *et al.*, 2000; Schweitzer *et al.*, 2006) and basal chordates (Gould *et al.*, 2005; Schweitzer *et al.*, 2006) based on database screening. High conservation of their structure and genomic organization indicates a widespread evolutionary importance of this protein family. The high number of PLP/DM-20 sequences has been used as one base for determining phylogenetic relationships among vertebrate groups (Tohyama *et al.*, 2000; Venkatesh *et al.*, 2001). Another less abundant tetraspan protein of mammalian PNS myelin is PMP22, a protein studied in part because mutations are related to peripheral nerve diseases (Suter and Scherer, 2003; Young and Suter, 2003; Suter, 2004). It is found in zebra fish (Wulf *et al.*, 1999)

and a homologue was identified in ascidian (Gould *et al.*, 2005), indicating that several tetraspan proteins, lipophilins, PMP22/claudins, and connexins may have been used for the original development of myelin sheaths.

MBP, a family of alternatively spliced members, is present in all CNS and PNS myelin sheaths (Campagnoni, 1988; Martenson and Uyemura, 1992) and, because of its recognized importance, has been termed the executive myelin protein (Moscarello, 1997). MBP is a member of the intrinsically disordered, highly adapted proteins (Harauz *et al.*, 2004). Perhaps with the openness of structure comes an attraction for post-translational modifications, which are numerous (Moscarello, 1997; Harauz *et al.*, 2004). The only study of post-translational modification of MBP in a nonmammal was conducted with MBP isolated from spiny dogfish brain and spinal cord. Modifications include phosphorylation, deamidation, and likely deimidation and praline hydroxylation. Clearly studies of MBP post-translational modification in other nonmammalian species will help clarify our emerging understanding of the roles these proteins play in glial cell development and myelination. Classic MBPs, the series of alternatively spliced proteins present in myelin, are members of a larger family of genes of OL lineage (GOLLI) that include four additional proteins transcribed from two additional upstream promoters (Campagnoni and Campagnoni, 2004). MBPs are needed for major dense line (extrusion of intervening myelin), as mutant mice (shiverer and mld) and rats (Long Evans shaker) that lack MBP have little myelin and, when it occurs, it is poorly compacted and contains an abundance of trapped cytoplasm (Privat *et al.*, 1979; Ganser and Kirschner, 1980; Kwiecien *et al.*, 1998). Furthermore, mammalian MBP isoforms that contain exon-2 are expressed developmentally early (Barbarese *et al.*, 1978), are enriched in radial component (Karthigasan *et al.*, 1996), a structure unique to CNS myelin (see below) and are targeted to nuclei where they may function in transcriptional regulation (Pedraza *et al.*, 1997). Interestingly, most likely the sequence for exon-2 does not occur in teleost fishes or amphibians based on analyses of the *Xenopus*, zebra fish and pufferfish databases (Gould, unpublished observations). Furthermore, only a single MBP homologue was identified in zebra fish (Brosamle and Halpern, 2002; Lyons *et al.*, 2005). Two alternative splice variants have been reported in elasmobranches, though both lack exon-2 (Saavedra *et al.*, 1989; Spivack *et al.*, 1993). cDNA sequences in the pufferfish database suggest some alternative splicing occurs there as well. Analysis of differences of MBP sequences can shed light on regions of the protein that might be used for signaling and for myelin compaction. A triproline region in mammalian and amphibian MBPs, thought to be structurally important in forming a hairpin loop, is absent in fish MBPs. No MBP homologues were detected in searches of the ascidian genome database (Gould *et al.*, 2005), indicating that, like P_0, MBP developed late in evolution.

In addition to P_0, MBP, and PLP/DM-20, there are a growing number of proteins associated with myelin sheaths proper and the process of myelination, based on comparison of earlier (Braun, 1984; Campagnoni, 1988) and later (Lazzarini *et al.*, 2004) reviews. Evolutionary studies of myelin proteins occurred at the time when the major structural proteins in isolated myelin were the focus (Waehneldt *et al.*, 1986b; Waehneldt, 1990; Jeserich and Waehneldt-Kreysing, 1992; Kirschner and Blaurock, 1992). Two minor-occurring proteins, CNP (Kurihara and Tsukada, 1967; Tsukada and Kurihara, 1992) and MAG (Everly *et al.*, 1973), have long histories as myelin-related proteins. Immunocytochemical studies have demonstrated that they are located near, but not within, compact myelin (Trapp *et al.*, 1988, 1989). CNP is present in bird and amphibian myelin (Kasama-Yoshida *et al.*, 1997), though not in fish myelin (Kasama-Yoshida *et al.*, 1997; Moll *et al.*, 2003). A related protein, goldfish regeneration-induced CNPase homologue (gRICH) that lacks CNPase activity, has been identified in goldfish (Ballestero *et al.*, 1995, 1997, 1999). A comprehensive review on CNP (Braun *et al.*, 2004) can be consulted for additional information. Furthermore, a recent study of transgenic mice lacking CNP expression suggests a crucial role for this protein in axon–glial cell communication (Lappe-Siefke *et al.*, 2003). Antibody-based evidence that MAG is ubiquitously expressed (Matthieu *et al.*, 1986) had been disputed (Zand *et al.*, 1991; Hammer *et al.*, 1993) and the issue was not resolved until recent screening of pufferfish and zebra fish genomes identified several MAG, also called siglec 4 (sialic acid-binding protein), isoforms in these fish (Lehmann *et al.*, 2004). Finding fish homologues of MAG, a protein associated with inhibition of myelin regeneration in the mammalian CNS (Filbin, 1995), will clearly impact efforts to understand the evolutionary loss of CNS regeneration. Another minor-occurring protein restricted to PNS myelin is PMP22, a protein involved in the process of myelin sheath formation (see above; Suter, 2004; Amici *et al.*, 2006), present in amphibians (*Xenopus* genome project) and fish (Wulf

et al., 1999), and which has a homologue in the ascidian, *Ciona intestinalis* (Gould *et al.*, 2005).

Within compact CNS myelin are radial bands, structures seen with electron microscopy (Peters, 1961). Although not studied widely, they are also found in amphibian CNS myelin (Schnapp and Mugnaini, 1976; Tabira *et al.*, 1978), though not any PNS myelin (Kosaras and Kirschner, 1990). Interestingly, the key structural proteins of radial bands, exon-2-containing MBP isoforms (Karthigasan *et al.*, 1996) and myelin-associated oligodendrocytic basic proteins (MOBP) (Yamamoto *et al.*, 1999), have not been identified in amphibians and other nonmammalian species.

Nodes of Ranvier, regions between internodal myelin and bracketed by paranodal loops, contain high concentrations of sodium channels and other proteins that are delivered to these sites via axonal transport (Poliak and Peles, 2003; Salzer, 2003). In the PNS, they are covered by microvillar extensions of adjacent Schwann cells. In the CNS, they are covered by a totally different cell, which is related to CNS astrocytes (ffrench-Constant *et al.*, 1986; Black *et al.*, 1989; Butt *et al.*, 1999) and expresses a proteoglycan, NG2 (Butt *et al.*, 1999; Martin *et al.*, 2001), that is well associated with the OL lineage (Dawson *et al.*, 2000). Almost nothing is known about the structural properties of nonmammalian proteins located in nodes of Ranvier and surrounding paranodes and juxtaparanodes. From comparative studies of proteins present in compact myelin, it is likely that antibodies to mammalian nodal, paranodal, and juxtanodal proteins will identify nonmammalian homologues and it would be rather straightforward to determine whether proteins involved in node and paranode formation and function behave the same in nonmammalian settings. Interestingly, some of the key components of paranodal junctions, contactin, and neurexin family proteins are used in glial ensheathment in insects (Bhat, 2003; Banerjee *et al.*, 2006).

A totally unrelated area that has not been considered from an evolutionary viewpoint is the origin of myelin-forming Schwann cells and OLs. The few studies that have been done with chickens and frogs are enmeshed in studies of mammals without due recognition of evolutionary significance (Richardson *et al.*, 2000, 2006; Qi *et al.*, 2002; Miller and Reynolds, 2004; Noble *et al.*, 2004; Rowitch, 2004; Jessen and Mirsky, 2005). A few studies have taken advantage of zebra fish with respect to understanding roles of olig family helix–loop–helix transcription factors (Park *et al.*, 2002; Shin *et al.*, 2003; Filippi *et al.*, 2005). Hopefully, the future will include a re-assessment of these studies in the light of evolution.

In addition a number of screens have emerged, including ones that identify proteins: (1) synthesized from mRNAs transported along with MBP mRNA to OL processes (Gould *et al.*, 2000); (2) essential for the development of myelin phenotypes in zebra fish, including transport of MBP mRNA to processes (Lyons *et al.*, 2005) and clustering of sodium channels at nodes (Talbot, personal communication); and (3) based on the presence of a signal sequence that targets Schwann cell proteins to plasma membranes, where they may be involved in interactions with axons and/or the basal lamina. The first screen has been applied to spiny dogfish and shows that some OL process mRNAs, though surprisingly, not MBP mRNA, are common to both fish and mammals (Gould, unpublished observations).

Studies of protein evolution are clearly impacting research on CNS myelin proteins with inhibitory influences on regeneration (Diekmann *et al.*, 2005; Schweigreiter *et al.*, 2006). Briefly, what these and others are doing is characterizing proteins, expressed in CNS myelin and/or OLs that inhibit regrowth of damaged CNS axons. It is well known that fish, some amphibians, chicks, and some mammals (Gaze, 1970; Stuermer *et al.*, 1992; Ferretti *et al.*, 2003) – the latter at premyelination stages only – are able to regenerate CNS axons following injury. Although it is not entirely clear why the ability to regenerate CNS axons is lost in birds and mammals following myelination, the presence of candidate proteins, including NOGO/RTN isoforms (Cadelli and Schwab, 1991; Chen *et al.*, 2000; GrandPré *et al.*, 2000; Prinjha *et al.*, 2000), NOGO/RTN receptor (Fournier *et al.*, 2001), MAG, and OL myelin glycoprotein (OMgp) (Spencer *et al.*, 2003; Woolf, 2003; Raisman, 2004; Sandvig *et al.*, 2004; Schwab, 2004; Domeniconi and Filbin, 2005; Schweigreiter *et al.*, 2006) suggests that there was a need to inhibit axon growth/elongation in regions (myelin-rich) where these proteins are located. With the identification of some of these molecules in fish (see above references), it will be possible to compare structural features of the proteins and expression patterns as a means to understand how they might selectively inhibit mammalian CNS regeneration.

Another important area that has not been considered from an evolutionary point of view is the axon–glial cell cross-talk involved in different stages of myelination. With rapid progress in mammalian systems, this is another area that should receive attention from evolutionary myelin biologists. Only when axons reach appropriate size, i.e., develop unique surface character, such as expressing sufficient amounts of neuregulin-1 type III on their surface, will OLs (Sherman and Brophy, 2005) and Schwann cells (Nave and Schwab, 2005; Sherman

and Brophy, 2005; Taveggia *et al.*, 2005) myelinate them. Furthermore, myelin thickness, at least in peripheral nerves, is dependent on the same neuregulin-erbB receptor signaling (Michailov *et al.*, 2004; Nave and Schwab, 2005). With knowledge of developmental time course of myelination in nonmammals, including birds (Ono *et al.*, 1995), reptiles (Nadon *et al.*, 1995), amphibians (Tabira *et al.*, 1978), teleost (Jeserich and Rauen, 1990), and cartilaginous fishes (Gould *et al.*, 1995), investigators will find ways of approaching evolutionary aspects of axon–glial cell interactions that are important for myelination.

2.23.5 Summary and Conclusions

One might wonder why, with the rapid progress in mammalian cell biology and molecular biology, the availability of many mammalian mutants with defects in myelination, and the knockout and knockin strategies to influence myelin-related proteins of interest, one should devote and, probably more importantly, fund efforts to study myelination in nonmammalian species. From the information already presented, it is clear that there has been an evolutionary driving force for generating myelinated axons that includes not only all gnathostomes, but also many invertebrates. Particularly in invertebrates, a variety of strategies have been developed and, clearly, knowledge of these strategies will provide a broader base for understanding how interactions between neurons, their large-caliber axons, and the glial cells with which they interact were focused on myelination. Since none of the invertebrates with myelinated axons have been or (to our knowledge) are planned to be subjects of whole-genome studies, the best alternative to obtain sequence information on myelin proteins and proteins important for myelination would be through proteomic methods. It is our hope that investigators with available knowledge and facilities will consider earthworms, shrimps, and/or other annelids/crustaceans, obtain sequences of proteins present in myelin-like membranes, and use this knowledge as a starting point for developing understanding of how the proteins participate in neuron/axon-generated myelin formation.

For those interested in using nonmammalian vertebrate models, tremendous advances in genomic research involving zebra fish (Key and Devine, 2003), medaka (Shima and Mitani, 2004), two species of pufferfish (Aparicio *et al.*, 2002; Jaillon *et al.*, 2004), amphibians (Hirsch *et al.*, 2002), chordates lacking myelin (amphioxus and sea lamprey) (Mulley and Holland, 2004), and urochordates (Dehal *et al.*, 2002; Meinertzhagen *et al.*, 2004) have been made. This is an exciting time. Obtaining protein sequences in published databases is relatively easy and straightforward (Brosamle and Halpern, 2002; Lehmann *et al.*, 2004). These groups identified zebra fish, and in some instances pufferfish, MBP, PLP-related DM-20, P_0, and MAG. Protein sequence information can be used in many ways to advance myelin research. Because of evolutionary pressures, domains in protein sequences important for function are most highly conserved and sequence alignments can be used to determine these domains and searches can be performed to see if these domains have orthologues and/or paralogues. Overall this information should help in supporting and/or negating structural models of known myelin proteins (see Shapiro *et al.*, 1996; Spiryda, 1998; Kirschner *et al.*, 2004; for discussions on P_0 structure and Martenson, 1992; for discussions on MBP structure). Clearly, the studies covered in this brief review are not comprehensive and we apologize to scientists whose research efforts and relevant studies were not cited.

Acknowledgments

We would like to acknowledge the support of the National Science Foundation (grant IBN-0402188, 10 RMG) and grants from the NIH (NS 23868 and NS23320) and Natural Sciences and Engineering Research Council of Canada (grant A6052 to BIR), whose support helped allow us to write this article.

2.24 Adult Neurogenesis and Neuronal Regeneration in the Teleost Fish Brain: Implications for the Evolution of a Primitive Vertebrate Trait

G K H Zupanc, International University Bremen, Bremen, Germany

Glossary

adult neurogenesis	The generation of new neurons during adult stages of development.
hyperplasia	Growth of a tissue or an organ by an increase in the number of cells.
hypertrophy	Enlargement of a tissue or an organ as a result of an increase in size rather than the number of constituent cells.
neuronal regeneration	The replacement of neurons lost to injury or neurodegenerative diseases by newly generated ones.

2.24.1 Introduction

In mammals, the potential to generate new neurons in the intact brain, or to replace neurons lost to injury or neurodegenerative disease, is severely limited. The former phenomenon, called adult neurogenesis, is restricted to two brain regions: the anterior part of the subventricular zone of the lateral ventricle, from where the immature neurons migrate via the so-called rostral migratory stream into the olfactory bulb (Altman, 1969; Luskin, 1993; Lois and Alvarez-Buylla, 1994; Lois *et al.*, 1996; Pencea *et al.*, 2001) and the subgranular zone of the dentate gyrus, from where the new cells migrate a short distance into the granule cell layer of the hippocampus (Altman and Das, 1965; Kaplan and Bell, 1984; Eriksson *et al.*, 1998; Gould *et al.*, 1999; Kornack and Rakic, 1999; Seri *et al.*, 2001).

However, neurogenic potential also persists in several other regions of the brain beyond embryonic stages of development. From these regions, cells have been isolated that are quiescent *in vivo*, but

proliferate and develop into neurons after treatment with proper exogenous factors *in vitro*, or after transplantation into the olfactory bulb or the hippocampus (Reynolds and Weiss, 1992; Suhonen *et al.*, 1996; Weiss *et al.*, 1996; Palmer *et al.*, 1999; Kondo and Raff, 2000; Shihabuddin *et al.*, 2000; see The Evolution of Arthropod Nervous Systems: Insights from Neural Development in the Onychophora and Myriapoda).

This neurogenic potential in the intact brain is closely linked to the ability to replace damaged neurons by newly generated ones, a phenomenon commonly referred to as neuronal regeneration. Increased proliferation of progenitor cells in the subgranular and subventricular zones, and even of quiescent neural progenitor cells in regions where adult neurogenesis is absent in the intact brain, has been observed after brain injuries (Magavi *et al.*, 2000; Chen *et al.*, 2004). However, such attempts of the adult mammalian brain to regenerate fall short because of the failure of the new cells to develop further and/or to survive for sufficiently long periods of time. After experimentally induced stroke, immature neurons born in the subventricular zone migrate to the striatal area damaged through the ischemic insult. Although these cells start to express markers for striatal medium-sized spiny neurons – the phenotype most severely affected by the insult – the majority of them die within a few weeks after the stroke (Arvidsson *et al.*, 2002). Most significantly, the total number of new neuronal cells is far too low to replace the degenerated neurons. In the latter study, the number of new neurons totaled just 1600, a rather insignificant number compared to the estimated 80 000 degenerated cells.

By contrast, teleost fish exhibit an enormous potential both for adult neurogenesis and for neuronal regeneration (for reviews, see Zupanc, 1999a, 2001, 2006). New neurons are continuously produced in dozens of regions of the adult brain, and their total number is at least one, if not two orders of magnitude larger than in the adult mammalian brain. In addition, teleost fish are capable of regenerating neural tissue after injury rapidly and with high efficiency. This advantage over mammals makes it particularly interesting to study adult neurogenesis and neuronal regeneration in teleosts. Elucidation of the cellular mechanisms mediating these phenomena in fish will not only answer fundamental biological questions, but is also likely to provide important insights into the factors that limit the generation of new neurons in the adult mammalian brain. Such investigations could, therefore, form the basis to define novel strategies for wound healing and treatment of neurodegenerative diseases.

2.24.2 Approaches to Study Cell Proliferation in the Adult Brain

Studies of cell proliferation in the adult brain have been based on the incorporation of [^{3}H]thymidine or the thymidine analogue 5-bromo-2′-deoxyuridine (BrdU) into newly synthesized DNA during the S-phase of mitosis. Following a specific survival time after the systemic administration, cells that have taken up [^{3}H]thymidine or BrdU are detected through autoradiography or anti-BrdU immunohistochemistry, respectively (Figure 1). The length of the postadministration survival time is determined by the aims of the investigation. Short survival times – typically 1–2 h – are employed to provide information on the sites where cells proliferate. Longer survival times – typically days, weeks, or even

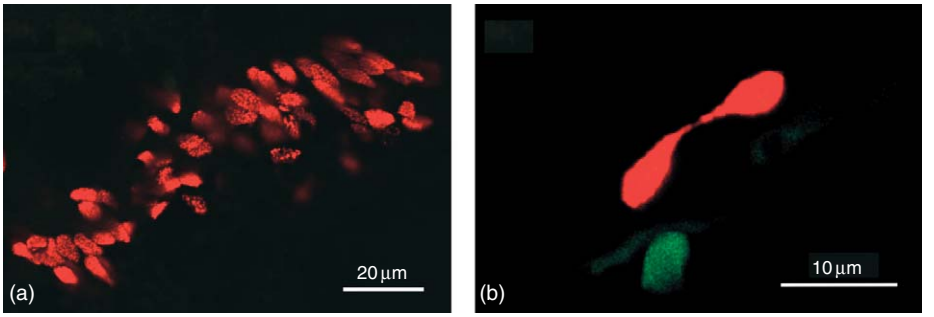

Figure 1 Confocal images of BrdU-labeled cells in the adult zebra fish brain at 2 days of survival after intraperitoneal injection of BrdU. a, Proliferation zone in periventricular gray zone of tectum opticum near its caudal end, revealed by labeling of mitotic cells with BrdU. In many of the labeled nuclei, a subdivision into labeled granules, probably corresponding to different domains of chromatin, is apparent. b, BrdU-labeled cell in ventral molecular layer of valvula cerebelli pars medialis, in the immediate vicinity of rhombencephalic ventricle. Evidently, the cell is in late telophase, as the two daughter nuclei are connected only by a thin string of labeled nuclear material. From Zupanc, G. K. H., Hinsch, K., and Gage, F. H. 2005. Proliferation, migration, neuronal differentiation, and long-term survival of new cells in the adult zebrafish brain. *J. Comp. Neurol.* 488, 290–319.

months – reveal details about the fate of the cells in S-phase at the time of the administration of [^{3}H]thymidine or BrdU. Comparison of the labeling pattern obtained after various survival times is used to reconstruct the path of migration of the young cells from their sites of proliferation to their final target site. Combination of [^{3}H]thymidine autoradiography or anti-BrdU immunohistochemistry with other methods, such as immunohistochemistry for neuron- or glia-specific markers, has proven a powerful approach to obtain information about the differentiation of the newly generated cells.

Quantitative analysis in the gymnotiform fish *Apteronotus leptorhynchus* – one of the major model systems in this area of research – has demonstrated that BrdU is metabolically available to label S-phase cells for approximately 4 h after a single intraperitoneal injection (Zupanc and Horschke, 1995). On the basis of this information, a survival time of 2 h was chosen for mapping of the proliferation zones and quantitative analysis of the rate of cell proliferation in the adult teleostean brain (Zupanc and Horschke, 1995; Zupanc *et al.*, 2005). Thus, BrdU was metabolically available for incorporation into newly synthesized DNA during the entire survival period.

2.24.3 Pattern of Cell Proliferation

Experiments employing post-BrdU-administration survival times of 2 h in *A. leptorhynchus* have shown that, on average, during any 2 h period, approximately 100 000 cells enter the S-phase of mitosis in the whole brain (Zupanc and Horschke, 1995). This corresponds to roughly 0.2% of the total number of cells in the adult brain of *A. leptorhynchus*. Approximately 25% of these new cells are generated in the telencephalon, diencephalon, mesencephalon, and rhombencephalon. The remaining 75% originate from the cerebellum.

In comparison to the enormous mitotic activity in the adult fish brain, the rate of cell proliferation in the adult mammalian brain is at least one, if not two, orders of magnitude lower. Louis and Alvarez-Buylla have estimated that, in adult mice, approximately 30 000 cells a day are formed in the subventricular zone, one of the two sites of ongoing neurogenesis in the adult mammalian brain (Louis and Alvarez-Buylla, 1994). This number corresponds to 0.03% of the estimated 110 million cells (Williams, 2000) in the whole brain of adult mice. In the dentate gyrus of the hippocampus – the second site where neurogenesis continues into adulthood in the mammalian brain – the production of only 9000 cells a day has been found in the adult rat (Cameron and McKay, 2001). The latter number corresponds to 0.003% of the approximately 330 million cells (Herculano-Houzel and Lent, 2005) in the whole brain of the adult rat.

2.24.4 Proliferation Zones in the Adult Fish Brain

Like in mammals, in the adult brain of *A. leptorhynchus* and other teleosts, the vast majority of the mitotic cells are found, at high concentrations, in small, well-defined areas of the brain (proliferation zones). Many of these zones are situated at or near the surfaces of ventricles or related systems. Although other zones, particularly in the cerebellum, are located in regions distant from any ventricle (see Section 2.24.4.4 below), many are derived from areas located at ventricular surfaces during embryonic stages of development. Then, as a result of the everted development of the fish brain during embryogenesis, the associated ventricular lumina are obliterated and translocated (Pouwels, 1978a, 1978b). In *A. leptorhynchus*, several dozen proliferation zones have been identified in the adult brain (Zupanc and Horschke, 1995; Figures 2 and 3). A similar large number has been found in two other teleostean species in which a detailed mapping of such zones has been performed – the three-spined stickleback (Ekström *et al.*, 2001) and the zebra fish (Zupanc *et al.*, 2005; Figures 4 and 5).

In the following, I will describe and discuss the pattern of cell proliferation in four regions of the teleostean brain that are of special interest from a comparative point of view: olfactory bulb, dorsal telencephalon, optic tectum, and cerebellum.

2.24.4.1 Olfactory Bulb

Quantitative analysis of BrdU labeling has shown that approximately 0.2% of all mitotic cells in the adult brain of *A. leptorhynchus* are found in the olfactory bulb. Most of these cells are spread over the external (glomerular) layer, whereas only a few mitotic cells are located in the internal cell layer (Zupanc and Horschke, 1995). Similar results have been obtained in other teleosts, including goldfish, Mediterranean barbel, carp, rainbow trout, and zebra fish (Alonso *et al.*, 1989; Byrd and Brunjes, 2001; Zupanc *et al.*, 2005). In the latter species, double-labeling experiments have revealed expression of the neuron-specific protein Hu by BrdU-labeled cells after longer survival times, indicating neuronal differentiation of the new cells (Byrd and Brunjes, 2001; Zupanc *et al.*, 2005).

Despite the low number of cells produced, neurogenesis in the olfactory bulb of teleosts is

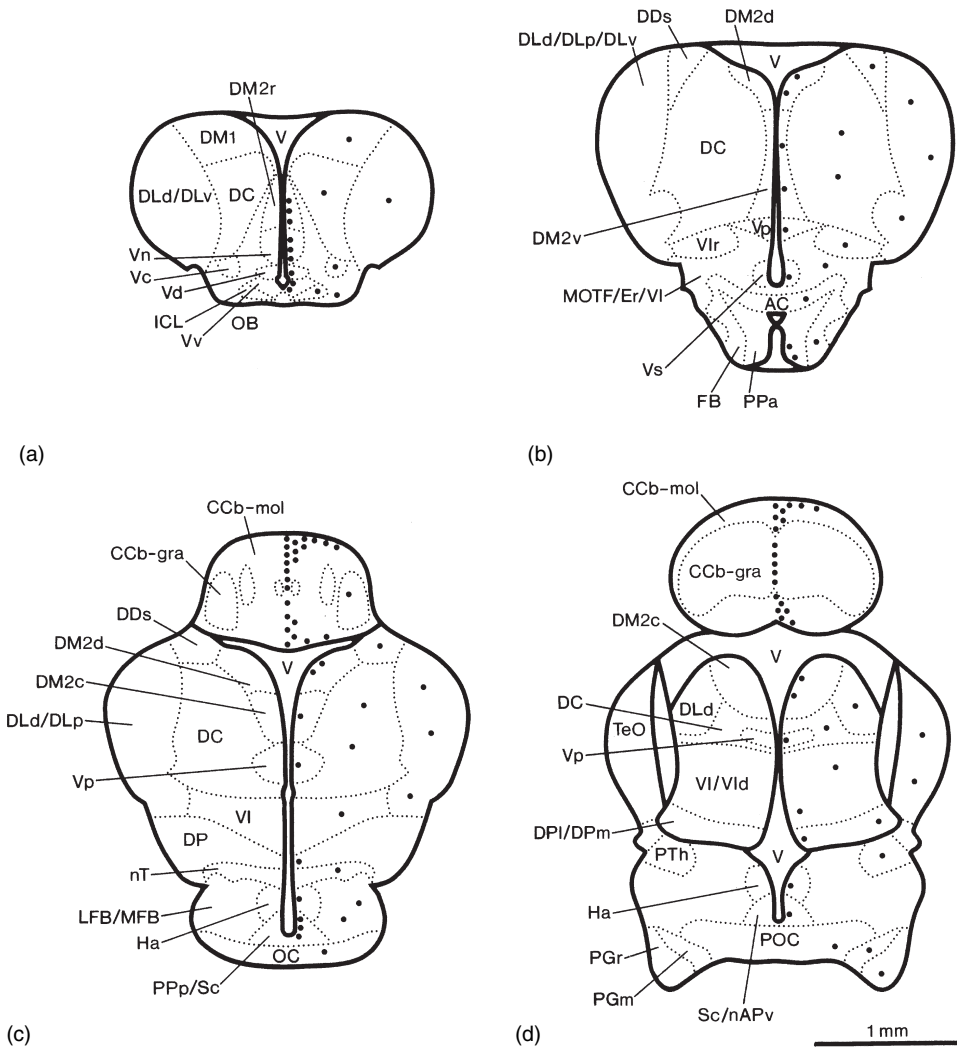

Figure 2 Proliferation zones in the telencephalon of adult *A. leptorhynchus*. The charts of transverse sections roughly correspond to levels 37 (a), 30 (b), 28 (c), and 26 (d) of the brain atlas of *A. leptorhynchus* (Maler *et al.*, 1991). Proliferation zones, as revealed by incorporation of BrdU into replicating DNA and subsequent anti-BrdU immunohistochemistry, are indicated by black dots. AC, anterior commissure; CCb, corpus cerebelli; DC, central division of the dorsal forebrain; DDs, superficial subdivision of dorsal division of the dorsal forebrain; DLd, dorsolateral telencephalon, dorsal subdivision; DLp, dorsolateral telencephalon, posterior subdivision; DLv, dorsolateral telencephalon, ventral subdivision; DM1, dorsomedial telencephalon, subdivision 1; DM2c, dorsomedial telencephalon, subdivision 2, caudal; DM2d, dorsomedial telencephalon, subdivision 2, dorsal; DM2r, dorsomedial telencephalon, subdivision 2, rostral; DM2v, dorsomedial telencephalon, subdivision 2, ventral; DP, dorsal posterior telencephalon; DPl, lateral subdivision of caudal dorsal posterior telencephalon; DPm, medial subdivision of caudal dorsal posterior telencephelon; Er, rostral entopeduncular nucleus; FB, forebrain bundle; gra, granule cell layer; Ha, hypothalamus anterioris; ICL, internal cell layer of olfactory bulb; LFB, lateral forebrain bundle; MFB, medial forebrain bundle; mol, molecular layer; MOTF, medial olfactory terminal field; nAPv, nucleus anterior periventricularis; nT, nucleus taenia; OB, olfactory bulb; OC, optic chiasma; PGm, preglomerular nucleus, medial subdivision; PGr, preglomerular nucleus, rostral subdivision; POC, postoptic commissure; PPa, nucleus preopticus periventricularis, anterior subdivision; PPp, nucleus preopticus periventricularis, posterior subdivision; PTh, nucleus prethalamicus; Sc, suprachiasmatic nucleus; TeO, optic tectum; V, ventricle; Vc, ventral telencephalon, central subdivision; Vd, ventral telencephalon, dorsal subdivision; Vl, ventral telencephalon, intermediate subdivision; Vld, ventral telencephalon, intermediate dorsal subdivision; Vlr, ventral telencephalon, intermediate rostral subdivision; Vl, ventral telencephalon, lateral subdivision; Vn, ventral telencephalon, nother subdivision; Vp, ventral telencephalon, posterior subdivision; Vs, ventral telencephalon, supracommissural subdivision; Vv, ventral telencephalon, ventral subdivision. interesting because the bulb is one of the two brain regions in which adult neurogenesis has been consistently demonstrated in mammals. Investigations in the latter taxonomic class have shown that progenitor cells of these neurons undergo cell division in the anterior part of the subventricular zone surrounding the lateral ventricles. From this proliferation zone, the neuroblasts

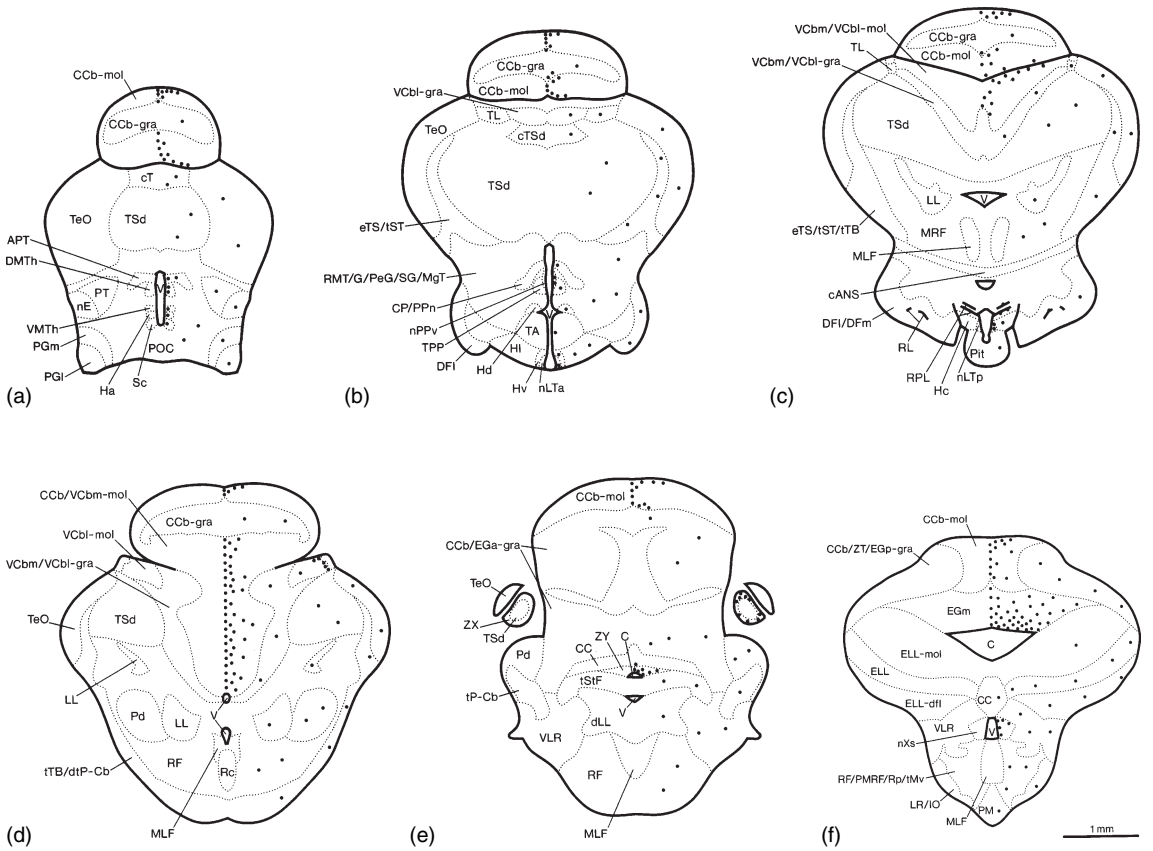

Figure 3 Proliferation zones in the diencephalon, mesencephalon, and rhombencephalon of adult *A. leptorhynchus*. The charts of transverse sections roughly correspond to levels 23 (a), 17 (b), 13 (c), 7 (d), 2 (e), and 8 (f) of the brain atlas of *A. leptorhynchus* (Maler *et al.*, 1991). Proliferation zones were revealed through labeling of mitotic cells with BrdU and are indicated by black dots. migrate, as chains of closely apposed cells, over several millimeters along a specific pathway – the rostral migratory stream – to the olfactory bulb, where they differentiate predominantly into granule neurons and, to a lesser extent, periglomerular interneurons (Altman, 1969; Luskin, 1993; Lois and Alvarez-Buylla, 1994; Lois *et al.*, 1996; Pencea *et al.*, 2001).

2.24.4.2 Dorsal Telencephalon

Among all telencephalic areas, the number of mitotic cells is largest in the dorsal, ventral, and posterior

Neurol.* 488, 290–319.

subdivisions of the dorsolateral telencephalon of *A. leptorhynchus* (Zupanc and Horschke, 1995). A similar concentration of proliferating cells has been reported for two other teleostean species, the three-spined stickleback (Ekström *et al.*, 2001) and the zebra fish (Zupanc *et al.*, 2005). Cells appear to proliferate in comparable areas of the dorsal telencephalon in the gilthead sea bream (Zikopoulos *et al.*, 2000), although comparison of the latter investigation with the results of the former studies is hampered by the rather coarse analysis of the distribution and the relative number of BrdU-labeled cells.

The high proliferative activity in the dorsolateral telencephalon is especially remarkable from a comparative point of view. Based both on neuroanatomical evidence (Northcutt and Braford, 1980; Nieuwenhuys and Meek, 1990; Braford, 1995; Northcutt, 1995; Butler, 2000; Vargas *et al.*, 2000) and on the results of functional studies (Rodríguez *et al.*, 2002; Portavella *et al.*, 2004), the lateral pallium of actinopterygian fishes (encompassing areas referred to in the zebra fish as the posterior zone of the dorsal telencephalic area and the ventral portion of the lateral zone of the dorsal telencephalic area) is thought to be homologous to the medial pallium or hippocampus of amniotes.

In mammals, the hippocampus is the second brain region in which adult neurogenesis continues into adult stages of development. New cells are formed in the subgranular zone of the dentate gyrus, from where the new cells migrate a short distance into the granule cell layer of the hippocampus and develop into mature granule neurons (Altman and Das, 1965; Kaplan and Bell, 1984; Eriksson *et al.*, 1998; Gould *et al.*, 1999; Kornack and Rakic, 1999; Seri *et al.*, 2001). Similarly, neurogenesis has been found in the adult hippocampus of reptiles (López-García *et al.*, 1988) and birds (Barnea and Nottebohm, 1994).

The subsequent development of the cells generated in the dorsal telencephalon has been examined in some detail in zebra fish by combining BrdU labeling with immunostaining against the neuron-specific marker protein Hu after post-BrdU administration survival times of up to 9 months (Zupanc *et al.*, 2005). These experiments demonstrated a large number of double-labeled cells in the medial, lateral, and posterior zones of the dorsal telencephalic areas, thus including the structure presumably homologous to the mammalian hippocampus. Most significantly, the number of these new neurons was several-fold larger than that in all remaining brain areas. This observation can be used as evidence for the importance of adult neurogenesis in the dorsal telencephalon of zebra fish. However, the function of this phenomenon remains elusive.

Some indication of the possible function of adult neurogenesis in the hippocampus has been obtained in mammals and birds. In the rat, more than an estimated 250 000 new cells are generated in the hippocampal dentate gyrus per month (Cameron and McKay, 2001). Roughly 50% of these cells acquire immunological properties of neurons within less than 2 weeks after entering the S-phase of mitosis. This number of new granule neurons generated each month corresponds to approximately 6% of the total size of the granule cell population, thus suggesting that adult neurogenesis plays an important role in the hippocampus. This notion is reinforced by the demonstration that the newly generated neurons in the rodent hippocampus exhibit physiological properties of mature functional hippocampal neurons (van Praag *et al.*, 2002). Furthermore, a number of functional studies suggests a close relationship between adult neurogenesis and certain types of learning mediated by the hippocampus. Such investigations have, for example, demonstrated that an enriched environment and learning enhance neurogenesis, especially through increasing the rate of survival of new neurons, whereas an experimentally induced reduction in neurogenesis results in an impaired performance in specific hippocampus-dependent learning tasks (Kempermann *et al.*, 1997; van Praag *et al.*, 1999; Shors *et al.*, 2001, 2002).

Evidence for an involvement of hippocampal adult neurogenesis in learning and memory processes has also been obtained through investigations in birds. In black-capped chickadees, it has been shown that newly formed neurons appear in the hippocampal complex during all times of the year, but with a marked peak in the fall (Barnea and Nottebohm, 1994). The new neurons live for a few months and then disappear. The peak in the formation of new neurons in the fall correlates with pronounced changes in the feeding behavior of chickadees. Then the diet shifts from insects to seeds. The birds hide a certain portion of these seeds and retrieve them after a period of hours or days. This requires enhanced spatial memory capabilities, which could be enabled by the recruitment of new neurons. In line with this hypothesis is the finding that there are more hippocampal neurons in juvenile chickadees than in adults (Barnea and Nottebohm, 1996). Similar to the situation in the fall, the excess production of neurons during juvenile stages is related to the need to learn a disproportionally huge amount of novel environmental information, compared to later stages when the individual is already largely familiar with its environment.

The discovery of adult neurogenesis in the teleostean homologue of the mammalian and avian

hippocampus has added an important piece of information to the biological understanding of this phenomenon. Comparison with other vertebrate taxa leads to the hypothesis that adult neurogenesis in the hippocampus is a primitive and highly conserved vertebrate trait. It will, therefore, be particularly exciting to identify the selection pressures that have led to the high degree of conservation of adult neurogenesis in the vertebrate hippocampus.

2.24.4.3 Optic Tectum

Analysis of cell proliferation has shown that in the optic tectum new cells are generated predominantly in a specific proliferation zone at the caudal pole. Such a pattern has been described for goldfish (Meyer, 1978; Raymond and Easter, 1983), *A. leptorhynchus* (Zupanc and Horschke, 1995), zebra fish (Marcus *et al.*, 1999; Zupanc *et al.*, 2005), gilthead sea bream (Zikopoulos *et al.*, 2000), and stickleback (Ekström *et al.*, 2001). The similarity in the pattern of cell proliferation among these rather distantly related species suggests that the proliferation zone in the caudal tectum is a widespread, and probably universal, source of germinal cells in the adult brain of teleosts.

In both zebra fish and *A. leptorhynchus* (Zupanc *et al.*, 2005; G. K. H. Zupanc, unpublished observations), examination of sections through the optic tectum taken after various post-BrdU survival times has indicated that the vast majority of the new cells continue to reside in the proliferation zone of the caudal tectum. Similar results have been obtained in goldfish by labeling of new cells with tritiated thymidine and examination of autoradiographs after various postadministration survival times (Meyer, 1978; Raymond and Easter, 1983). Taken together, these results suggest that the optic tectum grows primarily from its caudal end.

Interestingly, the presence of the proliferation zone in the caudal optic tectum appears to be independent of whether or not sensory input is dominated by the visual modality in the various species. Whereas in zebra fish, goldfish, guppy, stickleback, and gilthead sea bream visual cues play a predominant role in the context of many behaviors, *A. leptorhynchus* relies to a large extent on electric input for orientation and communication. It is unknown whether the differences in the amount of input received by the optic tectum from the eye lead to a quantitative difference in the number of new cells produced during adulthood. This possibility is worth examining because the optic tectum of *A. leptorhynchus*, when compared to the rest of the brain, is significantly smaller than in more visually guided species, such as goldfish and zebra fish.

2.24.4.4 Cerebellum

In *A. leptorhynchus*, approximately 75% of all new cells produced in the adult brain originate from proliferation zones within the various subdivisions of the cerebellum (Zupanc and Horschke, 1995). Qualitative analysis suggests a similar large number of proliferating cells in the cerebellum of other teleosts, including the guppy (Kranz and Richter, 1970), gilthead sea bream (Zikopoulos *et al.*, 2000), three-spined stickleback (Ekström *et al.*, 2001), and zebra fish (Zupanc *et al.*, 2005). In *A. leptorhynchus*, in two out of the three major cerebellar subdivisions – the corpus cerebelli and the valvula cerebelli – the vast majority of the cells are generated in the respective molecular layers. In the corpus cerebelli, these proliferation zones are largely restricted to areas at and near the midline in the dorsal and ventral molecular layers. In the valvula cerebelli pars medialis, these zones are found at the midline where they form distinct cell clusters exhibiting high mitotic activity. In the valvula cerebelli pars lateralis, the mitotic cells show a rather wide distribution within the molecular layer. In the third cerebellar subdivision of *A. leptorhynchus*, the eminentia granularis, the new cells are produced in a granule cell layer, the eminentia granularis pars medialis (Zupanc and Horschke, 1995; Zupanc *et al.*, 1996). Notably, mitotic cells are also found in the granule cell layer of the lobus caudalis of zebra fish (Zupanc *et al.*, 2005); this brain structure is thought to be homologous to the eminentia granularis pars medialis of gymnotiform fish (Bass, 1982). However, the number of labeled cells in the granule cell layer of the lobus caudalis of zebra fish is markedly lower than the number in the eminentia granularis pars medialis in *A. leptorhynchus*.

2.24.5 Development of the Young Cells in the Cerebellum

The subsequent development of the newly generated cells has been studied in detail in the cerebellum of two teleostean species: *A. leptorhynchus* and zebra fish. In the following, I will discuss several important aspects of this process.

2.24.5.1 Migration

In *A. leptorhynchus*, the new cells migrate from their sites of origin to specific target areas within the three cerebellar subdivisions (Zupanc *et al.*, 1996). These target areas are the granule cell layers

in both the corpus cerebelli and the valvula cerebelli partes lateralis and medialis (Figure 6). In the eminentia granularis, approximately 70% of the cells generated in the pars medialis migrate through the adjacent molecular layer to invade the second granule cell layer, the so-called eminentia granularis pars posterior (Figure 7). The remaining 30% of the cells continue to reside in the eminentia granularis pars medialis and the adjacent molecular layer. In all three cerebellar subdivisions, the majority of the young cells reach their target areas within 10 days after incorporation of BrdU.

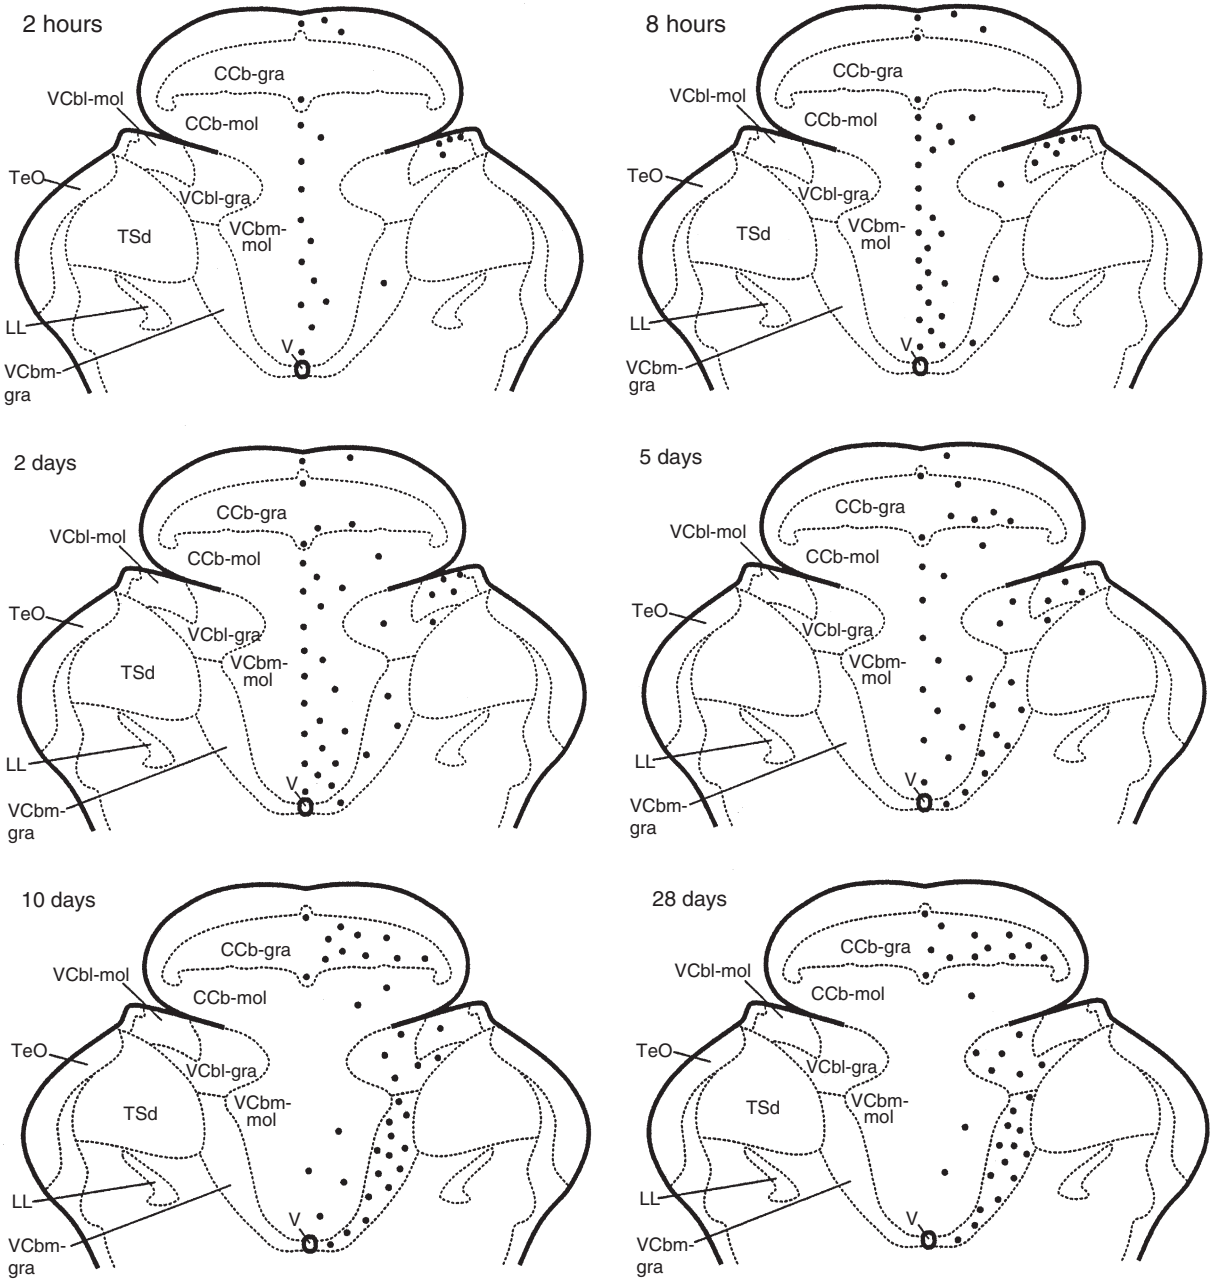

Figure 6 Development of cells generated during adulthood in the rostral cerebellum of *A. leptorhynchus*. The distribution of the young cells, identified by labeling with BrdU and indicated by black dots, is plotted after post-BrdU administration survival times ranging from 2 h to 28 days. The number of dots represents approximately the areal density of labeled cells. CCb-gra, granule cell layer of corpus cerebelli; CCb-mol, molecular layer of corpus cerebelli; LL, lateral lemniscus; TeO, optic tectum; TSd, dorsal subdivision of torus semicircularis; V, ventricle; VCbl-gra, granule cell layer of valvula cerebelli pars lateralis; VCbl-mol, molecular layer of valvula cerebelli pars lateralis; VCbm-gra, granule cell layer of valvula cerebelli pars medialis; VCbm-mol, molecular layer of valvula cerebelli pars medialis. After Zupanc, G. K. H., Horschke, I., Ott, R., and Rascher, G. B. 1996. Postembryonic development of the cerebellum in gymnotiform fish. *J. Comp. Neurol.* 370, 443–464.

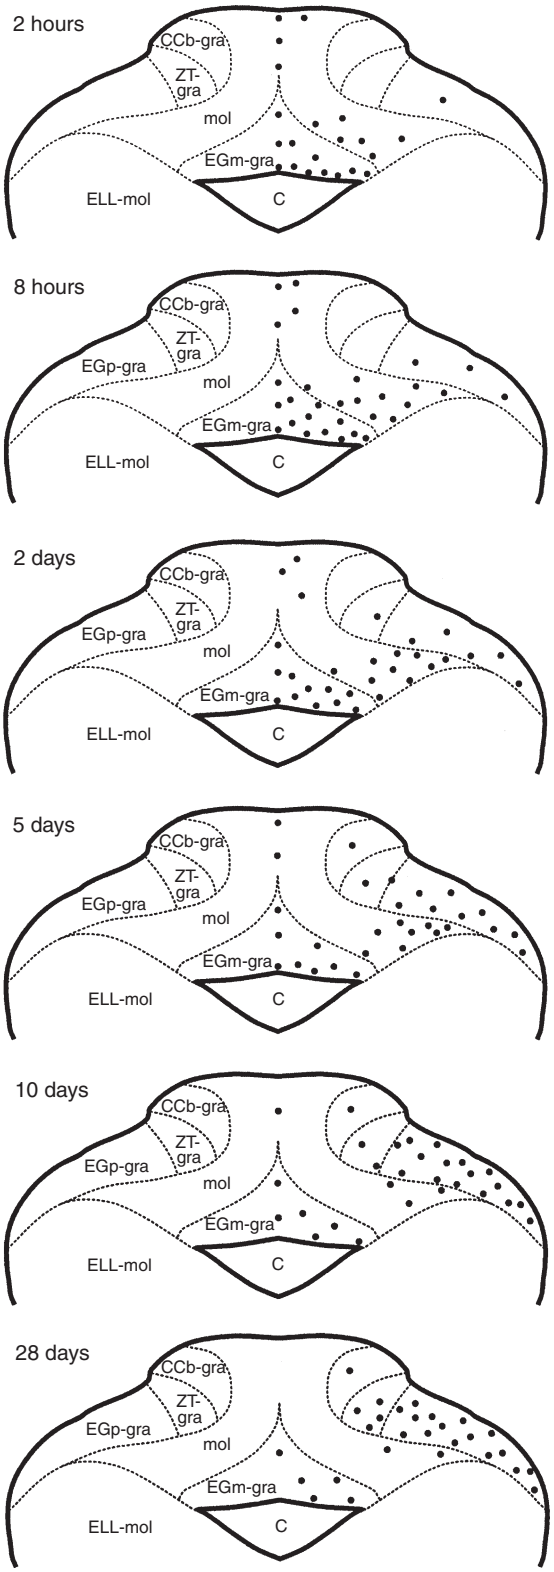

Figure 7 Development of cells born during adulthood in the caudal cerebellum of *A. leptorhynchus*. The principle of analysis and representation is identical to the one used in Figure 6. C, cerebellomedullary cistern; CCb-gra, granule cell layer of corpus cerebelli; EGm-gra, granule cell layer of eminentia granularis pars medialis; EGp-gra, granule cell layer of eminentia granularis pars posterior; ELL-mol, molecular layer of electrosensory lateral line lobe; mol, molecular layer of corpus cerebelli, eminentia granularis pars anterior, eminentia granularis pars medialis, and eminentia granularis pars posterior; ZT-gra, granule cell layer of transitional zone. After Zupanc, G. K. H., Horschke, I., Ott, R., and Rascher, G. B. 1996. Postembryonic development of the cerebellum in gymnotiform fish. *J. Comp. Neurol.* 370, 443–464.

Comparison of these patterns of migration in *A. leptorhynchus* with those found in zebra fish has revealed commonalities, but also interesting differences. As in *A. leptorhynchus*, in zebra fish the young cells generated in the corpus cerebelli and the valvula cerebelli migrate from their proliferation zones in the molecular layers to the corresponding granular layers (Zupanc *et al.*, 2005; Figure 8). In the caudal cerebellum, however, the migrational pattern differs between the two species. In contrast to *A. leptorhynchus*, there is no evidence in zebra fish that any significant portion of the cells that undergo mitosis in the granular layer of the lobus caudalis – the structure homologous to the eminentia granularis pars medialis of gymnotiform fish – migrate out of this structure (Figure 9). Thus, the new cells produced in the granule cell layer of the lobus caudalis of zebra fish show a similar absence of migratory behavior, as do the resident 30% of the cells generated in the eminentia granularis pars medialis of *A. leptorhynchus*. On the other hand, the approximately 70% of the new cells generated in the eminentia granularis pars medialis of *A. leptorhynchus* that migrate to the granule cell layer of the eminentia granularis pars posterior appear to lack a matching cellular population in zebra fish. This lack might be related to the fact that, in zebra fish, the number of mitotic cells in the granular layer of the lobus caudalis relative to other proliferation zones is significantly smaller than the relative number of S-phase cells in the eminentia granularis pars medialis in *A. leptorhynchus*.

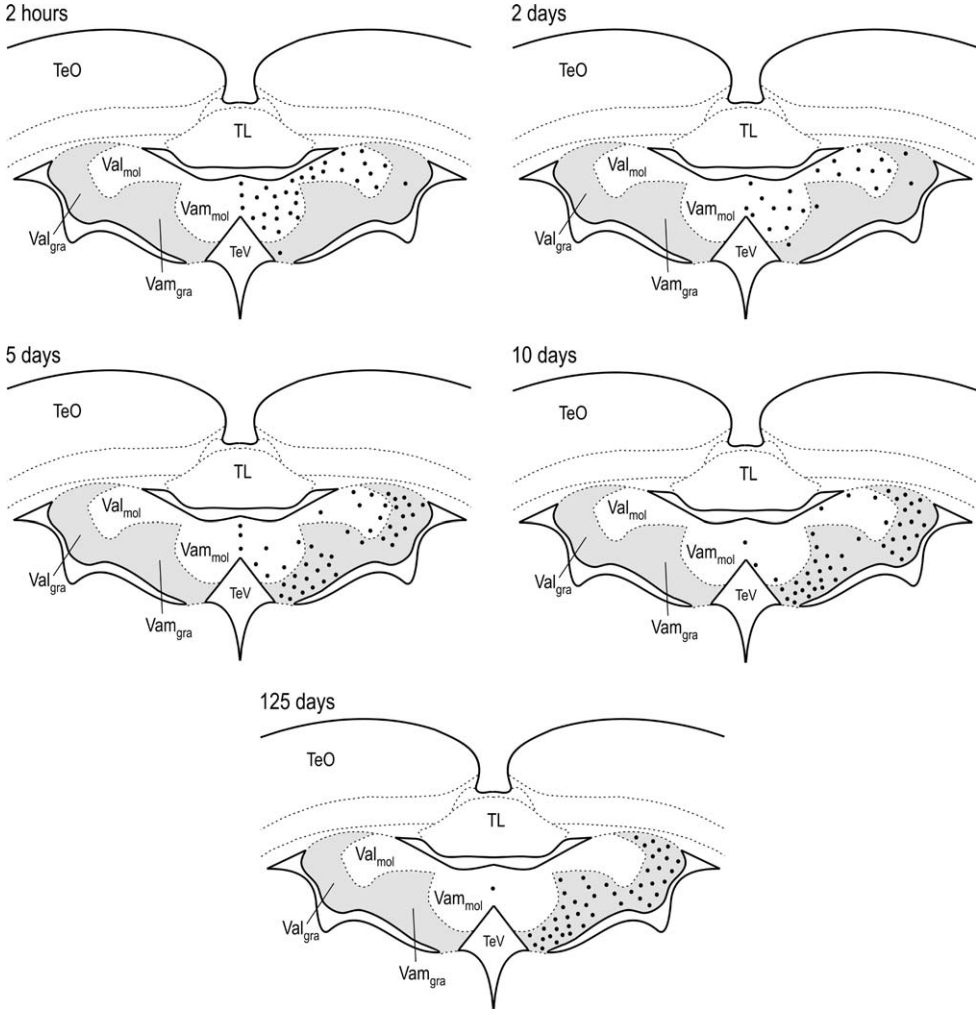

Figure 8 Schematic representation of the distribution of BrdU-labeled cells in the valvula cerebelli of adult zebra fish after various post-BrdU administration survival times. The location of labeled cells is indicated by black dots. The number of dots roughly represents the density of labeled cells in this brain region. TeO, tectum opticum; TeV, tectal ventricle; TL, torus longitudinalis; Val$_{gra}$, granule cell layer of the lateral division of the valvula cerebelli; Val$_{mol}$, molecular layer of the lateral division of the valvula cerebelli; Vam$_{gra}$, granule cell layer of the medial division of the valvula cerebelli; Vam$_{mol}$, molecular layer of the medial division of the valvula cerebelli. Neurol.* 488, 290–319.

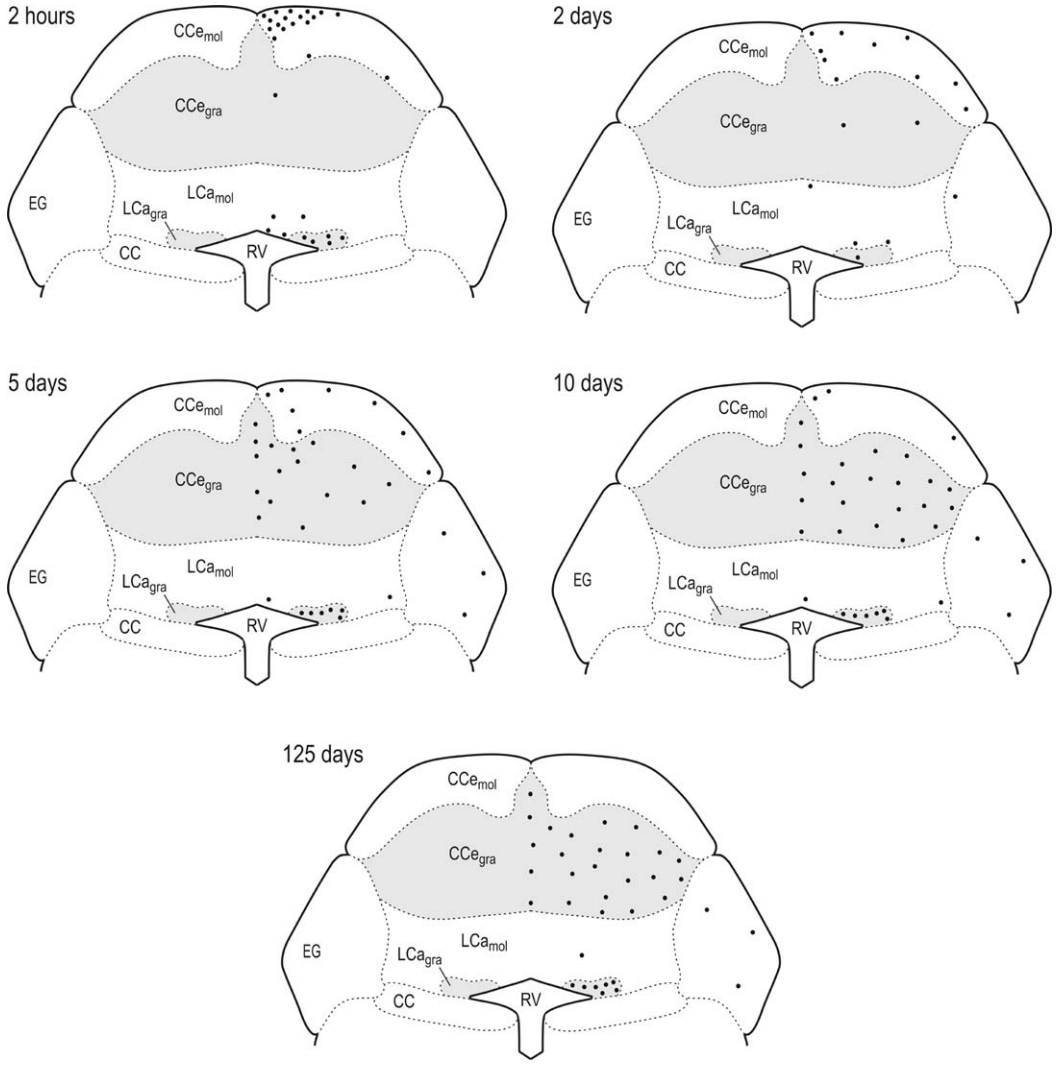

Figure 9 Schematic representation of the distribution of BrdU-labeled cells in the corpus cerebelli, eminentia granularis, and rostral part of lobus caudalis cerebelli of adult zebra fish after various post-BrdU administration survival times. The location of labeled cells is indicated by black dots. The number of dots roughly represents the density of labeled cells in this brain region. CC, crista cerebellaris; CCe$_{gra}$, granule cell layer of corpus cerebelli; CCe$_{mol}$, molecular layer of corpus cerebelli; EG, eminentia granularis; LCa$_{gra}$, granule cell layer of lobus caudalis cerebelli; LCa$_{mol}$, molecular layer of lobus caudalis cerebelli; RV, rhombencephalic ventricle. From Zupanc, G. K. H., Hinsch, K., and Gage, F. H. 2005. Proliferation, migration, neuronal differentiation, and long-term survival of new cells in the adult zebrafish brain. *J. Comp. Neurol.* 488, 290–319.

The difference in the pattern of cell proliferation between the two species might be causally linked to the massive electrosensory input received by the granule cell layer of the eminentia granularis pars posterior in gymnotiform fish (Sas and Maler, 1987), and the lack of such input in nonelectroreceptive fish. The caudal lobe and its homologous structure in gymnotiform fish may, therefore, be well suited to study, from a comparative point of view, the factors responsible for interspecies differences in proliferation and migration of new cells generated in the adult brain, as well as the functional consequences of these differences.

2.24.5.2 Guidance of the Migrating Young Cells

Several lines of evidence, obtained in *A. leptorhynchus*, suggest that, in the course of migration from their proliferation zones to the final target areas, the young cerebellar cells are guided by radial glial fibers (Zupanc and Clint, 2003). These fibers form two populations: one immunopositive for glial fibrillary acidic protein (GFAP), the other for vimentin. The morphology and distribution of these two fiber populations are similar but not identical, thus indicating a partial overlap. It is possible that in the course of their development, similar to the situation in mammals (Voigt, 1989), the fish radial glia first express vimentin, and then, while the

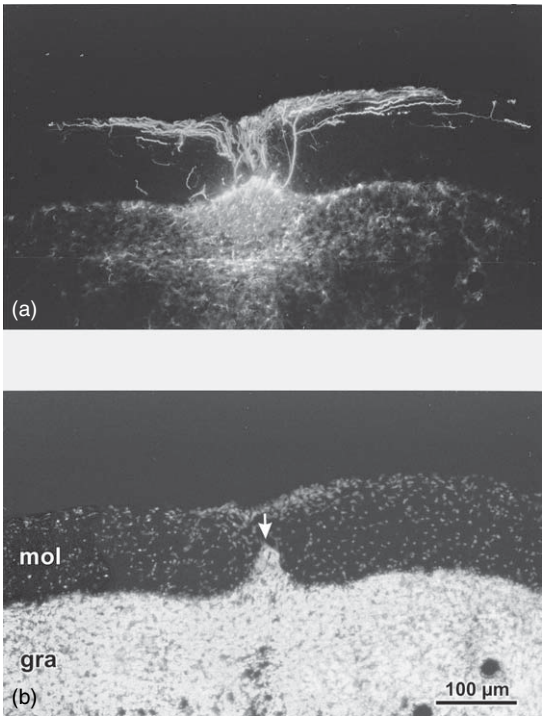

Figure 10 Radial glial fibers, identified by immunostaining against GFAP, in the dorsal portion of the corpus cerebelli, in *A. leptorhynchus* (a). At the midline of the dorsal granule cell layer (gra), the granule cell mass protrudes into the dorsal molecular layer (mol) by forming a tip (arrow), as is evident in the counterstain produced by applying the nuclear dye DAPI to the section (b). This tip is the origin of long fibers that initially take a trajectory parallel to the midline. As soon as they get close to the dorsal surface of the brain, these fibers split into two populations turning laterally to the left and right side, respectively. Following this turn, they continue to run parallel to the dorsal surface of the brain over a few hundred micrometers. As BrdU-labeling studies have shown, this fiber course exactly matches the route alongside which cells born in the molecular layer migrate into the granule cell layer. Reproduced from Zupanc, G. K. H. 2001. Adult neurogenesis and neuronal regeneration in the central nervous system of teleost fish. *Brain. Behav. Evol.* 58, 250–275, with permission from S. Karger AG, Basel.

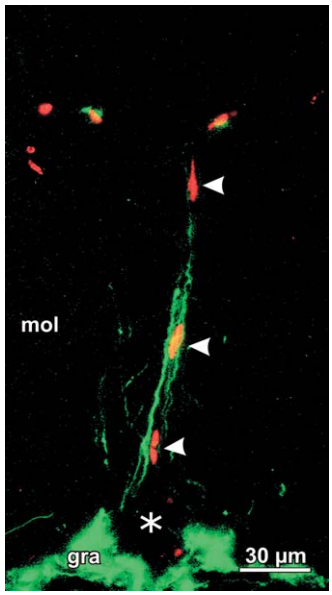

Figure 11 Guidance of young cells by radial glial fibers in the cerebellum of the *A. leptorhynchus*. Two days after the administration of the S-phase marker BrdU, the fish was killed, and the transverse section through the dorsal portion of the corpus cerebelli was immunostained against both BrdU (red) and GFAP (green). Long GFAP-positive radial glial fascicles run at the midline of the molecular layer (mol) through the so-called dorsal tip (asterisk) into the granule cell layer (gra). Several BrdU-labeled cells, indicated by arrowheads, are closely apposed to the radial glial fibers. Reproduced from Zupanc, G. K. H. 2001. Adult neurogenesis and neuronal regeneration in the central nervous system of teleost fish. *Brain Behav. Evol.* 58, 250–275, with permission from S. Karger AG, Basel.

vimentin expression is gradually reduced, an increasing amount of GFAP is produced. However, final verification of this hypothesis awaits further experimentation.

In all three cerebellar subdivisions, both the vimentin-positive fibers and the GFAP-expressing radial glial fibers delineate the path taken by the young cells in the course of their migration. For instance, in the corpus cerebelli such fibers originate from the tips formed at the midline by protrusion of granule cells from the granule cell layer into the dorsal and ventral molecular layers. Initially, the fibers run along the midline, but shortly before reaching the pial surface in the dorsal molecular layer, they make lateral turns and continue to run in lateral directions for up to several hundred micrometers (Figure 10). This fiber course exactly matches the route through which cells born in the molecular layer migrate into the granule cell layer. A similar matching between the distribution and orientation of GFAP- and vimentin-positive radial glial fibers on the one hand, and the migrational path taken by young cells on the other, is observed in the other two cerebellar subdivisions.

The hypothesis that radial glial fibers in the cerebellum provide a scaffolding for the migrating young cells receives further support by the results of double-labeling experiments. Intraperitoneal injection of BrdU, followed by sacrifice of the fish 2 days after administration (i.e., at a time when the young cells exhibit maximum migratory activity) reveals elongated BrdU-labeled cells in close apposition to GFAP-labeled radial glial fibers (Gheteu and Zupanc, 2001; Figure 11).

2.24.5.3 Regulation of the Number of New Cells by Apoptotic Cell Death

After arrival at their target sites within the cerebellum of *A. leptorhynchus*, the areal density of BrdU-labeled

cells drops by roughly 50% in the period 4–7 weeks after their generation (Zupanc *et al.*, 1996; Ott *et al.*, 1997). This decrease is thought to be due to apoptotic cell death. Such a mechanism of cell elimination has been suggested by experiments in which terminal deoxynucleotidyl-transferase-mediated dUTP-biotin nick end-labeling (TUNEL) of 3′-OH ends of DNA was employed (Soutschek and Zupanc, 1996). The latter approach is based on the identification of DNA fragmentation as a feature characteristic of apoptosis (Modak and Bollum, 1972; Gavrieli *et al.*, 1992; Surh and Sprent, 1994).

Studies applying TUNEL to brain sections of *A. leptorhynchus* have shown that a large number of cells continuously undergo apoptosis in the granular layers of the three subdivisions of the cerebellum (Soutschek and Zupanc, 1996). By contrast, the number of apoptotic cells is low in the molecular layers. This suggests that apoptosis is used as a mechanism to regulate the numbers of the young cells after they have reached their target areas.

A similar mechanism has been demonstrated in other brain systems, particularly those of mammals, during embryonic development. In these systems, apoptosis leads to the elimination of young cells which, after arrival at the target site, have failed to make proper connections with other neurons and to receive adequate amounts of specific survival factors produced by cells in the target area (Raff, 1992; Raff *et al.*, 1993).

2.24.5.4 Long-Term Survival of New Cells

In *A. leptorhynchus*, it is likely that most of the cells that have survived the massive wave of apoptotic cell death 4–7 weeks after their generation continue to exist for the rest of the fish's life. This is suggested by experiments in which post-BrdU-administration survival times of up to 440 days were employed (Zupanc *et al.*, 1996; Ott *et al.*, 1997). The latter period is equivalent to roughly half the adult life span of this species in captivity.

Long-term survival of new cells of at least 292 days has been demonstrated in a large number of brain regions of the zebra fish (Zupanc *et al.*, 2005). The entire life span of outbred zebra fish is roughly 3.5 years (Gerhard *et al.*, 2002), so that a survival time of 292 days covers approximately one-fourth of the entire life span and one-third of the remaining life expectancy after administration of BrdU (the fish used in the experiments received a single pulse of this thymidine analogue at an approximate age of 9–12 months).

A similar long-term persistence of new cells as found in *A. leptorhynchus* and zebra fish has been observed in the mammalian brain. In the granular layer of the hippocampus of adult mice, new neurons survive for at least 11 months (Kempermann *et al.*, 2003), which is equivalent to roughly half the life span of mice.

In *A. leptorhynchus*, long-term survival, together with the continuous production of new cells, leads to a permanent growth of the entire brain, except for very old fish in which the growth rate appears to reach a plateau. This parallels the continuous growth of the body in this species. A quantitative analysis has demonstrated that, while the body weight of the fish increases from 1 to 16 g, the total number of brain cells doubles from 5×10^7 to 1×10^8 (Zupanc and Horschke, 1995).

2.24.5.5 Neuronal Differentiation

A central question arising in the context of the generation of new cells in the adult fish brain concerns their cellular identity. This issue has been addressed in detail with regard to the zebra fish (Zupanc *et al.*, 2005). The approaches used include combination of anti-BrdU immunohistochemistry with immunostaining against Hu-C and Hu-D. The Hu family of RNA-binding proteins is neuron-specific and plays an important role in the development and maintenance of vertebrate neurons. These proteins have been shown to be expressed both by neurons generated during embryogenesis (Marusich *et al.*, 1994) and by neurons produced in the adult brain (Barami *et al.*, 1995).

Double-labeling experiments using this approach have revealed that, at post-BrdU administration survival times of 9 months, approximately 50% of the BrdU-labeled cells in the zebra fish brain express this neuron-specific protein. Such neurons are particularly abundant in the dorsal telencephalon, including the region presumably homologous to the mammalian hippocampus (see Section 2.24.4.2), but are also found in other areas of the brain.

Since after post-BrdU administration survival times of 7–10 months approximately 50% of all BrdU-labeled cells are situated in the granular layers of the corpus cerebelli and the valvula cerebelli partes lateralis and medialis, it is reasonable to assume that at least a part of the new cerebellar cells develop into granule cell neurons. Unfortunately, none of the anti-Hu antibodies tested thus far have failed to immunostain cerebellar granule cells. Therefore, using an alternative approach, the possible differentiation of young cerebellar cells into granule cell neurons has been examined by combination of BrdU labeling and neuronal tract tracing. Such experiments, conducted

in both *A. leptorhynchus* (Zupanc *et al.*, 1996) and zebra fish (Zupanc *et al.*, 2005), have indeed provided evidence in favor of the hypothesis that at least some of the cells generated in the adult cerebellum develop into granule cell neurons. Just as in these studies the BrdU-labeled granule cells were retrogradely traced by application of tracer substance to the molecular layers, the experiments also indicate that these cells have developed axons traveling from their somata in the granule cell layers to the corresponding molecular layers. Thus, it appears that they have integrated into the existing neural network of cerebellar neurons. It is unknown whether the axons of the newly generated granule cells make proper synaptic connections with other cells, such as Purkinje cells. It also remains to be examined whether the new granule cells are functional, and whether their physiological properties are similar to those of the older granular neurons.

2.24.6 Why Do Fish Produce New Neurons in the Adult Brain? The Numerical Matching Hypothesis

Why does the generation of new neurons cease in all but two regions of the mammalian brain during the early stages of development, but persist in many areas of the teleost fish brain throughout life? And why does adult neurogenesis specifically occur in the olfactory bulb and the hippocampus, but not in other areas of the adult mammalian brain?

A possible answer to these questions is suggested by the results of a comparative analysis of the differences in the development of motor structures and sensory organs between teleosts and mammals (Zupanc, 1999a, 2001, 2006). Although many species of teleosts and mammals grow during postembryonic stages of development and even throughout life, there is a distinct difference in the growth pattern between these two taxonomic classes. Whereas in mammals postembryonic growth is the result of an increase in size but not in number of individual muscle fibers (Rowe and Goldspink, 1969), in fish both the number of muscle fibers and the volume of individual fibers increase (Weatherley and Gill, 1985; Koumans and Akster, 1995; Zimmerman and Lowery, 1999; for review, see Rowlerson and Veggetti, 2001). It is, therefore, possible that the hyperplasia of peripheral motor elements prompts a concomitant increase in the number of central neurons involved in neural control of associated muscle activity.

Along similar lines, the number of sensory receptor cells, receptor organs, or receptor units in the periphery has been shown to increase with age in several species of fish. Such a formation of new sensory elements has been demonstrated for sensory hair cells in the inner ear of sharks (Corwin, 1981), for retinal cells in the eyes of goldfish (Johns and Easter, 1977), and for electrosensory receptor organs in the gymnotiform fish *Sternopygus darienses* (Zakon, 1984). Thus, like the formation of new motor elements, the continuous increase in the number of sensory elements in fish may lead to the generation of new neurons involved in the processing of sensory information, ensuring a numerical matching of central neurons and peripheral sensory elements.

New central neurons may also be generated if the sensory cells or muscle fibers in the periphery exhibit a turnover, instead of a net increase in total number. Then the production of a certain portion of sensory cells or motor fibers would lead to the generation of new central neurons (directly or indirectly) connected to them, whereas the degeneration of other sensory cells would be accompanied by a secondary degeneration of central neurons linked to this portion of peripheral elements. In such cases, the overall number of peripheral elements and central neurons would vary little, or not at all, over time, although changes in the number of sensory cells or muscle fibers still trigger changes in the number of central neurons so that a specific ratio between the two cellular populations is maintained.

In mammals, the production of sensory cells appears to cease by the end of gestation (e.g., Ruben, 1967), except for primary sensory neurons of the olfactory epithelium (Graziadei and Graziadei, 1979), which replace older olfactory neurons undergoing apoptosis (Magrassi and Graziadei, 1995). The axons of the primary sensory neurons make synaptic contacts with dendrites of mitral and tufted cells within the olfactory bulb. These cells project to the olfactory cortex, including the lateral entorhinal cortex. The latter structure, in turn, sends axons, via the lateral perforant path, to the hippocampus, which synapse on the distal dendrites of the dentate gyrus granule cells (Carlsen *et al.*, 1982; Insausti *et al.*, 2002; van Groen *et al.*, 2002, 2003). Thus, each of the two regions in which neurogenesis occurs within the adult mammalian brain – olfactory bulb and dentate gyrus – is part of the central olfactory pathway. Remarkably, also the entorhinal cortex, in which adult neurogenesis is absent, retains its neurogenic potential during adult life. Neurospheres from this region differentiate into neurons and glia *in vitro* and after transplantation to the adult dentate gyrus (Fontana *et al.*, 2006).

In fish, the matching hypothesis can explain the enormous mitotic activity in the cerebellum. Based

on anatomical, physiological, and behavioral experiments, the cerebellum, notably of weakly electric fish, has been proposed to play an important role not only in the well-established function of control and coordination of movements, but also in sensory processing. The latter has been demonstrated particularly in the context of the involvement of the cerebellum in tracking movements of objects around the animal, and in the generation and subtraction of sensory expectations (for reviews, see Paulin, 1993; Bell *et al.*, 1997). On the other hand, the lack of adult neurogenesis in the mammalian cerebellum could be causally linked to the absence of changes in the number of muscle fibers and sensory elements during periods of growth in the periphery.

At the central level, numerical matching has been demonstrated between the presynaptic granule cell population and its postsynaptic target neurons, the Purkinje cells, by making use of the neurologically mutant mouse strain lurcher. The cerebella of lurcher heterozygotes are characterized by early postnatal degeneration of several cell types, beginning with the loss of Purkinje cells during the second week of life. This stage is followed by degeneration of granule and olivary neurons and Bergmann glia (Swisher and Wilson, 1977; Caddy and Biscoe, 1976). In wild-type mice, there is a constant ratio of about 175 granule cells for each Purkinje cell. In lurcher chimeric mice, variation in the number of Purkinje cells is genetically caused, whereas the loss of granule cells appears to be a secondary, phenotypic consequence due to Purkinje cell loss (Wetts and Herrup, 1983).

In fish, there is some experimental evidence supporting the hypothesis that changes in the number of peripheral sensory elements lead to changes in the production of the corresponding central elements. Raymond *et al.* (1983) found that in goldfish permanent removal of the optic input by enucleation of the eye results in sustained depression of mitotic activity in the tectal proliferation zone on the denervated side compared to the intact one. Temporary denervation by optic nerve crush initially has a similar effect, but upon re-innervation of the tectum by the regenerating optic fibers, proliferation is enhanced on the experimental side compared to the control side.

2.24.7 Neuronal Regeneration

The enormous potential of teleost fish to continuously produce new neurons in the intact CNS during adulthood is closely related to a second phenomenon by which fish and other anamniotes are distinguished from amniote vertebrates: the ability to replace neurons lost to injury by newly generated ones. This so-called neuronal regeneration has been particularly well studied in three neuronal systems. The retina and its primary projection target, the optic tectum (for review, see Otteson and Hitchcock, 2003); the spinal cord (for review, see Waxman and Anderson, 1986); and the cerebellum (for reviews, see Zupanc, 1999a, 2001, 2006; Zupanc and Clint, 2003; Zupanc and Zupanc, 2006a). In the following, I will focus on the latter system, which is based on a series of investigations carried out in *A. leptorhynchus*.

2.24.7.1 The Lesion Paradigm

Investigations of the phenomenon of neuronal regeneration in the cerebellum of *A. leptorhynchus* have been greatly facilitated by the availability of a well-established lesion paradigm. This paradigm takes advantage of the prominent position of the corpus cerebelli, which forms a roof on top of the brain, except over the telencephalon (Figure 12a).

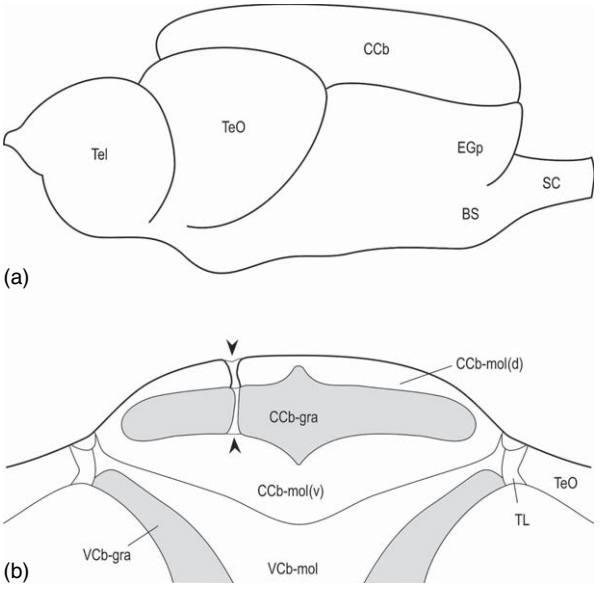

Figure 12 a, Side view of the brain of the brown ghost knifefish. One subdivision of the cerebellum, the corpus cerebelli (CCb), forms a roof on top of the brain, except over the telencephalon (Tel). Cerebellar lesions can, therefore, be made in a defined way by puncturing the skull of the fish with a surgical blade, without damaging other parts of the brain. b, Transverse section through the corpus cerebelli. The lesion path (arrowheads) travels through the dorsal molecular layer (CCb-mol(d)) and the granular layer (CCb-gra) roughly halfway between the midline of the brain and the lateral edge of the granular layer. BS, brainstem; CCb-mol(v), ventral molecular layer of corpus cerebelli; EGp, eminentia granularis pars posterior; SC, spinal cord; TeO, optic tectum; TL, torus longitudinalis; VCb-gra, granule cell layer of valvula cerebelli; VCb-mol, molecular layer of valvula cerebelli. Reproduced from Zupanc, G. K. H. and Zupanc, M. M. 2006a. New neurons for the injured brain: Mechanisms of neuronal regeneration in adult teleost fish. *Regen. Med.* 1, 207–216, with permission from Future Science Group.

Cerebellar lesions can, therefore, be made by puncturing the skull of the anesthetized fish with a sterile surgical blade, without damaging other parts of the brain (Figure 12b). Guided by landmarks on the fish's head, lesions are applied in a defined way, resulting in an approximately 1-mm-deep cut traveling in parasagittal direction and encompassing both the dorsal molecular layer and the granular layer of the corpus cerebelli.

Nissl stains of sections taken through the corpus cerebelli after various survival times have shown that the initially clearly visible path caused by the stab wound gradually becomes reduced with longer postlesioning survival times, until it disappears after a couple of weeks (Zupanc *et al.*, 1998). This indicates rapid and efficient neuronal wound healing.

2.24.7.2 Elimination and Removal of Damaged Cells

Detailed analysis has shown that the tissue repair is accomplished by a number of well-orchestrated processes. The first process involves the rapid elimination of damaged cells through apoptosis (Zupanc *et al.*, 1998), followed by removal of the resulting cellular debris by the action of microglia/macrophages (Zupanc *et al.*, 2003). Apoptosis was originally shown to regulate cell numbers in the mammalian brain during embryonic development (Raff *et al.*, 1993). It is believed that this type of cell death exerts a similar function in the intact fish brain during postnatal development (Soutschek and Zupanc, 1995, 1996; see Section 2.24.5.3). The involvement of apoptosis in the process of elimination of injured cells is remarkable because this contrasts with the situation in mammals. In the latter taxon, besides apoptosis (for reviews, see Beattie *et al.*, 2000; Vajda, 2002), necrosis occurs and appears to be the predominant type of cell death following lesions (Kerr *et al.*, 1987). Necrosis commonly leads to inflammation at the site of the injury (for review, see Kerr *et al.*, 1995). This inflammatory response triggers further necrotic events, thus gradually transforming the site of injury into large cavities devoid of cells (Zhang *et al.*, 1997). These cavities are typically bordered by scars that act as mechanical and biochemical barriers preventing the ingrowth of nerve fibers and the migration of cells into the lesion site (for review, see Reier *et al.*, 1983).

In *A. leptorhynchus*, the first apoptotic cells are detectable as early as 5 min after application of a lesion to the corpus cerebelli (Zupanc *et al.*, 1998). Thirty minutes after the lesion, the number of cells undergoing apoptosis reaches maximum levels. At 2 days postlesioning survival time, the number of apoptotic events, as indicated by TUNEL, starts to gradually decline until background levels are reached at approximately 20 days after the lesion (Figure 13).

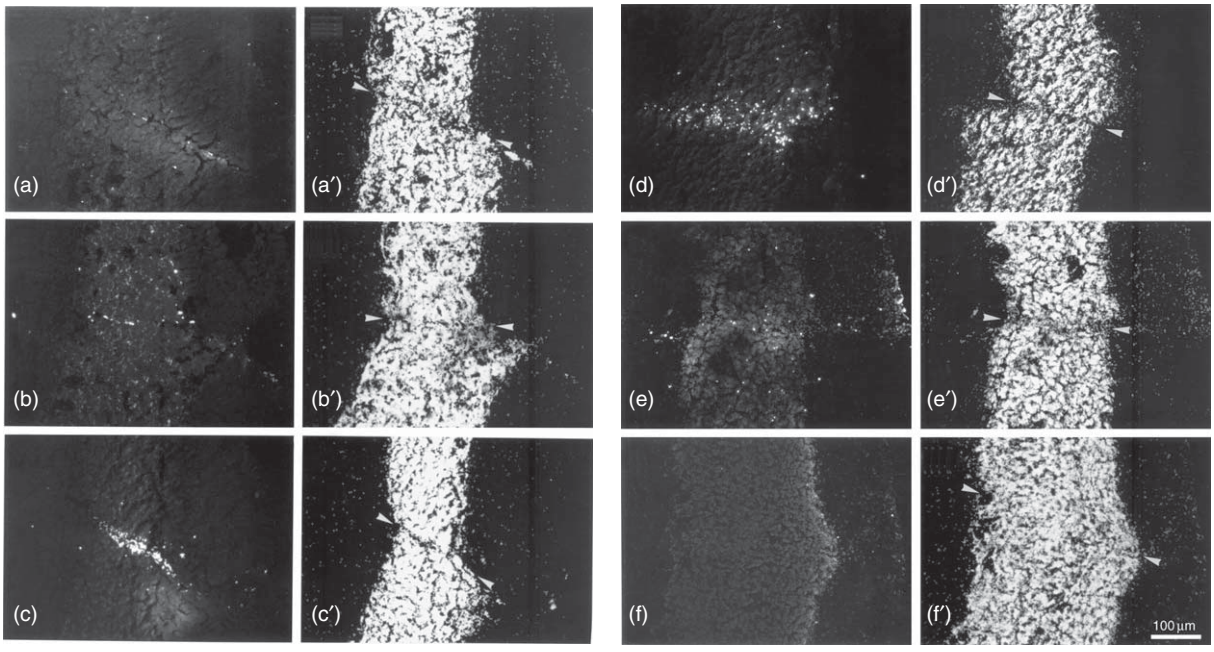

Figure 13 TUNEL-positive cells at the site of the lesion in the corpus cerebelli after survival times of 5 min (a), 15 min (b), 30 min (c), 1 day (d), 5 days (e), and 20 days (f). The location of the lesion is indicated by arrowheads in the DAPI counterstaining (a′–f′). The number of TUNEL-positive cells dramatically increases within the first 30 min, stays at high levels for another day, and then gradually declines to background levels. Reproduced from Zupanc, G. K. H., Kompass, K. S., Horschke, I., Ott, R., and Schwarz, H. 1998. Apoptosis after injuries in the cerebellum of adult teleost fish. *Exp. Neurol.* 152, 221–230, with permission from Elsevier.

Apoptosis is characterized by cell shrinkage, nuclear condensation, and production of membrane-enclosed particles that are digested by other cells. Most significantly, the side effects that accompany necrosis, such as inflammation of the surrounding tissue, are typically absent in apoptosis. This suggests that the use of this so-called clean type of cell death for the elimination of damaged cells is an essential component of the enormous regenerative capability of *A. leptorhynchus*.

Approximately 3 days after application of the lesion, the areal density of microglia/macrophages, identified by tomato lectin binding, starts to increase at and near the lesion site (Zupanc *et al.*, 2003; Figure 14). A similar increase, although less pronounced, is also seen in the contralateral hemisphere. The areal density of microglia/macrophages reaches maximum levels at approximately 10 days after the lesion and returns to background levels approximately 1 month after the lesion. The emergence of microglia/macrophages shortly after the number of apoptotic cells has reached maximum levels supports the notion that the former cells are involved in the removal of cellular debris caused by apoptotic cell death.

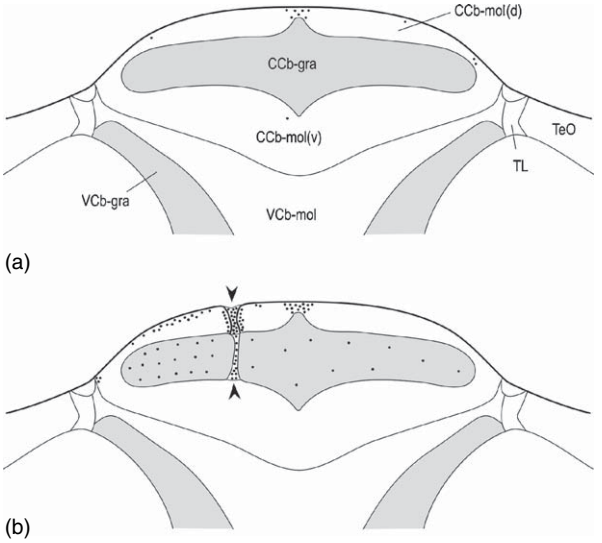

Figure 14 Distribution and relative density of lectin-labeled cells in the intact (a) and injured corpus cerebelli 10 days after setting the lesion (b). The schematic sketches are based on the analysis of camera lucida drawings of one complete series of lectin-labeled sections through the corpus cerebelli in one fish each. The number of black dots reflects the density of labeled cells in the various areas of the corpus cerebelli. The lesion (indicated by arrowheads) runs, in the case shown, from the brain surface through the dorsal molecular layer and the granule cell layer, without, however, entering the ventral molecular layer. CCb-gra, granule cell layer of corpus cerebelli; CCb-mol(d), dorsal molecular layer of corpus cerebelli; CCb-mol(v), ventral molecular layer of corpus cerebelli; TeO, optic tectum; TL, torus longitudinalis; VCb-gra, granule cell layer of valvula cerebelli; VCb-mol, molecular layer of valvula cerebelli. Evol.* 62, 31–42, with permission from S. Karger AG, Basel.

2.24.7.3 Generation of New Cells

The second major process mediating brain repair in *A. leptorhynchus* encompasses replacement of the neurons that are eliminated through apoptosis with newly generated ones. These neurons are recruited from two sources (Zupanc and Ott, 1999). First, new cells are produced in response to the injury in proliferation zones near the lesion; these areas of mitotic activity are detectable only after injury. Second, new cells are recruited from the pool of continuously generated undifferentiated cells.

The vast majority of cells of either of the two populations are produced 1–10 days following the lesion, with the maximum proliferative activity occurring at 5 days after injury. This upregulation of proliferative activity is thought to be due to an inductive effect exerted by the injury. In addition, cells that are born before the lesion also contribute to the restoration of damaged tissue. BrdU-labeling experiments have shown that cells generated as early as 2 days prior to lesioning of the cerebellum still participate in the process of regeneration (Zupanc and Ott, 1999).

The observation that cells generated before the injury can replace damaged neurons suggests a direct relationship between the continuous cell proliferation in the intact brain and the process of neuronal regeneration. The continuous provision of a pool of undifferentiated cells in the intact brain appears to enable fish to recruit new cells much more rapidly in the event of injuries than would be possible by recruiting only cells that are generated in response to such events. However, it is unclear whether this trait has, indeed, conferred a significant advantage in survival in the course of evolution. Individuals with brain injuries bear typically a dramatically increased risk of predation, particularly in the first few weeks before the wound has completely healed. It is, therefore, possible that the major driving force for the phylogenetic development of the continuous generation of new neurons in the adult brain has been the need to match the number of continuously produced new motor and sensory elements in the periphery of the intact organism (see Section 2.24.6), rather than the ability to regenerate brain tissue. Following this line of reasoning, the availability of a permanent pool of undifferentiated cells that can be rapidly accessed in case of an injury would be an epiphenomenon.

2.24.7.4 Migration and Differentiation of New Cells

As an important step in the further process of recruitment of the new cells for repair of the lesioned tissue, these cells have to migrate from the site of their production to the site of injury. Several lines of evidence suggest that this is achieved through guidance by radial glial fibers. Approximately 8 days following the lesion, the density of radial glial fibers, identified by morphological criteria and immunohistochemical staining against GFAP, increases greatly compared to the levels found in the intact cerebellum (Clint and Zupanc, 2001; Figure 15). This effect is restricted to the site ipsilateral to the lesion, and occurs at particularly high levels at and near the site of injury. The increase in radial fiber density is followed by a rise in the density of young cells, in the same cerebellar areas, approximately 2 days later. This arrival of young cells after the appearance of radial glial fibers, as well as the frequently observed close apposition of young cells to radial glial fibers, support the notion that radial glial fibers provide a scaffold to guide the young cells in the course of their migration from the site of origin to the site of injury.

Like the increase in areal density of GFAP-expressing radial glial fibers, the expression of vimentin in fibers at the site of the lesion and in the remaining ipsilateral molecular layer is upregulated in a specific spatiotemporal fashion (Clint and Zupanc, 2002). The areal density of vimentin-positive fibers increases significantly 15 days after application of a mechanical lesion to the corpus cerebelli and remains elevated throughout the time period of up to 100 days examined. It is possible that the vimentin-expressing fibers also represent a subpopulation of radial glia-like cells. Although there appears to be a certain degree of overlap between the two fiber populations, GFAP-positive fibers are typically found at greater distances from the lesion site in the ipsilateral hemisphere and exhibit a more elongated morphology than vimentin-positive fibers. Since the majority of the new cells arrive at the lesion site before the upregulation of vimentin, it is unlikely that this intermediate filament protein is involved in guidance of the migrating young neurons. Instead, vimentin may play a role in later developmental functions, such as promotion of cellular survival, differentiation, and/or outgrowth of dendrites.

Combination of BrdU labeling with neuronal tract tracing has shown that at least some of the new cells that replace damaged neurons are cerebellar granule cells (Zupanc and Ott, 1999). Because in

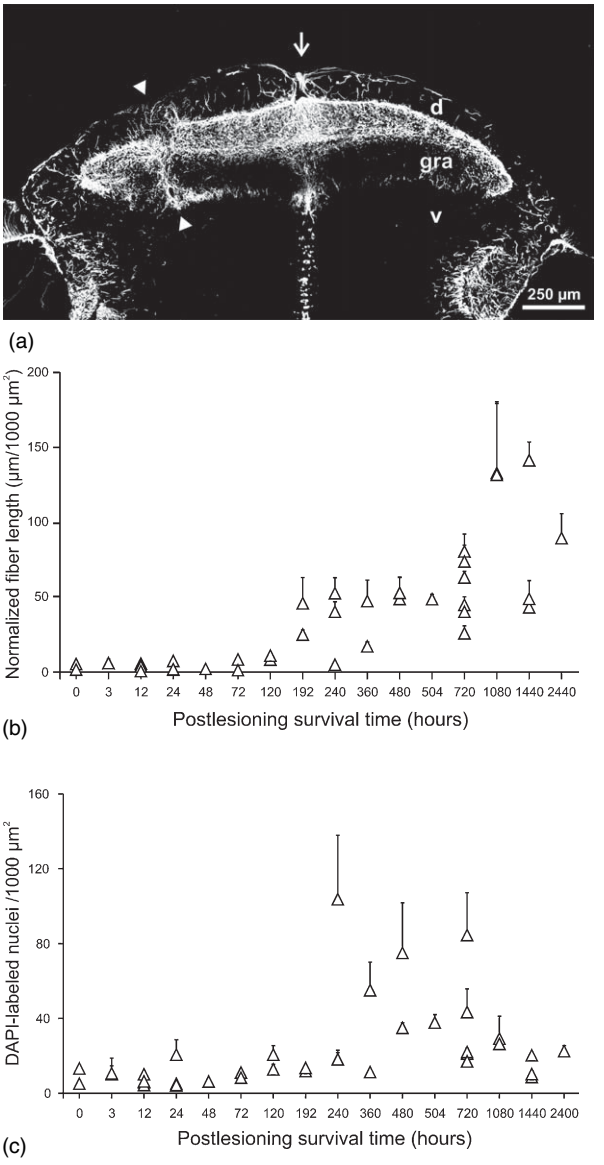

Figure 15 a, Transverse section through the corpus cerebelli of *A. leptorhynchus* 10 days after application of a mechanical lesion. The path of the lesion is indicated by arrowheads. The density of GFAP-labeled fibers is markedly higher at the site of the lesion and in the remaining ipsilateral dorsal molecular layer than in the contralateral dorsal molecular layer. The GFAP-stained radial glial fibers are also prominent at the midline (arrow), where they extend over considerable distances laterally in each hemisphere. d, dorsal molecular layer; gra, granule cell layer; v, ventral molecular layer. b, Areal density of lengths of GFAP-labeled fibers at the site of the lesion after various postlesioning survival times. c, Areal density of cells visualized by staining with the nuclear dye DAPI at the site of the lesion after various postlesioning survival times. The values plotted in (b) and (c) are means of individual fish. The survival time of '0' indicates the results of unlesioned fish. The vertical bars represent standard errors. Reproduced from Clint, S. C. and Zupanc, G. K. H. 2001. Neuronal regeneration in the cerebellum of adult teleost fish, *Apteronotus leptorhynchus*: Guidance of migrating young cells by radial glia *Dev. Brain Res.* 130, 15–23, with permission from Elsevier.

this study the granule cell neurons have been identified by deposition of the tracer substance into the molecular layer of the corpus cerebelli and through subsequent retrograde transport of the tracer to somatic regions, this result also shows that these cells have established axonal projections with the associated molecular layer.

2.24.8 Identification of Regeneration-Associated Proteins

One of the central goals of research on neuronal regeneration in fish is to gain an understanding of the molecular mechanisms mediating this phenomenon. A large-scale identification of protein candidates involved in the underlying processes in the teleostean brain has been carried out by combining the cerebellar lesion paradigm with differential proteom analysis (Zupanc *et al.*, 2006). In an initial study, a postlesion survival time of 3 days was chosen because a previous investigation has demonstrated the importance of this time point, especially for the recruitment of newly generated cells replacing the ones lost to injury (Zupanc and Ott, 1999). At 3 days following lesion, cell proliferation is dramatically upregulated, both in areas near the lesion and in proliferation zones that continuously generate new cells in intact fish.

For the proteome analysis, abundance of proteins in tissue from the site of the lesion was compared with the abundance of the same proteins in an equivalent region of the intact cerebellum. Two-dimensional gel electrophoresis of protein extracts from these two types of tissue samples revealed nearly 800 protein spots (Figure 16). Out of these total number of spots, spot intensity was significantly increased at least twofold in 30 spots and decreased to at least half the intensity of intact tissue in 23 spots (Figure 17). Since this investigation was restricted to the examination of cytosolic proteins, as well as proteins with isoelectric points between 4 and 7, the result indicates that the total number of proteins potentially involved in regeneration of the injured cerebellum at the postlesion survival time examined may well exceed 100.

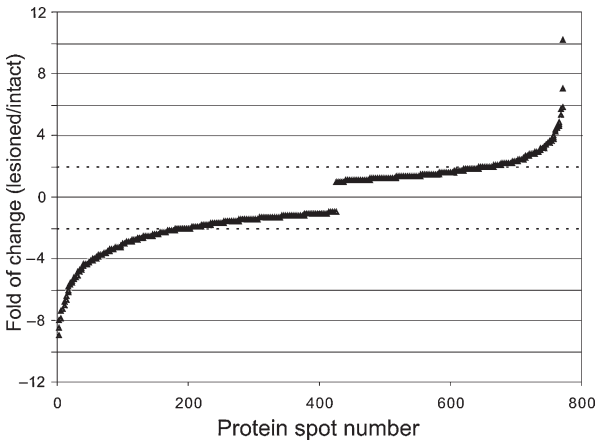

Figure 17 Scatter plot of the fold changes of 772 polypeptide spots in the corpus cerebelli of *A. leptorhynchus* 3 days after a lesion compared to unlesioned controls. Decrease in protein abundance is indicated by negative changes, increase by positive changes. Proteins are sorted in ascending order of the spot intensity change. The analysis is based on a comparison of the averaged spot intensities of four 2D gels from lesioned brains and three 2D gels from intact brains. The dotted lines indicate the +2-fold and −2-fold threshold. Reproduced from Zupanc, M. M., Wellbrock, U. M., and Zupanc, G. K. H. 2006. Proteome analysis identifies novel protein candidates involved in regeneration of the cerebellum of teleost fish. *Proteomics* 6, 677–696, with permission from Wiley-VCH.

The proteins associated with 24 of the 53 spots that showed significant intensity differences after application of a lesion to the cerebellum in *A. leptorhynchus* could be identified by peptide mass fingerprinting and mass spectrometry/mass spectrometry fragmentation. Table 1 lists these identified protein spots, together with the changes found in the lesioned corpus cerebelli, relative to an equivalent area in the intact corpus. Also included in this list are the proposed functions of these proteins in the process of tissue regeneration. Detailed analysis has shown that these proteins can be divided into three major groups:

1. The first group includes cytoskeletal proteins essential for the formation of new cells, such as β-actin and β-tubulin. The transient upregulation of β-actin expression appears to relate to the regeneration of injured axons in the area of the lesion and the development of axons of the newly generated cells, as suggested by immunohistochemical experiments (Zupanc *et al.*, 2006; see Section 2.24.9.1). The transient increase in abundance of β-tubulin is closely associated with the appearance of thin capillaries at the site of the lesion several days after application of the stab wound, presumably reflecting the generation of new endothelial cells (Zupanc *et al.*, 2006; see Section 2.24.9.2). Also included in this first group are proteins that mediate the correct assembly of these structural

Table 1 Differentially expressed proteins 3 days after application of a lesion to the corpus cerebelli of *A. leptorhynchus*. The proteins were identified by proteome analysis

Protein name	*Fold change*	*M_r/pI*	*Proposed function*
β-Actin	2.1	42/5.3	Cytoskeletal protein of axons
β-Tubulin	2.9	50/4.8	Cytoskeletal protein of axons and endothelial cells
β1-Tubulin	3.6	50/4.8	Cytoskeletal protein related to neurogenesis
Keratin-10	0.5	59/5.1	Intermediate filament protein; negative regulation of cell proliferation
Chaperonin containing tailless-complex polypeptide 1, subunit ε	2.4	60/5.4	Chaperoning of cytoskeletal proteins
Tropomodulin-3 and -4	2.3	40/4.7	Capping of slow-growing ends of actin filaments
Bullous pemphigoid antigen 1	4.2	38/6.4	Linking of actin with intermediate filament proteins
Myosin heavy chain	2.5	22/5.5	Cellular motility of axons
B2-Lamin	2.9	68/5.4	Nuclear assembly during mitosis
78 kDa glucose-regulated protein	3.7	73/5.0	Neuroprotection by reducing apoptotic cell death
Glutamine synthetase	2.2	42/6.4	Neuroprotection by converting glutamate into glutamine
Cytosolic aspartate aminotransferase	0.5	47/6.7	Neuroprotection by reduction of glutamate and aspartate
α-Enolase	2	48/6.2	Energy metabolism
β-Enolase	2.1	47/7.1	Energy metabolism
F-ATP synthase β-subunit	2.1	55/5.1	Energy metabolism
Vacuolar adenosine triphosphatase	2.5	69/5.4	Possibly regulation of cellular growth
Calcineurin	0.4	60/5.6	Regulation of apoptotic cell death
70 kDa heat-shock cognate protein	2.8	71/5.3	Protein folding; possibly regulation of development
Phosphoglycerate kinase	2.1	43/5.9	Glycolysis; modulation of DNA polymerization
Creatine kinase	2.3	43/5.5	Energy metabolism; regulation of cell proliferation
Bone marrow zinc finger 2	0.4	85/9.7	Transcriptional regulation
Regeneration-associated protein 1 (similarities to steroid sensitive gene-1 protein from *Danio rerio*)	4.2	100/9.7	?
Regeneration-associated protein 2 (similarities to protein CG9699-PG from *Drosophila melanogaster*)	0.4	50/6.2	?

M_r, molecular weight (kDa); pI, isoelectric point.

proteins. Among the latter are chaperonin-containing tailless-complex polypeptide 1, subunit ε, which might mediate chaperoning of cytoskeletal proteins; tropomodulins-3 and -4, which are known to perform a capping of slow-growing ends of actin filaments; and bullous pemphigoid antigen 1, which has been proposed to link actin with intermediate filament proteins.

2. The second group is comprised of proteins potentially involved in cell proliferation (such as keratin-10), cellular motility (such as myosin heavy chain), neuroprotection (such as 78 000-Da glucose-regulated protein, glutamine synthetase, and cytosolic aspartate aminotransferase), and energy metabolism (such as α- and β-enolase, as well as F-ATP synthase β-subunit). Remarkably, the abundance of glutamine synthetase is increased after cerebellar lesions in fish, whereas this enzyme is downregulated under traumatic conditions in the mammalian central nervous system. Such differences in the expression pattern of proteins between fish and mammals are particularly interesting because they are likely to provide a molecular explanation for the enormous difference in the regenerative potential between the two vertebrate groups.
3. The third group consists of a single protein, bone marrow zinc finger 2. This protein was first identified from a screen of zinc finger proteins expressed in the hematopoietic system (Han *et al.*, 1999). Although little is known about its expression pattern and function, its molecular structure and some experimental evidence suggest that it acts as a transcriptional regulator. Such evidence includes studies on Wilms' tumor, a pediatric kidney cancer. As has been shown, bone marrow zinc finger 2 associates with Wilms' tumor suppressor, another zinc finger protein, and inhibits transcriptional activity of the latter (Lee *et al.*, 2002). Nothing is known about its role in the nervous system. The proteome analysis of regeneration-associated protein in the cerebellum of *A. leptorhynchus* has provided the first indication of an expression of the gene encoding bone marrow zinc finger 2 in the brain and of a possible role in the process of brain repair. Since transcription factors function as master regulators of downstream proteins, bone marrow zinc finger 2 is an important candidate to examine the upstream mechanisms controlling regeneration of brain tissue. Interestingly, increase in abundance of several zinc finger proteins has also been found in a recent proteome analysis in the rat after spinal cord transection (Ding *et al.*, 2006).

2.24.9 Immunohistochemical Characterization of Regeneration-Associated Proteins

Based on the above-described proteome analysis and on immunohistochemical screening of candidate proteins in cryosections taken from the lesion site in the corpus cerebelli after various postlesion survival times, a number of regeneration-associated factors have been identified in *A. leptorhynchus*. The spatiotemporal expression pattern of four of them has been examined in detail: β-actin, β-tubulin, calbindin-D_{28k}, and somatostatin. The results of these investigations will be compared with the time course of the major regenerative processes, as described above and summarized in Figure 18.

2.24.9.1 β-Actin

Actin, one of the major constituents of the cytoskeleton, is highly conserved between species (for review, see Schoenenberger *et al.*, 1999). Together with other cytoskeletal proteins, it provides an intracellular scaffolding of the cell. In addition, actin is involved in cell motility and the transport of intracellular cargos to their destinations, particularly along the axon. One of its three major isoforms, β-actin, is a 42-kDa protein enriched in actively growing structures, or structures with a high capacity for morphological modifications, such as growth cones, filopodia, migrating cell bodies, axonal tracts, and dendritic spines (Kaech *et al.*, 1997; Bassell *et al.*, 1998; Micheva *et al.*, 1998). Similarly, regeneration studies have demonstrated an upregulation of actin within a few days after axotomy, reflecting the emergence of axonal sprouts and the concomitant needs to lengthen the axon shaft and to support membrane expansion at the growth cone (Tetzlaff *et al.*, 1991; Lund and McQuarrie, 1996; Lund *et al.*, 2002). Congruent with this finding, induction of axonal sprouting by treatment of the spinal cord of adult rats with antibodies against the neurite outgrowth inhibitor Nogo-A led to an increased transcription of α-actin (Bareyre *et al.*, 2002).

In *A. leptorhynchus*, Western blot analysis of tissue lysates from the area around the lesion in the corpus cerebelli has revealed a single protein band at approximately 42 kDa recognized by antibodies directed against a conserved β-cytoplasmic actin N-terminal peptide (Zupanc *et al.*, 2006). This molecular weight is virtually identical to that of the protein recognized by the same antibody in lysates from mouse cerebellum, thus suggesting that in the corpus cerebelli of *A. leptorhynchus* a fish orthologue of β-actin is expressed.

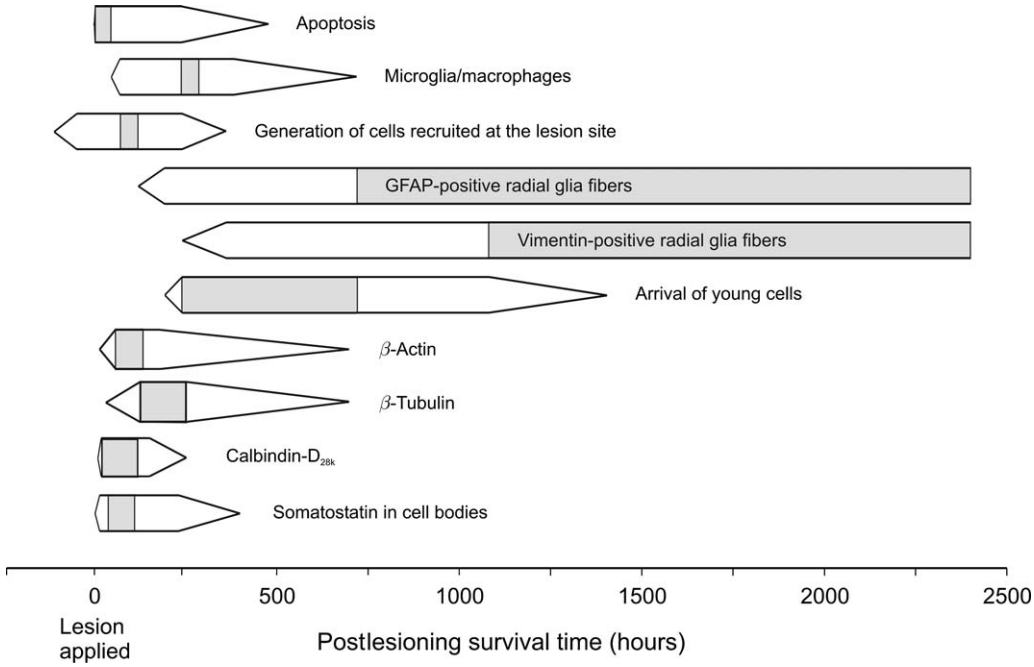

Figure 18 Schematic diagram of the time course of events in response to mechanical lesions applied to the corpus cerebelli of *A. leptorhynchus*. From the top these are: (1) Occurrence of apoptotic cell death at and near site of lesion (Zupanc *et al.*, 1998); (2) increase in density of microglia/macrophages throughout the corpus cerebelli (Zupanc *et al.*, 2003); (3) generation of new cells recruited to site of lesion 28 days after the injury (Zupanc and Ott, 1999; note that even cells born up to 2 days before the injury participate in the process of neuronal regeneration); (4) increase in density of GFAP-positive radial glia fibers at and near site of lesion (Clint and Zupanc, 2001); (5) increase in density of vimentin-positive radial glia fibers at and near site of lesion; (6) arrival of young cells at site of lesion (Clint and Zupanc, 2001); (7) upregulation of β-actin immunoreactivity at and near site of lesion (Zupanc *et al.*, 2006); (8) upregulation of β-tubulin immunoreactivity and appearance of new capillaries at and near site of lesion (Zupanc *et al.*, 2006); (9) upregulation of calbindin-D_{28k} immunoreactivity at and near site of lesion (Zupanc and Zupanc, 2006b); (10) upregulation of somatostatin immunoreactivity in somata of three cell types at and near site of lesion (Zupanc, 1999b). The first slope of each bar represents the time period during which the event shows an increase from background levels. The shaded area represents the peak period of the event. The second slope represents the time period during which the event decreases to background levels.

Immunohistochemical studies have shown that the fish orthologue of β-actin is exclusively expressed in fibers within the corpus cerebelli of *A. leptorhynchus* (Zupanc *et al.*, 2006). However, while such fibers are virtually absent in the intact corpus cerebelli (with the exception of an area at the midline of the granular layer; Figure 19a), β-actin-immunoreactive fibers appear in the area of the lesion as early as a few hours after the lesion. Between 1 and 5 days after lesion, these fibers develop into a dense, intensively labeled plexus (Figures 19b and 19c). After approximately 10–15 days, both the number of fibers and the intensity of the immunolabel gradually return to background levels (Figure 19d).

As in mammalian systems, it is likely that the transient upregulation of β-actin in the corpus cerebelli of *A. leptorhynchus* is associated with the regeneration of injured axons and the development of axons of newly generated cells. Such a notion is compatible with both the labeling pattern and the time course of the increase in protein abundance (Figure 18).

2.24.9.2 β-Tubulin

Tubulin, the principal component of microtubules, is a heterodimer of two closely related proteins, α- and β-tubulin, each with a molecular weight of approximately 50 kDa. Both the α- and β-subunit consist of a family of homologous isoforms, which appear to be related to different microtubule functions. Western blots using brain lysates of *A. leptorhynchus* have, in addition to the protein band at 50 kDa, revealed a second protein band at approximately 30 kDa (Zupanc *et al.*, 2006). The significance of this phenomenon is unclear because such an additional band has not been described in mammalian systems. Another remarkable feature of the anti-β-tubulin antibodies employed in this study was that they immunostained exclusively blood vessels and capillaries, both of which form a rich vascular bed in the granular and molecular layers (Figure 20a).

After application of lesions to the corpus cerebelli, both the composition of the immunolabeled

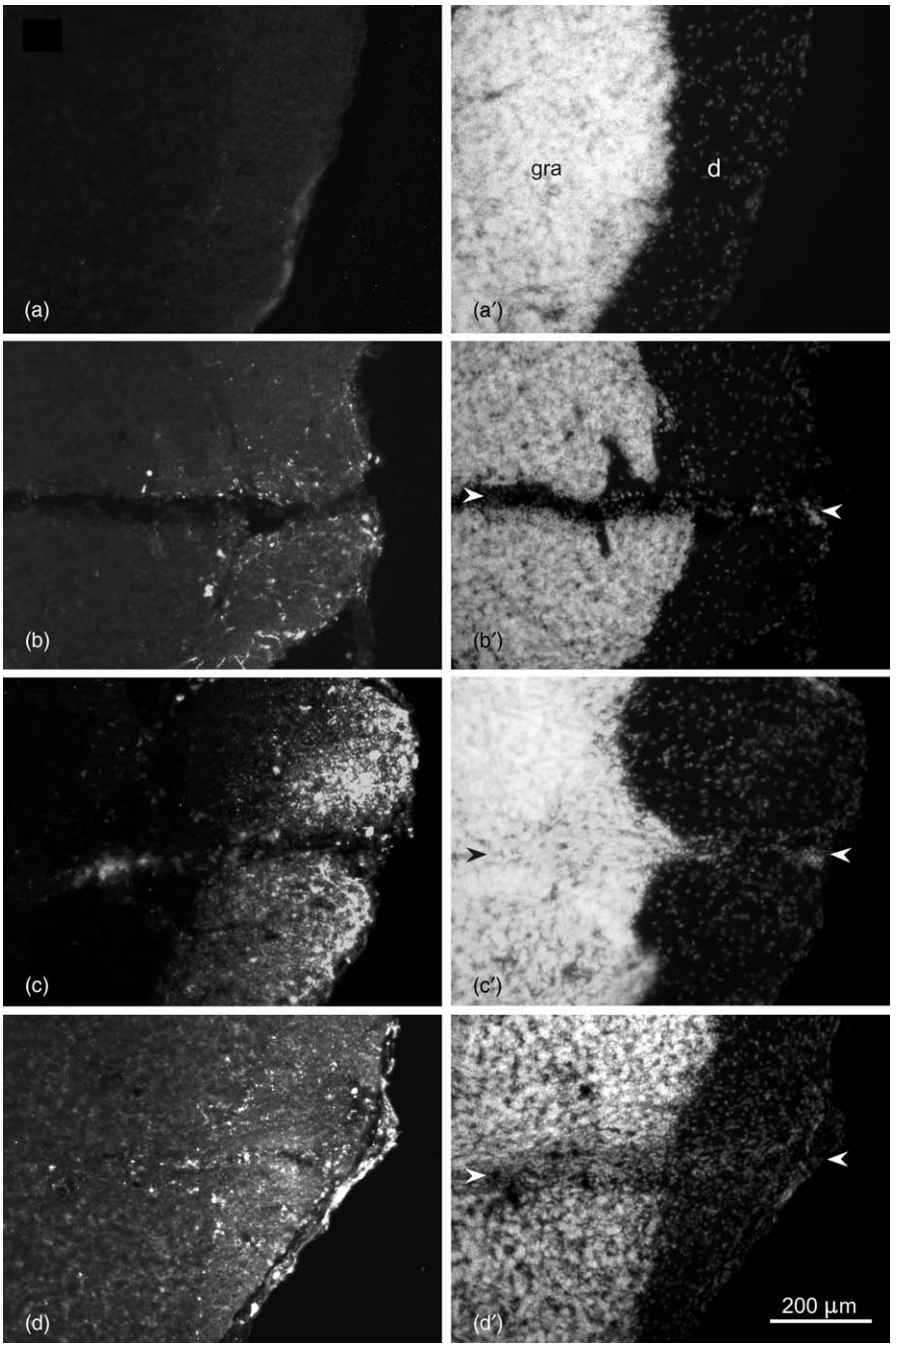

Figure 19 Pattern of immunostaining against β-actin in the intact (a) and injured (b–d) corpus cerebelli of *A. leptorhynchus*. In the DAPI counterstain of the transverse sections (a′–d′), the right hemisphere is shown with its granular layer (gra) and dorsal molecular layer (d) (dorsal: right; ventral: left; medial: up; lateral: down). The lesion path is indicated by arrowheads. Whereas in the intact corpus cerebelli immunolabeling is virtually absent (a), immunoreactive fibers have developed at 1 day after lesion in the area around the lesion within the dorsal molecular layer (b). At 3 days after lesion, the size of this fiber plexus and the intensity of immunostaining of fibers has increased (c). At 15 days after the lesioning of the cerebellum, both the number and the intensity of immunolabeling has declined compared to the pattern observed at the 3-day survival time (d). Reproduced from Zupanc, M. M., Wellbrock, U. M., and Zupanc, G. K. H. 2006. Proteome analysis identifies novel protein candidates involved in regeneration of the cerebellum of teleost fish. *Proteomics* 6, 677–696, with permission from Wiley-VCH.

structures and the intensity of the label exhibit pronounced changes (Zupanc *et al.*, 2006). In the first few days, the intensity of immunolabeling increases at the lesion site, compared to more distant regions or the equivalent areas contrallaterally or in the intact corpus cerebelli (Figure 20b). Five days after the lesion, the increase in the intensity of immunolabeling is paralleled by a pronounced rise in the

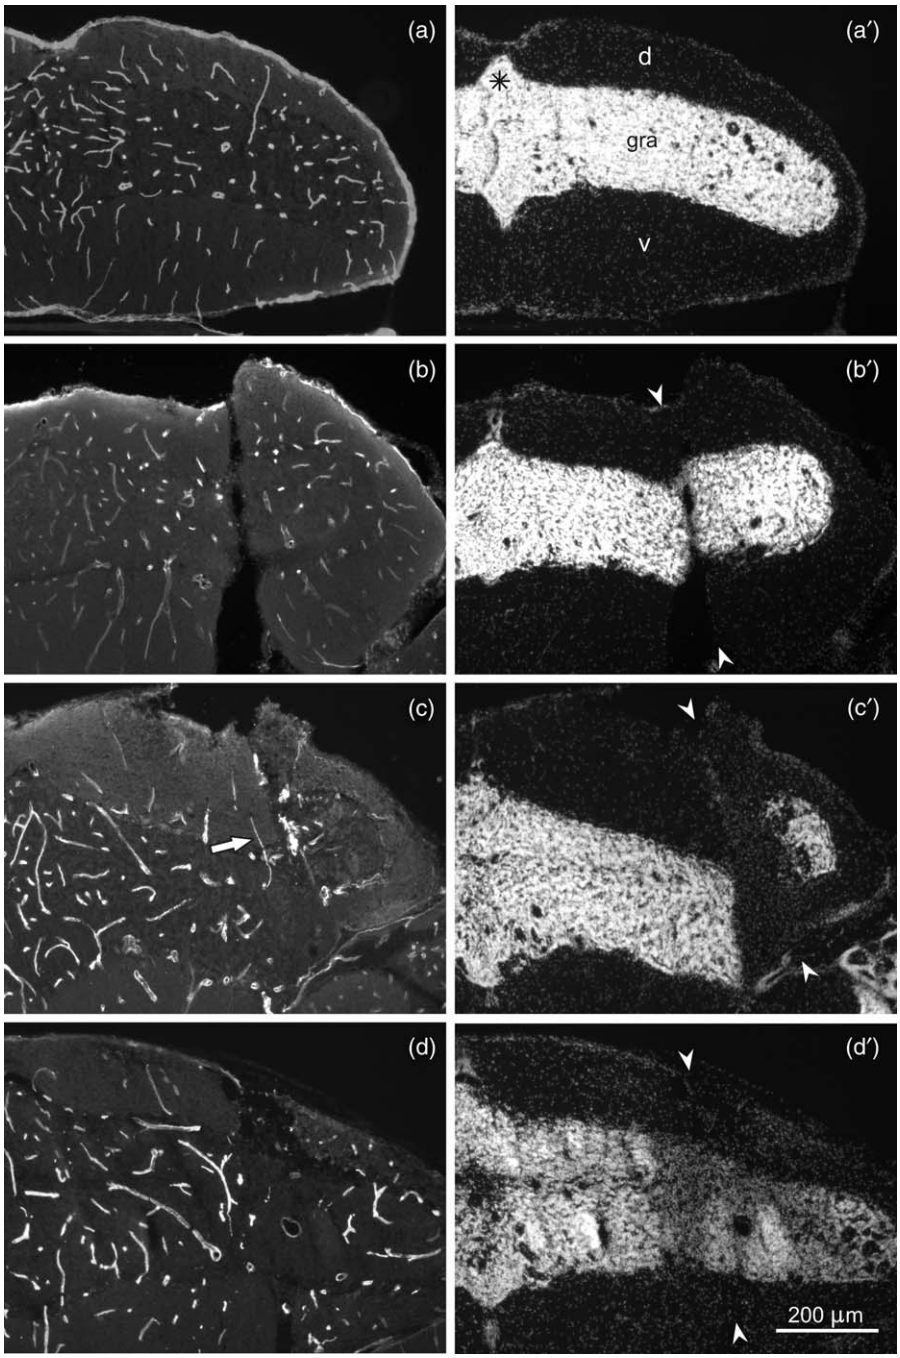

Figure 20 Blood vessels and capillaries immunostained against β-tubulin in the intact (a) and injured (b–d) corpus cerebelli of *A. leptorhynchus*. In the DAPI counterstain of the transverse sections (a′–d′), the right hemisphere is shown with its granular layer (gra), the dorsal molecular layer (d), and the ventral molecular layer (v) (dorsal: up; ventral: down; medial: left; lateral: right). The dorsal tip, a protrusion of the granule cell layer into the dorsal molecular layer at the midline, is indicated by * (a′) and the path of the lesion by arrowheads (b′–d′). Whereas in the intact CCb mostly large blood vessels are immunostained, and the intensity of immunolabeling is similar throughout the granular layer and the dorsal molecular layer (a), this pattern changes after application of a lesion (b–d). At 1 day after lesion, an increase in the intensity of immunolabeling is restricted to the area around the lesion (b). At 5 days after lesion, the intensity of immunolabeling remains elevated in the lesion path, but is also increased in other areas of the right hemisphere (c). In addition, the number of thin capillaries is increased in the area of the lesion. At 30 days after lesion, the lesion path and its immediate vicinity has become largely devoid of immunolabeled larger blood vessels, whereas, the number of immunolabeled thin capillaries in this area is higher than in the remaining regions of the CCb (d). Two of these thin capillaries are indicated by arrows. Note the restoration of a major part of the granular and molecular layers in the area of the lesion at the latter survival time, as evident through the DAPI counterstain (d′). Reproduced from Zupanc, M. M., Wellbrock, U. M., and Zupanc, G. K. H. 2006. Proteome analysis identifies novel protein candidates involved in regeneration of the cerebellum of teleost fish. *Proteomics* 6, 677–696, with permission from Wiley-VCH.

number of immunopositive vascular structures; the latter is mainly caused by the appearance of many thin capillaries (Figure 20c). At postlesion survival times of 10, 15, and 30 days, a gradual decline in the number of larger blood vessels is found in the area of the lesion, whereas the number of thin capillaries, particularly in the immediate vicinity of the lesion path, remains larger than in other areas of the corpus cerebelli (Figure 20d).

This pattern of immunolabeling suggests two major processes following a lesion: First, the blood vessels in the area of the lesion undergo cell death within a few weeks after the injury. Second, the depletion of large blood vessels is paralleled by a repopulation of the lesion area by thin capillaries, probably due to angiogenesis.

2.24.9.3 Calbindin-D_{28k}

Calbindin-D_{28k}, originally discovered as a vitamin D-dependent calcium binding protein with a molecular weight of approximately 28 kDa in the chick intestinal mucosa (Wasserman and Taylor, 1966), has been found in many types of tissue, including brain, in a variety of vertebrate species (for review, see Christakos *et al.*, 1989). Within the cell, this protein plays an important role as a calcium buffer in the maintenance of calcium homeostasis (for review, see Baimbridge *et al.*, 1992).

Western blot analysis of brain lysates of *A. leptorhynchus* has demonstrated the presence of a protein band with a molecular weight of approximately 28 kDa recognized by anti-rat-calbindin-D_{28k} antibodies. This suggests that this protein in the brain of *A. leptorhynchus* is similar to the mammalian form of calbindin-D_{28k} (Zupanc and Zupanc, 2006b). Immunohistochemical staining has indicated the absence of calbindin-D_{28k} immunoreactivity in most parts of the intact corpus cerebelli of *A. leptorhynchus*, including the region corresponding to the wider area of the lesion site in lesioned individuals.

Unlike the intact corpus cerebelli, calbindin-D_{28k} immunoreactive cell bodies and fibers are evident in the lesion path and the immediate vicinity of the lesion in the period between 16 h and 7 days after the lesion (Zupanc and Zupanc, 2006b; Figure 21). Both the number of immunolabeled cells and the intensity of the label are most pronounced 1–3 days after lesion. Analysis of the morphology of the immunostained cells by confocal microscopy suggests that most, and perhaps all of them, are granular neurons.

Since the transient upregulation of calbindin-D_{28k} is paralleled by a decline in the number of cells undergoing apoptotic cell death (Figure 18), it has been hypothesized that this protein exerts a neuroprotective function by buffering free intracellular Ca^{2+}, the concentration of which is commonly elevated after brain insults. Such a role of calbindin-D_{28k} has also been proposed in a variety of other brain systems and is supported by several lines of evidence, including age-related decreases in calbindin-D_{28k}-expressing neurons, particularly in brain areas selectively vulnerable in neurodegenerative diseases of the elderly (Iacopino and Christakos, 1990; Kishimoto *et al.*, 1998; Bu *et al.*, 2003; Geula *et al.*, 2003); reduced levels of calbindin-D_{28k} expression in the brains of humans suffering from neurodegenerative diseases, such as Alzheimer's, Parkinson's, and Huntington's, as well as in animal models mimicking such diseases (Iacopino and Christakos, 1990; Iacopino *et al.*, 1992; Ng *et al.*, 1996; Thorns *et al.*, 2001); the relative resistance of calbindin-D_{28k}-expressing neurons to neurotoxicity induced by glutamate, calcium ionophore, or acidosis (Mattson *et al.*, 1991); and an increase in the survival of neurons after various types of insults by overexpression of the gene for calbindin-D_{28k} (Ho *et al.*, 1996; Phillips *et al.*, 1999; Monje *et al.*, 2001; D'Orlando *et al.*, 2002). Such a neuroprotective effect is paralleled, and probably mediated, by the Ca^{2+}-buffering capacity of calbindin-D_{28k}, as hippocampal neurons expressing this protein, which are relatively resistant to neurotoxicity, exhibit a greater capability to reduce free intracellular Ca^{2+} levels than calbindin-D_{28k}-negative neurons in cell culture (Mattson *et al.*, 1991).

2.24.9.4 Somatostatin

Somatostatin (= somatotropin-release inhibiting factor, SRIF) is one of the most abundant neuropeptides in the mammalian brain, displaying concentrations between 1000 and more than 4000 pmol g^{-1} protein (Crawley, 1985). In mammals, the biologically active forms of somatostatin, a tetradecapeptide (SRIF-14), and an N-terminally extended form of SRIF-14 consisting of 28 amino acids (SRIF-28), are synthesized as part of a large precursor molecule (prepro-somatostatin) comprising 116 amino acids (for review, see Patel, 1992). This molecule, encoded by a single gene, is rapidly cleaved into the prohormone form (pro-somatostatin; 92 amino acids), which is further processed into various smaller molecules including SRIF-14 and SRIF-28. SRIF-14 is totally conserved from fish to human (Vale *et al.*, 1976; King and Millar, 1979). Additional forms of somatostatin have been identified in several fish species. These fish-specific

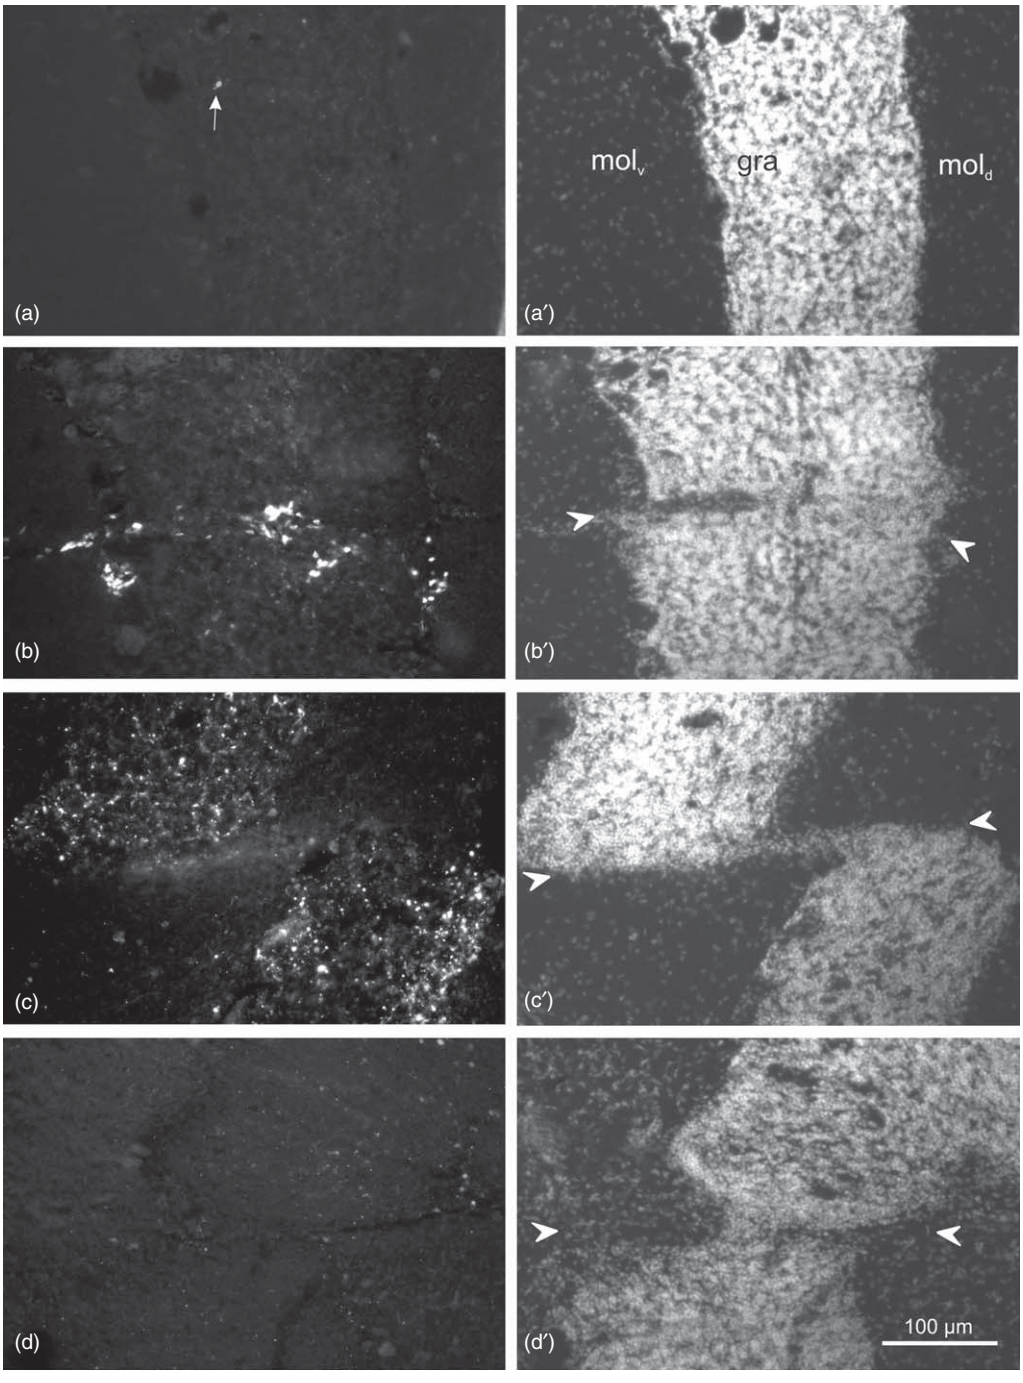

Figure 21 Calbindin-D_{28k} immunoreactivity in the intact corpus cerebelli (a) and the lesioned corpus cerebelli after survival times of 1 day (b), 2 days (c), and 7 days (d). The cytoarchitecture (gra, granular layer; mol_d, dorsal molecular layer; mol_v, ventral molecular layer), including the lesion path (arrowheads), are shown in the corresponding DAPI counterstains (a′–d′). In the intact corpus cerebelli, immunolabeling is sparse (a). The arrow points to a single immunopositive cell body. Intensively labeled cell bodies are associated with the path of the lesion at a postlesion survival time of 1 day (b). Labeled somata intermingle with an intensely labeled fiber plexus at 2 days postlesion (c). At 7 days postlesion, the number and intensity of immunolabeled structures are dramatically reduced and have almost reached control levels (d). Reproduced from Zupanc, G. K. H. and Zupanc, M. M. 2006b. Upregulation of calbindin-D_{28k} expression during regeneration in the adult fish cerebellum. *Brain Res.* 1095, 29–34, with permission from Elsevier.

forms are derived from a second gene, which apparently has been lost in the course of evolution leading to higher vertebrates (for review, see Patel, 1992).

In *A. leptorhynchus* and the closely related genus *Eigenmannia*, somatostatin-like immunoreactivity (Sas and Maler, 1991; Zupanc *et al.*, 1991a; Stroh and Zupanc, 1993, 1995, 1996) and somatostatin

messenger RNA (Zupanc *et al.*, 1991b) are widely distributed within the brain. The endogenous ligand interacts with specific receptors, as indicated by the demonstration of somatostatin-receptor binding sites (Zupanc *et al.*, 1994) and the molecular cloning and pharmacological characterization of a somatostatin receptor resembling the mammalian sst_3 receptor subtype (Zupanc *et al.*, 1999; Siehler *et al.*, 1999, 2005).

In the intact corpus cerebelli, very few cells displaying somatostatin-like immunoreactivity are found. However, their numbers increase dramatically at the lesion site 1 day after application of the stab wound and reach peak levels at 2 days, followed by a rapid decline to background levels between 5 and 10 days after lesion (Zupanc, 1999b; Figures 22 and 23).

Since the time period during which somatostatin is upregulated coincides with the period during which most of the cells later incorporated at the site of the lesion are generated (Figure 18), it is possible that this neuropeptide is involved in the regulation of cell proliferation. Indeed, a growth-inhibiting action of somatostatin is well established for numerous tumors (for review, see Pollak and Schally, 1998) and for the regeneration of several peripheral organs (Kokudo *et al.*, 1992; Thompson *et al.*, 1993; Zieleniewski and Zieleniewski, 1993; Bufalari *et al.*, 1996). Somatostatin appears to exert this function though a cell-cycle block due to G_1 arrest (Mascardo and Sherline, 1982) or through induction of apoptosis (Szende *et al.*, 1989; Srikant, 1995).

Alternatively, somatostatin may act as a trophic factor-like substance by influencing the early stages of differentiation of the young granule cell neurons. Evidence for such a function stems from developmental studies in mammals. In the cerebellum, somatostatin-binding sites are transiently expressed during a restricted period shortly after birth when the cerebellar granule cells are formed. Medium supplemented with somatostatin induces neurofilament synthesis in cultured granule cells (Taniwaki and Schwartz, 1995; Schwartz *et al.*, 1996), thus supporting the notion that this neuropeptide could act as a differentiation factor.

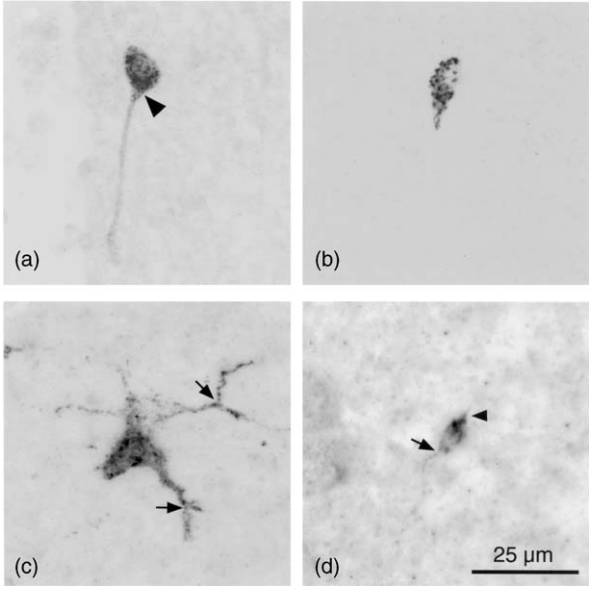

Figure 22 Confocal images of cell types in the corpus cerebelli expressing somatostatin after lesions. a, Cell type-1 is comprised of ovoid-shaped cells from which one process emerges (arrowhead). b, The cytoplasm of cells of type-1 is distinguished by grains filled with intensely labeled immunoreactive material. c, The typical feature of type-2 cells is the large, multipolar morphology. Their processes are relatively thick and bifurcate shortly after having emerged from the soma (arrows). d, Cells comprising type-3 are small. One process originating from the cell shown in the confocal image is clearly labeled (arrow). At the opposite pole, the initial segment of another process is visible (arrowhead). Based on their morphological features, type-1 cells are probably granular neurons, type-2 cells astrocytes, and type-3 cells microglia. Reproduced from Zupanc, G. K. H. 1999b. Upregulation of somatostatin after lesions in the cerebellum of the teleost fish *Apteronotus leptorhynchus. Neurosci. Lett.* 268, 135–138, with permission from Elsevier.

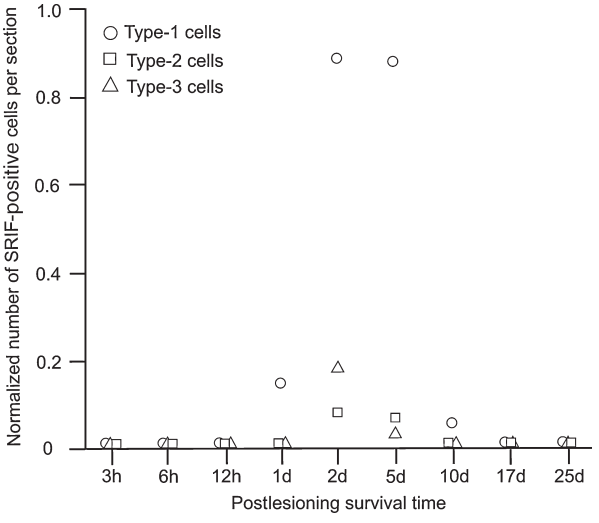

Figure 23 Temporal pattern of antisomatostatin immunoreactivity expressed by three different types of cells after application of lesions to the corpus cerebelli. In each of the three cell types, the level of SRIF is very low within the first 12 h following the lesion. Then, over the next few days, somatostatin expression, as assessed by the normalized number of somatostatin-positive cells per section taken through the rostrocaudal extent of the lesion, dramatically increases. This number has returned to background levels by day 17 after the lesion. Reproduced from Zupanc, G. K. H. 1999b. Upregulation of somatostatin after lesions in the cerebellum of the teleost fish *Apteronotus leptorhynchus. Neurosci. Lett.* 268, 135–138, with permission from Elsevier.

2.24.10 Toward an Evolutionary Understanding of Adult Neurogenesis

Although adult neurogenesis has been intensively studied over the last decade, particularly since its existence was demonstrated in the human brain (Eriksson *et al.*, 1998), an insufficient amount of comparative data is available to reach a comprehensive understanding of the evolution of this phenomenon. This applies not only to vertebrates as a whole, but also to any of the other major taxonomic groups. In teleosts, for example, a detailed mapping of the proliferation zones in the whole adult brain has been conducted in just three out of an estimated 25 000 species: *A. leptorhynchus* (Zupanc and Horschke, 1995), the three-spined stickleback (Ekström *et al.*, 2001), and the zebra fish (Zupanc *et al.*, 2005). In other important clades, such as hagfishes, lampreys, or cartilaginous fishes, thus far no detailed investigation of adult neurogenesis has been published at all.

Despite these limitations, it appears likely that adult neurogenesis is a trait shared by all teleost fish (see Section 2.24.4). Moreover, in any of the teleostean species examined thus far, neurogenesis occurs in many regions of the adult brain, and the number of new neurons is immense relative to the total number of brain cells.

In contrast, in mammals adult neurogenesis is limited to two brain regions, and the overall rate of neurogenesis relative to the number of cells in the whole brain is very low. These limits of neurogenesis could be causally related to the fact that the number of sensory receptor cells and muscle fibers remains constant in mammals during adult life. The only exception is the generation of new primary sensory cells in the olfactory epithelium, which may prompt neurogenesis in the olfactory bulb and the hippocampus (see Section 2.24.6).

One possible explanation for this difference between teleost fish and mammals is that neurogenesis in the adult brain is a primitive trait that already existed some 400 Mya in the common evolutionary ancestors shared by modern mammals, birds, reptiles, amphibians, and ray-finned fishes. One major function of this trait has been to ensure a constant ratio of motor (sensory) elements versus central elements within motor (sensory) pathways when the number of peripheral elements grows. However, as soon as the pattern of muscle growth shifted from hyperplasia more toward hypertrophy in the course of the evolution of mammals, the neurogenic potential of brain structures forming part of the motor pathway was reduced in parallel. A similar reduction in the number of neurogenic brain regions and in the rate of neurogenesis occurred when the formation of new sensory cells was more and more abandoned. According to this hypothesis, neurogenesis would have continued only in the olfactory bulb and the hippocampus as a consequence of the continued mitotic activity in the olfactory epithelium.

3.01 What Fossils Tell Us about the Evolution of the Neocortex

H J Jerison, University of California, Los Angeles, CA, USA

Glossary

allometric Applied to morphology, the measures of two different organs or of an organ and the whole body.

archaic orders Orders of mammals that are entirely extinct.

encephalization Enlargement of the whole brain relative to its expected size.

encephalization quotient (EQ) Gross brain size relative to expected brain size; expected brain size is determined by the regression of brain size on body size in an appropriate set of species on which data are available, the empirical quotient is the residual from the regression on log-log coordinates.

endocast Cast molded by the cranial cavity in vertebrates. Also called endocranial cast.

foramen magnum The hole at the entry of the spinal cord into the cranial cavity. It may be thought of as 'medulla' in an endocast, but is actually larger, containing blood vessels and sinuses in addition to medulla and anterior spinal cord.

fossil brains Fossil endocasts interpreted as brains.

holarctic Northern Hemisphere.

neocortex A thin sheet of many millions of nerve cells in the telencephalon of the brain of all living mammals, often considered as involved in conscious thought. All sensory information (vision, hearing, smell, taste, etc.) is known to be represented in various localized regions in the neocortex, frequently in many 'projection areas'. Higher functions such as intention, motivation, and attention are correlated with neocortical activation. It is a uniquely mammalian structure, and in histological sections, in living species, it has six layers of nerve cells as distinct from other brain structures with fewer layers or without layering.

neocorticalization Enlargement of neocortex relative to expected enlargement from brain-body analysis. It can be measured as the ratio of neocortical surface area to total brain or endocast surface area.

neotropical Southern Hemisphere (primarily South and Central America).

paleoneurology The science that deals with the fossil evidence of the nervous system and behavior. Primary evidence is from endocasts, but also evidence of behavior inferred from skeletal adaptations for running or climbing, dental patterns, animal tracks, and nesting sites.

progressive orders Orders of mammals in which living species have survived.

relative neocortical surface area Ratio of neocortical surface area to total endocast surface area.

3.01.1 Introduction

The story of the brain's evolution is told by casts of the cranial cavities of extinct species. These endocasts document much of the evolution of the mammalian brain during the past 65 million years, the Cenozoic era. A single late Jurassic fossil (Simpson, 1927; Jerison, 1973) had extended the known evidence to about 150 Mya, and other

explorations (Hu *et al.*, 2005; Kielan-Jaworowska *et al.*, 2005; Novacek, 1996) fill gaps in our knowledge of the Cretaceous period (65–145 Mya). Mammals first appeared during the Triassic period of the Mesozoic, and it may one day be possible to trace the history of the mammalian brain almost to its beginnings, perhaps 225 Mya (see The Evolution of Neuron Classes in the Neocortex of Mammals, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications).

Encephalization is the increase in relative size of the brain as a whole over geological time. Its history was reviewed in depth in Jerison (1973) (cf. Falk, 1992; Falk and Gibson, 2001). Other recent evolutionary analysis emphasizes methodological innovations in cladistic analysis, with major revisions of mammalian phylogeny (McKenna and Bell, 1997; cf. Simpson, 1945). This article is consistent with those revisions.

Our central topic is neocorticalization, the increase of the relative amount of neocortex in mammals. ('Relative' in this case refers to the ratio of surface area to total surface area of the endocast.) Identifiable neocortex is a feature of the external morphology only of mammalian brains, but neural structures with similar functional significance have also evolved in birds and reptiles (Butler and Hodos, 2005; Karten, 1997; Reiner *et al.*, 2005). Avian and reptilian brain structures homologous with mammalian neocortex must first have appeared in the common amniote ancestor of these classes of vertebrates, but fossils are unlikely to be helpful in identifying these earlier ancestral connections. The question for this article is whether there was a change in neocorticalization within the mammals as they evolved during the past 225 million years (see The Origin of Neocortex: Lessons from Comparative Embryology). Like the avian Wulst, which is absent in endocasts of the earliest birds, evidence of neocortex may have been absent in endocasts of the earliest mammals. We don't yet know, but I review what we do know in this article.

We know that the neocortex, like the brain as a whole, became relatively larger in some but not all mammalian lineages (Jerison, 1990). Neocortex is present in all living mammals. Fossils tell their history, and it is reassuring that their evidence is consistent with inferences from the comparative neuroanatomy of living species (Butler and Hodos, 2005; Johnson, 1990; Shimizu, 2001). Opossums and hedgehogs (*Didelphis virginianus* and *Erinaceus europaeus*) can still be viewed as 'primitive', and cats and dogs and monkeys may be thought of as 'advanced', although one recognizes that this is an arbitrary dichotomy. (Spellings and orthography in this article follow the rules of taxonomic nomenclature. Genus and species are italicized, genus capitalized and species in lowercase.) From the fossils, we learn approximately when some identifiable changes in the brain occurred and how they differed in different lineages. They are the real proof of what is otherwise conjecture, that in most mammal species the brain evolved to relatively larger size and that this encephalization was usually accompanied by increased neocorticalization. Surprisingly, there appears to have been no comparable change in the olfactory bulbs other than their reduction in primates evident since the Miocene (about 20 Mya) and their complete disappearance in at least some cetaceans even longer ago.

All of the neural adaptations recognizable in the fossils are ancient, many occurring tens of millions of years ago. The most recent changes have been within the hominins, the human lineage, in which the most recent measurable increases in encephalization appeared about 250 000 years ago in the Neandertal and sapient species (*Homo neanderthalensis* and *Homo sapiens*). (References in the text to Neandertal follow the current German spelling and capitalization of nouns. The Neandertals were named for the Neander Valley in which the first specimen was found in 1856. German is famous as a language that combines words and elongates them rather than keeping them as short phrases; thus, the Neander Valley (capitalized in English as a place name) was the 'Neanderthal' before the German spelling reform of 1908, when it became 'Neandertal'. The rules of taxonomic nomenclature preserve the first published name of *Homo neanderthalensis*. The initial capital letter for the German was dropped in the species name in deference to the taxonomic usage of lower case for species. The genus '*Homo*' is as named by Linnaeus in 1758. Specimens shown here are as catalogued in AMNH (American Museum of Natural History, New York), BMNH (Natural History Museum of London, British Museum), FMNH (Field Museum of Natural History, Chicago), WISC (University of Wisconsin), and UT (University of Texas, Department of Paleontology).) The evolutionary evidence is at the generic and species level. I review a few within-species differences (Figures 3 and 4), but these are small compared to between-species effects.

3.01.2 Fossil Brains

Molded by the cranial cavity, endocasts such as those reviewed here have been called fossil 'brains' (Edinger, 1929; see Kohring and Kreft, 2003). The

brain, as soft tissue, does not fossilize, of course, but endocasts in birds and mammals resemble brains with dura intact, and they often show the superficial pattern of sulci and gyri in remarkable detail. Further analysis relies on relationships of external structures to the functional and microscopic anatomy of brains in living animals. In this chapter, brains and endocasts are treated as equivalent to one another. For most purposes, one can ignore the small differences between them in size and shape and use the same terminology for parts of an endocast as for comparable parts of the brain.

Neocortex can be distinguished from other structures visible on the surface of an endocast in mammals by using the rhinal fissure as the landmark. The evidence is exemplified by the brain of the living armadillo shown in Figure 1a. Rhinal fissure can be traced backward from the dorsal margin of the olfactory tract, and the fissure visible on the brain is also visible on endocasts. Figure 1b is a coronal section to show how the rhinal fissure serves as the boundary between neocortex and paleocortex, with paleocortex identified by the darkly stained layer of neurons in lamina II. Neocortex is taken as dorsal to the rhinal fissure on brains and endocasts.

Endocasts can be made from the cranial cavity of any skull. Those made from fossils are of special interest, because they are a physical record of the actual evolution of the brain. Figure 2, for example, presents snapshots of three-dimensional (3-D) scans of endocasts of two Eocene fossil mammals that lived about 40 Mya, a prosimian primate *Adapis parisiensis* and an even-toed ungulate (artiodactyl), *Anoplotherium commune*. Their endocasts may be compared with the brains of the living bush baby (*Galago senegalensis*) and the living llama (*Lama glama*), a camelid distantly related to *Anoplotherium*. An endocast of another Eocene fossil artiodacyl, *Bathygenys reevesi*, is shown in Figure 5 and that of an archaic Paleocene herbivore (*Phenacodus primaevus*, order Condylarthra, 58 Mya) is shown in Figure 9.

The olfactory tract and rhinal fissure are easily distinguishable on the lateral surface of the endocasts of *Anoplotherium* and *Bathygenys*; they are less clear but also identifiable in *Phenacodus*. We identify and measure neocortical surface area as dorsal to the fissure. The rhinal fissure in *Adapis* follows a course very much like that in the living bush baby, partly hidden by the temporal lobe. To be able to see the rhinal fissure in this endocast, it has to be rotated a bit to display more of the ventral surface. One objective of 3-D analysis reported here was to rotate virtual endocasts in primates to expose neocortex and include primate measurements in the analysis of mammalian data. Neocorticalization is the increase of neocortex relative to the rest of the brain, and it can be measured as a ratio of surface areas on an endocast.

This article is primarily on a quantitative analysis, but there is one interesting qualitative feature evident in Figure 2 that may be important. Comparing the Eocene fossils and their living relatives there is an obvious difference in the flexure of the brain, in the extent to which it is curved about the primary anterior–posterior axis, which is more marked in the living ungulates than the primates but evident in both. For example, in the fossils, olfactory bulbs, forebrain, hindbrain, and medulla are more or less in a line like railroad cars. The brains of their living relatives are bunched up and more globular. The difference probably results from the patterns of relative growth of the skull and skeleton compared to

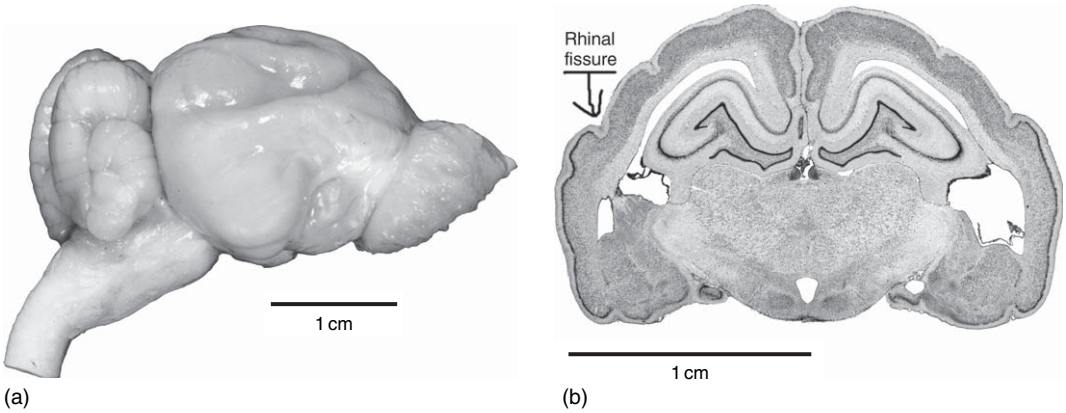

Figure 1 a, Brain of armadillo, *Dasypus novemcinctus*; rhinal fissure faintly visible dorsal to olfactory tract, then prominent further posteriorly. b, Coronal section of armadillo brain showing lamina II (dark stained layer) at border of rhinal fissure. Specimen WISC 60-465.

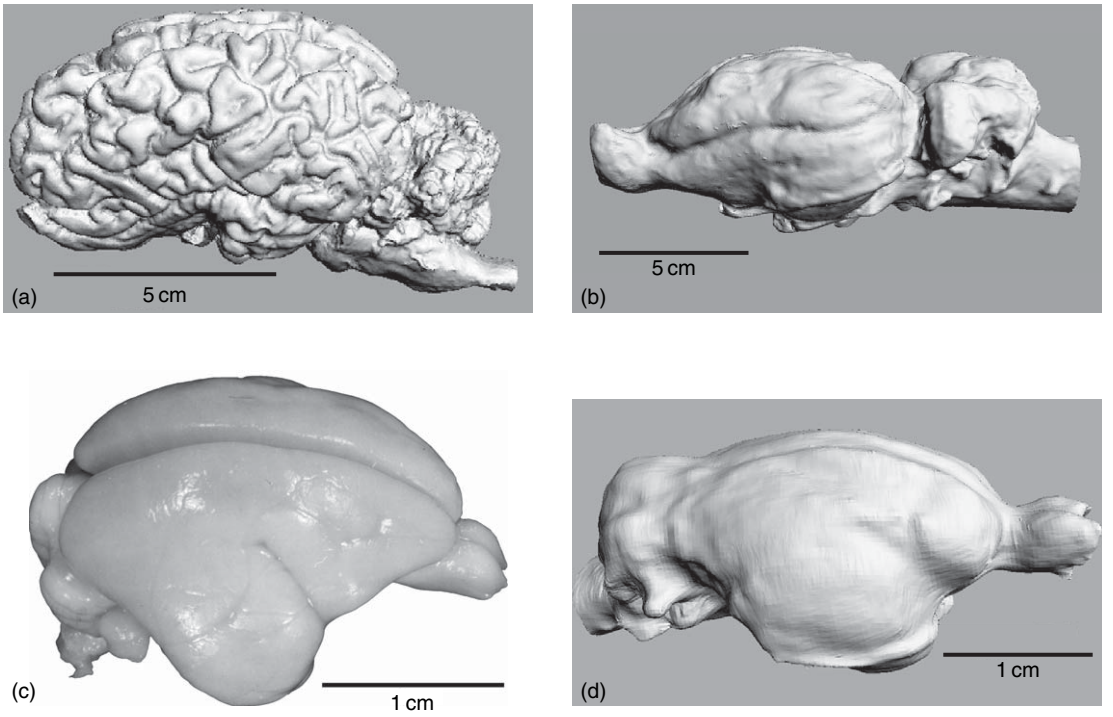

Figure 2 a, Brain and b, endocast in two artiodactyls, the living llama (*Lama glama*, WISC 65-139) and a 40-million-year-old camelid, A*noplotherium commune*, BMNH 3753. c, Brain of the living bush baby (*Galago senegalensis*, WISC 61-686) and d, endocast of a 40-million-year-old prosimian, *Adapis parisiensis*, FMNH 59259/BMNH 1340.

the growth of the brain, and is at least partly an epigenetic effect of squeezing a brain into the confines of the cranial cavity.

When an overall trend in skeletal growth resulted in enlargement of the cranial cavity, the brain can grow to fill and, to an extent, shape the cranial cavity. When trends toward encephalization became more prominent, the pressure was to maximize the amount of brain that could be packed into a given space. Later brains became more globular, primarily as an accommodation to maximize their volume relative to the space available for their growth. The change in shape as an evolutionary event would have been one of the changes that occurred at the Grande Coupure, the extinction of many species at the end of the Eocene and the beginning of the Oligocene about 33 Mya (Hooker *et al.*, 2004).

3.01.3 The Specimens and Their Measurement

The 78 ml plaster endocast of *Anoplotherium* in Figure 2 was prepared from the carefully cleaned cranial cavity of the fossil's skull (Palmer, 1913). This animal probably weighed about 80 kg, a weight comparable to that of the living llama in which the brain's volume is about 230 ml. *Bathygenys* (Figure 5) was a small artiodactyl that lived at the end of the Eocene, 35 Mya. It was about the size of the living chevrotain weighing about 5 kg. Its 12 ml natural endocast shown in Figure 5 is actually a piece of rock, but it unmistakably pictures the brain. One chevrotain (*Tragulus javanicus*) has been reported as weighing 4 kg with a 19 g brain (Nieuwenhuys *et al.*, 1998). The area of neocortex in both *Anoplotherium* and *Bathygenys* was 28% of the entire surface area of the endocast. In Oligocene species that lived about 30 Mya, such as the fossil horse Mesohippus, typical ratios are about 40% or more.

The volume of the endocast of *Phenacodus* (Figure 9) is 31 ml, and 16% of its surface area is neocortex. Its rhinal fissure is less marked than in the other endocasts illustrated here, but adequate for a measurement of the area of its neocortex. It was illustrated by Cope (1883). The endocast scanned for this analysis is a copy of the one made by Cope. Reconstructions of *Phenacodus* in life (Savage and Long, 1986) show it as living in a small herd of sheep-like five-toed animals. The weight of the fossil, estimated as 56 kg, is also appropriate for living sheep (*Ovis aries*) in which a brain weight of 130 g has been recorded.

Adapis, a prosimian primate that was a contemporary of *Anoplotherium*, weighed about 1.5 kg, and its endocast's volume was 8 ml. From skeletal

features, it has been reconstructed as a tree-dwelling lemuroid. The brain of the living galago, the bush baby, is shown for the comparison in Figure 2 because it is about the same size and shape as that of *Adapis*, but galago is a much smaller animal, weighing only about 250 g. A living lemur (*Lemur fulvus*) has been recorded with a body weight of 1.4 kg and had a 23 g brain.

The differences between the fossil and living brain sizes at comparable body sizes are examples of encephalization. Brains in most Eocene species averaged a quarter to half the size of living species in comparable niches and their relative size might be reported as 'encephalization quotients, EQs' – $0.25 < EQ < 0.50$ for Eocene fossils. Brain and body weight data on living species for comparisons are now available in many places. Some of the published data collections on living mammal species that I have seen have been in Count (1947), in Quiring (1950), and in Nieuwenhuys *et al.* (1998). I have published estimates on many fossil mammals (Jerison, 1973, 1990), and Holloway *et al.* (2004) has more data on primates in the human lineage.

EQs are not ratios of brain size to body size. They are ratios of measured brain or endocast size relative to expected size, and expected size is determined from the allometric relationship between brain and body size. That relationship is nonlinear and is usually described by the power function:

$$E = kP^{\alpha}, \qquad [1]$$

where E is brain size and P is body size in the same metric units (e.g., g or ml). There is some debate on correct values for the parameters k and α (see Jerison (2001)), but empirically the values $k = 0.06$ and $\alpha = 0.75$ are good approximate values as determined on large samples of living mammal species. When the equation is transformed logarithmically, it is

$$\log E = \alpha \log P + \log K. \qquad [1a]$$

Graphed on logarithmic coordinates, α is the slope and $\log k$ is the y-intercept of the best-fitting straight line. An encephalization quotient is the residual from that regression. For theoretical reasons (Jerison, 2001), I prefer $\alpha = 2/3$, in which case one must use $k = 0.12$ for computations. For a given set of parameters, it is an elementary exercise to compute an encephalization quotient.

To return to the specimens, the *Bathygenys* endocast in Figure 5 was made naturally. When this animal died, perhaps at a lakeside, its soft tissue decayed but its skull must have remained relatively undamaged. Sand and other debris could then pack the cranial cavity and could be covered and protected by layers of sediment. When the waters subsided, the skull and its contents eventually fossilized. Many millions of years later, the fossil was uncovered, presumably by erosion or earth movements. The fossilized skull must then have eroded, leaving only its hardened rock contents, the natural endocast. A lucky fossil hunter could find the specimen. Professor Jack Wilson of the University of Texas found the *Bathygenys* fossil, which he recognized as a natural endocast (Wilson, 1971), collected it for his paleontology department, and made it available for this report.

The plaster endocast of *A. commune* shown in Figure 2 is part of the history of anatomy and paleontology. A largely intact fossil skeleton of the whole animal was found in gypsum quarries in Montmartre, now part of Paris, and was named in 1804 by Baron Georges Cuvier. He noted that the fossil's canine teeth seemed short and ineffective as weapons – 'anoplos' is from the Greek for 'unarmed' and 'therium' for beast – hence, *Anoplotherium*. Serving under the Emperor Napoleon, Cuvier was director of the Muséum National d'Histoire Naturelle in Paris two centuries ago, and he undertook to demonstrate that fossils are evidence of the history of life.

At the time, fossils were sometimes considered to be mineral accretions that merely resembled living things. Cuvier accepted what we now recognize as the 'uniformitarian hypothesis', namely, that the present laws of nature have always been valid (Simpson, 1970). That he named the fossil according to his judgment of its teeth is a uniformitarian view that is natural for us. We share the judgment that they are not merely rocks that happened to look like teeth but were once teeth and had fossilized. The story is that in a public exhibition Cuvier 'dissected' his *Anoplotherium*, in which some of the fossilized vertebral column was exposed. The dissection was with hammer and chisel, and Cuvier pointed out that if what looked like the vertebral column had been the vertebral column of an animal that once lived, further exposure would reveal pelvic bones. It did. This was his way of proving that he had been working on the remains of an animal that was comparable anatomically to living animals.

Among the other endocasts and brains illustrated in this chapter, *Phenacodus* was collected and named by Edward Drinker Cope as mentioned earlier, and it was one of the bones of contention in the fossil feud of the late nineteenth century about discoveries in the American West (Wallace, 1999). The adapid endocast is from a skull presently at the Natural History Museum of London and was from the phosphorites of Quercy in southwest France, a Late Eocene site in which the fossils are about 40

million years old. Its endocast was first prepared a century ago under the direction of Elliot Smith (1903) and has had a prominent place in discussions of the evolution of the primate brain (LeGros Clark, 1962). This article's scan is from a later preparation for Professor Robert D. Martin, then at the Anthropology Department of University College, London (Martin, 1990). The brain of galago with which it is compared in Figure 2 is from the University of Wisconsin brain collection, a collection that I consulted for comparisons with almost all of the fossils analyzed for this chapter. At this writing, the Wisconsin collection can be viewed on the internet; see the 'Relevant Websites' section. Like the galago brain, the llama brain and the armadillo brain of Figure 1 are also in the Wisconsin collection. Some of that collection has been moved to Washington, D.C., and is now part of the National Museum of Health and Medicine of the Armed Forces Institute of Pathology.

Hundreds of fossil 'brains' have been collected throughout the world, either as natural endocasts or as latex or plaster casts made from fossil crania (Edinger, 1975), and they are available for study in the back rooms of many museums. The quality of an endocast as a model of the brain differs in different taxa. In fish, amphibians, and reptiles, the model is usually poor because when they mature their brains do not fill the cranial cavity. Semicircular canals and other auditory and vestibular structures are occasionally well preserved in many vertebrates (Rowe, 1996; Dominguez *et al.*, 2004). In mammals and birds, endocasts often provide accurate and detailed pictures of the external surface of the brain as in Figures 2, 5, and 9. Comparisons between brains and endocasts in living mammals indicate that only minor errors occur in treating endocasts as undissected brains.

Measurement of surface area in endocasts was essentially impossible until recently, when technologies were developed that enable us to scan and digitize irregular solids for computer analysis. The endocasts used for the 3-D analysis in this chapter were digitized with a laser scanner system and its associated software. After scanning, the surface areas were measured with that software to provide the data for Figures 7 and 8. At this writing, more details about the system are available on the internet; see 'Relevant Websites' section.

3.01.4 Brains and Endocasts

Why should we be concerned with simple-minded measurements of gross brain size? One obvious reason is that these are reliable measures that can be taken on fossils, and they enable us to quantify the evolution of the brain. Less appreciated is their utility for an understanding of the brain's work in living species, because gross brain size, either surface area or brain weight or volume, may estimate the total information-processing capacity of brains in living mammals. That relationship is inferred from Figure 3, which graphs surface area of living brains as a function of brain size. The number of neurons underneath a specific amount of surface appears to be constant in many species (Rockel *et al.*, 1980, but see also Haug, 1987 and Hofman, 1985, 1988). Since the total processing capacity of a neural system is related to the number of neurons in the system, total surface area must estimate the total number of information processing units in a brain. Analogously, the surface area of neocortex as a part of the brain measures the contribution of neocortex to the total amount of information processed by the brain. The surface–volume relationship as shown in Figure 3 is almost perfect with a product–moment correlation coefficient $r = 0.99$. Uniformitarianism suggests that this almost deterministic relationship was as true for fossil endocasts as it is for living brains, although there are questions raised at the end of this article among the 'caveats'.

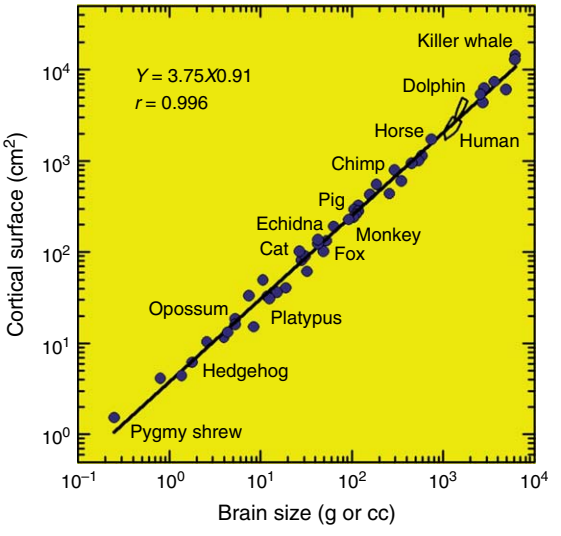

Figure 3 Total cortical surface area (including 'buried' cortex) as a function of brain size in 50 species of living mammals. Correlation: $r = 0.996$; regression: $Y = 3.75X^{0.91}$. A few of the species are labeled to suggest the diversity of the sample. Human and dolphin data are presented as minimum convex polygons enclosing 23 points for humans and 13 points for dolphins to suggest within-species diversity. Data from Brodmann (1913), Elias and Schwartz (1971), Ridway (1981), and Ridway and Brownson (1984). From Jerison, H. J. 1991. Brain size and the evolution of mind. 59th James Arthur Lecture on the Evolution of the Human Brain. American Museum of Natural History.

Figure 3 also provides information about within-species variability compared to that between species. In two of the species, humans (*H. sapiens*) and dolphins (*Tursiops truncatus*), it was possible to show the full range of individual data by enclosing those data in convex polygons that incorporate the complete samples. It is evident that the polygons are only slightly larger than the individual points graphed for the other species, each of which is a single datum for the species.

How good is an endocast as a representation of a brain? The obvious answer is in the endocasts and brains illustrated in this article. The relationship has been quantified for gross size in the human species and is shown in Figure 4. Although partly obscured by the well-known variability in human brain size, there is a strong relationship between brain and endocast (cranial capacity) as indicated by the high correlation coefficients. Endocasts and brains are equivalent to one another for information on size, with a small difference (about 7%) due to the fluids and meninges that surround the brain. The regression lines are parallel to one another, showing that the difference between endocast and brain follows the same rule for women and for men. This article is not concerned with the sex differences in human brain size, but that difference is also shown to complete the graphic summary of the data as published by Davis and Wright (1977).

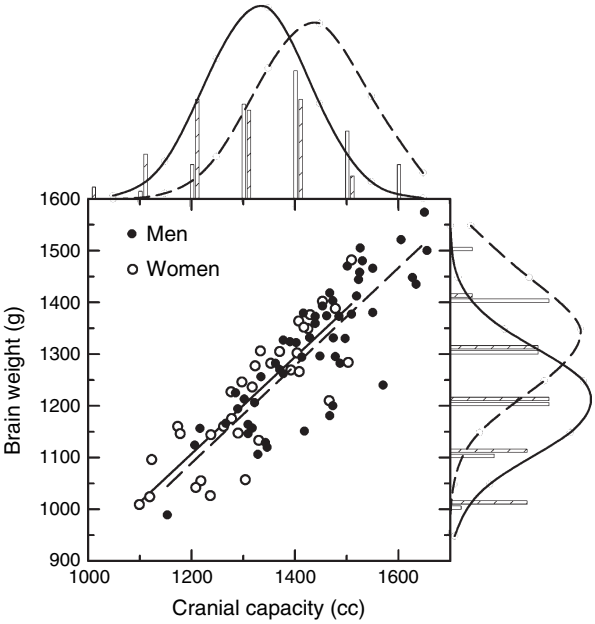

Figure 4 Relationship between brain size and cranial capacity (endocast volume) in 54 human male and 33 female cadavers. Solid lines and normal curves for males; dashed lines and normal curves for females. Mean brain size: male = 1308 g; female = 1221 g. Mean cranial capacity (endocast volume): male = 1431 ml; female = 1322 ml. Correlation coefficients, $r = 0.84$ for men; $r = 0.85$ for women. Regression equations: male, $Y = 0.94X - 44$; female, $Y = 0.94X - 16$. Marginal distributions shown by fitted normal curves. Data from Davis, P. J. M. and Wright, E. A. 1977. A new method for measuring cranial cavity volume and its application to the assessment of cerebral atrophy at autopsy. *Neuropathol. Appl. Neurobiol.* 3, 341–358.

3.01.5 Two-Dimensional Analysis of Neocorticalization

The first quantitative analysis of neocorticalization presented measurements of the areas of neocortex and olfactory bulbs in 2-D lateral projections in a sample of 35 fossil and 24 living species of carnivores and ungulates (Jerison, 1990). It was based on profiles of the endocasts in which rhinal fissures were visible, and the measure was the area of neocortex dorsal to the fissure. The 2-D analysis was also performed on the areas of the olfactory bulbs. Data for the analysis are illustrated in Figure 5a on the endocast of *Bathygenys reevesi*, discussed earlier; Figure 5b sketches the the areas that were measured.

The 2-D results are graphed in Figure 6 and show how the neocortical and olfactory bulb quotients in this sample changed with geological age during the Cenozoic era. The quotients are ratios of measured brain areas relative to their expected areas, with the latter determined by the regression of brain areas on the height of the foramen magnum (medulla). The measure on the foramen magnum followed a suggestion by Radinsky (1967) to use the foramen measure to control for body size differences in different species. The quantitative analysis was limited to neocortex and olfactory bulbs. Paleocortex and hindbrain were not analyzed because the curvature of the brain hides much of the paleocortex and because hindbrain regions such as the cerebellum are partly hidden under overlying neocortex. (Regression analysis such as this is often referred to as allometric analysis, the analysis of the measures of two organ sizes relative to one another.)

The results of the 2-D analysis as discussed in the original report (Jerison, 1990) were, first, that neocorticalization occurred, which is shown by the significantly positive slope of the regression of the neocortical quotient on geological age. Second, the olfactory bulbs did not change in relative size in these species during the Cenozoic. Taken together, these two results validated the method in that it could discriminate between the change and absence of change. A third result was that the 'archaic' fossil species, that is, species from orders of mammals that are now entirely extinct, were

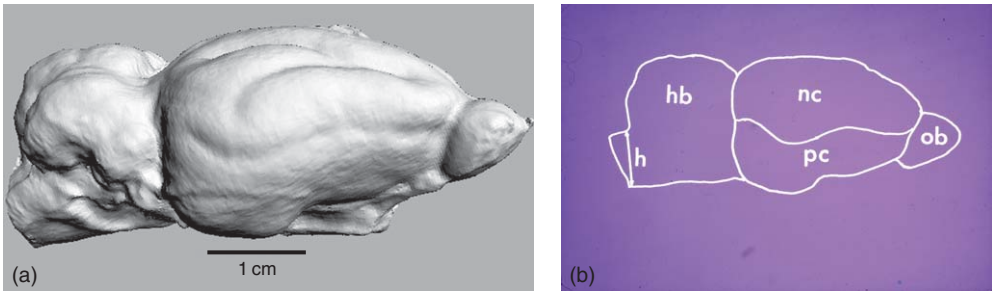

Figure 5 a, Natural endocast of *Bathygenys reevesi* (UT 40209-431). b, Profile of endocast, showing areas measured for Figure 6. nc, neocortex; ob, olfactory bulbs; h, height of foramen magnum. Not measured: pc, visible paleocortex; hb, visible hindbrain, including cerebellum.

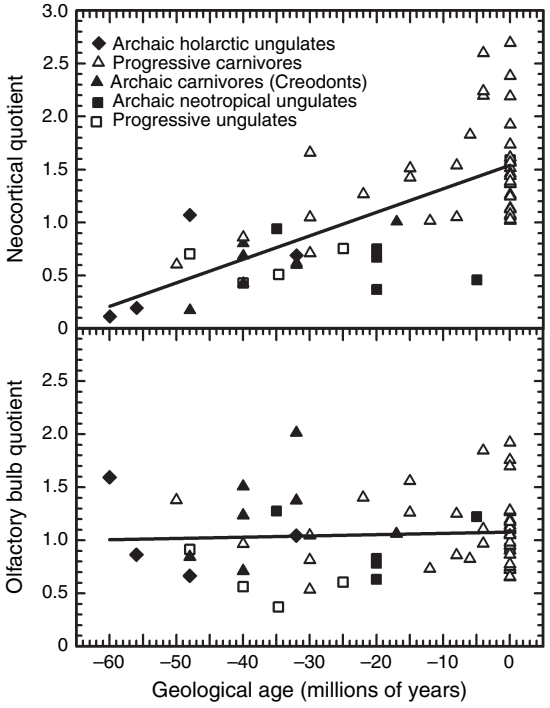

Figure 6 The 2-D analysis showing increased relative neocortical surface area (top) and stasis in olfactory bulbs (bottom) during the past 60 million years; see Figure 5. Quotients are residuals from regression of neocortex area and olfactory bulb area on foramen magnum height. They are interpreted as ratios of measured areas relative to expected areas on the basis of body size in this sample. 'Progressive' neocortical change noted here (positive slope of regression line; $r = 0.75$) demonstrates neocorticalization over time. Each point is a species. Archaic carnivores are from the order Creodonta. Other groups are discussed in the text. Redrawn from Jerison, H. J. 1990. Fossil evidence on the evolution of the neocortex. In: Cerebral Cortex (*eds.* E. G. Jones and A. Peters), vol. 8A, pp. 285–309. Plenum.

significantly below average in neocorticalization, falling below the regression line determined for the entire sample. This suggests positive selection for neocorticalization, that it improved fitness in an evolutionary sense.

The 2-D data on brain size are flawed because they are limited to profiles of the brain and do not measure the actual areas of the curved surfaces of the endocasts. They are also limited to species in which rhinal fissure is visible on the lateral surface, and this excluded primates from the analysis. When the 2-D analysis was published, it was not possible to perform an equivalent 3-D analysis with the technology available at that time. Such a technology has since been developed, and the analysis of 3-D images of endocasts is published here for the first time.

3.01.6 Three-Dimensional Analysis: Neocortex

The analysis of the newly acquired 3-D data on a larger sample of fossil and living mammals, which includes primates (Figure 7), confirms that there was progressive neocorticalization in mammals during the Cenozoic. The positive slope of the regression (Figure 7) is similar to that found in the 2-D analysis. The sample of 106 mammals included 84 fossil species and 22 living species. There were seven fossil primates: two hominins and five prosimians, including the *A. parisiensis* shown in Figure 2. The hominins were two Plio-Pleistocene australopithecines, *Australopithecus africanus* (the Taung specimen discovered by Raymond Dart in 1923) and *Australopithecus robustus* (SK 1585) from South Africa (see Tobias, 1971; Holloway *et al.*, 2004). There are partial endocasts for Oligocene and Miocene anthropoids (*Aegyptopithecus*, *Libypithecus*, and *Proconsul*; see Radinsky, 1979), which were sufficient to indicate that frontal and temporal lobes were in a primate-like configuration (Jerison, 2006), but they were too incomplete otherwise for this quantification. The 22 living mammal species included eight anthropoids (simians) and two humans. Primates have evidently always been above average in neocorticalization,

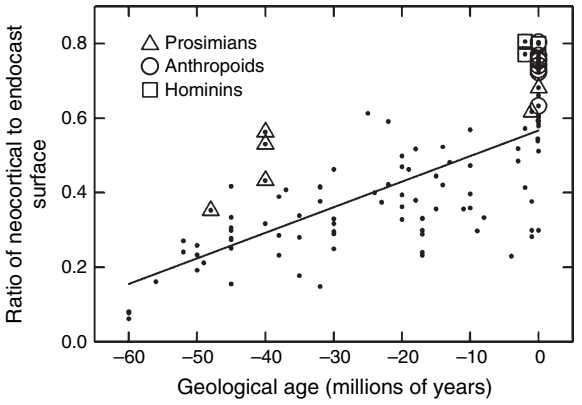

Figure 7 Relative size of neocortex measured in the 3-D analysis of the endocasts of 106 species of mammals during the past 60 million years. Points for prosimians are marked by triangles, hominins (including australopithecines) by squares, and anthropoids by circles. (All 106 species are shown as points, and identifying symbols surround the points.) Regression of neocortical ratio on geological age: $Y = 0.007X + 0.57$; $r = 0.72$. In living mammals, 57% of the endocast surface area is devoted to neocortex; the increase was about 7% per 10 million years. In living monkeys and living and fossil hominins, the ratio averages about 75%.

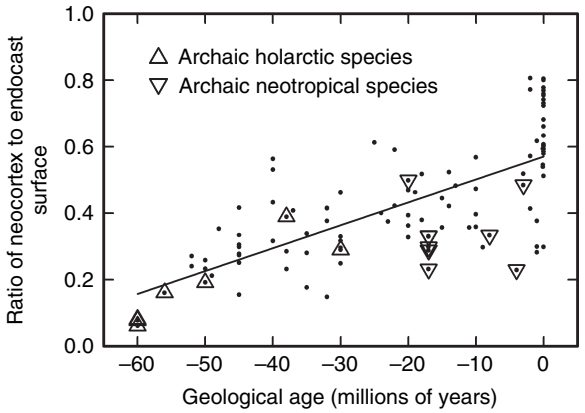

Figure 8 The same mammal species as in Figure 7, marked to distinguish 'archaic' from 'progressive' species, that is, species that are members of presently extinct orders or suborders of mammals from those that are members of surviving groups. Upright triangles for holarctic species, inverted triangles for neotropical species. Regression line is for the entire sample, and is the same as in Figure 7. Archaic species on average fall below the regression line.

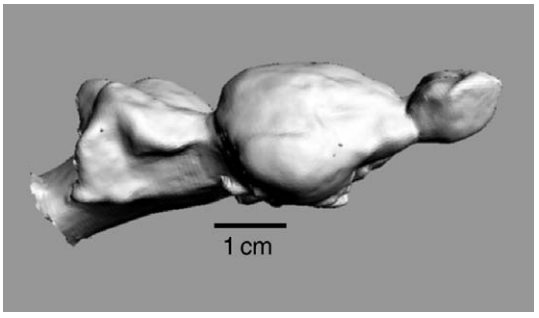

Figure 9 Endocast of *Phenacodus primaevus* (FMNH 59042/AMNH 4369), a late Paleocene archaic holarctic species (58 Mya).

that is, their data lay above the regression line determined for the entire sample as shown in Figure 7. Living and fossil hominins are typical primates on these measures. The highest ratio of neocortex to endocast surface area was a langur's (*Cercocebus albigena*) at 80.4% followed by one living human at 80.0%. A second living human endocast measured 77.7% and was topped by two other monkeys.

As in the 2-D analysis, it was possible to compare species from archaic orders with those from 'progressive' orders, and the data showing the difference are presented in Figure 8. The species in which endocasts were illustrated earlier in Figures 2 and 5 were progressive in that there are even-toed ungulates (order Artiodactyla) and primates (order Primates) living today.

Several orders of Miocene and Pliocene South American mammals, originally discovered as fossils by Charles Darwin in the 1830s on the voyage of the *Beagle*, are 'archaic', having no surviving species. Their data are included in Figure 8 and marked with inverted triangles. Erect triangles mark holarctic species from Europe and North America, also from extinct orders. Thirteen of the 15 archaic species fell below the regression line. The probability that this was a random departure from 'average' is less than 0.05 (chi-square test). The 3-D analysis thus supports the conclusion that neocorticalization contributes to fitness, that is, there was positive selection for neocorticalization.

Endocasts of archaic species are not superficially unusual. That of *P. primaevus* discussed earlier is shown in Figure 9. It might be distinguished from the other fossil endocasts because of slight differences in appearance, but it is also different quantitatively. At the animal's estimated body weight (56 kg), its expected endocast volume is 176 ml according to my preferred parameters of eqn [1]. The measured volume of the endocast at 31 ml results in an encephalization quotient of 0.18. Its ratio of neocortical area to total endocast area is 0.16, one of the lowest in the sample, and it is an example of the grade of encephalization and neocorticalization in most Paleocene mammals.

3.01.7 Three-Dimensional Analysis: Olfactory Bulbs

The 3-D quantitative analysis of neocorticalization reported here supplements but does not entirely replace the 2-D analysis. It omits the olfactory bulbs, which could not be measured reliably on too many of the fossil endocasts. There were obvious artifacts in many of them in the representation of olfactory bulbs. In preparing plaster endocasts from a skull, the region of the olfactory bulbs is cleaned out, and it is easy to make mistakes. The cribiform plate and the region of the turbinals has sometimes been excavated, resulting in artificially enlarged bulbs. In others, the olfactory bulbs may be incompletely excavated in preparing latex endocasts. Many natural endocasts, unlike the *Bathygenys* endocast illustrated in Figure 5, are also obviously distorted in the region of the olfactory bulbs. There were enough uncertainties in the sample of endocasts that were scanned for this article to make it inappropriate to present 3-D data on the olfactory bulbs without further study. Olfactory bulbs in the 2-D analysis were all sketched by neurobiologists familiar with normal living brains, who used that information in their reconstructions (see Jerison, 1990). The sketches were all published prior to the later quantitative analysis, and the areas in the 2-D analysis were measured independently of the sketching. The result that showed no change in the relative size of the olfactory bulbs was unexpected and unanticipated. Clearly unbiased, the conclusion of the 2-D analysis can be accepted at least provisionally, namely that the relative size of the olfactory bulbs remained more or less unchanged during the Cenozoic.

The evidence of the reduction of olfactory bulbs in primates and cetaceans is from comparative anatomy. The fossils suggest that their reduction in primates occurred after the Oligocene, when *Aegyptopithecus* lived; Radinsky's (1979) sketches indicate olfactory bulbs in *Aegyptopithecus* that were comparable to those in fossil prosimians (cf. *Adapis* in Figure 2) and relatively larger than in later anthropoid species. In Miocene and Pliocene anthropoids, the olfactory bulbs appear as reduced as in living species, and australopithecine olfactory bulbs are reduced comparably to those of living chimpanzees and humans. Fossil data on cetaceans were reviewed in Jerison (1973) and indicate either reduced or completely absent olfactory bulbs.

3.01.8 Caveats and Conclusions

Neocorticalization occurred in many lineages, and there appeared to be some increase in all mammal species after the Paleocene epoch. The overall increase is evident in the positive slope of the regression lines of the neocortical ratio on geological age. The increase was most dramatic in primates, where it is evident in the earliest record of their brains in the Eocene epoch, but even in 'primitive' living marsupials such as the koala (*Phascolarctos cinereus*), neocorticalization to the extent of 30% of the endocast surface is in advance of the Paleocene grade of the archaic *Phenacodus*.

Another conclusion is about the diversity of neocorticalization. The range between 30% in the living marsupial koala and 80% in living humans and langurs suggests the variety of niches for which neocorticalization could be selected. When I published the 2-D data 15 years ago, I thought that the correlation of 0.7 between geological age and neocorticalization and the scattered points in its graph (Figure 6) might be due to the inadequacies of 2-D measurements. The better method for determining and measuring surface area, and the larger sample for the measures in Figures 7 and 8, indicate that the variability is real and reflects the true diversity of adapations for neocorticalization in mammals.

The third conclusion which also verified the 2-D analysis indicated that neocorticalization contributed to fitness. The evidence is in the fate of archaic species, which were on the average less neocorticalized than progressive species. This kind of conclusion may seem obvious and hardly worth special mention, but it is difficult to find reasonable evidence for the fitness of quantifiable traits that evolved to different extents in different taxa. The unusual history of the olfactory bulbs in mammals is as instructive as that of the neocortex. Based on this trait living anthropoid primates (including *H. sapiens*) are a 'degenerate' order, and one can interpret the reduction in their olfactory bulbs as evidence of the relative unimportance of olfactory information in their lives. Stasis in the evolution of the olfactory bulbs is presumably the norm, and if primates had been included in the 2-D analysis their degeneracy might have been clearer. But humans write the histories, and in our accounts of the history of the brain, large olfactory bulbs have erroneously been taken as a sign of primitiveness rather than normality. Olfactory bulbs, large or small, are adaptive to specialized niches.

The final caveat is to be wary of conclusions based on endocasts rather than brains and to be wary of conclusions based on externals rather than on the fundamental structure and function of the brain. On the other hand, conclusions based only on the fundamentals have to follow a cladistic analysis of data on living species, comparing apparently

homologous traits and taking into account their differentiation in different living species. Johnson (1990) has reviewed cladistic analyses of neural evolution, and there have been several other important publications on phylogeny, which were cited in the opening paragraphs of the article. The conclusions, based on endocasts and limited to externals, provide a time dimension for the brain's evolution and broadly date the events.

I have emphasized the place of endocasts as providing direct evidence on the evolution of the brain and that the relevance of the evidence comes partly from relationships between superficial data such as brain size and more fundamental measures of the brain's structure and function. Figure 3, showing the relationship between the gross size of the brain and the extent of its cortical surface area, is a good example of the approach, illustrating a likely relationship between the gross measure of the brain itself and neural information processing capacity. In that graph, the dependent variable was total cortical surface, including surfaces buried in the fissures. For a closer look, consider Figure 10, which graphs the measured surface area of endocasts rather than brains as a function of their volume. Although the relationship is equally strong for brain measures and endocast measures in which cortex buried in the fissures is not measured, the difference between the slopes on logarithmic coordinates (the allometric exponent) is instructive.

In the endocasts (Figure 10), the slope is about two-thirds, which is the expected relationship among similar solids of different size. For example, in graphs of the surface–volume relationship in spheres of different size, the slope is exactly 2/3, as it is in cubes or any other solid object of any shape if shape is conserved as size changes. In an equation like eqn [1], $\alpha = 2/3$ for a given solid, and the differences among solids are in the parameter k. Regardless of their sizes, for all spheres, $k = 4.84$; for all cubes, $k = 6$. Figure 10 tells us that our endocasts were more alike in shape than we might have guessed, at least with respect to this aspect of their geometry. Figure 3, on the other hand, tells us that had we been able to work with the brains of these fossils rather than their endocasts we should have expected convolutedness to increase as volume increased, that is, convolutedness would be greater in larger brains. The change in convolutedness is reflected by the exponent $0.91 > 2/3$. That information is lost in working with endocasts. The high correlation coefficients save the day for a uniformitarian view. They indicate that the surface areas of portions of the neocortex buried in the sulci and fissures are also related in an orderly way to brain or endocast size. It is, therefore, likely that like actual brain surface area, the surface area of endocasts also estimates the information processing capacity.

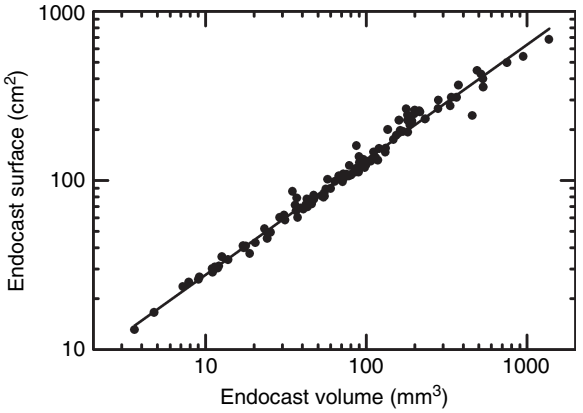

Figure 10 Surface–volume relations in endocasts as measured in the sample of 106 species used in the 3-D analysis. Product–moment correlation, $r = 0.992$; regression, $Y = 5.8X^{0.68}$.

3.02 The Origin of Neocortex: Lessons from Comparative Embryology

Z Molnár, A Tavare, and A F P Cheung, University of Oxford, Oxford, UK

Glossary

cell migration — The cortex comprises two types of neurons: glutamatergic pyramidal projection neurons and GABAergic interneurons. The two cortical cell populations are generated at different sites within the forebrain. The pyramidal neurons are generated in the local cortical germinal zone and migrate radially (perpendicular to the pial surface) to reach their final destination in the cortex. In contrast, most of the interneurons are born in the distant ganglionic eminence (neuroepithelium of the embryonic pallidum) and migrate tangentially (parallel to the pial surface) to reach the cortex.

germinal zone — In the embryonic brain, epithelium lining the ventricles (the ventricular zone) is a neurogenic source. In mammals, there is an additional adjacent layer of mitotic activity termed the subventricular zone. These compartments differ in size, organization, and in their modes of division. The proliferative cells in the ventricular zone undergo interkinetic migration, and have radially aligned nuclei. The subventricular zone contains cells with randomly oriented nuclei.

infragranular and supragranular — The mammalian neocortex (or isocortex) consists of six layers. Layer 4 is also called the granular cell layer. Layers 5 and 6 are referred to as infragranular and layers 2 and 3 are also called supragranular layers. Different cortical areas show considerable variations in the proportions of these components.

layers of the cortex — These are cells spanning the entire thickness of the wall of the embryonic forebrain extending perpendicular to the pial surface. These cells were previously assumed to act merely as scaffolds for newly born neurons to migrate along. They are now considered to be the source of most neurogenesis in the developing cortex.

radial glia — At the ventricular zone, radial glia divide to yield a new glial cell and a daughter cell which migrates away from the ventricular surface. This is termed asymmetrical division. The subventricular zone also participates in neurogenesis. Here the intermediate progenitors mostly undergo division to produce two identical daughter neurons, which migrate to the cortex. This is termed symmetrical division.

symmetrical and asymmetrical divisions

3.02.1 Constant Features of the Mammalian Isocortex

The mammalian six-layered cortex (neocortex or isocortex) is a great achievement of cortical

development and evolution (see The Evolution of Neuron Classes in the Neocortex of Mammals, Organization of a Miniature Neocortex – What Shrew Brains Suggest about Mammalian Evolution, Sparse Coding in the Neocortex, What Fossils Tell Us about the Evolution of the Neocortex). Cortical neurons are arranged into distinct layers according to their input and output in a very specific and conserved manner (Lorente de No, 1949; Toyama *et al.*, 1974; Peters and Jones, 1985). In spite of the enormous variations in cortical surface area, and in the sulci and gyri (Krubitzer, 1995; Krubitzer and Kahn, 2003), the basic cortical circuitry is similar. The laminar allocation of cells connecting to the thalamus, spinal cord, or intracortical areas is remarkably conserved among all mammals studied. Rockel *et al.* (1974) counted the number of neuronal cell bodies in a narrow radial strip (30 μm wide) through the depth of the neocortex in several different functional areas (motor, somatic sensory, area 17, frontal, parietal, and temporal) in different mammalian species (mouse, rat, cat, monkey, and human) and found that the numbers were surprisingly constant. The same absolute number (congruent to 110) even characterized all areas of all species, with only one exception (see below).

This conserved cortical cell number dogma was established before the availability of various neuronal markers. It would be important to revisit this idea with modern neuroanatomical tools. The principal neuronal types of the cerebral cortex are the excitatory pyramidal cells, which project to distant targets, and the locally projecting inhibitory nonpyramidal interneurons (Peters and Jones, 1985). Pyramidal neurons are generated in the cortical neuroepithelium and migrate radially to reach the cortex following an inside-first outside-last gradient (Rakic, 1995, 2005). Interneurons produced from the neuroepithelium of the embryonic pallidum also contribute to the formation of the cerebral cortex (Parnavelas, 2000; Corbin *et al.*, 2001). These cells migrate tangentially through the striatocortical junction to reach the cortex (Marín and Rubenstein, 2003). In rodent, only a few nonpyramidal cells are generated in the cortical ventricular zone (VZ). It is known that around 70–85% of cortical neurons are excitatory glutamatergic pyramidal neurons, while the rest are GABAergic interneurons. These basic proportions also seem to be constant in all mammals (DeFelipe, 2002).

In spite of the constant number and neuronal cell types in the cortex, the mammalian cortices exhibit remarkable variations in their thickness, relative proportions of their layers, and patterning of cells and fibers (Ramón y Cajal, 1911; Figure 1). The differences within the same brain across various cortical areas are equally fascinating (Brodmann, 1909). The transition between primary and secondary visual cortical areas in primate is perhaps the most striking change in cortical organization (Rakic, 1988), as the binocular part of area 17 of primates (macaque and human) has approximately 2.5 times more neurons (Rockel *et al.*, 1974, 1980). The structure of layer 4 is so different in primate primary visual cortex that it can be seen as the line of Gennari with the naked eye (Figure 1e). However, this transition should be considered as an exception rather than the rule, since this is the only currently known aerial boundary where the numbers of cortical cells in a unit column changed. The cytoarchitectonic differences between cortical areas reflect the subtle changes in different components of the cortical circuits needed to perform the computational function of that particular area. For example, motor cortical areas have a more prominent output layer, layer 5, while the granular layer is nearly absent. On the other hand, in primary sensory areas there is more emphasis on granular and supragranular layers (layers 4 and 2–3) at the expense of the infragranular layers (Brodmann, 1909).

3.02.2 Dorsal Cortex Contains Fewer Neurons in Nonmammalian Vertebrates

The major divisions of the brain are comparable and are remarkably well conserved across sauropsids (birds and reptiles) and mammals (Puelles *et al.*, 2000). The exception to this is the organization of telencephalic derivatives (Striedter, 1997, 2005). There are several hypotheses about the evolutionary rearrangement of different sectors of the forebrain to produce the neocortex in mammals (Northcutt and Kaas, 1995; Molnár and Butler, 2002a, 2002b; Butler and Molnár, 2002). In spite of the emerging anatomical and gene expression data (Fernandez *et al.*, 1998), identifying structures at the striatocortical junction of the forebrain of various vertebrates and elucidating homologies remains difficult (Bruce and Neary, 1995; Butler and Hodos, 2005; Molnár *et al.*, 2006). In contrast to the six-layered mammalian cortex, reptiles possess a three-layered cortex which is similar to layers 5 and 6 of mammals

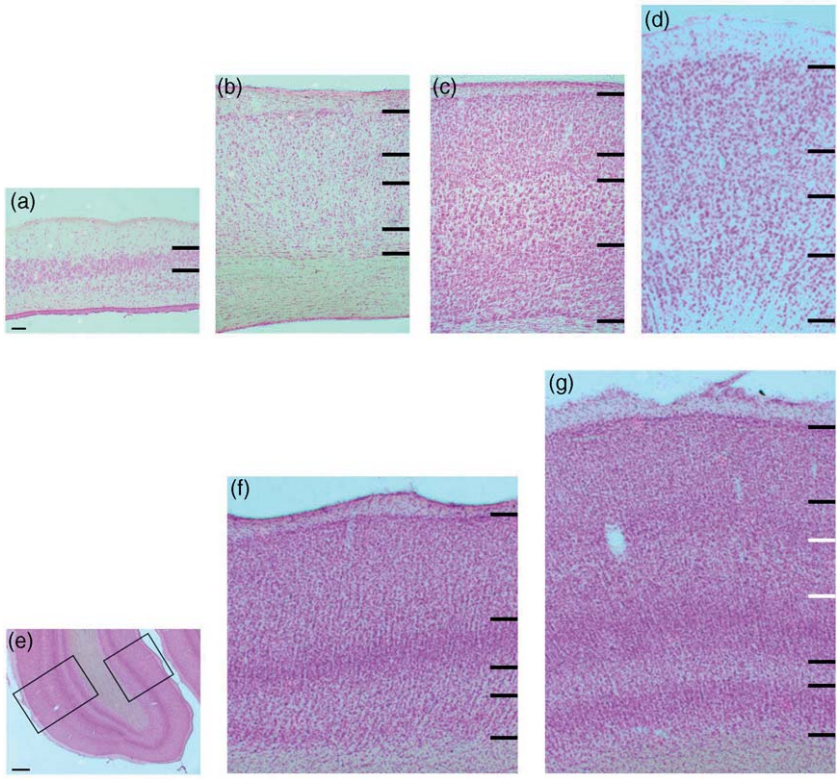

Figure 1 Nissl-stained coronal sections of four different amniote brains that demonstrate the similarities and differences in the cortical lamination in: a, Crocodile (Australian); b, hedgehog; c, mouse; d, cat; e–g, rhesus monkey. e, Low-power image was taken from the border of 17–18. Boxes in (e) depict the location of the images taken from areas 17(g) and 18(f). Bars mark the layering of the different cortices. White bars in (g) mark the partitioning of layer 4 into sublayers (a)–(c). Scale bar: 100 μm (a–d, f, g); 500 μm (e).

(Goffinet, 1983; Goffinet *et al.*, 1986; Reiner, 1991; Figure 1a). The isocortical homologue of birds is a pseudolayered structure, which is considerably different in organization to that of mammalian neocortex (Medina and Reiner, 2000). The most notable difference is that the mammalian cortex contains dramatically more neurons. Therefore, a question arises: where did the extra cortical cells come from in the mammalian brain?

3.02.3 What are the Major Changes in Cortical Neurogenesis in Mammals?

Much debate exists about the progression from the postulated primitive ancestor to the modern-day mammalian and reptilian cortices (Northcutt and Kaas, 1995). There are two theories on the (total) increase of mammalian cortical neurons. Both theories suggest that there are accessory sites of neurogenesis for the mammalian cortex. First, the equivalent cell migration hypothesis suggests that a considerable population of mammalian neurons are generated outside the neocortex and migrate into the cortex during development. This theory predicts relocation of corresponding cell groups in ancestral species at the reptilian mammalian transformation (Karten, 1997). Second, the dorsal cortical germinal zone elaboration hypothesis suggests that the generation of extra cortical neurons for the expanding sheet of cortical neuroepithelium and elaboration of the granular and supragranular cortical layers in mammals required an accessory site of proliferation within the cortical subventricular zone (SVZ) and the appearance of an intermediate progenitor population (Martínez-Cerdeno *et al.*, 2005; Molnár *et al.*, 2006).

Although one cannot directly study ancestral brains, study of comparative cortical development of extant species can still reveal the developmental mechanisms that change most considerably in mammals and other vertebrates, elucidating the steps of evolutionary progression. Unfortunately, current neurodevelopmental studies are limited to very few vertebrate species, making generalizations and comparisons difficult. Our own comparative

developmental analysis is based on six species: (1) turtle, (2) chick, (3) mouse, (4) rat, (5) macaque, and (6) human.

3.02.4 Are Cortical Neurons Produced Outside the Mammalian Cortex Supportive for the Equivalent Cell Migration Hypothesis?

It has been argued that equivalent circuits are present in the visual and auditory pathways in avian and mammalian telencephali (Karten, 1968, 1997). Although the basic components of these circuits (thalamic recipient cells, interneurons, and efferent projection neurons) are present in both avian and mammalian cortical circuits, their arrangement is very different. While these components are arranged into cortical layers in mammals (layers 4, 2–3, and 5–6 respectively), they are mostly situated subcortically in birds (Karten, 1991). In lizard, turtle, and bird, this subcortical structure is a large mass of cells protruding into the lateral ventricle above the striatum, called the dorsal ventricular ridge (DVR). The DVR hosts most of the neurons required for information processing in the equivalent circuits. As shown by a study in iguana (*Iguana iguana*), highly organized multiple representations involved in visual processing were observed in the DVR (Manger *et al.*, 2002). In comparison to the DVR, the three-layered dorsal cortex in the iguana appears rudimentary compared to the neocortex of mammals (Figure 1).

The recent discovery that the subpallium, a region outside the cortical neuroepithelium, contributes tangentially migrating neurons to the mammalian cerebral cortex generated a good deal of excitement (de Carlos *et al.*, 1996; Anderson *et al.*, 1997; Tamamaki *et al.*, 1997). In rodents, most of these neurons are derived from the medial ganglionic eminence (Lavdas *et al.*, 1999; Sussel *et al.*, 1999; Wichterle *et al.*, 1999; Xu *et al.*, 2004). This region of the forebrain did not correspond to the sector which was suspected to be homologous to the DVR. Moreover, these neurons are exclusively GABAergic interneurons and not excitatory pyramidal cells, which one would expect for the equivalent projection circuits.

3.02.5 Generation and Mode of Migration of the GABAergic Interneurons

The proportion of GABAergic neurons in avian pallial regions and their rather uniform distribution closely resemble the patterns seen in other vertebrates, including mammals (Veenman and Reiner, 1994; Jarvis *et al.*, 2005). In both cases, generation and differentiation of GABA neurons in the ventral forebrain regions specifically require *Dlx* family transcription factor expression (Stuhmer *et al.*, 2002). Likewise shared are *Emx* genes expressed in the cortical domain, which primarily generates excitatory glutamatergic neurons (Anderson *et al.*, 2002; Gorski *et al.*, 2002). The molecular mechanisms and the genetic pathways are conserved in phyla as distant as amphibians, reptiles, birds, and mammals. Orthologues of *Dlx* genes have been cloned in these vertebrates (Fernandez *et al.*, 1998; Puelles *et al.*, 2000), and these genes define homologous ventral forebrain domains. The DVR, which contains the neuronal elements of the equivalent circuit, according to Karten's (1997) hypothesis, lies between the *Dlx* and *Emx* expression domains (Fernandez *et al.*, 1998; Puelles *et al.*, 2000; Jarvis *et al.*, 2005) (Figure 2).

Though the dorsal cortex of sauropsids lacks several cell types found in the mammalian isocortex, both structures are comprised of two basic components required to build a functional cortex: the excitatory glutamatergic projection neurons and the inhibitory GABAergic interneurons (Goffinet *et al.*, 1986; Blanton *et al.*, 1987; Reiner, 1991, 1993).

During embryonic development, GABAergic neurons originate in the ventral subpallium and progressively colonize the dorsal pallium following distinct routes (Nadarajah and Parnavelas, 2002; López-Bendito *et al.*, 2004; Métin *et al.*, 2006). These streams are generally oriented tangentially to the brain surface throughout their path, but at the pallium/subpallium boundary, or within the VZ before reaching the cortical plate, where some cells reorient radially (Nadarajah *et al.*, 2002).

Comparative analysis of tangentially migrating neurons in birds revealed that, just as in mammals, most GABAergic interneurons originate in the ventral telencephalon (Cobos *et al.*, 2001). In slice cultures prepared from embryonic chick brains, GABAergic cells follow similar tangential routes in both subpallium and pallium, and show similar branched leading processes (Tuorto *et al.*, 2003). The similarities in the migration route and morphology to mammalian tangentially migrating interneurons suggest common mechanisms of development (Bellion *et al.*, 2005). Accordingly, the developmental sequence of GABAergic interneurons in the turtle cortex is reminiscent of tangential migration from ventral territories (Blanton and Kriegstein, 1991). In bird and turtle, the relative contribution of pallidum (or medial ganglionic eminence of the telencephalon) and paleostriatum (or lateral ganglionic eminence of the telencephalon) to the GABAergic population is debated (Cobos *et al.*, 2001; Tuorto

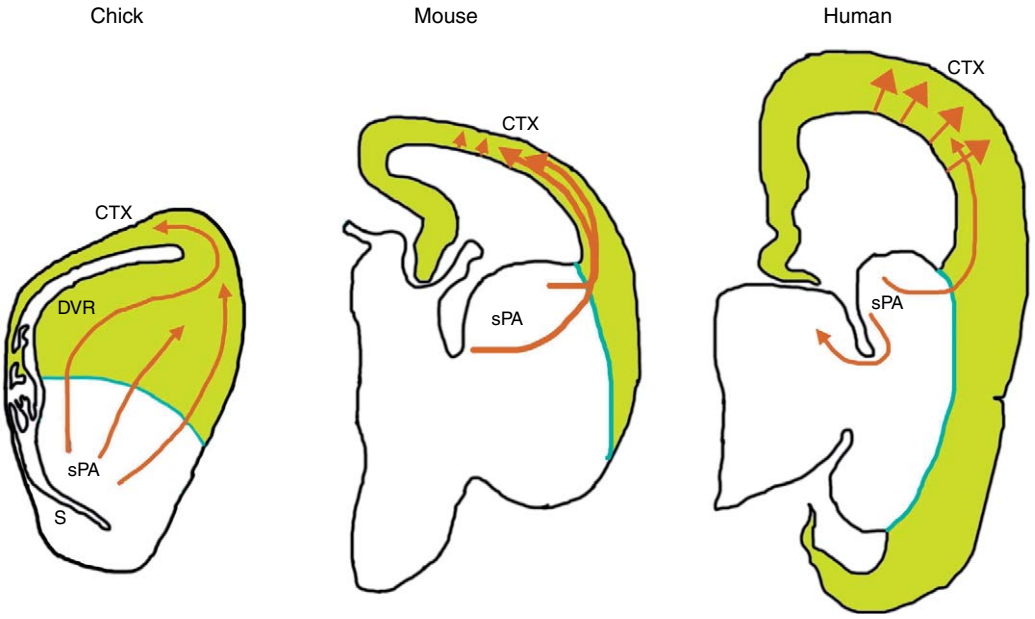

Figure 2 Common mechanism of subpallial origin and tangential migration of GABAergic neurons in bird, rodent, and human. Schematic outlines represent the cross sections through chick, mouse, and human forebrains. Orange arrows depict the migratory patterns of GABAergic neurons from subpallium (sPA). S, septum; CTX, dorsal cortex. See text for details. The left panel was inspired by Cobos *et al.* (2001) and the right panels by Tan (2002). Adapted from Molnár, Z., Métin, C., Stoykova, A., *et al.* 2006. Comparative aspects of cerebral cortical development. *Eur. J. Neurosci.* 23, 921–934, with permission from Blackwell Publishing.

et al., 2003). In rodent and primate, there also seem to be great differences in the proportion of GABAergic neurons generated locally in the pallium and the striatum/pallium (lateral and medial ganglionic eminences). In human, gene expression evidence suggests that a substantial fraction (65%) of cortical interneurons are generated by the pallium (Letinic and Rakic, 2001), whereas in rodents this estimate is only 5% (Letinic *et al.*, 2002; Tan, 2002).

In spite of all these current uncertainties, the neuronal production observed outside the cortex in mammals is not supportive of the equivalent cell migration hypothesis. Several expectations were not fulfilled by the tangentially migrating neurons. (1) The migrating neurons are purely GABAergic and do not contain any excitatory pyramidal neurons. (2) The origin of the migrating cells in mammals does not coincide with the domain which is considered homologous to the DVR. (3) Tangential migration is not unique to mammalian brains. In avian and probably reptilian brains, GABAergic interneurons also arise from a *Dlx* domain and migrate tangentially to the dorsal cortex. Therefore, it is more likely that changes in the local dorsal cortical neurogenetic program, together with some major rearrangements at the striatocortical junction (Molnár and Butler, 2002a), provided the foundation for remodeling the mammalian cerebral cortex (Molnár *et al.*, 2006).

3.02.6 Basic Pattern of Cortical Neurogenesis

The predecessor of the mammalian cortical plate is the preplate (or primordial plexiform zone), which contains a heterogeneous population of the earliest-born neurons of the cortex, and is considered to be the reptilian component of the mammalian neocortex (Marin-Padilla, 1978). The first neurons of the rodent and human cortex probably originate from subpallium and not from cortex (Bystron *et al.*, 2005). This is in line with the notion that Cajal–Retzius cells migrate in from various sources (Bielle *et al.*, 2005). Neurons subsequently generated from the cortical plate split the preplate into an outer plexiform layer and an inner subplate (Marin-Padilla, 1978; Smart and McSherry, 1982; Smart and Smart, 1982; Luskin and Shatz, 1985). Newly produced neurons migrate out of the germinal zone from the VZ towards the pial surface according to a strict timetable. In mammals, the cortical plate is destined later to become the six-layered structure of the mature cortex. The cortex is formed in an inside-first outside-last neurogenic gradient (Angevine and Sidman, 1961) where younger cohorts migrate beyond previously generated neurons to settle at the upper border of the cortical plate. Consequently, the oldest neurons of the cortex occupy the deep layers, whereas the upper layers are made of late-born neurons.

In all veterbrates, embryonic neurogenesis provides the majority of neurons that compose the adult brain. In the embryonic brain, epithelium lining the ventricles (the VZ) has long been known to be a neurogenic source (Sauer, 1936; Sauer and Walker, 1959; Sidman *et al.*, 1959). In mammals, an additional, adjacent layer of mitotic activity was also observed (termed the SVZ). It was believed that gliogenesis commences during late corticogenesis and continues perinatally in the SVZ (Privat, 1975), and hence neurogenesis and gliogenesis were thought to occur in the VZ and SVZ respectively (Sturrock and Smart, 1980; Bayer and Altman, 1991). These compartments differ in size, organization, and in their modes of division. The proliferative cells in the VZ undergo interkinetic migration, and have radially aligned nuclei. The SVZ contains cells with randomly oriented nuclei (Smart, 1973).

Radial glia were previously assumed to act merely as scaffolds for newly born neurons to migrate along, and until recently, their importance was unappreciated. They are now considered to be the source of most neurogenesis in the developing cortex (Malatesta *et al.*, 2000; Noctor *et al.*, 2002). At the VZ, radial glia divide asymmetrically to yield a new glial cell and a daughter cell which migrates away from the ventricular surface. Elegant time-lapse photography of individual neurons migrating in brain slices demonstrated that the SVZ also participates in neurogenesis and the VZ is not the sole neurogenic compartment (Noctor *et al.*, 2004). Noctor and his colleagues also showed that the daughter cells generated from asymmetrical VZ divisions head directly to their locations in the future cortex, while others choose to arrest in the SVZ, where they are termed intermediate progenitors. Here the intermediate progenitors mostly undergo symmetric division to produce two identical daughter neurons, which migrate to the cortex (Kriegstein and Noctor, 2004; Noctor *et al.*, 2004) (Figure 3). This work was further confirmed *in vivo* using direct labeling of neurogenic progenitors lying outside the VZ (Wu *et al.*, 2005), which demonstrated that cells marked in the SVZ subsequently gave rise to upper-layer pyramidal neurons.

Analysis of gene expression in the germinal zone revealed that the VZ and SVZ progenitor cells are controlled by different genes. Embryonic expression of *Svet1* (Tarabykin *et al.*, 2001), *Cux1*, and *Cux2* (Nieto *et al.*, 2004) are only seen in the SVZ but expression of these genes is absent in the VZ. Postnatally, these genes are confined to the supragranular and granular layers of the cortex. On the other hand, the transcription factor Otx-1 and Er81 labels cells in the VZ exclusively during embryonic stages, and later is confined to layer 5 and 6 or layer 5, respectively (Frantz *et al.*, 1994; Tarabykin *et al.*, 2001; Yoneshima *et al.*, 2006). Thus, the SVZ gives rise to neurons that go on to populate the upper cortical layers (2–4), whereas the VZ produces the earlier-born neurons which give rise to the deeper layers (5 and 6) of the cortex. Differential fate is a product of transcription factor action on divergent dividing and migratory properties.

In addition to the proliferation in the VZ and SVZ, it was recently found that there are further scattered divisions within the intermediate zone, cortical plate, and marginal zone in rodent and human. These abventricular divisions compose less than 10% of all divisions at any stage of any cortical area during development (Carney *et al.*, 2004; Carney, 2005). Nevertheless, it shows that scattered progenitor cells are also capable of division outside the two main proliferation compartments (Figure 4).

In summary, we favor the dorsal cortical germinal zone elaboration hypothesis on two accounts. By examining the cortical development in macaque, where the variety of supragranular layer cells is much more diverse, the germinal zone differentiates

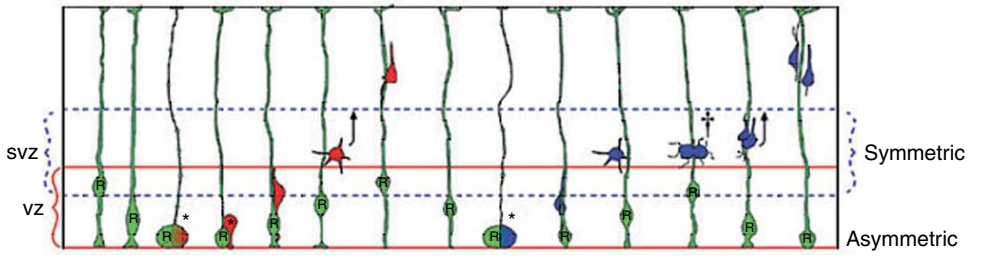

Figure 3 Two distinct programs of division and migration are observed in the germinal zone. Radial glia (R) self-renew and directly give rise to neurons (red) through asymmetric division in the VZ (*). Other neurons are generated from intermediate progenitor cells (blue) in the subventricular zone (SVZ) with terminal symmetric divisions (dagger). Figure 4 Coronal section through the right hemisphere of an E14 rat brain stained with phosphohistone H3 antibody to reveal the sites of cell divisions. Most of the divisions occur in the VZ lining the cortical neuroepithelium. There is a second major row of divisions in the SVZ, but there are further scattered divisions in the marginal zone (MZ), cortical plate (CP), and intermediate zone (IZ). There are large number of divisions in the medial and lateral ganglionic eminences (LGE, MGE). Scale bar: 100 μm. Unpublished figure from Carney *et al.* (2004) and Carney (2005).

further, with unique features not seen in rodents. On the other hand, the dorsal cortical neuroepithelium of nonmammalian vertebrates (turtle and chick) does not contain subventricular zone.

3.02.7 Neurogenesis in Primate Cortical Neuroepithelium

The developing primate cortex contains a unique compartment of the SVZ termed the outer SVZ (OSVZ) (Smart *et al.*, 2002). This site of proliferation has been shown to produce the majority of the supragranular layers (Lukaszewicz *et al.*, 2005). In rat and mouse, the supragranular layers are significantly smaller compared to macaque; thus, correspondingly, the SVZ is also much smaller (Smart *et al.*, 2002).

The work of Kennedy, Dehay, Smart, and colleagues produced some very interesting comparisons between mouse and macaque in cortical development (Smart *et al.*, 2002; Lukaszewicz *et al.*, 2005; Figure 5a). In mouse, the VZ is the major source of proliferation up until E15, after which it begins to regress in size. The SVZ appears at E13 but lags behind in proliferative terms, and begins to regress after E15 (Smart, 1973; Smart and McSherry, 1982). The relatively low germination activity in the SVZ is mirrored in the smaller proportion of the upper layers in the mouse neocortex. The SVZ in rodents accounts for no more than 35% of cortical proliferative population at E15 (Takahashi *et al.*, 1995). Accordingly, the supragranular layers occupy no more than a third of the thickness of the mature neocortex (Smart *et al.*, 2002). In contrast, the monkey has a very different process of proliferation. At a gross histological level, the size of the proliferative compartment (i.e., VZ + SVZ) rapidly increases in size from E65 onwards (Figure 5b). At this point, on the basis of histological appearance, the SVZ appears to have two distinct components: an inner SVZ (ISVZ) and a larger, OSVZ. Between E65 and E72, the OSVZ rapidly increases in size and becomes the major proliferative area of the SVZ, with the ISVZ contributing little. The dense, radially oriented precursors of the OSVZ constitute a unique feature, and birth-dating experiments showed that it generates the supragranular layers of the neocortex (Lukaszewicz *et al.*, 2005). The predominance of OSVZ in macaque could be due to the increased importance of the corticocortical connections and therefore the supragranular layers, where most corticocortical connections are formed. After E72, the OSVZ begins to decrease in size, accompanied by a corresponding increase in cerebral wall thickness, suggesting that the postmitotic cells are migrating to their future home in the cortex. By E78 the proliferative compartment has been fully split by the complete appearance of the inner fiber layer, with the ISVZ now attaching to the VZ but not the OSVZ (Figure 5) (Smart *et al.*, 2002).

It is possible that localized transcription factor expression of the SVZ and the VZ is responsible for the creation of certain neuronal subtypes. It is also possible that further compartmentalization of SVZ in primates is a correlate of higher neuronal diversity of supragranular layers (DeFelipe *et al.*, 2002). The contribution of SVZ in neuronal production seems to grow in evolution as the complexity of the cortex increases. The emergence of an additional proliferation zone and its diversification during cortical evolution might have been triggered by the necessity to produce more neuronal subtypes in different morphological compartments.

3.02.8 Cortical Neurogenesis in Nonmammalian Cortex

Our group became interested in examining the dorsal cortex of nonmammalian (turtle and chick) brains because these vertebrates do not possess a

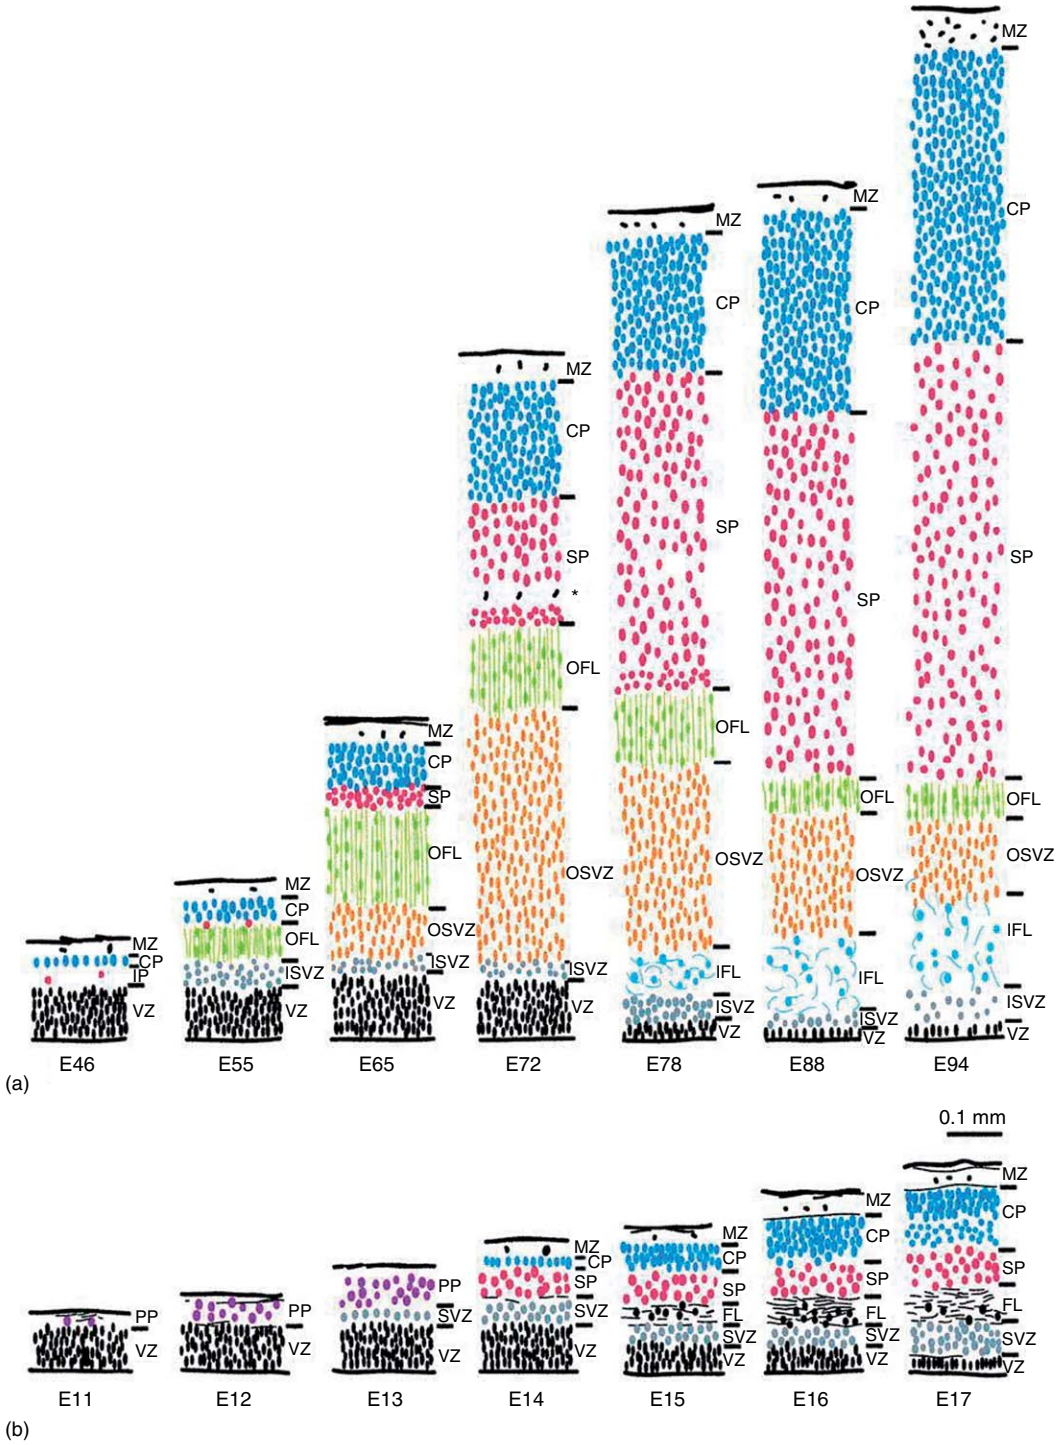

Figure 5 Comparison of histological sequences in the developing mouse and monkey telencephalic wall. These drawings are of transects through putative area 17 in monkey (a) and mouse (b) at comparable developmental stages. The depth of each layer is drawn to a common scale. The internal detail of each layer is not to scale but depicts the orientation, shape, and relative packing density of nuclei in each layer. The vertically aligned pairs have been chosen with reference to birth-dating experiments to illustrate corticogenesis at equivalent developmental stages. A curiously conspicuous clear layer marked by an asterisk (*), located in the deep subplate (SP), is transiently present at E72. At later stages it appears to merge into the SP. CP, cortical plate; IFL, inner fiber layer; ISVZ, inner subventricular zone; MZ, marginal zone; OFL, outer fiber layer; OSVZ, outer subventricular zone; SP, subplate proper; VZ, ventricular zone. Reproduced from Smart, I.H., Dehay, C., Giroud, P., Berland, M., and Kennedy, H. 2002. Unique morphological features of the proliferative zones and postmitotic compartments of the neural epithelium giving rise to striate and extrastriate cortex in the monkey. *Cereb. Cortex* 12, 37–53, Oxford University Press.

six-layered cortex, and the complexity and variety of neuronal types within them is more limited than in mammals. If indeed the generation of the upper layers of cortex found in mammals required an accessory site of proliferation, such as the SVZ, in addition to the VZ (Martínez-Cerdeno *et al.*, 2005; Molnár *et al.*, 2006), then this zone should be rudimentary or nonexistent in the reptilian and avian dorsal cortical neuroepithelium during embryonic development.

We examined the site of mitotic divisions in embryonic turtle and chick brains, paying special attention to the investigation of the presence or absence of abventricularly generated cells and the SVZ. Using phosphohistone H3 (a G2 and M-phase marker), we found that the distribution of mitotic cells in embryonic turtle and chick is fundamentally different from each other, and from rodent and primate (Lukaszewicz *et al.*, 2005). In turtle and chick cortex, there is a single major zone of proliferation with additional scattered abventricular divisions within the dorsal cortex (Figure 6). However, in certain regions of the chick brain (mesopallium, nidopallium, and striatum), two distinct proliferative zones are visible, whereas the turtle has only one (ventricular) organized zone of mitotic activity throughout the brain (Figures 6c and 6d). In turtle a significant proportion of division occurs abventricularly (highest in the striatum and septum), but these are scattered across the entire depth of the forebrain structures and never align into a distinct zone. VZ mitosis peaks in earlier stages (S18.5 and S20) before shifting to an increasingly abventricular site of proliferation in later stages (S23 and S25). In turtle, the major zone of activity is the VZ. Using Nissl-stained preparations, Martínez-Cerdeno *et al.* (2005, 2006) also suggested that the majority of the divisions are in the VZ, but noted the presence of a rudimentary SVZ. According to our own observations on the distribution of phosphohistone H3 immunoreactivity, there appears to be no organized zone outside the VZ anywhere in the embryonic turtle brain. Thus, one must conclude that the SVZ is absent in turtle (Figure 6a).

In the chick the situation is more complicated. An SVZ-like structure has been identified (Striedter and Keefer, 2000), but this sector appears restricted to the dorsolateral portion of the basal telencephalon. This finding remains controversial, especially as the SVZ is only found in this region. In the homologue of the dorsal cortex of the chick brain, the hyperpallium has a similar distribution of phosphohistone H3-labeled cells to turtle (i.e., VZ only; Figure 6b). Outside the cortex there appears to be a clear and distinct secondary zone of proliferation in the mesopallium and nidopallium (and, to a certain extent, in the striatum) above the VZ. This is clearly

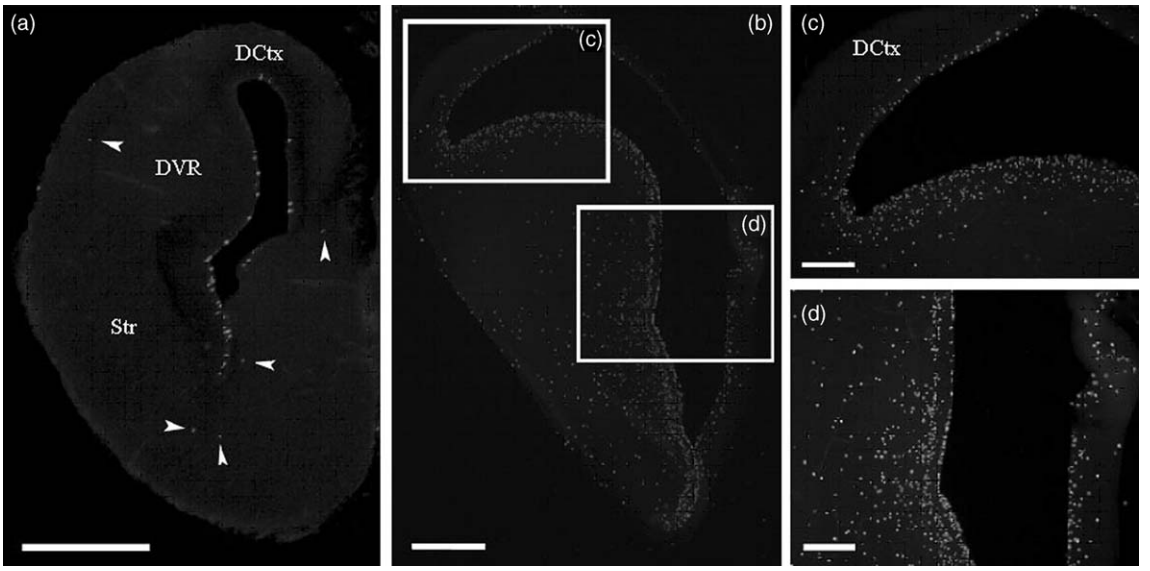

Figure 6 The lack of SVZ in turtle and chick dorsal cortex has been demonstrated with antiphosphohistone H3 immunohistochemistry. H3 immunofluoresence demonstrates mitotic activity in S18.5 turtle (a) and E8 chick (b) in the VZ and occasionally scattered abventricular proliferations (arrowheads in (a)). In turtle there is no organized SVZ in any part of the neuroepithelium. In chick, higher magnification (c, d) demonstrates an additional layer of proliferation superficial to the VZ in mesopallium and nidopallium in addition to more numerous scattered abventricular proliferation profiles. DCtx, dorsal cereberal neocortex; Str, Striatum. Scale bars: 500 μm (a, b); 200 μm (c,d).

demarcated by the presence of a band which separates the two zones, lacking in phosphohistone H3-labeled cells. Interestingly, this arrangement is not detected at any stages in the hyperpallium. This suggests that the SVZ is not a purely mammalian phenomenon in the forebrain, but it is unique for mammalian dorsal cortex together with the six-layered isocortex, to which SVZ provides neurons for more superficial layers (Noctor *et al.*, 2004; Wu *et al.*, 2005). As SVZ was absent in the hyperpallium, it seems likely that the presence of a precortical SVZ is an exclusive hallmark of mammals (Molnár *et al.*, 2006). This is one of the forces driving their cerebral complexity over other taxonomic classes. In support of this, recent data also suggest the SVZ is absent from amphibians (Wullimann *et al.*, 2005).

3.02.9 Evolving Cortical Progenitor Populations in VZ and SVZ

The absence of SVZ in turtle and chick hyperpallium indicates that the VZ directly provides the cells that subsequently form the dorsal cortex of the postnatal brain. Indeed, by examining the neurotransmitter organization and connections of turtle cortex, Reiner (1993) suggested that only the infragranular layers produced by the ventricular progenitors are present. It would be interesting to study further whether the fate of the reptilian or avian ventricular progenitors could be modified by providing appropriate gene expression patterns in the SVZ. Perhaps the turtle and chick dorsal cortical progenitor cells do have some innate ability to arrest in an SVZ-like region for additional symmetrical division. Moreover, several transcription factors show strong regional expression and could be used to map out VZ (*Pax6*) and SVZ (*NeuroD* and *Tbr2* co-expression) (Hevner *et al.*, 2006). The role of *Svet1* could be explored further by electroporating DNA into the VZ of turtle and chick isocortical homologues. The cell cycle parameters in different sectors of the turtle and chick germinal zone should be further studied. Measurements made using proliferating cell nuclear antigen (PCNA) immunohistochemistry and ^{3}H-thymidine pulse labeling revealed that cell cycle differs in duration in the germinal zones of monkey (Lukaszewicz *et al.*, 2005). The cell cycle is longer in the monkey OSVZ than in VZ (or comparable mouse), which may allow for the precise generation of a greater diversity of neurons that compose the supragranular layers (Figure 7) (Smart *et al.*, 2002; Molnár *et al.*, 2006).

Further study of the different cortical progenitor populations and their evolutionary origin could have general clinical implications. Various developmental diseases have a background of disrupted cortical formation (Francis *et al.*, 2006) and examining these cases could help expound the principles of cortical neurogenesis. The mechanisms involved in the formation of sulci and gyri of the brain are not fully understood (Van Essen, 1997). The lissencephalic cortex of mouse has been demonstrated to be a result of a less active SVZ. Drawing from this observation, lissencephaly in human may also result from inadequate SVZ proliferation. However, generalizations should currently be avoided until cortical neurogenesis is examined in gyrencephalic rodents and lissencephalic primates. According to the dogma on the cell numbers within a unit column of mammalian cerebral cortex, all mammalian cortices in all areas possess the same number of cells, with the exception of the primate primary visual cortex (Rockel *et al.*, 1974, 1980). If so, then the compartmentalization of the germinal zone should correlate more with the size of the cortical sheet and with the proportions and cell diversity of the supragranular cell layers. The cortical SVZ appears to be crucial for generating the increased cortical size and complexity (particularly the diversity of the upper layers) seen through the progression of mammalian evolution. While the SVZ is not unique to mammals, the development of a cortical SVZ appears to have been a crucial step in cortical evolution.

3.02.10 Summary and Conclusions

Comparative studies contribute to the debate on the possible evolutionary progression from the developmental mechanisms present in the postulated primitive ancestor to the modern-day mammalian and other vertebrate cortices (Northcutt and Kaas, 1995). We examined two theories that address the increased number of mammalian cortical neurons. Both suggest that there are accessory sites of neurogenesis for the mammalian cortex. The analysis of embryonic development does not support the equivalent cell migration hypothesis, although there is indeed a considerable population of mammalian neurons generated outside the cortex that migrate into the cortex during development; these neurons are exclusively GABAergic. More importantly, this process is not unique to mammals. We believe an increasing volume of work supports the dorsal cortical germinal zone elaboration hypothesis. In light of recent comparative investigations on embryonic cortical neurogenesis in frog, turtle, chick, rat, mouse, and macaque, it is more likely

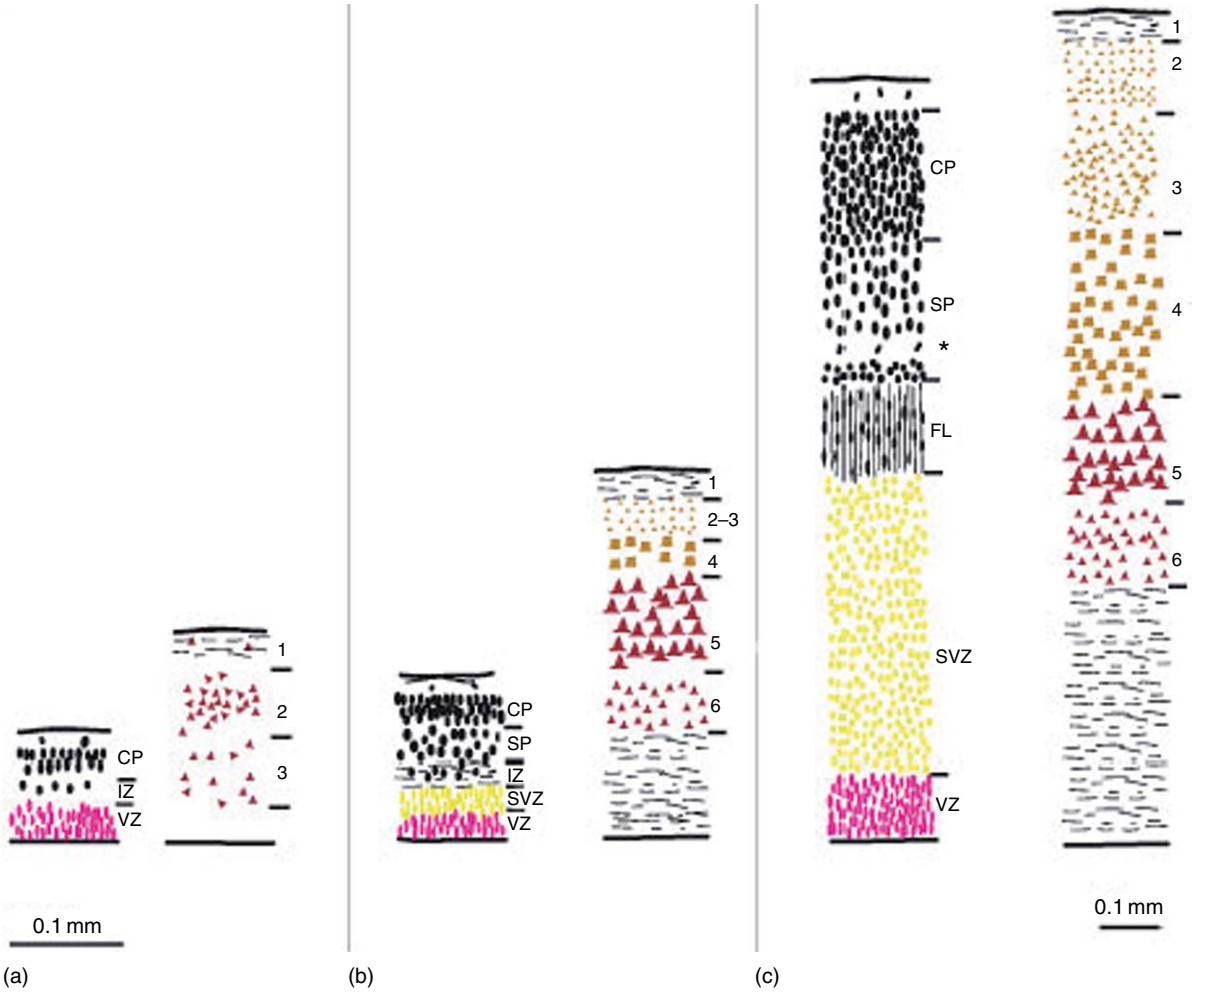

Figure 7 There is a strong correlation between the increase in supragranular layer complexity and the increase in subventricular zone between Turtle and chick (a); mouse (b); and monkey (c). The left panels for mouse and monkey are from Figure 5 from an E15 mouse and an E72 monkey. The right panels represent the layering in the adult. VZ and infragranular layers (6 and 5) are labeled red; SVZ and supragranular layers (2 and 3) are colored yellow. Note that the increase in the complexity of supragranular layers is accompanied by an increase in the SVZ during development. For clarity, SVZ includes ISVZ and OSVZ in the monkey panel. Adapted from Molnár, Z., Métin, C., Stoykova, A. *et al.* 2006. Comparative aspects of cerebral cortical development. *Eur. J. Neurosci.* 23, 921–934, with permission from Blackwell Publishing.

that the generation of extra cortical neurons for the larger cortical sheet and increasingly elaborate granular and supragranular cortical layers in mammals required the adoption of an accessory site of proliferation within the cortical SVZ, as well as the appearance of an intermediate progenitor population (Smart *et al.*, 2002; Kriegstein and Noctor, 2004; Noctor *et al.*, 2004; Martínez-Cerdeno *et al.*, 2005; Molnár *et al.*, 2006).

3.03 Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications

J H Kaas, Vanderbilt University, Nashville, TN, USA

Glossary

area	A major subdivision of neocortex. Each area performs a specific set of functions. Areas were called the "organs of the brain" by Brodmann (1909).
column or module	Subdivisions of areas that mediate a function or functions that are repeated many times within other modules of the same type within the area. Areas may have two or more types of intermixed modules.
cortical magnification	The greater representation in cortical areas of important parts of sensory surfaces in proportion to receptor density.
motor cortex	Subdivisions of cortex that are specialized to elicit and control body movements. Movements can be evoked by electrically stimulating motor cortex.
representation	Areas are said to represent a sensory surface, such as the retina, skin, or cochlea, when stimulation in different parts of the sensory surface activates neurons in different parts of the area in a matching or isomorphic pattern. Muscles and movements are also represented in areas of motor cortex. Some areas may have more abstract, higher-order representations.

3.03.1 Introduction

The evolution of the large human brain intrigued early investigators, such as Smith (1906) and Clark (1959), but their efforts to describe this evolution were greatly constrained by the limited information on brain organization and the few techniques to evaluate brain function available at that time. What they did have were extensive collections of brains, preserved in jars of fixative, and thin sections of brains stained for the cell bodies of neurons or for the myelin that wraps the axons of these neurons. Thus, they could carefully observe ways in which the brains of extant mammals varied greatly in size, the locations of fissures that indent the cortex and even in the architectonic appearance of cortex and other parts of the brain. Such early investigators recognized that the neocortex was a part of the brain that varied the most in size and that some portions of neocortex could be recognized as similar

enough that they were likely to be homologous across species. They concluded that early mammals had small brains with little neocortex, and mammals leading to humans had brains that were progressively larger and more complexly organized, with proportionally more neocortex. While these deductions were based on the appearances of the brains of a large array of species, they primarily depended upon detailed considerations of the brains of a few key mammals that were thought to represent stages or levels in the course of the evolution of human brains (for review see Kaas, 2002; Preuss, 2000).

Today, we are in a position to greatly expand on the efforts of such early investigators. Most importantly, we know so much more about the organization of the brains of a wide range of present-day mammals. The traditional Nissl, myelin, and Golgi stains have been supplemented by an ever-increasing array of histochemical and immunochemical protocols for revealing the architecture of brains and their structurally distinguishable parts. Electrophysiological approaches, especially microelectrode recording and stimulation procedures, have greatly expanded our understanding of brain organization, and this knowledge has been fortified and advanced by newer methods such as the optical imaging of patterns of evoked neural activity. We also know something about the sizes and shapes of the brains of long extinct mammals from the ever-increasing fossil record based on the endocasts of the brain cases of the preserved skulls (Jerison, 1973; Kielan-Jaworowska *et al*., 2004). Although this record tells us little about the functional organization of the brains of extinct mammals, it does yield information about brain sizes and fissure patterns.

Conceptual advances have been important as well (see Hodos and Campbell, 1969; Preuss, 1995a; Striedter, 1998). Early investigators assumed that various extant species could be used to represent stages or levels of mammalian evolution. The problem with this assumption is that any extant mammal is likely to contain a mixture of ancestral (plesiomorphic) and newer, apomorphic (specializations derived from an earlier state) traits or features. Of course, some mammals appear to have mainly primitive brain features, while others have many obviously advanced features. Thus, methods were needed to distinguish primitive from advanced traits. Otherwise, an advanced trait in a generally primitive brain could be mistaken for a primitive trait and vice versa. The current approach to this problem is to use cladistic analysis (see Eldredge and Cracraft, 1980; Wiley, 1981). In brief, some brain traits are recognized as present or absent in members of a clade of mammals (any group of mammals that have all descended from a common ancestor). The distribution of the trait across the phylogenetic tree of related mammals, the cladogram, tells you whether it is more likely (more parsimonious to assume) that the trait was present in a common ancestor, and was retained in many or all of the descendents, or subsequently evolved in one or more lines. Given this approach, there is a logical way to distinguish primitive from advanced (derived) traits, other than from their appearance or association with other traits. A common mistake of early and even current investigators was to consider simple or undifferentiated traits as primitive. For example, a few current investigators still support the theory of Sanides (1970) that poorly differentiated regions of neocortex are older and highly differentiated regions are newer. This may generally be the case, but it can be demonstrated not to be the case in some instances. For example, primary visual cortex (V1 or area 17) in the hedgehog has poorly differentiated cell types and cell layers are not very distinct (Kaas *et al*., 1970), while primary visual cortex in tarsiers is perhaps more distinctly laminated than in any other mammal (Collins *et al*., 2005). Yet, V1 is an equally old area in both mammals, having been present in the reptilian ancestors of mammals (see below). The histological structures of V1 had simply differentiated more in the line leading to tarsiers than in the line leading to hedgehogs (see The Evolution of Visual Cortex and Visual Systems).

To be fair, early investigators such as Eliott Smith and Le Gros Clark had some appreciation of the advantages of broad comparisons across members of a clade. They recognized that the easily identified corpus callosum, the bundle of axons that interconnects the two cerebral hemispheres, was a new feature in placental (Eutherian) mammal brains because all members of the placental clade have a corpus callosum, no members of the monotreme or marsupial clades have a corpus callosum, and no reptiles or other vertebrates have a corpus callosum. But only easily identified traits could be examined across a wide range of mammals at the time of their investigations. Recognizing many brain characters is still difficult, and thus premises about brain evolution still depend on too few observations (see Kaas, 2002). Fortunately, we have procedures to correct mistakes, and powerful ways of determining brain organization. A great aid to current cladistic studies of brain evolution is the progress that has occurred in understanding the details of the phyletic radiation of mammals. This understanding is based on both the fossil record, and the results of recent

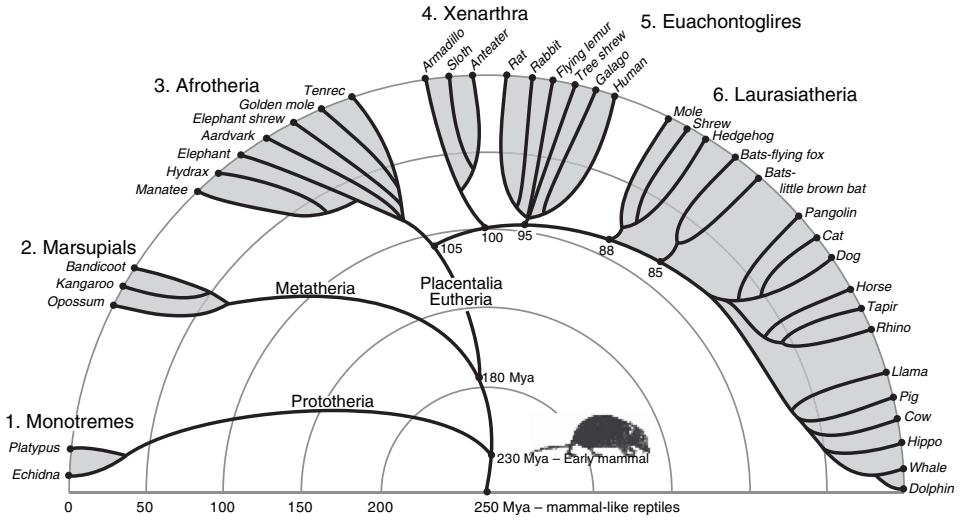

Figure 1 A broad overview of current understanding of the phyletic radiation of mammals. While uncertainties remain, current evidence supports the division of extant mammals into six major clades or superorders (1–6). The molecular evidence, together with the fossil evidence, allows estimates of the times of divergence for these major branches of the radiation and their sub-branches. Thus, early mammals emerged from mammal-like reptiles around 230 Mya. Most early mammals were shrew-like in appearance, and they changed little until the extinction of dinosaurs some 65 Mya. An early mammal is depicted at the center of the radiation, the starting point for mammals. Based on Murphy, W. J., Pevzner, P. A., O'Brien, J. O. 2004. Mammalian phylogenomics comes of age. *Trends Genet.* 20, 631–639.

molecular studies of phylogenetic relationships. As an example, we know from the discovery of fossil whales (Cetacea) with retained hind limbs (Gingerich *et al*., 2001), that whales evolved from a branch of even-toed ungulates (Artiodactyls), and molecular evidence supports the same conclusion (Shimamura *et al*., 1997). A version of a modern phylogenetic tree of the mammalian radiation, showing only the main branches, is shown in Figure 1. This depiction usefully guides the following discussion of brain evolution in mammals, which focuses on neocortex as a flexible structure that has been modified in many ways.

3.03.2 The Basic Structure of Neocortex and the Transition from Dorsal Cortex of Reptiles

In order to understand the different ways that neocortex has changed in the evolution of various mammals, it is useful to briefly review the basic organization of neocortex, and contrast it with its homologue, the dorsal cortex of reptiles (Figure 2; Northcutt and Kaas, 1995). The cortex is the outer sheet of tissue of the forebrain. In reptiles, three major regions are generally distinguished (Figure 3). A dorsomedial region forming the medial walls of the cerebral hemisphere has long been identified as a homologue (the same structure) of the mammalian hippocampal formation (e.g., Smith,

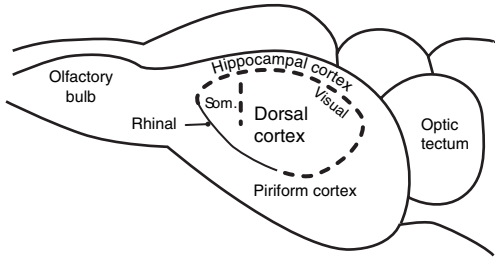

Figure 2 A dorsolateral view of the brain of a turtle showing subdivisions of the forebrain. The large olfactory bulb provides input to the lateral cortex (cf. Figure 3) that is the homologue of piriform cortex of mammals. A small dimple, referred to as the rhinal sulcus in mammals, separates dorsal cortex from lateral cortex, the homologue of piriform cortex. Dorsal cortex is the homologue of neocortex of mammals. Dorsal cortex has visual inputs from the lateral geniculate nucleus, as in mammals, and there is evidence for somatosensory (som.) inputs as well. The medial hippocampal cortex is the homologue of the mammalian hippocampus. The optic tectum is the homologue of the mammalian superior colliculus. Based on Hall, W. C., Ebner, F. F. 1970. Thalamotelencephalic projections in the turtle (*Pseudemys scripta*). *J. Comp. Neurol.* 140, 101–122.

1910; see Striedter, 1997 for review). In reptiles, this tissue does not have the coiled form of the mammalian hippocampus, but its location and appearance, with a single dense row of cell bodies sandwiched between layers of fibers, help identify it as the hippocampus. A dorsal sector, the dorsal cortex of reptiles, is the homologue of mammalian neocortex. Nevertheless, dorsal cortex is only

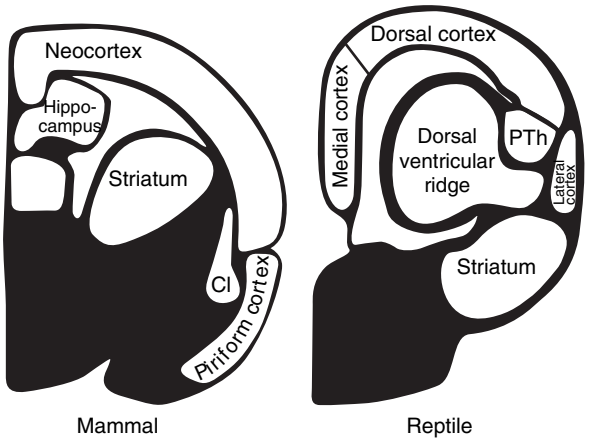

Figure 3 Schematic cross sections through the forebrain of a reptile and a small-brained mammal. Note that the dorsal cortex of reptiles, although smaller, corresponds in position to neocortex of mammals. PTh, pallial thickening; lateral (piriform) cortex; Cl, claustrum. Based on Striedter, G. F. 1997. The telencephalon of tetrapods in evolution. *Brain Behav. Evol.* 49, 179–213.

slightly modified in appearance from the medial hippocampal cortex. Dorsal cortex has a thin deep layer of fusiform neurons with horizontal dendrites, and a more superficial layer of more pyramid-like neurons with dendrites extending vertically into an overlying fiber layer (e.g., Ulinski, 1986). Together these two cell layers are rather thin, only a few cells thick, and unimpressive. Afferents from the thalamus enter from the lateral margin of dorsal cortex and course in the outer fiber layer to contact the dendrites of the cells below (Hall and Ebner, 1970). The ventrolateral part of dorsal cortex, termed the pallial thickening, is now thought to be the reptilian homologue of the mammalian claustrum (a thin sheet of cells internal to layer 6 of ventrolateral neocortex with interconnections with neocortex (see Dinopoulos *et al.*, 1992 for review). The lateral cortex of reptiles is considered the homologue of piriform (olfactory) cortex of mammals. The point of this brief description is to stress that mammalian neocortex is not really a new structure in mammals. Hence, many comparative neuroscientists prefer to call it isocortex for its uniform appearance in mammals. However, a comparison of dorsal cortex with neocortex illustrates that neocortex has new features and in that sense can be called new.

In contrast to dorsal cortex of reptiles, neocortex in all mammals is a rather thick structure, packed with neurons, that is traditionally described as having six layers of different functions (Figure 4). Across these layers, a species variable numbers of fewer than 100 to over 200 neurons are aligned in a vertical row. As neurons in this row (sometimes called a minicolumn) are densely interconnected, they constitute a functional unit that integrates the functional roles of neurons across all the layers. The functionally dominant inputs for such minicolumns consist of only a few closely related inputs from a location in the thalamus or other parts of cortex, which terminate largely on the small stellate or granular neurons of layer 4. Large pyramidal neurons of layer 5 provide outputs over long distances, mainly to subcortical structures such as the superior colliculus and spinal cord, but also to the other hemisphere and to other parts of cortex in the same hemisphere. Smaller pyramidal neurons in layer 3 provide most of the connections between different sectors of cortex while pyramidal and spindle shaped neurons in layer 6 provide 'feedback' projections to whatever thalamic nucleus or cortical area provides the driving input to layer 4 neurons, and projections to the claustrum (see Dinopoulos *et al.*, 1992). Other inputs to any sector of cortex include modulating feedback inputs to superficial (1, 2, and 3) and deep (5 and 6) layers from other areas of cortex, modulating inputs from the thalamus, and modulating inputs from various neurotransmitter specific nuclei (dopamine, serotonin, acetylcholine). Many of these modulating inputs terminate on the distal ends of dendrites of pyramidal cells. Neurons in different rows or minicolumns of neurons interact via horizontal connections stemming largely from layer 3 pyramidal cells. Layer 2 has small pyramidal cells. All layers contain stellate-shaped inhibitory neurons (~20% of the total) of several types that inhibit nearby neurons when they are activated by inputs from neurons in other structures or by nearby neurons. The great computational power of neocortex comes, in part, from this basic arrangement of neurons with specialized roles within and across layers, and the activation of a complete row of neurons by a few powerful inputs. All this while this activity is subject to modification by nearby inhibitory neurons, horizontal intrinsic connections, feedback connections from other areas of cortex and the claustrum, and various neurotransmitter modulating inputs from the brainstem and thalamus. All these connections allow the outputs of such a row of neurons to be modified by their activating patterns. Many of the modifications are instantaneous and short-lived, but highly active inputs can induce long-term changes in responsiveness as well (plasticity and perceptual learning). The result is great flexibility. In addition to this flexibility based on sensory experience and activity patterns unique to each individual, natural selection can genetically modify all the features of

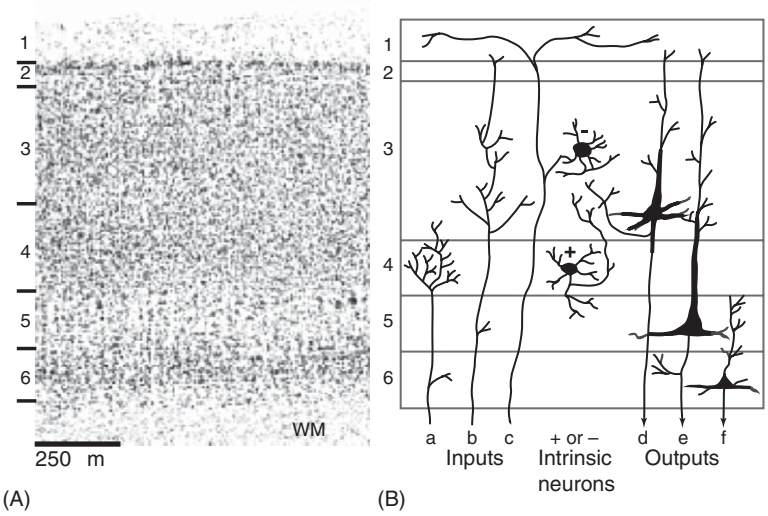

Figure 4 The laminar organization of neocortex in mammals. A, A thin slice of neocortex through primary visual cortex (V1) of a prosimian primate (galago) that has been stained to reveal the cell bodies (dark dots) of neurons, but not axons or dendrites. The cell bodies vary in shape and packing density across the thickness of cortex in a laminar pattern. Traditionally, six layers have been recognized, along with varying numbers of sublayers. Different cortical areas within a species vary in the appearance of the layers, from more to less distinct, and the same (homologous) area across species varies in appearance, but often they retain enough similarities to be identified. This cortex is just over 1 mm thick, with the cortical surface at the top of the photomicrograph and the white matter (WM) or fibers (axons) that connect cortex with other areas and structures at the bottom. B, A schematic of the cortical layers showing some of the types of neurons and connections. The major activating inputs are axons (a) from other areas of cortex or from the thalamus that terminate on stellate or granule cells in layer 4 (and inner layer 3). These 'spiny' stellate cells, thought to be modified pyramidal cells, have short dendrites within the layer, while sending axon branches to activate neurons in layers 3 and 5. Typically, the axons (a) activating neurons in layer 4 also have a branch that provides some activation of neurons in layer 6. Other inputs (b) include feedback, activating axons from other areas of cortex that terminate in layers 1–3 and layer 5. Other modulating inputs (c) from the thalamus and brainstem terminate in layer 1, and in layers 2 and 3. Most of the neurons in layers 2, 3, 5, and 6 are pyramidal neurons with short basal dendrites in the same layer, and a long apical dendrite that usually reaches layer 1. All layers have a portion of inhibitory stellate neurons (–) with short nonspiny dendrites and short axons. Axon inputs, spiny stellate cells (+) and pyramidal cells activate other such cells and the inhibitory neurons, which synapse on excitatory neurons to dampen their activity. Layer 3 pyramidal cells project to other areas of cortex and to subcortical targets. Layer 5 pyramidal cells project mainly to subcortical targets. Layer 6 cells provide feedback connections to the thalamus or other areas of cortex, as well as to the claustrum.

such rows of cortical neurons over generations, to alter and adjust functions. For example, the functions of any row of neurons can be changed by evolving different activating inputs, or different targets for the outputs.

There are two other basic features of neocortex that have contributed to it being such an important part of the brain in all mammals, and the dominant part of the brain in most mammals. The sheet of cortex that is made up of vertical rows of cells that form layers is subdivided across its surface into functionally distinct and specialized regions called areas that are often divided into smaller functionally distinct regions called columns or modules (the term, module will be used here). The concept of a cortical area goes back to early investigators, such as Brodmann (1909), who defined cortical areas as the 'organs of the brain', and identified areas by structural differences in the layers and neurons between sectors of cortex. The early evidence for functionally specialized areas came from observing impairments in abilities of humans and other mammals after damage to specific regions of neocortex. Areas can be small or large, depending on functional role and overall size of neocortex, but the general concept is that they constitute a region of cortex with sharp boundaries where neurons are related in function as a consequence of having specific types of inputs and specific targets for outputs (Kaas, 1982). The prototypical example of an area is V1, also known as area 17 or striate cortex, which receives most of the output of the dorsal lateral geniculate nucleus of the visual thalamus, and provides activating visual inputs to other areas of cortex. Each row of cells in V1 deals with inputs corresponding to a specific location in visual space, and adjoining rows deal with adjoining locations in space so that the V1 of each cerebral hemisphere forms a map or representation of the contralateral visual hemifield. Other areas receive inputs from other sensory modalities, or from other cortical areas, and have outputs to other types of structures. This allows areas to have great flexibility in function, while relying on similar minicolumns as the basic computational unit. Most

importantly, the relatively simple computations of cortical minicolumns, can result in very complex outcomes, just by the process of reiteration. The outputs of any cortical area provide inputs to other cortical areas where the computational functions are repeated. This means that the more cortical areas there are, the more steps in processing are possible, resulting in more sophisticated computations. Mammals with large brains and large sheets of neocortex generally have more cortical areas and more variable and sophisticated behavior. Cortical evolution in mammals is largely characterized by modifications that change the functions of cortical areas, and by the addition of cortical areas, thereby adding steps to the information processing sequences.

A further feature of cortex that adds to its flexibility is the cortical column or module (Kaas, 1982). Many, perhaps all, cortical areas are not uniform in function. Relative to its surface, a cortical area may be divided into a tile-like or band-like pattern of alternating blocks of neurons of related, but slightly different functions. Sensory receptors, and the computations based on inputs from these receptors, create different functional classes of neurons at various levels of processing in the nervous system. The projections of these classes to other structures can be combined for various types of integration, or segregated for further processing. Modules, which include neurons across cortical layers, are one way of maintaining functional segregation. As an unusual (perhaps unique) example of modular segregation, the ancestors of the highly specialized monotreme, the duck-billed platypus, evolved electroreceptors in the skin of its nose (bill), which is also highly sensitive to touch. What to do with this new type of input? The platypus uses the somatosensory system for analyzing the electroreceptor input by dividing the structures for processing tactile inputs into modules for tactile receptor inputs and modules for electroreceptor inputs. Thus, the part of primary somatosensory cortex of the platypus that represents the bill is subdivided into alternating modules of neurons processing information form either electroreceptors or tactile receptors (Krubitzer *et al.*, 1995). The reorganized and subdivided somatosensory system can now be used to detect the electrical activity of the muscles of prey as the platypus feeds in the water. Mammals have evolved different types of modules within cortical areas in the process of acquiring new and expanded functions. This ability of cortex to be modified by forming modules is another reason why cortex has been so important in brain evolution.

As another sign of the ability of cortex to evolve in different ways, separate classes of input to a cortical area may be segregated in sublayers rather than in modules (see Visual Cortex: Evolution of Maps and Mapping). For example, in primates, two classes of visual input, stemming from two classes of retinal ganglion cells (M and P), form segregated pathways to primary visual cortex, where they terminate either in the upper or lower half of layer 4, forming two functionally and morphologically distinct sublayers (Casagrande and Kaas, 1994). As another example, a different type of segregation occurs in the visual system of tree shrews, where the classes of retinal ganglion cells that respond to light onset (ON cells) or light offset (OFF cells) form segregated pathways that terminate in upper or lower sublayers of layer 4 of primary visual cortex (Norton *et al.*, 1985). Thus, different types of sublayers of the same layer can form in the same cortical area in different lines of mammalian evolution. Given this and other modes of modification, no wonder that neocortex has played such a critical role in mammalian evolution.

Before ending this section, we need to consider another variable feature of neocortex, the sensory representation. In some sense, cortical sensory areas constitute maps or representations of peripheral arrays of sensory receptors: the mechanoreceptors of the skin, the photoreceptors of the retina, and the row of sound sensitive hair cells of the inner ear. Mammals evolve different processing systems for these receptors by distributing them differently in the receptor sheet, and by providing some of them with proportionally more neurons in representations. Thus, behaviorally significant parts of receptor surfaces evolve greater numbers and densities of receptors, and by maintaining a set number of cortical neurons for each receptor, these parts of the receptor sheet activate larger parts of the cortical representations of the receptor sheets than do receptor surfaces with fewer receptors. Traditionally, this has been called the 'cortical magnification' of important sensory surfaces. Thus, the tongue and fingers are 'magnified' in the representation of body receptors in somatosensory cortex of humans, while the whiskers of the face are magnified in S1 of rats and mice. The auditory hair cells of echolocating bats that respond to the echo frequency have a large cortical magnification in primary auditory cortex, and many mammals have a magnified representation of the receptors of the central retina, used for detailed vision. The cortical processing machinery is reassigned in evolution as the distribution of receptors in the receptor sheet is changed to allow various behavioral specializations.

A related modification of the representations in cortex has been called 'afferent magnification' (Catania and Kaas, 1997) when some afferents, those with enhanced behavioral significance, gain more cortical space and cortical neurons than do others. Thus, when the receptors of the fovea of the retina, via their ganglion cells, project to the thalamus, they activate a larger cortical territory in V1 than predicted from the number of afferents (Azzopardi and Cowey, 1993). As another example, afferents from the behaviorally important 11th ray of the nose of the star-nosed mole activate more of primary somatosensory cortex than predicted from the number of afferents (Catania and Kaas, 1997). Thus, sensory systems can evolve to devote more cortical space and neurons for some inputs than for others in the same system. Both cortical magnification of receptor-dense sensory surfaces and afferent magnification of behaviorally important receptors and afferents have led to many well-recognized modifications of cortical representations (see Johnson, 1990).

In summary, we have outlined some of the major ways in which neocortex can be modified in the course of evolution to accommodate the behavioral specializations of various mammals. Examples indicate that these modifications do occur, but present understandings of brain organization in most mammals are too limited to allow an extensive survey of the brains of different species and a listing of derived features that have emerged as adaptations. Instead, this section of the review serves to remind us that neocortex is a uniquely organized but highly variable part of the mammalian brain, and suggests that this is the case because neocortex emerged in early mammals as an extremely flexible part of the brain where functions could be modified and extended in so many useful ways. Now we go on to a discussion of how neocortex in early mammals was probably organized, and then to some of the modifications that have occurred in some of the lines of descent. In doing this, we will briefly consider the implications of increasing the size of neocortex and cortical areas, something that has occurred repeatedly in cortical evolution. Even more briefly, we will note the implications of decreasing the size of the cortex from that of ancestors.

3.03.3 The Fossil Record: How Much Neocortex Did Early Mammals Have?

Mammals evolved from cynodonts, mammal-like reptiles, at least 230 Mya (Figure 1). The transition involved a loss of body mass, as early mammals were quite small, mostly shrew to mouse size, but occasionally cat size to coyote size (Hu *et al*., 2005; Kielan-Jaworowska *et al*., 2004). This small size dominated for over 150 million years, during which time the three major surviving lines of mammalian evolution emerged. The egg-laying Prototherian monotremes diverged very early from Therian mammals some 230 Mya, and the Metatherian marsupials diverged more recently from the Eutherian (placental) mammals some 180 Mya. Dental structures suggest that most early mammals were carnivorous and their small size indicates that they likely ate mostly insects. They may have foraged during the night, as most small mammals do today. Along with their small size, early mammals had small brains and little neocortex. Mammals maintained this body type until 65 Mya, when the massive dinosaur extinction took place, after which they rapidly diverged to occupy a diverse range of ecological niches via modifications in body size (see Falkowski *et al*., 2005) and form, including modifications in the brain. Today, there are over 4600 species of mammals. Here we briefly consider some of the fossil remains of some of the early mammals in order to develop some concept of what their brains were like. While there have been a number of publications describing these fossils, they have been collectively described in an extensive review (Kielan-Jaworowska *et al*., 2004).

Brain size varies with body size, as large mammals generally have larger brains than small mammals. Thus, comparisons of brain size across taxa to see if the brains have gotten bigger or smaller depend on comparisons of brain size of a given mammal to the predicted brain size for that mammal's body mass based on averages of mammals of given body masses (Jerison, 1973). For their body sizes, mammal-like cynodont reptiles had brains that were smaller than current mammals, and early stem mammals also had brains smaller than that predicted from body size (brain sizes were based on the size of the brain cavity in the skull). The reconstructed brain from a 85-million-year-old placental mammal is shown in Figure 5. The brain of this early mammal was obviously small. A hint of a rhinal fissure marks the transition from piriform (olfactory) cortex to neocortex. The high position of rhinal fissure indicates that neocortex was quite small. In addition, neocortex did not extend caudally to cover the midbrain, as it does in most extant mammals. The proportionally large olfactory bulb and piriform cortex indicate that much of the forebrain was olfactory in function, while the small neocortex apparently had a limited role in behavior.

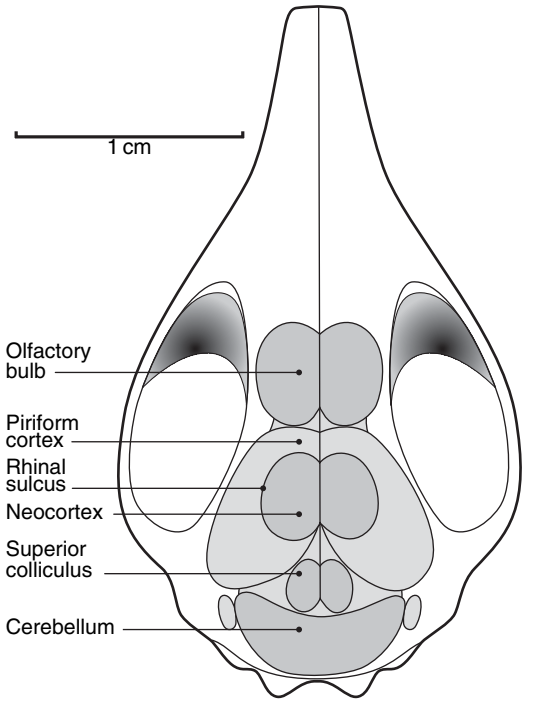

Figure 5 A reconstruction of the skull and brain (from the endocast) of an early (Late Cretaceous) Eutherian mammal (85 Mya). Primitive features of the brain include proportionally little neocortex compared to the olfactory bulbs and piriform cortex. The hemispheres are widely separated posteriorly, and they fail to cover the superior colliculus of the midbrain. Modified from Kielan-Jaworowska, Z., Cifelli, R. L., Luo, Z.-X. 2004. Mammals from the Age of Dinosaurs. Columbia University Press.

In summary, the fossil record provides some information about brain size in early mammals. Their brains were generally smaller for their size than the averages for current-day mammals, and they were not much different from the sizes of the mammal-like reptiles from which they emerged. Much of their forebrains were devoted to olfactory (piriform) cortex and the olfactory bulb. The suggestion of a rhinal fissure high on the lateral surface of some brain endocasts provides evidence that neocortex was proportionally very small.

3.03.4 How was the Neocortex of Early Mammals Subdivided into Functionally Distinct Areas?

As mentioned earlier, modern mammals are not necessarily completely modern. That is, some parts or features of their brains are likely to have been retained from ancient ancestors, while others have been greatly modified or created in more recent ancestors. It is said that evolution proceeds by tinkering, rather than by redesign (Jacob, 1977). Allman (1999) likened brain evolution to the process he noted when he visited a giant power plant of a major city. As greater and greater demands were placed over the years on the power plant, modifications and modernizations were needed to keep up with the demands. Yet, the power plant could never be shut down for a complete redesign. Thus, new control systems were added to old systems and a mixture of ancient to new features were integrated into one functional system. If we can identify the retained parts of brains in the brains of extant mammals, then we can reconstruct the major features of the brains of ancestors. The problem is how to do this. It was tempting for early investigators to infer that simple and undifferentiated brain features are the old ones retained from an ancient ancestor, while structurally complex and internally subdivided features are relatively new. This inference may generally work, as the assumption behind it seems logical, but it can lead to big mistakes, as the same (homologous) cortical area may range from highly differentiated to poorly differentiated in different extant mammals. Only the changes in the differentiation of the area, and not the area itself, differ in age. To avoid such mistakes, rules for reconstructing ancestral character traits have emerged (e.g., Brooks and McLennan, 1991) that assign widely shared traits among members of a clade (any group of mammals that have descended from a common ancestor) to a common ancestor. As members of any such group would have diverged from another at different times in the past and from different shared ancestors, each previous time of divergence is called a node in a cladogram, and characters that diverged from a node are compared, as well as characters inferred for a node from those of other previous nodes. By proceeding backwards in time, characters can be inferred for the last common ancestor of the clade. The optimization of the reconstruction, based on maximum parsimony criterion, can be a bit more complex, using downpass, uppass, and final optimizations (Cunningham *et al.*, 1998). In any case, the questionable assumption of simple-means-primitive is avoided.

Here we use the cladistic approach in a less formal way, largely because many brain features are difficult to identify without extensive investigation. The costs and time in investigation mean that few members of any clade have been well investigated. The difficulties in using a cladistic approach in studies of brain evolution, and the use of a truncated approach have been outlined elsewhere (Kaas, 2002). Here, we simply use the comparisons available to infer some of the major organizational features of neocortex of the first mammals.

A basic assumption of our truncated cladistic approach is that information about the organization of brains of extant mammals is not all equally useful. We know from the fossil record that early mammals had small brains with little neocortex. A number of current mammals, such as opossums, hedgehogs, tenrecs, and to a lesser extent, even rats and mice, have small brains with little neocortex, while several others, such as ourselves, have large brains with proportionally huge amounts of neocortex. Obviously, the large brains must have changed a lot, while the small brains may have changed relatively little. Thus, it should be easier to find the common features in small brains, if only because the needle is in a small haystack. Of course, more extensive cladistic comparisons are important, and they remain the ultimate test of any proposition. For instance, the small brains of echolocating bats have highly specialized (derived) areas of auditory cortex, and studying auditory cortex in these bats alone would lead to a highly misleading idea of how auditory cortex was organized in early mammals. Nevertheless, a productive approach seems to be to study small-brained mammals in as many of the major branches of the mammalian radiation as is practical, make inferences about the brains of early mammals from this data set, and then see how consistent these inferences are with what is more widely known about mammalian brains, including human brains.

We start our analysis by considering the organization of neocortex in the brains of members of four of the six major branches or superorders of the mammalian radiation (Figure 1). The earliest branch (230 Mya) with surviving members, the monotremes, is barely surviving as they are represented today by only two families, one genera of platypus and two of echidna. As these survivors are highly specialized in body form and brain organization as adaptations to unusual niches, we will return to them later. The marsupials or Metatherians, a line some 180 million years old, have been more successful, representing today about 7% of extant species in 16–18 families. They vary in brain size and shape, but most of the American opossums and Australian possums have small brains, with little neocortex, and the brains of some of these, especially the North American opossums, have been well studied. The highly varied superorder, Afrotheria, over 100 million years old, includes the very impressive and very large-brained elephants, but also the small-brained tenrecs, now almost completely restricted to the island of Madagascar. Tenrecs look like the reconstructions of stem mammals as if they stepped out of the distant past (Figure 6). Tenrecs were once

Figure 6 A photograph of the tenrec, *Echinops telfairi*, which is found in southwestern Madagascar. This small member of the Superorder, Afrotheria, retained many primitive characteristics in body form and appearance, so that it was previously classified with the insectivores of the Laurasiatherian superorder. Reconstructions of the appearance of early mammals look a lot like current day tenrecs. Reproduced from, figure 1, Krubitzer, L. A., Kunzle, H., Kaas, J. H. 1997. Organization of sensory cortex in a Madagascan insectivore, the tenrec (*Echinops telfairi*). *J. Comp. Neurol.* 379, 399–414, with permission from Wiley-Liss, Inc.

placed in the Insectivore order with hedgehogs and shrews, but molecular evidence indicates that they are only distantly related, and their many shared features are retentions of ancient mammalian features. Thus, their brains are small with very little neocortex. Another superorder that is nearly as old, Xenarthra, includes sloths, anteaters, and armadillos. These mammals do not have much neocortex, but little is known about how their neocortex is organized. However, somatosensory (S1) motor (M1), visual (V1 plus more temporal visual cortex) and auditory areas have been identified (e.g., Royce *et al.*, 1975). The highly varied members of the Laurasiatherian superorder include the large-brained whales and dolphins, as well as small-brained moles, shrews, and hedgehogs. As quite a bit is known about their brains, we will use them to represent the superorder. The other remaining superorder, Euarchontoglires, includes humans and other primates, and thus, they are of special interest. It also includes tree shrews and flying lemurs as our closest nonprimate relatives, and lagomorphs and rodents. As rats have rather small brains that have been intensively studied, they represent the superorder as we deduce common features across the superorders.

3.03.4.1 Primary Sensory Areas

The brain of the tenrec (Figures 7a and 7b) closely resembles that of early stem mammals (Figure 5) in

external appearance. In a dorsolateral view of the intact brain, a small cap of neocortex, marked by the shallow indentation of the rhinal 'sulcus', rests over the much larger olfactory brain, the piriform cortex, olfactory tubercle, and olfactory bulb. As with early mammals, olfactory processing dominated the forebrain. This is even more evident in the flattened brain. In tenrecs and other mammals,

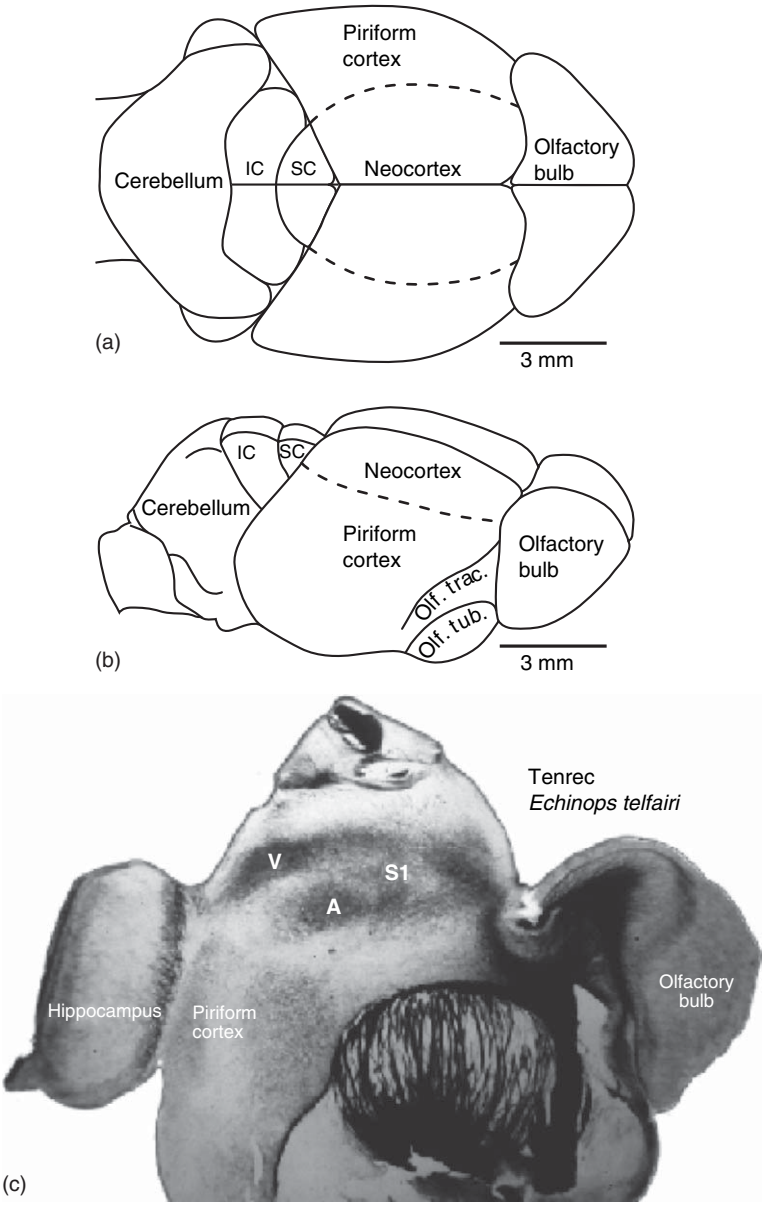

Figure 7 The brain of a Madagascan tenrec (*Echinops telfairi).* a, A dorsal view of the brain showing the small amount of neocortex relative to the large olfactory bulbs and piriform (olfactory) cortex. The small neocortex fails to cover the midbrain, as in the brains of early mammals (compare with Figure 5). b, A lateral view of the brain, showing the greater extent of piriform compared to neocortex. The line dividing neocortex from piriform cortex represents the rhinal sulcus, which is no more than a dimple in tenrecs. The olfactory tract (olf. trac.) and tubercle (olf. tub.) are apparent. c, A brain section stained for myelin that has been cut parallel to the surface after the cortex, hippocampus, and olfactory bulb have been separated from the rest of the brain and flattened. This preparation allows all of neocortex to be viewed as a single sheet, containing piriform cortex and the hippocampus. As in other mammals, the primary visual (V), auditory (A), and somatosensory (S1) areas stain darkly for myelin and are easily identified. Other areas of neocortex of tenrecs are shown in Figure 8b. At the top of the figure, neocortex of the medial wall of the cerebral hemisphere has been unfolded, and the fornix, a bundle of axons, is very dark, while the corpus callosum, a bundle of axons connecting the hemispheres, is less so. Next to the corpus callosum, the cingulate (limbic) cortex is lightly stained. The myelin dense region rostral to S1 may be primary motor cortex, M1. IC, inferior colliculus; SC, superior colliculus. Adapted from, figures 2 and 8, Krubitzer, L. A., Kunzle, H., Kaas, J. H. 1997. Organization of sensory cortex in a Madagascan insectivore, the tenrec (*Echinops telfairi*). *J. Comp. Neurol.* 379, 399–414, with permission from Wiley-Liss, Inc.

it is possible to separate the cortical sheet from the underlying basal ganglia and thalamus, flatten the whole sheet, cut it into thin sections parallel to the cortical surface, and stain these sections to reveal architectonically distinct subdivisions. For the small tenrec brain, it is relatively easy to also include the septal region below the corpus callosum on the medial wall of each hemisphere, the unfolded hippocampus, and the olfactory cortex and olfactory bulb (Figure 7c). In such sections, it is apparent that olfactory cortex is three or more times larger than neocortex, and that both the hippocampus and the olfactory bulb are nearly as large as neocortex. In a section stained for myelin, four regions stain darkly. One is primary visual cortex, V1 or area 17, another is primary somatosensory cortex, S1, or in primates, area 3b (Kaas, 1983). A third region is primary auditory cortex, and the fourth in frontal cortex may demarcate primary motor cortex, M1.

We find three of these areas of tenrecs, V1, S1, and A1, in opossums, hedgehogs, and rats (Figure 8), representing three other superorders. Indeed, these fields appear to exist in all examined mammals, with the possible exception for V1 of mammals with no functional object vision. Yet, even in the subterranean 'blind' mole rat, a small 'visual' area may be architectonically apparent (Cooper *et al.*, 1993), although involved in nonvisual functions. These three sensory areas may be not only early areas present in the first mammals, but also areas that emerge early in the development of cortex, possibly to organize the overall arrangement of other later developing areas in all mammals (Krubitzer and Kaas, 2005). Thus, V1, S1, and A1 may have been retained in extant mammals as necessary components of the developmental plan for neocortex. These three areas of cortex can be identified by a number of features, including direct

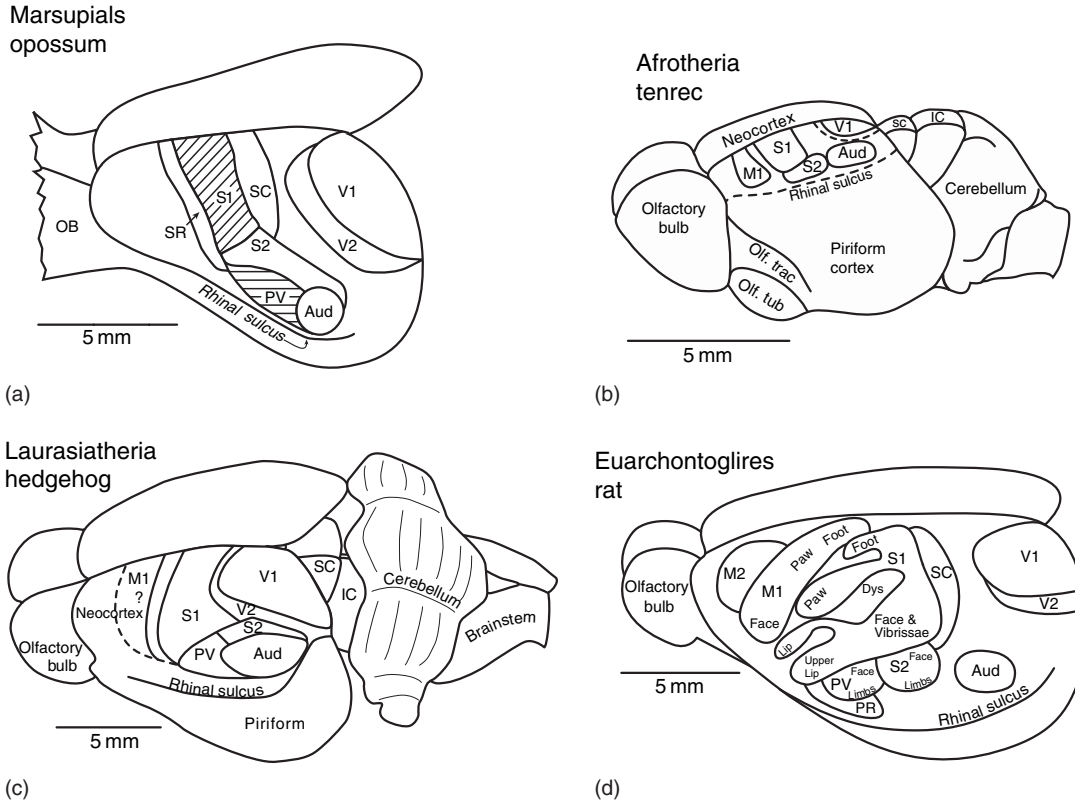

Figure 8 Dorsolateral views of the brains representing small-brained members of four of the major superclades of mammals. In each of these four brains, only a few areas of neocortex have been identified, and most of these are present in all four brains. All have primary and secondary visual (V1 and V2) and somatosensory (S1 and S2) areas, as well as a primary auditory area (Aud). The parietal ventral (PV) somatosensory area has been identified in three of these brains, but was not detected in tenrecs. Somatosensory fringe areas rostral (SR) and caudal (CR) to S1 may exist in all these mammals. A primary motor area, M1 has been identified in many placental mammals, but not in opossums. The presence of some areas in members of all four clades suggests that these areas were present in a common ancestor. a, The brain of a North American opossum (see Beck *et al.*, 1996, for details). b, The brain of a tenrec (see Krubitzer *et al.*, 1997, for details). c, The brain of a hedgehog (see Catania *et al.*, 2000). d, The brain of a rat (see Remple *et al.*, 2003). In (c) and (b), the brainstem is attached and the superior colliculus (SC) and the inferior colliculus (IC) both are apparent, as neocortex is so small that it fails to cover them. Adapted from Kaas, J. H. 2004. Evolution of Somatosensory and Motor Cortex in Primates. *Anat. Rec. Part A* 281A, 1148–1156, with permission from Wiley-Liss, Inc.

inputs from specific 'relay' nuclei of the thalamus, orderly representations of the corresponding receptor sheet in a characteristic manner, and a 'sensory' type of histological structure. At least one of these fields emerged in cortex well before the advent of mammals, as a dorsal lateral geniculate nucleus with inputs from the retina has been identified as projecting to a 'V1' of dorsal cortex of reptiles (Hall and Ebner, 1970). Auditory and somatosensory relay nuclei also exist in the thalamus of reptiles, but they appear to have largely subcortical (basal ganglia) targets. However, a small somatosensory region of dorsal cortex has been described in turtles (Figure 2). Cortical targets for the auditory thalamus apparently emerged with or directly before the first mammals (see Visual Cortex of Turtles).

The existence of a fourth area of neocortex of tenrecs, the primary motor area (M1), in the stem mammals remains unsettled. M1 has been identified in all placental (Eutherian) mammals that have been appropriately studied, so it is nearly certain that the common ancestor of all placental mammals had an M1. However, the evidence for M1 in marsupials and monotremes is uneven and a bit confusing. In placental mammals, M1 is located rostral to S1, with a narrow strip of somatosensory cortex separating the two (see below). In contrast, there is no convincing evidence of an M1 in marsupials (see Beck *et al*., 1996). M1 is usually identified by electrically stimulating cortex, as this will evoke movements that vary in type depending upon which part of M1 is stimulated. Hindlimb movements are evoked medially in the M1 strip; forelimb movements in the middle, and face, vibrissae, and tongue movements are evoked laterally in the M1 strip. In opossums (e.g., Beck *et al*., 1996; Frost *et al*., 2000), no movements could be evoked from the expected region of M1, although some movements were evoked by electrically stimulating S1, as in placental mammals. In addition, M1 can also be identified by architectonic characteristics that reflect the major function of M1 in motor control. Specifically, M1 does not have a distinct layer 4 of cortex, which is well developed in sensory areas, and it has at least a somewhat larger layer 5 containing large pyramidal neurons, as these are the motor output neurons to the brainstem and spinal cord. In opossums and other examined marsupials, there is no architectonic evidence for M1. Finally, patterns of connections can help identify M1. In Eutherian mammals, M1 receives somatosensory inputs from several somatosensory areas, as such sensory inputs are necessary to guide motor control. In opossums, such areas as S2 do not project to the expected location of M1. More significantly, M1 pyramidal cells project to motor neuron pools in the brainstem and spinal cord. In opossums, none of the cortex in the expected location of M1 projects to the spinal cord (Nudo and Masterton, 1990). While a small number of neurons in S1 and the second somatosensory area, S2, do project to the spinal cord, they terminate in the dorsal sensory part of the spinal cord, as do corticospinal projections from S1 in placental mammals, rather than in the motor neuron groups in the ventral spinal cord, as M1 projections do in placental mammals. Thus, it appears that opossums do not have a motor cortex, and whatever weak motor control cortex has on guiding motor behavior, it comes from somatosensory cortex. This lack of motor cortex is thought to account for the relative lack of skilled forelimb movements in opossums compared to rats (Ivanco *et al*., 1996).

A remaining puzzle is that opossums do appear to have a motor thalamus, a ventrolateral complex, VL, as defined by inputs from the deep cerebellar nuclei (Walsh and Ebner, 1973). VL projects to motor cortex in placental mammals, but its target in opossums appears to be S1 (Killackey and Ebner, 1973). One theory for the evolution of M1 is that M1 differentiated out of S1 (Frost *et al*., 2000; Lende, 1963), but there is no clear evidence for this, and M1 could have emerged in some other way. Another intriguing possibility that further study could rule out or verify, is that some of the marsupials with larger brains and better motor skills have independently evolved a motor cortex. In support of this speculation, the projections from the motor thalamus (VL) in some marsupials, appear to include some cortex rostral to S1 (e.g., Haight and Neylon, 1981).

Given that there is no evidence for a motor area in dorsal cortex of reptiles, and apparently no motor cortex in marsupials, together with the assumption that once evolved, a motor cortex would be too useful to abandon, a reasonable inference is that motor cortex evolved in the stem placental mammals after they diverged from marsupials. If so, monotremes should not have any motor cortex. However, this is presently uncertain. There is some evidence in both echidna and platypus that movements can be evoked in a region of cortex rostral to S1, and this cortex has architectonic features suggestive of M1 (see Krubitzer *et al*., 1995). It would be useful but probably difficult (because of limited opportunities for study) to obtain definitive evidence for M1 in monotremes. If M1 is present, we need to consider the possibility that M1 emerged with early mammals and was somehow lost in at least some marsupials. For now, the scenario that M1 evolved later with placental mammals seems more likely. If so, it is important to remember that neocortex still participated in motor control in

non-placental mammals. The somatosensory areas are more sensory than motor, but they do have motor functions.

3.03.4.2 Other Cortical Areas

What other subdivisions of neocortex were likely present in stem mammals? In all appropriately studied mammals, a second somatosensory area, S2, has been described as adjoining S1 on its lateral border (see Beck *et al*., 1996). S2 gets somatosensory inputs from S1, receives additional somatosensory inputs from the somatosensory thalamus, and projects to nearby sectors of somatosensory cortex and, in placentals, to motor cortex. S2 appears to be a component of neocortex in all mammals. An adjoining oval of cortex, the parietal ventral area, has been identified as present in a range of mammals, including many placentals (Krubitzer *et al*., 1986), marsupial opossums (Beck *et al*., 1996), and monotremes (Krubitzer *et al*., 1995). However, parietal ventral (PV) somatosensory area has not always been found, even after a detailed exploration of the appropriate region of cortex (Frost *et al*., 2000). PV closely resembles S2 in connections and architectonic features, so that it can be difficult to distinguish from S2. However, PV does have a separate representation of the contralateral body receptor sheet that mirrors that of S2, and evidence of two mirror-image representations provides clear evidence for PV. The evidence for PV in some species of the three major branches of mammalian evolution suggests that PV evolved in the early stem mammals, and has either been difficult to detect, or has been lost in some small-brained mammals (this is discussed in the following).

In mammals that have been tested, S1 projects to a narrow strip of cortex just rostral and just caudal to S1, as well as to S2 and PV (see Beck *et al*., 1996). These two strips of cortex appear by connections to be somatosensory in function, although they may be multisensory as well (Wallace *et al*., 2004). In either case, early mammals likely had four or five somatosensory areas, as well as perirhinal cortex with S2 inputs that would serve as a relay to the hippocampus.

In regard to visual cortex, most mammals appear to have several visual areas. With a few known exceptions, all carefully studied mammals have demonstrated a second visual area, V2 (Kaas and Krubitzer, 1991; Rosa and Krubitzer, 1999). V2 constitutes a visual area that borders V1 laterally (or rostrally in primates) along the representation of the vertical line of decussation of the retina (the vertical meridian through the center of gaze) of V1, and forms a smaller, mirror image of the representation of the contralateral visual hemifield that is in V1. Some investigators have interpreted the region of V2 of rats as consisting of a row of smaller visual areas (e.g., Montero, 1999), but this interpretation appears to stem from confusing modules within V2 as separate visual areas (Kaas *et al*. 1989). In many mammals, V2 is not homogeneous in function, but contains a row of patches or bands along its length that alternatively have somewhat different connections and functions. In a few other mammals, V2 appears to be absent. Thus, there is no evidence for V2 in the 'blind' mole rat (Cooper *et al*., 1993). In mammals with little visual function, V2 and other visual areas were likely lost in evolution. In addition, the least shrew (*Cryptotus parva*) has no V2 (Catania *et al*., 1999). Instead, V1 directly adjoins S1, leaving no space for V2. However, the 4–5 g adult least shrew is one of the smallest of mammals, probably near the limit in small size for mammals, and it may have lost V2 in evolution to allow other areas, such as V1 and S1, to remain large enough to preserve functions in its small brain. As cortical areas became smaller, they do so by having fewer neurons, and below some number of neurons, the functions of areas cannot be maintained. As the extremely wide distribution of V2 across mammalian taxa indicates that V2 evolved very early with or before the first mammals, the evidence for the absence of V2 in some mammals argues that cortical areas can be lost as well as gained.

By determining the connections of V1 and V2, other cortical areas with visual input can be identified. In a range of placental and marsupial mammals, V1 demonstrates connections with cortex just medial to V1 and just lateral to V2 (e.g., Martinich *et al*., 2000). Both the medial and lateral regions may contain one or more visual areas, and presumptive fields in these regions have been identified with different names by various investigators. A small region medial to V1 has been called prostriata in primates and the splenial visual region in other mammals (Rosa *et al*., 1997). Prostriata likely existed as a visual area in early mammals, as did one or more small visual areas lateral to V2. As a conservative estimate, early mammals had V1, V2, a prostriata, and a small visual area in temporal cortex for a minimum of four areas, but possibly five or six.

All mammals examined have a region of auditory cortex that is typically located in temporal cortex caudal to S1 and ventral to V2. Much of this auditory region has been characterized as primary auditory cortex, A1, on the basis of several criteria, including architectonic characteristics of sensory cortex,

auditory inputs from the principle (ventral) nucleus of the medial geniculate complex, and often, physiological evidence, not only for neurons responsive to auditory stimuli, but for a systematic representation of tone frequencies across the taxa (a tonotopic representation). A problem here in comparing species is that many taxa have more than one area that has some of the characteristics of primary auditory cortex. It is likely that across species different areas have sometimes been identified as the primary auditory area, A1, a field first identified in cats (see Kaas, 2005). A survey of studies on auditory cortex suggests that an area that represents tones from high to low frequencies in a rostrocaudal dimension across the field, as in cats, is present in a number of other studied placental mammals, and in opossums. This A1 may have been present in early mammals. But, the evidence for another primary-like anterior field, with a reversed order of tonotopic organization is also common, as well as for a bordering fringe of two or more secondary fields. From this evidence, it seems likely that early mammals had at least one primary auditory field, A1, and perhaps two, with a bordering belt of two or more secondary fields, for a total of three to five auditory areas. At least one of these fields may also have responded to somatosensory stimuli.

As a part of a system that is devoted to evaluating the quality of food, early mammals are expected to have one or more taste areas in neocortex. Comparative data are not extensive enough to allow this conclusion, but rodents (e.g., Sugita and Shiba, 2005) and monkeys (see Kaas *et al*., 2006) appear to involve both the tongue representation of primary somatosensory cortex, S1, and a laterally adjacent 'insular' region of cortex in processing gustatory information. This information in turn is relayed to a portion of orbital frontal cortex for an evaluation of the hedonistic properties of the ingested food. While there are great uncertainties, it seems reasonable to postulate that part of S1 as well as neurons lateral to S1 in dysgranular 'insular' cortex were involved in taste in early mammals, and the reward value of food objects was processed further in a orbital frontal area. In primates, the insula is an island of cortex in the depth of the lateral sulcus. The term is used here for the equivalent region of cortex in mammals without a lateral sulcus.

As with taste, there have been few comparative studies of the involvement of neocortex in nociception (pain) and temperature perception. Evidence from primates, cats, rabbits, and rodents implicates S1 and thus other somatosensory areas in at least the sensory-discriminative component of pain, while a region of anterior cingulate cortex on the medial wall of the cerebral hemisphere appears to be important in the affective-motivational component of pain (e.g., Johansen *et al*., 2001; Treede *et al*., 1999). A portion of 'insular' cortex lateral to S1 and S2 may be specialized for the affective component of pain. The same or a similarly located region of insular cortex may be important in processing thermal stimuli (e.g., Davis *et al*., 2004). What is not known is the extent to which pain and temperature depended on subcortical rather than cortical processing in early mammals, but the possibility or even likelihood of specialized cortical areas in insular cortex and/or cingulate cortex remains.

In regard to cingulate cortex of early mammals, current theory holds that this limbic cortex has perhaps four subdivisions, at least in some mammals (Vogt, 2005). Anterior cingulate cortex is involved in the important and basic functions of fear and avoidance behaviors, middle and posterior cingulate areas are sensory in some sense having to do with body and spatial orientation and somatosensory and visual functions. The retrosplenial region, adjacent to the splenium of the corpus callosum, is linked to the hippocampus and is thought to be involved in memory processing. Indeed, all of cingulate cortex appears to be involved in memory via associations with the hippocampus involving thalamic connections and cortical connections. Architectonic evidence for subdivisions of cingulate cortex have been described in a number of mammalian taxa, and nuclei of the anterior thalamus which project to these divisions have been recognized in the common laboratory mammals (Jones, 1985). Overall, more comparative study is needed, but the evidence supports the conclusion that the medial wall of the cerebral hemisphere of early mammals contained three to four, and possibly more, functionally distinct areas.

As noted above, cortex lateral to S1 includes S2 and other areas generally referred to as insular cortex. The insular region adjoins perirhinal cortex, the cortex along the rhinal sulcus. Perirhinal cortex appears to receive afferents from secondary somatosensory and visual areas, and have a role in fear-potentiated startle, via projections to the amygdala (Rosen *et al*., 1992), and memory via the hippocampus (Lin *et al*., 2000). A similar involvement of a perirhinal area in startle and memory may have characterized the neocortex of early mammals.

Finally, the significance of an orbital frontal area or region of cortex in taste has been mentioned, and this and other subdivisions of frontal cortex have been considered to be fundamental components of mammal brains (Preuss, 1995b; Uylings *et al*., 2003), although there are uncertainties about how to identify areas, and how to recognize them across species. As a

result, a broad comparative appreciation of the subdivisions of frontal cortex is lacking. Nevertheless, it seems reasonable to postulate that early mammals had two to four subdivisions of frontal cortex, including one or more divisions of orbital frontal cortex.

In summary, the fossil record indicates that early mammals had small brains with little neocortex. Comparative evidence from extant mammals suggests that this cortex was already subdivided into a considerable number of functionally distinct areas, including four or more visual areas, four or more somatosensory areas, two to three auditory areas, possibly a taste area separate from S1, two to four areas of frontal cortex, one or more perirhinal areas, and three or four cingulate areas. This produces an estimate of 17–21 cortical fields, and this could be somewhat of an underestimate. However, it seems unlikely that early mammals had more than 30 fields or many less than 17. As early mammals had little neocortex, perhaps 150–200 mm^2 per hemisphere, cortical areas would have been very small, possibly averaging about 10 mm^2 in surface area, with some areas being larger (e.g., S1) and others considerably smaller (e.g., S2). As areas were quite small, they may not have been subdivided into different classes of modules. Alternatively, a few areas such as V2 may have already been modular. However, more comparative evidence is needed to address these speculations. Finally, cortical areas differed in architecture (patterns of cell arrangements and other structural features), but the differences were not marked. The different functions of cortical areas depended more on connections, the inputs and outputs, than on specializations of areas in cellular and laminar structure.

3.03.5 What Happened to Neocortex in the Radiation of Mammals?

The short answer to the question above is 'different things' – but sometimes very little. As discussed above, the brains of some mammals appear not to have changed very much over the course of 230 million years. Opossums, hedgehogs, shrews, tenrecs, armadillos, and even rats and mice have retained small brains with relatively little neocortex. This cortex remains relatively undifferentiated in structure and cell types. Neocortex remains divided into a few areas, most or all of which were present in the first mammals. The placental mammals, hedgehogs, shrews, tenrecs, rats and mice, have added a cortical motor area, M1, rats and mice have differentiated a 'barrel field' of barrel-shaped modules representing individual whiskers of the face in primary somatosensory cortex, the smallest of shrews lost V2, and so on. But these are rather minor changes. Clearly, environmental niches can be found where brainpower is less important than reproductive capacity and other factors, and ancestral brains did not need to be changed very much.

3.03.5.1 Impressive Modifications of Small Brains

Even in small-brained mammals, several rather remarkable modifications of neocortex have occurred. To mention only a few, the brains of echolocating bats have specialized, without an expansion of cortex, to facilitate the tasks of flying and echolocating. The echolocating bats have an altered auditory system that over-represents the echo frequency and have specialized several auditory areas of cortex that perform computations based on echoes to locate and identify flying prey and avoid objects (Suga, 1995). The somatosensory system of bats has been modified (Calford *et al.*, 1985) for flying by representing the specialized sensory receptors, the Haarscheiben or touch domes with a protruding hair, on the wing and other parts of the body so that flight can be guided. Without these receptors, bats tumble and fall (J. M. Zook, personal communication). Some rodents and squirrels have emphasized vision by enlarging the visual midbrain structure, the superior colliculus, to 10 times its size in other rodents, and differentiating it structurally into more prominent layers and cell types (Kaas and Collins, 2001), while also adding, expanding, and differentiating subdivisions of visual cortex (Kaas *et al.*, 1989). The star-nosed mole has devoted much of its cortex to three large representations of the mechanosensory receptor structures, called Eimer's organs, that are tightly packed on the fleshy appendages of its nose (Catania and Kaas, 1997). This specialization allows the mole to detect and consume small prey at a rate that exceeds that of any other mammal (Catania and Remple, 2005). The duck-billed platypus blindly searches for prey with its eyes and ears shut in murky water by using sensitive tactile and electroreceptors on its rubbery bill (Krubitzer, 1998). To successfully occupy this niche, the platypus depends on a greatly modified neocortex that is dominated by several large representations of the receptors of its bill. The platypus devotes little cortical territory to visual or auditory cortex (Krubitzer *et al.*, 1995). Such specializations in even small-brained mammals indicate the great flexibility of neocortex as a computational structure. The vertical rows of neurons, modules composed of rows of neurons, and areas composed of modules in neocortex

can be reassigned in evolution to various tasks as needs arise. Similar modifications are seen in mammals that have also enlarged their brains, and modified them in other ways. For example, one can marvel at the great skill that raccoons have in blindly locating food items in water. Using their hands, they rapidly locate the source of tiny ripples and currents that are created by moving objects. This ability is made possible by extremely expanded representations in several areas of neocortex of the receptors of the hand (Welker and Seidenstein, 1959). Finally, it is hard not to be impressed with cebus monkeys, as we are members of a clade of primates without tails. Cebus monkeys use receptors on the glabrous pad of the tip of their tail to actively explore their environment and use their tail to retrieve objects of interest. This ability, of course, depends on devoting large portions of somatosensory areas of cortex to the tactile receptors of the tail (Felleman *et al*., 1983).

3.03.6 The Implications of Changes in Brain Size

Brains also change in other ways. One way that was obvious to early investigators such as Smith (1906) and Clark (1959) was that brains vary in size from very small to very large. Part of this variation, for uncertain reasons, is related to body size, so that brains tend to increase in size by an average factor of ~0.75 with increases in body size (Allman, 1999; Jerison, 1973). Such increases in brain size result typically in disproportionately large expansions of neocortex (Finlay *et al*., 2001), but such increases in neocortical size often do not seem to correlate with the acquisition of notably new abilities. For example, the behavior of lions, with much larger brains, do not seem to be remarkably different from those of domestic cats. Thus, we suspect that closely related mammals that are large or small might have brains with similar organizations, although the brains differ in size (this assumption needs careful evaluation). For example, the arrangement of sensory areas of neocortex seem to be roughly the same in the smaller brains of guinea pigs than the larger brains of capybaras (Campos and Welker, 1976), both related South American rodents. Yet, this cannot be completely true, as brains have a basic scaling problem. Large brains cannot simply be large versions of small brains, because the computational unit of the brain, the neuron, does not scale to large sizes with the brain, as the functions of neurons depend on their size (Bekkers and Stevens, 1970). Obviously, transmission times increase as the dendrites and axons of neurons get longer, unless they are modified by making them thicker, and in other ways. Neurons with longer, thicker axons result in brains that devote more of their volume to axons than the computational parts of axon terminations, dendrites, and cell bodies. As the cell bodies and dendrites of neurons do not vary much in size, larger brains are larger, in the main part, because they have more neurons and even more supporting glial cells. Having more neurons means that each neuron, while maintaining roughly the same number of contacts with other neurons, contacts a smaller proportion of the total number of neurons. This changes the organization of the processing network. To evolve large brains, these scaling problems can be reduced or solved in several ways, but mainly via increases in modular organization and local processing that decreases the need for long connections (Kaas, 2000b). To achieve this solution, large brains with much neocortex should have more cortical areas, and more functional subdivisions of areas into different types of modules, than small brains with little neocortex. There is much evidence to support this premise when species are considered across taxa, but not when one considers closely related members of a taxonomic group of different brain sizes. These later mammals may add neurons and disproportionately axon volume to neocortex with increases in brain size, while maintaining the basic cortical organization of the group. Without organizational adjustments, larger brains may just maintain brain functions, without appreciable gains in functions.

Another problem emerges if one considers the consequences of increasing the size of neocortex without adding modules or areas. If bigger brains are simply expanded versions of smaller brains, then the cortical areas must be bigger. Specific areas do vary greatly in size. V1, for example, is 700 times larger in surface area in a human than a mouse, and the cortex in humans is over twice as thick as in mice. This means that V1 in humans has many more neurons. The functions of cortical areas must, in part, depend on their sizes. Of course, one limit on any reduction in the size of a cortical area is that it must have enough neurons to perform its function. Cooper *et al*. (1993) have previously shown that the small sliver of primary visual cortex that is found in the 'blind' mole rat is too small to allow even a crude image. Thus, this cortex has become nonfunctional, at least for the purpose of object vision. Somewhat larger visual areas, with more neurons, may mediate object vision, but the pixels would be large and the image would not have much detail. This is largely due to the scope of the dendritic trees of neurons as they gather information over some limited portion of cortical area. As areas further increase in size, the

scope of the dendritic window gets proportionally smaller, and the area becomes more specialized for detailed vision at the cost of global vision. However, neurons are also influenced by thalamic inputs that terminate outside their dendritic arbors, via the horizontal intrinsic connections of neurons activated by those inputs. In V1 of a mouse, these short (~1 mm) intrinsic connections can tie all parts of V1 together so that the output of V1 can reflect global processing and directly mediate useful vision, but as V1 gets bigger and bigger, the outputs of individual neurons reflect less and less of what is happening in the total visual scene. Thus, the outputs of a large V1, as in macaque monkeys or humans, provide important details about a visual image, but not enough global information about the visual scene to guide most visual behavior. Other smaller visual areas would seem to need to make sense from the outputs of V1. A macaque monkey with V1 intact, but other visual areas missing, should be virtually blind (this has been difficult to test; see Nakamura and Mishkin, 1986). This line of reasoning suggests that in mammals with large amounts of cortex only a few cortical areas should be large. This general supposition seems well supported. Indeed, even V1 in large-brained mammals is not as large as it would be if it maintained a constant proportion of neocortex. Thus, V1 occupies proportionally more of neocortex in the smaller macaque brains than in the larger human brains (Kaas, 2000a).

The limited variability of neuron size and dendritic arbor size relative to the greater variability of brain size has the added implication that it is easier to change the functions of small cortical areas by adjusting dendritic arbor size than those of large cortical areas (Kaas, 2000b). In brief, increasing or decreasing the scope of the arbors in small areas has more impact on the sizes of receptive fields, and on the nature of processing from regional to global. Thus, pyramidal neurons in large areas may have smaller dendritic arbors than neurons in smaller areas (Elston *et al.*, 1996), as larger arbors would not enlarge receptive field sizes enough to alter functions in a significant way.

3.03.6.1 Larger Brains Often Have More Areas

We have discussed the possibility that in closely related species of different body size, the larger species with larger brains may not differ very much in terms of number of areas. However, when comparisons are made more extensively across mammalian taxa, brains do vary in number of areas, and larger brains tend to have more areas. While early investigators, such as Brodmann (1909), came to this same conclusion by studying cortical architecture in many different mammals, the evidence was not very strong as areas were subjectively defined and identified by subtle differences in histological appearance. More recently, it has been possible to define areas with more certainty by using the multiple criteria of architectonics, connectional, physiological, and gene expression differences. Unfortunately, such studies require a huge experimental effort, and results are more credible if verified by several research groups. It is fair to conclude that all of the cortical areas have not been defined with a high degree of certainty in any mammal, and for most taxa, very little is reliably known about how cortex is subdivided (see Kaas, 2005). Yet, it is clear from the results based on a few well-studied species that the number of areas is quite variable across species. For example, it is easy to see from only the shapes of the brains that squirrels and tree shrews have devoted proportionally more of their cortex to vision, as the visual occipital and temporal regions of neocortex are expanded over frontal motor, somatosensory, and prefrontal parts (Figure 9). Moreover, we know from previous studies that hedgehogs have few visual areas, perhaps four (Figure 8). While the full number of visual areas in either squirrels or tree shrews has not been determined, the number is certainly more than four. For squirrels, seven visual areas have been proposed, while nine have been described in tree shrews (Kaas, 2002). As these two mammals of about the same size are not closely related (Figure 1), more visual areas and proportionally more visual cortex

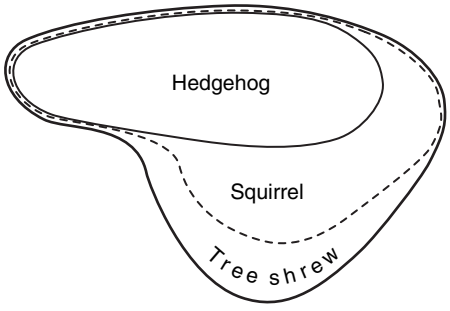

Figure 9 Differences in the shapes of brains suggest changes in function. Here, lateral views of the neocortex of a hedgehog, squirrel, and tree shrew are outlined. The brains have been scaled so that frontal cortex on the left is the same size to emphasize the differences in shape of temporal (ventral) and occipital (posterior) cortex. The highly visual squirrel and tree shrew have greatly expanded temporal and occipital regions of neocortex, and these regions are largely visual in functions. This trait is more pronounced in tree shrews than squirrels. These observations on extant mammals provide a rationale for deducing functional specialization of the brains of extinct mammals from the shapes revealed by skull endocasts.

evolved independently in both lines of descent. Domestic cats have been extensively studied, and they appear to have at least ten visual areas (see Grant and Shipp, 1991, for review). While there is uncertainty about how to divide visual cortex in macaque monkeys, recent proposals number over 30 visual areas (Felleman and Van Essen, 1991). The total number of visual areas in human brains is unknown, but clearly the number is large, as some estimates of total number of cortical areas place the number in the range of 150, possibly 10 times the number present in the first mammals.

Having more areas allows more sophisticated processing via the reiteration process, but also by increasing the number of parallel streams of processing (Kaas, 1989). Another important consequence is that the total amount of wiring (connections) in the cortex is decreased due to greater emphasis on regional processing (Mitchison, 1991). Finally, in large brains, the two hemispheres become less symmetrical in organization, so that areas in one hemisphere no longer have mirror-image counterparts in the other hemisphere. This effectively increases the number of areas while reducing the need for connections between the hemispheres via long axons that cross in the corpus callosum to connect matched pairs of areas (Ringo *et al*., 1994).

While we presently know far too little about how cortical areas are subdivided into classes of modules, we know that this does occur in some brain areas (see Purvis *et al*., 1992; Catania, 2002), and that the same area may be subdivided in different ways in different species. Monkeys have a V2 that is divided into repeating blocks of three types of band-like modules with different connections, architecture, and neural functions (Roe, 2003). In some mammals, including tree shrews and opossums, V2 is subdivided in another manner into modules with and without interhemispheric connections (Cusick and Kaas, 1986). Such modularity adds to the ways neocortex can vary across taxa, and provides a mechanism for grouping types of neurons that need to work together, thereby reducing the connection problem.

3.03.7 Summary and Conclusions

3.03.7.1 Neocortex Varies in Size and Complexity

An overview of the sizes and parts of brains of extant (living) mammals indicates that neocortex varies most in size and complexity relative to the rest of the brain. This indicates that neocortex is an important part of the brain for further study if one is interested in brain evolution. Such studies reveal that neocortex varies in many ways across taxonomic groups. Variations include those in morphological types of neurons, morphological specializations of the six layers that characterize cortex, types of modules that subdivide cortical areas into smaller functional units, proportions of cortical areas that are devoted to specific inputs, absolute size of areas, the size of areas relative to neocortex, intrinsic connections of areas, inputs and output targets of areas, number of areas, types and proportions of modulating inputs, the extent and distribution of interhemispheric connections, and so on. The great variability of these features suggests why neocortex has held center stage in studies of brain evolution in mammals. Neocortex varies in so many ways, allowing so many different adaptations to the environment.

3.03.7.2 Shared Features of Neocortex Organization Across Species Suggest Why Neocortex Is So Modifiable and So Important

The fundamental unit of computation is the vertical array or column of 100–200 neurons that are tightly interconnected, and driven by only a few specific inputs, while modulated and influenced by many other inputs. The grouping of neurons by functional role into layers, modules, and areas simplifies the process of modulating neuron responses by the responses of the most relevant other neurons via direct and indirect connections, as these neurons are nearby. The computations within each column transform the inputs to one or more different types of output, which can be sent to other cortical columns so that the computation process can be repeated with the addition of other inputs. Multiple cortical areas allow cortex to function in serial steps that transform simple computations into complex outcomes, and produce parallel streams that allow information to be used in many different ways.

3.03.7.3 The Fossil Record Indicates that Early Mammals Had Small Brains with Little Neocortex

The olfactory bulb and olfactory (piriform) cortex were relatively large, indicating olfaction was an important source of information about the external world. The small amount of neocortex suggested it played a modest role in regulating behavior. Some mammals with small brains and little neocortex have persisted up to present times, indicating that behavioral niches remain for mammals with limited brainpower. Perhaps because early mammals may have had brains close to the lower limit in size for mammals, few subsequent lines of evolution lead to

smaller brains. Instead, the fossil record indicates that increases in brain size, especially that of neocortex, occurred independently many times over, while some mammals with small brains continued to survive.

3.03.7.4 The Probable Organization of the Neocortex of Early Mammals Can Be Reconstructed, Using an Analysis That Identifies Brain Characters That Are Broadly Distribution Across Mammalian Taxa as Those Likely to Have Been Retained from a Common Ancestor

In a process known as a cladistic analysis, the emergence of novel brain features can be assigned to more or less distinct branching points in a phylogenetic tree (cladogram) for any group of mammals descendant from a specific common ancestor (recent or distant) based on parsimony. As identifying brain characters can be labor intensive and depend on costly experimental procedures, the process of reconstructing the organization of the neocortex of early mammals can be simplified by initially focusing on mammals with brains that resemble those of early mammals in size and proportions. The brains of hedgehogs, shrews, and other insectivores, together with those of tenrecs and opossums are strong candidates, but the brains of other mammals, such as rats, have only slightly increased the proportional size of neocortex, and thus they provide additional comparisons of clear value. Conclusions based on this limited sample can then be validated as consistent or challenged as inconsistent with observations from mammals with more derived brains, in terms of neocortex size and shape, so that all the major branches of the mammalian radiation are considered.

3.03.7.5 Early Mammals Had Poorly Differentiated Neocortex and Few Areas

A comparative analysis indicates that the neocortex of the first mammals was rather poorly differentiated into layers and different neuron types, although six layers of different types of connections and functions were present, as well as pyramidal cells, stellate calls, and two or more types of local circuit inhibitory neurons. Neocortex was divided into ~20 cortical areas, a small number in comparison to the 50–150 proposed for some extant mammals. More specifically, early mammals had a primary somatosensory area and 3–4 other somatosensory fields, primary and secondary visual fields and perhaps two other visual areas, a primary and one or more additional auditory fields, as well as areas of limbic, orbitofrontal, and endorhinal cortex. Motor functions depended on somatosensory areas until the advent of placental mammals, which were characterized by a primary motor area and possibly a secondary motor area. Thus, the neocortex of early mammals was dominated by areas devoted to analyzing sensory information. In several subsequent lines of descent, more sensory areas were added, increasing the complexity of the analysis of sensory information, and motor areas were sometimes added, increasing the sophistication of behavioral responses. Additional multisensory areas sometimes emerged that allowed computational outcomes to be more easily influenced by several sources of information.

3.03.7.6 Theories of the Subsequent Evolution of Neocortex in Mammals Can Be Guided by a Theoretical Consideration of the Implications of Increasing Brain Size

Larger brains with larger expanses of neocortex would not function efficiently without structural modifications. As neurons do not scale up very well with increases of brain size, large brains have more neurons. This generally means that neurons in large brains have connections with a smaller proportion of the total number of neurons than neurons in small brains. Thus, large and small brains function differently. In addition, larger brains require longer connections and thus more time for transmission unless axons are increased in thickness. In part, these connection problems can be addressed in evolution by devoting proportionally more of the larger brain to connections, resulting in decreases in neuron cell body densities in cortex, and having at least some longer, thicker axons. Connection problems can partially be addressed by evolving brains that are more modularly organized, as they became larger with an emphasis on local processing via short axons. Thus, mammals with larger brains and expansive neocortex are expected to have more cortical areas, more areas divided into more modules, more connections overall, and some connections over thick, long axons, but relatively fewer of the longer interhemispheric and subcortical connections. The functions of areas also depend on their size. As areas become larger, their intrinsic horizontal connections may become longer, but not in pace with the expansion of the cortical surface. Thus, neurons become less influenced by the activities of the increasingly distant other neurons in the area. This means that large areas transmit information to other parts of the brain only about a small subset of inputs to the areas. They provide detailed, but focused information. Neurons in smaller areas are influenced by neurons that are more widely distributed across the area, and the computation of local circuits of such neurons provides a more global (but

less detailed) picture of what is going on. Global views of sensory inputs are obviously more useful for directing behavior, but details can be valuable. Thus, a few large areas, and many small to moderately sized areas, would seem to provide the most useful system.

3.04 Captured in the Net of Space and Time: Understanding Cortical Field Evolution

L Krubitzer and D L Hunt, University of California, Davis, CA, USA

Glossary

analogous	Having the same function.
Baldwin effect	The ability of an animal to respond optimally to a given environment.
cortical domain	The portion of cortex devoted to a given sensory system.
cortical field	The fundamental organizational feature of the cortex.
cortical field magnification	The amount of cortex within a cortical field devoted to processing inputs from a behaviorally relevant body part is enlarged.
evolvability	The ability of an organism to generate heritable, selectable phenotypic variation.
genetic assimilation	How an environmentally induced phenotypic characteristic becomes genetically coded in a population.
homologous	A characteristic inherited from a common ancestor.
homoplaseous	An independently evolved characteristic that looks the same across species.
module	Smaller units of organization within a defined cortical field.
pleiotropy	A single gene controls numerous activities during development resulting in various phenotypic effects in the adult organism.

3.04.1 Introduction

Examination of a number of different mammalian brains demonstrates that brain organization, particularly the neocortex, varies dramatically across species. This variation in neocortical organization is accompanied by a considerable degree of behavioral diversity. Specifically, differences in cortical sheet size, organization, number of cortical fields, and connections are associated with differences in sensory, perceptual, cognitive, and motor abilities. How these differences in neocortical organization in mammals arise in evolution and how these alterations generate variable behavioral repertoires are difficult questions to investigate directly because the evolutionary process is highly dynamic, and alterations to the brain occur over hundreds of thousands to millions of years. Despite the fact that evolution cannot be studied 'head on', we can circumvent the problems associated with studying evolution in two ways. First, we can examine the products of evolution, namely extant mammals, and compare their brain organization, to make inferences about the evolutionary process. Alternatively, we can study the developmental processes that generate different aspects of brain organization, since the evolution of the neocortex is the evolution of the developmental mechanisms that give rise to adult phenotypes. We can then postulate how developmental mechanisms may have been altered to produce different phenotypes (see The Origin of Neocortex: Lessons from Comparative Embryology).

The use of the comparative approach has led to number of important insights regarding brain evolution. Likewise, studies of development, particularly recent molecular studies, have provided much

in various aspects of cortical development and organization. However, utilizing the comparative or the developmental approach in isolation in an attempt to uncover principles of brain evolution is problematic. In terms of the comparative approach, examining any extant mammal allows us to observe only a static moment in the evolutionary process. In essence, we have captured, in our net of space and time, a number of individual phenotypes, or individual snapshots, in a process that is constantly in a state of flux. We take these snapshots out of our net, use a number of different tools to dissect and examine them, and then put them together to make an evolutionary moving picture. The problem is that each extant mammalian brain that we observe is a frozen frame or moment in its own moving picture; it has its own evolutionary history and will move in a unique future trajectory. Further, this approach tells us little about the transition between frames and how phenotypic transformations may occur. This is where studies of cortical development merge with comparative analyses.

Studies of the development of the nervous system can strengthen our inferences regarding how phenotypic transitions occur by providing a number of possible mechanisms for this process. However, like the use of the comparative approach, using a developmental approach in isolation to understand brain evolution is problematic. While a number of recent studies provide insight into potential mechanisms that could be involved in some aspect of cortical organization, such as regulating cortical sheet size, they do not demonstrate that such a mechanism is actually being employed in a naturally evolving system (see The Evolution of Neuron Types and Cortical Histology in Apes and Humans). Thus, only by combining both the comparative approach and developmental approach can we appreciate the types of changes that have occurred in different lineages, predict how these transitions may have happened, and validate these predictions by manipulating some aspect of development and determining if the resulting phenotype is consistent with a type of neocortical organization that would naturally occur, as validated through comparative studies.

In this article, we begin by exploring what constitutes a cortical field and discuss homologous features of cortical organization across mammals. Next, we discuss the importance of distinguishing homology from instances of homoplasy when making comparisons across species. Because the concepts regarding what constitutes a cortical field are changing in light of new studies on molecular development, in the second section of this article we discuss some of the molecular aspects of cortical field development, and describe both intrinsic and extrinsic contributions to cortical development, and the role of peripheral morphology and behavior in shaping the cortical field throughout the life of an individual. Then, we discuss the evolution of the neocortex and outline the types of systems level modifications that have been made to evolving brains. Finally, we speculate on the idea that the neocortex evolves to be flexible, and that genetically based adaptations of the brain and body may initially have been activity-dependent features of organization that were present only under unique and consistent environmental conditions.

3.04.2 What is a Cortical Field? Homology, Homoplasy, and Analogy

A cortical field is considered to be the principal organizational feature of the cortex, and most neuroscientists would contend that the addition of cortical fields to the neocortex is what endows greater degrees of neural and behavioral complexity to mammals. Indeed, most would agree that the neocortex, in general, and cortical fields, in particular, are the essence of the mammalian brain; the feature that distinguishes mammals from other vertebrates. We raise the question of what is a cortical field because this issue is particularly important for the study of cortical evolution. If one is interested in the evolution of the neocortex and the addition of cortical fields, then defining homologous cortical fields across mammals is critical. Specifically, it is important to determine which features of the cortical field are most usefully compared across species, and ultimately to appreciate how these features change during evolution.

Although concepts regarding what constitutes a cortical field are changing in light of new studies on the molecular development of the neocortex, in adult mammals, a cortical field is determined by a number of well-defined anatomical, histochemical, and electrophysiological criteria. These criteria were previously outlined by Kaas (1982), and although not exhaustive, have enabled investigators to subdivide the neocortex in a variety of mammals with a high degree of success. Some of these criteria include a complete representation of the contralateral sensory surface (or visual field for visual cortical areas), a unique architectonic appearance, and a distinctive pattern of connectivity. Other criteria include utilization of some subset of neurotransmitters, or the presence of particular behavioral deficits when the area is lesioned. Because errors can be made in subdividing the neocortex when any single criteria is used in isolation, using a combination of criteria to subdivide the

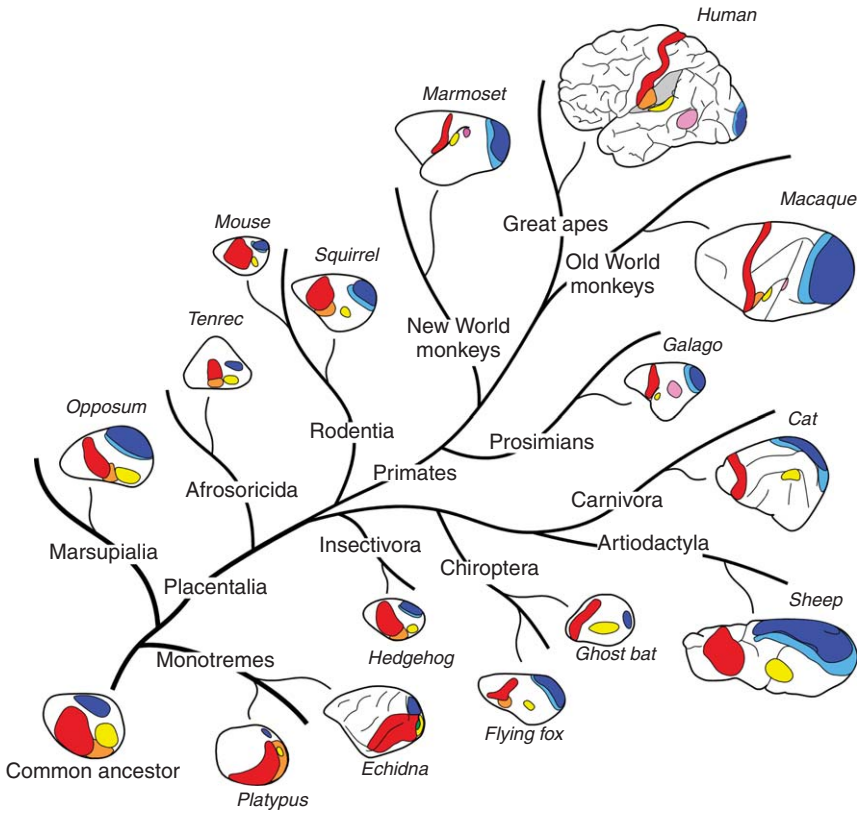

Figure 1 A phylogenetic tree depicting the relationships between major mammalian lineages. The cortex of each mammal contains a constellation of cortical fields that have been identified in all mammals examined. These cortical areas were likely inherited from a common ancestor, and therefore are homologous. Although the organization of the neocortex of the common ancestor is not known, a cladistic analysis allows one to infer the organization of unknown forms, such as the common ancestor. Dark blue = primary visual area; light blue = second visual area; red = primary somatosensory area; orange = second somatosensory area; yellow = primary auditory area; pink = middle temporal visual area. Redrawn from Krubitzer, L. and Kahn, D. 2003. Nature vs. nurture: An old idea with a new twist. *Prog. Neurobiol.* 70, 33–52.

neocortex allows for more accurate comparisons of cortical organization across mammals.

Using these criteria, it has been determined that in some mammals, such as mice, the number of areas that compose the neocortex is relatively small, on the order of 7–12 cortical fields. In other mammals, such as macaque monkeys, the number of cortical fields is larger, on the order of 30–50 cortical areas (see Kaas, 1988, 1993, for review). This increase in the number of cortical fields in some lineages, at least in part, is the neural basis of complex behaviors such as sophisticated communication (language in humans), learning, and cognition. While the number of cortical fields is highly variable in mammals, several cortical fields are common to all species (see Krubitzer, 1995; Krubitzer and Kahn, 2003; Krubitzer and Kaas, 2005). These fields include the primary sensory areas (primary visual area, V1; primary somatosensory area, S1; and primary auditory area, A1), second sensory areas (secondary visual area, V2; secondary somatosensory area, S2; secondary auditory area, A2, and rostral auditory area, R), as well as motor areas such as primary motor area, M1 (Figure 1). These fields are homologous because they have been identified in all mammals examined, and it is likely that these cortical areas arose early in mammalian evolution and were inherited from a common ancestor in all lineages, rather than having evolved independently in each group. As such, a number of features of organization are similar across groups of mammals including similarities in topographic organization, aspects of cortical architecture, and thalamocortical and corticocortical connections. Later in this article we will discuss the types of modifications made to this homologous plan of organization and how these modifications might have arisen in evolution.

A broad comparative analysis also indicates that some features of cortical organization look strikingly similar in different mammals, but this similarity is not due to inheritance from a common ancestor. Rather, these features are homoplaseous, and have independently evolved in each mammal.

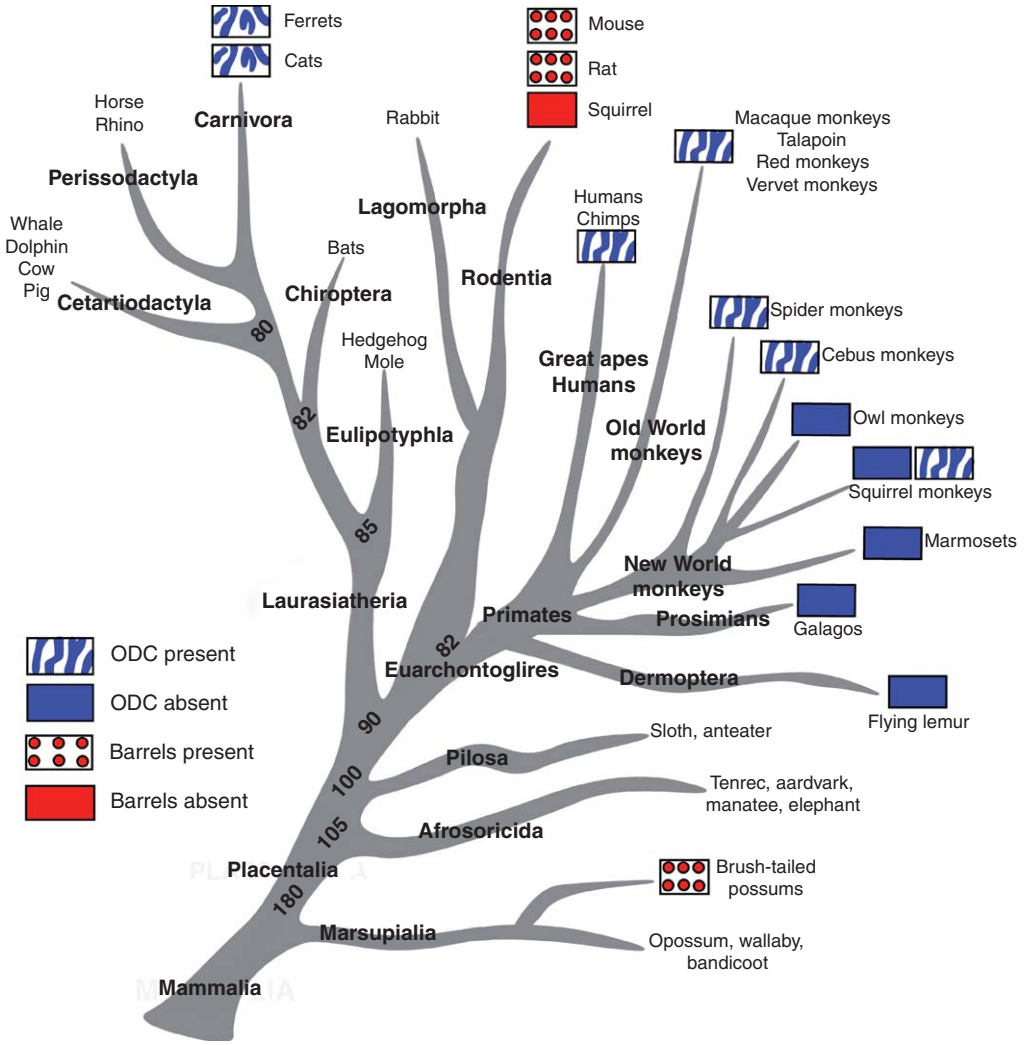

Figure 2 Homoplasy-independent evolution: a phylogenetic tree depicting the relationships between major mammalian lineages and the emergence of independently evolved features of cortical organization. Because the emergence of barrels in mice and rats arose independently from those in brush-tailed possums, they are considered as homoplaseous rather than homologous. Likewise, the presence of ODCs in ferrets and cats arose independently from those in some primate lineages. The fact that such similarities in organization emerge in different lineages despite over 90 million years of independent evolution indicates that the evolution of the neocortex is highly constrained. It also indicates that although the features themselves are homoplaseous, their presence could reflect the presence of homologous developmental mechanisms. Phylogenetic relationships based on Murphy, W. J., Pevzner, P. A., and O'Brien, S. J. 2005. Mammalian phylogenetics comes of age. *Trends Genet.* 20, 631–639.

An excellent example of a homoplaseous feature of the neocortex is the barrel field in the rat and mouse, and the brush-tailed possum (Figure 2; Weller and Haight, 1973; Weller, 1993). An out group comparison indicates that no intervening group of mammals has barrel cortex. Thus, the most parsimonious explanation for their presence in each group is that they have evolved independently in rodents and brush-tailed possums. Another example of homoplasy is the presence of ocular dominance columns (ODCs) in carnivores and some primates. ODCs are present in great apes and humans (Tigges and Tigges, 1979; Horton and Hedley-Whyte, 1984), Old World monkeys (e.g., LeVay *et al.*, 1975; Florence and Kaas, 1992), and a few species of New World monkeys (e.g., Florence *et al.*, 1986; Rosa *et al.*, 1992). They are absent in other New World monkeys, prosimians, and dermopotera (Figure 2), and in all other clades except carnivores (e.g., Löwel and Singer, 1987; Law *et al.*, 1988). This out-group comparison indicates that ODCs arose in primates after the divergence of New and Old World monkeys from prosimians (approximately 70 Mya), and that ODCs were lost in some New World species. The presence of ODCs in only two species of carnivores suggests that ODCs arose

independently in carnivores and primates, since the lineage that leads to carnivores diverged from that leading to primates over 90 Mya, and no intervening groups possess ODCs. What is remarkable about ODCs and the barrel cortex is that despite 90–180 million years of independent evolution, the arrangement of these modules looks very similar in carnivores and primates, and in rodents and brush-tailed possum respectively.

When making cross-species comparisons, there is often an assumption that homologous fields perform the same function or are analogous. However, this may not be the case. For example, over the years, a solid case for the presence of V1 in a variety of species has been established. All data indicate that V1 resides on the caudal pole of occipital cortex, contains a complete, first-order representation of the visual hemifield, receives connections from the dorsal division of the lateral geniculate nucleus (LGNd) of the thalamus, and has a striated appearance in tissue that has been sectioned perpendicular to the cortical layers and stained for Nissl substance. In cortex that has been sectioned tangentially and stained for myelin, V1 appears as a densely myelinated wedge at the caudal pole of the neocortex. Given these identifying features, V1 is proposed to be homologous across all mammals, and to form a basic component of a visual processing network in the mammalian neocortex. But what of analogy? Does it naturally follow that V1 as a homologous cortical area has a similar function or set of functions across groups of mammals?

The answer is 'no'. If we examine V1 in the mouse and compare it to V1 in the macaque monkey, several differences emerge. Most notable are the addition of modules to V1, such as orientation and ODCs, the addition of visual cortical fields, and the concomitant change in cortical connections in monkeys. Thus, V1 in monkeys and mice varies substantially in organization, and intrinsic and extrinsic connectivity. To illustrate this concept we have drawn a simple circuit containing three separate nodes (cortical fields A, B, and C in Figure 3). These nodes have a homologous pattern of interconnection across mammals (connections 1, 2, and 3 in Figure 3). In some groups of mammals, the nodes have been further subdivided to mimic the generation of modules (Figure 3). In addition, new nodes, representing new cortical areas, have been added to the network (D, Figure 3), which result in the addition of new connections and a potential re-weighting of existing connections between homologous nodes. This example shows that because of the emergence of new organizational features

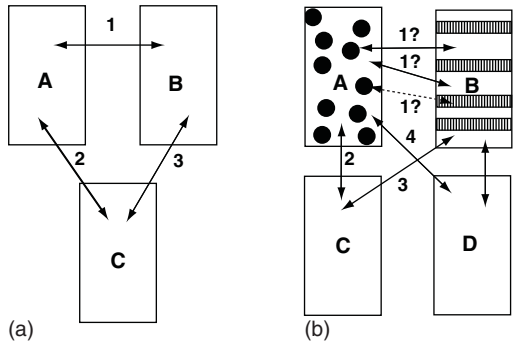

Figure 3 A hypothetical processing network (a) originally consisting of three cortical fields (A, B, and C) with a set of interconnections (1, 2, and 3). The evolution of this network (b) includes the addition of a new cortical field (D), the emergence of modules within existing cortical fields (circles in A and stripes in B), the emergence of new connections (4), and the re-weighting of existing connections (compare thick vs. thin line of connection 2 in (a) and (b)). These types of changes that naturally occur in evolution, indicate that homologous cortical fields may not be analogous since the interconnection relationships change and intrinsic processing modules emerge.

(modules), new inputs, and a re-weighting of retained connections, homologous cortical fields may not have the same function.

In answer to the question posed at the beginning of this section 'what is a cortical field?', we believe that it may be fruitful to consider cortical fields, at least in part, as homologous patterns of interconnection upon the cortical sheet. These patterns appear to be quite robust across species, and are associated with the emergence of specific architecture and neural properties in the developing nervous system. While maintaining their global relationships, these patterns shift, or 'float' upon the cortical sheet within the life of an individual (particularly during development), and to a greater extent, within and across species over time.

3.04.3 The Development of Cortical Fields

It has been appreciated for some time that both genes and the environment, as broadly defined, contribute to the development and the organization of the neocortex. How each of these factors contributes to development is couched in the long-standing 'nature vs. nurture' debate (see Krubitzer and Kahn, 2003 for review). Fortunately, the issue of the inherent, genetic contribution to the cortical phenotype has recently crystallized into hypotheses which are amenable to vigorous experimentation regarding the temporal and spatial distribution of genes and proteins that occur in development, and give rise to aspects of cortical organization including

cortical field location, size, and connectivity. The 'nurture' side of the debate has also become more experimentally tractable, and questions regarding the activity-dependent cellular mechanisms that alter aspects of development including the expression of genes, regulation of synaptic morphology and function, and dendritic and axon growth are now being examined. The problem is that in some instances it is difficult to draw a distinct line between genetic and epigenetic contributions to the phenotype, and the two become intricately intertwined.

3.04.3.1 Nature: The Contribution of Genes to Cortical Field Development

Understanding how genes control cortical field development can be broken into three broad categories. First, there are several genes that are intrinsic to the neocortex which control specific aspects of cortical development. The expression of these genes occurs in the normal developing system, and their action is independent of neural activity. Second, the expression of some genes in the central nervous system is induced by activity and requires feedback from the developing system to become activated. Finally, there are genes that regulate aspects of the body plan and peripheral morphology that contribute substantially to aspects of cortical organization.

3.04.3.1.1 Activity-independent genes intrinsic to the neocortex Recent work indicates that genes intrinsic to the neocortex, or the developing ventricular zone, control a number of aspects of cortical development, all of which have a large impact on the organization and function of the neocortex in the adult phenotype. Some examples include the regulation of the size of the cortical sheet, cortical field coordinates in the rostrocaudal and mediolateral axis, and thalamocortical connectivity.

In terms of the overall size of the cortical sheet, studies on cell cycle kinetics of neocortical progenitor cells in the ventricular zone indicate that the size of the cortical sheet is intrinsically regulated and that there are a number of plausible ways in which this regulation can occur. In general terms, the number of cells in the developing ventricular zone can be increased by extending the length of time that cells undergo symmetric divisions, and/or the rate at which cell divisions occur. A comparative analysis of small-brained mammals, such as mice, and large-brained mammals, such as macaque monkeys, indicates that cortical neurogenesis is both prolonged and accelerated in macaque monkeys compared to mice (Kornack and Rakic, 1998; Kornack, 2000). Several hypotheses regarding the specific genes and proteins involved in this process and the types of alterations to the kinetics of division have recently been proposed. For example, 'beta-catenin' is an intracellular protein that is expressed in neuroepithelial precursor cells during neurogenesis (Chenn and Walsh, 2002). In transgenic mice that over express a form of this protein, the size of the neocortex increases dramatically. This massive increase in the size of the cortical sheet is due to an increase in the proportion of progenitor cells that re-enter the cell cycle and continue mitotic division. Another gene proposed to alter cell cycle kinetics is *Brain Factor-1* (*BF-1* or *Foxg1*). This gene is expressed in telencephalic progenitor cells (Tao and Lai, 1992), and regulates cell proliferation and differentiation in the developing neocortex (Hanashima *et al*., 2002). *BF-1* is regulated by *FGF2*, which is also involved in regulating cortical sheet size by determining the number of cycles of division that progenitor cells undergo during cortical neurogenesis. For example, injections of FGF2 into the ventricle of embryonic rats results in a substantial increase in cortical volume (Vaccarino *et al*., 1999), and FGF2 knockouts have smaller neocorticies (Raballo *et al*., 2000). These studies indicate that the disproportionate size of the neocortex in different lineages could be regulated in several ways by different genes that affect the kinetics and timing of cell division in the ventricular zone.

Related studies of cell cycle kinetics in monkeys indicate that primary areas, such as V1, may be specified very early in development, during neurogenesis. For example, in primates, V1 is characterized by an increase in cell density and laminar complexity compared to other cortical areas, and compared to other mammals. In development, the rate of production cells in the ventricular zone is higher in the region where V1 will ultimately reside than in other regions (DeHay *et al*., 1993). Differences in laminar histogenesis for different regions of the ventricular zone have also been observed in mice (Polleux *et al*., 1997). These studies indicate that areal differences arise very early in neocortical development, well before thalamic innervation of the neocortex occurs.

In addition to intrinsic mechanisms that operate during cortical neurogenesis to specify cortical fields, recent work indicates that somewhat later in cortical development, the transcription factors *Emx2* and *Pax6* are involved in the expression and

patterning of downstream genes in the rostrocaudal axis of the neocortex, and potentially even cortical field size. For example, experiments in which these genes are deleted result in shifts of downstream genes such as *Cad8* and *Cad6* either rostrally (for *Emx2* deletion) or caudally (for *Pax6* deletion; Bishop *et al*., 2000). In addition to the observed changes in gene expression, *Emx2* and *Pax6* mutants also exhibit alterations in thalamocortical connectivity. In experiments in which *Emx2* is deleted and the neocortex is rostralized (e.g., rostral cortical fields are shifted caudally), cortex at the caudal pole that would normally receive thalamic input from the LGN receives inputs from the ventral posterior nucleus (VP) (which normally projects to somatosensory cortex rostral to this region; Bishop *et al*., 2000). Furthermore, mice in which *Emx2* is overexpressed have a significantly larger V1 than in normal animals (i.e., cortex has been caudalized; Hamasaki *et al*., 2004).

In terms of connectivity, some of the cadherins appear to regulate thalamocortical connectivity. For example, *Cad6*, *8*, and *11* are expressed in unique subsets of thalamic afferents (Suzuki *et al*., 1997; Korematsu and Redies, 1997). Further, *Cad6* is colocalized with the synaptic marker, synaptotagmin, and is correlated with the formation of synaptic connectivity between a source and its target in the developing nervous system (Inoue *et al*., 1998). The ephrins have also been proposed to play a role in thalamocortical development. While their presence in locations extrinsic to the neocortex, such as the ventral telencephalon, serves a role in gross topographic guidance, they appear to intrinsically mediate the refinement of thalamocortical connectivity within a cortical field (see Vanderhaeghen and Polleux, 2004 for review). For the development of cortical connections, recent work has demonstrated that FGF2, which may be regulated by *Emx2*, is involved in guiding (modulating) corticocortical connections (Huffman *et al*., 2004). Thus, the transcription factor *Emx2* controls a genetic cascade involved in structure formation, location, and connections.

It is important to note that evolutionarily, this type of regulation of events imposes formidable constraints on the developing and evolving nervous system. Given the constraints imposed by such a contingent system, it seems inevitable that very small changes in the timing and spatial distribution via base substitutions, recombination, and transposition, for example, of any one of the genes involved in these aspects of cortical field development can have a very large effect on the phenotype.

As mentioned earlier, a recent perspective on how cortical fields should be defined is to consider the subdivisions or areas of the neocortex from a spatiotemporal perspective. In this view, cortex is examined over time as a series of coordinated patterns of gene expression which are thought to be involved in generating features of the neocortex that will ultimately be realized in the adult, such as cortical layering, architecture, transmitter utilization, and connectivity. While this perspective is certainly important from both a developmental and evolutionary perspective, it may not be appropriate to define a cortical field in terms of the patterns of gene expression exhibited early in development for two reasons. First, the direct relationship between a functionally defined cortical field and some pattern or patterns of gene expression has yet to be established. Second, in the neocortex, early patterns of gene expression often represent potential, while the adult form directly generates the behavior that is the target of selection.

3.04.3.1.2 Activity-dependent regulation of genes that control aspects of cellular morphology, connection, and function In addition to the genes we described above, a number of studies describe intracellular, molecular mechanisms that are driven and regulated by neural activity, and generate changes in the temporal expression of genes within a cell employing these mechanisms. Altering the expression of genes can change aspects of synaptic morphology. For example, recent work demonstrates that increases in intracellular calcium, due to changes in neuronal activity, trigger a cascade of events, including the activation of the cAMP pathway and phosphorelation of CREB, which binds to the regulatory region of a gene and induces transcription of genes (see Finkbeiner and Greenberg, 1998; West *et al*., 2001 for review). There are several different types of molecules which are regulated by activity, and which in turn are involved in synaptic modeling during development. One of these is a class of proteins called neurotrophins. These proteins are relevant to the discussion above because their levels and secretion are regulated by activity, they are expressed in synapses, and they regulate morphological changes in both the pre- and postsynaptic elements (McAllister *et al*., 1995, 1999; Lein *et al*., 2000; McAllister, 2001 for review). Neurotrophins such as brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and neurotrophic factor 4/5 (NT4/5) play a number of important roles in nervous system development

including mediation of rates of neuronal survival (see Levi-Montalcini, 1987; Miller and Kaplan, 2001 for review), induction of cell migration out of the ventricular zone (Borghesani *et al*., 2002), regulation of the extent of axon outgrowth (Segal *et al*., 1995), enhancement of dendritic outgrowth, and stimulation of protein synthesis in dendrites (Aakalu *et al*., 2001).

Another group of molecules recently identified by Shatz and colleagues (Corriveau *et al*., 1998; Huh *et al*., 2000) are the class I major histocompatibility complex (class I MHC) antigens. The expression of class I MHC is reduced in the developing cat LGN with the application of tetrototoxin (TTX) via intraocular injections given *in utero* (Corriveau *et al*., 1998). TTX blocks neural activity by deactivating sodium channels. In cats that are monocularly deprived during the critical period, class I MHC expression is reduced in the eye-specific layers of the LGN that were deprived. Further, in mice lacking class I MHC, refinement of retinogeniculate connections is incomplete (Huh *et al*., 2000). Thus, as in the above example for BDNF, activity controls the expression of these molecules, which in turn alters aspects of synaptic development.

While the above descriptions are brief and the intracellular processes that are modified by activity are not completely known, there are a number of potential intracellular mechanisms and molecules involved in nervous system construction whose action is modulated by activity. In the beginning of this section on development, we suggested that the boundary between genetic and activity-dependent contributions is somewhat blurred. This is the case for the scenario described above in which activity regulates gene expression, which in turn regulates aspects of nervous system construction and function. This type of activity-dependent regulation depends on calcium sensitive intracellular mechanisms that may be genetically determined and intrinsic to the composition of the cell. If this is the case, then the ability of the developing organism to respond to environmental fluctuations may be genetically specified and selected for in evolution, but the resulting phenotype would only be expressed in a particular environment (Krubitzer and Kahn, 2003; Krubitzer and Kaas, 2005). If the environment is stable, the specific phenotypic characteristic generated would be stable, and in essence would masquerade as an evolutionary (heritable) phenomenon.

3.04.3.1.3 Genes extrinsic to the neocortex but intrinsic to the organism contribute to aspects of cortical development and organization All mammals have a conserved body plan that includes forelimbs with distal appendages, hind limbs with distal appendages, a trunk, neck, head, face, snout, two eyes, two ears, one nose, and one mouth. Interestingly, this basic plan has been conserved in all vertebrates, due to genetic constraints, and like the neocortex, has been modified in a very limited fashion. Homeodomain genes, such as T-box genes and Hox genes, are involved in specification of the body plan; they arose early in the evolution of living organisms, and are highly conserved across taxa from arthropods to vertebrates (e.g., Patel, 2003; Boncinelli *et al*., 1994; Schilling and Knight, 2001; Banerjee-Basu and Baxevanis, 2001; Showell *et al*., 2004).

Despite the restrictions these genes place on the evolving body, morphological diversity of the limbs, head, and face abound. For example, limbs have been modified into wings (bats), flippers (dolphins), hoofs (ungulates), claws (cats), and hands (primates). For the head and face, alterations have been made to the location of the eyes on the head, the size, location, and mobility of the pinna, and the presence of vibrissae, follicles on a nose, or specialized oral structures. At a finer level of organization, the receptor arrays associated with a specialized morphology and behavior also undergoes modifications. However, like those of the body and brain, they are generally limited in number and include:

1. alterations in the location of receptors,
2. alterations in the density of receptors,
3. alterations in the number of receptors,
4. addition of new receptors, and
5. sensitivity of receptors.

Specific examples of some of these modifications would include the disproportionate amount and density of cutaneous receptors on the glabrous digit tips of the hands of primates, the concentration of cones at the fovea of primates and visual streak in rabbits (Hughes, 1977), the differential expansion of particular portions of the basilar membrane devoted to ultrasonic frequencies in echolocating bats (Ramprashad *et al*., 1979), and the addition of electrosensory receptors in the bill of a platypus (Scheich *et al*., 1986; Manger and Pettigrew, 1996), to name a few.

Not only does the actual structure of the body part contribute to features of cortical organization, but also how these body parts are utilized and modified for exploration is equally important. For example, for the somatosensory system, primates tactually explore objects with their glabrous hands, elephants with their distal trunk, muriad rodents with their vibrissae, the star nosed mole with the

many follicles of the nose, and the naked mole rat with their teeth (see Catania, 2005). Thus, body parts and associated receptor arrays that are used repeatedly and uniquely have large amounts of cortical space devoted to their representation in both sensory and motor cortex. Indeed, without exception, behaviorally relevant, specialized sensory receptor surfaces occupy a greater amount of cortical space than less relevant surfaces. This is observed at the sensory systems level in cortical domain allocation, and at the level of the individual cortical field (cortical magnification). A cortical domain is the amount of space allotted to a particular sensory system, and this differs for different mammals, even those with approximately the same size cortical sheet. For example the amount of cortical territory devoted to processing visual inputs is greater in the highly visual squirrel than in the mouse (Figure 4; Rosa and Krubitzer 1999). In terms of cortical field magnification, the amount of cortex devoted to processing inputs from the fovea is greatly enlarged in V1 of primates compared to the amount of cortex devoted to processing inputs from the rest of the eye. For the somatosensory cortex, in S1 and other

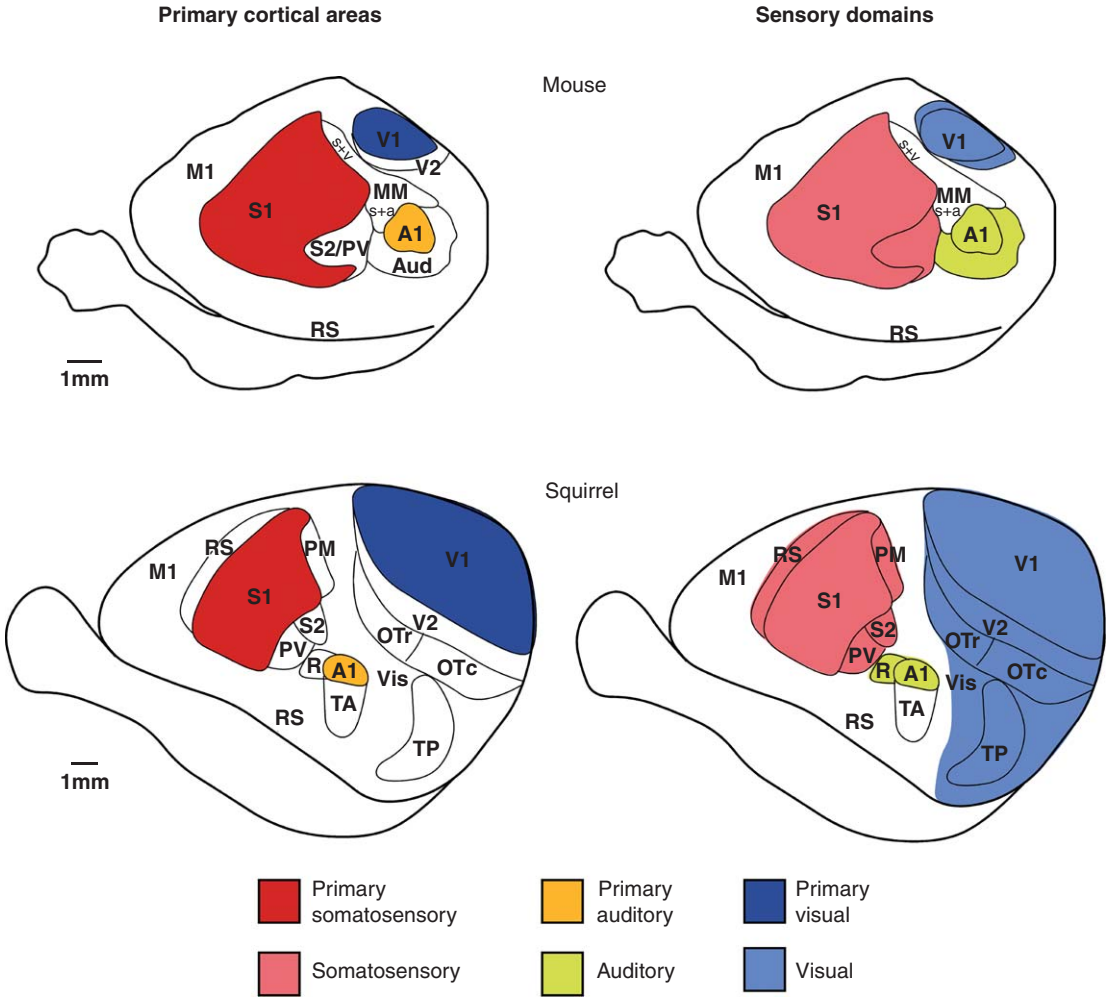

Figure 4 The organization of primary cortical areas and sensory domain allocation in the mouse (top) and squirrel (bottom). Each of these rodents occupies a particular niche and relies on different sensory systems for survival. The mouse is a terrestrial rodent that explores and navigates with its vibrissae, while the squirrel is an arboreal rodent that relies heavily on vision. Differences in cortical organization are observed at both the level of the cortical field and cortical domain. In the mouse, the primary somatosensory area is relatively large and occupies a good deal of cortex, while in the squirrel the primary visual area is relatively large compared to other primary sensory fields. Sensory domains, or the amount of cortex devoted to processing inputs from a particular sensory system, are also distributed differently in each species. In mice, the somatosensory domain is relatively large, while in the squirrel, the visual domain is extremely large and occupies at least one third of the entire cortical sheet. a, auditory; A1, primary auditory area; Aud, auditory; M1, primary motor area; MM, multimodal; OTc, caudal occipital-temporal cortex; OTr, rostral occipital-temporal cortex; PM, parietal medial area; PV, parietal ventral area; RS, rhinal sulcus; s, somatosensory; S1, primary somatosensory area; S2, secondary somatosensory area; v, visual; V1, primary visual area; V2, secondary visual area; Vis, visual.

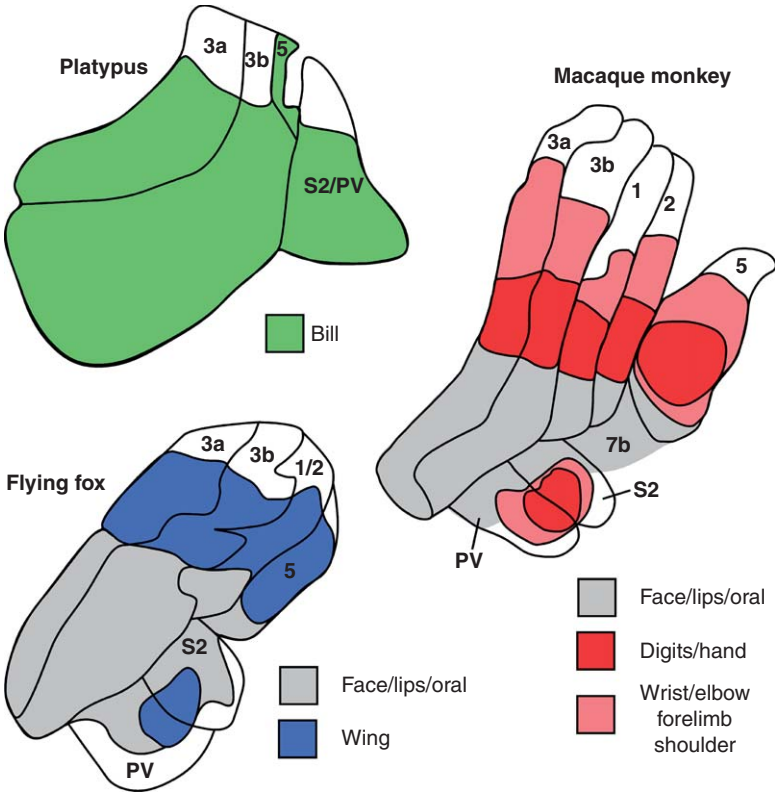

Figure 5 Cortical magnification of behaviorally relevant body parts within the somatosensory cortex of different mammals. In the duck-billed platypus, the bill representation (green) dominates all three somatosensory fields identified (R or area 3a, 3b, or S1, and S2/PV). In the highly dexterous macaque monkey, the representation of the glabrous digits (dark red), forelimb (light red), and oral structures (gray) dominate all somatosensory fields identified. In some fields, such as area 5, the magnification of the hand and forelimb dominates almost the entire field. Finally, in the flying fox, the wing (blue) and oral structures (gray) dominate all somatosensory areas identified.

cortical fields, the hand and mouth representations are magnified in primates, the wing and mouth representations are magnified in the flying fox, and the bill representation is magnified in the platypus (Figure 5; see Krubitzer and Disbrow, 2005 for review). As noted earlier, these specialized receptor surfaces are interfaced with the stimulus to be explored via specialized motor sequences. Thus, the motor system and the behaviors that allow for this interface are an integral part of sensory reception and cortical organization.

Since there is clearly an important relationship between cortical organization, peripheral morphology, and use, it is important to understand how body morphology evolves and how variability in body morphology is achieved in different lineages. Interestingly, the questions regarding diversification of the body plan in mammals are the same as those that arise when considering diversity in neocortical organization. Given the rather large constraints imposed on a basic plan of organization by these homeodomain genes, how can morphological diversity arise? It has been suggested that while the protein coding sequence of these homeodomain genes is relatively static across lineages, divergence in the regulatory portion of the gene can account for much of the morphological diversity observed in mammal body plans (Cretekos *et al.*, 2001). Thus, slight differences in the temporal and spatial patterning of genes generates large modifications in body plan organization. For example, the expression of a gene involved in the specification of the body plan (Hoxd9–13) was compared in two mammals with strikingly different forelimb morphology, the short-tailed fruit bat and the mouse (Figure 6; Chen *et al.*, 2005). Comparison of the distribution of Hoxd9–13 in bats and mice revealed that there were significant differences in the expression of this gene in the distal forelimb (dfl), but not the hindlimb, in later stages of limb development. Specifically, the anterior expression boundary of Hoxd9–13 in the bat is shifted posteriorly in the mouse (Figure 6). Thus, phenotypic diversity, or the transition from one phenotype to another that occurs in evolution, could be accomplished by subtle shifts in the expression of genes involved in

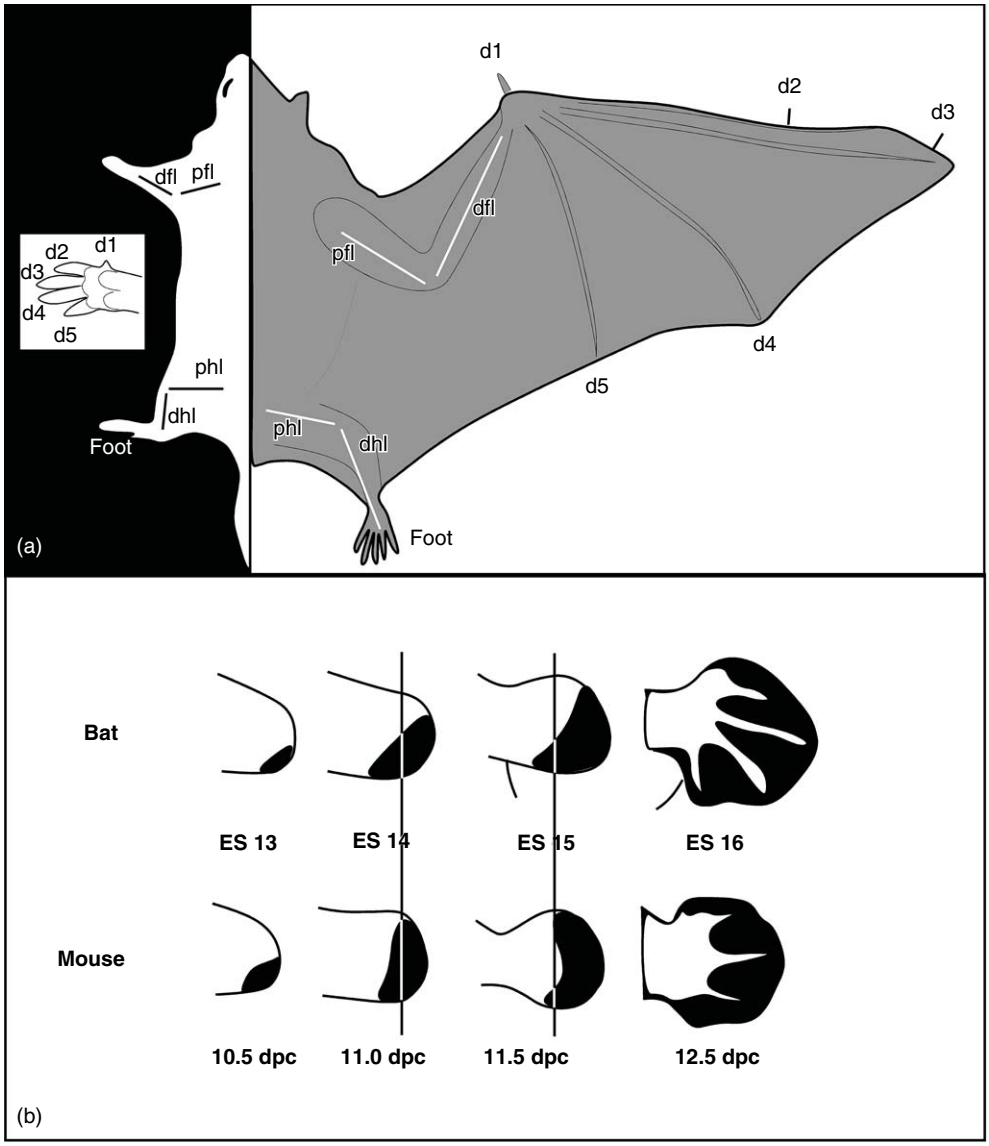

Figure 6 a, The body plan in mice and bats has a similar structural organization. Major body axis such as proximal and distal forelimbs and hind limbs (pfl, dfl, phl, and dhl), as well as individual digits (d1–d5), can be identified in both animals. However, modifications have evolved in each lineage in the form of the forepaw of a mouse and the wing of a bat. b, The expression pattern of Hoxd13 in the developing forelimb of the bat and mouse. The extent of the expression differences in bats and mice is evident during particular phases of limb development (bat ES 14, ES 15; mouse dpc 11, dpc 11.5), and such differences in homeodomain gene expression patterns could, at least in part, account for variations in forelimb morphology observed in each species. Such differences in expression are not noted for the hindlimb. dfl, distal forelimb; dhl, distal hindlimb; dpc, days post coitus; ES, embryonic stage; pfl, proximal forelimb; phl, proximal hindlimb. a, Modified from Cretekos, C. J., Rasweiler, J. J., and Behringer, R. R. 2001. major aspects of body and brain development. It should be noted that alterations in the temporal and spatial dynamics of gene expression have been known to account for variation of body segmentation in insects for some time (see Davis and Patel, 2002). It is only relatively recently that these well-established ideas from work on insects have been used to understand the evolution of the mammalian nervous system.

The case of body plan organization is another example where the boundary between intrinsic genetic contributions to the phenotype and activity dependent or environmental contributions are often difficult to draw. As Figures 4 and 5 illustrate,

specialized body morphology and use affect cortical domain allocation and sensory field magnification. The genes, which are involved in setting up the body plan organization, do not exclusively determine the final morphology of a particular body part, nor the resultant cortical organization. Indeed, several extrinsic factors related to the development of a body part contribute to the organization of the neocortex. For example, use directly affects the skeletal morphology, which in turn affects cortical organization. Several studies have shown that alterations in mastication behavior in development, often brought about by changes in diet, have a direct effect on craniofacial morphology (He, 2004), skull dimensions (Katsaros *et al*., 2002), mandibular morphology (Bresin, 2001), and bone density (Davies *et al*., 2005). The types of diet that produce such alterations during development are associated with hard versus soft food sources and the presence or absence of particular nutrients. Other extrinsic factors, which directly contribute to the development of body morphology and indirectly to cortical organization, are factors such as temperature, humidity, salinity, diet (see Johnston and Gottlieb, 1990 for review) and even gravity (e.g., Singh *et al*., 2005). The observation that body plan morphology can be altered by epigenetic factors is analogous to the observations made for the neocortex. That is, despite the very large constraints imposed by regulatory genes on fundamental aspects of body morphology or cortical organization, a large degree of phenotypic variability is still possible, and alterations to the body plan can indirectly alter cortical organization.

3.04.3.2 Nurture: How Activity Contributes to the System Level Aspects of Cortical Development and Organization

The relationship between the cortical domain, cortical field magnification, peripheral morphology, and use in the adult mammalian neocortex has important implications for developmental and adult plasticity, and evolution. In terms of development, it seems clear that peripheral morphology, sensory receptor organization, and the specialized motor programs that are part of efficient sensory reception, play a very large role in determining a number of aspects of cortical organization that are observed in adult mammals. Several series of recent experiments in our laboratory in which peripheral sensory receptor arrays have been physically excised or activity has been modified throughout development underscore this point. For example, in a recent study *Monodelphis domestica* were bilaterally enucleated well before the retinal ganglion cells reached the diencephalon and before the thalamocortical afferents reached the neocortex (Kahn and Krubitzer, 2002). Using electrophysiological, anatomical, and architectonic analyses in these animals after they reached adulthood, we found large shifts in sensory domain allocation, in that all of cortex that would normally be occupied by the visual system was occupied by the auditory and somatosensory system (Figures 7a and 7b). Interestingly, architectonically defined area 17 was still present, although reduced in size, and major thalamic projections from the LGN were preserved. However, there were also alterations in thalamic projections in that area 17 or 'V1' received additional input from the VP nucleus, the medial geniculate (MG) nucleus, and nuclei in the anterior group (Kahn *et al*., 2006). Further, corticocortical connections were altered in that area 17 received inputs from S1, A1, and frontal cortex. These patterns of thalamocortical and corticocortical connections are not observed in normal *Monodelphis* (Kahn *et al*., 2000).

Related experiments in congenitally deaf mice revealed much the same results (Hunt *et al*., 2005, 2006). These experiments were somewhat more subtle in that the sensory receptor array was not removed, but the ability to transduce auditory stimuli was eliminated in these animals throughout development. As with the blinded animals, congenitally deaf mice had large alterations in sensory domain allocation and alterations in cortical and thalamocortical connections (Figures 7c and 7d). All of cortex that would normally process auditory inputs contained neurons responsive to visual and somatic stimulation (Hunt *et al*. 2006). A surprising observation was that this lack of sensory driven activity resulted in alterations in connectivity at very early stages of sensory processing. In addition to its normal targets, the retina also projected to the MG nucleus and middle layers of the superior colliculus, structures generally associated with auditory processing (Hunt *et al*., 2005).

In adult mammals, plasticity within cortical fields has been observed, but the magnitude of the reorganization is much less pronounced than that observed in developing animals. The studies that examined the relationship between sensory experience and cortical map reorganization detailed the precise conditions under which plasticity will occur and described the map changes that were generated under those conditions. For example, studies in which monkeys were trained on digit discrimination tasks demonstrated a direct relationship between increased discrimination performance and an increase in the cortical space in

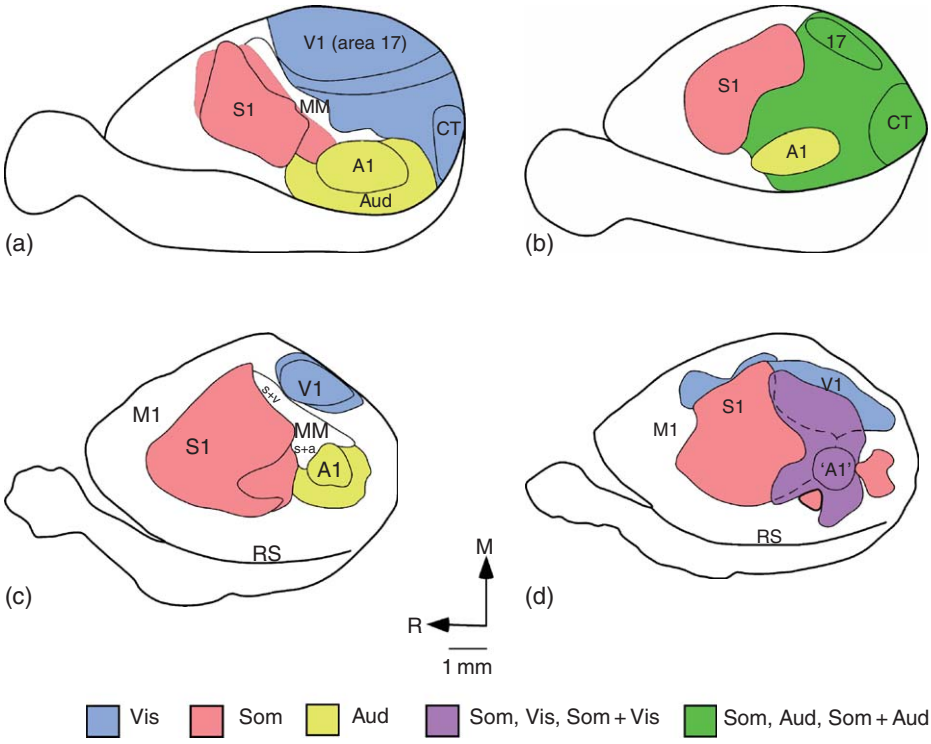

Figure 7 The organization of neocortex in normal opossums (a), normal mice (c), opossums bilaterally enucleated very early in development (b), and congenitally deaf mice (d). In the normal animals, both cortical fields and cortical domains are illustrated. In the bilaterally enucleated opossum, all of cortex that would normally be involved in visual processing, contains neurons responsive to somatic, auditory, or both somatic and auditory stimulation (green). In the congenitally deaf mouse, the cochlea is still present and a reduced eighth nerve exists, but no auditory driven activity is present. In this mouse all of cortex that would normally be devoted to processing auditory inputs contains neurons responsive to somatic, visual, or both somatic + visual stimulation. In both of these animals, the cross modal plasticity is extremely large such that all of cortex that is deprived of normal inputs is responsive to new types of sensory stimulation. In both mice and opossums, the cortical areas deprived of their normal inputs can still be identified architectonically, but at least in the opossum, the fields are smaller than in normal animals. a, auditory; A1, primary auditory area; Aud, auditory; M1, primary motor area; MM, multimodal; RS, rhinal sulcus; s, somatosensory; S1, primary somatosensory area; Som, somatosensory; v, visual; V1, primary visual area; Vis, visual. b, Modified from Kahn, D. M. and Krubitzer, L. 2002. Massive cross-modal cortical plasticity and the emergence of a new cortical area in developmentally blind mammals. *Proc. Natl. Acad. Sci. USA* 99, 11429–11434. d, Data from Hunt, D. L., Yamoah, E. N., and Krubitzer, L. 2006. S1 (area 3b) devoted to the trained digit, while no expansion of adjacent nontrained digits was observed (Figure 8a; Recanzone *et al.*, 1992a, 1992b). Further, a requisite of the expansion was that the animal must attend to the task; repeated passive stimulation of the digit alone did not result in an expansion. Similar results have been observed for the auditory and motor cortex. In the auditory system, discrimination training of particular frequencies leads to an expansion of the cortical space devoted to that frequency (Figure 8b; Recanzone *et al.*, 1993). Likewise, training in a motor control task that involves particular hand movements, results in an expansion of those movement representations in motor cortex (Nudo *et al.*, 1996). These studies are important because they are the first to demonstrate a direct relationship between alterations in the neocortex with learning, and thus, the neural substrate for behavioral fluidity within the life of the individual.

The studies of developmental and adult plasticity demonstrate that peripheral morphology, sensory driven activity, and in normal circumstances, the behaviors associated with sensory reception play a large role in generating aspects of cortical organization including sensory domain assignment, cortical field size, the amount of space devoted to representing a particular body part or sensory receptor surface, and cortical and subcortical connectivity. These alterations are independent of the genes intrinsically expressed in the neocortex, which restricts the avenues along which evolution can travel. Thus, despite these restrictions, a fair amount of functional and anatomical fluidity is possible both within the life of an individual and in species over the course of evolution.

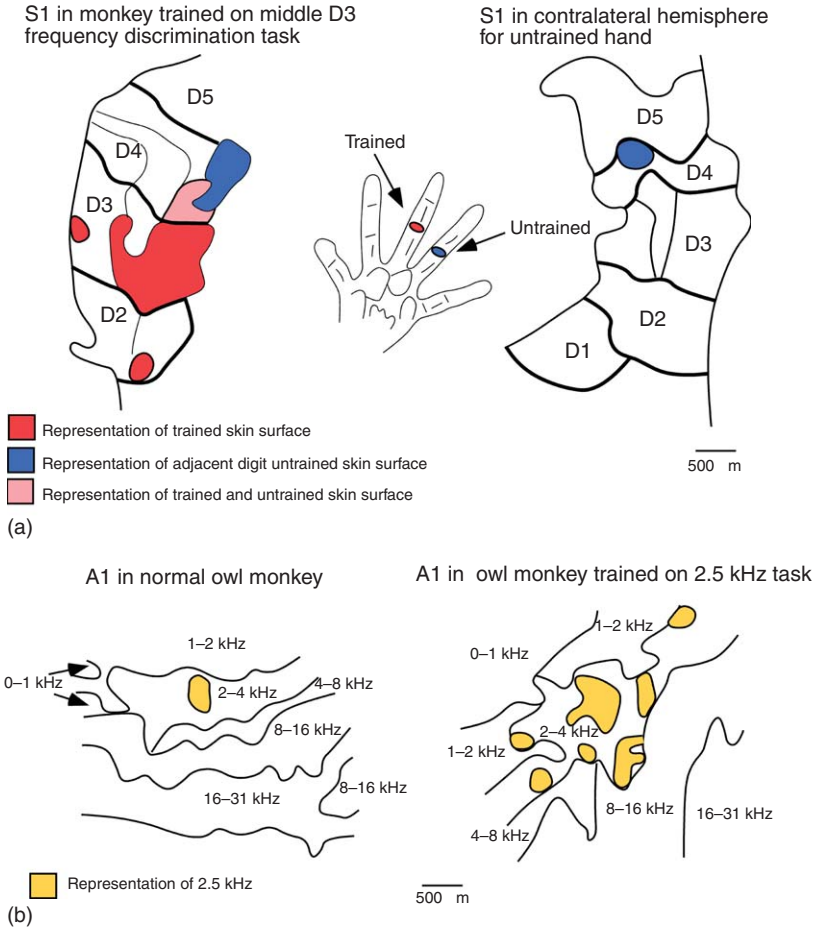

Figure 8 Cortical plasticity in adult owl monkeys following: a, somatosensory and b, auditory training. In the somatosensory cortex, training on somatosensory discrimination tasks increases the animal's ability to detect differences between two different stimuli, and this improvement in discriminatory ability is associated with an increase in the amount of neocortex devoted to representing the skin of the trained digit (red). In this case, the middle glabrous D3 was trained, and the contralateral S1 representing that portion of D3 (red) had an expanded representation compared to nontrained digits (blue). This plasticity was not observed in the hemisphere ipsilateral to the trained hand. Indeed, the portion of the cortex that represents the same location on the skin of the hand opposite to that trained was so small it was not found. A similar result was observed for the primary auditory cortex (A1). In owl monkeys trained on a 2.5 kHz discrimination task, the amount of cortex devoted to representing this frequency was expanded (b, yellow in left panel). A1, primary auditory area; S1, primary somatosensory area. a, Modified from Recanzone *et al.* (1992a, 1992b). b, Modified from Recanzone, G. H., Schreiner, C. E., and Merzenich, M. M. 1993. Plasticity in the frequency representation of primary auditory cortex following discrimination training in adult owl monkeys. *J. Neurosci.* 13, 87–103.

3.04.4 The Evolution of Cortical Fields

Earlier in this article we described the basic plan of cortical organization that all mammals possess, likely due to inheritance from a common ancestor (homology). Despite the large alterations that can occur in peripheral morphology, use, and lifestyle, the basic aspects of organization and connectivity of these fields are highly stable across lineages. However, there are modifications to this plan of organization, and a comparative analysis reveals that, at least at the systems level, these modifications take a similar form. In this section, we will describe some of the alterations that have been made to the cortical sheet in general, and to cortical fields in particular. We then postulate how some of these changes may have arisen in evolution, based in part on the information we have gained regarding the developmental mechanisms that construct cortical fields and their connectivities.

3.04.4.1 Changes in the Size of the Cortical Sheet

In addition to considering the cortical field in isolation, it is also necessary to consider general features of the brain as a whole that vary in predictable ways across species, which in turn have a large impact on the internal organization of the neocortex and the cortical field. The most

obvious feature is a change in the size of the brain and the size of the cortical sheet. Observations in a variety of mammalian brains indicate that there are two distinct types of changes in cortical sheet size, one in which the entire brain and its parts, including the neocortex, increase in size proportionately, and one in which there is a disproportionate expansion of the neocortex relative to the size of the rest of the brain.

Proportional changes in the overall size of the brain can result in an absolute increase in the size of the cortical sheet and the size of cortical fields. For instance, marsupials range in size from 4g to 67kg. Like the body, the range in brain size in marsupials is extreme. The marsupials we have examined in our laboratory include the dunnart (marsupial mouse, *Sminthopsis crassicaudata*), striped possum (*Dactylopsila trivirgata*), quoll (*Dasyurus hallucatus*), and short-tailed opossum (*Monodelphis domestica*; see Huffman *et al.*, 1999). In all but the striped possum, the most remarkable difference in the brains of these animals is that of absolute size. For example, the quoll and dunnart are both Polyprotononts from the family *Dasyuridae*. They differ substantially in body size with the dunnart weighing an average of 10g, and the quoll weighing an average of 750g. However, both are terrestrial hunters, occupy a similar niche, and have similar sensory specializations related to their predatory lifestyles (i.e., well-developed visual system). Examination of the neocortex of each animal demonstrates a clear difference in absolute size. However, much of the organization in terms of relative location and size of primary cortical fields are remarkably similar. This is best illustrated when the quoll brain is scaled to that of the dunnart. This scaling of brain size to body size and neocortex size relative to the rest of the brain is observed in other orders of mammals as well. For example, in a wonderful comparative analysis by Campos and Welker (1976), the neocortex of the capybara and guinea pig were compared. These investigators demonstrated that the size and relative location of primary cortical fields in the very large capybara compared to the much smaller guinea pig scales with the size of the body and the size of the brain as a whole (Figure 9).

The idea that the size of a cortical field scales linearly with brain size must be qualified. Comparative analysis has also shown that with dramatic specializations in the sensory epithelium, concomitant changes occur in the amount of neocortex devoted to that specialized sensory system, and the sizes of primary areas associated with that sensory system increase. Thus, if cortical sheet size is held constant and the internal organization of two highly derived species is compared, then differences in the allotment of neocortex and cortical field size can be readily observed.

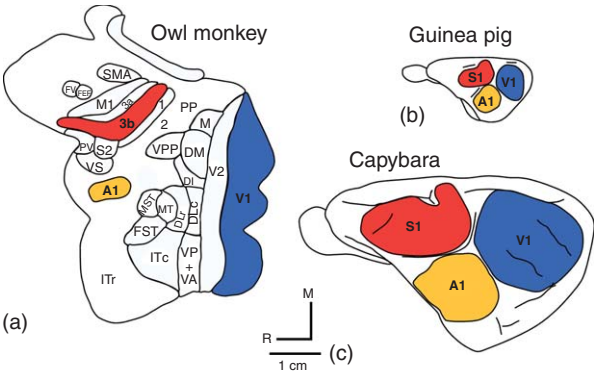

Figure 9 The organization of primary cortical fields in the: a, owl monkey; b, guinea pig; and c, capybara drawn to scale. In some species, the size of the brain has increased with body size, and the neocortex has increased in size proportionately with the rest of the brain (capybara). In this case, cortical field size has scaled linearly and the organization of the neocortex is much like that of other smaller rodents such as the guinea pig. In mammals, such as the owl monkey, whose body size is about ten times smaller than that of the capybara, the neocortex has enlarged disproportionately to the rest of the brain, although its absolute size approximates that of the guinea pig. With this disproportionate increase, the size of primary fields is reduced and more cortical fields are present. A1, primary auditory area; DLc, caudal division of dorsolateral visual complex; DLr, rostral division of dorsolateral visual complex; DM, dorsomedial visual area; FEF, frontal eye field; FST, fundal superior temporal area; FV, frontal ventral eye movement field; ITc, caudal division of inferotemporal cortex; ITr, rostral division of inferotemporal cortex; M, medial visual area; M1, primary motor area; MST, medial superior temporal area; MT, middle temporal visual area; PP, posterior parietal cortex; PV, parietal ventral area; S1, primary somatosensory area; SMA, supplementary motor area; V1, primary visual area; V2, secondary visual area; VA, ventral anterior area; VP, ventral posterior nucleus; VPP, ventral posterior parietal area; VS, ventral somatosensory area. a, Adapted from Krubitzer, L. and Kaas, J. H. 1993. The dorsomedial visual area of owl monkeys: Connections, myeloarchitecture, and homologies in other primates. *J. Comp. Neurol.* 334, 497–528. b and c, Modified from Campos, G. B. and Welker, W. I. 1976. Comparisons between brains of a large and a small hystricomorph rodent: Capybara, Hydrochoerus and guinea pig, Cavia; neocortical projection regions and measurements of brain subdivisions. *Brain Behav. Evol.* 13, 243–266.

The second type of size change that can occur is a disproportionate increase in the size of the neocortex compared to the rest of the brain. This results in a change in the pattern of neocortical organization. As in proportional increases in brain size, a disproportionate increase results in an absolute increase in the size of homologous cortical fields; however, the increase is less extreme than in the former type of size change. Furthermore, with a disproportionate

increase an additional organizational change to the neocortex is observed in that the number of cortical fields increases (Figure 9). This is nicely illustrated by comparing species that have different sized bodies, a similar absolute neocortical size, but a different neocortical size relative to brain and body size. For instance, although the capybara is well over 50 times the size of the owl monkey (50–70 kg vs. 1 kg), the neocortex of the owl monkey is disproportionately expanded, and its absolute size approximates that of the capybara. Examination of the neocortex of both species reveals very different types of organization. In the capybara, V1, A1, and S1 are large and compose much of the neocortex. In the owl monkey, V1, A1, and S1 are smaller than in the capybara, but many more cortical fields are present (Figure 9).

The question of how a disproportionate increase in neocortical size results in an increase in cortical field number is difficult to answer. It is possible that an increase in cortical field number, with an increase in the size of the neocortex relative to the rest of the brain, is due to a physical mismatch in the target (cortical sheet) and the projection zone (dorsal thalamus), or to a mismatch in the molecular coordinates between the thalamus and the cortex. This mismatch may result in new combinations of thalamocortical connections projecting to the expanded cortical sheet, in addition to the retained, highly restricted thalmocortical patterns of the primary and second sensory fields.

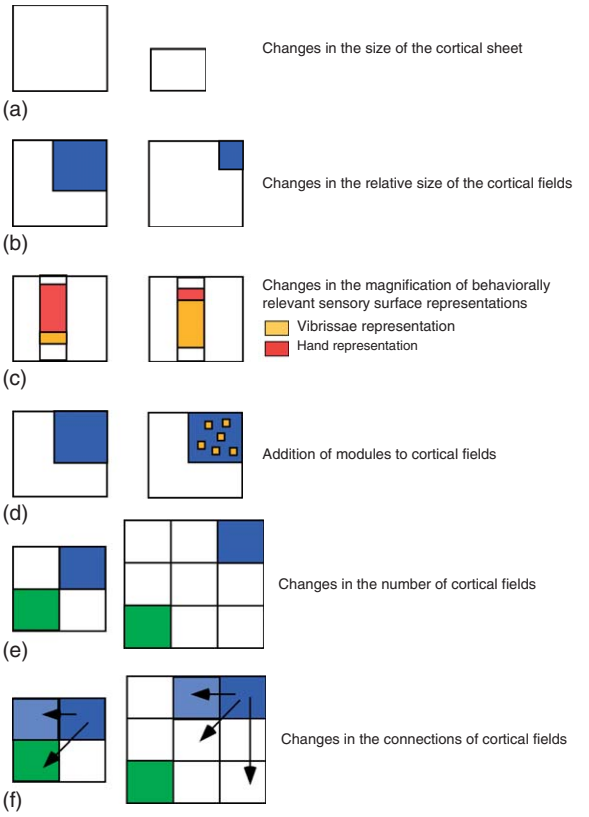

Figure 10 Modifications to the neocortex: a schematic representing the types of systems level changes that have evolved in different mammals. These changes, although few in number, presumably account for the wide range of behavioral differences observed in different lineages. Modified from Krubitzer, L. and Kaas, J. 2005. The evolution of the neocortex in mammals: How is phenotypic diversity generated? *Curr. Opin. Neurobiol.* 15, 444–453.

3.04.4.2 What Features of the Cortical Field Have Changed during Evolution?

In addition to changes in the size of the cortical sheet, several types of modifications have been made to the evolving neocortex (Figure 10). These modifications have been well documented (Krubitzer, 1995; Krubitzer and Kahn, 2003; Krubitzer and Kaas, 2005) and include:

1. changes in the relative size and internal organization of cortical fields,
2. changes in lamination of cortical fields,
3. changes in cell types,
4. changes in cortical thickness,
5. changes in the connections of cortical fields,
6. changes in the number of cortical fields,
7. the addition of modules to cortical fields, and
8. changes in the size of the cortical sheet (see above).

Interestingly, the brevity of this list of possible systems level modifications that brains have undergone or potentially could undergo suggests that it must be extremely difficult to modify the neocortex in evolution. Indeed, while we cannot predict the exact changes that may occur in future brains, we could predict with a fair amount of certainty what would not happen, and the types of changes that one would likely see. The observation that the types of modifications that have been made to the brain are limited indicates that these systems level modifications can generate a tremendous amount of phenotypic variability in terms of behavior.

3.04.4.3 The Module and Cortical Field Evolution

The module has been described in sensory cortex for a variety of different mammals (Figure 11). Modules are smaller units of organization that reside within a classically defined cortical field, and they have a long and dynamic history. Mountcastle (1957) described the first module, termed the cortical

column, almost 50 years ago (also see Mountcastle, 1978). He described the cortical column as a fundamental unit of cortical organization composed of a vertical group of cells extending through all of the cortical layers. This unit should not be considered as a fixed structure, but as a continuum with set dimensions, and no absolute boundaries. The modern concept of the module is different than its original conception in that it refers to different configurations of horizontal or tangential cell groups that do have fixed boundaries, and do not necessarily traverse all cortical layers. We have defined modules as "small architectonic, neuroanatomical, and physiological territories that can be distinguished from other tissue within the classically defined cortical field" (Manger *et al*., 1998).

Modules have been observed in a number of different cortical fields in different mammals and examples include barrels in rodent S1, blobs in V1 of primates, stripes in S1 of the star-nosed mole, ocular dominance bands in V1 of primates, and cytochrome oxidase (CO) bands in V2 of primates, to name a few (Figure 11). Although modules are a common feature of cortical organization that most mammals share, in most instances they are homoplaseous. The similarity of size and structure of modules across mammals argues that large constraints must be placed on evolving nervous systems. While evolution has been likened to a 'tinkerer', the bag of tools used to generate new phenotypes and the genetic material available for construction is highly limited. Thus, while the particular module itself may be homoplaseous, its presence may be due to homologous developmental programs (coordinated patterns of genetic interactions) that unravel in a particular molecular, neural, and sensory environment.

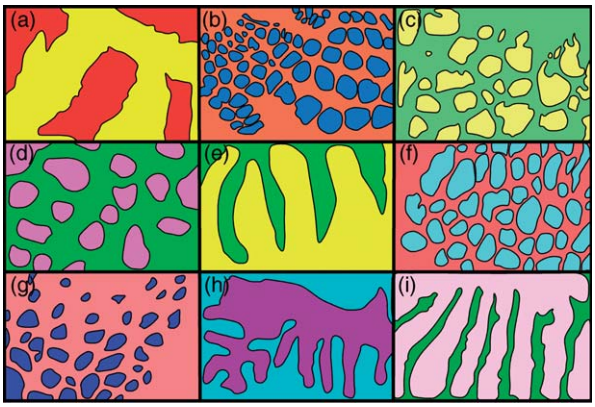

Figure 11 A schematic representing the many types of modules that have been identified in different sensory cortical areas in different mammals. While independently evolved or homoplaseous, the similarity in structure, shape, and size indicates that there are similar constraints imposed on the evolving and developing nervous system. a, Myelin bands in V2 of squirrel monkeys; b, barrel cortex in S1 of rats; c, modules in insular cortex of dolphins; d, clusters in entorhinal cortex in macaque monkeys; e, ODCs in V1 of talapoin monkeys; f, clusters in entorhinal cortex of humans; g, barrel cortex in S1 of brush-tailed possums; h, electrosensory/mechanosensory bands in S1 of platypus; i, rhinarium bands in S1 of the star-nosed moles. Modified from Manger, P., Sum, M., Szymanski, M., Ridgway, S., and Krubitzer, L. 1998. Modular subdivisions of dolphin insular cortex: Does evolutionary history repeat itself. *J. Cog. Neurosci.* 10, 153–156.

The identification of modules within cortical fields has implications for how a cortical field is defined. The traditional, and still dominant, view of cortical organization holds that the neocortex is compartmentalized into highly discrete cortical areas. However, the evidence for modular organization in cortical fields calls into question the traditional view of neocortical compartmentalization. Modules meet most of the criteria that generally are used to define a cortical field in that they are architectonically or histochemically distinct, have a unique set of connections, and contain neurons that are functionally distinct. When considered together, they form a complete representation of the sensory epithelium. An apt comparison between traditional and modern views of cortical fields is illustrated well for V1 and V2 of squirrel monkey neocortex (Figure 12). Until relatively recently, V1 and V2 were described as discrete, homogeneous representations of the visual hemifield with a distinct architectonic appearance and pattern of connectivity. The use of new histochemical staining techniques, optical imaging techniques, and fine-grained electrophysiological exploration of these fields has provided a very different view compared to traditional views. Rather than appearing as homogenous regions of cortex, both V1 and V2 have been further divided into modules. V1 is composed of blobs, interblobs, orientation columns, and ODCs. V2 is composed of thick and thin CO dense bands as well as interbands, and contains multiple representations of the visual hemifield.

Electrophysiological recording experiments of V2 in cebus monkeys and optical imaging experiments in macaque monkeys indicate that there is a re-representation of the same portions of the visual hemifield in these different bands (Rosa *et al*., 1988; Roe and Ts'o, 1995). Therefore, there is more than one map of the visual field in V2, and the separate maps are architectonically, histochemically, and connectionally distinct. These results suggest that 'chunking' V2 into one large, coherent field may

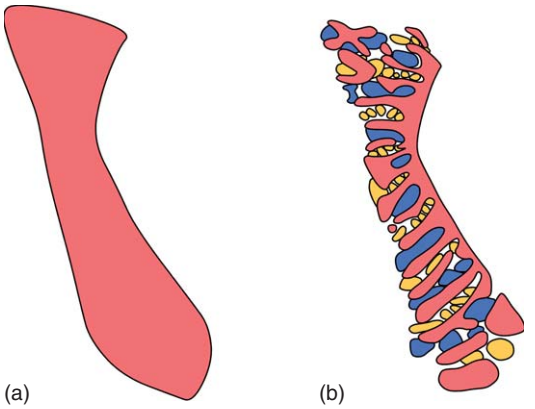

Figure 12 A schematic representing the: a, traditional and b, modern view of the organization of V2 in monkeys. Traditionally, V2 was considered to be a single, homogenous field adjacent to the rostral border of V1. Anatomical and functional studies (Rosa *et al.*, 1988; Roe and Ts'o, 1995) of the organization of V2 have since determined that it is modularly organized, and that there appear to be three independent representations of the visual field within this traditional area, associated with different histochemically identified stripes. These different strips, or bands in V2, have different patterns of connectivity. Thus, a new interpretation of this region of cortex is that three separate, completely interdigitated fields exist within the traditional V2. Adapted from Krubitzer, L. and Kaas, J. H. 1990. Convergence of processing channels in the extrastriate cortex of monkeys. *Vis. Neurosci.* 5, 609–613.

not be appropriate. Rather, V2 in primates could be considered as three separate, interdigitated fields (Figure 12).

In terms of modular organization and the evolution of cortical fields, we have proposed previously (Krubitzer, 1995; Krubitzer and Kahn, 2003) that modules reflect a stage in cortical field evolution within a lineage; that 'snapshot' alluded to in the introduction of this article. As noted earlier, we believe that a cortical field represents, at least in part, some patterns of connectivity on the cortical sheet. Within the life of an individual (particularly during development), and across species over time, this pattern of connectivity can shift such that the position of homologous fields is geographically displaced (Figure 13). Further, there are discontinuities within a cortical field (modules) that may represent an invasion of new inputs, discorrelated with existing inputs. This could represent fields completely embedded within other fields, as we believe is the case for V2. Over time, if selected for, these inputs coalesce and form partially invaginated regions, which may ultimately completely coalesce to form a new cortical field (Figure 13; see Krubitzer, 1995; Krubitzer and Kahn, 2003 for full explanation). Thus, the different modular and nonmodular organization of cortical fields within different sensory systems in different mammals represents different stages of this process in each lineage.

3.04.4.4 What Constrains Cortical Evolution?

There are three observations from comparative studies which indicate that neocortical evolution must be highly constrained. The first is the very presence of a common constellation of cortical fields, which was outlined in Section 3.04.2. That these fields and aspects of their connectivity and function can be modified substantially is without question. However, what is notable is that they have never been completely lost, even in highly derived mammals, such as the blind mole rat, which has micro-ophthalmic eyes covered by skin and a highly degraded retinofugal pathway (Klauer *et al.*, 1997; David-Gray *et al.*, 1998). The reduced visual system in blind mole rats is only involved in the circadian system. Yet, despite the lack of use of this system for visual functions, the geniculo-cortical pathway is still intact, and area 17 or V1, as architectonically defined, is still present and resides in the far rostral pole of the neocortex. The second observation is the very limited types of systems level changes that have been made to the brain, as outlined above. This suggests that the neocortex is not altered in a random fashion. The final, related observation is the instance of homoplasy. The fact that remarkably similar modules have formed, despite hundreds of millions of years of independent evolution, indicates that considerable constraints are placed on evolving nervous systems and that modularity is a part of this process.

What imposes constraints of the evolving neocortex? Primarily, genes constrain evolution and limit the types of phenotypic modifications that are possible, and these constraints are due to both pleitropy and contingency. Genetic pleitropy, or the fact that a single gene controls a number of activities in development, leads to functional integration, and as a result, it exerts a restriction on the number of possible changes that could be effected by any particular gene. Genetic contingencies restrict neural development and evolution in that any genetically mediated event is most often dependent on one or more prior genetic events and in turn may instruct some combination of downstream genetic events. Thus, it is rather difficult to substantially modify an organism by extreme genetic manipulations. This suggests that small genetic alterations can generate large phenotypic

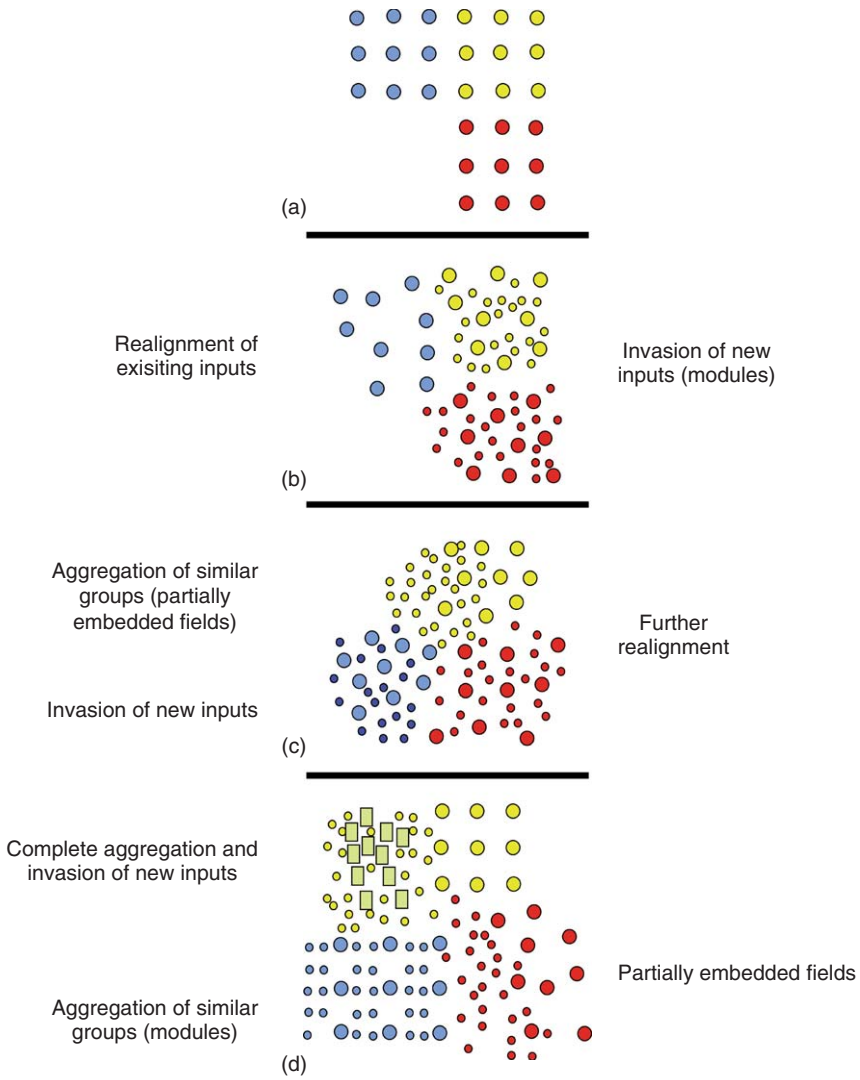

Figure 13 A theory representing the relationship between modules and the evolution of cortical fields. a, represents a hypothetical state of the neocortex with different colored circles representing a cortical field, or some pattern of thalmocortical interconnections within a field. An invasion of new inputs to existing fields (b, small red and yellow dots) results in a modular organization within these fields and a realignment of existing inputs. Modularly organized inputs may aggregate to form a partially embedded field (small yellow dots in (c)), causing a further realignment of fields, and new inputs may invade existing fields (small blue dots). Inputs that initiated within a cortical field and formed a modular arrangement (yellow dots), may completely aggregate to form a new field, and new inputs may invade this field (yellow squares). We propose that this is how cortical fields evolve and that each figure (a–d) illustrates snapshots or frozen frames that we observe in extant mammals. Modified from Krubitzer, L. 1995. The organization of neocortex in mammals: Are species differences really so different? *Trends Neurosci.* 18, 408–417.

modifications and that phenotypic change can be accomplished in the absence of nonactivity-dependent genetic change.

In addition to genetic forces, there are also substantial constraints imposed on evolving nervous systems by the environment in which an animal operates. When we discuss the nervous system, we rarely talk about physics, but the physical parameters of any environment are set and quantifiable. For example, nervous systems must contend with gravity, self-movement, and the movement of objects and other animals in time and in the three dimensions of our universe. The physical parameters of a stimulus are also important, and include the presence or absence of photons, the rate at which a stimulus travels and bends through space, the diffusion of molecules through different media, and the perturbations of molecules in different media, such as changes in air pressure. Although the amount and patterns of a physical stimulus that impinge on any given mammalian sensory receptor array may be distributed

differently in different terrestrial and aquatic environments, and in diurnal versus nocturnal mammals, the actual physical unit that is transduced, such as a photon, is invariant and therefore serves to anchor the evolutionary boat. While it seems clear that genes and their highly coordinated activities constrain a system, it is important to keep in mind that within a population of individuals, both the spatial and temporal expression of genes involved in the processes described above are normally distributed. This natural variability allows for some degree of flexibility within a relatively fixed genetic environment. Energy, while absolute, is variably distributed within any environment such that the amount and pattern of photons falling on a retina, for example, is different in different ecospheres. While we have noted above that both genes and the physical parameters of the environment constrain the development and evolution of mammalian neocortex, and ultimately behavior, it should be noted that the combinatorial possibilities of these two fixed parameters can generate a high number of degrees of freedom for potential phenotypic outcomes despite these constraints.

Despite these constraints, it is clear that sensory driven activity and the animal's own movement within an environment can generate a large amount of phenotypic variability. We have discussed the types of systems level changes that can occur with variable use and under particular environmental conditions in the developing and adult nervous system. But, how do such alterations become genetically encoded within a population and ultimately evolve?

At first reading, the idea that acquired traits can somehow evolve seems to smack of Lamarkianism. However, the notion that a living organism's ability to respond to environmental fluctuations has a genetic basis is relatively well established and compatible with Darwinian selection. This idea was formulated over a century ago by Baldwin (1886, 1902), and termed the Baldwin effect. The Baldwin effect is the ability of an animal to respond optimally to a particular environment. This effect could hold true for behaviors as well as anatomical features or aspects of functional organization of the neocortex. Thus, the Baldwin effect is the idea that genes for plasticity evolve, and that the phenotype that is optimal for a given environment could become genetically encoded and evolve if the genes that encode for plasticity and those for the actual phenotypic feature in question covary (Figure 14). This characteristic would then be selected for and be displayed even in the absence of the original environmental stimulus that induced it. This phenomenon was experimentally tested by Waddington and termed genetic assimilation (Waddington, 1959, 1961).

A related process has recently been described as 'evolvability'. Evolvability is the ability of an organism to generate heritable, selectable phenotypic variation (Kirschner and Gerhart, 1998). These authors propose that selection for evolvability has occurred and has three components. At the level of the individual, the ability to be flexible would contribute directly to physiological fitness. At a group level, individuals within the group would be buffered against the lethal effects of mutation. Finally, at the level of the clade, such an ability would allow the clade to radiate into new (emptied) environments. Recently, experimental support for the notion that evolvability is a selected trait has been put forward by Earl and Deems (2004). They find evidence that the rate at which genetic change in the form of recombination, substitutions, and transpositions occurs is variable in different lineages and is genetically encoded.

Taken together, it appears that activity can regulate gene expression which, in turn, can regulate anatomical and functional characteristics of the developing nervous system within an individual lifetime. This process, or the ability to respond to some external stimulus, is optimal in some individuals and can be selected for (the Baldwin effect). In a particular environment, an optimal trait can become genetically encoded in a population and evolve if there is a strong correlation between phenotypic and genotypic space (genetic assimilation). Finally, the ability to respond optimally and to assimilate, while maintaining a fundamental plan of organization, is a variable trait itself, and is the target of selection (evolvability).

3.04.5 Conclusions

How should we view the evolution of the cortical field? While a cortical field has been previously proposed to be a fixed, genetically determined structure that occupies some area on the cortical sheet, a comparative analysis highlights the dynamic nature of a cortical field within the life of an individual and over generations within and across lineages. We believe that the cortical field is an event or a process, not an entity that is easily captured. While genes and the physical environment impose severe constraints on this process, neural activity within the developing organism generated by the highly constrained physical

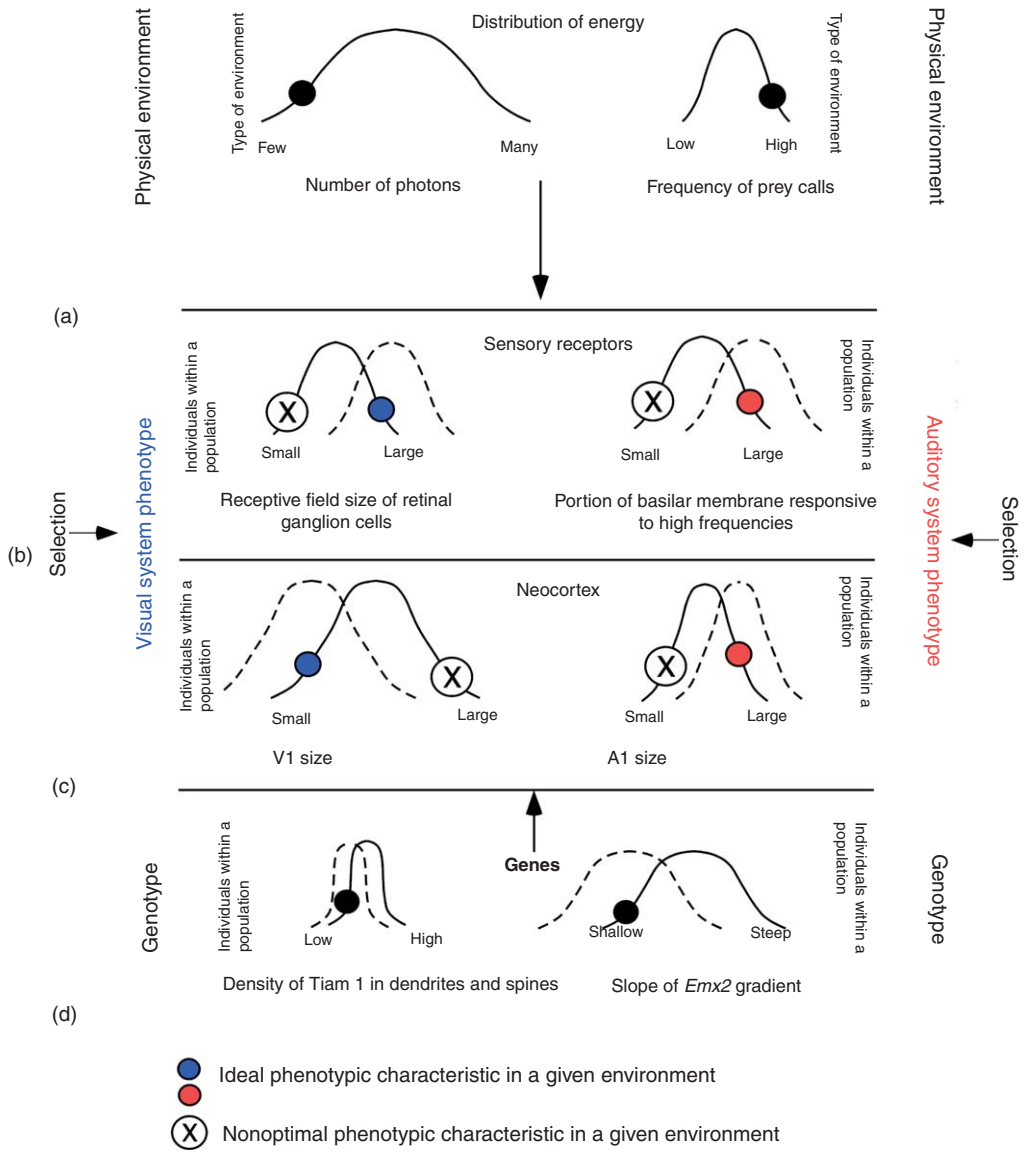

Figure 14 A schematic illustrating the Baldwin effect and genetic assimilation, and how features of cortical organization that are initially activity dependent, become encoded by genes and evolve. Within a particular environment (a), light levels may be low, and prey call frequency may be high (black dots on the distributions in a). The optimal sensory receptor phenotype (b), receptive fields size of ganglion cells distribution of frequency on the basilar membrane (blue and red dots respectively) are normally distributed within a population. For the neocortex (c), the optimal phenotype for this environment would be a small V1 and a large A1 (blue and red dots respectively). These size differences of cortical fields are normally distributed within a population. Finally, particular genes which are normally distributed in a population (d) control aspects of cortical field organization either directly via *Emx2*, or indirectly through activity-dependent mechanism (e.g., Tiam 1). Although natural selection acts on the phenotype, the genes that control for the particular phenotype in question as well as plasticity may co-vary, and thus allow activity-dependent contributions to the phenotype to become genetically encoded and evolve. This type of selection could shift the distribution (dashed lines) of genes that both enable plasticity (activity dependent), as well as those directly determine the characteristic (e.g., Emx2 and size of cortical fields). A1, primary auditory area; V1, primary visual area. Modified from Krubitzer, L. and Kaas, J. 2005. The evolution of the neocortex in mammals: How is phenotypic diversity generated? *Curr. Opin. Neurobiol.* 15, 444–453.

parameters of the environment, and the movement of the organism itself in time and space, serves to loosen these constraints. An extant mammal represents only a snapshot in this process. This snapshot may give the impression that a cortical field is static, when, in reality, we have simply caught a frozen moment in the continually moving picture of life.

3.05 Cortical Evolution as the Expression of a Program for Disproportionate Growth and the Proliferation of Areas

B L Finlay and P Brodsky, Cornell University, Ithaca, NY, USA

Glossary

allometry	The study of alterations in form causally correlated with changes in size.
cortical area	A proposed unit of the cortex, typically containing a topographically mapped representation of a sensory, motor, or computed surface, and a characteristic set of thalamic inputs and subcortical outputs.
module	In computer science and cognitive science, a functionally encapsulated unit performing a particular computation. In neurobiology, often used to refer to any repeating unit of structure.
pleiotropy	The case where a single gene contributes to the execution of many functions, preventing its optimization for any single function.
prosomere	Hypothesized embryonic segmental structure of the forebrain.
radial unit hypothesis	The hypothesis that the essential unit of mature cortical function, the cortical column, and also the unit of evolutionary selection and replication is the assembly of neuroblasts migrating to the cortical plate on a single radial glial guide in development.
sensory exploitation	The idea that in the evolution of communication systems, the sender evolves to maximally activate the generic sensory system of the receiver.
subnet	An assembly of neurons performing a logical unit of computation.
symmetric and asymmetric cell division	Symmetric cell divisions give rise to identical daughter cells, both capable of further division; asymmetric division produces a cell that will become a differentiated mature form.
topographic map	The feature of retention of nearest-neighbor relationships when one array of neurons projects upon another.

3.05.1 General Introduction to Developmental Structure in Brain Evolution

Evolved structures are the result of successful adaptation to the environment, and evolution occurs by the variation and selection of genetic programs, as they are expressed in the development of the organism and in mature phenotype. In this article, we will discuss the evolution of the cortex in a developmental context, focusing on how the various versions of cortex we see in different mammalian radiations are expressions of a generally conserved developmental program, produced over variable lengths of time and variable scales. In classical evolutionary biology (Gould, 1977, 1980), conserved developmental programs are often viewed as constraints, limiting the range of variation offered for selection (see Principles of Brain Scaling). Possible reasons for stabilization of developmental programs are multiple. Very early events in development may become fixed, as they may contribute to the structure of so many mature systems no single system can be caused to vary independently. Or, independent of development, single genes may contribute to disparate functions (termed pleiotropy) so that variation in the gene cannot be linked to the optimization of a single system. More recently, however, the extent to which fundamental developmental programs are conserved across phyla has proved to be quite breathtaking and caused a substantive rethinking of the significance of conservation, away from the negative-to-neutral interpretations of constraints just described. Rather, the explanatory focus has shifted to the structures of genetic systems that allow robustness and stability to coexist with variability (Gerhart and Kirschner, 1997; Radman *et al.*, 1999; Wilkins, 2001).

Conserved features include the polarity, symmetry, and segmentation of the fundamental invertebrate and vertebrate body plan (Duboule and Dollé, 1989; Graham *et al.*, 1989); the designation of areas for special senses and limbs (Callaerts *et al.*, 1997); the control of the cell cycle and symmetry-breaking events that control cell cycle entry and exit; and other features of cell specification (Gerhart and Kirschner, 1997). Many particular mechanisms central to nervous system construction are similarly stable across taxa, such as mechanisms for axon extension and inhibition (Dickson, 2002), mechanisms for approaching and crossing the neural midline (Stein and Tessier-Lavigne, 2001), and activity-dependent stabilization of synaptic connections (Greenough and Bailey, 1988; see Scaling the Brain and Its Connections). Though highly conserved, such a set of fundamental mechanisms seems ill-described as constraints. If these fundamental mechanisms represent optimal or near-optimal solutions to repeatedly encountered developmental problems, the sense of the word 'constraint' as limit is poorly applied to them.

A longer view of the definition of 'adaptation' and 'environment' than each particular animal's interaction with its immediate physical setting will provide some of the appropriate context for understanding why developmental programs are likely to be conserved along with the conserved neural circuitry that the developmental programs will eventually represent. In addition, a more sophisticated understanding of how complex behavioral functions might be distributed over the essentially conserved architecture but widely varying size of the cortical surface is absolutely essential. We will discuss the evolution of complex sensory and behavioral functions first.

An example from current neuroethology of a phenomenon called sensory exploitation throws better light on what kinds of possible adaptations are good solutions to conflicting adaptive demands (Ryan, 1998). In the first days of neuroethology, the observation that an anolis lizard might have a bright orange dewlap that it extends for aggressive displays, or a male frog a particular croak with acoustic features that attracts females of its own species were hypothesized to be roads to insight into neural coding in both sensory and motor systems (and they were, but not in the way anticipated). Researchers imagined isomorphic specializations in the nervous systems of both the senders and the receivers, from the sensory periphery on into the central nervous system.

While there must be some committed circuitry for conspecific recognition, even after years of work neuroethologists generally failed to find specific adaptations in receivers, especially in the sensory periphery, when comparing closely related species using different signaling systems – that is, there were no orange dewlap detectors in the retina, or anywhere else in early visual processing. Instead, they found that the signaler had evolved to produce a maximally perceivable signal for the receiver's sensory system or a maximally contrastive signal for the immediate environment, thus exploiting the generic visual or auditory system of the receiver (Ryan and Rand, 1995; Persons *et al.*, 1999). This makes sense when the multifunctional nature of sensory systems is understood: the same visual system that must respond to aggressive social signals must also recognize food, recognize threat, navigate terrain, and respond to a wide range of other social signals,

which simply cannot be realized computationally with any efficiency as a collection of committed detectors (Field, 1994).

The style of the initial steps of neuroethology has unfortunately traveled unmodified into some current theorizing about cortical organization, sometimes replacing detectors with modules. One example is the discussion of the evolution of primate vision and the neural representation of trichromacy in the cortex (Barton, 1998). In this case, the differentiation of a photopigment capable of improving discrimination in the red–green end of the visual spectrum is attributed to the single function of fruit detection with associated central nervous system alterations rather than a neatly placed transducer employing generic contrastive processing, which can measurably improve not only the discrimination of particular fruits, but their ripeness, leaf maturity, other edible prey, assignment of boundaries and edges to improve navigation through cluttered forest environments, social signaling, and so forth (Moller and Hurlbert, 1996; Nickle and Heymann, 1996; Regan *et al.*, 2001; Dominy and Lucas, 2001; Finlay *et al.*, 2005b). Views of how behavioral adaptations are translated into neural specializations will be important when we examine hypotheses about how cortical areas might proliferate.

What environment are organisms adapted to? In classic adaptation scenarios, individuals compete for reproductive success in a stable environment, improving their perceptual capacities, signaling of reproductive quality, and physiological and behavioral abilities in general, producing an adaptive walk through a universe of potential adaptive states responsive both to environmental pressures and the nature of the particular competition they have engaged (Dawkins, 1976, 1986). This type of scenario often generates greater and greater specialization, particularly arms races in the means of sexual selection. However, most individuals in their own lifetimes or in their immediate ancestors' lifetimes have faced environments of great disturbance: climatic shifts and ecological catastrophes both local and global (Alvarez *et al.*, 1980; Albritton, 1989). Those individuals that survive have the robust and stable genomes and nervous systems suitable for both classes of environments, the stable and the catastrophic. Our genomes and nervous systems contain histories both of adaptive specialization in stable environments and successful survival through massive environmental changes (Gerhart and Kirschner, 1997).

Finally, as our sophistication grows both in understanding nervous systems (e.g., Schüz and Miller, 2002) and generalized computer and network structures (Watts and Strogatz, 1998; Nolfi and Floreano, 2002; Newman, 2003), we are beginning to get a better idea of what kinds of modifications might be necessary to scale up brains to larger bodies, adapt brains to new behavioral niches, and produce intelligent behavior. Quite analogously to the first-pass detector guess for how to evolve sensory systems, often the first guess about how to generate a new behavior is to propose a new committed module for the brain (Chomsky, 1975; Barkow *et al.*, 1992; Fodor, 1992), which has rarely proved to be the actual case; for many of the same types of reasons, committed detectors are poor solutions to sensory problems. In addition, it proves that aspects of modular construction (to be discussed) pose difficult challenges for nervous system scaling.

The allometry of scaling of brains with bodies (Jerison, 1973; Schmidt-Nielsen, 1984) and the coscaling of sensory systems are phenomena that have never been satisfactorily understood (Finlay *et al.*, 2001). Why brains should scale regularly in size with bodies at all is unclear, as we know that in many nonbiological systems there is no need for the size of a control system to match the physical size of the entity controlled. Why visual acuity should scale roughly with body size (Kiltie, 2000) and why the ratio of brain size to body size is somewhat better correlated with behavioral complexity than absolute brain size alone (Jerison, 1973; but see Gibson, 2002) are similar puzzles (see Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals). Our available explanatory schemes have not coped well with these questions, but the application of new work in the properties of network architectures may begin to help.

In the following pages we will review some of the basic generalizations of how mammalian nervous systems tend to scale and adapt, and how those are linked to conserved developmental programs. When possible, we will try to evaluate whether we are looking at conserved programs that exist because of some constraint limiting the range of evolutionary solutions, or conserved programs that represent selected optimal solutions. Finally, we will propose and evaluate some exploratory models of network scaling in this evolutionary and developmental context.

3.05.1.1 A Conserved Order of Neurogenesis across Mammals and Its Relationship to Brain Allometry

In 1995, in an initial analysis of the relationship of variations in the order and relative duration of

neurogenesis to variations in the size of mammalian brain regions, Darlington and Finlay compared two large sets of data on both phenomena and found an unusually close and predictable relationship (Finlay and Darlington, 1995). Using the information collected for primates, insectivores, and bats for comparable brain regions by Stephan *et al.* (1981), a data set that has been the subject of numerous analyses, we first reiterated a finding that had been known before, but not usually highlighted: approximately 97% of the variance in the sizes of brain parts was predicted by the size of the whole brain, and 99% if a second limbic or olfactory factor was added (Gould, 1975; Jolicoeur *et al.*, 1984; Barton *et al.*, 1995; Figure 1a). This was an unusual emphasis, because most investigators, interested in mapping the 'differences' in size of brain parts to 'differences' in animal's behavior and niche, disposed of the shared variance and examined the residual variance, using various statistical approaches (Barton and Harvey, 2000; Clark *et al.*, 2001; de Winter and Oxnard, 2001). Since we were interested in the relationship of absolute volumes of brain or neuron numbers to neurogenesis, it was necessary, as well as fortuitous, to focus our attention on shared variance.

In addition to the predictability of brain component scaling from brain size, a second important feature was disproportionality – different brain components enlarge with markedly different slopes, such that the mammalian brain comes to be dominated in volume by different structures as it enlarges, notably the cortex. The large human cortex is just the size it should be for a primate brain our size (Hofman, 1989) and for absolutely larger brains, like the elephant's, the cortex is an even greater proportion of total brain volume.

The proximate cause of the disproportionality in the enlargement of brain parts can be understood by looking at neurogenesis, how neurons are generated in early development across mammalian species (Figure 1b). The ordinal position of the peak day that neurogenesis ceases for each cell group and structure in the brain is very highly conserved in the mammals studied (this end of neurogenesis is called the cell group or structure's birthday), although the total duration of neurogenesis varies from approximately 10 days in the mouse to over 100 days in monkeys. A two-factor equation can be written that captures 99% of the variance in this species/structure matrix (Clancy *et al.*, 1999, 2001).

Underlying the conservation of ordinal position, however, is a very strong nonlinearity: the numbers of cells generated do not increase linearly with extended developmental time, but exponentially over time, reflecting the doubling and redoubling

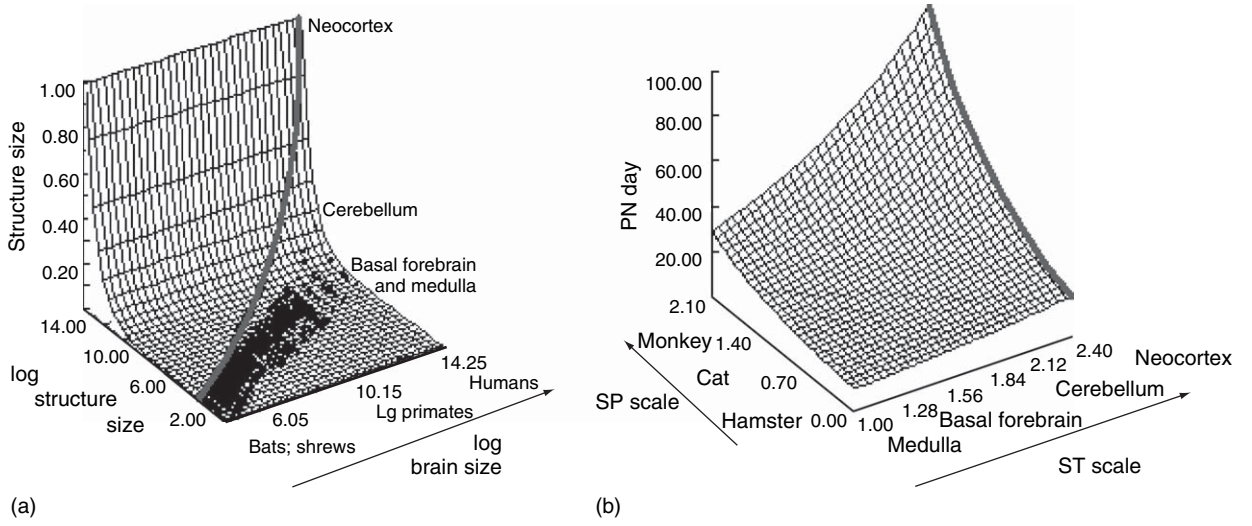

Figure 1 a, A combined log (*y*-axis) and nonlog (*z*-axis) plot of brain structure volumes versus log brain volume (*x*-axis) for the 131 primates, bats, and insectivores of the Stephan data set. This style of graphing is chosen to highlight both the predictability and disproportionality of those structures scaling at the steepest slopes with respect to brain size, particularly the neocortex. b, Model of the predictability of the birth date of a structure in a species given the ordinal position of each structure's birth date across animals (structure scale, ST) and the relative duration of neurogenesis in a species compared to others (species scale, SP). The seven species modeled in this analysis are hamsters, mouse, rat, spiny mouse, possum, cat, and monkey; 51 neural structures are modeled, from motor nuclei of the medulla to cortical layers. Those structures with high ST values are the latest-generated ones and are the same that become disproportionately large as brain volume enlarges. Lg primates, large primates such as rhesus macaque and the anthropoid apes; PN day, number of days postconception. a, Redrawn from Finlay, B. L. and Darlington, R. B. 1995. Linked regularities in the development and evolution of mammalian brains. *Science* 268, 1578–1584.

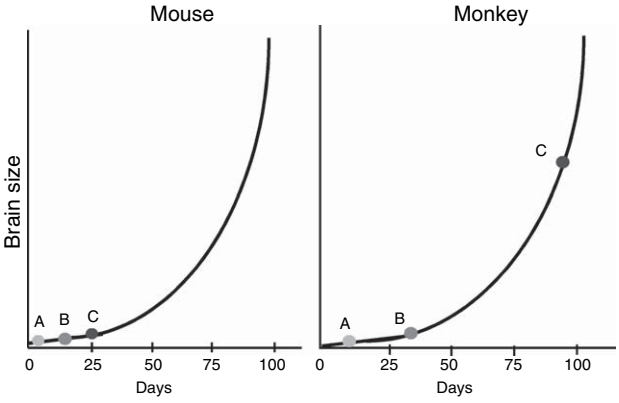

Figure 2 Late equals large. A schematic of the consequences for eventual size of a structure generated early (A), intermediate (B), or late (C) in the order of neurogenesis for a species with a short period of neurogenesis and a small brain, like a mouse, versus one with a long period of neurogenesis and a large brain. In the long-development species, the precursor pool for late-generated structures has a longer time to multiply and becomes disproportionately large.

nature of the symmetric phase of cell division in early embryogenesis (Figure 2). The consequences of exponential growth for lengthening the period of neurogenesis by roughly a factor of 10, the ratio difference from mouse to monkey, are quite different for the end neuron number in structures with early birth dates (like the medulla), middle birth dates (like the midbrain), and late ones (like the cortex). Our shorthand term for this relationship is late equals large.

Thus, particular parts of the brain increase disproportionately by a 'developmental rule'. This was quite a disturbing finding in that most previous accounts of disproportionate enlargement of some parts of the brain were cast as special adaptations due to the virtues of those parts. Particularly, some special organization or adaptive advantage was usually ascribed to the cortex to produce its disproportionate size in primates and ourselves: its efficient layering, the columnar structure, its hierarchical/parallel associative connectivity. However, the developmental rule that will produce a disproportionately large cortex in a large animal is already present in the much smaller stem primates with their small cortices, who presumably had no particular plans of their own for generating a useful structure to house a language cortex or any other kind of elaborated cognition. In addition, after a decision to allocate more tissue volume to olfactory-limbic structures or to cortex, the cortex scales disproportionately in all mammalian radiations we have studied (Reep *et al.*, 2007).

Before we go on to discuss this perplexing observation and the relationship of brain structure and function in evolution, we will go into a little more detail about just what the developmental rule is. We have published a number of further analyses and reviews to which we refer the reader for detail about such subjects as differences in neurogenesis in eutherian and noneutherian mammals (Darlington *et al.*, 1999), closer structural analyses including scaling of the thalamus (Finlay *et al.*, 1998, 2001), the special case of the limbic system concentrating on olfactory bulb and hippocampus (Kaskan and Finlay, 2001; Reep *et al.*, 2007), the scaling of the visual system (Kaskan *et al.*, 2005; Finlay *et al.*, 2005b), and the relationship of other developmental events to neurogenesis (Clancy *et al.*, 1999, 2001).

3.05.1.2 Prosomeres Are the Developmental Units Organizing the Duration of Neuron Proliferation in the Forebrain

Mammals differ from most other vertebrates by confining most of their neurogenesis to early development, rather than generating brain throughout life (there are exceptions to this generalization, of much current interest; Scharff, 2000). Does the conserved order of neurogenesis we see reflect a random pattern that happened to crystallize at the time of divergence of mammals, or some more fundamental organization? It proves that the conserved pattern of early neurogenesis we see, as well as where ongoing neurogenesis can be found in adult mammalian brains, can be explained by reference to an organizational scheme defined by patterns of expression of regulatory genes and transcription factors in early neurogenesis, the prosomere model (Rubenstein *et al.*, 1994). The basic axes that define this structure are common to the entire brain, which begins as an extended plate, the neural plate, which subsequently rounds up and connects its lateral-most edges to become the neural tube. The neural tube, whose original form is most obviously visible in the spinal cord, consists of repeating segments of similar fundamental structure with local variations. The part of the plate (and later tube) near the midline is called basal for its embryonic position, and in the spinal cord, this basal plate gives rise to motor neurons. The lateral part is called alar, Latin for wing, again for embryonic position, and in the spinal cord will produce secondary sensory neurons. The topology of the embryonic tube is maintained in the adult brain, with generative areas that initially neighbored each other, producing neighboring but translocated adult neurons. The embryonic relationships of cell groups in the adult brain can be recovered using classical neuroanatomical methods combined with painstaking developmental observations up to

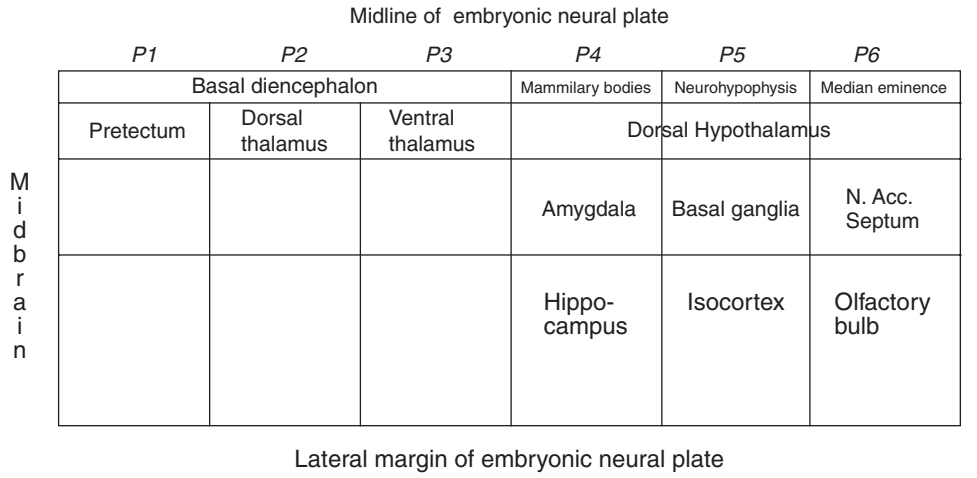

Figure 3 Components of prosomeres, the embryonic segments of the telencephalon, described by Rubenstein *et al.* (1994). The lateral-most part of the early neural plate is the part that undergoes the most extended cell division and becomes disproportionately large in large brains. N. Acc., nucleus accumbens.

about the level of the midbrain. The extended and convoluted pattern of neurogenesis in the forebrain, however, makes it impossible to track unlabeled cell groups from their place of origin. The ability to visualize gene expression gradients was required in order to trace each cell group back to its position of origin on the two axes of the embryonic brain, anterior–posterior and basal–alar.

An assignment of the traditionally named brain parts to this axial system of 'prosomeres' is given in Figure 3. For the most part (with some exceptions), as adult brain divisions reflect embryonic neural tube positions, these assignments can be made unambiguously. Hypothalamic and some basal forebrain structures are in the basal prosomeres; the large cellular masses of the forebrain, for example, the basal ganglia, are intermediate, and the cortical structures – olfactory bulb, hippocampus – most lateral or alar. If embryonic axial position is correlated with birth date (Finlay *et al.*, 1998), both axes contribute to the solution, but the alar–basal axis predominates, with late birth dates for cell groups associated with alar positions, early birth dates with basal. Our shorthand for the relationship of timing of neurogenesis to brain part size 'late equals large' can now be extended to a spatial axis of gene expression 'lateral equals late equals large'. Note that for two of the most anterior structures in the most lateral–alar position, the olfactory bulb and hippocampus, there is in fact no terminal birth date and neurogenesis continues throughout life, even in mammals (Bayer, 1980, 1983). For the cortex, at the same alar position, neurogenesis does appear to stop (Rakic, 2002; there is debate on the issue; Gould *et al.*, 1999).

Therefore, the conserved pattern of neurogenesis is not the crystallization of an arbitrary order that happened at some point in mammalian evolution, but is an expression of an axial pattern that at least in part is common to all vertebrates. The fact that the telencephalon is a likely division (but not the only one) for disproportionate enlargement across all vertebrates, and the cortex specifically enlarges in mammals appears to find its roots in this aspect of embryonic structure.

3.05.1.3 Brain Adaptations, Specializations, and Residual Variance

It is important to understand the actual physical characteristics of brain evolution to understand the nature of the shared and residual variance. In the Stephan data set (Stephan *et al.*, 1981), brain weights vary from a fraction of a gram to over a kilogram, a factor of about 20 000. At any particular brain weight, the residual variance of individual structures is approximately 2.5; that is, two species similar on the two factors (whole brain and limbic) might commonly have individual structures varying by over a factor of 2, occasional pairs considerably larger, which would be very conspicuous to an investigator looking for individual or species differences in the sizes of brain components. It also proves that the distribution of variance in volume across structures is quite uneven (Glendenning and Masterton, 1998).

This residual variation is an interesting aspect of species variation, and we do not discount it as an important window into brain structure, but we have set our job to understanding the significance of the factor of 2 in the context of the factor of 20 000, not the factor of 2 alone. Should we expect all adaptation-relevant increases in brain size to be carved out of the residual variation? The answer is

no, but it requires that our assumption of structure–function identity be loosened somewhat, particularly in the case of potentially multimodal regions like the cortex. There is no doubt that the sensory periphery is usually committed to its particular tasks – olfactory bulbs are for chemoreception, the retina for vision, and later on we will list large differences in the sensory periphery for animals in particular environmental niches that require different types of competence. A useful analogy for understanding brain evolution is the two-hit model of cancer initiation (Knudsen, 2001). In order for tumor genesis to begin, both proliferation 'and' mutation must occur. Rather than selecting for increased size for a function bound to a particular structure, a structure that has accessible variation in its size (first hit) may be well placed to acquire new functions, either by genetic specification (second hit) or through the epigenetic route of experience.

3.05.2 The Particular Case of Proliferation of the Cortex

The proliferation of the cortex, considering either total volume or general structure, is not identical across all mammals, and we would note a few of the interesting differences before concentrating on some commonalities. First, different radiations of mammals appear to allocate proliferation preferentially between limbic forebrain (olfactory bulb and hippocampus) and iso- or neocortex, with carnivores and primates showing more neocortical proliferation and insectivores, rodents, and anteaters greater olfactory bulb and hippocampus proliferation (Gould, 1975; Jolicoeur *et al.*, 1984; Reep *et al.*, 2007). As is well known, the cortex increases in area as it enlarges, but not exclusively – the cortex also increases in depth, as measured in number of neurons and particularly those concentrated in the upper cortical layers – in the smallest brains, a differentiated layer 4, the thalamic input layer, cannot often be detected, while in primate brains, often layer 4 has obvious sublamination (Valverde, 1990). Interestingly, the cetacean brain does not show an increase in depth with increasing size, suggesting an altered pattern of proliferation (Hof *et al.*, 2000). Finally, there is a great amount of local variation in such features as periodic expression of cytochrome oxidase, and various neurotransmitter receptors and neuromodulators both within the cortex, which have not been assessed systematically across species. Here we will discuss the proliferation of cortical areas, the size of cortical areas in relationship to niche, and some aspects of connectivity.

3.05.2.1 What Is a Unit of Cortex in Developmental Terms?

3.05.2.1.1 Radial units and cortical areas These two concepts, the first a developmental process and the second a characteristic of the mature cortex, are the best-known hypotheses about the structure of evolutionary variability in the cortex. Rakic has proposed that the radial unit, which is a region in the embryonic neural tube containing the precursor cells that will give rise to almost all of the cell types in an adult cortical column, named after the radial glia that provide the highway from the ventricular surface, is the fundamental unit of cortical proliferation (Rakic, 1990). By extending development, as measured in cell cycles producing the precursor cells in the cortical ventricular zone, more radial units are generated, generating more cortical columns and more cortical areas (Takahashi *et al.*, 1997). Rakic has characterized the generation of new cortical areas as a developmental negotiation between the cortex and the thalamus between their prespecified arrays of regions, initial protomaps (Rakic, 1988).

Cortical areas were first described as features of adult cortical organization: within the general uniformity of cortical layering, discontinuities in cell size, density, and total number and differences in axon distribution were noted (Brodmann, 1909). These regions of cytoarchitectonic discontinuities correspond to areas receiving particular thalamic input and thus correspond to the representation of modalities, which are usually topographically mapped, and a host of other features (Kaas, 1987; Krubitzer, 1995). At least the primary sensory and motor areas (V1, A1, and S/M1) are specified in their relative locations in the embryonic cortex by early polarizing events (Ragsdale and Grove, 2001). Thus, a cortical area could be an addressable unit of cortex variation and evolution: perhaps the whole set of instructions for producing a new area could be duplicated, as Kaas has suggested, much as the number of segments in a vertebrate whole body plan may increase or decrease under selection. In addition, if a cortical area is a unit analogous to a body plan segment, secondary modifications might be able to be attached to it, just as the segments of an insect body or vertebrate spinal cord have pronounced local specializations. Thus, new features could be attached to specific regions, like ultrahigh temporal resolution in cortical areas used for echolocation in bats (Suga *et al.*, 1981; see Somatosensory

Adaptations of Flying Mammals). Similarly, cortical areas could reasonably be increased or reduced in size, depending upon the relationship of their modality to each species' particular adaptive needs.

3.05.2.1.2 Multidimensional models The physical nature of scaling of biological tissue over the range of cortical surface areas that go from millimeters to meters requires some amplification of the first two hypotheses. A large cortex, or cortical area, appears to have much more internal detail than a smaller cortex. By this we mean that a large cortex contains not only more cortical columns and identifiable areas, but also more anatomical features such as stripes, puffs, and blobs in transmitter expression, and aspects of activity, interleaved ordered thalamic, intracortical, and callosal connectivity, as well as the elaborated functional maps correlated with the anatomical differences. They neither appear to be scaled-up versions of a stem insectivore cortex, nor the stem cortex replicated over and over across the cortical surface. All mammalian cortices, with the exception of those of monotremes, which differ in topology, appear to share three fundamental sensory and motor regions, and elaborate themselves along the same general lines, but with substantial variation in the details of all the features of cortical organization described above (Krubitzer, 1995).

Various hybrid models have been proposed, therefore, beginning from the assumption of a cortex that has specification of the rules of connectivity and general organization for three primary sensory areas, and then also for elaborating the cortical structure as it expands in size and functionality. One aspect of several of these models is the idea that cortical areas and other features arise in a combinatorial fashion by the interplay of genetically specified and environmental sources of variation. Because of some unusual aspects of gene expression in cortical neurons, cortical neurons themselves may generate an unusual variety of phenotypes (Kaushal *et al.*, 2003). Maturational gradients in cell generation and innervation in combination with intrinsic periodicities in the expression of various neurotransmitters and neuromodulators and the core set of specified cortical regions may also cause emerging arealization and segmentation, realized at different scales (Kingsbury and Finlay, 2001). Finally, intrinsically produced and environmentally specified activity is a powerful organizer of cortical areas in experimentally rewired cortices, and presumably must also be in development when it is unperturbed (Pallas, 2001).

Other than the very general feature of the allometric scaling of the cortex and some of its areas previously described (for example, Frahm *et al.*, 1984), and some systematic features of changes in the pattern of cortical cytoarchitecture with cortical size (Valverde, 1990), systematic comparisons of cortical organization at different scales that might allow us to better discriminate hypotheses about the process of cortical evolution have not been done. We undertook to quantify the manner in which the cortex proliferates, in the number of areas, and in the size of identifiable cortical areas, using primarily the extensive cortical mapping work in a variety of species of Kaas and Krubitzer as our sources for these analyses (Finlay *et al.*, 2005a). Both of our investigations using measurements taken from published studies have as their fundamental question, what the units of cortical expansion and differentiation might be and their developmental mechanisms.

3.05.2.2 Proliferation of the Number of Cortical Areas

The number of cortical areas increases generally with brain size, but the regularity of the increase was not known. We examined the proliferation of the number of cortical areas with respect to brain size in 24 mammals representing six orders, comparing visual, somatosensory, and total areal proliferation (Finlay *et al.*, 2005a). For each species, we ascertained or measured overall brain weight and overall cortical surface area; for the details of the studies employed, how a cortical area should be defined, the method of measurement and statistical analysis, we refer the reader to the original study. However, we will briefly describe our central choices and tactics.

Not all researchers agree on the definition or the number of cortical areas. Some make significantly fewer subdivisions (for example, Zilles, 1985), while others argue for the existence of a large number of smaller areas even in small brains (for example, Olavarria and Montero, 1990). Essentially, we chose to remain agnostic on the true definition of a cortical area and to rely instead on the pragmatic consideration of which explicit criteria allow us to examine the most species. The arguments of Kaas and Krubitzer on what constitutes an area are, however, compelling (for example, Kaas, 1987; Krubitzer, 1995). Their criteria for identification of an area are multidimensional, and include the presence of a fully mapped visuotopic, somatotopic, or other computed dimension, internally consistent patterns of thalamic, intracortical, and callosal input and output, and in some cases identification of the features of cortical cytoarchitecture or neurotransmitter or modulator expression.

The number of cortical areas might be best predicted by one of several independent variables,

including cortical surface area, or the weight of the whole brain, or one of the various formulas for encephalization, the ratio of brain to body weight. There was (and still is) good reason to suspect that in the case of two animals with equal absolute brain sizes, the more encephalized one might have a greater number of cortical areas. Unfortunately, in this data set overall, the largest-bodied animals and most encephalized are all primates, and the smallest, and least encephalized are all insectivores. Thus, the two measures of cortical area and encephalization are highly correlated ($r = 0.98$, $R^2 = 0.96$, $n = 19$). In addition, brain weight also correlates highly with cortical surface area, ($r = 0.95$, $R^2 = 0.91$, $n = 19$). Since total cortical surface area is the most proximate variable to the dependent variables we measured (number of cortical areas, ocular dominance column width, and axonal spread in the cortex), we have done our statistical analyses with respect to total cortical surface area, but in explanation of these data, the co-variation of cortical area with other brain measures should not be forgotten. Finally, because species may share traits through common descent rather than through independent adaptation, we employed the method of the comparison of independent contrasts (Purvis and Rambaut, 1995) in order to correct for the effects of phylogenetic relatedness.

Figure 4 shows the predictability of the 'number' of cortical areas overall, somatomotor areas only, and visual areas only from total surface cortical area (note we compare the number of areas, as a name of a unit of cortex, to the surface area, a measure of the cortex, an unfortunate ambiguity arising from their normal terminology). Though all three relationships were regular and highly statistically significant, surface area captured less of the variance when predicting the number of visual areas. The unusual scaling of striate cortex, which particularly in the primate lineage does not divide into subareas as the somatomotor regions do, may account for some of this variation.

The observation that the log of cortical area strongly predicts the log of the number of cortical areas shows that the relationship is predictable, but a logarithmic graph is not directly instructive about the kind or number of developmental mechanisms underlying this pattern of proliferation. As most biological developmental mechanisms bear some relationship to cell size, they operate over finite physical distances and not their ratios. To better visualize the change in cortex size for comparison to developmental mechanisms, the number of cortical areas is plotted against cortical surface area 'without' logarithmic transformation in Figure 5. For increases from the smallest cortices (from 10 to 400 mm^2),

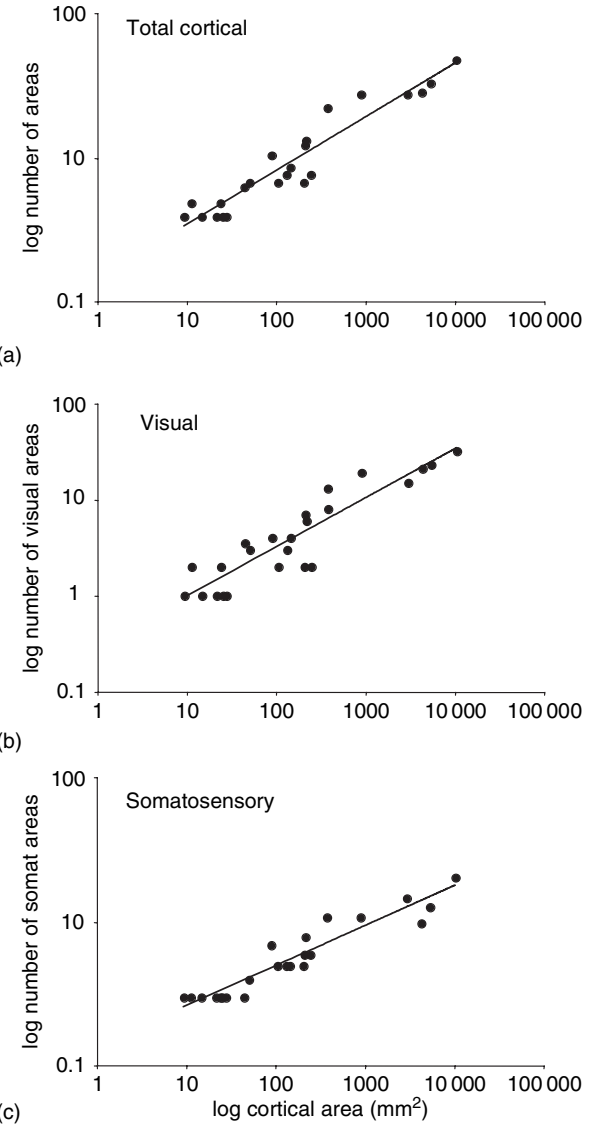

Figure 4 Simple regression of a, log total cortical area proliferation on log cortex surface area (log total areas = 0.172 + 0.379 log area, $R^2 = 0.89$, $n = 23$); b, visual area proliferation (log visual areas = –0.529 + 0.509 log area, $R^2 = 0.82$, $n = 24$); and c, somatomotor area proliferation (log somatomotor areas = 0.154 + 0.287 log area, $R^2 = 0.87$, $n = 23$).

cortical area proliferation is rapid. Thereafter, however, only massive increases in cortical area produce new cortical areas. It is also important to understand the absolute range of cortical surface expansion: in the approximately 500-fold range of the cortical areas graphed, the entire cortex of the least shrew (*Cryptotis parva*) could fit comfortably within a small fraction of the striate cortex alone of the rhesus monkey (see Finlay *et al.*, 2005a for the data employed and list of sources).

With the exception of the primary cortical areas, whose approximate position and boundaries appear to be fixed by early genetic specification, the

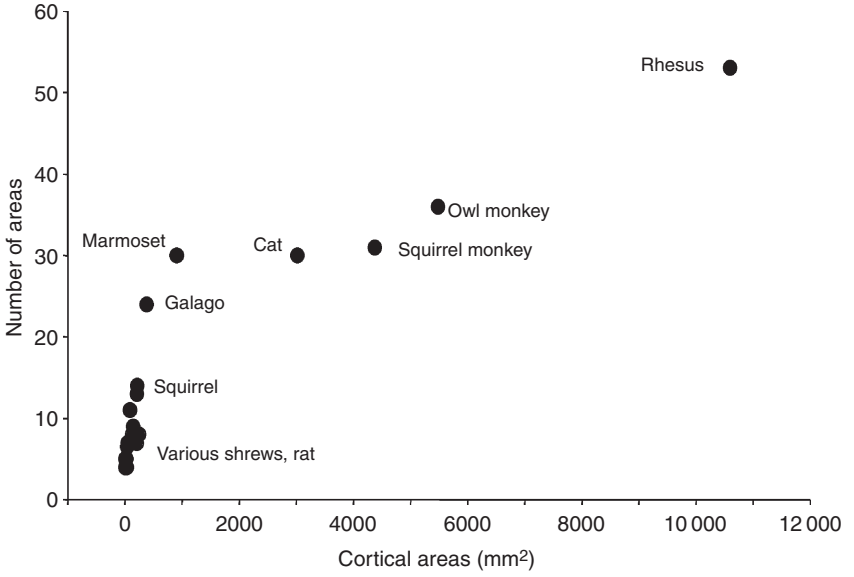

Figure 5 The number of cortical areas plotted as a function of cortex surface area, without logarithmic transformation.

mechanism by which other cortical areas emerge is not understood, but the size ranges over which the rate of proliferation changes, suggests two separate mechanisms. As cortical area increases from approximately 20 (the smallest shrews) to 400 mm^2 (galago) the number of cortical areas increases rapidly, from 4 to 24. Thereafter, another 400–4000 mm^2 of cortical area nets only another six cortical areas (those animals with 30 cortical areas enumerated are the cat, the marmoset, and the squirrel monkey). However, it is at the brain size of cats and small monkeys that the well-studied substructure of visual cortical areas begins to emerge, the ocular dominance columns, puffs, and blobs of primary visual cortex (Hubel and Wiesel, 1962, 1968), and we suggest that the cortical areas of small brains and the morphological specializations such as ocular dominance columns within cortical areas of large brains may both be manifestations of the same underlying developmental mechanism, activity-dependent axonal (and dendritic) sorting. The spatial extents of single axon arbors, dendritic trees, and ocular dominance columns in the cortex essentially do not scale with brain size (Kaas, 2000; Finlay *et al.*, 2005a; see also Manger *et al.*, 1998). Most models of stripe-in-topographic-map formation in brain tissue essentially pit axon–axon affinities against axon–substrate affinities (for example, Swindale, 1980). We hypothesize that as brains get bigger, more specific aspects of sensory stimuli may provide the correlational structure necessary (that is, the increased axon affinities) to allow the segregation of new, functionally specific cortical areas once additional volume of cortical tissue (diluting axon–substrate affinities) is made available. We have no model, as yet, for the increase in cortical areas in the largest brains.

Therefore, though the nature of peripheral sensory specializations may have a direct effect on the nature of the maps formed in the cortex, we are proposing that cortical areas also proliferate by a developmental rule, at least over the smaller ranges of brain size. This hypothesis is distinct from the idea of a cortical area as a specially selected, modular processing region. While a cortical area might be heavily involved in the processing of a particular submodality important to a species, we propose it emerges due to developmental rules present in all species (axon–substrate affinities and Hebbian fire-together, wire-together) influenced by its peripheral specialization and not the selection of new mapping and processing rules.

3.05.2.3 The Size of Cortical Areas, Sensory Specializations, and Behavioral Niche

The relative size of cortical areas in animals specialized for different niches can also inform us whether it is possible to select for the size of a cortical area and allocate resources to a particular modality differentially by changing developmental rules. Using essentially the same data sources and methods of the prior analysis, we quantified instead the surface area of primary sensory cortices (visual, somatomotor, and auditory), and the total cortical surface area devoted to the same modalities in either nocturnal or diurnal animals (Kaskan *et al.*, 2005). The nocturnal animals of this analysis all make use of their eyes for nocturnal vision, such as the rat, possum, or

owl monkey, and are not fossorial animals whose eyes have degenerated (for this contrast, see Cooper *et al.*, 1995). The fundamental assumption to be tested is that nocturnal animals should allocate fewer resources to vision and more to somesthesis and audition, and thus, across taxa, nocturnal animals should show a grade shift with a smaller primary, or total visual cortex with respect to total cortical area, and relatively larger somatosensory and auditory regions.

Prior to comparing animals in different niches, we first examined the scaling of cortical areas independent of niche and replicated a finding that has already been described in various studies with completely different species – that the volumes of identifiable cortical areas or regions each have specific, statistically discriminable allometric scaling with total cortical area, with primary visual cortex scaling at a steeper slope than other primary sensory regions (Frahm *et al.*, 1984; Stevens, 2001). The observation that frontal cortex scales at a steeper slope than other cortical regions and that humans have a larger but predictable volume of frontal cortex (Jerison, 1997; Semendeferi *et al.*, 2002) is analogous to this analysis.

Figure 6 plots the regression slopes of V1 (a) and total visual cortex, including all secondary visual areas of the parietal cortex (b) for 20 nocturnal and 8 diurnal species against total neocortex. Again, as measured by the method of independent contrasts, no significant difference appears between nocturnal and diurnal mammals in their visual cortical scaling – either in V1 or in all visual cortical areas. The regression plots themselves are notable

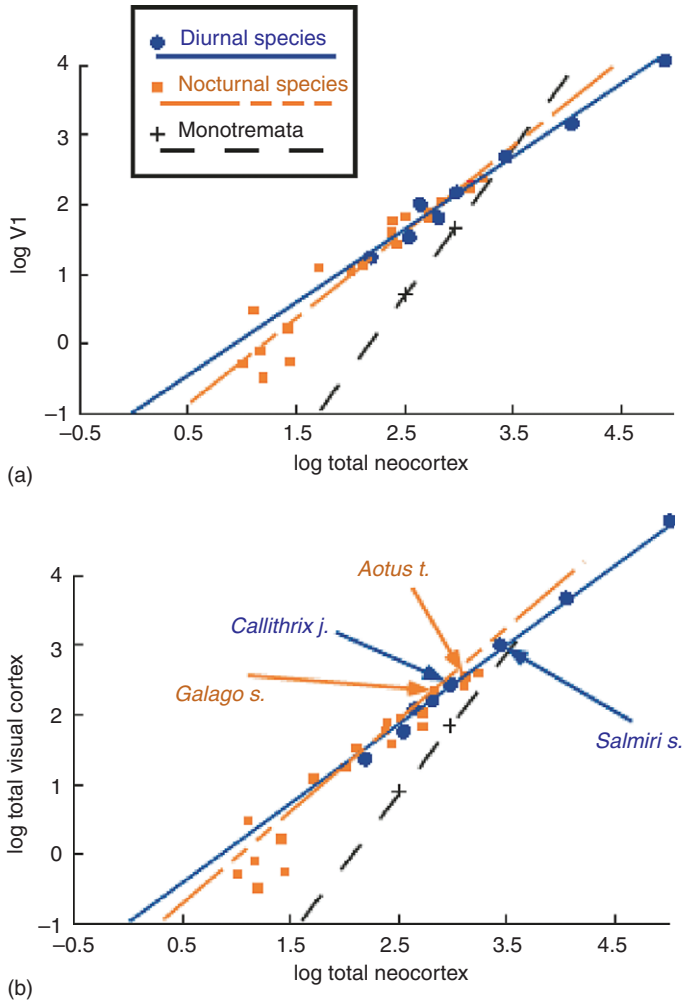

Figure 6 The volume of primary visual cortex (a) or all mapped visual cortical areas (b) versus total cortex volume in nocturnal (orange points) and diurnal animals (blue points). There is no statistically significant difference between these groups for visual cortex or motor or somatosensory cortex (not shown). Reproduced from Kaskan, P., Franco, C., Yamada, E., Silveira, L. C. L., Darlington, R., and Finlay, B. L. 2005. Peripheral variability and central constancy in mammalian visual system evolution. *Proc. R. Soc. Biol. Sci.* 272, 91–100.

for their complete overlap. If diurnal animals devoted more cortex to vision, we would expect to see a grade shift in these plots, with the diurnal regression line displaced upward but parallel to the nocturnal. Neither did nocturnal animals possess more somatosensory or auditory cortex – primary nor total – as might be expected if they could designate more anatomically defined cortical areas to modalities important in the dark. The retinas of these animals are quite different, as would be expected, with nocturnal animals possessing many more rods. Since we were able to capture statistically significant differences in the allometry of V1 and total visual cortex compared to other cortical areas independent of niche, our confidence that we could detect a difference between nocturnal and diurnal species in cortical organization is reasonable.

Should a nocturnal visual system require less neural volume than a diurnal visual system? If the nocturnal computational problem of vision could be demonstrated to be harder, it could be argued that it should require more. Our central observation is that it appears to require neither less nor more (as defined by cortical area volume) in the face of greatly different photoreceptor distributions. Nevertheless, the interpretation that greater usage should have a direct correlation with the size of corresponding neural systems is prevalent in the literature (Barton *et al.*, 1995; Barton, 1998; Barton and Harvey, 2000). These observations range from large tactical allocations of brain mass between the limbic system and neocortex, attributed to preference for the visual modality, to very specific differences in cell types associated with fugivory versus folivory. In the latter case, it is perplexing that subtle differences in visual requirements for frugivory versus folivory should be associated with differences in visual system organization, while major differences to accommodate nocturnality and diurnality should not. Niche, brain size, and cortex size are difficult to dissociate in primates. It may be, therefore, that the observations are confounded by conserved scaling phenomena unrelated to function. Alternatively, frugivory and a certain visual cortical organization might be necessarily related, but with selection on gross brain size as the only means of inducing the required detail in brain organization. For example, in a study of dexterity in animals whose dexterity ranged from hooves to hands, brain area devoted to control of the forelimbs was highly positively correlated with dexterity, but the area devoted to the forelimbs was in turn accounted for entirely by total neocortex size (Nudo and Masterton, 1990).

The hypothesis that visual cortex differs between nocturnal and diurnal mammals may yet be true, in two different ways: first, other aspects of cortex than size must surely be important, and second, our measurement of size may inaccurately assess true functional allocation. Evolution might well act on variables such as dendritic structure or density, receptive field size, axonal arborization, myelination or basic cell physiology; for example, consider the intriguing case of dyslexia, now associated in some of its forms with difficulties in detecting rapid transients in more than one modality (Merzenich *et al.*, 1993). Differential expression of some feature of synaptic transmission in the cortex may allow some individuals to represent information in rapid stimulus transients, producing ordered phonemic representations (Petersen and Fiez, 1992), while others without it do not. Details of basic cortical processing could well be different in animals of different niches.

Considering the second point, how well do the anatomically defined cortical areas reflect actual functional allocation in the cortex? A number of new imaging and other functional studies suggest that we may have been overimpressed by the major thalamic input to an area when cortical regions were named, and we thus assess true functional allocation inaccurately. Functions may play more freely over the cortical matrix specified early in development than we have imagined, with the most likely substrate through long-range intracortical connectivity. We find violations of modality specificity of cortical areas in evolution, where, for example, the visual cortex comes to respond to auditory stimulation in the blind mole rat (Bronchti *et al.*, 2002), in essentially normal function, where the auditory cortex responds to the visual stimulation of lip-reading (Calvert *et al.*, 1997), in experimental rewiring of visual information into auditory areas (Gao and Pallas, 1999), and in cases of sensory loss in humans where visual cortex becomes critical to tactile Braille reading in the early and late blind (Sadato *et al.*, 1996). In the adult, our understanding of corticocortical connectivity is limited, but recent work shows that connections may be widespread and fail to conform to traditional hierarchies and notions of connectivity (Falchier *et al.*, 2001; Rockland, 2001). Thalamocortical connections also show a distributed nature with a matrix of superficially projecting cells not confined to the intralaminar nuclei, which may serve to bind sensory experiences by connecting multiple cortical and thalamic areas (Jones, 1998). On the whole, the findings that such broad structure–function matches in the cortex exist imply that the neocortex is not a piecemeal collection

of areas, each with its own discrete function, but a generalized processing device.

3.05.2.4 Integration of Individual Variability and Developmental Plasticity into an Evolutionary Account

A final perplexing feature in the understanding of brain size regulation is the report of remarkable individual variability in the size of cortical areas, which would seem to be in stark contradiction to the very regular scaling we have just described in allometric studies. We will assume that published allometric studies have managed to determine representative mean structure volumes for scaling work and that the scaling results are accurate at the species level for which they are intended. Here we address the question of how we are to understand the importance of structure sizes if individual members of a species may occasionally but substantially differ from one another in the relative sizes of brain parts.

What kinds of variations are reported at the individual level, within species? The best information comes from a number of studies of the primate visual system, particularly the rhesus macaque. Van Essen *et al.* (1984) have found individual animals whose primary visual cortex differed by a factor of 2 or more. Similarly, the variability of the human visual cortex exceeds substantially the variability of the entire cortex (Gilissen and Zilles, 1995). There are only a few studies, to our knowledge, of the variability at the individual level of the number and arrangement of cortical areas (Qi and Kaas, 2004; Airey *et al.*, 2005), but comprehensive imaging of individuals may soon allow this kind of comparison to be made. Few of these observations have as yet been tracked onto individual variation in visual capacity, and it would be interesting to do so. However, there is reason to believe that with the exception of variations in cell density in the visual periphery that directly affect acuity, the basic processing of the visual system is robust to wide variations in number of neurons in interconnecting populations, due to the equilibrating effect of processes such as activity-dependent stabilization in early development and compensatory norming in adulthood, producing the remappings described in the previous section.

Preferential allocation of space to various kinds of sensory specializations is commonplace 'within' particular cortical areas (Suga *et al.*, 1981; Silveira *et al.*, 1989; Catania and Kaas, 1997). In addition, complete loss of a sensory system either phylogenetically (Cooper *et al.*, 1995) or very early in development reduces the volume and area of a cortical area through the epigenetic route of degeneration of the intermediate thalamic nucleus (Finlay and Pallas, 1989; Rakic *et al.*, 1991; Kahn and Krubitzer, 2002). Both of these kinds of alterations, within-modality specializations, and sensory system loss, seem likely to use the epigenetic pathway of mapping a new thalamic organization onto the cortex rather than alteration of cortical specification.

All evidence reviewed so far – regular allometric scaling of the entire cortex (Finlay *et al.*, 1998, 2001), of particular cortical areas (Jerison, 1997; Stevens, 2001; Kaskan *et al.*, 2005), and of the number of cortical areas (Finlay *et al.*, 2005a); independence of specific cortical area volume from niche (Kaskan *et al.*, 2005); individual variability (Van Essen *et al.*, 1984); and developmental plasticity (Pallas, 2001) – converges on the same interpretation. The regularity of major components of neural allometric scaling, best predicted by cross-mammalian developmental constraints, suggests that mismatches of neural ratios or of typical structure/function allocations must be a regular, compensated phenomenon in mammalian evolution (Xiong and Finlay, 1996). The independence of the relative size of primary sensory areas from niche (Kaskan *et al.*, 2005) and the coupling of dexterity to whole cortex size rather than the relative size of the somatomotor cortex (Nudo and Masterton, 1990) suggest that the relative size of a cortical area with respect to the whole cortex is either very difficult to change or unimportant to function. Large individual differences in the sizes of particular brain areas unaccompanied by flagrant disabilities tell the same story about individual development, as do innumerable instances of developmental plasticity. Thus, particularly for intrinsically cross-modal structures like the cortex, structure and function may not be uniquely linked at neurogenesis, and neural resources may be allocated to new functions as necessary. The fact that we have named a structure visual cortex (because that is typically what it does) does not prevent it from becoming Braille cortex when circumstance permits (Sadato *et al.*, 1996).

3.05.3 Computational Considerations in Cortex Proliferation

The description of the evolution of brain size, cortex size, and the size and number of cortical areas is qualitatively and quantitatively consistent, but fundamentally unsatisfying. With the exception of very broad, tactical allocations of space to different classes of neural processing (such as cortex vs. hippocampus; McClelland *et al.*, 1995) either for

whole vertebrate radiations (Gould, 1975; Finlay *et al.*, 1998) or for very broad behavioral niche (Clark *et al.*, 2001; de Winter and Oxnard, 2001), we have not found much to tie features of brain organization to environmental niche, nor to any aspect of behavior. All we have done is to speak negatively about premature allocation of function to structure and speak vaguely and positively about the cortex as a general-purpose processing device. Yet the brain, a very expensive tissue to maintain, increases with body size at an extremely predictable rate for parts that have a direct relationship to body size, and for parts that do not. Sensory systems, particularly in what appears to be their central allocation of neural volume, do not economically scale their size to their apparent usage. Cortical areas proliferate in a fairly direct relationship to overall cortical area, and there is really no direct evidence of any kind as yet linking any explicit feature of behavioral adaptation to genetically produced changes in cortical architecture. We will argue now that the missing component of our understanding may be the nature of network architecture in the brain, particularly the cortex, and an understanding of how networks scale.

We now approach the question of brain scaling and resource allocation in a different manner, considering candidates for the class of network architecture that the cortex might possess (Milo *et al.*, 2004), with a brief review of what is known about their scaling properties. We will then lay out one toy model of a network whose properties we can perturb to see the nature of its scaling. It is important to understand here that we are making no claim that the cortex necessarily resembles the model that we are exploring here. Rather, we employ models to make hypotheses about how networks might scale in an explicit and testable manner, and in so doing, perhaps recognize in the behavior of the models some aspects of cortical scaling and brain–body allometry that have been determined empirically.

3.05.3.1 What Are the Dynamics of Brain Scaling?

As brains get bigger, it is important that they do so efficiently. Brains face the problem of fitting into necessarily limited spatial and metabolic budgets (for example, Aiello and Wheeler, 1995), placing a premium on brains that minimize the amount of tissue not contributing to the organism's fitness. While pruning unnecessary cells is a relatively simple matter, decreasing average axon length is a considerably more complex problem. A longer axon is just as good as a shorter one computationally, but the longer one squanders the brain's spatial and metabolic budgets (Swindale, 2001). The ratio of somas to axons and dendritic trees decreases with scale, requiring new wiring strategies (Zhang and Sejnowski, 2000). Moreover, brain size is limited to the amount of space the head can provide, given that the head has more functions than enclosing the brain, and by the sheer expense of hauling a heavier body part. In mammals, head size itself is under some constraint by the female reproductive organs (Leutenegger, 1982).

Given the brain's limited spatial and metabolic budgets, a wide range of fundamental questions in brain network architecture must be addressed. Does the same network architecture apply to the scaling of large and small brains? What are the properties of various classes of proposed modules in the brain, from the sense of repeating, open units such as a cortical column, to encapsulated, closed processing units in the sense of Fodor (1983, 2000)? What happens when new functions are introduced into new networks, or the size of components is altered? In the following section, we outline a few of the issues arising in our first explorations of these computational questions.

There are several immediate consequences of body scaling. Different body types and sizes require different motor programs to maintain a reasonable level of energy efficiency. Additionally, changes in body type and size also change the relative muscle mass and pH buffering capacity, which in turn directly affects what motor programs will maximize the aerobic to anaerobic ratio. Typically, the larger and more complex the body type, the greater the required level of motor sophistication and physics modeling (Keimel and Roth, 1992).

While receptive field sizes and higher-level convergence vary not only across species but even across the body of a single animal, there appear to be minimum tactile acuity levels beyond which larger body size requires a larger somatosensory region in the brain. In specialized systems of various well-studied mammals, from the star-nosed mole, to the echolocation systems of bats, to the primate fovea, an increase in sensory organ acuity is closely related to the relative volume of primary sensory cortex devoted to the high-acuity region (Suga *et al.*, 1981; Silveira *et al.*, 1989; Catania and Kaas, 1997). For instance, in the acoustic fovea of bats, a hypertrophied sensitivity to a particular frequency in the cochlea is paralleled by a highly disproportionate amount of auditory cortex devoted to that frequency. Since such sensory foveas are not simply increases in receptor density, but also interrelated with unusual motor and perceptual processing demand, the subsequent within-area cortical

gerrymandering may be the result not only of an increase in afferents but of a need for more computational power. Any necessary relationship between the number of afferent units and the amount of cortical area necessary to process their signals has not, to our knowledge, been documented. Thus, the dynamics that couple afferent numbers with total brain size is an unexplored question. We will argue that a critical component of understanding brain–body allometry lies in the governing dynamics of wiring strategies employed by the brain.

3.05.3.2 Classes of Wiring Strategies

A wiring strategy is a plan by which neurons, or groups of neurons, interconnect efficiently (that is, minimize metabolic and spatial expense) while taking into account the settings of several parameters, perhaps the most important of which is overall brain size. For the purposes of this paper, we will focus our discussion on synaptic interconnections at the level of cortical columns, nuclei, or lobes; or more generally, groups of neurons, which we refer to as subnets. Ultimately, to be efficient, a wiring strategy must attain good performance on two axes: reuse and intersubnet communication.

1. *Interconnecting subnets for the purpose of reuse*. To increase efficiency, subnets should combine and produce behavior not implemented by any one subnet. The recombination of subnets results in a reuse of existing resources, conserving the number of neurons needed to accomplish any given set of tasks. Such reuse of cortical resources is very commonly observed in current imaging work. Increased executive demand and task difficulty, for instance, causes activation of the frontal cortex for a variety of different tasks across different modalities (Duncan and Owen, 2000). How subnet reusability might be achieved is a question we will address later.
2. *Interconnecting subnets for the purpose of communication*. The fundamental purpose of the brain is to control the body. No matter how elaborate the internal architecture, on output, the brain must act as a whole and cannot execute contradictory commands. Different subnets, participating in the planning and execution of any given task, must maintain some level of communication to ensure that eventually subnets work in concert with each other. In order to avoid the kind of dysfunctional situations seen following spinal cord or corpus callosum transection, which essentially produces two brains in one body (Sauerwein and Lassonde, 1994), every neuron in the brain must be connected to every other neuron in the brain either directly or indirectly.

Both subnet reusability and subnet interconnectivity can be regarded as two sides of the same problem. The average distance – measured by the number of synapses, or the number of hops, any neuron is from any other – directly dictates:

1. the extent to which that neuron can be reused in different neural circuits;
2. the recombinatorial power of the subnets, to which that neuron belongs; and
3. the ability of those subnets to communicate with other subnets.

To maximize 1, 2, and 3, a connection strategy must minimize average hop count. There are various ways this can be accomplished, depending upon computational goals and constraints.

3.05.3.2.1 Small worlds The problem of minimizing the average hop count has been extensively studied and modeled (Watts, 1999). Consider a daisy-chained group of nodes arranged in a circle. The maximum (worst case) internode distance is the number of nodes in the chain minus one; the average is the number of nodes in the circle divided by two. Provided there are two or more nodes in the circle, the constant formula for the average hop count remains fixed irrespective of the number of nodes. However, with just one projection, spanning the diameter of the circle, both the worst case as well as the average internode distance is dramatically reduced. By adding just a few long-distance projections, the average distance between neurons could be decreased in just the same way.

However, small worlds has been primarily used to model connections between computers on the Internet or the connections between people in a social network. While it has been argued (Manev and Manev, 2004) that a small world network could be a reasonable description of the brain, there are important aspects to small world networks that make them unsuitable as a model for synaptic connectivity. Unlike computers, humans, or mail hubs, neurons are not routers that are capable of directing a message to its appropriate destination. They have only one axon and any message a neuron sends reaches every dendrite on which the axon terminates. Moreover, individual neurons are virtually never mere communication relays: they process and mutate incoming data in the process of transmission.

Furthermore, single-neuron-to-single-neuron communication is not the essential wiring challenge. In most mammalian neural systems, an individual

neuron has very little computational weight. Rather, parcels of processed information are sent in parallel from one subnet on to other subnets. Neural subnets of even very modest complexity would be unlikely to communicate with each other via a single synapse; the process of decoding a binary serial stream requires many more resources than sending the data in parallel. It is important to recognize that maintaining a certain number of degrees of separation between neurons (or average hop distance) is not a wiring strategy in and of itself, but the result of a wiring strategy. Random projections, for example, could easily reduce the degrees of separation between subnets and yet be useless in actually transmitting the relevant information.

3.05.3.2.2 Nearest neighbor If the small world model does not seem to be a good model for the mammalian brain, what other models are there? Arguably, an alternative approach to efficiency would involve physically moving related subnets closer to each other, decreasing the average synapse length, although the average node distance (hops) would remain unchanged. If, for instance, two subnets are both responsible for processing information from the same modality, it might make sense to move them as close to each other as possible. The principle of minimizing axon length might be driving sensory systems to stay together in the cortex and may also be behind the ubiquitous feature of topographic maps (Kaas, 1997). On the other hand, intramodal processing of various kinds is central to cortical processing at every stage, which will necessarily disrupt wiring strategies dependent on single-modality topography. The nature of the topographic dimension to be represented often varies with the processing stage, for example, moving from cochleotopic to spatiotopic representations within the auditory system. Overall, the Hebbian fire-together, wire-together strategy cannot produce a single nearest-neighbor solution based on modality, though it may contribute to aspects of the wiring strategy.

3.05.3.2.3 Modules So far this paper has not attempted to define subnets in any other way than as simply a group of neurons working in tandem. Sometimes, such constellations of neurons have been called modules: self-contained components that are used in combination with other modules. In terms of neural circuitry, a module is a cluster of interconnected neurons that have a set of input neurons and a set of output neurons – collectively called an interface – with any number of interconnected neurons in between. Additionally, a module provides a particular functionality to other modules without requiring other modules to know how the functionality is implemented.

Modules, as a concept borrowed from computer science, strive for opacity and encapsulation, such that their implementation is hidden behind an interface that defines the scope and nature of the set of inputs and outputs the module can accept and produce (Parnas, 1972). Software-like modules have been argued to exist in the brain (Chomsky, 1975; Fodor, 1983). There are several reasons why software-like modules might make sense in a neural context. Modules are extensible – that is, modules place no requirements on the internal wiring of other modules nor connect to internal components, and thus can be added *ad lib*. Moreover, modularity could provide a level of insulation from conflicts and cross-talk that can arise in complex multifunctional systems, especially ones that have been extended by accretion (like evolution). Often, a degree of modularity is required to prevent clusters of neurons from being reused in different circuits. For example, fail-safe critical systems such as those controlling heart rate and respiration should function as autonomous (and potentially redundant) modules, but leave open a command interface that can accept high-level input. Neuroethologists have uncovered a number of systems that rely on such command neurons (Nolen and Hoy, 1984).

On the other hand, modules are not fault tolerant. A modular system requires massive redundancy to cope with the complete or even partial failure of any one module. Most significant to our discussion, though, is that modules increase the average hop distance: the bigger the module, the greater the hop distance. In other words, a smaller ratio of interface neurons to hidden neurons results in a greater average distance between any two neurons in different modules, subsequently decreasing the reusability of that module's neurons. Additionally, larger modules tend to implement more complex and therefore less abstracted units of computation, which leads to a decreased reusability of the module as a whole. Because of these wasteful features, the brain is not likely to pursue a strategy of using more than a few large modules.

3.05.3.3 Exploring the Effects of Uncoordinated Scaling in a Neural Net

Because neither nearest-neighbor nor modular wiring strategies seem likely to give a full account of the wiring of the mammalian brain, from the arguments above, and because the units of small-world networks have properties quite unlike neurons, we have chosen to employ a standard,

three-layered neural net architecture to explore the effects of scaling on network configuration. We address the effect of scaling up any part of a network architecture on the properties of the rest of the network; our interest is to gain some insight as to why the sizes of the various sensory surfaces, motor interfaces, and brain parts are so closely correlated as species scale in evolution when energetic efficiency would suggest part-by-part independence should be preferred. Prefacing with our conclusion, we find that scaling any kind of subnet within a neural net also causes a scaling response in all neighboring subnets, and arguably in all the subnets within a system.

3.05.3.3.1 The model employed We used a standard neural net architecture of either 64 or 128 nodes, limiting the number of connections to a unit in the net to 10. First, we trained a 64-node neural net on either one of two arbitrary tasks chosen not because of their similarity to any known neural process, but because they have been well studied. These two tasks are character recognition and graph fragment completion, two of the first tasks to be successfully implemented by artificial neural networks and still in use today (i.e., the US post office uses neural nets to read zip codes). No interesting differences between these two tasks emerged in net configuration and we will not address this aspect further. In order to understand the allocation of function within the neural net, we made lesions in one node at a time and measured the decrease in firing rate across all other nodes.

The absolute value in the change of firing rate across all nodes has very high contrast consequent to this lesion, with a small group of nodes significantly more affected by the lesion than all the others (Figure 7), revealing subnet contours (Figure 8).

When a subnet node is in a feedforward position, the nodes afferent to it are not affected by the lesion. Nodes affected by a lesion are fewer in number than would be expected by random, proportional interconnections.

Through single-node lesion testing, we found nine subnets in the 64-node network. We repeated the experiment with a 128-node network performing the same character recognition task (which had a proportionally scaled input layer) and found 13 subnets. Though not surprising, the first point to take note of is that average subnet size increased in response to an increase in the number of nodes in the hidden layer. With the task remaining constant, while the number of nodes doubled (128:64), the number of subnets did not double (13:9). Average subnet size went from 7.1 nodes to 9.8 nodes.

Suppose that the body becomes bigger, generating a larger S1 to maintain sensory acuity (Figure 8). Does this have consequences for the rest of the brain (or net) that the larger S1 is patched into? To explore the effects an enlarged S1 required by an enlarged body on the structure of the rest of the network, we artificially enlarged sections of the 64-node network to see whether or not the average subnet size increased. For each replication of the experiment, we grafted just one subnet from the 128-node network into an untrained pool of 64 nodes minus the number of nodes in the grafted subnet, thus entering a subnet of an average of 9.8 nodes, fixed in size, into a neural net that normally generates 7.1-node subnets. In each replication of a single subnet graft, we permuted over every possible placement of the grafted subnet into the 64-node net, principally to avoid any configuration that would artificially isolate any nodes and decrease the net size artifactually, examining only the best results from the permutations, in terms of task performance (i.e., percentage of characters correctly identified). After grafting, each 64-node net was trained, but with the provision that the grafted

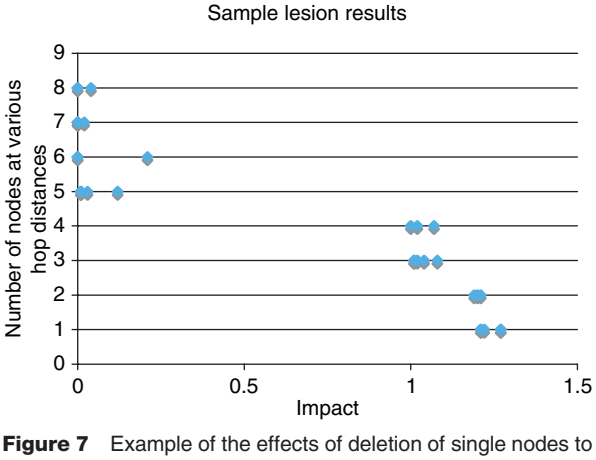

Figure 7 Example of the effects of deletion of single nodes to show connectivity structure within a neural net.

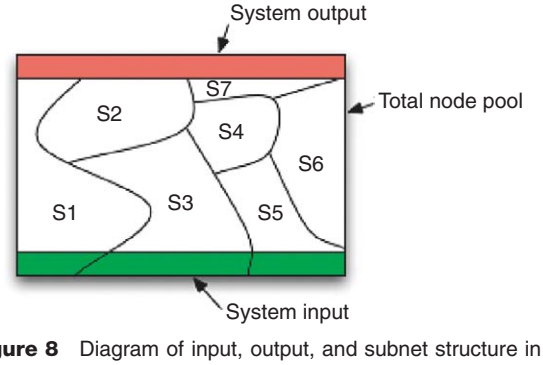

Figure 8 Diagram of input, output, and subnet structure in a trained neural net.

subnets were immutable. Grafted subnets contributed to the solution of the task, with the initially untrained net reconfiguring around the grafted component. For each neural net with a scaled-up graft, we found a smaller number of total subnets (and therefore larger average subnet size) than was the result in the original 64-node net experiment. There was an average decrease of 1.8 subnets to a mean of 7.2, with eight nodes per subnet including the grafted subnet and an average performance drop of 17% (failed character recognition or graph fragment completion). The decrease in number of subnets is significantly greater than the simple decrease expected by a subtraction of a subnet of 9.8 nodes; we trained nets on the same two tasks with 64 minus *N* nodes, where *N* is the size of each graft and is on average 9.8. Even when normalized to 64 minus *N* over 64, the control group produced a larger number (10) of smaller sized subnets that on average contained 5.4 nodes.

In summary, we found that when one subnet is scaled up in number of nodes, the other subnets in the network will scale up as well when trained, propagating the size of the new, larger unit throughout the net at the expense of subnet count as well as task performance. To maintain performance, we presume that other nodes would have to have been added in compensation, though we have not yet performed this experiment. Below, we will argue that the larger, grafted subnet is propagating its size through the net because of problems in input/output (IO) matching.

3.05.3.3.2 Possible causes of network scaling behavior Within any pool of nodes, such as the 64- and 128-node nets we used, there is always an interface to put input into the net, and register its output. However, subnets within that pool also have their own interfaces used to communicate across subnet boundaries. Subnet communication sends output from one subnet and feeds it to the input of another. As such, the number of subnet output neurons in the upstream subnet is tightly coupled with the number of subnet input neurons in the downstream subnet. Increasing the IO layer of any one subnet should cause subnets that are connected to the scaled subnet to widen their IO layers as well.

A quick look at the feedback nature of the nervous system suggests that IO matching will cascade (Figure 9). Potentially, in a strictly feedforward network, IO matching might only occur between the superscaled subnet and its immediate neighbors. However, any subnets that communicate not only with the scaled subnet, but also with each other would also have to scale their output layers to maintain compatibility with each other, causing a systemwide IO width increase cascade. Multiple types of compensation for systemwide scaling could possibly result, reconfiguring subnets in various ways. Even so, scaling any single component will inevitably tend toward a decrease in the number of resources dedicated to providing computational services as compared to the number of resources spent on wiring in the new, larger component.

At large scales, the increase in the number of subnets causes another kind of fragmentation of net structure when engaged in the same tasks. To maintain a relatively stable and low number of average hops, it is necessary for subnets to be directly connected to a number of other subnets that is proportional to the total number of nodes in the pool. This means as the pool grows larger, subnets will on average experience an increase in the number of other subnets to which they are directly connected. Ordinarily, downstream subnets converge on a single input layer, and upstream ones receive their input for multiple terminations of the same output layer. However, it may be the case that not all downstream subnets are sending information in the same encoding, or it may also be the case that some downstream subnets are transmitting information that could clobber other senders' output. In both cases, there is a need for a dedicated set of interfaces to the same subnet, such that input from different subnets may be coming in on different nodes.

As the number of nodes in a pool grows, so too does the likelihood that within any given set of

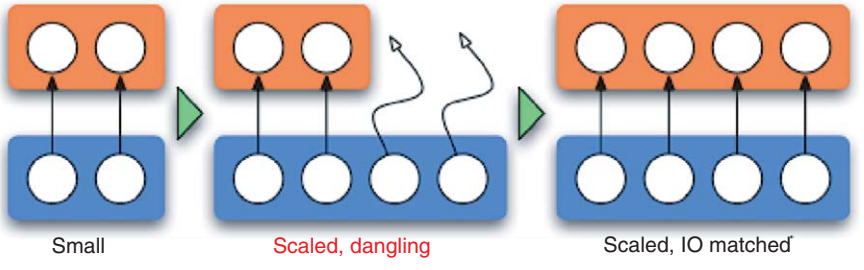

Figure 9 Diagram of the cascade of the magnitude of input/output (IO) units within a neural net.

subnets connected to the same subnet, some of the members of the set will require their own dedicated interface on the subnet to which they are connected. The result is a larger number of neurons in the interface layers and a smaller number of neurons in the hidden layers, increasing the number of nodes involved in IO, leaving fewer nodes available for actual computation. This phenomenon, like IO matching, makes subnets less efficient as the pool to which they belong scales up.

We suspect that simply inserting more neurons between the input and output neurons to improve processing power is not a viable way around the cascading scale effect, though we intend to investigate this kind of manipulation in future work. First, some subnets may already exist that cannot be significantly upgraded because they are at or close to the apex of the resource consumption to the computational power ratio. Secondly, certain important types of subnets, such as those that store memory, would require an increase in the IO layer to provide greater capacity, and more memory requires a larger interface to address that memory. Here too, the larger interface would trigger a cascading scale effect; any subnet interested in storing or retrieving information would need the ability to handle the memory's address space.

We believe that the decrease in both task performance and the number of modules as the result of grafting superscaled modules suggests why evolving brains scale in a coordinated manner. When a system is presented with a scaled-up component, it undergoes a systemwide reorganization that both changes underlying intermodule wiring strategies and the number and function of the modules themselves. The scaling of an area of the brain such as the somatosensory strip, S1, would have a profound impact on the rest of the brain. This cortical area participates not only in somatosensory analysis, but also is activated during word-finding tasks with a somatosensory component (Pulvermuller, 2001). The underlying mechanism that drives the correlation between behavioral complexity and relative but not absolute brain size may be the scaling properties of neural networks.

3.05.4 Overview: Distinguishing Developmental and Computational Structure from Constraint

3.05.4.1 What Are the Units of Brain Architecture in Development, Evolution, and Mature Function?

Developmental and evolutionary biologists and computational scientists attempting to understand the brain are all engaged in parallel quests to describe the fundamental units of brain structure and a syntax for their interaction. Each addresses a separate kind of change in the brain, over evolution, development, or while functioning. Much is to be gained by understanding how the requirements of each aspect of brain change reinforce and constrain each other. Much confusion is the result, however, if the structure in variation of these different types of brain change is arbitrarily assumed to be the same, or if terms are exported and imported between areas of study without particular attention to their referents. The unit of a cortical area is a good example of this. In the initial stages of studying mature cortex physiology, the cortical area was viewed as an extremely important level of analysis, in that each area was hypothesized to take its input and perform a particular transform of it before passing it up to the next, from area 17 to 18, to 19, and so on (Hubel and Wiesel, 1998). As is well known, neither the circuitry (DeYoe and Van Essen, 1988) nor the functional allocation proved to be very well described this way (for example, Schiller, 1993). Although debate persists for some particular cases (for example, Gauthier *et al.*, 1999; Haxby *et al.*, 2001; Grill-Spector *et al.*, 2004), most agree that perceptual or cognitive functions of even minor complexity are rarely associated uniquely with particular cortical areas and are usually highly distributed across the cortical surface (one example each from four independent functional domains: Andersen, 1995; Duncan and Owen, 2000; Haxby *et al.*, 2001; Pulvermuller, 2001). So, while the cortical area remains an extremely important aspect of cortical syntax, containing topographically ordered sensory and computed maps and highly constrained thalamocortical and downstream connectivity, comparison of present box diagrams of information flow for disparate functions would show much overlap and subdivision.

The researchers examining the developmental neurobiology of the cortex also began by concentrating on the cortical area, the holy grail of this enterprise to determine if particular cortical areas were genetically unique in the absence of patterning input. The essential hypothesis to be tested was whether the structure of mature cortical areas could be identified in the initial deployment of cells. Thus, researchers were very interested to determine if location in the cortical germinal zone was faithfully transmitted to the mature cortex, to determine if the nature of cortical areas could be fixed at the time of neurogenesis (Austin and Cepko, 1990; Rakic, 1990), or whether the properties of cortical areas could survive embryonic transplant

(O'Leary and Stanfield, 1989) or thalamic rewiring (Pallas, 2001). Though the picture is very far from complete, we now know that the primary sensory and motor areas may be identified by the graded pattern of gene expression that serves both to organize the polarity of cortical maps and direct early thalamocortical and intracortical connectivity (Ragsdale and Grove, 2001). Whether any comparable specification exists for areas other than the primary sensory and motor regions is not known, but it appears unlikely, and even within the most specified regions, much residual plasticity is retained (Kingsbury and Finlay, 2001). Developmental neurobiology has therefore produced evidence for unique specification of only a few of the multiple areas that are seen in the mature brain.

Comparative neurobiologists found evidence for a conserved set of primary regions across mammals (Krubitzer, 1995), but as this paper has argued, there is reasonable evidence that cortical areas proliferate predictably as a function of cortex size, and very little evidence to suggest that the relative size or number of cortical areas is related to niche-specific requirements or special adaptation (Nudo and Masterton, 1990; Kaskan *et al.*, 2005). We suggest that the comparative evidence is consistent with essentially three types of cortical areas, a set of primary sensory regions that are genetically specified and conserved across mammalian brains, a set arising from axonal sorting interactions in relatively small brains and similar to other features of local cortical topography such as ocular dominance columns and cytochrome oxidase blobs, and a final set arising from some unknown mechanism at very large scales.

The relationship of the concept of a cortical area in evolution, development, and mature function is subtle, important, and complex, but it is no longer the simple concept that the cortical area is the computational unit of the functioning cortex, the genetically specified fundamental unit of the developing cortex, and the selected-on unit of cortical evolution. Are there other candidates for fundamental units of brain development and evolution?

The developmental radial unit and its outcome in the mature brain (Rakic, 1990), the cortical column, is certainly a central aspect of the story, but our first explorations in the computational aspects of scaling suggest we might look for units at an intermediate level of analysis. Subnets emerged in neural nets trained on generic tasks, revealed by their relatively greater interconnectivity. These subnets have properties in computer simulations that demonstrate how cascading IO scaling is also likely to be a problem in real-world brain scaling. Subnets may be an essential unit of a neural wiring strategy, using modularity at a micro scale, where clusters of neurons implement logical units of computation, rather than the higher-level behaviors that have been the focus of most modular accounts of the brain. The demonstration of similar subnet structure in the brain and investigation of their scaling properties in brains of different sizes would be useful: possible candidates might be like the axonal architectures that link the cortical representations of extended visual contours or other spatial structures that can appear either early in development (Fitzpatrick, 2000) or later as a result of learning (Gilbert *et al.*, 1996).

A particular subnet need not be restricted to use within a single class of behavior; it can be used concurrently across different and functionally unrelated subnets. To grow larger, a subnet would recruit neurons from subnets with which it already shares neurons. Conversely, to contract, a module would relinquish neurons shared with neighboring micromodules increasing the number of neurons dedicated to a single module. Subnets might also be replicated across the brain, especially when it is cheaper to replicate than connect; the probability a subnet will replicate is inversely related to its size and directly related to the number of other subnets that depend on it.

3.05.4.2 Allometric Constraints May Show Us the Scaling Properties of Brain Networks

At this point, we may turn around to look at some of the most highly conserved aspects of mammalian brain scaling and raise them as potential points of interest for their network scaling properties. At the most basic level of proliferation, the change in number of motor neurons will be less than the proliferation of secondary sensory neurons as brains enlarge. Why?

Looking at the proliferation of the thalamus, it is quite notable that the primary sensory regions, the lateral geniculate, medial geniculate, and ventrobasal nuclei have their terminal birth dates earliest and proliferate at a greatly reduced rate compared to the rest of the thalamus and, of course, with respect to the cortex. For the pulvinar and frontally connecting regions of the thalamus, neurons are even conscripted in large brains from new regions to expand their size. Our initial work would suggest that the primary thalamic regions might be kept small, perhaps even to some detriment to acuity, to minimize the number of neurons wasted on IO functions and allow the proliferation of large numbers of

reusable subnets (Gilbert *et al*., 1996). Finally, it is clear that the size of large regions of the brain, cortex, olfactory bulb, hippocampus, and cerebellum may enlarge differentially, usually at a rate characteristic of whole radiations. How does the wiring between large regions stay exempt from the scaling and wiring constraints we have described thus far?

3.05.4.3 Where Do We Look for Species-Specific Adaptations in the Brain?

We have described several kinds of sources for species differences in the brain already, including the residual variation left after allometrically predictable variation is taken into account, the obvious possibility of modifications of neuronal architecture and function, and our two-hit model for placing new functions in areas destined to become disproportionately large in large brains by virtue of their developmental placement. We end with a plea that further investigation of the nature of brain scaling and neuroanatomical evolution abandon models of brain function that have not been used in sophisticated analysis of brain function for the last 25 years, and consider the network structure of the brain, and how computations might be deployed over networks of different scales. Hypothesis development in this next phase of understanding brain evolution will require that the hypotheses be explicit about the nature of networks and the nature of the computations embodied there.

3.06 Mosaic Evolution of Brain Structure in Mammals

R A Barton, University of Durham, Durham, UK

Glossary

allometric	Changes in the quantitative value of a trait (e.g., brain size) with changes in some other measure of size (e.g., body mass). Positive allometry refers to a relationship in which the trait changes more rapidly than size (e.g., as in neocortex size relative to brain size); negative allometry refers to a relationship in which the trait changes more slowly than size (e.g., brain size relative to body size).
correlated evolution	The tendency of traits to change together with statistical predictability across independent evolutionary events.
grade differences	A significant difference between phylogenetic groups in the quantitative value of a trait after controlling for another variable (usually size).
haplorhine	The phylogenetic suborder of primates that includes apes, monkeys, and tarsiers.
insectivore	A taxonomically varied grouping of mammals including the order Insectivora (shrews, hedgehogs, and moles) and tenrecs.
orbital convergence	The degree to which the orbits face in the same direction.
partial correlation	The correlation between two variables with the effects of variation in other variables held constant.
strepsirhine	The phylogenetic suborder of primates that includes lorises and lemurs.
taxon (pl taxa)	A grouping of organisms according to their placement within a system of hierarchical classification, usually based on phylogenetic relationships.

3.06.1 Introduction

Organisms tend to evolve in a coordinated fashion. Hence, as overall size increases, so does the size of limbs, muscles, tendons, and internal organs, and this is necessary for the organism to function efficiently. A large proportion of the variance in the size of individual body parts is therefore in some sense explained by overall size. On the other hand, parts also vary independently of overall size: "The concept of mosaic evolution dictates that organs will evolve in different ways to meet varying selective pressures" (Gould, 1978, p. 66). For example, whereas the size of the testes correlates closely with the size of other organs and overall body size, testes of promiscuously mating species are large relative to body size as an adaptation for sperm competition (Harcourt *et al.*, 1996). As with the organs of the body, individual brain components may vary in adaptively specialized ways, independently of variation in whole brain size. Unlike bodily organs, however, brain components have extensive neural interconnections to support the integrated processing of information, potentially limiting the importance of mosaic evolution. Nevertheless, individual components are grouped within structurally and functionally differentiated neural systems specialized for handling particular cognitive operations, upon which natural selection might act at least partly independently of evolutionary change in other systems:

> . . . a relatively large brain may result from differential increase in the size of the cortical mass, subcortical structures, or the cerebellum. . .It is axiomatic that those areas of the brain that do increase in size are often related to specializations in certain sense organs, and correlate with the collection, storage and retrieval of specific kinds of data relevant to the niches the animals exploit (Eisenberg, 1981, p. 276).

Comparative tests of this hypothesis are of three broad types, each of which examines variation in the size of individual components after accounting for the effects of overall brain size or of the size of other brain components: tests for taxonomic differences in component size, tests for correlated evolution between separate components of the same functional system,

and tests for correlated evolution between brain components and behavioral ecology. Most analyses of these issues use the invaluable data on brain structure volumes produced by Stephan *et al.* (1981, 1991). Because many of the components measured by Stephan *et al.* are anatomically and functionally heterogeneous, and because functional systems are distributed across these components, they tend to show strong patterns of covariation (Finlay and Darlington, 1995). For example, the visuomotor system includes nuclei in the thalamus, pons, cerebellum, and neocortex, so natural selection on visuomotor abilities may have caused coordinated evolution of all four structures as well as the fiber tracts connecting them. This means that analyses must be capable of distinguishing between patterns of coordinated evolution resulting from selective size change in distributed neural systems and patterns of coordinated evolution resulting from developmental processes (see Cortical Evolution as the Expression of a Program for Disproportionate Growth and the Proliferation of Areas).

3.06.2 Taxonomic Differences in Relative Size of Brain Structures

A prominent feature of brain structure variation in mammals is the extent of variation in the size of the neocortex. In humans, the neocortex comprises approximately 75% of total brain volume, whereas in some shrews the equivalent figure is under 10% (Frahm *et al.*, 1982). However, the presence of a proportionately large neocortex in large-brained species is not in itself evidence for selection specifically on the neocortex, because the size of the neocortex scales with positive allometry relative to other brain parts (Frahm *et al.*, 1982; Finlay and Darlington, 1995). This allometric relationship appears to be due to the scaling of cortical connectivity and therefore of the white matter component of the neocortex (Frahm *et al.*, 1982; Ringo, 1991; Zhang and Szenowski, 2000; Barton and Harvey, 2000) (see Scaling the Brain and Its Connections). Nevertheless, statistically significant differences in neocortex volume between taxa are apparent even after taking allometric scaling into account. Compared with insectivores, primates have a relatively large neocortex, and within primates, haplorhines have a larger neocortex than do strepsirhines (Barton and Harvey, 2000). After controlling for the size of other brain structures, the neocortex is on average approximately five times larger in primates than in insectivores, with some comparisons yielding 10-fold differences (Barton and Harvey, 2000). The differences in neocortex size are mirrored by differences in the size of visual cortical regions relative to the rest of the neocortex (Barton, in preparation) and by differences in the volume of a subcortical visual structure, the lateral geniculate nucleus (Barton, 1999), suggesting that visual specialization may underlie neocortical evolution in primates (see below) (see The Evolution of Visual Cortex and Visual Systems).

The mosaic nature of change in brain proportions during primate evolution is clearly apparent when the sizes of major components are plotted against body mass (Figure 1; see also Barton, 2000). Some

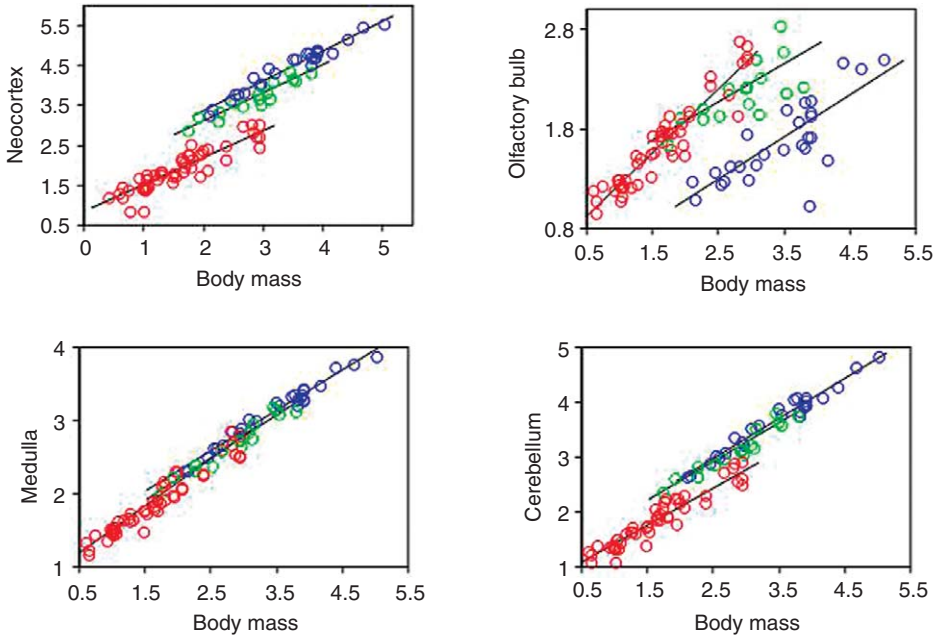

Figure 1 Taxonomic differences in the volume of four brain structures. Log-transformed structure volumes are plotted against log-transformed body masses. Red circles, insectivores; green circles, strepsirhine primates; blue circles, haplorhine primates.

components (e.g., the neocortex and cerebellum) show clear grade differences between taxa, whereas others (e.g., the medulla) do not. In addition, there are different grade effects for different structures: both neocortex and cerebellum size are greater in primates than in insectivores, but only neocortex size differentiates between strepsirhine and haplorhine primates. On the other hand, cerebellum size is greater in apes than in other catarrhines (Rilling and Insel, 1998) and the cerebellum is also enlarged in some cetaceans (Marino *et al.*, 2000). The main olfactory bulbs are larger in strepsirhine primates and insectivores than in haplorhine primates, a difference that is at least partly associated with adaptive radiation into nocturnal and diurnal niches (Barton, 2006). Finally, comparison of individual structures in species with similar brain sizes reveals the extent of system-specific size change. The superior colliculus is approximately 10 times larger in ground squirrels than in rats, despite the overall similarity in brain and body size (Kaas and Collins, 2001).

An important methodological point arising from the patterns of mosaic evolution illustrated in Figure 1 is that correlation coefficients and regression slopes computed across species without regard to phylogenetic effects are incorrect (Nunn and Barton, 2001). For example, the slopes computed across phylogenetic grades will give the impression that the size of the neocortex scales with a much steeper exponent than is the case for other structures, but this is largely an artifact of the evident phylogenetic effects (Barton and Harvey, 2000). This is important, because scaling exponents have been taken as being indicative of developmental mechanisms limiting mosaic brain evolution (Finlay and Darlington, 1995).

3.06.3 Correlated Evolution between Components of Functional Systems

If specific neural systems were targets of natural selection, the components of such systems, which may be distributed across major brain subdivisions, should have changed in size together, but independently of change in other systems. Tests for correlated evolution use phylogenetic comparative methods such as independent contrasts (Felsenstein, 1985; Harvey and Pagel, 1991). Correlated evolutionary change in functionally linked brain components, independent of change in other structures, is indicated by significant multiple regression coefficients or partial correlations between contrast values. For example, contrasts in visual cortex size correlate significantly with contrasts in lateral geniculate nucleus (LGN) size, holding constant the effects of variation in other brain components (Barton *et al.*, 1995), indicating that the visual system has evolved independently of overall brain size (see The Evolution of Visual Cortex and Visual Systems). In general, partial correlations between structures within neural systems seem to be ubiquitous: among a range of brain systems, anatomical and functional connections closely predicted significant positive partial correlations between pairs of structures in two mammalian orders (Barton and Harvey, 2000). In some cases, it has been possible to test the prediction of correlated evolution at the level of individual nuclei. In the cortico-cerebellar system, connected nuclei in the hind-, mid-, and forebrain have evolved together (Whiting and Barton, 2003). Of the four main vestibular nuclei and three cerebellar nuclei, the two that have direct connections (the lateral vestibular and middle cerebellar nuclei) are those that show correlated evolution after controlling for the size of other structures (Figure 2). Hence, anatomical connections

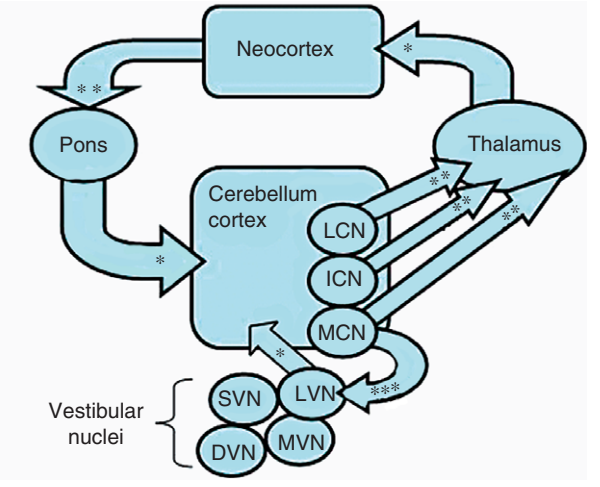

Figure 2 Correlated evolution among components of the cortico-cerebellar-vestibular system. The diagram summarizes analyses presented in Whiting and Barton (2003). Independent contrasts in the volume of each component were regressed on volume contrasts in connected components and in other brain structures. Asterisks represent significant partial regression coefficients between contrasts in the connected components, controlling for other brain structures. For example, the pons and neocortex exhibit significantly correlated evolutionary change, controlling for variation in the rest of the brain. The two nuclei in the cerebellum and vestibular complex that have direct anatomical connections (MCN and LVN) correlate even after accounting for variation in other cerebellar and vestibular nuclei, indicating that functional anatomy predicts correlated evolution at a detailed level. MCN, medial cerebellar nucleus; ICN, interposed cerebellar nucleus; LCN, lateral cerebellar nucleus; LVN, lateral vestibular nucleus; SVN, superior vestibular nucleus; DVN, descending vestibular nucleus; MVN, medial vestibular nucleus. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$.

predict detailed patterns of correlated evolution. The presence of connections between nuclei across major subdivisions of the brain explains why those subdivisions have tended to evolve in a coordinated fashion (Finlay and Darlington, 1995; Barton and Harvey, 2000).

The fact that brain nuclei co-vary in accord with their functional connections can be used to help resolve uncertainty among neuroscientists about aspects of brain organization. Comparative analysis may therefore contribute to systems neuroscience. One example concerns debate about the structural and functional integrity of the amygdala. On the basis of anatomical, pharmacological, and electrophysiological data, Swanson and Petrovich (1998) called into question the existence of the amygdala as a structurally and functionally coherent unit, arguing that the term amygdala refers to a collection of disparate nuclei that are really parts of different neural systems. Some other researchers, however, have drawn attention to the dense connections between nuclei within the amygdala (see Aggleton, 2000). The problem lies in deciding what constitutes sufficient evidence to conclude that the amygdala either does, or does not, exist as a structurally and functionally integrated entity, hence breaking the cycle of claim and counterclaim based on affinities among nuclei and differences between them, respectively. The crux of the matter is how such nuclei evolved. Like all complex biological traits that function conspicuously well, neural systems exist by virtue of the fact that they evolved by the process of natural selection (Young *et al*., 2000). Therefore, the question of whether particular components constitute parts of a unified neural system or structure is essentially an evolutionary question: did they evolve together, in a coordinated fashion, and in a way that cannot be attributed merely to their integration within a larger, more global system (e.g., the limbic system, or even the brain as a whole)? Phylogenetic analysis of comparative data in primates and insectivores clearly shows that the amygdala coheres as an evolutionary unit: after controlling for variation in a range of other brain structures, including other limbic structures, separate groups of nuclei in the amygdala show significantly correlated evolution (Barton *et al*., 2003), hence refuting the claim that they are parts of entirely different neural systems (see Evolution of the Amygdala in Vertebrates).

To what extent can the evolution of central neural structures be linked to specializations in certain sense organs (Eisenberg, 1981)? Analysis of data on the primate visual system supports the hypothesis that various features of the morphology of peripheral visual structures, including the degree of orbital convergence, size of the eyes, the density of retinal ganglion cells, and the size of the optic nerves, correlate with the relative size of the visual cortex (Barton, 2004; Barton, in preparation). Similarly, among insectivores, species differences in the organization and fine structure of cortical areas are associated with differences in peripheral sensory specializations (Catania, 2000).

3.06.4 Correlated Evolution between Individual Components and Behavioral Ecology

Comparative studies have begun to reveal the ecological correlates of mosaic brain evolution in mammals. In primates, visual system evolution and olfactory system evolution are both associated with ecology, though in different ways (Barton *et al*., 1995; Barton 1996, 1998, 2006, in preparation). Diurnality is associated with increased relative volume and cell number in parvocellular, but not magnocellular, layers of the LGN, and decreased olfactory and accessory olfactory bulb volume (Barton *et al*.,1995; Barton, 1998, 1999). The evolutionary dissociation between parvo- and magnocellular pathways accords with experimental data on functional segregation within the visual system and on behavioral attributes of different species. Parvocellular projections to the visual cortex mediate fine-grained, acute and color vision, abilities that are characteristic of diurnal primates (Allman and McGuinness, 1988; Allman, 1999). Parvocellular LGN size and visual cortex size also correlate positively with the degree of frugivory and with social group size, independently of the correlation with activity period (Barton 1998, 1999), suggesting that visual system evolution may have been affected by several aspects of lifestyles. The size of the accessory olfactory bulbs, which mediate pheromonal processing, are, as expected, more closely associated with social variables, such as group size (in platyrrhines) and spatial dispersion (in strepsirhines) than with ecological variables such as diet (Barton, 2006). Correlated evolution between individual brain structures and behavioral ecology has also been documented in other mammalian taxa. In carnivores, relative olfactory bulb size correlates positively with home range size and negatively with aquatic habits (Gittleman, 1991). In bats, wing area and habitat complexity correlate with the relative size of the auditory inferior colliculi (among echolocating species) and with relative hippocampus size (Safi and Dechmann, 2005).

3.06.5 Explaining Brain Size as a Function of Mosaic Evolution: Visual Specialization in Primates

The functional significance of brain size has been extensively debated (e.g., Jerison, 1973; Holloway, 1974; Striedter, 2005). In general, larger brains contain more neurons and synapses and are therefore in some sense computationally more complex than smaller brains. Support for the idea of mosaic brain evolution suggests that we can be more specific and describe at least the broad types of information processing that have been enhanced during brain expansion (or compromised during brain size reduction) in particular lineages. Primates again provide an example. In addition to being large-brained, primates are visually specialized. These visual characteristics include the following: a high degree of orbital convergence associated with stereoscopic vision; a concentration of ganglion cells in the central retina; a greatly expanded representation of the central field in visual cortex; a distinctive pattern of projections between eye and brain; a distinctly laminated LGN within which information from the same hemifield of each retina is brought into visuotopic register in separate layers, before converging on numerous single binocular neurons in the visual cortex; and relatively numerous and extensive visual cortical regions (Allman and McGuinness, 1988; Allmann, 1999). This suite of visual features was a fundamental component of the adaptive shift in the evolution of the first primates, but there is variability in most or all of these features within the order. This interspecific variability correlates with overall brain size. The degree of orbital convergence and the relative size of the LGN and primary visual cortex correlate with overall neocortex size and brain size relative to body size (Barton, 1998, 2004). Hence, the evolution of large neocortices and large brains relative to body size was associated with disproportionate expansion of the visual system. Thus far, this is the only documented case in which size variation in a specific neural system has been related to variation in brain size. Motor systems may also be implicated: the evolutionary expansion of the neocortex correlates with increases in cerebellum size, independently of overall brain size (Whiting and Barton, 2003). Given the role of the cerebellum in the sensory control of movements, these results may together indicate that brain size evolution in primates is associated with enhancements of fine visuomotor control. Broader understanding of mammalian brain size evolution will require investigation of mosaic size change across a variety of neural systems and phylogenetic lineages.

3.06.6 Conclusions

The components of any adaptive complex, such as the mammalian brain, by definition undergo coordinated evolution. At the same time, functional differentiation of neural systems within the mammalian brain potentially creates scope for a mosaic pattern of evolutionary change overlying the allometric covariation of individual components. Comparative analyses unequivocally show that specific systems and structures have evolved in part independently of change in overall brain size and that such system-specific change correlates with behavioral ecology. The fact that patterns of correlated evolution predict anatomical and functional relationships means that phylogenetic comparative analysis can be used to test hypotheses about brain organization. The increase in neocortex and overall brain size during primate evolution is associated with disproportionate expansion of the visual system and with other aspects of visual specialization, such as increased orbital convergence, as well as with cerebellar expansion. Hence, primate cognitive specialization may be based on the elaboration of visual and visuomotor systems.

3.07 Developmental Studies on Rewiring the Brain: What They Tell Us about Brain Evolution

J R Newton, D T Page, and M Sur, Massachusetts Institute of Technology, Cambridge, MA, USA

Glossary

arealization	A process by which neuroectoderm that will give rise to the cerebral cortex is partitioned into anatomically and functionally distinct areas.
cerebral cortex	A telencephalic structure where learning, memory, reasoning, and sensory perception occur.
lateral geniculate nucleus (LGN)	A subdivision of the thalamus that normally processes and relays visual information.
medial geniculate nucleus (MGN)	A subdivision of the thalamus that normally processes and relays auditory information.
thalamus	A diencephalic structure that processes and relays information from the senses to the cortex.
transcription factor	A molecule that regulates the transcription of other genes.

3.07.1 Introduction

Understanding neural development can inform us about how a brain structure evolves. By examining the development of a cortical region, one can elucidate the role that molecular cues and afferent inputs play in determining the evolution of a cortical structure, its function, and associated behaviors. Cross-modal experiments provide insight through a gain-of-function approach, whereby inputs of one sensory system are redirected to a different sensory modality. This allows the role of intrinsic and extrinsic factors to be distinguished and their relative contribution to cortical structure, function, and behavior to be determined. Here we will discuss how molecular cues in early development may influence the evolution of a cortical structure, as well as how rewiring visual inputs to innervate the auditory pathway provides insight into the role of patterned electrical activity as a key extrinsic factor determining the ultimate organization and function of a structure (see A History of Ideas in Evolutionary Neuroscience, Relevance of Understanding Brain Evolution).

3.07.2 Early Development and the Evolution of Cortical Structure: Molecular Influences on Cortical Arealization

The mammalian cerebral cortex develops as a continuous sheet of cells that is divided into anatomically and functionally distinct areas during the course of development (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates). This results in a pattern of cortical areas that is generally consistent among individuals within a species but varies between species, especially with respect to size and areal position (Krubitzer and Kahn, 2003). Influence over the pattern of these areas can potentially come from two sources: extrinsic sensory input, which reaches the cortex in an area-specific manner, and intrinsic molecular cues, which are encoded in the genome and expressed during development. Identifying the contributions of each of these is essential for understanding the mechanisms underlying the formation and diversification of the cerebral cortex. The first indication of arealization in the developing cortex is regional gene expression (Rubenstein *et al.*, 1999). Two studies have used mice in which thalamocortical axons fail to reach the cortex to examine the effect of blocked sensory input on early arealization

(see The Role of Transient, Exuberant Axonal Structures in the Evolution of Cerebral Cortex). Interestingly, in these mice (*Gbx2*$^{-/-}$ or *Mash1*$^{-/-}$), the initial expression of regionally expressed cortical genes appears normal (Miyashita-Lin *et al.*, 1999; Nakagawa *et al.*, 1999). This indicates that patterned gene expression occurs independent of extrinsic factors and argues that cortical pattern formation may be investigated using a logic similar to that used to study pattern formation in other embryonic tissues.

Identifying interactions among networks of transcriptional factors and signaling pathways has been critical in understanding the basic mechanisms of embryonic patterning (Wolpert, 2002). While a variety of transcription factors have been implicated in cortical arealization (O'Leary and Nakagawa, 2002; Sur and Rubenstein, 2005), one of the most heavily studied is Emx2. This molecule is expressed in a gradient across the caudal cortex, and a loss of Emx2 function results in an expansion of the rostral cortical markers at the expense of markers for the caudal cortex (Bishop *et al.*, 2000). Constitutive overexpression of Emx2 in mouse cortical precursors using *nestin cis*-regulatory elements is capable of altering both the size and position of primary sensory areas, and this change is complementary to that seen when Emx2 function is reduced (Hamasaki *et al.*, 2004). Intercellular signaling also appears to be involved in arealization, with the most well-studied pathway being the Fgf receptor (Fgfr) pathway. Fgf8, which is a secreted ligand in this pathway, is expressed in a high-rostral, low-caudal gradient across the mouse cortex during development. One study has shown that Fgf8 is capable of changing the location and patterning of mouse cortical areas when ectopically expressed early in embryogenesis (Fukuchi-Shimogori and Grove, 2001). Furthermore, mice homozygous for a hypomorphic Fgf8 allele show rostral shifts in the expression of arealization marker genes (Garel *et al.*, 2003), and projections that originate in the caudal cortex project ectopically into the rostral cortex (Huffman *et al.*, 2004). Fgf8 and Emx2 appear to interact with one another during cortical development (Fukuchi-Shimogori and Grove, 2003; Garel *et al.*, 2003; Hamasaki *et al.*, 2004), although the nature of this interaction awaits clarification.

Thinking about cortical arealization as a network of molecular interactions can help us understand how changes in cortical properties may have arisen in evolution. Subtle mutations at the genomic level may result in alterations in molecular interactions that can lead to profound phenotypic changes when amplified over the course of development. This, in turn, provides a mechanism for bringing about gross phenotypic change in evolution (reviewed in Pires-daSilva and Sommer, 2003). It is possible to imagine, for example, that a mutation causing a subtle change in expression level or binding affinity in a patterning molecule such as Fgf8 may result in a significant change in cortical arealization, which would then be subject to evolutionary selective pressure. This can also help us understand how the wiring of sensory input into the cortex may change during evolution. In addition to mediating early arealization, intrinsic factors also function in establishing thalamic input into the cortex (Lopez-Bendito and Molnar, 2003). For example, loss of function of the transcription factors Pax6 and Emx2 disrupts normal thalamocortical pathway development (Bishop *et al.*, 2000; Hevner *et al.* 2002; Jones *et al.*, 2002), and the Ephrin signaling pathway also appears to be involved in targeting thalamic projections into the cortex (Gao *et al.*, 1998; Vanderhaeghen *et al.*, 2000). Thus, molecules involved in establishing thalamocortical connections may act as substrates for evolutionary changes in cortical wiring.

3.07.3 Development of Structural Organization: Sensory Influences on Cortical Organization and Connectivity

Although early patterned gene expression in the cortex appears to occur independent of extrinsic factors such as the amount and pattern of electrical activity in input pathways, these can exert a substantial influence at both early and late stages of development and provide insight into the evolution of a cortical structure. For instance, while ocular dominance columns are present before eye opening (Rakic, 1976; Crowley and Katz, 2000; Crair *et al.*, 2001), the existence of retinal waves of spontaneous activity suggests that electrical activity generated within the developing brain may also contribute to the early establishment of central visual connections (Meister *et al.*, 1991; Wong *et al.* 1993).

Subsequently, visual experience plays a vital role in shaping the organization and connections of visual cortex. A balance of activity between the eyes appears to be essential for normal cortical development during the critical period, when visual experience has its maximal effect, with disruptions

to the amount or the pattern of electrical activity in only one eye having the greatest impact on cortical structure. For instance, monocular deprivation during the critical period induces robust changes in the anatomy and physiology of visual cortex (Wiesel and Hubel, 1965; Hubel *et al.*, 1977; LeVay *et al.*, 1980). In contrast, binocular deprivation during the critical period has little influence on ocular dominance columns, indicating that the balance of activity rather than the absolute level of activity is critical for the formation of intracortical connections during the critical period (Crowley and Katz, 1999). Even though these loss-of-function experiments suggest that input activity has a profound influence on the organization of the cortex, they cannot distinguish between the contributions made by the overall amount of activity and the specific pattern of activity in inducing these cortical changes.

Artificially induced strabismus, which alters the spatial correlation between the two eyes but not the overall level of activity, causes ocular dominance columns within primary visual cortex to become exclusively monocularly driven (Lowel and Singer, 1992). More generally, gain-of-function paradigms, such as the one used in rewiring experiments, allow separation of the relative influence of patterned visual activity from that of the amount of activity or of intrinsic factors in specifying the function and organization of a cortical area. In these experiments, visual input is redirected to the auditory pathway by inducing retinal ganglion cell axons to innervate the medial geniculate nucleus (MGN) through surgical removal of its normal inputs at birth (see Figure 1). This creates an alternative target for retinal axons and allows functional connections to form in the auditory thalamus, conveying visual information through existing thalamocortical connections to primary auditory cortex (A1). Such rerouting has been done in mice (Lyckman *et al.*, 2001), ferrets (Sur *et al.*, 1988; Roe *et al.*, 1990, 1992, 1993; Sharma *et al.*, 2000), and hamsters (Schneider, 1973; Kalil and Schneider, 1975; Frost, 1982; Frost and Metin, 1985).

Retinal axons do not enter the MGN during normal development or in adulthood, but do so when the MGN is deafferented during an early developmental window. Molecular characterization of the denervated MGN indicates that removal of normal inputs upregulates molecules that promote sprouting in other systems, presumably attracting axons of the optic tract to branch and innervate the nucleus (Ellsworth, 2004). Remarkably however, once retinal axons enter the MGN, they pattern themselves in a manner similar to that in their major thalamic target, the lateral geniculate nucleus (LGN; see Figure 2a). Indeed, experiments examining the patterning of

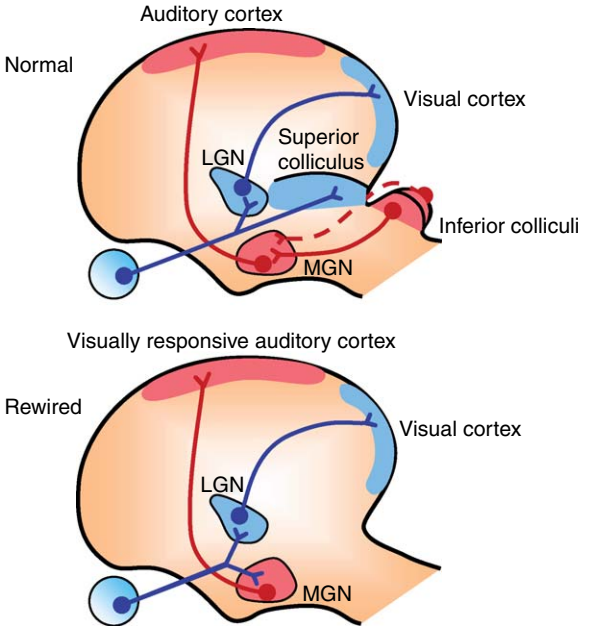

Figure 1 Schematics of the principal visual (blue) and auditory (red) pathways in normal (upper panel) and rewired animals (lower panel). LGN, lateral geniculate nucleus; MGN, medial geniculate nucleus. Modified from Sur, M., and Rubenstein, J. R. 2005. Patterning and plasticity of the cerebral cortex. *Science* 310, 805–810.

retinal innervation in the LGN and the rewired MGN suggest that the same intrinsic molecules facilitate pattern formation in both nuclei. In the normal mammalian visual pathway, retinal input is organized retinotopically in the LGN and is segregated into discrete eye-specific regions. A similar eye-specific segregation occurs in the rewired MGN (Ellsworth *et al.*, 2005), with input from the right and left eye showing little overlap (Figure 2b). There appears to be conservation of patterning molecules across sensory modalities, with molecules such as the ephrins and their respective Eph receptors expressed in multiple gradients throughout the developing thalamus, including the LGN, MGN, and ventrobasal (VB) nucleus. In addition, in ephrin knockout mice, this eye-specific patterning is disrupted similarly in the LGN and rewired MGN (Figure 2a; Ellsworth *et al.*, 2005). Thus, the ephrins appear to shape rewired retinal projections in the same way they influence normal LGN patterning. Therefore, ephrin expression in the MGN and throughout the auditory pathway may provide a scaffold as well as impose target-derived constraints on the extent to which connections along the auditory pathway are shaped by visual input.

Nevertheless, visual activity, which has a very different spatial and temporal pattern than auditory activity, leads to visual responses in

rewired A1 that resemble responses in primary visual cortex (V1) (Sur *et al.*, 1988; Roe *et al.*, 1990, 1992; Sharma *et al.*, 2000). Extracellular electrophysiology and optical imaging of intrinsic signals find that neurons in rewired A1 develop visual response features such as orientation and direction selectivity (Roe *et al.*, 1992; Sharma *et al.*, 2000) as well as an orderly retinotopic map (Roe *et al.*, 1990). That is, rewired A1 neurons are selective for different attributes of a visual stimulus such as a direction of stimulus motion, a particular line orientation, or a retinotopic location (size and receptive field location in visual space) of the stimulus. Each neuron has a slightly different preference for these features compared to its neighbors, such that a coherent stimulus feature map develops in rewired A1, similar to the one found in V1. Optical imaging experiments reveal that a systematic map of orientation information develops in rewired A1, which is similar to the orientation map found in V1 (Sharma *et al.*, 2000). This orientation map in rewired A1 contains iso-orientation domains, where the neurons all respond to the same preferred orientation, organized around pinwheel centers (Figure 3).

In addition to influencing the organization of visual response feature maps, the visual inputs directed to rewired A1 also shape its local and long-range

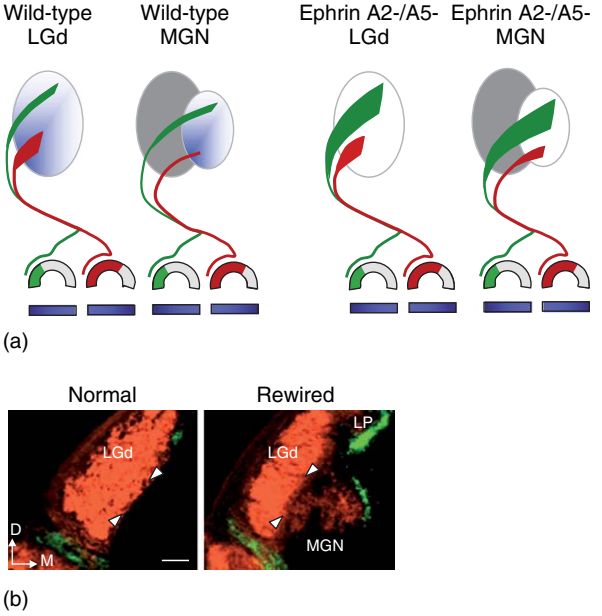

Figure 2 Target-mediated cues influence normal and novel retinal projections. a, Schematic representation of Eph–ephrin interactions in the retina and retinal targets in wild-type and ephrin knockout mice. Contralateral projections are labeled in red; ipsilateral projections are labeled in green. Ephrin expression is represented by the blue gradient within the target nuclei, while Eph receptor expression is depicted by the blue gradient under each retina. Left, in wild-type mice, ipsilateral axons arise from the temporal retina and express high levels of EphA receptor. As a result, these axons target regions of the dorsal lateral geniculate nucleus (LGd) with low ephrin-A expression. A similar ephrin gradient is also apparent in the MGN. As a result of these parallel ephrin gradients, eye-specific projections are similar in the LGN and rewired MGN: in rewired wild-type mice, ipsilateral retino-MGN projections target regions of the MGN with low ephrin expression. Right, in ephrin-A knockout mice, ipsilateral axons still show high EphA-receptor expression but target broader regions of the LGN and MGN. Ipsilateral axons spread ventrally in both the LGN and rewired MGN of ephrin knockout mice. b, Representative coronal sections in a normal (left) and a rewired (right) mouse. In the rewired mouse, the retinal axons overshoot the medial boundary of the LGd and project into the MGN. Enhanced retinal projections into the lateral posterior (LP) nucleus are also seen in rewired mice. Retinal axons are labeled with alexafluor conjugated CTB. Contralateral projections are labeled red and ipsilateral projections are labeled green. White arrowheads mark the LGd/MGN boundary. Scale bar: 0.1 mm. Modified from Ellsworth, C. A., Lyckman, A. W., Feldheim, D. A., Flanagan, J. G., and Sur, M. 2005. Ephrin-A2 and -A5 influence patterning of normal and novel retinal projections to the thalamus: Conserved mapping mechanisms in visual and auditory thalamic targets. *J. Comp. Neurol.* 488, 140–151.

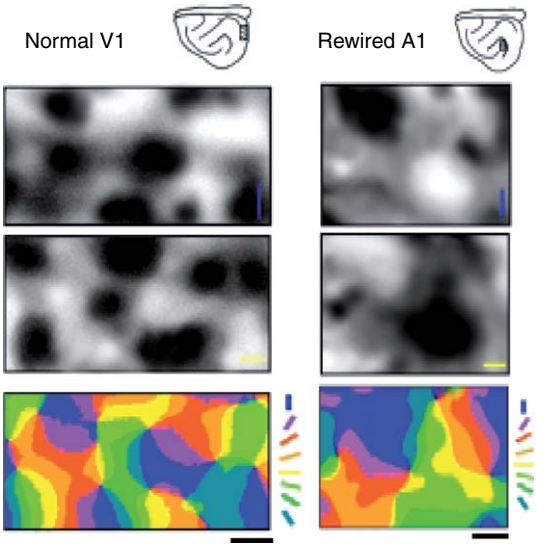

Figure 3 Orientation maps in normal visual cortex and rewired auditory cortex demonstrate the role of input activity in cortical development. Left, lateral view of normal primary visual cortex (V1) in the ferret brain. The upper two panels show activity maps in normal V1 using optical imaging of intrinsic signals in response to vertical and horizontal grating stimuli, respectively. Dark regions denote areas of high activity. The bottom map is a composite map of all orientations tested. The color key to the right of the panel shows the orientations represented. Right, lateral view of rewired primary auditory cortex (A1) in the ferret brain. The upper two panels represent the single orientation activity maps generated in rewired A1 under the same conditions as the left panels. The bottom map is a composite map of all orientations tested. The color key to the right of the panel shows the orientations represented. Scale bars: 0.5 mm. Modified from Sharma, J., Angelucci, A., and Sur, M. 2000. Induction of visual orientation modules in auditory cortex. *Nature* 404, 841–847.

connections such that they resemble connections in V1 (Sharma *et al.*, 2000). Rewired A1 neurons form connections between domains with the same orientation preference, just like V1 neurons. The patchy connections seen in V1, which are often elongated along the orientation axis of the injection site, are also observed in rewired A1 (Gao and Pallas, 1999; Sharma *et al.*, 2000). This differs significantly from the band-like connections that extend along the isofrequency axis in normal A1. At the same time, despite the similarities in the organization of visual information and connectivity of rewired A1 and V1, there are several notable differences. Rewired A1 orientation domains are larger and less orderly, as are horizontal connections relative to V1. In addition, the receptive fields in rewired A1 are larger (Roe *et al.* 1992) and spatial acuity of the rewired auditory pathway is lower than the normal visual pathway (von Melchner *et al.*, 2000). This may result from the large contribution of retinal W cell inputs to the rewired MGN (Roe *et al.* 1993). These differences may also reflect underlying structural constraints imposed by A1 that cannot be modified by experience (e.g., certain patterns of connections within and between the A1 cortical layers). Even though receptive fields and orientation domains in rewired A1 are larger than in visual cortex, these rewiring experiments provide powerful evidence that patterned visual activity plays an instructive role in the establishment of cortical connections by modifying the function and organization of a cortical area.

3.07.4 Specification of Cortical Areas: The Relationship between Inputs, Outputs, and Function

In addition to having a profound influence on cortical organization and physiology, rewired visual inputs can influence behavior. A study of unilaterally rewired ferrets suggests that patterned visual inputs influence behavior and drive the outputs of A1 (von Melchner *et al.*, 2000). Unilaterally rewired ferrets were trained to discriminate between light and sound (Figures 4a and 4b). After training, the ferrets were tested with a light presented in the rewired visual field. The normal and rewired ferrets primarily responded at the visual reward spout, an expected result given that the rewired hemisphere receives visual information through both the normal visual inputs to visual cortex and the rewired projection from the retina to the MGN to auditory cortex (Figures 4c and 4d). The normal visual projection from LGN/lateral posterior (LP) nucleus to the rewired hemisphere was then ablated, and after a period of recovery the ferrets were retested with a light presented to the rewired visual field. The rewired ferrets still responded primarily at the visual reward spout, indicating that the intact projection from the retina to the MGN to auditory cortex is capable of mediating the response to the visual stimulus (Figure 4c). The normal ferrets, however, responded at chance levels at the visual reward spout when retested after ablation of the LGN/LP and superior colliculus (SC) (Figure 4d). Finally the auditory cortex was ablated, and the rewired ferrets were again retested after a period of recovery. The rewired ferrets now responded at chance levels at the visual reward spout, indicating that the animals were no longer able to identify the visual stimulus, presumably because they were blind in the rewired visual field (Figure 4c). Thus, the rewired projection from the retina through the MGN to auditory cortex is able to mediate visual behavior and this visual input influences the behavioral function of the auditory cortex.

In addition, rewired visual projections in mice influence learned behavior mediated by subcortical pathways, such as conditioned fear (Newton *et al.*, 2004). In fear-conditioning experiments, a discrete auditory cue is paired with a mild foot shock, which induces rapid conditioned fear after as few as one tone-shock pairing (Fendt and Fanselow, 1999; LeDoux, 2000). In contrast, a discrete visual cue is less effective, requiring many more light-shock pairings to elicit a defensive response to the light alone (Heldt *et al.*, 2000). Dense direct connections from the MGN to the lateral nucleus of the amygdala (Figure 5a) are thought to be crucial for auditory cued conditioned fear responses (Rogan and LeDoux, 1995; Doron and LeDoux, 1999; see also LeDoux *et al.*, 1984; LeDoux, 2000; Namura *et al.*, 1997). In contrast to the direct auditory pathway from the MGN to the amygdala, visual inputs primarily reach the amygdala through indirect pathways (Doron and LeDoux, 1999; Shi and Davis, 2001). Visually cued conditioned fear is thought to be mediated by projections from the LGN to V1/V2 to visual association area TE2/perirhinal cortex (Pr) to the amygdala, or by projections from LP to V2/TE2/Pr to the amygdala (see Figure 5a; Shi and Davis, 2001).

A study of adult sham lesion and rewired mice suggests that the rewired visual input to the MGN mediates the acceleration of visually cued fear conditioning (Newton *et al.*, 2004). Under these circumstances, the rewired visual inputs to the MGN are able to elicit the output fear response normally associated with an auditory stimulus. In these experiments, adult sham lesion and rewired

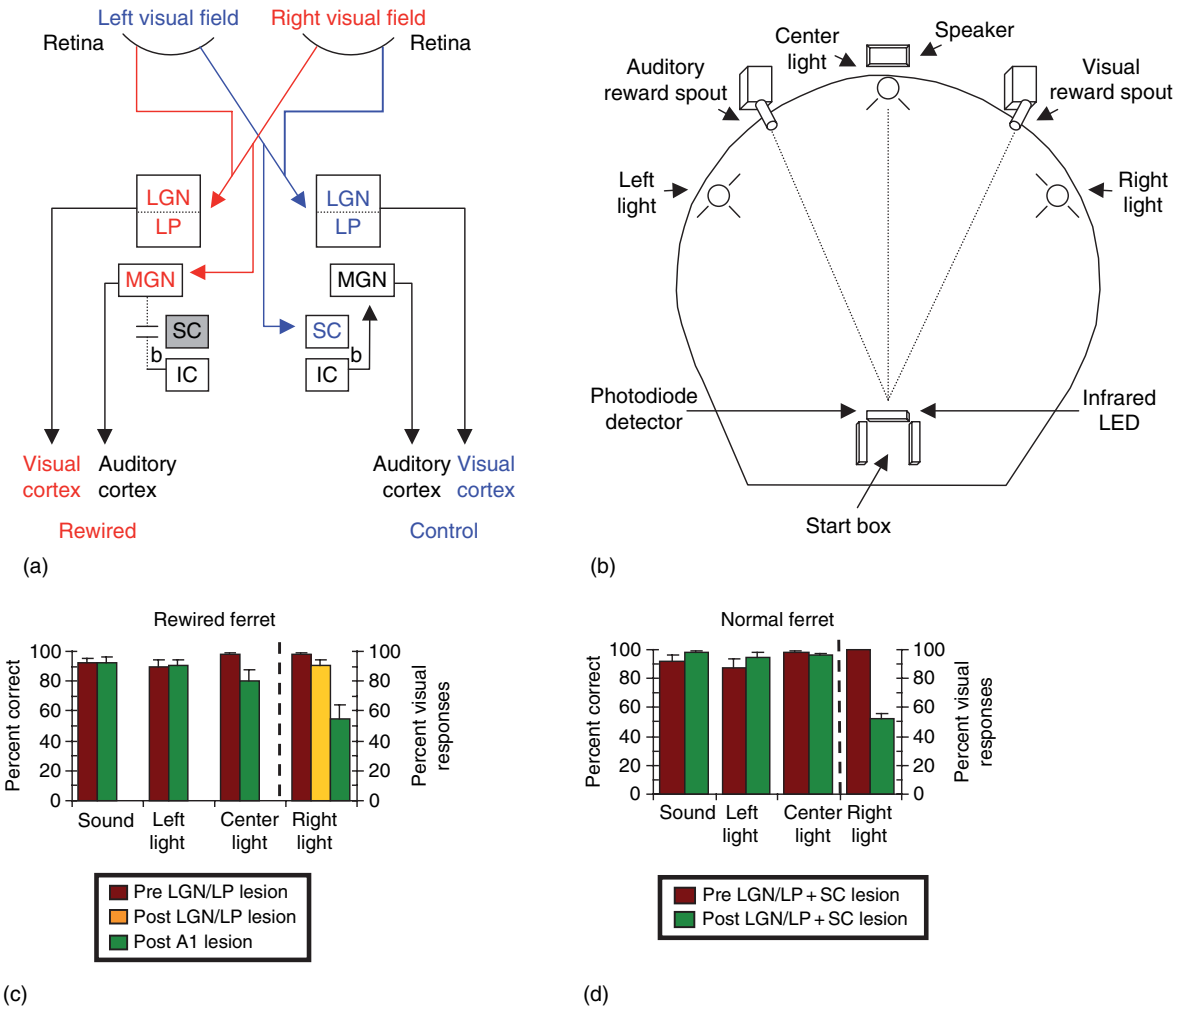

Figure 4 Retinal projections routed to the auditory pathway mediate visual behavior in rewired ferrets. a, Pathway from the retina to the visual thalamus, including the LGN and the lateral posterior (LP) nucleus, and to the superior colliculus (SC) in the control hemisphere (right); and to the LGN/LP and MGN in the rewired hemisphere (left). The SC and adjacent brachium (b) of the inferior colliculus (IC) were ablated neonatally in the left hemisphere. Visual projections in each hemisphere represent the contralateral visual field. b, Experimental apparatus and the design of the behavioral experiment. Dashed lines denote the borders of the left and right monocular fields and the direction of central gaze. Animals were rewarded at the right spout after a light in the left monocular field, and at the left spout after a sound from a central speaker. Subsequently, their responses to light in the right monocular field were tested. Animals initiated trials by standing in the start box with their muzzle between the infrared LED and a photodiode detector. c, Response of a rewired ferret to sound and light stimuli under three separate conditions: after training with sound and light stimuli, but before the ablation of the visual LGN/LP pathway (red bars); after the LGN/LP lesion (yellow bar; only the response to the right light is shown); and after the A1 lesion in the rewired hemisphere (green bars). Response bars (mean ± s.d.) depict the performance in the final 10–19 days in the pre-LGN/LP lesion condition, and in the first 10–18 days in the post-LGN/LP and post-A1 lesion conditions. d, Response of a normal ferret to sound and light stimuli under two separate conditions: after training with sound and light stimuli, but before the ablation of the LGN/LP and SC pathways (red bars) and after (green bars). Response bars depict performance in the final 9 days in the pre-LGN/LP + SC lesion condition, and in the first 12 days in the post-LGN/LP + SC condition. Modified from von Melchner, L., Pallas, S. L., and Sur, M. 2000. Visual behaviour mediated by retinal projections directed to the auditory pathway. *Nature* 404, 871–876.

mice underwent three sessions of fear conditioning with either a visual or an auditory cue (three cue-shock pairings per session) and behavioral testing after each session. The cued testing behavior of the different groups after one fear conditioning session are depicted in Figure 5b. Consistent with previous studies, after one session of fear conditioning, light-conditioned sham lesion mice did not freeze significantly more during the cue presentation compared to the habituation period (Figure 5b). Light-conditioned rewired mice, however, froze significantly more during the cue presentation after only one session of fear conditioning, as did tone-conditioned sham lesion and rewired mice.

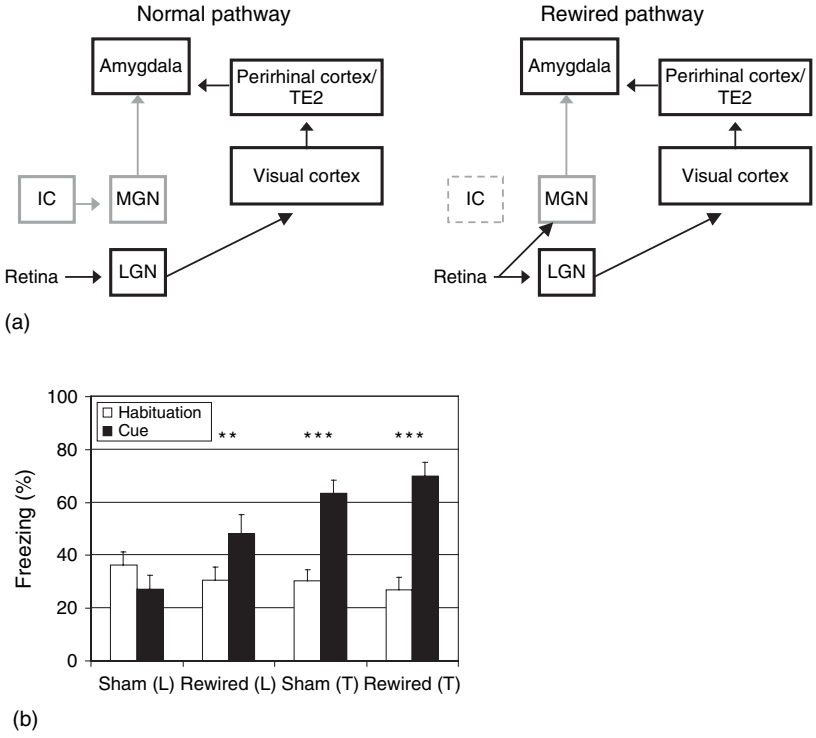

Figure 5 Retinal projections to the auditory pathway mediate visually cued learning in rewired mice. a, Simplified schematic of the principal visual (black) and auditory (gray) cued fear conditioning pathways in normal (left) and rewired mice (right). The IC (shown as a dotted box) was lesioned bilaterally in neonatal mice to induce retinal projections to the MGN. IC, inferior colliculus; LGN, lateral geniculate nucleus; MGN, medial geniculate nucleus. b, The mean freezing per group during the habituation (white bar) and cue presentation (black bar) periods of the cued testing session after one session of fear conditioning, with error bars denoting the standard error of the mean (significant paired *t*-tests, ** $p < 0.01$, *** $p < 0.001$). Modified from Newton, J. R., Ellsworth, C., Miyakawa, T., Tonegawa, S., and Sur, M. 2004. Acceleration of visually cued conditioned fear through the auditory pathway. *Nat. Neurosci.* 7, 968–973.

These findings indicate that the behavioral function of a target (in this case, the amygdala) is influenced by its inputs, and that it can activate the output response associated with the target. Thus, existing pathways can convey novel information to central structures, and this information is capable of mediating behavior.

3.07.5 Rewiring Experiments and Brain Evolution

Despite the limitations of rewiring experiments, this line of research demonstrates that the developing brain has an extraordinary capacity to reorganize itself and adapt to its inputs. Furthermore, the influence of molecular cues in early development on cortical arealization and the impact of rewired visual inputs on the organization and the connectivity of subsequent auditory structures provide insight into the evolution of a cortical area. In essence, these gain-of-function experiments provide information on certain principles by which novel connections might become functional and even adaptive, setting the stage for evolutionary change. During evolution, targets may express novel molecular cues as a result of mutations, and these, in combination with existing molecular cues, may form new structural patterns and functional connections. The electrical drive provided by these novel inputs can be utilized by target structures to form network connections that enable these structures or their downstream targets to process the novel information. Certain downstream pathways driven by the novel input may confer substantial adaptive advantage, as exemplified by rapid visually cued fear conditioning in rewired mice caused by novel retinal inputs to the MGN and subsequent utilization of the projection from the MGN to the lateral amygdala.

More generally, the studies discussed in this article suggest that there is a dynamic interplay between intrinsic and extrinsic factors throughout the evolution of a cortical region. Both factors play a critical role in determining the overall structure and function of a cortical area, but tend to exert their greatest influence at different times and in complementary ways during development.

3.08 The Evolution of Neuron Classes in the Neocortex of Mammals

P R Hof, Mount Sinai School of Medicine, New York, NY, USA
C C Sherwood, The George Washington University, Washington, DC, USA

Glossary

Afrotheria A clade of placental mammals that is thought to have originated in Africa at a time when it was isolated from other continents. This clade contains Paenungulata (elephants, hyraxes, and sirenians), Afrosoricida (tenrecs and golden moles), Tubulidentata (aardvarks), and Macroscelidea (elephant shrews). Molecular data indicate that the Afrotheria diverged from other placental mammals 110–100 Mya.

Anthropoidea A primate clade that includes New World monkeys, Old World monkeys, apes, and humans. Tarsiers are the sister group to the Anthropoidea.

Boreoeutheria A clade of placental mammals that encompasses Euarchontoglires and Laurasiatheria. This taxonomic division within the Boreoeutheria occurred 95–85 Mya in the Cretaceous.

Cetartiodactyla A clade of placental mammals that includes cetaceans (whales, dolphins, and porpoises) and artiodactyls (even-toed ungulates). This phylogenetic grouping is based on molecular evidence indicating that cetaceans evolved from within the artiodactyls and have their closest relationship with the hippopotamus and then ruminants (cattle and deer).

Euarchontoglires A supraordinal clade of boreoeutherian placental mammals that includes Rodentia, Lagomorpha, Dermoptera, Scandentia, and Primates.

Hominidae A primate clade that includes great apes (orangutans, gorillas, chimpanzees, and bonobos) and humans. The hylobatids (gibbons and siamangs) are the sister taxon to the Hominidae.

homoplasy A structure that is the result of convergent evolution, where organisms that are not closely related independently acquire similar characteristics. Homoplasy is contrasted with homology, which means that structures have a common origin derived from a shared ancestor.

Laurasiatheria A supraordinal clade of boreoeutherian placental mammals that includes Cetartiodactyla, Perissodactyla, Carnivora, Pholidota, and Eulipotyphla.

marsupials A clade of mammals in which the female has a pouch where the young is nurtured through early infancy. There are approximately 280 species of living marsupials, with the majority being native to Australia and the remainder living in South America (however, there is a single North American native marsupial species, the Virginia opossum).

monotremes A clade of mammals that lay eggs, rather than giving birth to live young like marsupials and placental mammals. The extant representatives of this group, the platypus and the echidnas, are indigenous to Australia, New Guinea, and Tasmania. Fossil evidence, however, suggests that monotremes were once more widespread.

placental mammals A clade of mammals in which the fetus is nourished during gestation by a placenta. This group encompasses the majority of living mammals.

Xenarthra A clade of placental mammals present today only in the Americas. This group includes sloths, anteaters, and armadillos. Molecular data indicate that the Xenarthra diverged from boreoeutherian mammals 100–95 Mya.

3.08.1 Introduction

A diverse array of neuron types populates the mammalian neocortex. Physiological activity within a cortical area, in turn, is largely determined by interactions among these different cell types and incoming afferents. Neurons in the cerebral cortex of mammals can be divided into two major classes on the basis of morphology and function, pyramidal excitatory cells, and inhibitory interneurons. Each class includes many subtypes that can be identified by their size, shape, dendritic and axonal morphology, and connectivity. These neuronal subtypes exhibit a variable distribution among cortical layers and regions, and some are differentially represented among species (see Hof *et al.*, 1999, 2000; Hof and Sherwood, 2005). Neurons can be further classified based on their expression of various proteins, such as neurofilament proteins (NFPs), calcium-binding proteins, and neuropeptides.

The morphology of a given neuron, particularly of its dendritic arborizations, reflects the size of its receptive field and the specificity of its synaptic contacts. Thus, the structure of the dendritic arbor as well as the distribution of axonal terminal ramifications confer a high level of subcellular specificity in the localization of particular synaptic contacts on a given neuron. The three-dimensional distribution of the dendritic tree is also a key factor with respect to the type of information transferred to the neuron. A neuron with a dendritic tree restricted to a particular cortical layer may be receptive to a very limited pool of afferents, whereas widely expanding dendritic branches typical of large pyramidal neurons will receive highly diversified inputs in the cortical layers through which the dendrites course. Considering the variability in cortical morphology, size, and cellular organization in mammals, it is important to investigate how specific characteristics of cortical microcircuitry differ among species, and how these cellular phenotypes could be used to assess taxonomic affinities and functional differences among species.

3.08.2 Neuronal Typology and Chemical Specialization

3.08.2.1 Pyramidal Neurons

Pyramidal neurons are the principal excitatory neuronal class in the cerebral cortex. They are highly polarized neurons, with a major orientation axis orthogonal to the pial surface of the cerebral cortex. Their cell body is roughly triangular on cross section, although a large variety of morphologic types exist with elongate, horizontal or vertical fusiform, or inverted perikaryal shapes. They typically have a large number of dendrites that emanate from the apex and from the base of the cell body. The span of their dendrites may cover several millimeters and their somata are found in all cortical layers except layer I, with predominance in layers II, III, and V. Small pyramidal neurons in layers II and III of the neocortex have a restricted dendritic tree and form vast arrays of axonal collaterals with neighboring cortical domains, whereas medium to large pyramidal cells in deep layer III and layer V have a much more extensive dendritic tree and furnish long corticocortical connections. Layer V also contains very large pyramidal neurons disposed in clusters or as isolated, somewhat regularly spaced elements. These neurons are known to project to subcortical centers such as the basal ganglia, brainstem, and spinal cord. Finally, layer VI pyramidal cells exhibit a greater morphologic variability than those in other layers, and are involved in certain corticocortical as well as corticothalamic projections. The dendrites of pyramidal cells show large numbers of dendritic spines that receive most of the excitatory synaptic inputs. As many as 40 000 spines can be encountered on a large pyramidal neuron.

The major excitatory output of the neocortex is furnished by pyramidal cells. Their axon extends in most cases from the base of the perikaryon and courses toward the subcortical white matter and gives off several collateral branches that are directed to cortical domains generally located within the vicinity of the cell of origin. While many of these branches ascend in a radial, vertical pattern of arborization, a separate set of projections also travels horizontally over long distances. One function of the vertically oriented component of the recurrent collaterals may be to interconnect layers III

and V, the two major output layers of the neocortex. Horizontal intrinsic connections are positioned to recruit and coordinate the activity of modules of similar functional properties while inhibiting other domains. Together these recurrent projections function to set up local excitatory patterns and coordinate the output of neuronal ensembles. NFP immunoreactivity, chiefly recognized by the expression of dephosphorylated epitopes of NFP medium and heavy molecular weight subunits, characterizes a subpopulation of pyramidal neurons in the neocortex of mammals that exhibits clear regional and species differences in their distribution and densities (Hof *et al.*, 1992, 1996; van der Gucht *et al.*, 2001, 2005; Kirkcaldie *et al.*, 2002; Boire *et al.*, 2005; Figure 1). The expression of NFP has been studied most comprehensively in primates, where it has been shown that this protein is enriched in a subset of large pyramidal neurons that have an extensive dendritic arborization, are distributed in well-defined laminar positions, form highly specific long corticocortical projections, and show regional specificity in their distribution patterns (Campbell and Morrison, 1989; Campbell *et al.*, 1991; Hof and Nimchinsky, 1992; Carmichael and Price, 1994; Hof and Morrison, 1995; Hof *et al.*, 1995b; Nimchinsky *et al.*, 1995, 1996, 1997; Preuss *et al.*, 1997, 1999; Sherwood *et al.*, 2003a; Vogt *et al.*, 2001, 2005). Although the precise function of NFP is not completely understood, its restricted distribution among certain subsets of corticocortical circuits in primates suggests that it confers unique neurochemical and morphologic properties subserving a range of highly specialized functions in neocortical connectivity, as well as selective vulnerability to neurodegenerative diseases unique to humans (Hof *et al.*, 1995a, 1995b; Nimchinsky *et al.*, 1996; Bussieère *et al.*, 2003; Hof and Morrison, 2004). NFP may be present, to some degree, in functionally homologous subsets of cortical output neurons in many species.

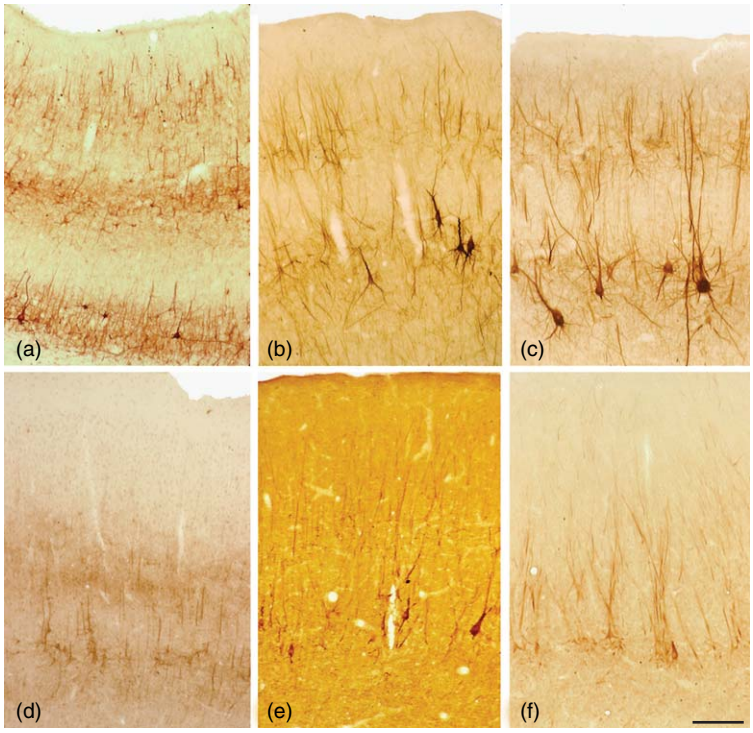

Figure 1 Examples of cytoarchitecture and cellular typology using an antibody against NFP. a, Organization of the primary visual cortex in a long-tailed macaque monkey (*Macaca fascicularis*). NFP-immunoreactive neurons are predominant in layers III, IVB, and V. b and c, Distribution of NFP-immunoreactive neurons in the primary visual cortex of two carnivores, the dog (b, *Canis familiaris*), and the California sea lion (c, *Zalophus californianus*). Note the prominent labeling of very large cells in layer V and smaller cells in layer III, whereas layer IV in the middle is devoid of labeled neurons. The large size and extensive dendrites of NFP-immunoreactive neurons is obvious. d, NFP-immunoreactive cells in the visual area of the camel (*Camelus dromedarius*). The labeled neurons are relatively small and predominate in the deep layers. e and f, NFP immunolabeling in the visual cortex of the pigmy sperm whale (e, *Kogia breviceps*), and of the beluga whale (f, *Delphinapterus leucas*). Note the prominent clusters of large immunoreactive neurons in layer IIIc/V only. Scale bar (on f): 300 μm. Reproduced from Hof, P. R. and Sherwood, C. C. 2005. Morphomolecular neuronal phenotypes in the neocortex reflect phylogenetic relationships among certain mammalian orders. *Anat. Rec. A* 287, 1153–1163, with permission from John Wiley & Sons, Inc.

3.08.2.2 Spiny Stellate Cells

Spiny stellate cells are the other class of cortical excitatory neurons and are found in highest numbers in neocortical layer IV. The spiny stellate cell is a small multipolar neuron with local dendritic and axonal arborizations. These neurons resemble pyramidal cells in that they are the only other cortical neurons with large numbers of dendritic spines, but differ from them in lacking most of an apical dendrite and having a restricted dendritic arbor that generally does not extend beyond the layer in which the cell body resides. The axons of spiny stellate neurons are primarily intrinsic and form links between layer IV, that receives a major input from the thalamus, and layers III, V, and VI. In some respects, the axonal arbor of spiny stellate cells mirrors the vertical plexuses of recurrent collaterals, albeit in a more restricted manner. Given its axonal distribution, spiny stellate neurons appear to function as a high-fidelity translator of thalamic inputs, maintaining strict topographic organization and setting up initial links of information transfer within a cortical area.

3.08.2.3 Inhibitory Interneurons: Basket, Chandelier, and Double Bouquet Cells

There is a large variety of interneuron types in the cerebral cortex. These neurons contain the neurotransmitter γ-aminobutyric acid (GABA), and exert strong local inhibitory influences on postsynaptic neurons. The dendritic and axonal arborizations of interneurons offer important clues as to their role in the regulation of pyramidal cell function. In addition, many morphologic classes of GABAergic interneurons can be further defined by a particular set of neurochemical characteristics. Three major subtypes of cortical interneurons are classically described, principally based on rodent and primate studies, namely basket, chandelier, and double bouquet cells. It must be noted, however, that interneurons exhibit a rich variety of size and morphologies, such as clutch cells, neurogliaform cells, Martinotti-type and Cajal–Retzius cells, bipolar cells and other stellate cells, and multipolar neurons, which all have diverse representations depending on the brain region as well as on the species studied.

Basket cells are characterized by axonal endings that form a basket of terminals surrounding a pyramidal cell soma and provide most of the inhibitory GABAergic synapses to the soma and proximal dendrites of pyramidal cells. One basket cell may contact numerous pyramidal cells, and in turn several basket cells can contribute to the pericellular basket of one pyramidal cell. The basket cells have a relatively large soma and multipolar morphology with dendrites extending in all directions for several hundred micrometers such that the vertically oriented dendrites cross several layers. Their axon arises vertically, quickly bifurcates and travels long distances, forming multiple pericellular arrays as it spreads horizontally. The basket cells predominate in layers III and V in the neocortex and are numerous amid hippocampal pyramidal neurons.

Chandelier cells generally have a variably bitufted or multipolar dendritic tree. The defining characteristic of this cell class is the very striking appearance of its axonal endings. In Golgi or immunohistochemical preparations, the axon terminals appear as vertically oriented cartridges, each consisting of a series of axonal swellings linked together by thin connecting pieces making them look like old-style chandeliers. These neurons synapse exclusively on the axon initial segment of pyramidal cells. Most of the chandelier cells are located in layer III and their primary target appears to be pyramidal cells in layer III, and to a lesser extent layer V. One pyramidal cell may receive inputs from multiple chandelier cells, and one chandelier cell may innervate more than one pyramidal cell. This cell exerts powerful inhibition on postsynaptic pyramidal cell firing.

Double bouquet cells are mostly prevalent in layers II and III, and are also present in layer V of the neocortex. These interneurons are characterized by a vertical bitufted dendritic tree and a tight bundle of vertically oriented varicose axon collaterals that traverse layers II through V. Many double bouquet cells synapse on spines of pyramidal cells and most of their remaining synapses are on fine dendritic shafts, in striking contrast to the basket and chandelier cells. Another subclass of double bouquet cell has similar synaptic targets but primarily in layer V, thus influencing the activity of different populations of pyramidal cells.

GABAergic interneurons can also be classified in nonoverlapping subtypes based on their content in the calcium-binding proteins parvalbumin (PV), calbindin (CB), and calretinin (CR), as well as several neuropeptides (Hendry *et al.*, 1989; Andressen *et al.*, 1993; Condé *et al.*, 1994; DeFelipe, 1997; Gonchar and Burkhalter, 1997; Glezer *et al.*, 1998; Morrison *et al.*, 1998; Hof *et al.*, 1999; Markram *et al.*, 2004). CB- and CR-expressing interneurons share many morphologic similarities, and are mainly bitufted, bipolar, and double bouquet neurons, as well as a few pyramidal neurons, with minimal overlap among these subpopulations in the rodent and primate neocortex (Rogers, 1992; DeFelipe, 1997; Morrison *et al.*, 1998). PV-immunoreactive neurons are mainly observed in layers II

to V, and are principally basket and chandelier cells (Blümcke *et al.*, 1990; Van Brederode *et al.*, 1990; Hof and Nimchinsky, 1992; Condé *et al.*, 1994; Nimchinsky *et al.*, 1997). PV has also been reported to occur in certain pyramidal neurons in primate somatosensory and motor cortex (Preuss and Kaas, 1996; Sherwood *et al.*, 2004).

3.08.3 Relationships of Neurochemical Phenotype and Phylogenetic Affinities

3.08.3.1 General Phylogenetic Patterns

Phylogenetic patterns in the distribution of NFP and the three calcium-binding proteins appear to be associated with interspecific variation in other aspects of the cytoarchitecture of mammalian neocortex. Monotremes (i.e., echidnas and the platypus) are the sister taxon to all therian mammals. In these species, neurons containing CB, CR, and PV are found throughout the cortex, although CR-immunoreactive neurons are most dense in the piriform cortex where they predominate as a polymorphic phenotype. In monotremes (Hof *et al.*, 1999), CB and PV comprise morphologic types that resemble those found in placental mammals, including large PV-immunoreactive multipolar neurons that are similar to basket cells. In echidnas, however, PV is present in a unique cell type characterized by a large pyramidal-like or multipolar morphology that is common in layers V and VI. Such PV-labeled neurons have not been observed in any other mammalian species. It is also worth noting that the Australian echidna (*Tachyglossus aculeatus*) presents NFP-expressing cells in layer V of its neocortex (Hassiotis *et al.*, 2004). Although there are no studies of NFP staining in the most closely related taxon, the platypus, NFP is enriched in layer V neurons in the marsupial tammar wallaby (*Macropus eugenii*) throughout its cortex, as well as occasionally in layer III neurons of select sensory and association regions (Ashwell *et al.*, 2005). In placental mammals, NFP-containing pyramidal neurons are found frequently in layers III, V, and VI. Thus, NFP-rich cells in layer V may be interpreted as a conservative trait among mammals, with variable patterns of NFP expression in other layers having arisen in different lineages in subsequent evolution (Figure 1).

All species of marsupials examined to date display comparable staining patterns in the neocortex for PV, CB, and CR (Hof *et al.*, 1999). The most prevalent calcium-binding protein in marsupials appears to be CR, which is present in numerous small bipolar neurons located in layers II and III, as well as small pyramidal-like neurons in layers V and VI in the lateral cortex. Compared to CR-immunoreactive neurons, CB is more sparsely present in bipolar and bitufted neurons in the supragranular layers throughout the cortex, and in some larger multipolar neurons in the deep layers. A major difference between marsupials and other mammalian taxa is the remarkable paucity of PV-immunoreactive neurons and fibers. PV is observed only in a few small interneurons, whereas it is much more prevalent in other small-bodied mammals as well as in primates and carnivores. Surprisingly, PV-containing neurons in layer II have a morphology resembling double bouquet cells that are usually labeled by CB in rodents and primates. This may represent a neuronal specialization in certain marsupials that is not found in placental mammals.

A current limitation to interpreting regional patterns of distributions of neuron classes is the paucity of data from the phylogenetic groups that diverged close to the base of the adaptive radiation of placental mammals, the Xenarthra (i.e., sloths, anteaters, and armadillos) and Afrotheria (i.e., tenrecs, golden moles, elephant shrews, aardvarks, manatees, hyraxes, and elephants). Substantially more is known regarding variation in cortical architecture of the other placental mammals, the Boreoeutheria. Among boreoeutherian mammals, species showing a high degree of morphologic differentiation of neocortical areas, a variable development of layer IV, and substantial variation in neuronal size and packing densities across the cortical plate are also generally characterized by a balanced representation of the three calcium-binding proteins and morphological diversity of NFP-immunoreactive pyramidal neurons across cortical regions (Hof *et al.*, 2000). In contrast, species characterized by greater cytoarchitectural monotony throughout the cortical mantle, a poorly defined or lack of layer IV in most regions, and the presence of very large pyramidal cells in all neocortical areas, display a predominance of CB- and CR-containing populations in comparison to PV-immunoreactive neurons, and rather uniform NFP-containing pyramidal cell morphology. The first type occurs in primates, rodents, carnivores, and to some extent megachiropterans, as well as in tree shrews and lagomorphs. Most of the taxa that are characterized by this cortical organization are members of the supraordinal group Euarchontoglires, with the exception of carnivores and bats. In contrast, the second type of cortical organizational pattern is present in cetaceans, artiodactyls, and perissodactyls, which are all

members of the Laurasiatheria. Thus, the distribution of these particular aspects of the cortical phenotype follows a major taxonomic division that occurred about 80–90 Mya at the base of the radiation of boreoeutherian mammals (Murphy *et al.*, 2001a, 2001b). While these general patterns appear to differentiate cortical organization in major boreoeutherian clades, the lack of data from xenarthrans and afrotherians makes it difficult to clearly establish which character states are conservative and which are derived for placental mammals. This is a particular challenge because cortical cell types in monotremes and marsupials often differ significantly from placental mammals and from each other. Our examination of calcium-binding protein immunoreactivity in the xenarthran giant anteater (*Myrmecophaga tridactyla*), however, shows similarities with marsupials and cetartiodactyls in that PV-immunoreactive neurons are very sparse, whereas CB- and CR-immunoreactive neurons are expressed in a morphologically diverse population of cells that includes a high frequency of pyramidal neurons (Hof and Sherwood, 2005; Figures 2 and 3).

3.08.3.2 The Distribution of Some Neuron Classes Closely Matches Phylogenetic Affinities

Reports of the cyto- and chemoarchitecture of odontocete cetaceans, particularly of visual and auditory regions, and analysis of neocortical neurons in a few large artiodactyls have revealed commonalities in cortical organization between these sister taxa (Morgane *et al.*, 1988, 1990; Glezer *et al.*, 1992, 1993, 1998; Hof *et al.*, 1992; 1999). In both groups, PV is present only in sparsely distributed large stellate neurons located in layer IIIc/V. A few small pyramidal neurons in layer III also exhibit PV immunoreactivity in dolphins. In cetaceans and artiodactyls, CB- and CR-immunoreactive cells are far more numerous than PV-immunoreactive cells, occurring in large fusiform, bipolar, or multipolar neurons in layers I, II, and superficial layer III. CB-containing neurons are much less numerous and less intensely stained than CR-immunoreactive neurons. The CR-containing neurons located in layer I have a morphology quite comparable to that of the bipolar/bitufted CB- or CR-expressing neurons typically seen in layer II of other mammals such as rats, carnivores, and primates (Ballesteros Yáñez *et al.*, 2005), whereas the CR-containing neurons in layers II and III are much larger and more variable in shape than in other species, with a predominance of multipolar and fusiform types. These neurons have long dendrites that extend into layers I and III. Very large CR-immunoreactive neurons are also encountered in layers V and VI, especially in the neocortex of large artiodactyls, such as the giraffe (*Giraffa camelopardalis*), llama (*Lama glama*), and camel (*Camelus dromedarius*), whereas they are less numerous in the pig (*Sus scrofa*), and in smaller ruminants. A few pyramidal-like neurons in layer III are also faintly CR-containing in dolphins, and the large pyramidal neurons in layer IIIc/V contain low levels of CB. The distribution and morphology of NFP-immunoreactive neurons are also comparable in cetaceans and artiodactyls, but differ considerably from those in primates, carnivores, and rodents. In cetartiodactyls, NFP is expressed in very large pyramidal neurons located in the deep portion of layer III and in upper layer V (Hof *et al.*, 1992). These neurons are present as clusters of three to six neurons, regularly spaced throughout the cortical mantle and intensely labeled with prominent apical dendrites extending well into layer I, with no major regional variability in their densities.

Another cell class that shows a restricted phylogenetic distribution is the spindle-shaped neuron, which is found exclusively in the cerebral cortex of hominids (i.e., great apes and humans). Spindle-shaped cells are characterized by a vertical, fusiform morphology, very large size, and high levels of NFP immunoreactivity (Nimchinsky *et al.*, 1995, 1999). They are prevalent in a restricted sector of the anterior cingulate cortex (areas 25, 24a, and 24b; Vogt *et al.*, 1995) and are also numerous in the anteroventral agranular insular cortex (see The Evolution of Neuron Types and Cortical Histology in Apes and Humans, Role of Spindle Cells in the Social Cognition of Apes and Humans). These neurons are found exclusively in hominids and have not been reported in any other mammalian species investigated thus far (including other primate species; Nimchinsky *et al.*, 1999; Hof *et al.*, 2000). The volume of spindle-shaped cells is strongly correlated with encephalization, which is not the case for the other neuron types (Nimchinsky *et al.*, 1999). These spindle-shaped cells are a particular type of projection neuron, as they send an axon in the subcortical white matter, although their exact domain(s) of projection cannot be ascertained in the species in which they are present. They may, however, provide well-defined projections, similar to Meynert cells or Betz cells (Sherwood *et al.*, 2003b). Furthermore, although CR-immunoreactive pyramidal neurons have been reported in the entorhinal cortex of several mammalian species, CR-containing small pyramidal neurons in layer Va of anterior cingulate cortex (area 24) appear to be present exclusively in hominids, possibly indicating a recent evolutionary character in

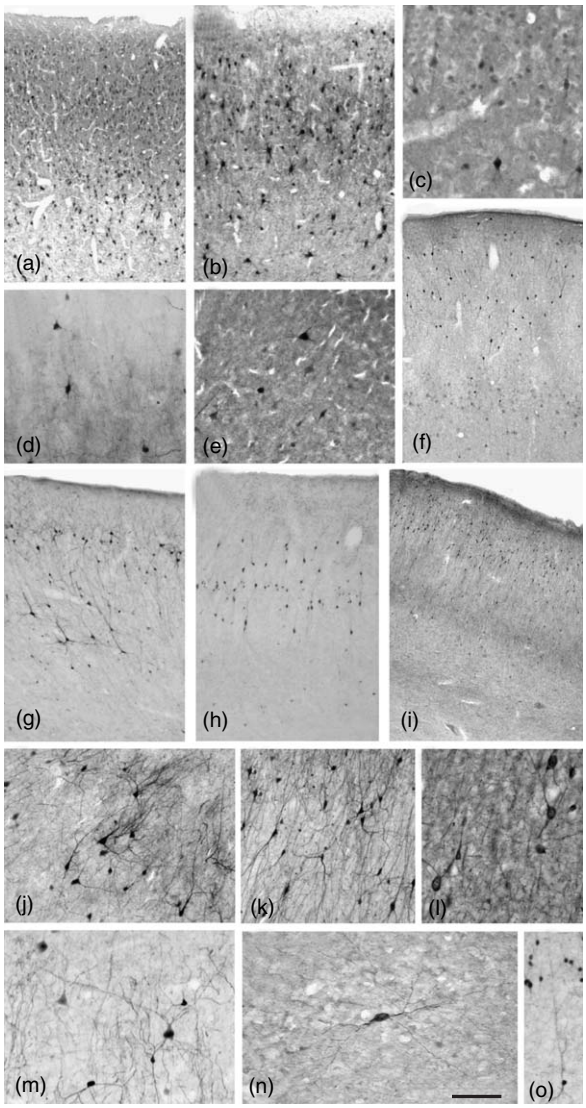

Figure 2 Immunoreactivity patterns of calcium-binding proteins in the neocortex of various mammals. a and b, CB (a) and PV (b) immunoreactivity in the primary somatosensory cortex of the echidna (*Tachyglossus aculeatus*). There is a large population of small neurons that express CB, whereas PV is contained in a heterogeneous collection of neurons, some very large and multipolar. This differs radically from other members of the Australian fauna (Hof *et al.*, 1999), such as the koala (*Phascolarctos cinereus*, c), which displays a rather sparse population of CB-containing cells. d and e, The giant anteater (*Myrmecophaga tridactyla*) is also characterized by a sparse population of relatively large CB-immunoreactive multipolar neurons (d) and PV-expressing neurons (e). These patterns are fully distinct from that in rodents (f, CR immunoreactivity in the somatosensory cortex of the chinchilla, *Chinchilla laniger*), carnivores (g, CR immunoreactivity in a dog motor cortex displaying bipolar neurons as well as pyramidal-like neurons), and a cetacean visual cortex (h, the bottlenose dolphin, *Tursiops truncatus*). Layers I and II are particularly enriched in the cetacean (layer II is located about one-third down from the top of the photomicrograph). Panels (i–l) show details of the chemoarchitecture of the frontal cortex of a Siberian tiger (*Panthera tigris*). CR-immunoreactive neurons exhibit a typical distribution predominating in the superficial layers (i, k), and large multipolar CB-immunoreactive (j) and PV-immunoreactive (l) neurons are encountered in deep layer III. Large multipolar CR-containing neurons are found in layer III of a dog (*Canis familiaris*) primary motor area (m). Note the large size of this neuron and compare it to the CR-immunoreactive giant neuron located in layer VI of a giraffe (n, *Giraffa camelopardalis*), and to a typical bipolar neuron in layer III of the mouse visual cortex (o, *Mus musculus*). Scale bar (on n): 300 μm (a, b); 400 μm (f–i); 50 μm (c–e, j–o). Reproduced from Hof, P. R. and Sherwood, C. C. 2005. Morphomolecular neuronal phenotypes in the neocortex reflect phylogenetic relationships among certain mammalian orders. *Anat. Rec. A* 287, 1153–1163, with permission from John Wiley & Sons, Inc.

this primate clade (Hof *et al.*, 2001). These observations of multiple novel cellular specializations suggest the occurrence of functional modifications along the hominid lineage during the last 15–20 My in cortical regions that play major roles in the regulation of autonomic function, cognition, self-awareness, emotionality, and vocalization (Figures 2 and 3).

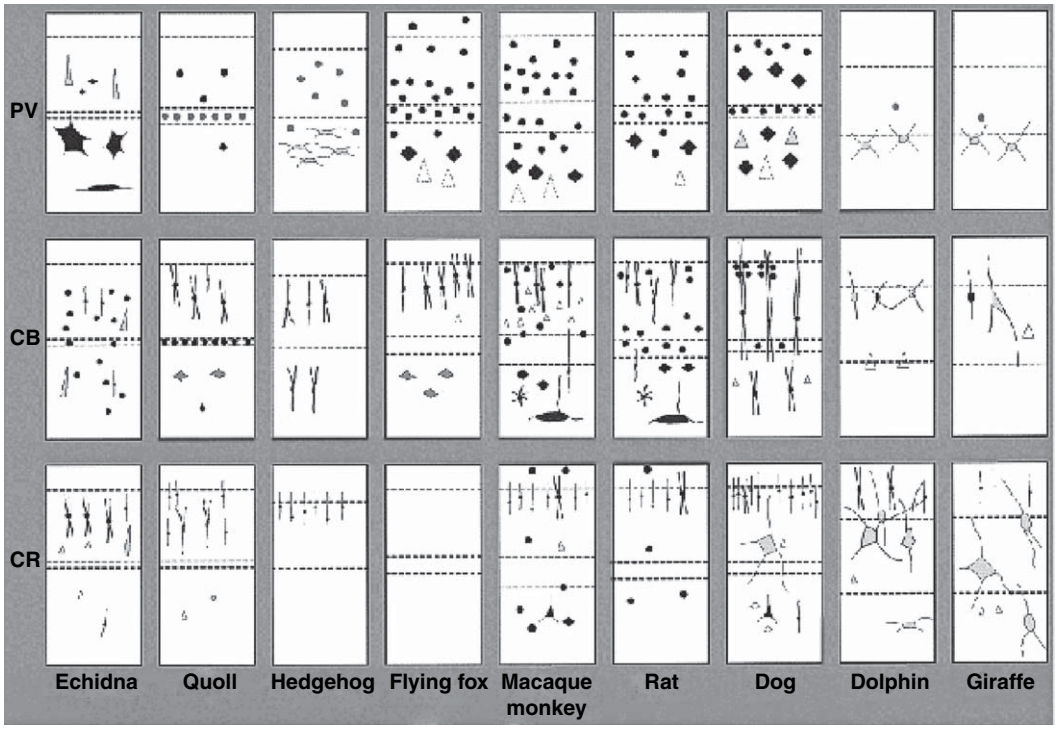

Figure 3 Schematic representation of the major calcium-binding protein-immunoreactive neuronal types in the mammalian neocortex. A few representative species of monotremes, marsupials, and placentals are shown. Many species have comparable neuronal types, especially with respect to small CR-immunoreactive bipolar neurons and CB-containing bitufted and double-bouquet cells. Primates, rodents, and carnivores, with the exception of CR, tend to show comparable patterns. The shading of the neurons indicates the relative intensity of the staining. Faintly labeled neurons are shown as empty symbols, moderately labeled neurons as gray symbols, and intensely labeled neurons as black symbols. Dotted triangles indicate the presence of PV-immunoreactive basket terminals on pyramidal neurons. Triangles represent pyramidal and pyramid-like neurons; black dots represent small multipolar or round neurons; diamonds represent large multipolar neurons and basket cells. Other symbols identify CB- and CR-immunoreactive bipolar, bitufted, and double bouquet cells, as well as neurons with atypical morphology. Note the presence in the monkey and the rat of CB-immunoreactive neurogliaform (represented as small star-shaped elements), and Martinotti cells (shown as large, ovoid horizontally oriented elements), in layers V and VI, that have not been reported in other species. On each panel, the dashed lines identify layers I and IV. Note the thick layer I and the absence of layer IV in cetaceans and ungulates. Layer IV is also not clearly defined in the hedgehog. Adapted from Hof, P. R., Glezer, I. I., Condé, F., *et al.* 1999. Cellular distribution of the calcium-binding proteins parvalbumin, calbindin, and calretinin in the neocortex of mammals: Phylogenetic and developmental patterns. *J. Chem. Neuroanat.* 16, 77–116, Elsevier.

3.08.3.3 Other Phylogenetic Distributions of Cortical Neuron Classes Indicate Convergent Evolution

Although many aspects of cortical architecture reflect phylogenetic affinities, it is likely that many cortical phenotypes present examples of homoplasy, where certain characters have evolved independently in nonrelated groups of mammals. In this regard, it is noteworthy that there are several traits shared by Carnivora and Euarchontoglires, such as the distribution and typology of calcium-binding protein-containing neurons (Glezer *et al.*, 1993, 1998; Hof *et al.*, 1999; Ballesteros Yáñez *et al.*, 2005). For example, in the dog neocortex, PV is present in a large population of morphologically diverse interneurons with a typology generally comparable to that observed in anthropoid primates. Some of these large multipolar neurons may be basket cells, due to the presence of PV-immunoreactive basket terminals around unstained pyramidal perikarya. Furthermore, CR is present in a very dense population of bipolar and double bouquet cells in layer II and the upper portion of layer III, as observed in primates and rodents. These aspects of chemoarchitecture in carnivores that are similar to primates, rodents, and other Euarchontoglires are not derived from a common ancestral state and hence have arisen due to convergent evolution. Other features of carnivore cortical organization resemble traits observed in their close relatives in the Laurasiatheria, the perissodactyls and cetartiodactyls, and so were probably inherited

from the last common ancestor of these taxa. For example, in canids, felids, and pinnipeds, gigantic intensely labeled CR-immunoreactive, multipolar neurons occur in layer III of agranular motor cortices. These neurons are morphologically comparable to the very large CR-containing neurons found in layers III, V, and VI throughout the neocortex of large artiodactyls and cetaceans (Hof *et al.*, 1996, 1999), which shows a poorly differentiated layer IV only in certain regions (Morgane *et al.*, 1990; Glezer *et al.*, 1993, 1998; Hof *et al.*, 1999). It is interesting that in spite of many similarities in cortical organization and connectivity between carnivores and primates, the dog neocortex displays several differences in neurochemical organization compared to anthropoids (Hof *et al.*, 1996, 1999). Canids have a high degree of cellular specialization in primary motor and sensory cortices, contrasting with fairly homogeneous patterns in association cortices. Large PV- and CB-containing pyramidal cells are present only in primary motor and visual regions, and high numbers of large PV-immunoreactive basket cells and multipolar CR-containing interneurons occur only in primary motor, somatosensory, and visual areas (Hof *et al.*, 1996).

Besides these observations in carnivores, other examples show that the distribution of cortical neuron classes exhibit a mosaic pattern of evolution, with some unique specializations, in particular lineages and other examples of homoplasy (for instance, a paucity of PV expression is observed in the neocortex of cetartiodactyls and marsupials). The predominance of CB and CR in the neocortex and subcortical systems of cetartiodactyls is similar to the calcium-binding protein distributions observed in microchiropterans and hedgehogs but differs from that in rodents and primates (Glezer *et al.*, 1993, 1998; Hof *et al.*, 1999). In addition, large multipolar PV-containing neurons are found in the deep layers of the neocortex of hedgehogs and dolphins, unlike in rodents, carnivores, and primates, where PV-expressing cells are more common in layers III and IV. It is also notable that megachiropterans are characterized by the absence of neocortical expression of CR, whereas their thalamic neurons do express it.

3.08.4 Functional Considerations

Calcium-binding protein-containing interneurons are known to influence the activity of pyramidal neurons in a manner specific to each cell class (Condé *et al.*, 1994; DeFelipe, 1997; Hof *et al.*, 1999; Ballesteros Yáñez *et al.*, 2005), and as such the role of calcium-binding protein in cortical integration is likely to be similar to a large degree among rodents, carnivores, and primates, suggesting that similar mechanisms exist across boreoeutherian mammals at least. However, differences are present at the level of particular neuronal subclasses, as recently revealed in a study of CB-expressing interneurons in primates compared to rodents, lagomorphs, carnivores, and artiodactyls (Ballesteros Yáñez *et al.*, 2005). These authors reported that, in the nonprimate species, axon bundles of CB-immunoreactive double bouquet cells are not observed except for some in the visual cortex of carnivores, indicating that although somata that resemble typical CB-expressing cell types from primates can be found in these species, their axonal projections are likely to differ from primates. Whether such differences in axonal organization can be extended to PV- and CR-immunoreactive neurons remains to be demonstrated.

The degree to which functional interpretations of biochemical neuron types can be applied to all mammalian orders is difficult to determine owing to large differences in morphological phenotypes and distributions for any given cell type across species. The relative rarity of PV-immunoreactive neurons in cetaceans and artiodactyls could be interpreted as an ancestral retention for the Laurasiatheria because it also occurs in other laurasiatherians such as echolocating bats and hedgehogs, which may show many plesiomorphic features (Glezer *et al.*, 1988). The neocortex of cetaceans and large artiodactyls appears to contain an inordinate number of cortical modules revealed by clusters of large NFP-containing pyramidal cells in layer IIIc/V (Glezer *et al.*, 1988; Morgane *et al.*, 1988; Hof *et al.*, 1992). Much cortical integration in cetaceans may take place in the cellular, thick layer I that contains 70% of the neocortical synapses in these species (Glezer and Morgane, 1990). Consistent with this observation, most CB- and CR-containing interneurons are located in layers I and II in cetaceans, and the few PV-immunoreactive cells lie in nearby layers IIIc/V and VI pyramidal cells. The PV-immunoreactive neurons may represent basket cells, and axons of CB- and CR-immunoreactive interneurons may be located in a position to interact with inputs to the neocortex and connect the apical dendrites of the deep layers of pyramidal neurons (Glezer *et al.*, 1988; Morgane *et al.*, 1988). It is possible that in cetartiodactyls calcium-binding protein-immunoreactive neurons play a comparable role in neocortical microcircuits as in primates and rodents. The similarities in neurochemical specialization of the cetartiodactyl

neocortex parallel the paleontological and molecular evidence, indicating that these species share a relatively recent common ancestor, and that much like primates, the evolution of the species with the largest brains (the delphinids) is a recent event (Marino *et al*., 2005).

Although there are major gaps in our knowledge of the evolutionary history of neocortical organization in mammals and of the chemical organization of the cerebral cortex in most species, collectively these observations indicate that brain organization and neurochemical cellular specialization reflect evolutionary relationships among many mammalian species.

3.09 Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals

G Baron, Université de Montréal, Montreal, QC, Canada

Glossary

allometry	Variation of the size of any body part or organ relative to body size during ontogeny or phylogeny.
basal insectivora	The most primitive forms of extant mammals (Tenrecinae).
Cuvier's ratio	Relative brain size = brain weight/body weight.
isopoderal	The same body weight.
niche, ecological	The total of interactions of an organism in an ecosystem.
progression index	The ratio of the size of a brain or brain structure in a given species to the size of that structure in a hypothetical average isoponderal basal insectivore. It shows how many times a brain or brain structure is more or less developed in a given species than in a basal insectivore of the same body size.
size index	See 'progression index'.

3.09.1 Introduction: Brain Size and Evolution

The evolution of biological systems is characterized by an increase in functional efficiency, and an important indicator of functional efficiency is size (see The Evolution of Encephalization). Numerous neuroanatomical investigations have demonstrated that the size of the brain or a given brain structure is related to the size of the animal or species and the functional requirements of its habits (e.g., Stephan and Pirlot, 1970; Baron, 1974; Gittleman, 1991). The functional capacity of a brain or brain structure increases as its functional units increase. Large brains are more efficient and capable of more complex functions than small brains. Size is therefore an indicator of evolutionary progress. Since brain size shows variations, not solely related to body size, an important question with respect to brain evolution concerns the most appropriate statistical method for calculating biologically meaningful differences in the size of the brain and brain parts. This problem has been discussed in detail for Primates (Stephan *et al.*, 1988). The authors stated that a useful method (1) must be easily applicable to large numbers of specimens and species, (2) should provide similar values for related species sharing similar morphological and ecoethological features, and (3) should demonstrate that differences in values are compatible with known data on behavior and ecology. It is therefore reasonable to expect that brain size of *Homo sapiens* should have the highest value.

3.09.2 Methods of Comparing Brain Size

3.09.2.1 Reliable Measurements of Brain Size

For valid comparisons, solid data based on reliable measurements and appropriate scaling methods are required. The volume of a brain obtained after histological treatment (fixation, embedding, dehydration) is markedly less than the volume of the fresh brain. The degree of shrinkage differs in each brain and depends on the type of fixation (Bauchot, 1967; Stephan *et al.*, 1981). To obtain comparable data, the volume values must be transformed to fresh brain volumes using a correction factor (fresh-brain volume/fixed-brain volume). The volume of

fresh brain is obtained by dividing the weight of the fresh brain by the specific brain weight (1.036 g cm^{-3}; Stephan, 1960). The same correction factor is used for all brain structures, though the shrinkage may not be uniform. Such differences may be neglected because they are difficult to ascertain and are likely to be small.

3.09.2.2 Standard Brain Size Values

It is practically impossible and to some extent useless to get average values for each brain structure in each species. In comparative studies, it is more constructive to invest in as many species as possible than in many specimens from one species. To obtain brain part volumes representative of a given species, they must be transformed into standard volumes by a conversion factor (C_{sta}) based on the species' average brain size, which is easier to obtain than the average volume size of the various brain structures (C_{sta} = weight of standard fresh brain/weight of individual fresh brain). Employing standards produces good approximations of the unknown mean from a few or even just a single specimen.

3.09.2.3 Problems in Brain Size Scaling

To scale brains by their absolute size is not valid because available data show that, for example, brain weight (BrW) varies within the same genus. In the genus *Myotis* (mouse-eared bats), BrW ranges from 124 mg (*M. muricola*) to 485 mg (*M. myotis*).

Several attempts have been made to compare brains by their relative size (RBrS). Within extant mammals, BrWs vary from 62 mg, in the shrew *Suncus etruscus*, to about 7800 g in the sperm whale (*Physeter macrocephalus*). The ratio between the smallest and any given brain could be used as a relative measure to evaluate brain evolution. However, such ratios are biased. Closely related species of different BrW have different ratios. Furthermore, large mammals such as whales have higher ratios than humans. To compensate for the influence of body size, Cuvier (1845) expressed RBrS as the ratio of BrW/BoW (body weight). But these RBrS measurements, called Cuvier's ratios, are in general high in small species (4.23% in *Sylvisorex granti*, 3.33% in *Suncus etruscus*) and low in large species (0.019% in *P. macrocephalus*, 0.086% in the African elephant *Loxodonta africana*). Such differences exist even in closely related forms. In shrews of the genus *Sorex*, RBrS varies from 1.99% in *S. palustris*, with a BoW of 14.6 g, to 3.26% in *S. cinereus*, with a BoW of 5.16 g. The RBrS of humans (2.05%) is roughly identical to that of the mouse but smaller than that in several shrews. Therefore, RBrS expressed either by BrW ratio between the smallest and any given brain or by Cuvier's ratio does not meet the requirements and is inappropriate for scaling brain size. RBrS values determined by the two methods progress in opposite directions. When BoW is ignored ($BoW^0 = 1$), the values increase from small to large species. When BoW is fully taken into account (BoW^1), the values decrease with increasing body size. This means that in a given taxonomic group, brain size increases less rapidly than body size. The power of the BoW that gives similar RBrS in closely related species must therefore lie between 0 and 1 (see Principles of Brain Scaling).

3.09.2.4 Determination of Relative Brain Size

3.09.2.4.1 The allometric formula Although it seems reasonable to assume that a large body needs more neurons than a small body to control muscles, the relationship is not linear. In a plot of brain size relative to body size, the points do not scatter around a straight line but around a curved line representing a decreasing BrW/BoW ratio. In other words, increased brain size does not keep pace with increased body size. Moreover, not all isoponderal (same BoW) animals have the same brain size. Snell (1892) was the first to produce a very simple equation characterizing the relationship between brain size and body size: $h = k^s\ p$, with h representing brain weight; k, body weight; p and s, psychic and somatic factors, respectively. Snell's work can be considered the starting point of modern quantitative studies on brain evolution.

His power function was extended by Klatt (1919), Huxley (1924), and others to a wide range of biological phenomena that are characterized by differential growth. The term 'allometry' was introduced by Huxley and Teissier (1936), who also proposed more generalized symbols to be used in the allometric formula $y = bx^a$. The exponent of allometry a corresponds to s, which, according to Snell (1892), represents the relationship between BoW and that part of the BrW that may be attributed to somatic factors. Huxley (1924) stressed that the allometric exponent is not a ratio between two sizes but between two growth ratios. The coefficient b, corresponding to p, represents that part of brain size that exceeds the proportion of the brain dependent solely on body size and reflects the contribution to brain size from nonsomatic sources. Jerison (1973) also considered the brain to be the sum of two independent, somatic and nonsomatic, components.

3.09.2.4.2 Calculation of RBrS Based on Snell's power function or Huxley and Tessier's allometric formula, it is easy to calculate $RBrS = BrW/BoW^a$. The power function represents a curved line which in its logarithmic transformation plots a straight line: $\log BrW = \log RBrS + a \times \log BoW$. In this form, the allometric equation becomes a powerful tool for showing the differential size increase of the brain relative to body size. A major problem in calculating RBrS is determining the value of the exponent *a*. It is either estimated from an assumed model of the expected relationship or found empirically by fitting the equation to a set of data. As early as 1867, the Russian anthropologist Alexander Brandt hypothesized that brain weight should be proportional to the surface of the body, because an animal interacts with the environment through the surface of its body. Snell (1892) proposed a power of 2/3 for estimating the surface area of the body. Dubois (1897) was the first to calculate the exponent *a* by using two species with the same psychic level and found values near 0.56. However, the reliability of Dubois' method must be questioned. It assumes that the two species used for the calculation are at the same evolutionary level, and thus assumes that the problem is already solved. There are no grounds whatsoever to claim that two related species differing in size occupy the same evolutionary level (Bauchot and Platel, 1973). A major breakthrough in calculating *a* and RBrS came with the use of logarithmic transformation of the power function (Huxley, 1924). The data points scatter around a straight line in which RBrS is the y-intercept, and the exponent *a* is the slope of the line. The great advantage of the log form is to ease statistical handling (Figure 1).

Since the data points representing the selected species of a sample do not lie on a straight line, an important question concerns the production of a best-fit line, which minimizes deviation of the variables from the line. Three methods are generally used to produce this line. (1) The least-squares regression analysis (e.g., Huxley, 1932), which is the most commonly used, minimizes the sum of squared vertical residuals. (2) The principal major axis analysis minimizes the sum of squared residuals perpendicular to the line (Jolicoeur, 1965). (3) The reduced major axis analysis minimizes the sum of the areas of triangles bounded by the best-fit line and lines connecting it with the data points, parallel with the respective coordinate axes (e.g., Kermack and Haldane, 1950). The least-squares analysis has often been rejected as inappropriate for studying allometry because it assumes that one variable is measured with no errors. However, both BrW and BoW are subject to random fluctuations (Kuhry and Marcus, 1977). Steudel (1982) maintained that BoW should be considered the independent variable because allometry is essentially the variation of a structure relative to body size. Nevertheless, when the data points are highly correlated, the three procedures give similar results (Sprent, 1972).

3.09.2.4.3 Standards for brain size comparison RBrS is usually considered brain size relative to BoW. However, BoW is rejected by several authors because

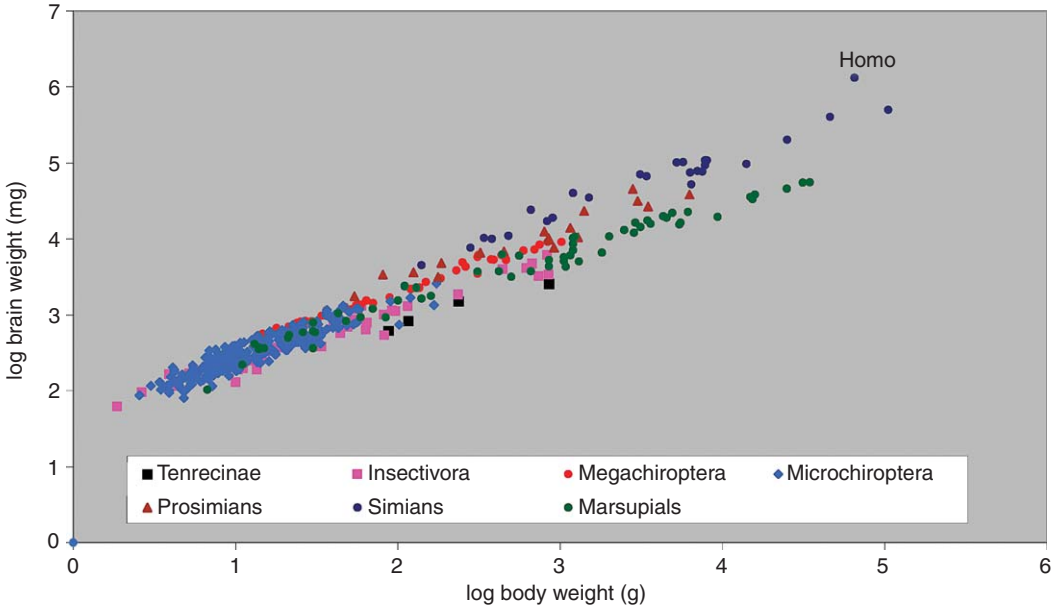

Figure 1 Brain weight (in milligrams) plotted against body weight (in grams) in a double logarithmic scale.

of strong individual variations due to actual food intake, gravidity in females, seasonal changes, age, and other factors. To avoid such problems, RBrS has sometimes been determined relative to body length. In some species, especially big mammals such as whales, body length is easier to measure than BoW. However, a one-dimensional measure is less accurate than BoW. Furthermore, length depends on shape. Long animals do not have larger brains than short animals of the same BoW (Stephan, 1954). A more frequently used standard of comparison is the size of a particular brain part, mainly the medulla oblongata, expressed as weight, volume, length, or cross-sectional area (e.g., Passingham, 1975) or the weight of the brainstem (e.g., Portmann, 1942). The use of the brainstem or medulla oblongata (OBL) as a substitute for body size is not recommended because it is not possible to determine their precise size macroscopically. Furthermore, they are not independent of brain size and are strongly influenced by higher brain centers and adaptations. Although the OBL is the most conservative of the major brain parts, the number of its pyramidal and extrapyramidal fibers is correlated with the isocortex (neocortex, NEO) and the striatum (STR). The sizes of the inferior olive and the ventral pons (VPo) increase with the cerebellum (CER) and NEO. VPo is often considered part of the brainstem and hence, the reference system. However, its percentages vary from 0.37% in *Echinops telfairi* (Insectivora) to 37.17% in *Homo* (Matano *et al.*, 1985a). The OBL of water-adapted animals is characterized by hypertrophy of the trigeminal nucleus (TR). In the semi-aquatic insectivore *Potamogale velox*, TR constitutes 21% of OBL, in contrast to 13% in the terrestrial hedgehog *Erinaceus europaeus*. Radinsky (1967) used the size of the foramen magnum as a standard for comparison when only skulls and no body size were available.

Despite intraspecific variations, BoW remains the most reliable standard for brain size comparisons. Since, in a given species, BoW is generally more variable than BrW, certain rules have to be applied in order to obtain the most reliable data. During ontogeny, the brain reaches adult size sooner than the body. The low RBrS found in animals living in captivity is due to their being overweight. Free-living chimpanzees were found to have BoWs uniformly around 46 kg (Stephan *et al.*, 1988), whereas values up to 80 kg are reported in the literature (Bauchot and Stephan, 1969). In general, the range of variation is rather small in wild animals. The brain can be considered an image of the body in reflecting not only differential muscle mass and sensorial areas but also the relative functional importance of various body parts. Furthermore, differences in body size also correspond to differences in the occupied niche.

3.09.2.4.4 Reference line slope Determining a common slope is crucial for interspecific comparisons of brain size. The slopes of the best-fit lines depend on the taxonomic level of the sample. It follows that the taxonomic level at which the allometric analysis is performed affects not only the slope, but also the residuals, which reflect size differences of the brain and its parts relative to the reference line. Authors who used samples belonging to several orders found slopes ranging from 0.66 (Bonin, 1937) to 0.91 (Stephan *et al.*, 1988). Many of them decided that the size increase of mammalian brains is best reflected by a slope of 0.75. Other authors have estimated the slope for lower taxonomic levels such as genera, families, or orders and found wide variation. Slopes of higher taxonomic groups are usually steeper than those of groups at a lower taxonomic level (Passingham, 1975). However, when using larger samples with a greater range of body size (>2), slopes become similar (Stephan *et al.*, 1988, 1991; Baron *et al.*, 1996). To avoid erroneous slopes, Rempe (1970) proposed a canonical method for determining the slope. This method gives each subfamily or family its appropriate weight when calculating a common slope. Taxonomic groups for which more data are available and/or those with a large BoW range have more influence on the slope than do those with poor data. For the total of 68 subfamilies or families of Insectivora, Scandentia, Chiroptera, Primates, and Marsupialia with more than one species examined, the common slope for brain size relative to BoW was found to be 0.66, which corresponds to the value postulated by Snell and others. The same method can be used to calculate the common slope for any brain part relative to BoW. The slopes of the five main components range from 0.58 (mesencephalon, MES) to 0.68 (telencephalon, TEL); the telencephalic components range from 0.57 (hippocampus, HIP) to 0.73 (NEO), and the brainstem sensory structures range from 0.50 (cochlear complex) to 0.62 (funicular complex). It follows that the size changes of different brain parts relative to body size take place at different rates (Table 1).

The slopes are important because of their effect on RBrS comparisons within species of different BoW. If a steep slope is used, RBrS systematically appears larger in species with small BoW than in species with large BoW within the same family. The RBrS values obtained from a steep regression line based on a mixed mammalian sample (mouse–elephant line) are often devoid of any biological

meaning and may result in such oddities as a similar RBrS in *Homo* and small prosimians or higher values in small prosimians than in large simians. In contrast to the slope of the reference line, which determines the biological meaning of brain size and brain parts, the position of the reference line does not affect the RBrS ratios of different species.

3.09.2.4.5 The reference group A major problem in evolutionary biology is to decide which characters are primitive and which are advanced. Since it is impossible to obtain information on the quantitative composition of the brain in primitive fossil mammals, the Tenrecinae (Insectivora), probably the most primitive forms of extant mammals, were chosen as the reference group (basal Insectivora). Their brains are expected to be similar to those of the extinct forms considered forerunners of mammalian orders and thus provide the best possible approximation to the unknown brain structure of extinct primitive mammals. Stephan's (1967) progression or size indices (PIs or SIs) provide a simple and efficient tool for comparing the degree of evolution of brains and brain parts directly. The PI of a given brain structure in a given species is the ratio of the size (weight or volume) of that structure to the size of that structure in a hypothetical average isoponderal basal insectivore. A PI thus shows how many times a brain or brain structure is more or less developed in a given species than in a primitive insectivore of the same size. A critical evaluation of the use of PIs in statistical analyses was given by Jolicoeur *et al.* (1984).

3.09.2.5 Progression Indices of Brain Structures in Mammals

Major parts of the brain steadily increase in size from Tenrecinae (basal Insectivora) to Simians and *Homo* (Figure 2). The smallest increase in PIs was found for OBL, the largest for NEO. In humans, OBL is only 1.87 times larger than that of Tenrecinae and 1.42 times larger than the average index of Insectivora. The large brain components are heterogeneous structures, each containing cell populations relating to different functions. The OBL contains sensory nuclei receiving information about the environment as well as motor nuclei controlling precise muscle activities. The increased size of such large heterogeneous brain components does not likely reflect an increase in a specific function. Similar PIs may result from differential growth in functionally different brain centers (mosaic evolution, see Mosaic Evolution of Brain Structure in Mammals). For example, the PI of OBL (144) in the semi-aquatic *Neomys fodiens* (Insectivora) is similar to those of *Scotonycteris zenkeri* (146, Megachiroptera), *Molossus molossus* (145, Microchiroptera) and the marsupial *Aepyprymnus rufescens* (144). However, these animals differ considerably in the PIs of TR (194, 90, 97, 62) and those of the cochlear nuclei complex (CON) (53, 130, 209, 129) (Stephan *et al.*, 1991; Baron *et al.*, 1996) (Table 1).

The size increase of the MES from Insectivora to Primates is more pronounced than that of OBL. MES occupies the second place in Insectivora, Megachiroptera, and Primates. In Microchiroptera and marsupials, its enlargement is, however, greater

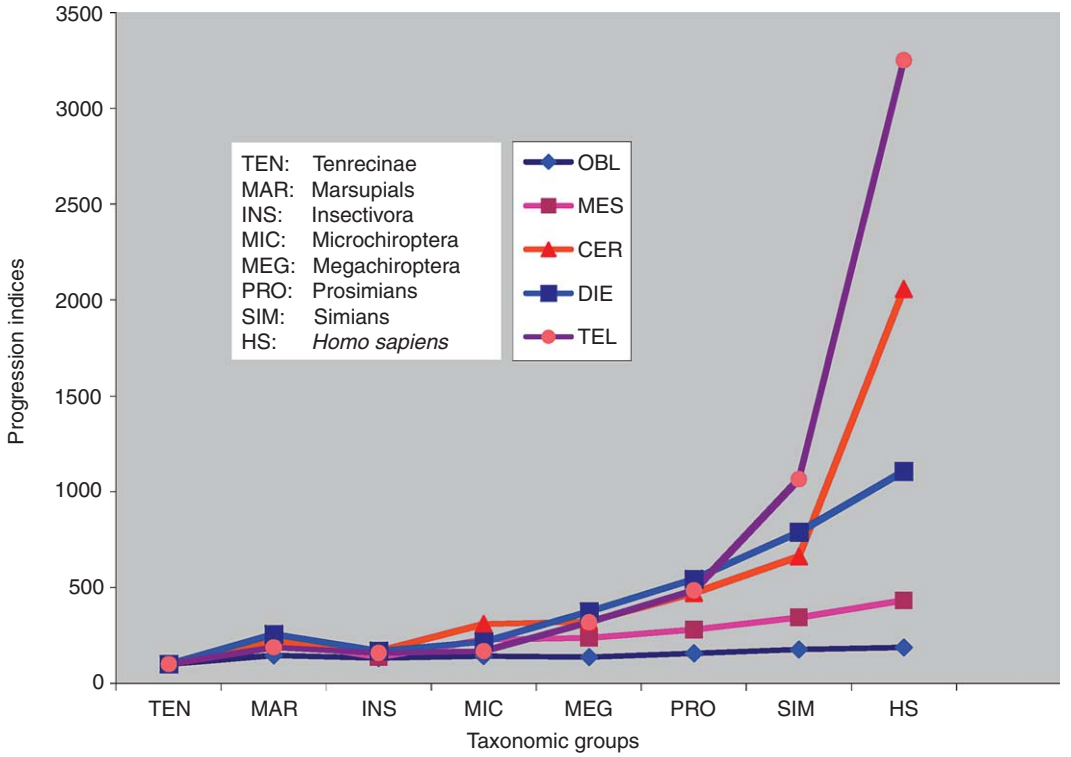

Figure 2 Progression indices of the five fundamental brain parts related to the average of the four species of Tenrecinae (PI = 100). Abbreviations for brain structures as in Table 1.

than that of TEL. The two components of MES, the tegmentum (MTG) and tectum (MTC), show divergent evolutionary trends in Chiroptera, with Megachiroptera having a larger MTG but smaller MTC than Microchiroptera. Of the tectal components, the visual colliculi superiores (SUCs) are better developed in Megachiroptera, whereas the auditory colliculi inferiores (INCs) are larger in Microchiroptera (Baron *et al.*, 1996). The two chiropteran suborders also differ in the quantitative organization of MTG. The auditory nuclei of the lateral lemniscus are more than three times larger in Microchiroptera than in Megachiroptera (Baron, 1974).

The size increase of the cerebellum (CER) is even greater than that of MES. In *Homo*, CER is 20.57 times larger than in Tenrecinae and 3.25 times larger than in nonhuman simians. In Microchiroptera, CER shows the greatest enlargement of the five fundamental parts. The size increase of the intracerebellar nuclei medial (MCN), interposed cerebellar nuclei (ICN), and lateral cerebellar nuclei (LCN) reflect the differential development of the three longitudinal zones of the CER (vermis-MCN, pars intermedius-ICN, hemisphere-LCN). The ICN is in all groups the smallest, while LCN is the largest or very close to the largest (Megachiroptera).The vermis-MCN component is concerned with postural tone, equilibrium, and locomotion of the entire body. The intermediate-ICN zone controls movements of the proximal limbs, and the hemisphere-LCN zone controls the distal parts. The evolutionary progress of CER in mammals is characterized by strong enlargement of the lateral zone. The medial zone is much less progressive and even smaller in apes and humans than in prosimians and monkeys. This evolutionary trend reflects the progression of complexity in motor patterns from simple movements to the very skilled movements of the hand and fingers (Matano *et al.*, 1985b). In bats, the high PIs of the LCN reflect the involvement of the anterior distal limbs in flight (Baron *et al.*, 1996).

The diencephalon (DIE) is clearly enlarged in the average Insectivora compared with the Tenrecinae. There is a steady increase from Insectivora to Primates and *Homo*. The average PI of the DIE of marsupials lies between those of Microchiroptera and Megachiroptera. In Insectivora, Megachiroptera, prosimians, and marsupials, it is the most progressive of the five encephalic main components. Studies of the ontogenetic development have revealed that DIE may be divided into four horizontal zones: the dorsal epithalamus (ETH), thalamus (THA), subthalamus (STH), and hypothalamus (HTH). Allometric

analysis in Insectivora and Primates reveals the existence of at least two major developmental gradients in the quantitative changes of the diencephalic zones during evolution. Though quite limited, the size increase of ETH and HTH is most accentuated in the earlier phyletic phases (from Insectivora to prosimians). THA and STH increase in a more continuous manner from Insectivora to higher Primates and *Homo*. The most progressive parts of the DIE have major direct connections with the NEO and the striatum (STR). ETH and HTH are functionally related to limbic structures (Baron, 1979).

The TEL is a highly heteromorphic brain part with purely cortical (NEO; schizocortex, SCH; HIP) and purely subcortical subdivisions (STR), as well as a mixture of cortical and subcortical elements (paleocortex, PAL; septum telencephali, SEP; amygdala, AMY). The olfactory bulbs are a special type of allocortex. Functionally, the TEL may be subdivided into olfactory components, limbic structures, motor centers, and higher brain centers. Only in simians and particularly in humans is TEL the most progressive of the five main components of the brain. In Microchiroptera and Marsupialia, its SI is second only to OBL.

Olfactory structures (main olfactory bulb, MOB; PAL) are clearly reduced in all taxonomic groups compared with Tenrecinae, except in Megachiroptera (Figure 3). PAL is a fairly heterogeneous brain part, with the components differing in their PIs. It comprises structures with PIs similar to those of MOB and structures characterized by a size increase. Of the olfactory cortices, the retrobulbar region (anterior olfactory nucleus) has similar PIs to MOB. In simians and especially in humans, the PIs of the prepiriform cortex and olfactory tubercle are clearly larger than those of MOB (Baron *et al.*, 1987). The deviations of PAL PIs from the trends in MOB may indicate changes in the functional role.

The limbic system (Figure 3) is composed of a group of moderately progressive structures comprising the HIP, SCH, SEP, and AMY. The progression of the entire limbic system is in Insectivora and Microchiroptera about 1.5, in marsupials 1.7, in nonhuman simians 2.2, in prosimians 2.3, in Megachiroptera 2.5, and in humans 4.4 times larger than in Tenrecinae. In nearly all taxonomic groups under consideration, HIP and SCH are more progressive than SEP and AMY. The only exception is in Microchiroptera, where HIP is clearly smaller than AMY.

The allometric size of AMY increases slightly in Insectivora (114) and marsupials (122) and moderately in Chiroptera (165) and prosimians (170). In nonhuman simians, it is more than twice (210) and in humans four times as large as in Tenrecinae. AMY can be divided into the lateral amygdala (LAM), or corticobasolateral group including magnocellular (MCB) and cortical nuclei, and the medial amygdala (MAM), combining several

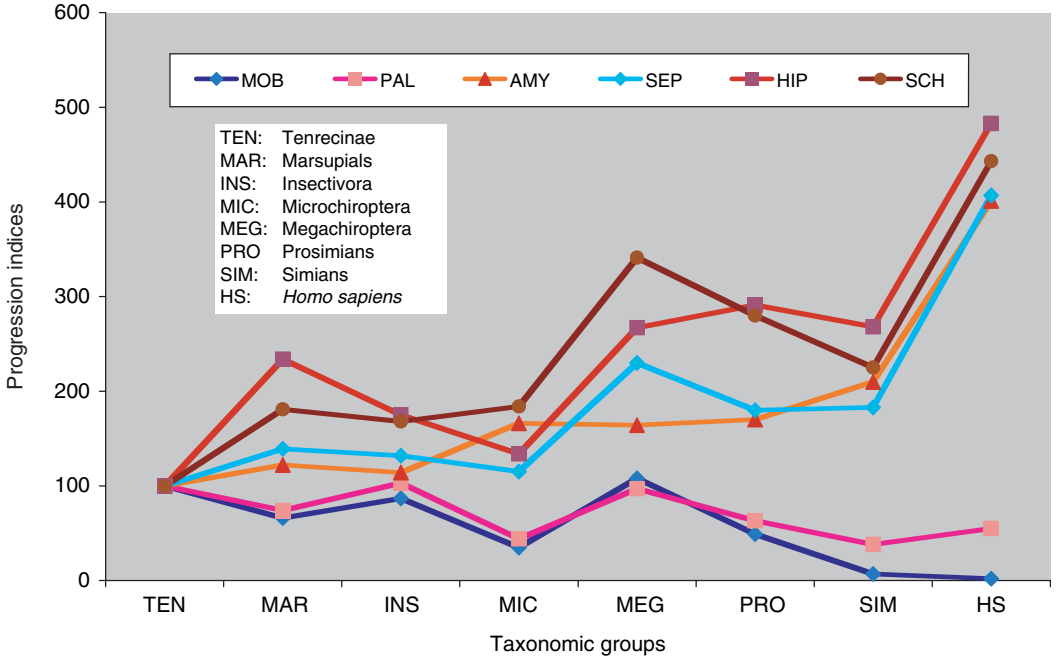

Figure 3 Progression indices of the olfactory and limbic brain structures related to the average of the four species of Tenrecinae (PI = 100). Abbreviations for brain structures as in Table 1.

distinct grisea. In all primate species, LAM has higher indices than MAM. LAM is best characterized by its connections with sensory systems in the NEO and PAL. Its progressive evolution suggests increasingly complex interactions with the environment. MAM is characterized mainly by its connections with autonomic centers in the brainstem (see Stephan *et al.*, 1988). The indices indicate that visceral functions are essentially the same in primitive and higher mammals.

In Microchiroptera, the PI of SEP (115) is lower than the average PI in Insectivora (132) and marsupials (139). In Megachiroptera, PI (230) is even larger than in Primates (182). In humans, SEP shows the same size increase (407) as AMY. Measurements of septal nuclei in some Insectivora and Primates (Andy and Stephan, 1966) indicate that all the major nuclei except for the nucleus septalis triangularis and bed nucleus of the anterior commissure contribute to the size increase of the septum during phylogeny.

The average PIs of SCH are highest in Megachiroptera (341) and prosimians (280). In humans, it is close to the PIs of the other limbic structures. The relative size within SCH of the two main components, entorhinal and presubicular cortices, do not change.

The average PI of HIP is lower in Microchiroptera than in Insectivora and lower in nonhuman simians than in prosimians. In *Homo*, HIP is the most progressive of the limbic structures. The data indicate that the progression of HIP is not continuous in the ascending primate scale. The marsupial average lies between those of Micro- and Megachiroptera. Not all of the HIP parts increase to the same extent. Investigations on HIP components from Insectivora through Primates show a marked enlargement of area CA 1 (see Stephan *et al.*, 1991).

STR (Figure 4) shows a steady increase in the eutherian taxonomic units under consideration. The index value in *Homo* is about 14 times as large as that of Tenrecinae. The most common function attributed to the STR is related to motor processes. However, there is increasing evidence of functions of the basal ganglia not easily characterized as motor. In fact, STR is not only connected with motor structures but also with the association cortex and limbic system.

Many studies support the conclusion of earlier investigations (e.g., Stephan and Andy, 1964) that the NEO is the most progressive and most discriminative component of the mammalian brain. The high progression indices may be considered the prime factor in mammalian evolution and indicative of the successful progress of mammals (see Cortical Evolution as the Expression of a Program for Disproportionate Growth and the Proliferation of Areas; Figure 4).

The differential growth of brain parts and nuclei as expressed by the progression indices clearly shows that adaptive radiation occurred at various taxonomic levels (e.g., Stephan *et al.*, 1988, 1991;

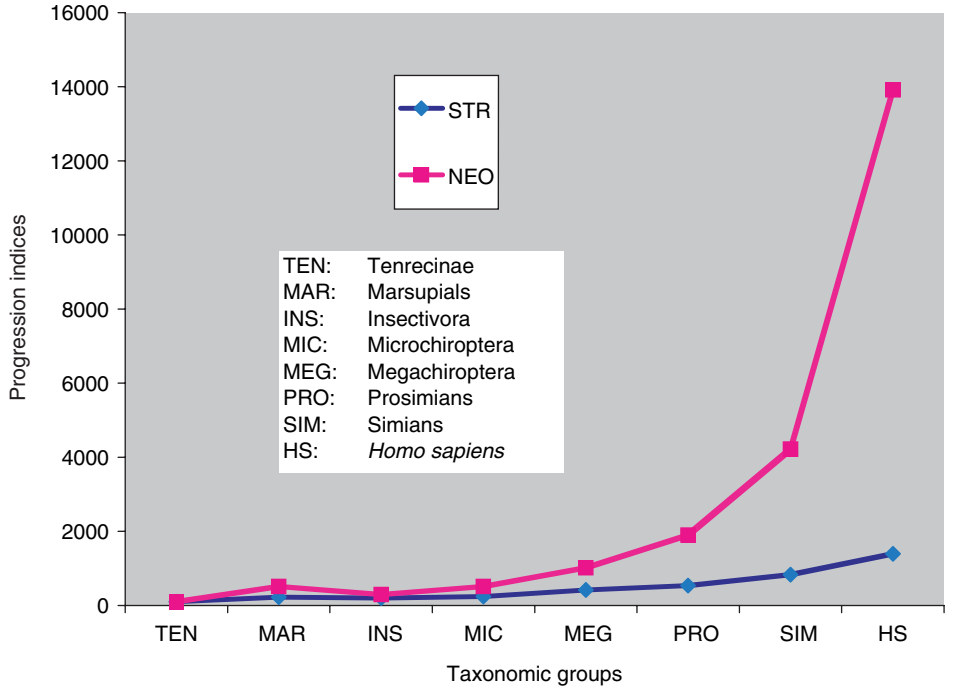

Figure 4 Progression indices of the STR and NEO related to the average of the four species of Tenrecinae (PI = 100).

Baron *et al.*, 1996). Thus, PIs measure differences between species by the amount of brain evolution that has occurred since their separation.

3.09.2.6 Brain Center Correlations

Brain components do not develop independently of each other. They are parts of a functionally integrated system, the output of which is coordinated behavioral patterns. One may, therefore, assume that most brain structures are more or less correlated in size, but that structures belonging to the same functional unit by virtue of direct fiber connections should show better correlation than those with no immediate functional relationship. However, to avoid misinterpretations, it should be stressed that strong correlation does not necessarily indicate functional interdependence. It is only one of the possible explanations. Correlations between the PIs of the major brain parts are almost exclusively positive and highly significant. The only negative correlations are with the olfactory structures MOB and PAL. However, none of the negative values even comes close to statistical significance, despite the large sample ($n = 466$). Moreover, the picture is largely the same for correlations at lower taxonomic levels except for Insectivora, with the only significant negative correlation being between olfactory structures and OBL, and for Microchiroptera and prosimians, with no negative correlations. The negative correlation in Insectivora is due to semi-aquatic species with their hypertrophied tactile trigeminal system and reduced olfactory system. The strongest correlations exist between NEO, STR, DIE, and CER, the highly integrative centers of sensory and motor modalities with multiple interconnections. Equally strong correlations in all taxonomic groups except simians are found for MOB and PAL, indicating direct projections from the MOB to PAL. The absence of correlation in simians is due to an increase of non-olfactory components during phylogeny. The correlations between limbic structures are highly variable and differ among taxonomic groups. Limbic structures are known to be interconnected by multiple pathways but differ in their precise function (Table 2).

3.09.2.7 Ecological Niche and Size Differences in Brains and Brain Parts

The brain reflects the complexity and specificity of a species' ecological niche. The characteristics of a niche that exert the strongest selective pressures on the survival of an organism and hence the evolution of its nervous system are (1) the trophic niche, including the type of food, its spatiotemporal distribution, and the feeding strategy, (2) the avoidance of predation, and (3) reproductive behavior. Other aspects of the ecological niche such as habitat structure and complexity, social organization and behavior, and other ecological descriptors may have a determining influence on the three groups of behavior and are widely interdependent. PI comparisons within each taxonomic group in which radiation of particular traits occurred independently clearly show the influence of similar selection pressures on brain evolution. To avoid similarity due to common selective pressures being confounded with similarity due to phylogenetic propinquity, authors use methods that correct for phylogeny, such as the independent contrasts technique (Felsenstein, 1985; Purvis, 1991; Pagel, 1992).

To understand the impact and nature of ecological pressures on brain evolution, structures with well-defined functions are more revealing than heterogeneous brain parts.

Numerous studies have shown that brain size and structure vary with ecoethological adaptations and in particular with dietary specialization (Pirlot and

Stephan, 1970; Stephan and Pirlot, 1970; Baron, 1974; Eisenberg and Wilson, 1978; Clutton-Brock and Harvey, 1980; Baron *et al.*, 1996). It has been shown that quantitative brain composition varies not only with food type but also with the occupied foraging biotope. The impact of predation pressure on brain evolution has not received much attention. One reason may be that many defense mechanisms are related to social behavior and strongly depend on the habitat's characteristics.

The impact of sexual selection on brain evolution has been shown in several species. Sex-linked HIP size differences were found to be related to differences in home range size and in solving spatial problems related to navigation (Jacobs *et al.*, 1990). Size differences in hypothalamic structures implicated in both reproductive and social behavior are reported in dimorphic voles (Shapiro *et al.*, 1991)

3.10 Organization of a Miniature Neocortex – What Shrew Brains Suggest about Mammalian Evolution

K C Catania, Vanderbilt University, Nashville, TN, USA

Glossary

chemoarchitecture	The appearance of the fine structure of a brain area as revealed by various histological tissue stains.
encephalization	The relative size of the brain compared to the expected size of the brain for a given body weight.
eutherian	A placental mammal. Marsupial and placental mammals form the two major groups of extant mammals.
lissencephalic	Refers to a neocortex that is smooth, lacking gyri and sulci.
neocortex	The six-layered sheet of neural tissue that forms the outer layer of the mammalian forebrain.

3.10.1 Introduction

A well-documented trend in mammalian evolution has been an increase in absolute and relative brain size (Jerison, 1973). This is evident from fossil skulls of early stem mammals and brain endocasts that have been identified for some early eutherians. An outstanding review of the current understanding of early mammalian evolution and brain–body size relationships can be found in a recent text by Kielan-Jaworowska *et al.* (2004). From the available evidence, it seems clear that early mammals had small brains with little neocortex. As a result, small-brained mammals, particularly members of the order Insectivora, have been of long-standing interest for investigations of mammalian brain evolution (Ebner, 1969; Lende, 1969; Kaas *et al.*, 1970; Valverde and Facal-Valverde, 1986; Glezer *et al.*, 1988; Michaloudi *et al.*, 1988; Stephan *et al.*, 1991; Regidor and Divac, 1992). These species (Insectivora) are thought to resemble ancestral mammals in a number of respects. For example, fossil evidence suggests that ancestral mammals were shrew-like in size, habits, and external form.

Despite this crucial fossil evidence regarding the morphology of ancestral species and the overall size and proportions of their brains (Kielan-Jaworowska, 1983, 1984, 1986; Jerison, 1990; Kielan-Jaworowska *et al.*, 2004), the internal organization of ancestral brains cannot be determined from fossils. Instead, our best attempts to reconstruct this organization must come from analysis of the brains of extant species. The general approach is to examine the diversity of brain organization across modern lineages of mammals, and to determine those characters that are shared by most species and therefore likely inherited from a common ancestor, and those characters that are unique to specific lineages of mammals and therefore most likely independently and more recently evolved. Kaas (1982, 1987, 1989) provides several reviews of this approach and the conclusions that can be drawn from considering comparative studies of modern mammalian brains.

However, in addition to these comparative studies, it also seems reasonable to consider how brains are organized in modern species that resemble ancestral species in many respects. The aim of this article is to outline relatively recent results from investigations of shrew neocortex, because these species represent some of the smallest mammals on the planet and they resemble ancestral mammals in a number of respects. This is of course the major reason for the long-standing historical interest in the brains of small mammals that exhibit primitive characteristics.

At the same time, we must keep in mind that living species are not ancestors, and the mosaic nature of evolution may (as usually does) result in many primitive features combined with more derived traits that do not represent an ancestral condition. Nevertheless, small-brained mammals such as shrews can give us some insights into possible ancestral brain organization. By learning how the smallest mammal brains are organized, we can at

for sensory areas that 'may' have existed in early mammals with diminutive areas of neocortex.

It is possible that there are limitations on the size and form of small sensory areas due to functional and developmental constraints. If a minimal number of neurons is necessary for processing information in sensory areas, we might predict that cortical areas would occupy a greater proportion of cortex in very small-brained mammals. Alternatively, if we attribute much of the size increase of cortex in larger mammals to simply dealing with information from a larger body, then we might predict that sensory areas in very small mammals would be proportionally reduced in correspondence to their equally small bodies. Areas could overlap extensively in a tiny brain, as has been reported for S1 and M1 in the North American opossum (Lende, 1963; but see also Beck *et al*., 1996) or they might retain the sharp borders characteristic of virtually all primary and secondary areas of larger-brained mammals. If some characteristics of cortex organization are typical for very small brains, we might postulate similar conditions for ancestral species with little neocortex. Thus in addition to providing important comparative information regarding the organization of cortex in insectivores and mammals in general, studies of shrews with very small brains may help guide theories of cortical evolution by indicating which hypotheses about small-brained ancestral mammals are most tenable.

3.10.2 Brain Size in Ancestral Mammals

It is commonly stated in the literature that ancestral mammals had small brains with little neocortex. However, this is best appreciated by viewing some of the fossil evidence to scale. Figure 1 provides schematics of fossilized skulls redrawn in outline form from Kielan-Jaworowska *et al*. (2004). Early stem mammals are shown in Figure 1a. No attempt has been made to illustrate forebrain size for the early stem mammals as endocast data were not available. However, it is clear that the absolute size of the head was relatively small in these species, and that within the cranium, the forebrain occupied a relatively small proportion of the available space (see Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals).

Considerably more information is available from early eutherian mammal fossils (Figure 1b). These specimens were also small animals with relatively small heads; however, there is an apparently much larger space for the forebrain (see The Evolution of Encephalization). Although endocranial data are available for only four specimens from the Mesozoic (Kielan-Jaworowska *et al*., 2004), the relative sizes of

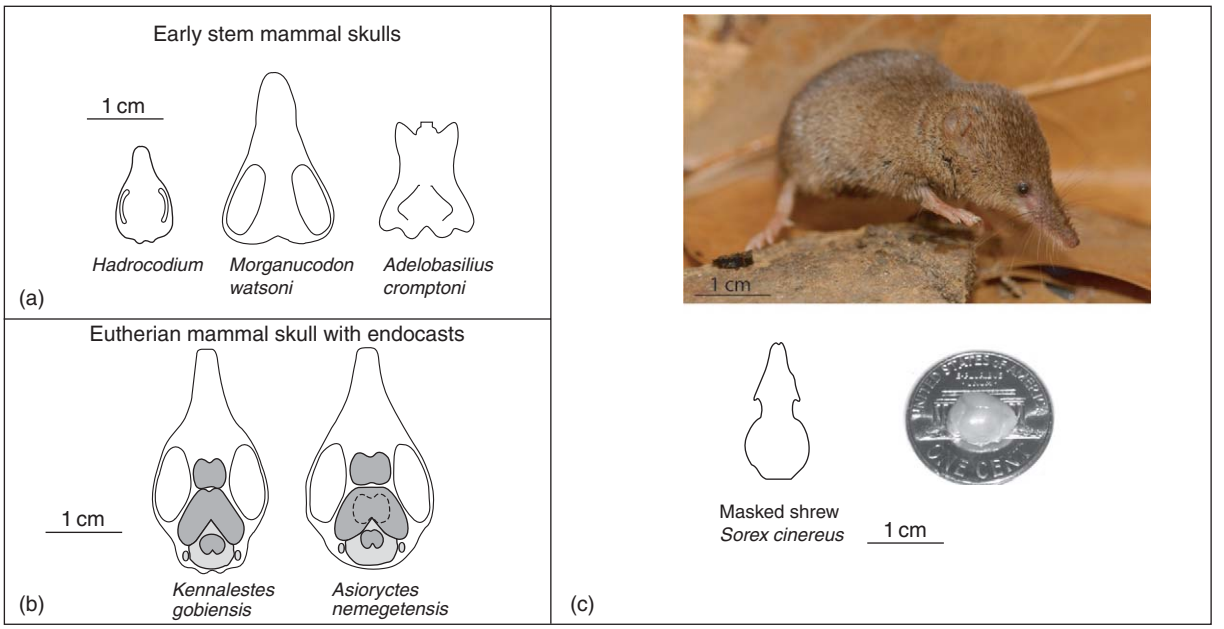

Figure 1 The skulls of early mammals compared to the skull and brain of a masked shrew. a, Reconstructions of skulls of some early stem mammals shown at true size. b, Schematics of early eutherian mammal skulls with endocast data showing brain sizes and subdivisions. The dotted line in *Asioryctes* indicates the possible location of the rhinal sulcus, suggesting these species may have had very little neocortex. c, A masked shrew with an outline of a masked shrew skull (bottom left) and a masked shrew brain on a penny (bottom right). Note that all illustrations are life size and at the same scale across the panels. Schematics for (a) and (b) are redrawn from illustrations in Kielan-Jaworowska, Z., Cifelli, R. L., and Lou, Z. X. 2004. Mammals from the Age of Dinosaurs. Origins, Evolution, and Structure. Columbia University Press.

the cerebral hemispheres, olfactory bulbs, and cerebellum are apparent. The presumptive neocortex was lissencephalic, and the two hemispheres were widely separated posteriorly such that the superior colliculi were exposed. One of the most interesting clues to brain organization in these species comes from the hint of the rhinal sulcus in *Asioryctes nemegetensis*. Evidence for this landmark is not conclusive; however, it does suggest, along with the exposed colliculi, that these early mammals had relatively little neocortex (see The Origin of Neocortex: Lessons from Comparative Embryology). In addition to this direct fossil evidence, it has been well established that neocortex occupies a proportionally larger part of the brain in large brains compared to small brains, in general, across different mammal species (e.g., Finlay and Darlington, 1995; Finlay *et al*., 2001; see The Evolution of Neuron Classes in the Neocortex of Mammals, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications). This in turn means that neocortex occupies a proportionately smaller part of small brains in general.

From these considerations it seems clear that neocortex was relatively small in ancestral mammals, and that a major trend in evolution has been an increase in absolute brain size and in the size of the neocortex (see What Fossils Tell Us about the Evolution of the Neocortex). This makes the brains of shrews interesting to consider from a number of perspectives. Figure 1c shows a masked shrew, weighing only 3 g, an outline of a masked shrew skull, and a masked shrew brain on a penny – all at the same scale (and at the same scale as the skulls in Figures 1a and 1b). It is hard not to conclude, from the swollen appearance of the shrew's cranium compared to the appearance of the available fossils, that an increase in relative brain size (i.e., encephalization) has played an important role in mammalian evolution. Of course our interest in shrew brain organization stems from the comparatively small size of the brain compared to other extant mammals (Stephan *et al*., 1991).

3.10.3 Organization of Neocortex in the Smallest Mammals

Despite the long-standing historical interest in shrews for comparative brain research, it is only recently that microelectrode recordings were made from their neocortex to determine how these brains are organized. By examining five different species of shrews using a combination of electrophysiological recordings and analysis of flattened brain sections, a fairly complete picture of their cortical organization was obtained (Catania *et al*., 1999). Some of the most compelling data come from the brain of the diminutive masked shrew. This species approaches the lower size limits for mammals (approximately 3 g) based on physiological considerations (Schmidt-Nielson, 1984).

An important and convenient finding in this species was a series of chemoarchitectural subdivisions that delineated cortical areas. Although cortical recordings were not made in this particularly small shrew species, the subdivisions visible in the flattened cortical preparation correspond to similar areas from which recordings were made in other shrews, allowing the different subdivisions to be identified (Catania *et al*., 1999). Such visible subdivisions are not apparent in all mammal brains, but when they do occur, they provide a detailed picture of brain organization.

Figure 2a shows the flattened cortex from a masked shrew that has been processed for the metabolic enzyme cytochrome oxidase. The various locations of

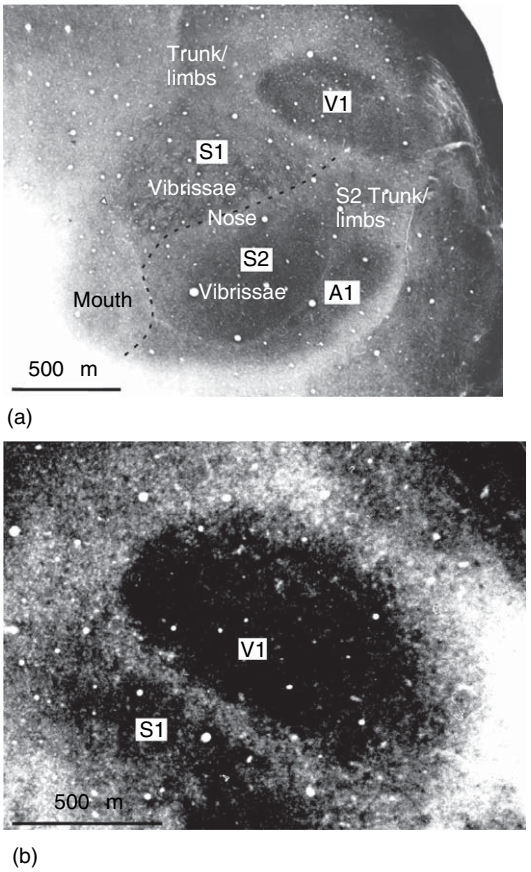

Figure 2 A section of cortex from *Sorex cinereus* (the masked shrew) demonstrating the direct adjacency of cortical areas in a single section processed for cytochrome oxidase. a, Each cortical area has a distinctive appearance, while subareas (such as mouth, vibrissae, and trunk) within S1 and S2 are also distinct. V1, primary visual cortex; S1, primary somatosensory cortex; S2, secondary somatosensory cortex; A1, primary auditory cortex. b, A close-up view of the border between S1 and the V1 in a masked shrew (opposite hemisphere from plate a). The small space suggests there are no intervening cortical areas.

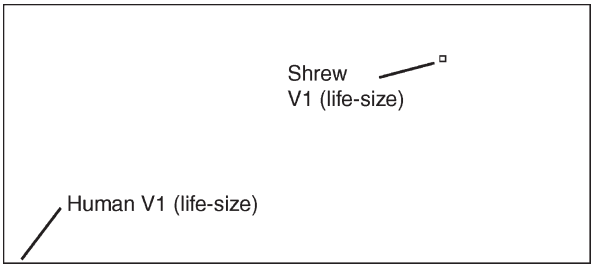

Figure 3 The relative size of primary visual cortex (V1) in a masked shrew (0.75 mm^2) compared to V1 in a human (approximately 2500 mm^2).

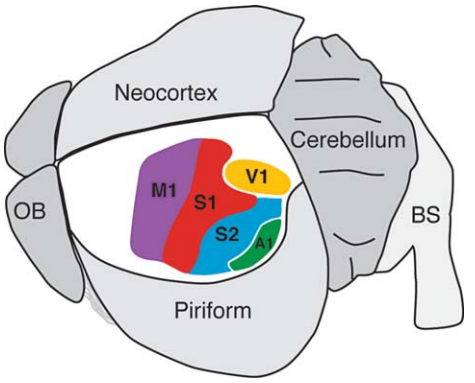

Figure 4 Summary of cortical organization in shrews. The sensory areas are located in caudal, lateral cortex. Two representations of the contralateral body surface correspond to S1, the primary somatosensory area, and S2, the second somatosensory area. Auditory cortex was found at the extreme caudolateral end of neocortex, partially surrounded by S2. Note the close adjacency of sensory areas. This condition seems to exclude the possibility of intervening higher level or association areas typical of other larger-brained mammals. OB, olfactory bulb; BS, brain stem; V1, primary visual cortex; A1, auditory cortex; M1, motor cortex. Adapted from Catania, K. C., Lyon, D. C., Mock, O. B., and Kaas, J. H. 1999. Cortical organization in shrews: Evidence from five species. *J. Comp. Neurol.* 410, 55–72.

different body-part representations are indicated. Evidence was found for a number of different cortical areas, including primary somatosensory cortex (S1), secondary somatosensory cortex (S2), primary auditory cortex (A1), and primary visual cortex (V1). In addition, a study by Nudo and Masterton (1990), examining the location of corticospinal projecting neurons, indicated the probable location of motor cortex (M1) in shrews (see Catania *et al.*, 1999, for details).

There are several obvious conclusions from these data. First, shrews have only a few cortical subdivisions. However, these areas are not overlapping, are delineated by chemoarchitectural features, and have sharp borders. The recording data from a number of other shrew species additionally suggest that these cortical areas are well organized internally (i.e., have topographic representations of sensory surfaces). Second, there is little or no room for intervening cortical areas between those visible in the cytochrome oxidase preparation. This is emphasized in an enlarged view of the S1–V1 border in the masked shrew (Figure 2b). For example, it is difficult to envision a secondary visual cortex (V2), with its characteristic topographic representation of the visual hemifield, compressed into the small space between V1 and S1. Finally, the absolute size of these areas provides a striking illustration of the changes that have occurred for some cortical areas in the course of mammalian evolution. Ancestral mammals probably had a V1 that was similar in size to V1 in shrews. Figure 3 is a schematic showing the actual area of masked shrew V1 (0.75 mm^2) compared to V1 in humans (about 2500 mm^2).

Figure 4 shows a summary of cortical organization in the masked shrew. This schematic illustrates the major finding, that the number of cortical sensory and presumed motor areas in shrews is extremely limited. Most mammals have at least some, and often extensive, cortical territory intervening between S1, V1, and A1. This does not appear to be the case in shrews, which have a relatively large S2 occupying much of this intervening territory. As a result, shrews appear to have fewer cortical areas than any other mammal that has been well studied.

3.10.4 Implications for Mammalian Brain Evolution

Comparative data from a wide range of mammals would suggest that ancestral mammalian cortex contained a number of cortical subdivisions, including at least S1, S2, a parietal ventral (PV) somatosensory area, V1, V2, probably at least three auditory areas including A1, in addition to a handful of motor areas. This conclusion stems from comparative studies in which these cortical areas were identified in virtually every studied mammal (for reviews, see Kaas, 1989, 1987; Krubitzer, 1995; Krubitzer *et al.*, 1993, 1995; Krubitzer and Kaas, 2005). The general idea is that characters, in this case cortical areas, found in a wide range of mammals are most likely homologous and therefore retained from a common ancestor. In contrast, those cortical areas that are found in only a few species (e.g., Broca's area) are likely to be more recent innovations unique to one or only a few lineages.

At the same time, however, it is important to consider, in addition to this comparative data, some of the constraints that may be imposed on brain organization based on the known morphology of ancestral mammals. Fossil evidence suggests that early mammals were relatively small and had small brains with little neocortex. Shrews are not

ancestral mammals, but they do have a tiny neocortex similar in size to that of the earliest mammals that gave rise to modern lineages. The results of studies investigating their cortical organization suggest that they have fewer cortical areas than would be predicted from comparative studies of other mammals, and indeed that they are unique in having fewer cortical subdivisions than any other mammal species that has been examined in detail. If this is a constraint imposed on small mammal brains generally, then it is possible that the earliest mammals also had very few cortical areas, perhaps fewer than would be predicted from comparative studies of larger mammal brains.

3.11 The Effects of Domestication on Brain Size

D C T Kruska, Christian-Albrechts University at Kiel, Kiel, Germany

3.11.1 What is Domestication? What is a Domesticated Animal?

The domestication of animals can be defined as a special time-dependent and dynamic process whereby humans once started isolating some individuals of certain wildlife species and later began breeding these animals to provide a product or service useful to humans. Therefore, selection by nature is replaced by human-controlled 'artificial' breeding and selection of specific features for this animal group.

As is commonly recognized, the domestication process was a special revolutionary event during the cultural history of the human species, since no advanced civilization ever existed without domesticated animals and plants. This is still valid today when contrasting native human societies (e.g., bushmen, aborigines, and Indian tribes) who are still living as hunters and gatherers with the rest of modern human societies. The dynamics of domestication and its special consequences make for very interesting comparisons with their wild-type cohorts. Prior to domestication, nearly all members of a human society were involved in searching for their own food, whereas with progressive domestication in modern societies, only a relatively small group is involved in food 'production' and trade to supply the majority of the population with food, thereby allowing these individuals to become non-food-producing specialists (e.g., scientists, artists, politicians, businessmen, and soldiers). Additionally, with the enormous mass increase of the human population on earth, there is a corresponding increase in the number of many domesticated mammals. These increases led to further expansion of agricultural land with the consequence of suppression, destruction, and extinction of wild species and natural wildlife communities. Thus, domestication has wide-reaching consequences for the animal being domesticated, human evolution, and the niches that these nondomesticated animals occupy.

Domestication of animals began with the Paleolithic people. During the initial phase of domestication, they transformed from a nomadic shifting group to a more sedentary lifestyle with ensured resources for food, clothes, and other needs. According to archeological evidence, the first domestications of certain species happened at different times in the past, but most probably evolved independently in three major regions of the world: southwestern Asia and the Mediterranean region, South America from the Andes to Mexico, and East and Southeast Asia. Different domesticated animals and plants are characteristic for these different centers, although today there is some overlap in the animals domesticated. The first evidence of a domesticated mammal, the dog, is dated back to approximately 14 000 or 12 000 years ago. Domestication of the dog was followed by that of sheep and goats, approximately 11 000 BP, and then other animals later on. These data give a rough impression of the duration of domestication, although the actual start of this process most probably occurred even earlier. It must be remembered that bony remains of domesticated animals can be recognized only through differences from the original wild ancestor and these differences may not have emerged during the initial phase of domestication. Extremely long durations of domestication such as several thousand years are, however, valid for a few species. Several others were clearly domesticated much later and even recently some animals are still in the initial phase of domestication. This is particular true for some rodents, such as rats, mice, and gerbils, which were domesticated only a few decades ago. Nevertheless, these mammals may equalize their duration differences (in terms of number of years domesticated) with larger-sized 'older' domestications through apparently greater reproduction rates and generation shifts per year. Thus, when it comes to comparisons of this parameter, comparing years of domestication alone is problematic.

Of course, different domesticated mammals were selectively bred to serve very diverse human demands; e.g., for production of meat, fat, milk, and fur, as well as for work, research, and for use as pets. Differences in such usage occur not only from one species to another but within species as well. Consequently, selective breeding goals are numerous and constantly changing both within and across species.

As a group, domesticated mammals are not a taxonomic unit in a general zoological sense, but despite their numerous differences, they can be generally defined as a special group of animals thriving under human care. Once isolated from their natural niche, they were influenced and bred by humans for a greater number of generations. In contrast to their ancestors still living in the wild, domesticated animals as a group share a common 'ecological niche', the domestication, although this artificial niche has some degree of variability. In this sense, wild species kept in zoological gardens or circuses are not domesticated animals nor are other species or individuals under human care that are not purposely bred over many generations for special needs. Likewise, tame wild mammals are not domesticated. Taming and habituation may be of certain importance when selecting wild individuals for further breeding, but this is generally a modificatory effect and not a special phenomenon of domestication. Some domesticated animals may be rather untamed and aggressive and habituation is at least possible with wild as well as domesticated animals.

The number of wild ancestors of species that have been domesticated, often called the stem species, is rather small. Thus, only a few mammalian species of the five orders Rodentia, Lagomorpha, Carnivora, Artiodactyla, and Perissodactyla can be listed as having led to domesticated forms. These are summarized in Table 1. As a result of domestication, we recognize an enormous and arbitrary changeability and diversification of the organism. Domesticated forms are at first very much different than the

Table 1 Ancestral wild mammalian species and their domesticated descendents

Wild species	*Domesticated relatives*
Rodentia	
Mus musculus (House mouse)	Laboratory mice
Rattus norvegicus (Norway rat)	Laboratory rats
Ondatra zibethicus (Muskrat)	Ranch muskrats
Meriones unguiculatus (Mongolian gerbil)	Laboratory gerbils
Mesocricetus auratus (Syrian hamster)	Golden hamsters
Cavia aperea (Cavy)	Guinea pigs
Chinchilla laniger (Chinchilla)	Ranch chinchillas
Myocastor coypus (Coypu)	Ranch coypus
Lagomorpha	
Oryctolagus cuniculus (European wild rabbit)	Rabbits
Carnivora	
Mustela putorius (Polecat)	Ferrets
Mustela vison (American mink)	Ranch mink
Canis lupus (Wolf)	Dogs
Vulpes vulpes (Red fox)	Ranched silver foxes
Alopex lagopus (Arctic fox)	Ranched blue foxes
Felis silvestris (European wild cat)	Cats
Procyon lotor (Raccoon)	Ranch raccoon
Perissodactyla	
Equus przewalskii (Przewalski horse)	Horses
Equus africanus (African wild ass)	Asses
Artiodactyla	
Sus scrofa (European boar)	Pigs
Llama guanacoe (Guanaco)	Llamas and alpacas
Camelus ferus (Wild camel)	Dromedaries and Bactrian camels
Rangifer tarandus (Wild reindeer)	Domestic reindeers
Bubalis arnee (Arni, Indian wild buffalo)	Water buffalos
Bos primigenius (Aurochs)	Taurine cattle
Bos mutus (Wild yak)	Domestic yak
Bos javanicus (Banteng)	Bali cattle
Bos gaurus (Gaur)	Gayal or mithan
Capra aegagrus (Bezoar goat)	Goats
Ovis ammon (Mouflon)	Sheep

ancestral wild type in outer appearance, anatomy, physiology, ethology, and other biological parameters. In addition, domesticated mammals that derived from one wild ancestor are also impressively different, which becomes clear through differences between certain breeds, races, or strains. Very often extremely small 'dwarfs' or larger-sized 'giant' breeds were 'created' through domestication. Whereas the wild ancestors appear rather uniform and only slightly different from subspecies to subspecies, the domesticated derivatives are extremely different. This is especially important for a zoological interpretation and understanding when contrasting the results of domestication as a consequence of artificial human interference with evolutionary phenomena that occurred under natural conditions.

3.11.2 Domestication versus Evolution

Domestication and evolution are, in principle, characterized through the changeability of the animal, although the way in which changes occur for each process is different. However, both of these processes generally can be assumed as having started from an individual intraspecific variability of a wild species and a common gene pool. Only a certain part of the wild population, most probably individuals that had already gradually preadapted to future domestication, were isolated and followed the special genetic drift under artificial selection. Depending on the domestication time, this selection resulted in a special radiation of different breeds. It is, however, important to point out that no new species ever occurred due to domestication. All of the many well-defined different races of dogs, cats, and breeds or strains of other domestications are still the same species as their ancestors. Domesticated mammals still can, and in several cases they frequently do, interbreed with their wild relatives of common ancestry and produce fertile offspring. Changes from a wild ancestor to domesticated derivatives consequently constitute an intraspecific (within species) phenomenon. However, the variability of domesticated forms deriving from one ancestral wild type alone is especially great and impressive. This demonstrates, in principle, the general potency for changeability of the organism no matter what selective forces are in power, be it natural or 'human-designed'. Although changes due to domestication are not recognized within the variability of a wild species, these changes must at least derive from the wild type gene pool. In fact, this had already been recognized by Darwin (1868) in pre-Mendelian times, when he designated domestication as the greatest experiment man ever made with animals, that is, it is the greatest experiment with respect to the time it takes to domesticate, the number of individuals involved, and the results obtained. Diverse aspects of the domestication phenomenon are treated in the books of Clutton-Brock (1987), Mason (1984), Herre and Röhrs (1990), and Zeuner (1963), to name only a few.

Evolution, on the other hand, also is assumed to have started from an intraspecific variability of a species, but certainly with otherwise preadapted forms in a different genetic drift. This occurred during long geological times and by phylogenetic radiation to the origin of new species, reproductively isolated, and also different from the ancestor from which they radiated and other newly emerged sibling species. These changes are connected with special adaptations to certain lifestyles. In an interspecific (between species) comparison, differences in biological parameters for recent wild types are evident.

Given this scenario, and the ideas regarding domestication and evolution that have emerged, it is of interest to investigate and interpret the effects of domestication on the size and structure of the central nervous system.

3.11.3 Domestication and Total Brain Size

Rough estimates of the domestication effect on the brain size can be obtained through comparisons of brain cavity sizes of domesticated derivatives with those of their wild ancestors. Such investigations had already been performed at earlier times (e.g., Darwin, 1868; Klatt, 1912, 1921) using more or less bulky, but mostly anonymous samples of museum materials. As is usually common in skull comparisons, these studies used divariate analyses evaluating brain cavity sizes with reference to the greatest skull lengths. This was performed because brain size is dependent on body size and the greatest skull length of wild species normally serves as an indicator of body size. Such analysis generally resulted in smaller brain cases for the domesticated forms than for their wild ancestors with identical skull length.

However, comparisons of this kind are problematic for two reasons, especially when it comes to quantitative estimates of a domestication effect. First, in most cases, domestication has additionally influenced skull dimensions, as well as the total skull proportioning. Thus, in a very arbitrary way, skull conformity, including the skull length, also changed

due to domestication in a special mosaic mode (see Mosaic Evolution of Brain Structure in Mammals). Consequently, this reference measure does not reflect the body size of wild and domesticated forms to the same degree and therefore is not a reliable reference. This fact becomes especially clear through comparative investigations performed on identical materials concerning the three relationships of brain cavity size (third root)/skull length versus brain weight/body weight, and skull length/body weight (third root) for wild species and their domesticated relatives (Sorbe and Kruska, 1975; Kruska and Sidorovich, 2003). At comparable body weights, domesticated mammals normally have smaller and shorter skulls. A second problem is that brain cavity sizes are not always consistent with the actual brain sizes. Differences between these two parameters occur. Normally these are greater in larger skulls than in smaller ones. This is a problem even within mammalian species, such as in dwarf versus giant races of a domesticated species (Röhrs and Ebinger, 1983). Consequently, comparative analyses on skulls may be of help in characterizing trends, but not for specific details of brain organization.

More accurate quantitative results can be obtained if fresh brain weights are obtained from a large sample of healthy adult individuals whose body weights are known. Although such data are seldom available, there have been some samples of brains from several individuals of wild ancestry and related domesticated forms including different races, breeds, or strains. This material allows allometric calculations of the brain size to body size relationship for both the wild progenitor and the domesticated derivatives. In this respect, it is especially noteworthy to recognize that in this case, intraspecific analyses are dealt with. As commonly known, in a double log plot, the relationship of brain to body size can be characterized by the linear function with the formula

$$\log y = a \log x + \log b,$$

where y is the brain weight, x is the body weight, a is the slope of the allometric line, and b is the intercept with the y-axis in $x = 0$.

In such double log plots, the individual data points from differently sized individuals are arranged in a distribution ellipsis and allometric lines generally can be calculated in different manners. However, the main axis, at best, expresses the position of such distribution ellipses and consequently is better suited to comparisons.

Such investigations, respectively contrasting wild with domesticated forms, were performed in the past for several species (see Kruska, 1988, 2005) and they have produced similar results for diverse species in several ways.

At first, slope values of intraspecific allometrical calculations are rather similar for diverse species. They rank between $a = 0.20$ and $a = 0.30$, normally $a = 0.25$. Only occasionally do they reach $a = 0.40$, especially in species with a very prominent sexual dimorphism (see Evolution of the Sexually Dimorphic Brain). Consequently, these intraspecific lines clearly are less steep than interspecific lines when diverse species with a similar encephalization are concerned. These slope values are between $a = 0.56$ and $a = 0.63$. Second, the data from the wild ancestors are associated with one allometric line and those from the domesticated derivatives are associated with a significantly different allometric line. Both of these lines show identical slopes and thus run parallel to one another. This undoubtedly means that domestication has not affected the general dependency of the brain on body size or vice versa, but domestication has changed the brain size. Third, the domesticated individuals very often show a greater variability of brain size at any given body weight. Their distribution ellipses of data clearly are wider. This indicates that the selection pressure on brain size in the domestication process is less strong than natural selection. Fourth, on average, domesticated mammals have smaller brains than their wild ancestral relatives of similar body size. No brain size increase for the domesticated forms has ever been documented and most likely will never be obtained in the future. Moreover, to learn how strongly domestication has affected brain size on average, differences can be calculated from the $\log b$ values of the two parallel lines. This results in species-specific percentage decrease values for the domesticated compared with the wild ancestral type (=100%). As an example, Figure 1 shows the situation for wild European boars (*Sus scrofa*) versus domesticated pigs (*S. scrofa* f. dom.). Independent of body size, brain size decreased by 33.6% in pigs due to domestication. This result is also depicted in Figure 2.

Comparable investigations for some other species resulted in species-specific average decrease values due to domestication for the total brain size independent of body size. These data are listed in Table 2, which demonstrates that the dimensions of the decrease due to domestication vary considerably and range from 0% in laboratory mice to 34% in pigs. However, as is also evident, the brains of the less encephalized species of Rodentia and Lagomorpha have decreased relatively little and range from 0% in laboratory mice to 15% in laboratory gerbils. Moreover, with the exceptions of laboratory mice

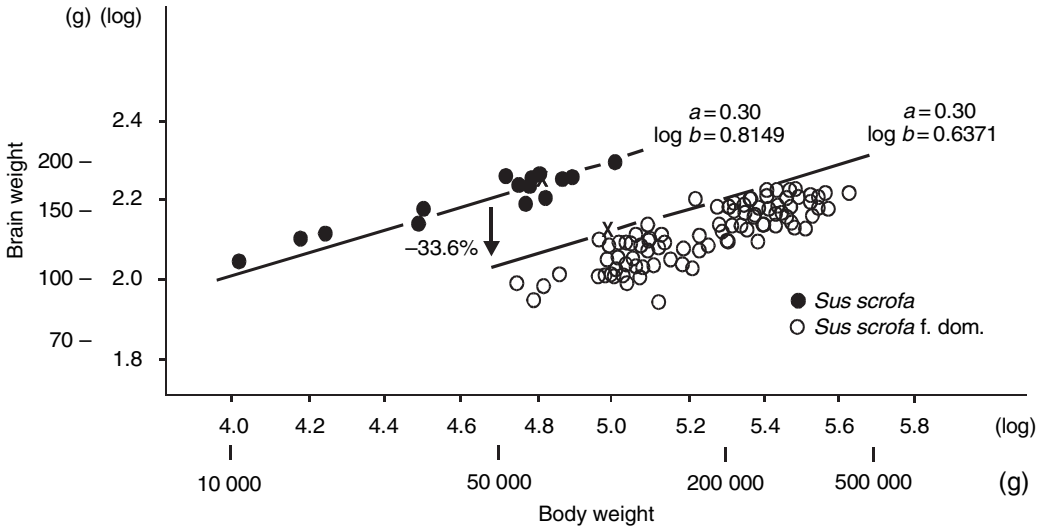

Figure 1 Intraspecific relation of brain to body size in European boars (*S. scrofa*) and different pig races (*S. scrofa* f. dom.) with average allometric lines. The body weights of boars are net body weights (total body weight minus viscera); those of pigs are actually total body weights. The allometric line for pigs therefore is displaced to the left by 45% subtraction of total body weight (10% for viscera, 35% for fat) to make this parameter comparable for both groups. Reproduced from Kruska, D. 1970. Vergleichend cytoarchitektonische Untersuchungen an Gehirnen von Wild- und Hausschweinen. *Z. Anat. Entwickl. Gesch.* 138, 291–324, with permission.

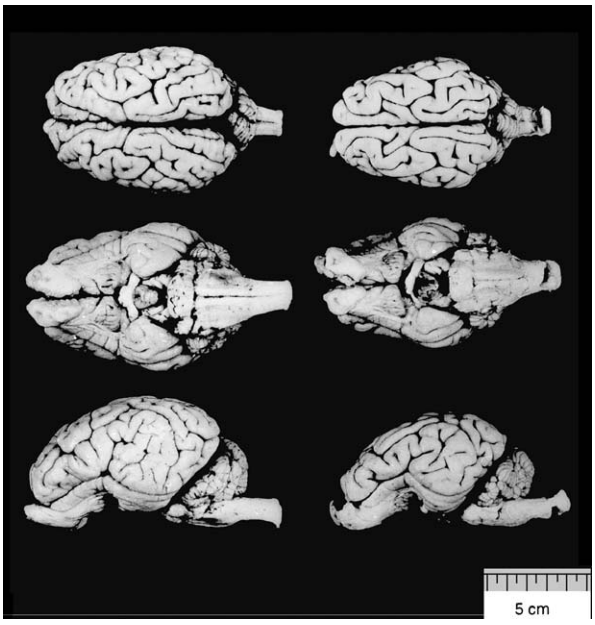

Figure 2 The brains of a European boar (left) and a pig (right) in dorsal, ventral, and lateral views. The boar and the pig were of comparable net body weight; European boar, 53.0 kg; pig, 52.8 kg. and albino laboratory rats, the values from 12% in pigmented laboratory rats to 15% in laboratory gerbils are rather similar for four very diverse species (*Rattus norvegicus*, *Meriones unguiculatus*, *Cavia aperea*, and *Oryctolagus cuniculus*). In contrast to this, the decrease values for the more strongly encephalized Carnivora, Perissodactyla, and Artiodactyla species clearly are greater. They range from 16% in

horses and donkeys to 34% in pigs. Here again, four species (*Mustela putorius*, *Canis lupus*, *Felis silvestris*, and *S. scrofa*), which are ethologically very different, show rather similar and very large decrease values in brain size of approximately 30%.

These data indicate that there is a relationship among evolution, encephalization, and domestication. Species that have larger brains through natural selection and evolution appear to lose more brain tissue during the domestication process than do those species with naturally smaller brains. In addition, the rather similar decrease values of very different domesticated species led to the following conclusion: it seems that the convergent domestication effect is comparable to other convergent effects in phylogeny based on similar ecological niche adaptations that were reached by diverse species in different radiations and on different evolutionary plateaus (e.g., aquatic, arboricole, underground lifestyles). During domestication – of course – this is the case on an intraspecific level concerning brain size with exclusively regressive trends. Whereas changes in overall brain size due to domestication are of interest, the next important step in understanding the domestication process is to characterize the effect of domestication on individual and diverse parts of the brain.

3.11.4 Domestication and Brain Subdivisions

The question now is: are all the diverse subdivisions of the brain reduced to the same extent due to domestication as is the whole brain? This was addressed by comparative quantitative analyses in diverse species through equidistant serial sectioning of several individual wild type versus domesticated brains (Kruska and Stephan, 1973). This method allows calculations of fresh brain tissue volumes of diverse brain parts and adjacent allometrical comparisons of average data. Decreased values due to domestication are available for some species for the five fundamental brain parts including the telencephalon, diencephalon, mesencephalon, cerebellum, and medulla oblongata. Measurements of these structures resulted in a large range of different decrease values as is comparatively scaled in Figure 3. As can be seen, little conformity is evident between the diverse species concerning the arrangements of these brain parts from greatest to least decrease. However, with the exceptions of gerbils and mink (two species that were relatively recently domesticated), all the other species consistently show the telencephalon as having decreased to the greatest extent of all the brain parts. This is especially impressive since the investigated wild-type forms are differently encephalized. Very

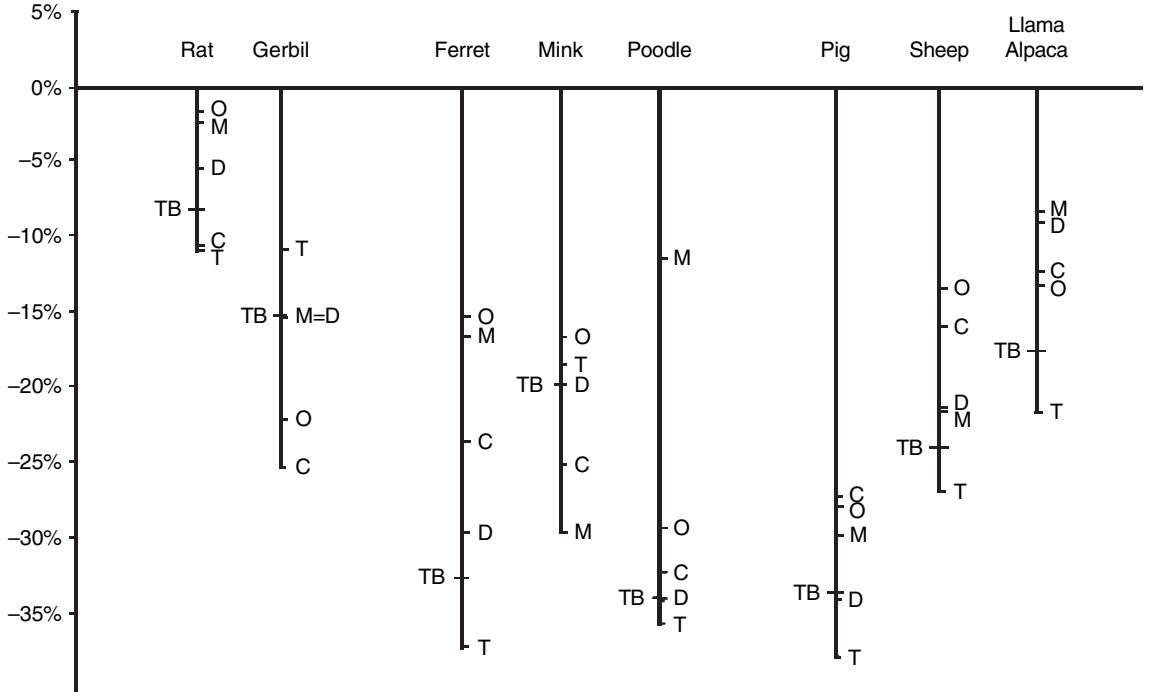

Figure 3 Scaling of size decrease values of total brain and the fundamental brain parts of several species from the wild to the domesticated forms (for authorships of studies, see Kruska, 1988, 2005). TB, total brain; T, telencephalon; D, diencephalon; M, mesencephalon; C, cerebellum; O, medulla oblongata.

roughly, such differences in encephalization on two general plateaus result from comparisons of relative values; e.g., in species of Rodentia, the telencephalon accounts for only 54% (wild gerbil) to 56% (Norway rat) of total brain size, whereas the corresponding values for species of Carnivora and Artiodactyla clearly are greater (polecat/American mink 69%; wolf 82%; European boar/mouflon/guanaco 72%).

In addition to these similar effects of domestication in several different species, it appears that within the telencephalon, the total neocortex (white and gray matter) has decreased to the greatest extent compared to other subdivisions of the telencephalon and even the total brain. This is indicated in Figure 4. Thus, those brain parts in which higher level functions are generated, such as the neocortex, are most affected by domestication. The implication is that under natural conditions, the neocortex, compared to structures that perform more life-sustaining functions, such as the nuclei of the brainstem, is expendable. Although similar decreases in the size of the neocortex are evident in an interspecific comparison,

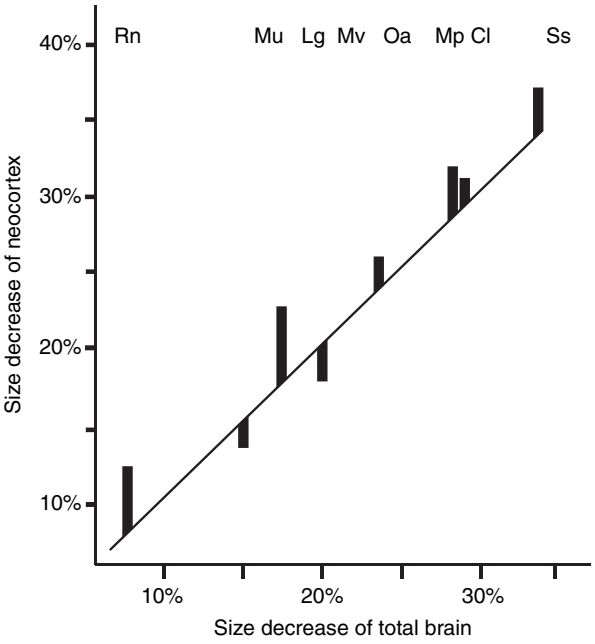

Figure 4 Relation between size decrease values of neocortex and total brain due to domestication in several species. The line serves as an orientation assuming that neocortex has decreased to same extent as total brain. Thus, bars above the line indicate a greater decrease intensity for the neocortex; those below the line indicate a lesser decrease intensity for the neocortex. Rn, *R. norvegicus*; Mu, *M. unguiculatus*; Lg, *L. guanacoe*; Mv, *Mustela vison*; Oa, *Ovis ammon*; Mp, *Mustela putorius*; Cl, *Canis lupus*; Ss, *Sus scrofa*. Reproduced from Kruska, D. C. T. 2005. On the evolutionary significance of encephalization in some eutherian mammals: Effects of adaptive radiation, domestication, and feralization. *Brain Behav. Evol.* 65, 73–108, with permission.

decrease values vary for different brain subdivisions intraspecifically as well. This is particularly true for several nuclear masses that serve certain functional systems, e.g., sensory systems for olfaction, vision, and hearing; motor structures of pyramidal and extrapyramidal quality; and limbic structures. Such species-specific decrease values are listed in Table 3. Consequently, all these diverse interior structures have also decreased from the ancestral wild form to the derived domesticated form. These data show a very variable mosaic picture regarding the decrease intensity not only between species, but also within species from one functional system to another and within the systems as well. Furthermore, concerning the latter, there are some exceptions; e.g., the olfactory bulb as a primary center of olfaction is more strongly reduced in contrast to secondary olfactory areas of the allocortex in gerbils, mink, pigs, and sheep, but this is not the case in microsmatic llamas. Similar results for decrease values were obtained for visual structures, such as the lateral geniculate nucleus versus the visual cortex. Both of these structures are visuotopically organized and one would expect rather similar decreases in both these nuclear masses. However, this is the case only for pigs, whereas in rats and mink the lateral geniculate nucleus is more strongly decreased than the striate cortex and in sheep this pattern is reversed. Again, within the auditory system of pigs, the cochlear nucleus and the medial geniculate body are decreased to a lesser extent than are the other structures, especially the auditory cortex. Similar inconsistencies occur for diverse motor structures.

Also of interest is the effect of the domestication process on size changes of limbic structures. In the mammalian telencephalon, these are mainly represented by the complexly organized hippocampus, the septum, the schizocortex (entorhinal region, pre- and parasubiculum), and some medial nuclei of the amygdala. These brain structures are interconnected with the anterior nuclei of the thalamus, with the habenular complex, and most prominently with the hypothalamus; together these form the limbic system. This system is in general assumed to represent the 'visceral brain' (MacLean, 1992). The hippocampus is the main center of this system and, although influenced by other brain regions (including the neocortex), it mostly acts endogenously. Thus, this nuclear formation plays an important functional role in several behavioral complexes, such as emotionally guided behavior and individual self-protection, but additionally in learning and memory. The hippocampus itself shows, of course, its own evolutionary changes with size increase and progressive structural differentiation in diverse mammalian radiations but

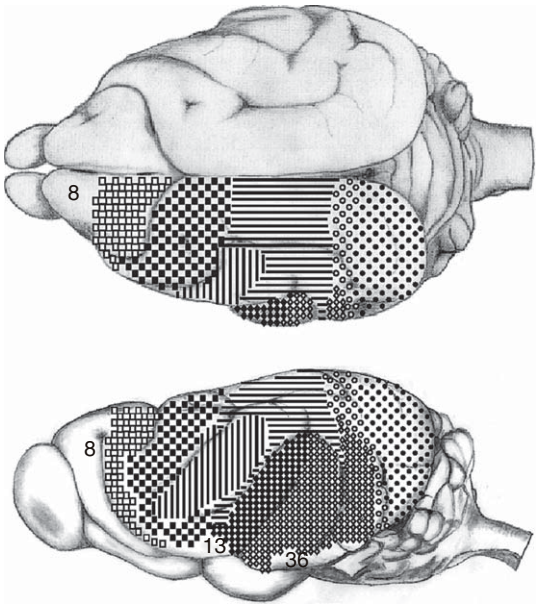
basically certain emotional reactions, especially aggression and other affective functions, general attention, as well as motivating and activating functions certainly seem to be guided, controlled, and regulated by this limbic center.

All of the various telencephalic structures of the limbic system are also smaller in domesticated mammals than in their respective ancestral wild-type forms. This can be seen in Table 3 for the sum of these structures and the entire hippocampus as well. Here again, some inconsistencies are evident when decrease values are compared within species, and such inconsistencies occur more prominently in a between-species comparison. Nevertheless, most notably the hippocampus decrease values are extremely high for poodle, pig, and sheep. In these highly domesticated mammals, this main limbic center is decreased in size by over 40%. This is a most remarkable degree of mass decrease, which exceeds even the decrease value for total brain and neocortex size. The fact that this brain part is characterized by very densely packed neurons suggests that the size changes induced by domestication might have a very special and immense functional effect on the hippocampus. Such functional and behavioral changes may enable humans to keep and handle large mammals without danger. Humans most probably have sought these changes unconsciously or consciously through breeding, especially during the initial phase of domestication. Some domesticated species, such as llamas, do not show such clear decreases in the size of the hippocampus.

Another, rather similar phenomenon of the mosaic of size changes due to domestication can be documented for the entire neocortex and is concerned with the subdivisions of the structure termed cortical fields or cortical areas (see Cortical Evolution as the Expression of a Program for Disproportionate Growth and the Proliferation of Areas). Unfortunately, there is only scattered information available for some of these in different species (Kruska, 2005) except for the mink (*Mustela vison*). In this species, the total neocortex was cytoarchitectonically investigated following the criteria of Brodmann (1909) and several different histologically defined areas were recognized and delineated by Danckers (2004). Danckers very accurately investigated both hemispheres of six (three male, three female) wild and six (three male, three female) ranch mink (Dark Standard) brains and calculated fresh volumes of gray matter for areas of neocortex using equidistant serial sections. She found no significant differences in gray matter volume of the diverse areas (at least the larger ones) in relative composition (total neocortex gray matter = 100%) between individuals and sexes within the wild type and within the domesticated form, respectively. On average, however, differences occurred between the wild and the ranch mink groups. On the basis of an allometrically calculated size decrease for total neocortex gray matter due to domestication at an amount of 21.5%, she arrived at rather different decrease values for different neocortical areas. These decreased values are indicated for some regions of different functional importance on the dorsal and lateral hemispheres in Figure 5. The



Cortical areas	Decrease values (%)
● Primary visual cortex (area 17)	15
○ Secondary visual cortex (areas 18, 19)	8
◆ Primary auditory cortex (area 50)	16
◇ Secondary auditory cortex (areas 20–22)	16
||| Primary somatosensory cortex (area 1)	28
≡ Secondary somatosensory cortex (areas 5, 7, 52)	22
■ Primary motor cortex (area 4)	26
□ Secondary motor cortex (area 6)	25

Figure 5 Surface extents of diverse cytoarchitectonical areas on the dorsal and lateral views of the cerebral hemisphere of a female wild mink and average decrease values of these due to domestication. Reproduced from Danckers, J. 2004. Cytoarchitektonische Arealisierungen des Neocortex beim Mink (*Mustela vison*) und vergleichend-quantitative Untersuchungen zwischen der Wild- und Haustierform. Diss. thesis, University of Kiel, with permission.

neocortical areas involved in motor functions of the pyramidal system and those for somatosensory functions are clearly more strongly decreased in size than are those serving visual and auditory functions. Most probably, such size changes from a wild to a domesticated type are somewhat different in other species in quality and quantity, since this seems to be dependent on the evolutionary and species-specific plateau of the wild ancestor's brain composition but additionally on the selection aims of domestic breeding. Nevertheless, the mosaic mode of these changes due to domestication is a general phenomenon (see Mosaic Evolution of Brain Structure in Mammals).

3.11.5 Domestication and the Sense Organs

Sense organs were compared in wild ancestral and domesticated derivatives although the data are limited. Nevertheless, decreases in the number of receptor cells in the olfactory epithelium of the nose and in the retina of eyes from boar to pig were comparable in quantity with those of the associated sensory brain nuclei. Decreases in certain structures of the ear, e.g., volume of tympanic cavity, size of auditory ossicles, bony cochlea, spiral length of cochlear duct, basilar membrane, and total number of cochlear hair cells in the organ of Corti, were also found in comparisons of wild and laboratory rats. Most often, eye weights were allometrically compared within several species with a general decrease due to domestication (Herre and Röhrs, 1990; Kruska, 2005). Very regrettably, topographic organization and counts of ganglion cells in the retina were studied in detail only in wolves and dogs (Peichl, 1992) and wild versus ranch minks (Steffen, 2000). A pronounced visual streak of high ganglion cell density from the nasal to the temporal side was characteristic only for the wolf retina, whereas in dogs this was not recognized or at least clearly less pronounced. Also, the total number of ganglion cells was decreased in dogs. Unfortunately, the investigated dogs were small breeds, approximately half the size of wolves, and body size differences were not taken into account.

The investigations on mink were based on intraspecific allometries and therefore are of special value for a quantitative approach. From a sufficient database of wild and ranch mink, it appears that ranch mink eyes are 17% smaller in weight and the surface area of the retina in 39 ranch mink versus 11 wild mink was on average 22% smaller for animals with the same body size. The relationship of eye to retina size remains the same in both types. Within the retinas of 10 wild mink, there was a scanty visual streak from the nasal to the temporal side. Although this streak was not very well pronounced, a comparative topography was never recognized in any of the 46 ranch mink retinas investigated (Figure 6). This is a convergent phenomenon since similar observations were made in canids. The topography of ganglion cells and their densities were highly diverse in the ranch mink; their total number was decreased on average by 15%. Receptor cells were also compared in quality, number, distribution, and relationship, with the general result of less clear organization and a decrease in number in the domesticated form. These changes found in the retina are quantitatively in good agreement with the results for the primary visual area of the hemispheres of this species.

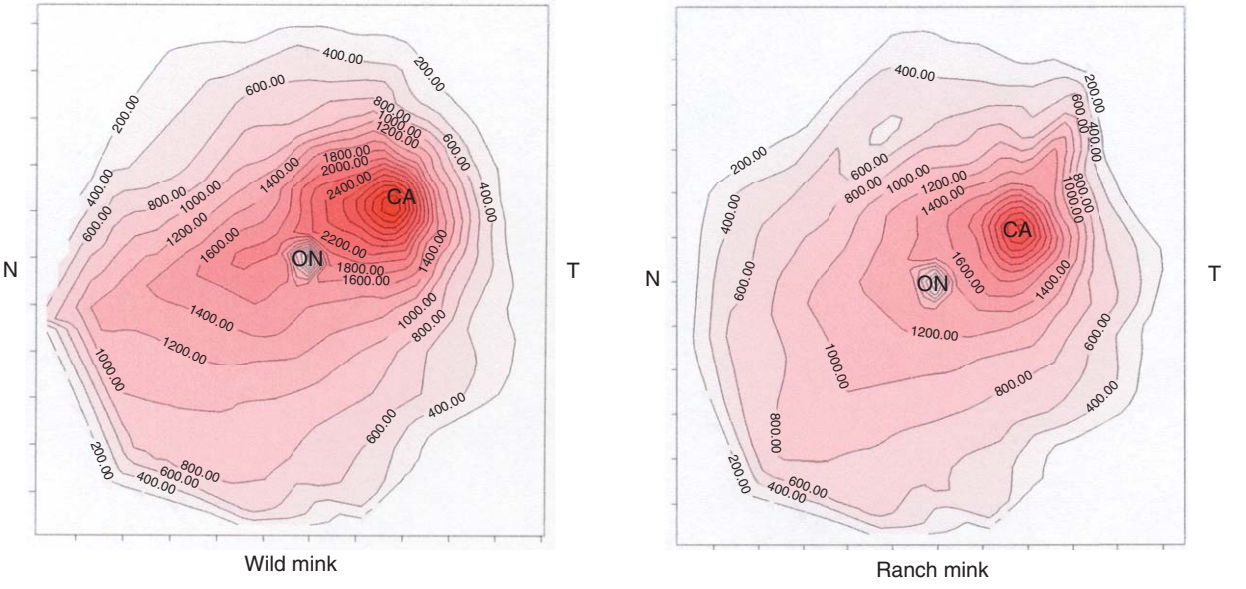


Figure 6 Topography of ganglion cells in the retinas of wild and ranch mink eyes expressed by isodensity maps. A 'visual streak' of high ganglion cell density clearly is more pronounced in the wild mink as is the larger number and greater density of ganglion cells in the central area (CA). N, nasal side; T, temporal side; ON, optic nerve. Reproduced from Steffen, K. 2000. Vergleichender quantitativer Nachweis sowie topographische Analyse von Ganglienzellen und Zapfen in der Retina von Wildmink (*Mustela vison energumenos*) und Farmmink (*Mustela vison* f. dom.). Diss. thesis, University of Kiel, with permission.

3.11.6 Conclusions

Brain size and structural composition are mainly genetically determined. The intraspecific differences of both these parameters from a wild ancestor to a domesticated derivative therefore must be evaluated as consequences of selective breeding through human interference during the domestication process. In this view, domesticated mammals in general provide proof for the intraspecific variability and the evolutionary malleability of the central nervous system. However, the actual size and structure of the entire brain itself cannot be the subject of selective breeding. Rather, it is likely that particular behaviors in different breeds were selected for, and the brain changes are an indirect result of this selection. Additionally, it can be argued that domestication in any case started with only some individuals in which the normal variability of the species gradually was preadapted to the special conditions of domestication. However, the quantitative comparative analyses revealed that domestication of very diverse mammalian species always is connected with a decrease in its functional performance that is evidence at least by behavioral changes. In any case, different degrees of total brain decrease and that of certain brain structures from species to species demonstrate that the phylogenetic and evolutionary plateau of cerebralization and specialization of the wild species and its species-specific peculiarities are rather complicated and likely apply to selective breeding for domestication. Nevertheless, the dimensions of intraspecific differences in brain size and brain composition between the wild ancestor and its domesticated derivatives are unique and are not observed in individuals that are caught in the wild and then tamed. Furthermore, keeping wild species in zoological gardens for several generations does not lead to brain size decreases. Likewise, feralization of domesticated mammals into the wild over many generations does not restore brain size to that of the wild species again, which means that "once domesticated, always domesticated" (Kruska, 2005).

Consequently, brain size changes due to domestication can be understood as special adaptations at the species level that are directed by human interference to the special ecological niche of domestication even though this might be very diverse and broad.

3.12 How to Build a Bigger Brain: Cellular Scaling Rules for Rodent Brains

S Herculano-Houzel, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil
B Mota, Centro Brasileiro de Pesquisas Físicas, Rio de Janeiro, Brazil
R Lent, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

Glossary

allometry Modification in the proportion of the various parts of an organism or structure, like the brain, as it increases in overall size.

anisotropic Any structure whose components – neuronal cells, in the case of the brain – are distributed unevenly in different directions. The brain, with its white matter tracts and gray matter regions organized in laminae and nuclei, is a highly anisotropic structure.

glial density Number of glial cells per mg or ml of tissue, measured as the number of glial somata or nuclei found per unit volume or mass.

hypermetric growth Growth of a structure that surpasses the rate of growth of another. Cerebral cortex is a typical example of hypermetric growth at the expense of other brain regions.

isometric growth Growth of a structure at the same rate of growth of another structure.

neuronal cells When determined by the isotropic fractionator, 'neuronal' refers to cells whose nuclei express neuronal nuclear antigen (NeuN), detected immunocytochemically.

neuronal density Number of neuronal cells per mg or ml of tissue, measured as the number of neuronal somata or nuclei found per unit volume or mass.

neuronal size Has often been used in the literature as shorthand for 'size of neuronal somata'. We define it here as the total size of a neuronal cell, including the whole of its dendritic and axonal arborizations and the immediately surrounding extracellular space.

neuropil The ensemble of axonal and dendritic arborizations in a brain region.

non-neuronal cells All the cells in the brain that do not express a neuronal phenotype. This includes glial and endothelial cells. When determined by the isotropic fractionator, 'non-neuronal' refers, by exclusion, to cells whose nuclei do not express NeuN, detected immunocytochemically.

power function Any mathematical equation of the form $Y = aX^b$, meaning that Y varies as a power function of X, that is, according to the exponent b of X. When b is larger than 1, Y grows faster than X. If b is a positive value below 1, Y grows slower than X. Negative values of b mean that Y actually decreases as X grows. If b is unity, the function becomes linear, as Y varies directly as X multiplied by a.

stereology The study of the three-dimensional properties of brain structures, or of any other tissue, through the measurement of microscopic sections of the whole. Usually, stereology involves the measurement of parameters such as cell or synaptic density within a tissue section of known volume, and extrapolation to the volume of the entire tissue.

3.12.1 Introduction

Brain size varies by a factor of 100 000 across mammalian species (Count, 1947). Several variables probably contribute to determine adult brain size within and across species: number of neurons, number of glial cells, cell body size, dendritic and axonal arborization volume, vasculature, and extracellular space. Although the cellular composition of the brain is one of the major determinants of its computational capacities (Williams and Herrup, 1988), little is known about how it varies with brain size. What are the cellular scaling rules that determine brain allometry? How do number of neuronal and non-neuronal cells contribute to structure size? What are their relative contributions across species of different brain sizes? Do different brain structures gain neurons and overall mass at the same rate?

3.12.2 Where Volumetry and Stereology Have Gotten Us

3.12.2.1 Bigger Animals Have Bigger Brains, and Bigger Brains Have More and More Cortex

Comparative studies of mammalian brain anatomy have been largely limited to analysis of volumetric data on large brain divisions of different species published by a small number of labs (Stephan *et al.*, 1981; Frahm *et al.*, 1982), often based on measurements of only one brain of each species. These have established that brain size is related to body size by a power law of exponent inferior to 1.0 (Martin, 1981; Fox and Wilczynski, 1986), such that brain size increases with body size, but at a slower pace (Figure 1a). The cerebral cortex increases hypermetrically in volume in relation to the remaining brain structures (Figure 1b), such that, within each order, the relative size of the cerebral cortex increases with brain size (Figure 1c): larger brains are more and more dominated by cortex (Frahm *et al.*, 1982).

In comparison, larger brains have isometrically larger cerebella, which accompany almost linearly the size of the cerebral cortex (Figure 1d), and retain a stable relative size with increasing brain size: larger brains have cerebella of the same relative volume (Figure 1e).

3.12.2.2 Bigger Brains Have Decreasing Neuronal Density

From visual inspection only, Nissl (1898) observed that neurons are distributed more sparsely in larger brains. Stereological measurements soon confirmed his observation, showing that neuronal density declines in the cerebral cortex as a power function of increasing brain volume with a small, negative exponent of −0.32 (Tower and Elliot, 1952). Further stereological studies showed that the numerical relationship between brain size and neuronal density is valid from the smallest mammalian species, such as insectivores (Stolzenburg *et al.*, 1989) to species with brains much larger than human, such as dolphin, elephant, and whale (Tower, 1954; Garey and Leuba, 1986; Haug, 1987; Figure 2a). Nonstereological measurements have found the same relationship in rodents (Herculano-Houzel *et al.*, 2006a). The direct, negative relation between cortical neuronal density and brain size is an interesting indication that intelligence does not bear a simple relationship to neuron density and thus to the degree of axodendritic complexity in the cerebral cortex (Tower and Elliot, 1952).

In principle, two factors might account for the decreased neuronal density in larger cerebral cortices: increased neuronal size (including the neuropil), and increased relative number of the interspersed glial cells. Both seem to apply: Ghouse Shariff showed in 1953 that smaller neuronal densities are associated with larger neuronal somata in the primate cerebral cortex, a finding that was later replicated in insectivores (Stolzenburg *et al.*, 1989); and it was soon confirmed that larger cortices do have larger and larger relative number of glial cells to each neuron (see The Evolution of the Cerebellum in Anthropoid Primates).

3.12.2.3 Bigger Brains Have Much More Glia

Friede (1954) defined the glial index of the cerebral cortex: the ratio between number of glial and neuronal cells (g/n ratio), which he believed to vary

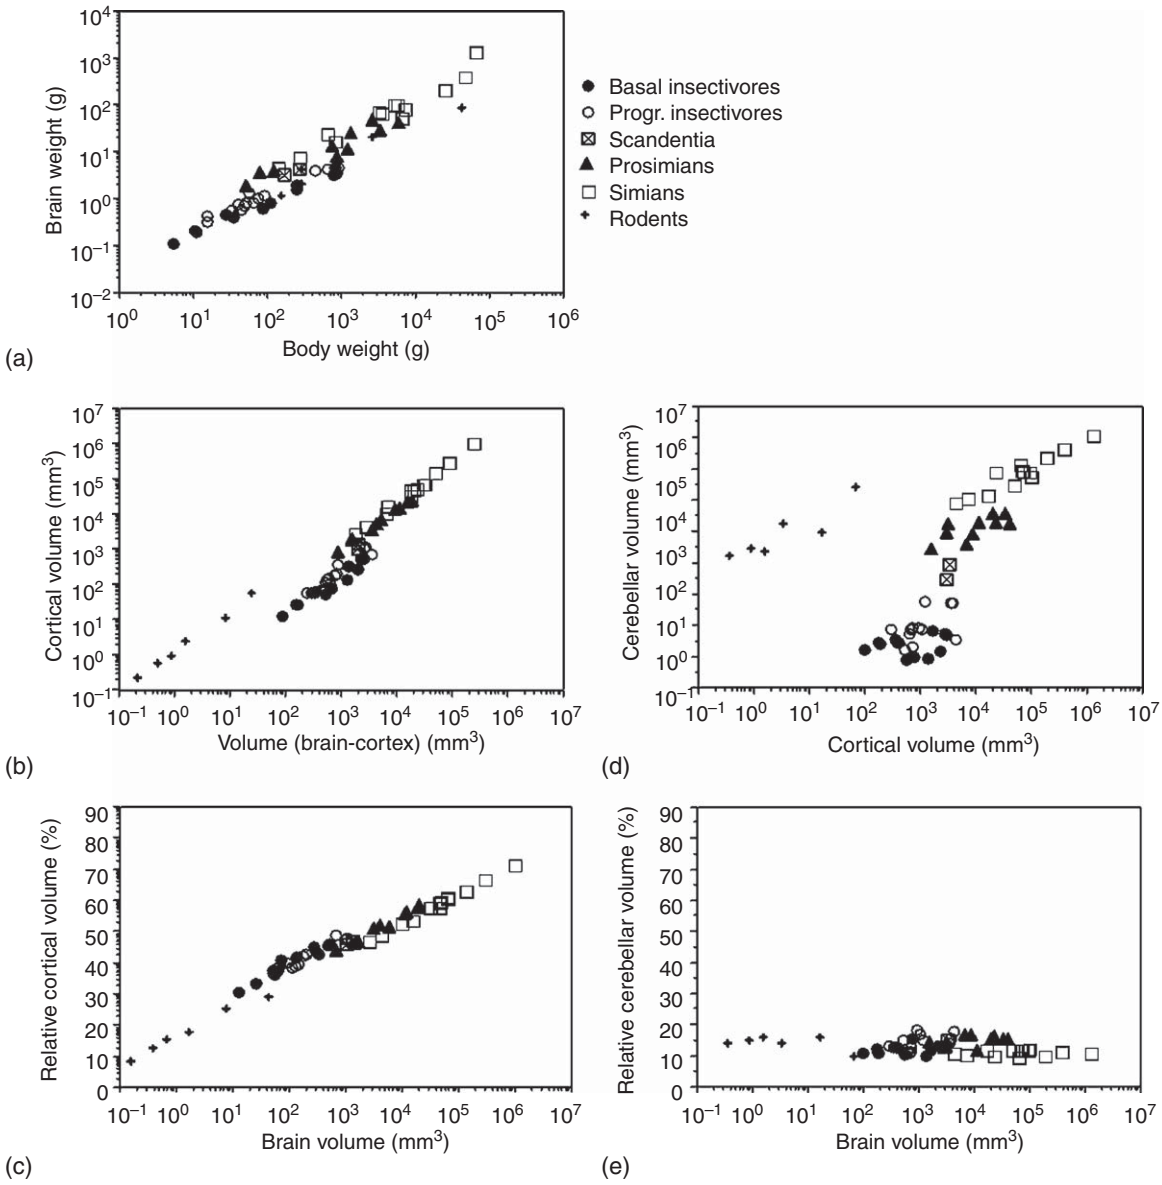

Figure 1 Brain scaling across mammalian species. a, Brain size scales hypometrically with body weight. Power law exponents relating the two parameters vary between 0.60 and 0.80. b, Absolute cortical volume (or mass, for rodents) scales hypermetrically compared with the remaining, noncortical brain structures. Power law exponents relating the two parameters vary between 1.10 and 1.20. c, Relative cortical volume (or mass, for rodents) increases with increasing brain size within each group. d, Absolute cerebellar volume (or mass, for rodents) scales hypometrically compared with cerebral cortex, with power law exponents of 0.8–1.0. e, Relative cerebellar volume (or mass, for rodents) remains invariant among all groups, regardless of increasing brain size. Data from Stephan, H., Frahm, H., and Baron, G. 1981. New and revised data on volumes of brain structures in insectivores and primates. *Folia Primatol.* 35, 1–29; Frahm, H. D., Stephan, H., and Stephan, M. 1982. Comparison of brain structure volumes in insectivora and primates. I: Neocortex. *J. Hirnforsch.* 23, 375–389; and Herculano-Houzel, S., Mota, B., and Lent, R. 2006a. Cellular scaling rules for rodent brains. *Proc. Natl. Acad. Sci. USA* (in press).

according to the phylogenetic position of the species, such that an increasing proportion of glia would indicate a more highly developed cortex. It was soon demonstrated, however, that the g/n ratio in the cerebral cortex increases with brain size rather than with an ill-defined phylogenetic scale that placed the human species on top (Figure 2b; see The Evolution of Neuron Types and Cortical Histology in Apes and Humans). Fin whales have a cortical g/n ratio of 4.54, compared to 1.78 in humans (Hawkins and Olszewski, 1957). Stolzenburg *et al.* (1989) later proposed that the g/n ratio actually increases with increasing thickness of the cortical wall rather than with total brain or cortical weight.

In any case, it has been widely believed that the relative glial expansion has trophic and metabolic

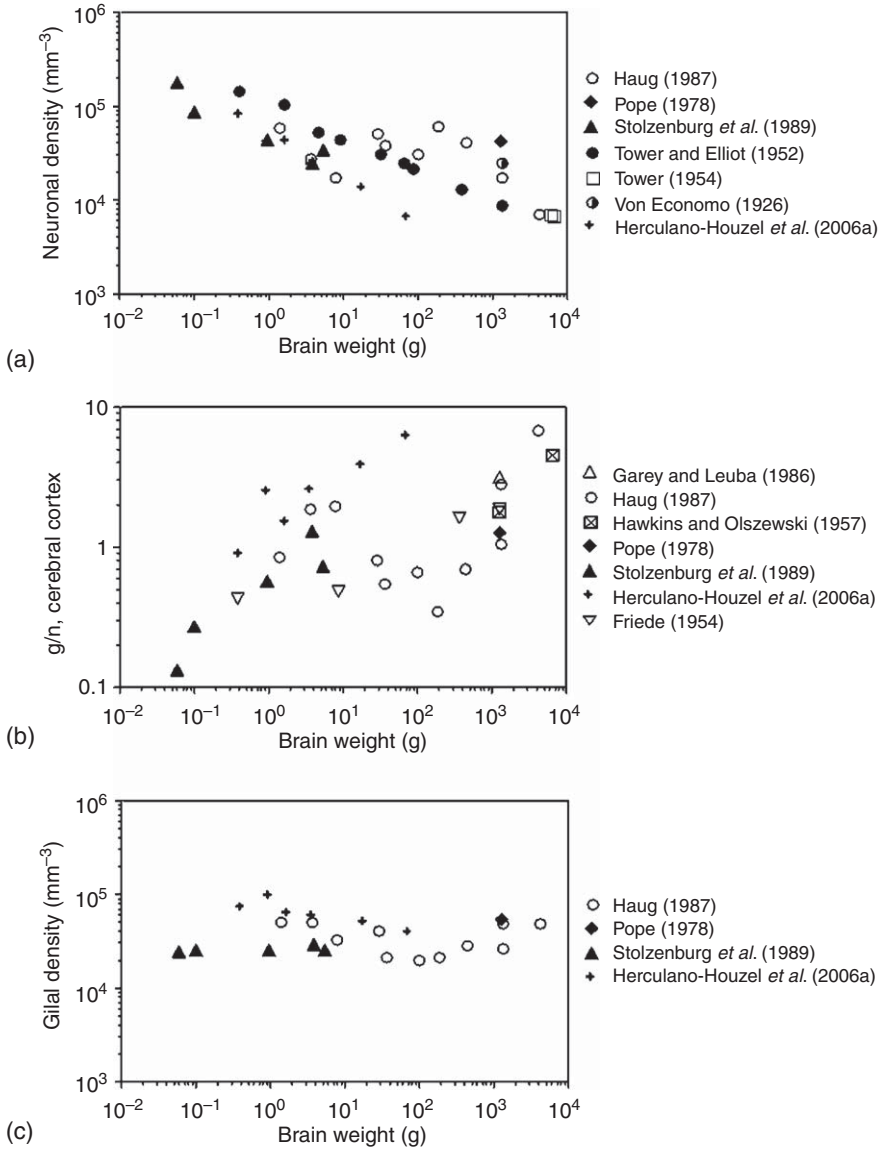

Figure 2 a, Scaling of neuronal density; b, g/n ratio; and c, glial density in the cerebral cortex of different species. All graphs were drawn from data reported in the references listed.

meaning, in accordance with the traditional view that these cells have a supportive function for neurons (Friede, 1954; Reichenbach, 1989). However, the numeric expansion of glial cells relative to neurons seems to contradict the observation that the neuronal need for metabolic support remains similar across species (Nedergaard *et al.*, 2003). Hypothetically, this discrepancy might be settled if, as the brain increases in size, a larger number of glial cells were a compensation for their small size relative to increasingly larger neurons. However, data on the relative scaling of neuronal and glial cells in the brain are lacking in the literature.

Interestingly, the increased g/n ratio is not accompanied by any major variation in glial density, which has been reported either to vary widely but independently of brain size (Haug, 1987), to remain stable (Stolzenburg *et al.*, 1989), or to show a marginally significant decrease (Herculano-Houzel *et al.*, 2006a) across mammalian species of increasing brain size. Inspection of data pooled from these sources shows that, compared to neuronal density and given the relatively high variation in experimental data obtained by different authors, glial density can be considered to remain relatively invariant across species of different brain size (Figure 2c).

3.12.3 The Need for Cell Counts, and the Trouble with Estimating Total Number of Cells with Stereology

Glia are widely said to be the most numerous cell type in the brain (Doetsch, 2003; Nishiyama *et al*., 2005), and to be 10–50× more numerous than neurons in humans (Kandel *et al*., 2000). Evidence for this assertion, however, is scant. Stereology, the only available tool for addressing cell numbers until recently, relies on the determination of cell densities in small sectors of tissue. Total cell numbers can in principle be estimated by multiplying cell density and volume of given brain regions, which is how mouse neocortex was estimated to have about 10 million neurons (Schüz and Palm, 1989), for instance.

There are, however, several problems with this approach to determining total number of cells in large brain regions or even the whole brain. First, brain tissue is highly anisotropic: neuronal density varies widely across cortical areas and subcortical nuclei, which would have to be sampled separately. This problem is solved in part by techniques with ingenious sampling strategies such as the optical fractionator, which allowed a recent estimate of the total number of neurons in the human cerebral cortex at about 20 billion (Pakkenberg and Gundersen, 1997). However, precise determination of neuronal density in the samples is still a key issue. Neuronal densities in human cerebral cortex have been estimated to be as low as 8750 mm^{-3} (Tower and Elliot, 1952), and as high as 48100 mm^{-3} (Shariff, 1953), with intermediate estimates of 24500 mm^{-3} (Von Economo, 1926), 25000 mm^{-3} (Haug, 1987) and 41300 mm^{-3} (Pope, 1978). Even if cortical volume were assumed to remain constant across samples, estimates of total number of neurons in cortex based on these densities would vary about 5×.

Precision of measurements of cortical volume, however, is also an issue: even with the highest estimate of neuronal density found in the literature, Shariff's value of 115.2 cm^3 for one cortical hemisphere would yield a total of 11 billion neurons in both hemispheres, a value that is still too low compared to Pakkenberg and Gundersen's (1997) more recent estimate of about twice that.

Even if measures of neuronal density and volume could be considered precise, stereological determination of total number of cells in the whole brain would require its parcellation into a prohibitive number of structures of defined volume and homogeneous density. This incompatibility explains why there are data in the literature on densities and total cell numbers in well-defined brain nuclei, but no attempts to use stereology to determine total number of neurons or non-neuronal cells in the brain of any mammalian species.

3.12.3.1 Why Stereological Estimates of Total Cell Number Yield Invalid Relationships

A further limitation of stereological determinations of total cell numbers is that these will, by definition, depend on the volume of the structure of interest, and therefore variations in number of cells estimated in this way cannot be compared to variations in structure volume across species. Stereological methods, thus, should not be applied to the examination of cellular brain scaling rules across species. Haug (1987) employed neuronal densities to calculate the total number of neurons in the cerebral cortex of various mammals, and reported it to vary as a power function of cortical volume with an exponent of 0.95. However, this is an invalid power law relationship that seems only to reflect variations in volume of the cerebral cortex, and does not reveal any real relationship with the number of cells. This is so because, since neuronal density varies as a very small power of cortical volume, the latter always varies much more than its density. Total number of neurons estimated as the product of density and volume will thus necessarily reflect mostly the variation of structure volume and be very little affected by variations in neuronal density, yielding invalid power law relationships of exponent close to 1, as Haug found. This is in strong contrast to the much larger exponent of 1.760 obtained when total number of cortical neurons are determined independently of cortical volume (Herculano-Houzel *et al*., 2006b; see below).

Similarly, Stevens (2001) has used the product of structure volume and neuronal density to examine how variations in total number of neurons correlate between the lateral geniculate nucleus (LGN) and primary visual area (V1) of several primate species (Stevens, 2001). The estimated exponent of 3/2, however, mirrors the 3/2 exponent relating LGN and V1 volumes across the species, since thalamic and V1 neuronal densities vary little compared to their volumes. It is most probable, therefore, that this exponent does not reveal a true relationship between number of neurons in the two structures. The questionable nature of the relationships reported by Haug (1987) and Stevens (2001) can be confirmed by shuffling neuronal density values across the species being compared, which, as expected, does not affect the exponents obtained, as they reflect mostly the variations in structure

volume. Volume-independent estimates of total number of neurons are required in order to determine how they really relate to brain volume.

3.12.3.2 The Problem with the Idea That Volume Indicates Computational Power and the Need of Total Cell Numbers

Many authors are interested in allometric rules of brain scaling from a functional point of view, as brain size, or encephalization, has long been accepted as an indicator of computational and cognitive capabilities and even intelligence (Jerison, 1985; Reader and Laland, 2002; Sol *et al*., 2005). In the absence of data on total number of neurons, different authors have focused their studies on the analysis of published volumetric data, derived mostly from Heinz Stephan's group (Stephan *et al*., 1981; Frahm *et al*., 1982). Thus, a number of studies have compared the absolute size of brain regions (Finlay and Darlington, 1995), their proportional size relative to one another (Barton and Harvey, 2000; de Winter and Oxnard, 2001), and relative to the whole brain (Clark *et al*., 2001). Based on the same data, these authors have proposed, respectively, that different brain regions evolve concertedly, in mosaic, or even as scalable versions of a same set of proportions, called cerebrotype, within a given taxon but not among them.

Strikingly, conclusions drawn from the same data can be conflicting. For instance, while the neocortical fraction of the brain increases from 14% in basal insectivores to 80% in humans (Frahm *et al*., 1982), the cerebellar fraction of brain volume varies little across species of various mammalian orders, a discrepancy taken to argue against the hypothesis that the cerebellum works in service of the neocortex (Clark *et al*., 2001). However, cerebellar and cerebral cortices increase concertedly both in surface area (Sultan, 2002) and in volume (Barton, 2002). Given that these parameters are adopted by most authors to indicate computational capacity, this evidence has been taken to suggest a functional dependence of one structure upon the other. A conciliatory view holds that cerebellum and neocortex evolved together, but with the cerebellum evolving more slowly than neocortex (Barton, 2002).

These conflicting interpretations demonstrate that cortical volume and surface, although informative measurements and widely used in the literature, particularly in relation to intelligence, cognitive abilities, and versatility, are only indirect indicators of computational capacity. As both cerebral (Douglas and Martin, 2004) and cerebellar (Leiner *et al*., 1991) cortices have modular structures, their computational capacity can be related more directly to the number of modules in each structure, and thus to the number of neurons in each structure, independently of total cortical surface or volume, characteristics that are affected by other variables such as non-neuronal volume. Thus, one way of clarifying the issue of how cerebral and cerebellar cortices are structurally, functionally, and evolutionarily related might be through the comparative analysis of the number of neurons in these structures.

3.12.3.3 A Nonstereological Way Out: The Isotropic Fractionator

The isotropic fractionator is a novel method developed recently in our lab which allows the nonstereological determination of the absolute number of neuronal and non-neuronal cells in different brain regions (Herculano-Houzel and Lent, 2005). It consists in transforming highly anisotropic brain structures into homogeneous, isotropic suspensions of fixed cell nuclei which can then be counted and identified immunocytochemically as neuronal or non-neuronal. The method can be applied either to the brain as a whole or to its dissected parts, such as cerebral cortex or cerebellum, and their respective number of cells can next be added up in order to obtain a whole-brain estimate. Estimates of total cell, neuronal and non-neuronal numbers in any brain structure can be obtained in 24 h, and vary by less than 10% among animals. Since the estimates obtained are independent of brain volume, they can be used in comparative studies of brain volume variation among species and in studies of phylogenesis, development, adult neurogenesis, and pathology. We have used the isotropic fractionator to compare the cellular composition of cerebral cortex, cerebellum, and remaining areas of the adult brain of six species of the order *Rodentia*, from mouse to the giant Amazonian capybara (Herculano-Houzel *et al*., 2006a), and are currently expanding this analysis to primate species (Herculano-Houzel *et al*., 2006b).

3.12.4 How to Build a Bigger Brain

Across the six rodent species examined, body mass varies over 1000-fold, from about 40 g in mouse to over 40 kg in capybara, while brain mass varies by less than 200×, accompanied by a smaller increase of 45× in total number of cells, an even smaller 23× increase in total number of neurons but a relatively large 86× increase in total number of non-neuronal cells (Figure 3). All data mentioned henceforth

Species	Body mass	Brain mass	#Cells	#Neurons	#Non-neuronal
Mouse	40 g	0.416 g	109 M	71 M	38 M
Hamster	168 g	1.020 g	166 M	90 M	76 M
Rat	315 g	1.802 g	331 M	200 M	131 M
Guinea pig	311 g	3.759 g	478 M	240 M	238 M
Agouti	2843 g	18.365 g	1941 M	857 M	1084 M
Capybara	47500 g	76.036 g	4870 M	1600 M	3270 M
Variation	1188	183	45	23	86

Figure 3 Total number of neuronal and non-neuronal cells in the brain of six rodent species. Average body mass, brain mass (in grams), total number of cells, neurons and non-neuronal cells (in millions) in the brain of six rodent species, shown in the same scale. Relative variations in each parameter from mouse to capybara are listed in the bottom.

regarding the cellular composition of rodent brains were reported in Herculano-Houzel *et al.* (2006a).

3.12.4.1 Bigger Brains Have a Constant Relative Number of Neurons in Cortex

As reported previously for other mammalian orders, relative size of the cerebral cortex increases significantly with brain size among rodent species (Frahm *et al.*, 1982; Figure 4a). Interestingly, this expansion in size is not reflected in the distribution of total brain neurons. Regardless of total brain size, cerebral cortex in all six species contains a relatively stable 18% of all brain neurons. This is in contrast to the distribution of total brain non-neuronal cells, which become relatively more numerous in the cortex as it expands in larger-brained species (Figure 4a). The long-acknowledged cortical expansion in bigger brains, thus, at least in the order Rodentia, does 'not' reflect any increasing allocation of brain neurons to the cortex, but only of non-neuronal cells, presumably glia.

3.12.4.2 Bigger Brains Have Relatively More Neurons in Cerebellum

The cerebellum represents a steady 14% of brain mass across rodent species, as reported for other mammalian orders (Clark *et al.*, 2001). Remarkably, its fraction of total brain neurons is 'not' stable: larger cerebella concentrate more and more of all brain neurons, from 59% in mouse to 72% in capybara (Figure 4b) but, in contrast to the cerebral cortex, they concentrate a steady fraction of all brain non-neuronal cells.

The increase in the relative number of cerebellar neurons can be explained through the addition of neurons to the cerebellum as a power function of the number of cortical neurons with an exponent >1.0, estimated at 1.113. The total number of neurons actually increases faster in the cerebellum than in the remaining of the brain, with an exponent of 1.181. Contrary to all expectations from volumetric data, the fact that the cerebellum gains neurons at a faster rate than all other brain structures, cerebral cortex included, and concentrates increasing fractions of all brain neurons shows that the total number of functional integrative units – neurons – increases faster in cerebellum than in cortex. This finding calls into question the validity of using surface and volume measurements as indicators of computational capacity. Given the modular structure of both cerebral and cerebellar cortices, the addition of neurons – and therefore supposedly of more modules – increases the computational capabilities of both networks, and therefore their total number of neurons should be a far more direct indicator of functional capacity than structure volume and surface, which are inflated by non-neuronal cells and connecting fibers of larger caliber. Thus, it has to be concluded that despite the volumetric expansion of the cerebral cortex as brain size increases within the order Rodentia, its

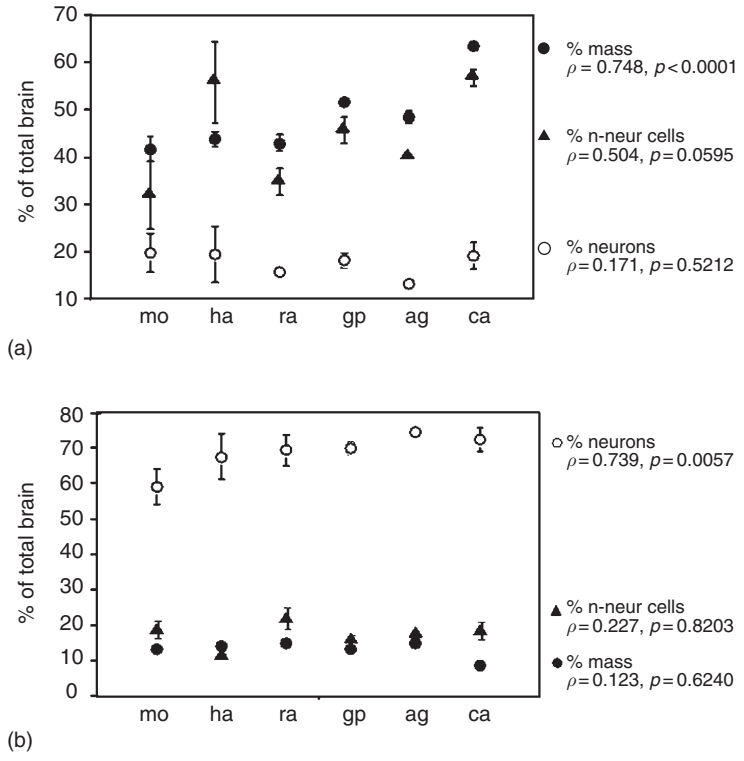

Figure 4 Cerebral cortex expands in relative volume, but retains stable relative number of neurons, while larger cerebella hold increasing relative number of neurons in an unchanging relative volume. Points represent relative distribution of mass, number of neurons, and number of non-neuronal cells in the cerebral cortex (a), and cerebellum (b) of six rodent species (mouse (mo), hamster (ha), rat (ra), guinea pig (gp), agouti (ag), and capybara (ca)). Each point corresponds to one individual animal. Correlation coefficients and *p*-values for Spearman rank correlations are given.

computational capacities may remain stable, while those of the cerebellum may actually increase. Interestingly, this does not seem to correlate with the motor abilities of the species, as, for instance, agoutis, which manipulate food with their front paws, have a richer motor repertoire than the much larger capybara, endowed with a larger relative number of cerebellar neurons. However, this may just come to show that, as noted recently (Leiner *et al*., 1991), the cerebellum is much more than a merely motor structure.

3.12.5 Cellular Scaling Rules for Rodent Brains

As shown in Figure 3, larger rodent brains contain increased number of neurons, as expected, and this is true for cerebral cortex, cerebellum, and the remaining areas separately. In striking contrast to Haug's (1987) estimate based on neuronal densities and volume (see above), the results obtained non-stereologically with the isotropic fractionator show that the power law relating cortical mass to its number of neurons has a large exponent of 1.760. This means that a 10× larger rodent cortex would have only 3.6× more neurons, or that a 10× increase in the number of cortical neurons would result in a 58× larger cortex. Other factors, such as increased neuronal size and increased non-neuronal mass, must therefore also contribute significantly to cortical expansion.

3.12.5.1 More Neurons, Many More Non-Neuronal Cells

Direct estimation of number of cells with the isotropic fractionator shows that larger brains are built with more neurons, but with even larger number of non-neuronal cells. The latter are related to the total number of neurons by a power law with exponent >1 (1.554 in cerebral cortex, 1.254 in cerebellum). This proportional expansion of the non-neuronal cell population results in the increasing g/n ratio observed both in cerebral cortex (Figure 2c) and cerebellum as these structures become larger.

Interestingly, the mass of all the structures examined increase as power laws of their respective number of non-neuronal cells with similar exponents of close to 1.0, and non-neuronal cell

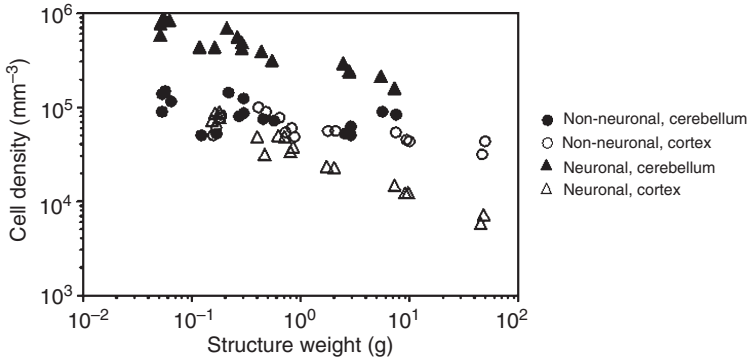

Figure 5 Cerebral cortex and cerebellum have different neuronal densities across rodent species, but similar non-neuronal cell densities. Neuronal (triangles) and non-neuronal (circles) densities are plotted on the *y*-axis against weight of the respective structure, cerebellum (filled symbols), and cerebral cortex (open symbols).

densities are strikingly similar both across brain structures and species. In fact, although across all species the cerebellar g/n ratio is much smaller than the cortical ratio, these structures share similar non-neuronal densities (Figure 5).

3.12.5.2 Neurons Become Larger As They Are Added; Glia Do Not

The different scaling of neuronal and non-neuronal cell densities with brain size suggests that these two cell types vary differently in average size: as they become more numerous, neurons must increase in size faster than non-neuronal cells.

Indeed, mathematical analysis of all the power laws obtained experimentally suggests that average neuronal size increases proportionally to the total number of neurons raised to the power of 0.760 in cerebral cortex and 0.370 in cerebellum. In comparison, the estimated variation in average non-neuronal cell size among rodents is much smaller: it follows a power law function of total number of non-neuronal cells with very small exponents of 0.114 in cerebral cortex, and 0.063 in cerebellum. This means that if the number of cortical neurons is multiplied by 100, their average size increases 33.1×, while a similar increase in the number of cerebellar neurons is accompanied by an increase in average neuronal size of only 5.5×. In contrast, 100× more numerous non-neuronal cells in the cerebral cortex will be on average only 1.7× larger, and if they become 100× more numerous in the cerebellum, their average size will increase only 1.3×.

We find that capybaras have 22× more cortical neurons than mice, and the average neuronal size is estimated to be 10× larger. The larger rodent has even more cerebellar neurons than the mouse (a 27× increase), but the average neuronal size is estimated to be only 3.4× larger. At the same time, capybaras have 153× and 82× more non-neuronal cells than mice in the cerebral cortex and cerebellum, respectively, but these cells are estimated to be only 1.8× and 1.3× larger.

Since increasing number of neurons result in larger brain size, it is expected that these neurons increase in size, with longer, highly branched processes to maintain long-distance connectivity as brain size increases, as well as larger somata to support them. However, increases in average neuronal size are observed to contribute 'less' to final structure size than changes in total number of neurons, and the 'larger' the increase in this number between two species, the 'smaller' the relative contribution of average neuronal size to final structure size. This is consistent with a strong selective pressure against increased neuronal size, lest the brain becomes too large too fast as it gains neurons (Harrison *et al.*, 2002). The faster increase in cortical neuronal size compared to cerebellum is in good agreement with the known architecture of cerebral and cerebellar cortices, the former composed of relatively large number of neurons with large cell bodies and extensively arborized processes that span long distances (Douglas and Martin, 2004), the latter composed mostly of much smaller neurons with a single, long, and comparatively local arborization (Leiner *et al.*, 1991).

In contrast, increasing number of non-neuronal cells are added to the brain in the absence of large changes in average non-neuronal cell size. Compared to neurons, glial cells act locally, so it is reasonable to expect that, as the brain grows and glial cells are added in large numbers, they retain a volume that is small enough to perform local functions of regulating the microcirculation and synaptic transmission (Nedergaard *et al.*, 2003).

It will be interesting to see whether data on neuronal and non-neuronal cell size will match our estimates as they become available by direct

measurement. According to our estimates, a rodent brain with a human-sized cerebellum would be expected to have *c.* 900× more cerebellar non-neuronal cells that are on average only 1.5× larger than in mouse cerebellum. Recent measurements of human astrocytes have shown that they are only 3× larger than mouse astrocytes (Oberheim *et al.*, 2005), which seems to be good evidence that non-neuronal cell size indeed changes very little with cell number. Similarly, Purkinje cells are 50× more numerous in human (Andersen *et al.*, 1992) than in rat cerebellum (Korbo *et al.*, 1993), and would therefore be expected to be 4.2× larger in the former, according to our estimates; in the literature, these cells have been found to have a 2.5 × bigger perykaryon (Korbo and Andersen, 1995), which falls close enough to the expected value, given that the dendritic and axonal arborizations were not considered in that study.

3.12.5.3 Glial Mass to Match Neuronal Mass: Something Remains Constant

In the midst of all the power laws that relate changing number of cells, their average volumes, and the resulting size of brain structures, it is interesting to find that one parameter remains constant: the ratio between 'total' neuronal and 'total' non-neuronal 'masses' in a given brain structure, that is, the ratio between the product of total number of neurons and their average mass, and the product of total number of non-neuronal cells and their average mass in a structure. This follows mathematically from the relationships between number of neuronal and non-neuronal cells and their relationships with structure size, and occurs simultaneously with the increased ratio between number of non-neuronal and neuronal cells (the g/n ratio) with larger brain size.

The constant total g/n mass ratio is achieved as the increased neuronal mass, resulting from larger number of neurons that increase significantly in size, is matched by the addition of much larger number of non-neuronal cells of only slightly larger size. In this way, a 2× increase in total neuronal mass is accompanied by an equal 2× increase in total non-neuronal mass, and yields a 2× increase in brain size. The overall mass constraint suggested by our data is compatible with the recent notion that glial cells serve as dynamic regulators of neuronal production, function and phenotype, and organize brain tissue into functional compartments (Nedergaard *et al.*, 2003). On the other hand, an increase in number of glial units would favor a growing participation of these cells in neural computation, as has been proposed recently (Allen and Barres, 2005; Volterra and Meldolesi, 2005), without compromising their role in regulatory and support functions. The constant neuronal/non-neuronal mass ratio also settles the apparent discrepancy between the numeric expansion of glial cells compared to neurons, while the neuronal need for metabolic support remains similar across species (Nedergaard *et al.*, 2003).

We have proposed this constant balance between total neuronal and non-neuronal mass in the brain to be a major mechanism driving changes in brain size. The constant total g/n mass ratio could be achieved economically if gliogenesis were regulated according to the number of neurons generated in each structure. This would take place during the development of each individual, as the increased neuronal proliferation that has been proposed to drive cortical growth across species (Rakic, 1995) is followed by gliogenesis, which is largely postnatal (Sauvageot and Stiles, 2002). Glial precursor proliferation is density-dependent and ceases once a steady-state glial density has been achieved, most likely by cell–cell contact inhibition (Zhang and Miller, 1996). Given the relatively invariant non-neuronal densities observed both across brain structures and species, we have suggested that continued gliogenesis until confluency is reached in a formerly purely neuronal tissue, such as newborn cerebral cortex, is a likely candidate mechanism by which the number of neuronal and non-neuronal cells are related and by which the ratio between total neuronal and non-neuronal mass could be kept constant across species.

3.12.6 Conclusions

Comparative analysis of the cellular composition of the mammalian brain is starting to confirm some trends expected from volumetric and stereological studies, and to reveal novel principles of brain scaling. Our studies with the isotropic fractionator have confirmed that neuronal density decreases with increasing size of cerebral cortex and cerebellum while non-neuronal cell density remains relatively stable; further, the g/n ratio in these structures increases with structure size. Additionally, these studies have revealed that:

1. variations in total number of neurons contribute more than variations in neuronal size towards final structure size;
2. average non-neuronal cell size changes very little across brains of different sizes;
3. the number of non-neuronal cells seems to be regulated according to the number of neurons

in the structure such that, as a result, total g/n mass ratio remains constant within a structure as its size varies; and
4. unexpectedly, the cerebellum gains neurons at a faster rate than the cerebral cortex, and concentrates increasing fractions of all brain neurons as brain size increases, despite the volumetric expansion of the cerebral cortex.

We have suggested that this latter finding is a consequence of a greater increase in average neuronal size in the cerebral cortex than in the cerebellum, matched by a corresponding increase in total non-neuronal mass. Although the cerebellum gains neurons faster than cerebral cortex, the average size of its neurons increases much more slowly, and once the non-neuronal population expands to match the total neuronal mass in these structures, the result is a much inflated cerebral cortex that still holds the same number of neurons relative to the whole brain. In this manner, volumetric expansion is dissociated from expansion of the neuronal population. This latter finding has important implications for the functional relationship and computational capacity of these structures, as discussed above.

It is important to realize that the current view of encephalization and neocorticalization as adaptive and selected traits in evolution (Jerison, 1985) are based on volumetric relationships that do not hold at the cellular level of brain composition, and therefore may not be reliable indicators of function. The very concept of encephalization carries the built-in assumption that brain size is indeed a measure of computational capacity as it puts forward the notion that a larger than expected brain size endows species with better cognitive capabilities. However, our data indicate that, at least in rodents, neocorticalization is only apparent; when it comes to number of neurons, it is the cerebellum that becomes expanded in larger brains.

It is interesting to wonder how the view of neocorticalization would be different today if studies of cellular scaling rules had been available earlier: given the increasing concentration of neurons in the cerebellum, perhaps we would deal today with concepts of cerebellarization of the brain, instead of neocorticalization as traditionally considered. Indeed, in light of the recent discoveries on the functional contribution of glial cells to intercellular signaling, in concert with neurons (Allen and Barres, 2005; Volterra and Meldolesi, 2005), there is actually the novel possibility that it is the increasing numerical predominance of glial cells in the cerebral cortex that accounts for the expected increase in computational power of larger brains.

3.13 Scaling the Brain and Its Connections

M A Changizi, California Institute of Technology, Pasadena, CA, USA

Glossary

area-infiltration The average percentage of neurons in a cortical area to which a neuron connects. This appears to be invariant across mammals.

area-interconnectedness The average percentage of areas in the brain to with which an area connects. This appears to be invariant across mammals.

cortical area Groups of neurons that communicate with one another largely via short-range, non-white-matter connections; whereas the connections between neurons in different areas are largely made by long-range, white-matter connections. This definition of area is related to one of the three principal experimental criteria for identifying areas, namely the pattern of connectivity to other parts of the neocortex (the other two criteria concern histology and topographic maps).

encephalization quotient, EQ Intuitively, it measures how big the brain is once we have corrected for body size. Because brain mass scales as the 3/4 power of body mass, EQ is brain mass divided by the 3/4 power of body mass.

epiphenomenal Phenomena that are not strictly functional, but are a side effect of something that is. A side effect of design features.

invariant In scaling studies, when a biological property is said to be 'invariant', it means that that property does not tend to change as a function of brain size. It does not mean that the property does not vary in other ways, e.g., from brain area to brain area.

minicolumns Thin neuroanatomical structures extending through the thickness of gray matter. The number of neurons in a minicolumn appears to be approximately invariant across mammals (namely on the order of 100). Both minicolumns and modules appear to be invariant-sized computational units of the neocortex.

modules Used to refer to a variety of neuroanatomical structures larger than minicolumns, but smaller than cortical areas, such as columns, blobs, barrels, and stripes. The number of neurons in a module appears to be approximately invariant across mammals. Both minicolumns and modules appear to be invariant-sized computational units of the neocortex.

Murray's law An empirical relationship between the diameter of a parent segment

of a tree and its daughter segments. Murray's law states that the cube of the diameter of the parent is equal to the sum of the cubes of the daughters. Evidence suggests that this law applies to neural arbors, albeit with considerable variation.

neocortical scaling — The study of the manner in which neocortical features change from small to large brains, with the aim of identifying fundamental principles governing the organization of the neocortex.

principle of economical well-connectedness — The mammalian neocortex satisfies the principle of well-connectedness, but does so in such a way that it minimizes wiring volume. Intuitively, the principle says to cheaply maintain an invariant level of interconnectivity, both at the intra- and interarea levels.

principle of invariant area-infiltration — When a neuron makes connections within an area, the number of synapses it makes is, on average, some invariant fraction of the number of neurons in the area. This invariance property is referred to as 'invariant area-infiltration', because, independent of brain size, neurons have, on average, sufficiently many synapses to 'infiltrate' an invariant fraction of the neurons in an area.

principle of invariant area-interconnectedness — The average number of area connections per area scales approximately proportionally with the total number of areas.

principle of well-connectedness — The mammalian neocortex satisfies both the principle of invariant area-infiltration and the principle of invariant area-interconnectedness.

3.13.1 Introduction

At first glance, larger brains seem more complex than smaller brains, having a greater number of synapses per neuron, greater surface convolutedness, more cortical areas, and disproportionately more white matter. However, brain size does not correlate with behavioral repertoire size as measured by ethologists (Figure 1), leading one to suspect that these seemingly increasingly complex features of larger brains are not underlying more complex computations (although see Brain Size in Primates as a Function of Behavioral Innovation for within primates). Instead, these seemingly complex features may be epiphenomenal consequences of making larger (not 'smarter') brains: it may be that a larger brain must satisfy certain invariant anatomical constraints that are fundamental to its function, and it is the satisfaction of these constraints in larger brains that leads to the seemingly complex features. In this light, the goal of studying how brains scale up in size across mammals is to identify the invariant anatomical constraints that are fundamental to brain function. Section 3.13.2 enumerates many of the neocortical changes that occur from small to large brains. Section 3.13.3 identifies key connectivity constraints that appear to be essential to brain function, no matter the size of the brain. In particular, these connectivity constraints are called 'invariant area-infiltration' and 'invariant area-interconnectedness', summed up as 'invariant well-connectedness'. Section 3.13.4 explains how brains appear to satisfy these invariant connectivity constraints in an economical fashion, and that this is what explains why brains scale up in the broad manner that they do.

3.13.2 The Empirical Scaling Relationships

In this section, I review many of the changes the mammalian neocortex undergoes from small (see Organization of a Miniature Neocortex – What Shrew Brains Suggest about Mammalian Evolution) to large brains (see the third column of Table 1 for a summary). It must be recognized that these empirical scaling relationships are only zeroth-order descriptions of the neocortex, capturing neither ecology-dependent variation in brain organization nor important architectonic differences within brains (see Principles of Brain Scaling).

3.13.2.1 Number of Neurons, Synapse Density, Number of Synapses per Neuron, Network Diameter

One of the oldest neocortical scaling results is that the number of neocortical neurons, N, scales up disproportionately slowly compared to gray matter volume, V_{gray}, and in particular, $N \sim V_{gray}^{2/3}$ (Tower and Elliott, 1952; Tower, 1954; Jerison, 1973; Passingham, 1973; Prothero, 1997b). Alternatively, $V_{gray} \sim N^{3/2}$. Although the volumetric density of neurons therefore

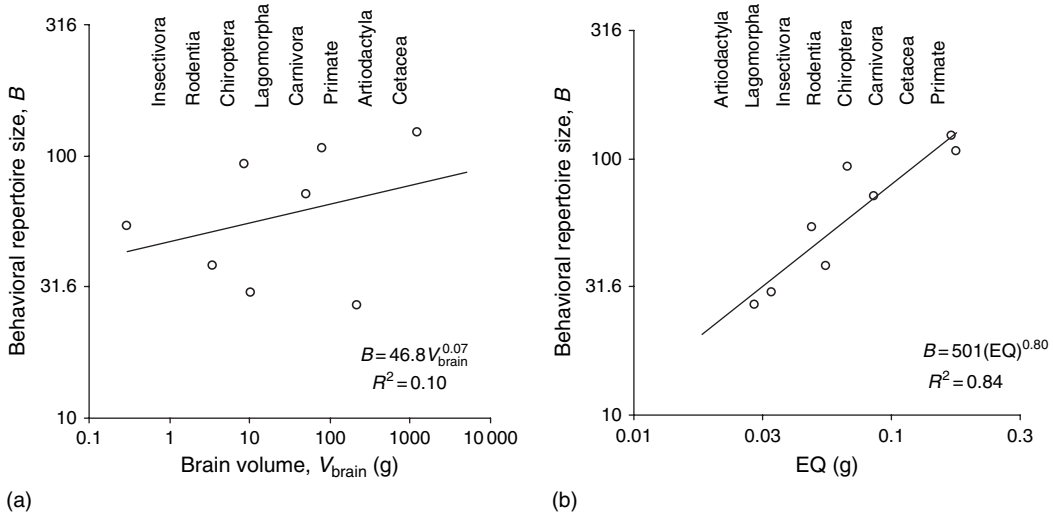

Figure 1 The neocortical scaling features are due to an increase in brain size, not due to an increase in behavioral complexity. This is because brain size does not correlate with behavioral repertoire size, as is shown in (a) which shows average behavioral repertoire sizes, B, for eight mammalian orders compiled from the ethology literature (Changizi, 2003a, 2003b) vs. brain volume, V_{brain} (averaged from animals measured in Hrdlicka (1907), Von Bonin (1937), Crile and Quiring (1940), Stephan *et al.* (1981), the Stephan Collection, Hofman (1982), Haug (1987)). There is no significant correlation between them ($df = 6$, $t = 0.82$, $p > 0.2$). As is shown in (b), however, behavioral repertoire size does increase as a function of the 'encephalization quotient', or EQ ($df = 6$, $t = 2.37$, $p < 0.05$). (EQ is brain mass (g) divided by the 3/4 power of body mass (g), which measures how big a brain is once one has corrected for how large the animal is; this is the appropriate normalization because brain mass increases as the 3/4 power of body mass (see Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals).) The moral here is that the explanation for the neocortical scaling features probably will not appeal to increasing brain 'complexity'; instead, the explanation is likely to appeal to physicomathematical constraints in making a larger – but not necessarily 'smarter' – brain.

Table 1 Empirical and predicted (via the economical well-connectedness hypothesis) scaling exponents for a variety of neocortical quantities as a function of the number of neurons, N (top), and as a function of gray matter volume, V_{gray} (bottom). The 'formula' column shows the predicted exponent, parameterized by the parameter α, where $A \sim W^{\alpha}$. The final three columns show the predicted scaling exponent for three specific values of α: $\alpha = 1$, where the number of areas scales up as fast as possible (consistent with the well-connectedness constraints); $\alpha = 0.76$, the value of α that leads to the total wire volume scaling up as slowly as possible; $\alpha = 0$, where the number of areas remains constant as a function of brain size

				Optimal		
X		*Empirical*	*Formula*	$\alpha = 1$	$\alpha = 0.76$	$\alpha = 0$
Exponent z in $X \sim N^z$						
No. of connections per neuron	δ	≈ 0.5	$1/(1+\alpha)$	0.500	0.568	1.000
Axon radius	R	≈ 0.167	$1/(3+3\alpha)$	0.167	0.189	0.333
Gray matter volume	V_{gray}	≈ 1.5	$(2+\alpha)/(1+\alpha)$	1.500	1.568	2.000
Surface area	S	≈ 1.33	$(5+3\alpha)/(3+3\alpha)$	1.333	1.379	1.667
Thickness	T	≈ 0.167	$1/(3+3\alpha)$	0.167	0.189	0.333
White matter volume	V_{white}	≈ 1.77–2	$(7\alpha+4)/(3\alpha+3)$	1.833	1.765	1.333
No. of area connections per area	D	≈ 0.5	$\alpha/(1+\alpha)$	0.500	0.432	0.000
No. of neurons per area	W	≈ 0.5	$1/(1+\alpha)$	0.500	0.568	1.000
No. of areas	A	≈ 0.5	$\alpha/(1+\alpha)$	0.500	0.432	0.000
Exponent z in $X \sim V_{gray}^z$						
No. of neurons	N	≈ 0.67	$(1+\alpha)/(2+\alpha)$	0.667	0.638	0.500
Axon radius	R	≈ 0.1	$1/(6+3\alpha)$	0.111	0.121	0.167
No. of connections per neuron	δ	≈ 0.33	$1/(2+\alpha)$	0.333	0.362	0.500
Surface area	S	≈ 0.9	$(5+3\alpha)/(6+3\alpha)$	0.889	0.879	0.833
Thickness	T	≈ 0.1	$1/(6+3\alpha)$	0.111	0.121	0.167
White matter volume	V_{white}	≈ 1.15–1.33	$(7\alpha+4)/(3\alpha+6)$	1.222	1.126	0.667
No. of area connections per area	D	≈ 0.33	$\alpha/(2+\alpha)$	0.333	0.275	0.000
No. of neurons per area	W	≈ 0.33	$1/(2+\alpha)$	0.333	0.362	0.500
No. of areas	A	≈ 0.33	$\alpha/(2+\alpha)$	0.333	0.275	0.000

decreases, the volumetric density of synapses appears to remain approximately constant as a function of gray matter volume (Abeles, 1991). Together, these two scaling results entail that the average number of synapses per neuron, δ, increases as the 1/3 power of gray matter volume; that is, $\delta \sim V_{\text{gray}}^{1/3}$ (see Figure 2). Or, as a function of the number of neurons, $\delta \sim N^{1/2}$.

Interestingly, although the number of synapses per neuron scales up considerably more slowly than the number of neurons, the scaling is sufficiently fast to maintain a low network diameter (i.e., the average number of axons that must be traversed to get from any neuron to another): assuming that the neocortex is small-world (i.e., having sufficiently many axons connecting otherwise-separated parts of neocortex that the network diameter can be approximated as that of a random network), the network diameter may be approximated as $\Lambda \approx (\log N)/(\log \delta)$, which manipulates to $\Lambda \approx 2 \times [1 + (\log c)/(\log N)]$, where c is the proportionality constant in the equation $\delta = cN^{1/2}$ (Changizi, 2001b). For sufficiently large brains, Λ approaches 2; also, estimates of c are on the order of 1, meaning that perhaps the network diameter is $\Lambda \approx 2$ in actual neocortices.

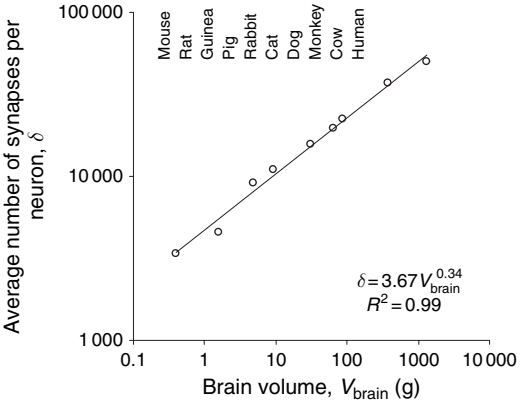

Figure 2 The average number of synapses per neuron, δ, scales as the 1/3 power of gray matter volume, V_{gray}. The plot shows the average number of synapse per neuron, δ, vs. brain volume, V_{brain}. The synapse numbers are computed using data from Tower and Elliott (1952), who present data for how neuron density decreases in larger brains (namely, it decreases as the $-1/3$ power of brain volume). Since volumetric synapse density remains invariant as a function of brain size (Abeles, 1991; Changizi, 2001b), a neuron density decrease corresponds to a proportional increase in the number of synapses per neuron. The synapse values were computed assuming that the average number of synapses per neuron in human is 50 000; this choice of 50 000 serves to set the proportionality constant, but does not affect the scaling exponent. In addition to concluding that $\delta \sim V_{\text{gray}}^{1/3}$, it also follows that $\delta \sim N^{1/2}$, where N is the total number of neocortical neurons. (This plot shows brain volume along the x-axis, not gray matter volume, but measured exponents for gray matter volume vs. brain volume are approximately 1:0.983 (Prothero, 1997a), 0.982 (Hofman, 1991), 1.054 (Hofman, 1989), 1.04 (Prothero and Sundsten, 1984), 1.06 (Frahm *et al.*, 1982), and 1.08 (Jerison, 1982). For this reason, it is empirically justified to use brain volume as a proxy for gray matter volume, and this is done in some upcoming figures as well.)

3.13.2.2 Surface Area, Thickness, Minicolumns, and Columns

The neocortical gray matter is a sheet on the outside of the brain (with white matter axons filling the center). There are neuroanatomical structures called minicolumns extending through the thickness of the neocortical gray matter from pia to white matter (Mountcastle, 1957, 1997; Tommerdahl *et al.*, 1993; Peters, 1994; Jones, 2000), and the number of neurons in a minicolumn (i.e., along a thin line through the thickness of gray matter) appears to be approximately invariant (on the order of 100) as a function of gray matter volume (Rockel *et al.*, 1980; Prothero, 1997b; Changizi, 2001b). Because of the neuron density decrease discussed earlier (namely neuron density $\rho_{\text{neuron}} \sim V_{\text{gray}}^{-1/3}$), it follows that gray matter thickness, T, must increase as the 1/9 power of gray matter volume, $T \sim V_{\text{gray}}^{1/9}$, and indeed this is what has been measured (Hofman, 1985, 1989, 1991; Jerison, 1982; Prothero and Sundsten, 1984; Prothero, 1997a). Because gray matter volume is equal to its surface area, S, times its thickness, T, it also follows immediately that $S \sim V_{\text{gray}}^{8/9}$, something also measured. Surfaces of geometrically similar objects scale as the 2/3 power of volume, and the fact that this exponent of approximately 8/9 is greater than 2/3 means that the neocortex surface cannot remain geometrically identical as the brain enlarges, but must, instead, become increasingly convoluted, as it does in larger brains. We see, then, that gray matter thickness and surface area scaling follow from (1) the neuron density decrease in larger brains, and (2) the invariant number of neurons in a minicolumn.

Minicolumns are not the only anatomical structure in gray matter that appears to have an invariant number of neurons: the number of neurons in a neocortical 'module' (such as columns, blobs, barrels, stripes) also does not appear to vary as a function of gray matter volume (see Changizi, 2003b, using data from Manger *et al.*, 1998). Such fundamental invariant-sized structures are found in a wide variety of complex network, and may be invariant in size for reasons of economical scaling (see Changizi *et al.*, 2002; Changizi, 2003b; Changizi and He, 2005).

3.13.2.3 Axon Caliber and White Matter Volume

We saw earlier that the number of synapses per neuron, δ, scales as the 1/3 power of gray matter volume (or as the square root of the number of neurons). Biological structures with more 'leaves' are almost always supported by thicker 'trunks', and we should

therefore expect that as the number of synapses per neuron increases, axon calibers and soma diameters should increase. Indeed, white matter axon caliber, R, appears to increase in size in larger brains (Harrison *et al.*, 2002), and, in particular, approximately as the 1/9 power of gray matter volume, $R \sim V_{gray}^{1/9}$ (Shultz and Wang, 2001). (Soma diameter for spinal motor neurons also scales approximately as the 1/9 power of gray matter volume (Changizi, 2001b).) It follows that axon caliber scales as the 1/3 power of the number of synapses per neuron, $R \sim \delta^{1/3}$, or $R^3 \sim \delta$. Because volumetric synapse density is invariant as a function of gray matter volume (see Section 3.13.2.1), the linear dimensions of synapses must be invariant, and the relationship $R^3 \sim \delta$ can be rewritten as $R^3 \sim \delta \times R_{synapse}^3$, where $R_{synapse}$ is the linear dimensions of a synapse. This equation is a version of Murray's law (Murray, 1926), which is an optimality principle relating a parent branch caliber to the caliber of its daughter segments, and is approximately consistent with the parent–daughter diameters of a wide variety of kinds of neural arbor (Cherniak *et al.*, 1999; Chklovskii and Stepanyants, 2003; see How to Build a Bigger Brain; Cellular Scaling Rules for Rodent Brains).

White matter volume, V_{white}, follows from the above scaling exponents as explained below. Assuming the number of white matter projecting neurons, N_{white}, scales proportionally to the total number of neurons, N, $V_{white} \sim N \times L \times R^2$, where L is the average length traveled by a white matter axon, and R is the caliber of a white matter axon. We saw earlier that $N \sim V_{gray}^{2/3}$ and $R \sim V_{gray}^{1/9}$. If L is taken to be the linear dimensions of the gray matter, then $L \sim V_{gray}^{1/3}$, and $V_{white} \sim V_{gray}^{11/9}$. If, however, L is taken to be the linear dimensions of the white matter, then $L \sim V_{white}^{1/3}$, and some algebraic manipulation leads to $V_{white} \sim V_{gray}^{4/3}$ (Changizi, 2001b). Indeed, measured exponents tend to be around 1.2–1.3 (Frahm *et al.*, 1982; Hofman, 1989, 1991; Allman, 1999; Zhang and Sejnowski, 2000; Bush and Allman, 2003). White matter volume, then, scales up disproportionately quickly as a function of gray matter volume, and this is due to white matter axon caliber increasing as it does (and this, in turn, is due to the increasing number of synapses per neuron): if white matter axon caliber were constant, then white matter volume would scale proportionally with gray matter volume (Changizi, 2001b).

3.13.2.4 Number of Areas and Number of Area Connections per Area

The neocortex is partitioned into functionally distinct 'areas', an area which is a contiguous anatomical region involved in some suite of related computations. The labs of Kaas, Krubitzer, and colleagues have determined the boundaries of many areas in a wide variety of mammals, and by compiling results from their studies it is possible to estimate the total number of areas across 19 mammals of varying brain size (see Figure 3). The number of areas, A, scales approximately as the 1/3 power of gray matter volume, $A \sim V_{gray}^{1/3}$, or $A \sim N^{1/2}$ (Changizi, 2001b, 2003b; Changizi and Shimojo, 2005). It follows that the average number of neurons per area, W, also scales as the 1/3 power of gray matter volume, $W \sim V_{gray}^{1/3}$, or $W \sim N^{1/2}$. Note that although the average number of neurons per area scales as the 1/3 power of gray matter volume, some areas such as V1 and V2 appear to violate this average tendency, scaling as the 2/3 power of gray matter volume, or proportional to the total number of neurons (Changizi and Shimojo, 2005; see Captured in the Net of Space and Time: Understanding Cortical Field Evolution, Mosaic Evolution of Brain Structure in Mammals).

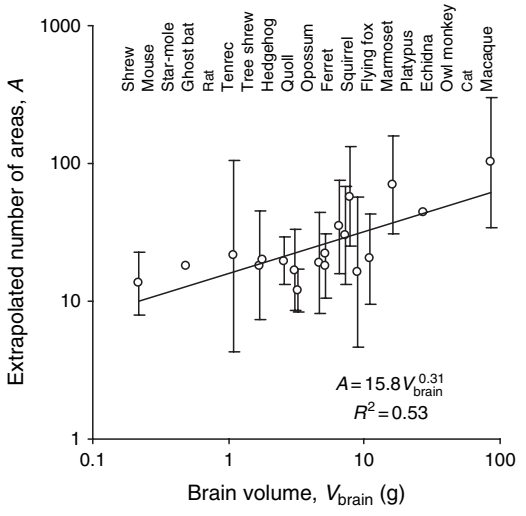

Figure 3 The number of cortical areas, A, and the average number of neurons per area, W, each scale as the 1/3 power of gray matter volume, V_{gray}. The plot shows the extrapolated number of cortical areas, A, vs. brain volume, V_{brain}. (Standard deviation bars are shown.) For each of 19 mammals studied by Kaas, Krubitzer, and colleagues, the average fraction of neocortex taken up by a cortical area was measured (Changizi and Shimojo, 2005). For example, if the average neocortical area takes up 5% of the neocortex, then the extrapolated total number of areas is 1/0.05 = 20. The 'extrapolated number of areas' is the inverse of this fraction. The data are from the following papers: Catania *et al.* (1999), Krubitzer and Huffman (2000), Krubitzer (1995), Northcutt and Kaas (1995), Krubitzer *et al.* (1995, 1997), Lyon *et al.* (1998), Beck *et al.* (1996), Manger *et al.* (2002), Kaas (1987). The best-fit scaling exponent is 0.31 (95% confidence interval is (0.16, 0.46)), or approximately $A \sim V_{gray}^{1/3}$. The average number of neurons per area, W, can be computed from this as follows: $W = N/A$, where N is the total number of neocortical neurons. The total number of neocortical neurons scales as the 2/3 power of brain volume, so $W \sim (V_{brain}^{2/3})/(V_{brain}^{0.31}) = V_{brain}^{0.36}$, or approximately $W \sim V_{brain}^{1/3}$. Note also that this means A and W each scale approximately as the 1/2 power of the number of neurons, N.

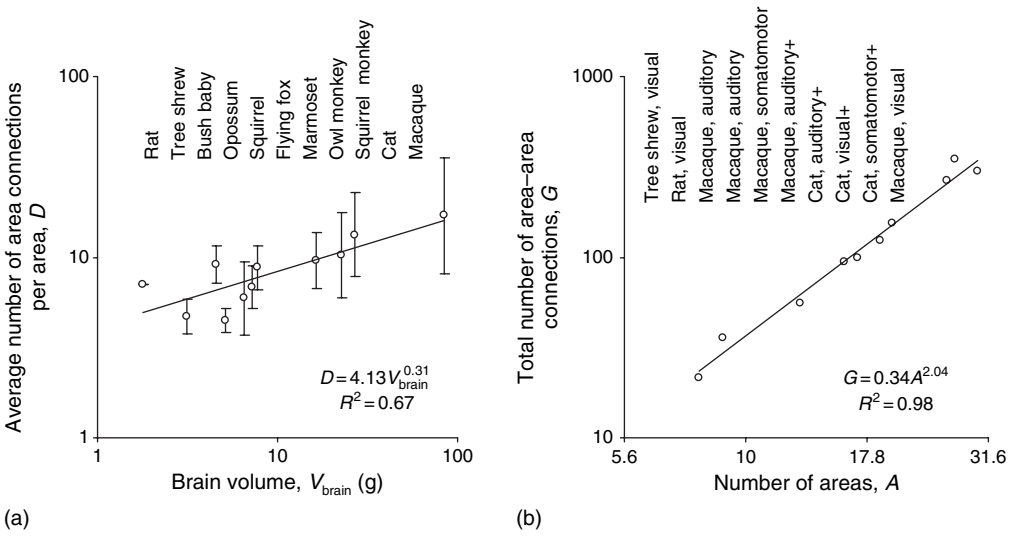

Figure 4 The average number of area connections per area, D, scales as the 1/3 power of gray matter volume, V_{gray}. a, Plot of the average number of area connections per area, D, vs. brain volume, V_{brain} (standard deviation bars shown) for 12 mammals accumulated from approximately one dozen articles in the literature (see Changizi and Shimojo, 2005). For each animal, the number of area connections has typically been measured within the literature only for a relatively small number of areas, and usually from visual or somatosensory areas. The data are from the following papers: Kahn *et al.* (2000), Beck *et al.* (1996), Lyon and Kaas (2001, 2002a, 2002b), Beck and Kaas (1998), Krubitzer and Kaas (1990a, 1990b), Collins *et al.* (2001), Lyon *et al.* (1998), Fabri and Burton (1991), Krubitzer *et al.* (1986, 1993), Kaas *et al.* (1989), Scannell *et al.* (1995), Lewis and Van Essen (2000). The best-fit scaling exponent is 0.31 (95% confidence interval is (0.145, 0.468)), so that it is approximately the case that $D \sim V_{gray}^{1/3}$ (and $D \sim N^{1/2}$). b, Plot of the total number of area–area connections, G, vs. the number of areas, A, in 'area-subnetworks' of tree shrew, rat, cat, and macaque (Changizi, 2003b; Changizi and Shimojo, 2005). These data were compiled from the following papers: Lyon *et al.* (1998), Coogan and Burkhalter (1993), Hackett *et al.* (1998), Young (1993), Kaas and Hackett (2000), Scannell and Young (1993). The best-fit scaling exponent is 2.04 (95% confidence interval is (1.807, 2.263)), or approximately $G \sim A^2$. Because the total number of area–area connections, $G = A \times D$, we can derive that $D \sim A$. Recalling that $A \sim V_{gray}^{1/3}$, we conclude again that $D \sim V_{gray}^{1/3}$ (and $D \sim N^{1/2}$).

Areas connect to other areas via white matter axons, and the average number of areas to which an area connects (or, the average number of area connections per area), D, scales approximately proportional to the 1/3 power of gray matter volume (Changizi and Shimojo, 2005), that is, $D \sim V_{gray}^{1/3}$, or $D \sim N^{1/2}$ (Figure 4). This can be shown by measurements of the average number of area connections per area across a variety of studied areas (mostly visual and somatosensory) in a variety of mammals (Figure 4a), and also by measuring the total number of area connections in 'area subnetworks' within tree shrew, rat, cat, and macaque (Figure 4b). These area and area-connection scaling relationships are consistent with the 'square-root compartment' conjecture by Braitenberg (Braitenberg, 1978, 2001; Braitenberg and Schuz, 1998; see Cortical Commissural Connections in Primates).

3.13.3 Two Fundamental Connectivity Constraints: Invariant Well-Connectedness

Two surprising and important implications concerning connectivity spring from the variety of scaling exponents discussed in Section 3.13.2.

3.13.3.1 Invariant Area-Infiltration

The first important observation concerning connectivity is that both the average number of synapses per neuron, δ (Figure 2), and the average number of neurons per area, W (Figure 3), scale approximately as the 1/3 power of gray matter volume (or as the square root of the total number of neocortical neurons). Therefore, $\delta \sim W$, that is, the average number of synapses per neuron scales approximately directly proportionally with the average number of neurons per area. When a neuron makes connections within an area, the number of synapses it makes is, on average, some invariant fraction of the number of neurons in the area (Figure 5a). This invariance property is referred to as 'invariant area-infiltration', because, independent of brain size, neurons have, on average, sufficiently numerous synapses to 'infiltrate' an invariant fraction of the neurons in an area. In humans, the average number of synapses per neuron, δ, is on the order of 10^4–10^5 and the average number of neurons per area, W, is on the order of 10^8 (given $N \approx 10^{10}$ neurons and $A \approx 100$ areas), and thus $\delta \approx cW$, where the proportionality constant is $c \approx 10^{-4}$–10^{-3}. That is, on average,

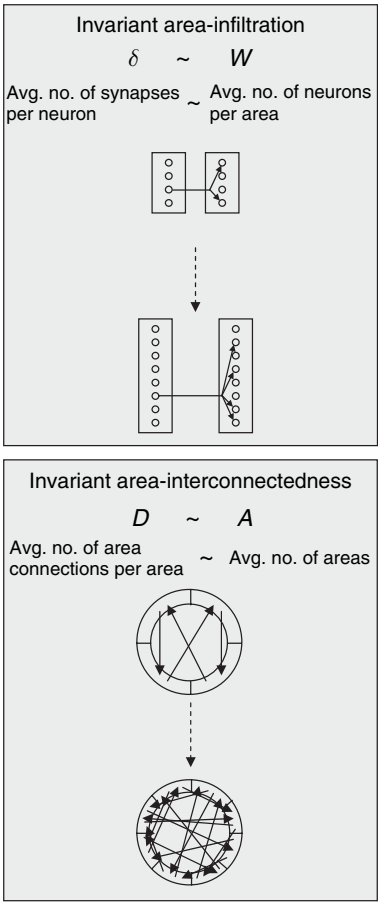

Figure 5 Two fundamental connectivity invariants found in the mammalian neocortex, summarized as 'invariant well-connectedness'. The first is 'invariant area-infiltration', which is the empirical observation that the average number of synapses per neuron, δ, scales approximately directly proportionally with the number of neurons per area, W (namely, each of these quantities scales approximately as the 1/3 power of gray matter volume (see Figures 2 and 3)). The second is 'invariant area-interconnectedness', which is the empirical observation that the average number of area connections per area, D, scales approximately directly proportionally with the number of areas, A (namely, each of these quantities scales approximately as the 1/3 power of gray matter volume (see Figures 3 and 4)).

neurons connect to on the order of 10^{-4}–10^{-3} of the neurons in an area, independent of the number of neurons in an area.

3.13.3.2 Invariant Area-Interconnectedness

The second important observation concerning connectivity is that both the average number of area connections per area, D (Figure 4), and the number of areas, A (Figure 3), scale approximately as the 1/3 power of gray matter volume (or as the square root of the total number of neocortical neurons). Therefore, $D \sim A$, that is, the average number of area connections per area scales approximately directly proportionally to the number of areas (Figure 5b). Equivalently, the total number of area connections scales approximately as the square of the number of areas (something we saw in Figure 4b). This invariance property is referred to as 'invariant area-interconnectedness'. The proportionality constant in $D \approx cA$ may be estimated from Figure 4b, which is $c \approx 0.34$, that is, each area connects to approximately 1/3 of the areas in neocortex, independent of the number of areas (although this is likely to be an overestimate because Figure 5 is for subnetworks which are probably more highly interconnected than is the entire neocortex).

3.13.3.3 Invariant Well-Connectedness

The mammalian neocortex appears to satisfy both connectivity invariances mentioned above – invariant area-infiltration and invariant area-interconnectedness – and joint satisfaction of these is referred to as invariant well-connectedness. Maintaining invariant neuron-interconnectedness for the entire neocortex (i.e., where the average number of synapses per neuron would scale proportionally to the total number of neocortical neurons) would be exorbitantly expensive (Deacon, 1990; Stevens, 1989; Ringo, 1991), and so, instead, the mammalian neocortex takes a two-tiered approach: (1) invariant neuron-interconnectedness 'within areas' (i.e., invariant area-infiltration), and (2) invariant area-interconnectedness among areas in the entire neocortex. Satisfaction of these two invariances is inexpensive relative to maintenance of invariant neuron-interconnectedness for the entire neocortex. Invariant area-infiltration appears to be due to a requirement that some minimum level of interconnectivity be achieved 'within' areas in order for areas to properly function. And invariant area-interconnectedness appears to be due to a requirement that some minimum level of interconnectivity be achieved 'between' areas in order for the entire neocortex to properly function. There is, however, currently no explanation for why mammalian brains have been selected to conform to these invariances. Nor is there an explanation for why there are two tiers, and not more.

3.13.4 Economical Neocortex

Thus far, I have reviewed the empirical scaling relationships (Section 3.13.2) and identified two important connectivity invariance principles that govern neocortical scaling (Section 3.13.3). However, I have not yet provided an explanation for why the neocortex scales up in the ways that it

does. Although, as mentioned above, I have no explanation for why the mammalian neocortex conforms to the principle of invariant well-connectedness; might it be that given that the mammalian neocortex must (for some reason) conform to this principle, then the other neocortical scaling features follow? The answer is 'no': satisfaction of invariant well-connectedness does not entail the other scaling exponents, for there are multiple possible ways of scaling a brain while satisfying invariant well-connectedness. In particular, invariant well-connectedness only states that $\delta \sim W$ (invariant area-infiltration) and $D \sim A$ (invariant area-interconnectedness); it does not say how the average number of neurons per area, W, and the number of areas, A, relate to one another.

In fact, W and A scale approximately proportionally to one another (each scales approximately as the 1/3 power of gray matter volume, or as the square root of the number of neocortical neurons), and it suffices to explain this, and the other scaling exponents then do follow. Although invariant well-connectedness does not entail the proportional relationship between W and A, if we hypothesize that the neocortex is selected to satisfy invariant well-connectedness in a volume-optimal manner – 'economical well-connectedness' – then it is possible to explain why it is approximately the case that $W \sim A$. There is considerable evidence to date that there is strong selective pressure for 'wire-optimality' in the brain (Cajal, 1995; Kaas, 1977, 1989, 1995, 1997, 2000; Cowey, 1979, 1981; Barlow, 1986; Durbin and Mitchison, 1990; Mitchison, 1991, 1992; Ringo, 1991; Ringo *et al.*, 1994; Cherniak, 1992, 1994, 1995; Young, 1992; Traverso, 1992; Jacobs and Jordan, 1992; Ruppin *et al.*, 1993; Van Essen, 1997; Cherniak *et al.*, 1999, 2004; Chklovskii, 2000; Chklovskii and Koulakov, 2000; Changizi, 2001a, 2003b, 2005; Changizi *et al.*, 2002; Chklovskii *et al.*, 2002; Klyachko and Stevens, 2003; Changizi and He, 2005; see Neural Wiring Optimization).

Changizi (2001b) presented a simple argument for why economical satisfaction of well-connectedness would explain $W \sim A$ (i.e., the number of neurons per area scaling proportionally with the number of areas). Namely, a greater number of synapses per neuron, δ, will tend to lead to a greater amount of volume devoted to 'wiring' (because more synapses per neuron requires more arborization and thicker 'trunks' supporting the arbor). Therefore, we would expect the number of synapses per neuron to scale up as slowly as possible, so long as well-connectedness remains satisfied. Because the number of synapses per neuron must scale proportionally to the number of neurons per area (i.e., $\delta \sim W$, or invariant area-infiltration), wire economy consequently expects the number of neurons per area, W, to scale up as slowly as possible. The slowest that the number of neurons per area can scale up is proportional to the number of areas, because (by invariant area-interconnectedness) each area must have sufficiently many neurons to connect to an invariant proportion of the total number of areas. So, the number of neurons per area must scale proportionally with the total number of areas, that is, $W \sim A$.

This argument above relies on the simple heuristic 'fewer synapses per neuron tends to entail lower overall wiring volume', and from it and the hypothesis of well-connectedness one can derive $W \sim A$ (and all the scaling relationships discussed earlier). However, this heuristic hides the fact the total volume of wire in the neocortex depends not only on the number of synapses per neuron, but also on how far neurons must reach. For the remainder of this section I put forth a more rigorous derivation of how wiring volume depends on different scaling strategies relating W and A. We will see that wiring optimality does indeed predict that W and A should scale approximately proportionally to one another, just as the simple heuristic argument predicted. The contents of the remainder of this section are somewhat more mathematical, and if one is content with the heuristic argument above, one may jump to the conclusion.

3.13.4.1 Economical Satisfaction of Invariant Area-Infiltration

Before explaining more rigorously why it is volume optimal for the average number of neurons per area, W, to scale proportionally with the number of areas – which is key to deriving the other scaling exponents – it is useful to see that invariant-infiltration itself is volume optimal (see Figure 6). Suppose an area needs to infiltrate the neurons in some other area. One extreme strategy – the actual strategy – is to, as the number of neurons per area, W, increases, have a fixed number of neurons carry out the infiltration, but have the number of synapses per neuron, δ, increase proportionally with W. If M is the number of neurons in the area responsible for the infiltration, then for the actual strategy, $M \sim W^0$ and $\delta \sim W$. The other extreme strategy is to keep δ invariant as W increases, and increase the number of neurons doing the infiltration proportionally with W; for this alternative strategy, $M \sim W$ and $\delta \sim W^0$. More generally, suppose that $M \sim W^\beta$, where β is a constant from 0 to 1. $\beta = 1$ corresponds to the actual scaling strategy for

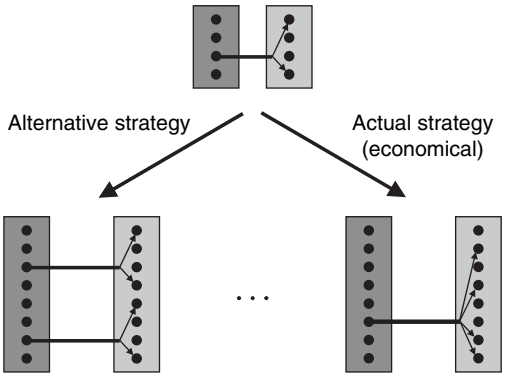

Figure 6 Illustration that the actual scaling strategy for invariant area-infiltration is volume optimal. The neocortex across mammals appears to economically maintain a constant degree of area-infiltration, no matter the size of the areas, where 'area-infiltration' is the fraction of neurons in an area to which a neuron connects. On the right is shown the actual scaling strategy, where, when the number of neurons per area is doubled, the number of neurons connecting from one area to the other remains the same, and the number of connections per neuron is doubled. The neural volume required is $V_{actual} = LR^2_{actual}$, where L is the distance between the areas, and R_{actual} is the caliber of a white matter axon. From Murray's law (see Section 3.12.2.3), $R \sim \delta^{1/3}$, where δ is the number of synapses per neuron, and so $V_{actual} \sim L\delta^{2/3}_{actual}$. Since $\delta_{actual} = 4$ in this illustration, $V_{actual} \sim L4^{2/3} = L2^{4/3}$. On the left is shown an alternative strategy, where, when the number of neurons per area is doubled, the number of neurons connecting from one area to the other doubles, and the number of connections per neuron remains the same. The neural volume required for this strategy is $V_{altern} = 2LR^2_{altern}$, where the '2' in front is due to there now being two white matter axons in the illustration, rather than one. From Murray's law, $V_{altern} \sim 2L\delta^{2/3}_{altern}$, and since $\delta_{altern} = 2$, $V_{altern} \sim 2L2^{2/3} = L2^{5/3}$. Therefore, $V_{altern} = 2^{1/3}V_{actual}$, and the actual strategy is cheaper.

infiltration, and $\beta = 0$ corresponds to the opposite extreme. To infiltrate the area, it must be that $M\delta \sim W$. It follows that $\delta \sim W^{1-\beta}$. The volume of wire required to implement the infiltration is given by $V = MLR^2$, where L is the distance required for the connection, and R is the axon caliber. As discussed in Section 3.13.2.3, $R \sim \delta^{1/3}$, and thus we have $R \sim W^{(1-\beta)/3}$. The volume of wire can be written now as $V \sim LW^{\beta}W^{2(1-\beta)/3} = LW^{(2+\beta)/3}$. Assuming that L is the same under any of the alternative scenarios, V scales up most slowly when β is minimal, namely at $\beta = 0$, corresponding to the case where $\delta \sim W$, the actual case found in the neocortex (see Section 3.13.3.1). That is, the most economical way for an area to infiltrate another is to send a constant number of neurons, and have the number of connections per neuron increase proportionally with the number of neurons in the area; not to increase the number of neurons in the area devoted to connecting to an area. Also, when combined with the invariant area-interconnectedness constraint, we can conclude that the total number of white matter neurons per area, W_{white}, is expected to scale proportionally with the number of cortical areas, A, that is, $W_{white} \sim A$. We will utilize this result below in our further theoretical development.

3.13.4.2 Economical Satisfaction of Invariant Well-Connectedness

We now consider the possible ways of parcellating the neocortex. At one extreme, there could be a fixed number of cortical areas, A, and the number of neurons per area, W, would scale directly proportionally with the total number of neurons (Figure 7, left side). In this case, $A \sim W^0$. At the other extreme, the fastest the number of areas can increase is proportionally with the number of neurons per area (Figure 7, right side), because invariant area-interconnectedness requires that there be enough neurons per area to connect to an invariant fraction of the total number of areas. In this case, $A \sim W$. Generally, this space of scaling possibilities is given by $A \sim W^{\alpha}$, where α ranges from 0 to 1 (see the x-axis of Figure 7).

Which value of α should we expect for the neocortex? The 'economical' hypothesis is that the manner of scaling up the number of areas – that is, the setting of the parameter α – is such that the total neuronal wiring volume scales up as slowly as possible (subject to the satisfaction of the invariant well-connectedness constraint). The total volume of wire, $V_{totalWire}$, can be split into the volume of intra-area wire, $V_{intraWire}$, and the volume of white matter, $V_{whiteWire}$, that is, $V_{totalWire} = V_{intraWire} + V_{whiteWire}$. The volume of intra-area wire is given by $V_{intraWire} = (N_{intra})(L_{intra})(R_{intra})^2$, where N_{intra} is the total number of neocortical neurons involved in intra-area connections, L_{intra} is the average length of an intra-area connection, and R_{intra} is the average caliber radius of the major axon for intra-area connections. Similarly, the volume of white matter is given by $V_{whiteWire} = (N_{white})(L_{white})(R_{white})^2$. We would like to write $V_{totalWire}$ as a function of the total number of neurons, N, and the parameter α, so that we may determine the value of α that minimizes the scaling rate for $V_{totalWire}$. By utilizing the two well-connectedness constraints, along with our earlier observations concerning optimal area-infiltration, we will be able to write each of the terms above – N_{intra} and N_{white}, R_{intra} and R_{white}, and L_{intra} and L_{white} – as a function of N and α.

N_{intra} and N_{white}. The total number of white matter neurons, N_{white}, is equal to the number of white matter neurons per area, W_{white}, times the total number of areas, A; that is, $N_{white} = (A)(W_{white})$.

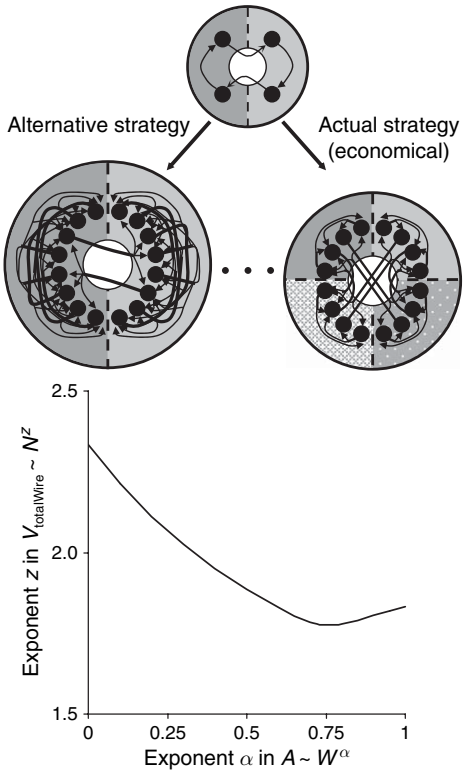

Figure 7 Illustration that the actual scaling strategy for invariant well-connectedness is near volume optimal. To maintain invariant well-connectedness, area-infiltration (the fraction of neurons in an area to which a neuron connects) *and* area-interconnectedness (the percentage of areas in the neocortex to which an area connects) must remain constant as brain size increases. On the right is shown the actual scaling strategy, where when the number of neurons in the brain, N, quadruples (from 4 to 16), the number of areas, A, approximately doubles (from 2 to 4), i.e., $A \sim N^{1/2}$. For this case, the number of areas scales proportionally with the number of neurons per area, W, which also doubles (from 2 to 4), i.e., $A \sim W^\alpha$, where $\alpha = 1$. Invariant area-infiltration is satisfied by doubling the number of neurons to which each neuron (both inter-area and intra-area) connects (from 1 to 2). Invariant area-interconnectedness is achieved by doubling the number of areas to which each area connects (from 1 to 2). This actual scaling strategy can be summarized by the exponent $\alpha = 1$, which leads (see Section 3.13.4.2) to the total volume of wire scaling as $V_{totalWire} \sim N^z$, where $z = 11/6 = 1.83$; this is shown in the plot (bottom) of the exponent z as a function of α. On the left is shown an alternative strategy, where, when the number of neurons in the brain quadruples (from 4 to 16), the number of areas remains constant (at 2). The relationship between the number of areas and number of neurons per area is therefore $A \sim W^\nu$, where now $\alpha = 0$. For this case, invariant area-infiltration is satisfied by quadrupling the number of neurons to which each neuron connects (from 1 to 4). Invariant area-interconnectedness is achieved by having each area connect to just one other area, just as in the smaller brain. This alternative scaling strategy can be summarized by this exponent $\alpha = 0$, which leads to the total volume of wire scaling as $V_{totalWire} \sim N^z$, where $z = 7/3 = 2.33$; this is shown in the plot (bottom) of the exponent z as a function of α. The exponent $z = 2.33$ for the alternative scaling strategy is very significantly higher than the $z = 1.83$ for the actual scaling strategy, and the latter exponent is near the optimal of 1.765 occurring at $\alpha = 0.76$. See Section 3.13.4.2 for the more general derivation.

By virtue of the optimality argument discussed in the previous section, the number of white matter neurons per area must scale in proportion with the total number of areas; that is, $W_{white} \sim A$. Thus, we may write $N_{white} \sim A^2$. We also know that the total number of neurons, $N = WA$ (where W is the average number of neurons per area), and along with the α power law relationship, $A \sim W^\alpha$, we have that $N \sim (A^{1/\alpha})(A)$, or $A \sim N^{\alpha/(1+\alpha)}$. Therefore, $N_{white} \sim N^{2\alpha/(1+\alpha)}$. Also, $N_{intra} = N - N_{white}$.

R_{intra} and R_{white}. We learned earlier (Section 3.13.2.3) that $R \sim \delta^{1/3}$, where R is the radius of an axon caliber. From this and invariant area-infiltration, $\delta \sim W$, we may write that $R \sim W^{1/3}$. Recalling the α power law relationship, $A \sim W^\alpha$, we have that $R \sim A^{1/(3\alpha)}$. We saw earlier that $A \sim N^{\alpha/(1+\alpha)}$, and thus $R \sim N^{1/[3(1+\alpha)]}$. We assume in this derivation that every neuron in the neocortex scales up proportionally with one another (in terms of the number of synapses per neuron), and therefore this proportionality relationship for R is valid for both R_{intra} and R_{white}.

L_{intra} and L_{white}. The average length of an intra-area connection, L_{intra}, is given by the average linear dimensions of an area, $L_{intra} \approx (V_{gray}/A)^{1/3}$, where V_{gray} is the total volume of gray matter. Gray matter volume is modeled as scaling proportionally with the total number of synapses in the network. This is, in fact, true across actual mammalian neocortices, because synapse density does not vary with neocortex size (Abeles, 1991), so doubling the gray matter volume means doubling the total number of synapses. The total number of synapses is equal to the total number of neurons times the number of synapses per neuron, or $N\delta$. Thus, $L_{intra} \sim (N\delta/A)^{1/3}$. We have seen earlier that $\delta \sim W$ (because of the invariant area-infiltration constraint), and along with the α power law relationship $A \sim W^\alpha$, we can conclude that $\delta \sim A^{1/\alpha}$. We have also seen earlier that $A \sim N^{\alpha/(1+\alpha)}$, and we may derive that $L_{intra} \sim N^{2/[3(1+\alpha)]}$. We treat the average length of a white matter axon, L_{white}, as the linear dimensions of the brain, whose volume scales approximately proportionally to gray matter volume (Changizi, 2001b), and so $L_{white} \approx V_{gray}^{1/3}$. Similar to the way we derived the relationship for L_{intra}, we get the relationship $L_{white} \sim N^{(2+\alpha)/[3(1+\alpha)]}$.

We are now in a position to write the total wire volume, $V_{totalWire}$, as a function of N and the parameter α. $V_{totalWire} = V_{intraWire} + V_{whiteWire} = (N_{intra})(L_{intra})(R_{intra})^2 + (N_{white})(L_{white})(R_{white})^2$, and plugging the values derived above, we have

$$V_{totalWire} \sim (N - N^{2\alpha/(1+\alpha)})(N^{2/[3(1+\alpha)]})(N^{1/[3(1+\alpha)]})^2 + (N^{2\alpha/(1+\alpha)})(N^{(2+\alpha)/[3(1+\alpha)]})(N^{1/[3(1+\alpha)]})^2.$$

With some algebraic manipulation, this becomes

$$V_{\text{totalWire}} \sim (N^{(4/3)/(1+\alpha)})[N + N^{(7/3)\alpha/(1+\alpha)} - N^{2\alpha/(1+\alpha)}].$$

Across the range of values for α (i.e., from 0 to 1), I numerically computed the scaling exponent of $V_{\text{totalWire}}$ as a function of N (Figure 7). The exponent is minimal – and the total wire volume scales up most slowly – when $\alpha = 0.76$. In particular, when $\alpha = 0.76$, the $V_{\text{totalWire}} \sim N^{1.7748}$. In contrast, for $\alpha = 0$, the case where the number of areas remains constant with network size, $V_{\text{totalWire}} \sim N^{2.33}$. On the other hand, when $\alpha = 1$, corresponding to the fastest that the number of areas can scale up, $V_{\text{totalWire}} \sim N^{1.833}$, which is not much faster than the optimal scaling at $\alpha = 0.76$. Accordingly, the predictions made by the economical well-connectedness hypothesis are very similar if we use $\alpha = 1$ instead of $\alpha = 0.76$.

Table 1 shows the approximate empirical scaling exponents for the variety of neocortical quantities discussed in Section 3.13.2 (both as a function of the number of neurons, and as a function of gray matter volume), along with the predictions of the above 'economical well-connectedness' model, and one can see close agreement, whether one uses the predicted exponent for the optimal $\alpha = 0.76$, or one uses the $\alpha = 1$ approximation.

3.13.5 Conclusion

Here we have summarized a variety of changes the neocortex undergoes in the transition from small to large brains (Section 3.12.2), pointed out two fundamental connectivity invariances (Section 3.12.3), and showed that the economical satisfaction of these invariances is central to an explanation of the many scaling features (Section 3.12.4). More specifically, mammalian neocortices appear to conform to two principles of connectivity, referred to as invariant well-connectedness. The first is invariant area-infiltration, which is the observation that the average number of synapses per neuron scales approximately proportionally with the average number of neurons per area. There appears to be, then, strong selective pressure across mammalian neocortices for the average number of synapses per neuron to scale up just fast enough that neuron-interconnectedness 'within areas' can remain invariant, 'and' that when an area connects to another area, the average neuron making the connection has a sufficient number of synapses to infiltrate an invariant fraction of the neurons in the area. The second principle of connectivity is invariant area-interconnectedness, which is the observation that the average number of area connections per area scales approximately proportionally with the total number of areas. There appears, then, to be strong selective pressure across mammalian neocortices for the number of area connections per area to scale up just fast enough that area networks can maintain an invariant level of area-interconnectedness. Equivalently, there is selective pressure for the total number of area–area connections to scale as the square of the total number of areas. These two principles of invariant well-connectedness – and the two hierarchical tiers of invariant interconnectedness – appear to be central to the organization of the mammalian neocortex, and the economical satisfaction of these invariances leads to the average number of neurons per area scaling approximately proportionally to the total number of areas. Since the total number of neocortical neurons is just the product of the number of neurons per area and the number of areas, it follows that the latter quantities scale as the square root of the total number of neocortical neurons. Because of invariant area-infiltration, it follows that the average number of synapses per neuron must also scale up as the square root of the total number of neocortical neurons, and a consequence of this is that neuron density decreases and axon caliber increases as discussed in Section 3.12.2 (and these, in turn, were key to understanding why surface area and white matter volume scale the way they do).

We see, then, that these scaling relationships are primarily due to selective pressure for economically satisfying invariant well-connectedness, and are thus 'epiphenomenal', that is, are not signs of more complex computations *per se*. Left unanswered is what exactly is so important about conforming to invariant well-connectedness. There is clearly a theoretical elegance to the principle, but I have no *a priori* theoretical reason for why it should be selected for, nor why there are two tiers rather than, say, three.

Also left unanswered is why brain size increases with body size, namely approximately as the 3/4 power of body mass. Given the contemporary proclivity for treating the brain as a biological computer, it is mysterious why a larger, but not more behaviorally complex, mammal should require a larger brain at all, much less one that scales so considerably with body size. If brain size did not vary with body size, these scaling problems would, of course, vanish. We are currently in the embarrassing situation of understanding why neocortical features vary with brain size as they do, but not understanding why brains vary in size so much in the first place (see Constraints on Brain Size: The Radiator Hypothesis).

3.14 Sparse Coding in the Neocortex

D J Graham and D J Field, Cornell University, Ithaca, NY, USA

Glossary

kurtosis	The fourth statistical moment of a distribution; measures the degree to which a distribution is peaked and heavy-tailed; a Gaussian has a kurtosis of 0.
natural scene	An image of the natural world.
sparse code	A method of representing information that shows a low activity ratio; a code for which most coding units are inactive most of the time.

3.14.1 Introduction: Optimality in Biological Systems

For any biological system, an account of why the system is structured as it is requires consideration of a number of interacting forces including the uses (or goals) of the system, the environment in which the system must function, and the constraints that history and biology put on the design (see The Origin of Neocortex: Lessons from Comparative Embryology, The Evolution of Neuron Classes in the Neocortex of Mammals, Organization of a Miniature Neocortex – What Shrew Brains Suggest about Mammalian Evolution). It might seem reasonable to assume that the constraints of evolution and development play a large role in determining the design of any neural system. However, a range of recent studies have argued that neural systems have found highly efficient solutions for representing environmental information. These studies have explored topics from retinal coding (Sterling, 2004) to the computations provided on the semicircular canals with respect to head rotations (Squires, 2004) to the optimal cortical layout that minimizes neural wiring (Van Essen, 1997; see Neural Wiring Optimization). In all these studies, there remain intriguing questions regarding how close these solutions are to optimal, and how evolution and development lead to this optimality.

In this article, however, we focus on a general aspect of sensory representation called sparse coding. We argue that there is widespread evidence of such coding in neural systems across a variety of species. We look briefly at the question of what is meant by sparse coding and then ask why sensory systems would profit from performing such coding. We argue that the natural environment is inherently sparse and codes that take advantage of this structure can be both metabolically efficient and useful for learning. However, the constraints involved in producing a highly sparse code can be severe: if representing each object and pose requires a different set of neurons, the system would need a very large number of neurons indeed. We believe that many vertebrates have developed a strategy of combining high sparseness with invariance, a strategy that overcomes the combinatorial explosion of a highly sparse code. In this chapter, we address the extent to which sparseness is an optimal coding solution for natural data, and the additional processing strategies that may have shaped cortical evolution in vertebrates.

3.14.2 Defining Sparse Coding

Sparse coding generally refers to a representation where a small number of neurons are active, with the majority of the neurons inactive or showing low activity (e.g., Field, 1987, 1994; Rolls and Tovee, 1995). In his influential single neuron doctrine, Barlow (1972) suggested sparseness as one of the principles important to sensory representation. However, sparse coding in its extreme form results in a representation sometimes called a grandmother cell code. In such a code, each object in the world (e.g., your grandmother) is represented by a single cell. One might argue that a large brain with tens of

billions of neurons can certainly handle a few hundred thousand object-level neurons. And there are many studies showing that neurons exist that can be highly selective to faces and other objects (e.g., Kendrick and Baldwin, 1987; Quiroga, *et al.* 2005). However, those promoting the usefulness of sparse representations are not proposing that the ultimate goal is to have one neuron for every object – and certainly not for a particular view of every object. We believe that sparseness helps learning and prediction even at early stages of sensory processing, like those found in V1. But too much specificity or sparseness can actually make learning harder. We will explore this question later in the article.

Two lines of evidence support the notion that sparse representations are common in neural systems: the first comes from physiology, the second from computational and theoretical research. In each case, the evidence requires a definition of sparseness. There have been several definitions of sparseness and a number of ideas regarding what sparse codes actually represent.

Sparseness can be defined over a population of neurons at a given point in time (population sparseness) or it can be measured for a single neuron over some window of time; the latter is called temporal or lifetime sparseness (Willmore and Tolhurst, 2001) and it is sometimes referred to as nonparametric selectivity (Lehky *et al.*, 2005). For a given distribution of responses, we obtain a histogram of activity. One might think that the simplest definition of the sparseness of this distribution is to simply measure the proportion of active neurons, or how often a neuron is active. However, the histogram of activities is usually defined over a window of time and is therefore not binary. In response to any population of stimuli (e.g., natural scenes), one typically obtains a distribution of activities (a distribution of spike probability), so the measures of sparseness refer to the relative shape of the distribution.

Two definitions of sparseness are widespread. The first – the Treves–Rolls measure (eqn [1]) – is more appropriate for measuring the sparseness over time for real spiking neurons (Rolls and Tovee, 1995). The second definition uses kurtosis (the fourth statistical moment of a distribution) as its metric (eqn [2]) and it is more useful for modeled neurons and computational studies, where a comparison of different codes and transforms is necessary (Field, 1994):

$$S = \frac{\left((1/n)\sum_i r_i\right)^2}{(1/n)\sum_i r_i^2}, \qquad [1]$$

$$k = (1/n)\sum_{i=1}^{n} \frac{(r_i - \bar{r})^4}{\sigma^4} - 3. \qquad [2]$$

These measures are applied to histograms of responses over a population of neurons or for a given neuron over time. With the Treves–Rolls measure, the sparseness approaches zero as the neuron is either off or highly on (for a given time window). With the kurtosis measure, large values occur when a response distribution deviates maximally from the Gaussian state by being sharply peaked and heavy-tailed. Highly kurtotic behavior produces a relatively high probability of either a small or large response, and a relatively low probability of a mid-level response. Both measures can be sensitive to outliers.

3.14.3 Physiological Evidence for Sparse Coding

Much of the discussion in recent years regarding sparse coding has come from the computational and theoretical literature, but there is considerable physiological evidence for sparse representations in most biological systems. For a neuron with a full response and refractory time of 5 ms, the maximal firing rate would be 200 Hz. A system that is providing a maximal information rate would fire at approximately half the time, i.e., at 100 Hz. Although neurons may reach such rates, neurons do not maintain these rates for more than brief periods. We do not know of any neural systems that maintain such high firing rates for extended periods.

Such a high firing rate would require considerable energy resources, so much so that Attwell and Laughlin (2001) argue that the limited biochemical energy available for producing action potentials must limit the average firing rates of neurons to less than 1 Hz. Further, Lennie (2003) estimates that the limited resources imply that at any given time, only 1/50th of any population of cortical neurons can afford to show high firing rates. Therefore, for biochemical reasons alone, we should expect a considerable degree of both lifetime and population sparseness. Olshausen and Field (2005) further argue that even in areas that have been well studied – areas like V1 – these low average firing rates imply that a significant number of neurons will have such low firing rates as to be missed entirely by the typical search strategies.

As noted by Olshausen and Field (2004), there are a number of studies suggesting that many neural systems utilize highly sparse codes. DeWeese *et al.* (2003), recording from auditory neurons in the rat, have demonstrated that neurons in A1 can reliably produce a single spike in response to a sound. Evidence from olfactory systems in insects (Perez-Orive *et al.*, 2002;

Theunissen, 2003), somatosensory neurons in rat (Brecht and Sakmann, 2002), and recordings from rat hippocampus (Thompson and Best, 1989) all demonstrate highly sparse responses. Prefrontal cortex shows similar sparseness in behaving rhesus monkeys (Abeles *et al.*, 1990). As the authors of the latter study say, most areas of association cortex are "not carrying out any computations for the majority of the time."

Motor neuron representations are often described as a population code, where it is proposed that the accuracy of a movement is guided by the degree of activity of a relatively large population of neurons (see Georgopoulos, 1986). Here too, we find evidence of sparse responses. Some motor neurons in layer 6 of rabbit motor cortex will produce just one spike during some movements (Beloozerova *et al.*, 2003). And stimulation of a single neuron in the rat is sufficient to deflect a whisker (Brecht *et al.*, 2004).

With respect to sparse coding, the most widely studied sensory system is the visual system. Much of this work, which we discuss below, has been motivated by information theoretic issues. The area also contains a wealth of experimental data. In inferotemporal (IT) cortex, a wide range of studies supports the notion that neurons are selective to high-level object dimensions, and to features such as faces and hands. Such neurons are believed to show some degree of invariance over position, size, pose, brightness, etc. Nevertheless, unless we are to assume that such objects fall within the neuron's receptive field at least half of their waking life, we should expect these neurons to show a high degree of sparseness. Indeed, Baddeley *et al.* (1997) found that cells in IT show sparse responses to natural stimuli, to a similar degree as do cells in V1.

Much of the most interesting work tying together the statistics of natural signals and physiology comes from work on the responses of V1 neurons. Vinje and Gallant (2000, 2002) found that V1 neuron responses in macaque become more and more sparse as the size of a natural stimulus is increased beyond the classical receptive field. Stimulation in the classical receptive field also produced sparseness, which could reflect the rather arbitrary nature of the classical/nonclassical delineation. Moreover, stimulation in the nonclassical receptive field showed the following results:

1. increased sparseness for individual neurons during repeated presentations (lifetime sparseness);
2. increased sparseness across the population of neurons tested (population sparseness); and
3. decreased correlation in neighboring neurons, thereby whitening the response.

The results presented here provide examples of the sparse behavior of neurons in primate visual cortex under naturalistic conditions. Although we cannot argue that a sparse coding strategy is ubiquitous in the cortex, these results do support the implication that sparse coding is widespread in the nervous systems of the mammals tested. We also find evidence of sparse coding across a variety of nonmammalian species. In addition to the creatures mentioned above, the selectivity of sensory neurons has been supported by studies in amphibians (e.g., Ewert, 1980), turtles (Ammermüller *et al.*, 1995), and insects (e.g., Strausfeld and Lee, 1991; Lehrer and Srinivasan, 1992; Perez-Orive *et al.*, 2002).

Any form of selectivity implies that neurons will show a degree of sparseness in the natural environment, since selectivity by definition means neurons respond only to a portion of the possible environmental stimuli. Answering the question of why sensory systems show highly selective responses will require innovative ways of thinking about sparseness. In the next section, we consider an information theoretic approach to sparse coding and we compare this to an approach that argues for sparse coding as a result of the metabolic constraints on neural firing. We argue that both approaches will likely be needed to explain all aspects of sparse coding in neural systems.

3.14.4 Two Views of Sparse Coding

3.14.4.1 Maximizing Information Transfer

Consider a neuron, or population of neurons, that has a mean firing rate and some distribution around that mean. With a limit on the range of possible firing rates, the maximum information transfer occurs when all states of the channel are used with equal frequency: a flat distribution of firing rates. If the bound on a distribution is instead the variance of the responses (rather than the range of responses), the distribution with the greatest information rate (greatest entropy) is a Gaussian. The visual system appears to follow neither of these models. A sparse code means that neural firing rates will show a highly peaked, non-Gaussian distribution, i.e., one that does not produce maximum information transfer. Moreover, as sparseness increases, the information rate drops. Why might this be a good idea?

In general, we argue that the information rate of the system should match the information rate of the input. Natural stimuli are not random. As far as the visual system is concerned, natural scenes are not

arrays of random points of light. Rather, they are constrained by strong correlations between neighboring regions, and image discontinuities are usually defined by edges. This predictability implies that a high information rate is simply unnecessary. By taking advantage of the redundant properties of images, sensory codes can get away with sending less information and using fewer spikes.

For example, consider a collection of 5×5 pixel images that each contain one block letter of the alphabet. If we looked at the histogram of any given pixel, we might discover that the pixel was on roughly half the time. However, if we were to represent these letters with templates that respond uniquely to each letter, each template would respond just 1/26th of the time. This letter code is more sparse – and more efficient – relative to a pixel code. Although no information is lost, the letter code would produce the lowest information rate.

Moreover, a representation that was letter based would provide a more efficient means of learning about the associations between letters. If the associations were between individual pixels, a relatively complex set of statistical relationships would be required to describe the co-occurrences of letters (e.g., between the Q and U). Sparseness can assist in learning since each unit is providing a relatively complete representation of the local structure (Field, 1994).

Of course, the natural world does not consist of letters. Natural scenes are highly structured and can be modeled to a first approximation as a sparse collection of local features (e.g., edges). Early work by one of us (Field, 1987, 1994) showed that if the receptive fields of V1 neurons are modeled as a collection of linear templates, then the responses of those neurons to natural scenes are highly sparse. Furthermore, when the parameters of the modeled neurons were altered from those of V1 neurons, the sparseness dropped, suggesting that the parameters were near to optimal given the constraint of having a linear array of model neurons.

A stronger test of this hypothesis was developed by Olshausen and Field (1996), who trained a neural network to find the most sparse representation for a population of image patches drawn from natural scenes. The network was trained to develop a set of filters that would maximize sparseness and losslessness in its representation of natural scenes. Given these two criteria, the network settled on a set of filters with considerable similarity to simple cell receptive fields in V1 (Figure 1).

This basic sparse coding algorithm is quite similar to techniques that search for independent solutions by minimizing response entropy (that is, by searching for non-Gaussian response histograms). The family of these techniques has been called independent components analysis or ICA (Bell and Sejnowski, 1997). The name ICA is a bit unfortunate since the solutions are almost never independent, given natural input. But the approach has been applied to a wide range of problems and it has been employed to account for a variety of properties in early visual neurons, including spatiotemporal tuning (e.g., van Hateren and Ruderman, 1998) and spatiochromatic properties (e.g., Hoyer and Hyvarinen, 2000), and generalization of the approach has been used to model some nonlinear properties of neurons (Hyvarinen and Hoyer, 2000). In early vision, Graham *et al.* (2005) show evidence that sparseness is likely a factor contributing to the utility of center-surround receptive field organization, along with decorrelation and response gain. Furthermore, sparse codes of natural sounds have been shown to produce temporal response profiles with properties similar to those of early auditory neurons (Lewicki, 2002).

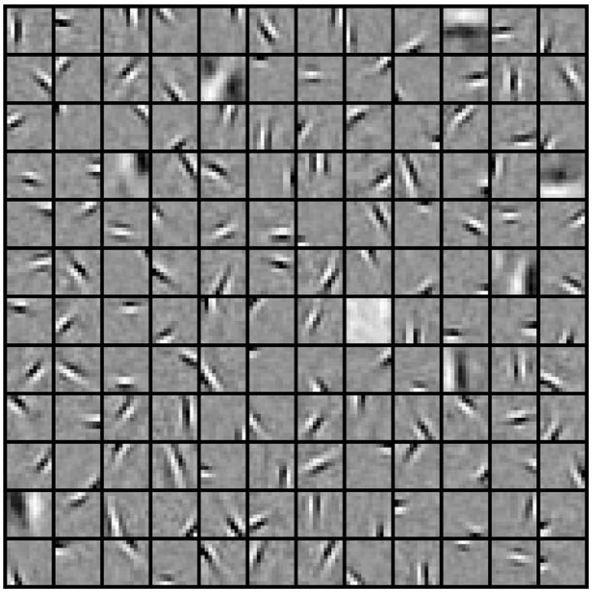

Figure 1 Results of a neural network that searches for a sparse code using filters to describe 12×12 pixel image patches drawn from a collection of natural scenes (Olshausen and Field, 1996). The collection of filters shown represents the 256 templates that the network found for describing each patch. When any given natural scene patch is multiplied by this family of filters, one finds that most of the responses are near zero and a small set of filters produces large responses (those matched to the image structure). The templates have been shown to provide a good first-order account of the responses of cortical V1 simple cells, suggesting that such simple cells are optimized to provide a sparse code for natural scenes. Adapted from Olshausen, B. A. and Field, D. J. 1996. Emergence of simple cell receptive field properties by learning a sparse code for natural images. *Nature* 381, 607–609.

This entire line of work suggests that sparseness in neural firing is primarily a result of efficiently matching the neuron's response properties with the sparse statistical structure of the environment. There remain a number of questions as to how a biological system might achieve this efficient representation. Although the particular method used by Olshausen and Field (1996) may not be biologically plausible, it is argued that learning algorithms exist that could train a system to achieve a sparse code. The advantage of learning such a code is that the properties of individual neurons need not be predetermined or coded in the genome of the organism. Rather, what is required is that the system evolve only a general sparse coding strategy. Given appropriate input, a learning algorithm would serve to produce the proper neural response properties and it would help to tile the neurons in a way that allows the correct spacing as a function of the different parameters of selectivity (e.g., position, scale, orientation). Although there is little evidence of such a learning algorithm in insects and animals with relatively simple brains, the evolution of a sparse learning algorithm may be widespread in larger brains. However, the argument is not that the system must necessarily learn from the natural world. Rather, one intriguing possibility is that the system learns from the patterned structure of the spontaneous activity in the developing organism (e.g., Wong, 1999).

It is not yet clear whether the patterns of spontaneous activity are sufficient for generating the receptive field properties found in the newborn. However, such an approach would provide a relatively simple means for producing a large number of neurons with efficient tuning. The learning algorithm also has the advantage that it can accommodate a large variation in cell number. If any evolutionary mutation or developmental change results in a larger (or smaller) brain, the learning algorithm should be capable of adapting to the system and adjusting the tiling appropriately.

Could all neurons in higher areas from V1 to IT simply be exhibiting sparse coding as a means of efficiently representing the natural world? This may be possible. A number of investigators are exploring ways to extend these ideas of efficient coding to higher levels. It is clear that these more complex representations require a form of nonlinear coding that makes the tests of efficiency considerably more difficult, though attempts to model nonlinear behavior of neurons with such efficient coding approaches have met with some success (e.g., Schwartz and Simoncelli, 2001; Wiskott and Sejnowsi, 2002).

However, there is a penalty that applies to learning if the system is too sparse. An extremely sparse code (one in which neurons are highly selective for specific objects in specific poses, lighting, etc.) would have neurons that fired quite rarely. In order to effectively learn about the world, any system must keep track of the relative probability of co-occurrences. No matter how a neural system keeps track of these co-occurrences, if they occur too rarely it would be impossible to determine whether any feature is statistically related to any other feature. We cannot learn about how 'faces' behave in particular situations if we have a neuron for every unique face. It is important that the system be invariant at some level so that we can collapse across instances of the category. Most presentations of objects or events will occur just once or not at all during development if the object is defined too precisely.

From the perspective of learning, then, a code that is too sparse becomes intractable even if there were enough neurons to accommodate it. Consequently, a system must also build invariance into the code in order to develop and function efficiently. With high-level objects such as faces, this learning constraint would require that the face-selective neurons be invariant to dimensions along which the face varies in different settings (lighting, pose, size, etc.). Thus, both invariance and selectivity are necessary for achieving an efficient, sparse representation of sparse natural input. Indeed, this invariance is a known property of visual neurons. As neurons are found to be more selective, we find greater degrees of invariance. The complex cells in V1 show selectivity to scale (spatial frequency), and orientation, and they show small amounts of invariance to position. Higher-level neurons in IT and medial temporal cortex may show much higher selectivity to faces, hands, etc. However, they also show much greater invariance to lighting, pose, and size (Rolls, 2000). In one study of human medial temporal cortex (Quiroga *et al.*, 2005), neurons were found that were selective to particular actresses (Jennifer Aniston) while invariant to pose, lighting, and position in the image.

We therefore argue that although the evolution of large brains may allow a larger number of highly selective neurons, the constraints of learning require that the selectivity go hand in hand with a greater degree of invariance. Although there have been a number of proposals regarding how invariance is achieved in the mammalian systems (Olshausen *et al.*, 1993), no firm answer has emerged. We know that some of the simpler visual systems, such as those of *Drosophila*, do not show such invariance

(Dill *et al.*, 1993). However, it remains unclear how such invariance has evolved, and what we might expect from systems that show only partial invariance.

3.14.4.2 Metabolic Constraints

We conclude our discussion by returning to the issue of metabolic constraints. Could we argue that primary evolutionary pressure driving toward sparse coding is one related to the metabolic costs of neural firing? As noted earlier, both Attwell and Laughlin (2001) and Lennie (2003) argue that there are not enough resources to achieve anything but a low-activity system. Moreover, when we find sparse activity in frontal cortex (Abeles *et al.*, 1990), it is more difficult to argue that the sparse activity must arise because it is mapping the sparse structure of the world. Even at early levels, if sparseness were metabolically desirable, there are a number of ways of achieving sparseness without matching the structure of the world. Any one of a wide variety of positively accelerating nonlinearities would do. Simply giving the neurons a very high threshold would achieve a sparse code, but the system would lose information. We argue that the form of sparse coding found in sensory systems is useful because such codes maintain the information in the environment, but do so more efficiently. We argue that the evolutionary pressure to move the system toward a sparse code comes from the representational power of sparse codes.

However, we do accept that metabolic constraints are quite important. It has been demonstrated that at the earliest levels of the visual system, ganglion cells (Berry *et al.*, 1997) and lateral geniculate nucleus cells (Reinagel and Reid, 2000) show sparse (non-Gaussian) responses to temporal noise. A linear code, no matter how efficiently it was designed, would not show such sparse activity, so we must assume that the sparseness is at least in part due to the nonlinearities in the system and not due to the match between the receptive fields and the sparse structure of the input. Since the results show sparse responses in nonsensory areas, we must accept that metabolic constraints may also be playing a significant role.

3.14.5 Conclusions

We are therefore left with a bit of a puzzle. We know that higher levels of the visual system show considerable sparseness: neurons fire at rates far below their maximal rate. However, we cannot conclude that sparseness is only a result of an efficient mapping of the sparse structure of the world. Metabolic efficiency must also be considered, independent of the statistical structure of the world. In addressing the question of why a system is sparse, we must accept that widespread sparseness in cortex is due to several factors. Many of us believe that the metabolic constraints are secondary, however, and that artificial visual systems will someday incorporate much of the coding we find in neural systems. The constraints of evolution, metabolism, anatomy, and development all play a role in determining why the nervous system is designed the way it is. But one should not presume that these constraints force the system toward some nonoptimal solution. At present, the evidence suggests that the nervous system has evolved a highly efficient learning algorithm for discovering and representing the structure in the world. And the sparse responses of neurons are an integral component of that efficient representation.

3.15 Evolution of the Somatosensory System – Clues from Specialized Species

K C Catania, Vanderbilt University, Nashville, TN, USA

Glossary

areas	This term is often used to describe separate subdivisions of the brain and neocortex. In the neocortex different areas generally have a number of identifying features, such as unique appearance in histological stains (cytoarchitecture), unique connections to other areas, unique cellular responses, and result in specific deficits following damage. Some well-known cortical areas include primary somatosensory cortex (S1), primary visual cortex (V1), and primary auditory cortex (A1).
cortical barrel	A circular region of the neocortex visible in various histological stains of the somatosensory area in rodents where touch information from a single whisker projects. First recognized by Woolsey and Van der Loos (1970) in mice.
cortical magnification	The relative size of a representation, or processing area for a sensory input, in the cortical map. This generally refers to the larger representations of behaviorally important sensory inputs as compared to less important inputs. A common example in humans is the large area of cortex devoted to processing touch information from the hand relative to other, larger body parts (such are the leg or back) that have a proportionally much smaller representation in the cortex.
cytochrome oxidase	A mitochondrial enzyme. Processing brain tissue to reveal the distribution of this enzyme often reveals different subdivisions, particularly in the neocortex. Cortical barrels can be seen in the distribution pattern of this enzyme (Figure 1).
Eimer's organ	A small (40–80 μm) swelling in the nasal epidermis of talpid moles that contains and orderly array of mechanoreceptors used for tactile discriminations. Similar to a push-rod in montotremes.
electrosensory/ electroreception	Electroreception is the ability to detect weak electric fields in an aquatic environment through dedicated sensory organs (electroreceptors). This sense is sometimes used by predators (e.g., sharks) to detect the small electric fields given off by prey.
neocortex	The outer six-layered sheet of brain tissue in mammals where much of the information from sensory receptors projects. Often shortened to 'cortex' in discussions of the mammalian brain. Many investigators prefer the term 'isocortex' to avoid the implication of an invalid phylogenetic sequence suggested by the term 'neo'.
mystacial vibrissae	The large, mobile whiskers on the face of a rodent.

ocular dominance column	Stripes of cortical tissue in layer 4 of primary visual cortex that receive input from the lateral geniculate nucleus, relayed from primarily only one eye. Each stripe is generally bound by similar stripes representing the opposite, contralateral eye.
receptors	In this context, 'receptors' refers generically to the sensory organs and nerve endings that receive and communicate sensory information from the environment. More specific modality designations include mechanoreceptors, photoreceptors, electroreceptors, etc.
saccade	A saccade is a sudden, jerky movement. The term 'saccade' is most frequently used in reference to an eye movement. In the visual system a saccade is the characteristic sudden movement of the eye that positions different parts of a visual scene on the retinal fovea.
sensory representation	Generally refers to a topographic map of primary afferent inputs to the central nervous system (CNS). In the case of the somatosensory system, the sensory representations reflect the distribution of mechanoreceptors in the skin, and as such they form a 'map' of the body surface that can be identified in neocortex by recording the activity of nerve cells in response to stimulating the skin.
somatosensory cortex	The area of neocortex that receives and processes touch information from mechanoreceptors on the body.
tactile fovea	The descriptor draws an analogy between the high-resolution retinal fovea in the visual system and the high-resolution part of the star-nosed mole's nose used for detailed, tactile investigations of object of interest. A similar analogy with the visual system has been made in the auditory system of bats, where an 'auditory fovea' is said to represent the most important echolocation frequencies.

3.15.1 Introduction

The somatosensory system provides a rich source of diversity for revealing principles of mammalian brain evolution. At the same time, it is daunting to consider the number of different aspects of mammal bodies that have changed in the course of evolution and often challenging to identify examples of brain specializations that can be confidently attributed to specific sensory adaptations. Consider, for example, the vast difference in brain size between shrews – that resemble ancestral mammals in many respects – and humans, that have only recently emerged on the evolutionary landscape (Figure 1).

This comparison highlights some of the challenges to deciphering mammalian brain evolution, as the differences between shrew and human brains may parallel the differences between the small brains of early stem mammals and the larger and more complex brains found in many modern lineages. The comparison of a human brain to a shrew brain seems appropriate as an introduction because it not only illustrates a range of mammal brain sizes, but also because insectivores hold a particularly important historical position in theories of mammalian brain evolution. Fossil evidence indicates that the earliest ancestral mammals had brains and bodies similar to those of modern insectivores, particularly shrews that have little neocortex (Kielan-Jaworowska, 1983, 1984). As a result, a number of theories of brain evolution have been based on the premise that modern insectivore brains resemble those of ancestral species (Lende, 1969; Glezer

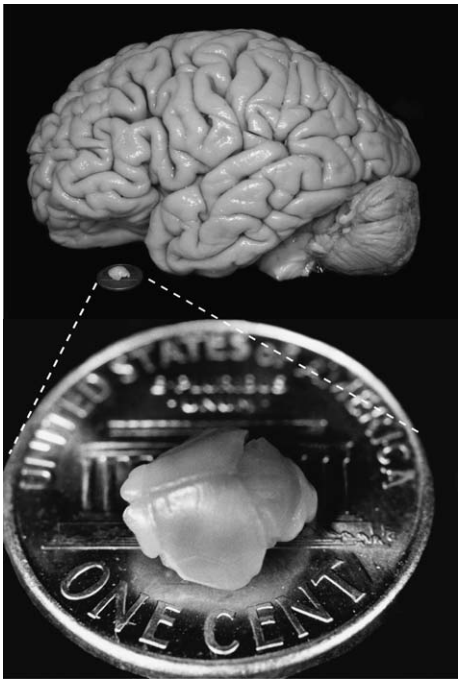

Figure 1 An adult human brain compared to the brain of a shrew. The upper panel shows the two brains at the same scale, with the shrew brain resting on a penny for scale. The lower panel shows the shrew brain enlarged.

et al., 1988; see Deacon, 1990, for review). This historical trend was bolstered by early recording experiments in hedgehogs (Lende and Sadler, 1967) and moles (Allison and Van Twyver, 1970) which indicated that insectivore cortex was poorly differentiated with overlapping cortical subdivisions. However, recent investigations of insectivores (Catania, 2000a) have revised our conception of these species as primitive mammals with poorly organized brains and thus historical theories of brain evolution based on early investigations of insectivores need to be reconsidered.

Before developing theories for how somatosensory cortex may have evolved in different lineages, it is first essential to describe what is known about the products of evolution. What are the major differences in brain organization observed across different species? What facets are unique to particular lineages, and what has been conserved across taxa? What solutions to sensory processing have recurred in the course of evolution and may thus illuminate constraints on the ways brains can be modified?

Although the brains of only a small percentage of extant mammals have been examined in detail, recent investigations of somatosensory cortex have expanded our understanding of brain organization in mammals that range from standard laboratory rats (Remple *et al.*, 2003) to monotremes (Krubitzer *et al.*, 1995; Krubitzer, 1998) and marsupials (Beck *et al.*, 1996; Rosa *et al.*, 1999; Huffman *et al.*, 1999; Catania *et al.*, 2000) representing important branches of the mammalian radiations. By considering the organization of cortex in selected species, it is possible to draw some general conclusions about how cortical organization has changed in the course of mammalian evolution.

In addition to our growing understanding of brain diversity across species, a number of recent advances in the ability to modify gene expression during the course of development have allowed investigators to mimic the process of brain evolution in the laboratory. Thus, on a small scale, some of the diversity that is observed across species can be generated within species by manipulating gene expression (Fukuchi-Shimogori and Grove, 2001). This in turn suggests potential mechanisms by which brains may have been modified in the course of evolution (Rakic, 2001).

Finally, in discussing the evolution of somatosensory areas in the brain, it is important to simultaneously consider the mechanosensory periphery. After all, the main function of the somatosensory cortex is to process information from these receptors and there is an intimate association between the sensory periphery and the central nervous system (CNS) during the course of both development and evolution.

3.15.2 How Have Brains Changed in the Course of Evolution?

3.15.2.1 Areas May Be Added to the Processing Network

There is still much disagreement and uncertainty regarding the organization of cortex and the identity of areas in many of the most intensively investigated species (see Kaas, 2005). However, it is nevertheless clear from comparative studies that larger brains differ significantly from the smaller brains in living mammals, and by extension that larger brains of modern species differ from the small brains of ancestral species that gave rise to these lineages (see Jerison, 1973; Kaas, 1987a, 1987b, 1995, 2005; Krubitzer, 2000). This is exemplified by comparing the shared cortical areas between shrews and humans (Figure 2). Shrews are particularly interesting because many of them represent the lower size range for the mammalian body and brain (see Schmidt-Neilsen, 1984). Shrews are also particularly interesting because fossil evidence indicates that early mammals also had small brains with little neocortex. Thus, understanding constraints on the organization of a small neocortical sheet may help us infer how early mammalian cortex was organized.

Shrew brains were found to have only a few cortical sensory areas with sharp borders as determined from both electrophysiological and histological evidence (Catania *et al.*, 1999). These areas include primary and secondary somatosensory cortex (S1 and S2), primary visual cortex (V1), primary auditory cortex (A1), and motor cortex (M1). Human brains also contain these same subdivisions in similar relative position in the cortex (i.e., V1 is caudal in cortex, A1 is lateral, M1 is most rostral). This comparison demonstrates two important and very general findings in mammals. First, diverse mammal species share a number of cortical areas in common. Second, larger-brained mammals tend to have more cortical subdivisions. The greater number of intervening cortical areas is not illustrated in Figure 2 for humans, but can be appreciated from the schematic in Figure 3, which illustrates the number of cortical subdivisions in a shrew compared to the estimated number of cortical subdivisions in a macaque. Whereas shrews have only five known cortical areas with little room for additional subdivisions (Catania *et al.*, 1999), macaques are thought to have over 50 different areas (see

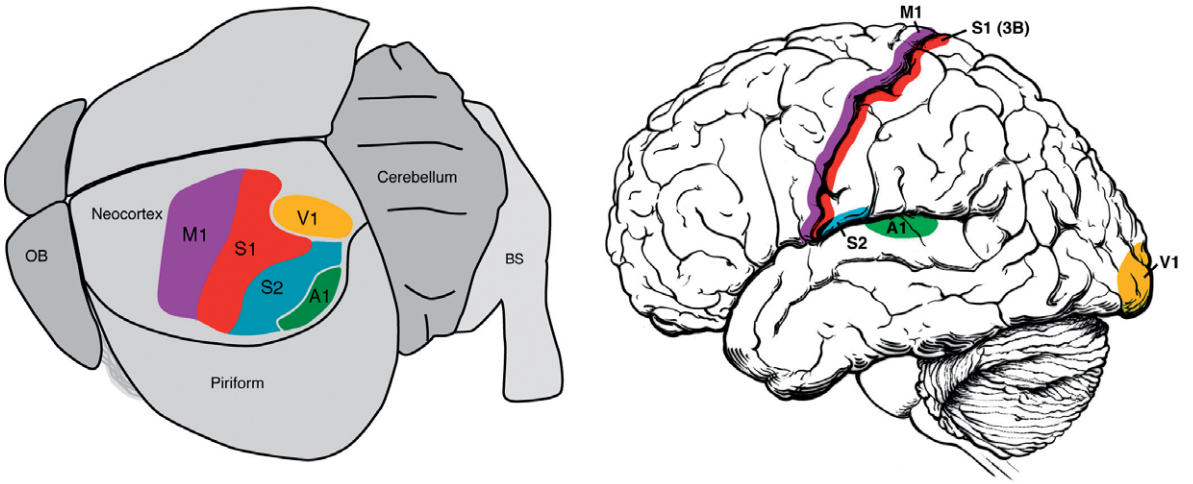

Figure 2 Shared cortical areas between a shrew and a human. Left side shows a shrew brain and cortical areas, including primary somatosensory cortex (S1), secondary somatosensory cortex (S2), primary visual cortex (V1), primary auditory cortex (A1), and primary motor cortex (M1). The same (homologous) cortical areas are depicted in the human brain on the right. Human have many additional cortical areas that are not illustrated, whereas shrews have little room for additional cortical subdivisions. OB, olfactory bulb; BS, brainstem.

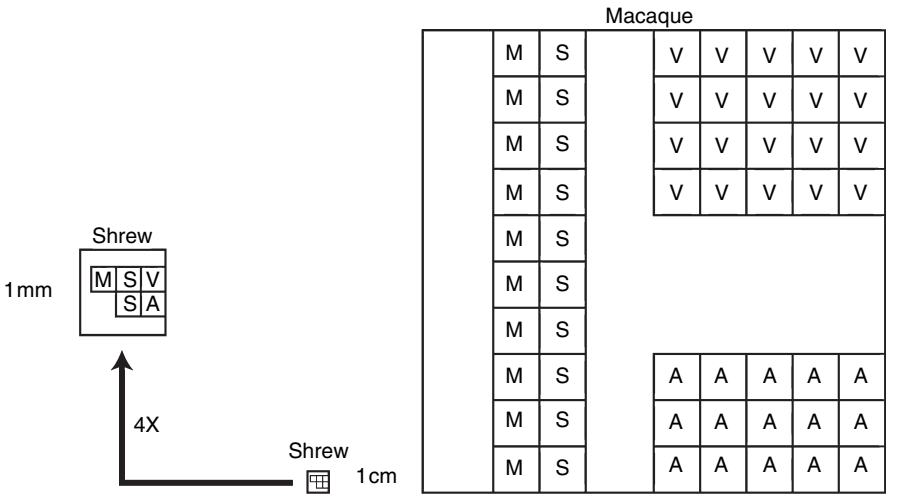

Figure 3 A schematic representation of cortical organization in a small-brained (shrew) and large-brained (macaque monkey) mammal. Shrews have as little as 0.15 cm^2 of neocortex, whereas macaques have roughly 72 cm^2 – a 480-fold difference. Humans, with approximately 800 cm^2 of neocortex, do not fit on the figure, but have neocortex with over 5000 times the surface area of a shrew. Given that shrews are similar in size and habits to ancestral mammals, there has clearly been a tremendous enlargement of cortex in many mammalian lineages. In addition to getting larger, the internal organization of cortex has changed as well. Many cortical subdivisions have been added in larger-brained mammals, and this can be appreciated by comparing the enlarged shrew brain (far left) to the macaque brain. The letters denote visual (V), auditory (A), somatosensory (S), and motor areas (M). Shrews have only a few cortical subdivisions, whereas macaques have many. The illustration is not intended to show the relative size or location of cortical areas. Reproduced from Catania, K. C. 2004. Correlates and possible mechanisms of neocortical enlargement and diversification in mammals. *Int. J. Comp. Psychol.* 17, 71–91.

Kaas, 1995 for review) and additional areas will almost certainly be identified in macaque cortex.

This observation is perhaps not surprising; however, it does raise additional questions regarding brain scaling and evolution. It is clear that large-scale changes to brain organization have occurred in many mammalian lineages – for example, in the primate and carnivore orders that have more cortical subdivisions than smaller-brained rodents and insectivores (Kaas, 1982). Greater numbers of cortical subdivisions are often considered to be an important underlying substrate for increased intelligence and behavioral complexity. Yet, it is difficult to separate factors related to brain scaling from

those related to increased processing ability. For example, as brain areas increase in size, local connections must increase in length to maintain a similar degree of global connectivity. Such increases in lengths of axons and dendrites must be accompanied by increases in their diameters in order to maintain similar conduction times between cells (Ringo *et al.*, 1994). The main point is that increasing the size of a brain and its cortical areas includes many engineering challenges and thus some cortical areas may become subdivided simply to maintain the status quo (Kaas, 2000).

In addition, it is often difficult to confidently identify a particular brain specialization related to increased behavioral complexity or processing ability when comparing distantly related species, such as insectivores and primates, as some traits may be most common in a given lineage without an obvious adaptive value. This has been termed the taxon level effect (Pagel and Harvey, 1989). One way to more confidently identify specializations related to a particular behavioral or sensory ability is to look in closely related mammals of similar brain and body size, in which only one dimension of a sensory system has changed in a particular member of the group.

3.15.2.2 The Star-Nosed Mole – A Case Study in Somatosensory Evolution

Comparing the somatosensory systems of different mole species provides what might be considered a natural experiment in the elaboration of the mechanosensory portion of the nose and corresponding representations in the brain. Unlike most other mammals, moles use the skin surface of the snout – rather than vibrissae – to explore their environment through touch. But the degree of elaboration of the nose and associated sensory organs differs greatly across species. Consider, for example, the eastern American mole (*Scalopus aquaticus*) in Figure 4. This species is a more generalized mole that resembles the kind of ancestral condition from which the star-nosed mole evolved (Catania, 2000b). How does brain organization differ between star-nosed moles and the less specialized but closely related eastern American mole?

Microelectrode recordings from the brain of *Scalopus* reveal a somatosensory cortex similar in many general respects to that found in the star-nosed mole (Figure 5a). A relatively large S1 contains a representation of the body with caudal body parts (tail and hindlimb) located medially in cortex and the face and nose represented more laterally. As in star-nosed moles, a relatively large S2 is found as a mirror image of S1 in more lateral and caudal cortex. This basic layout of two relatively large

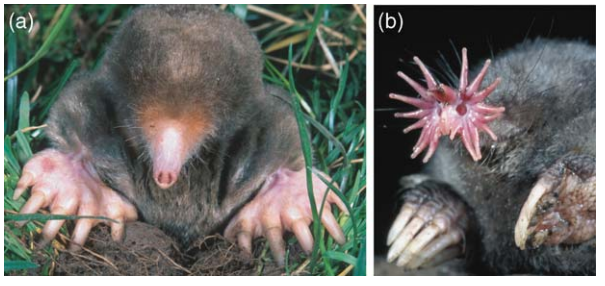

Figure 4 Comparison of two mole species. a, The eastern American mole (*S. aquaticus*) is the least specialized mole resembling the probable ancestral condition for moles (Catania, 2000b). b, The star-nosed mole (*Condylura cristata*) is the most specialized mole with a snout consisting of 22 mechanosensory appendages.

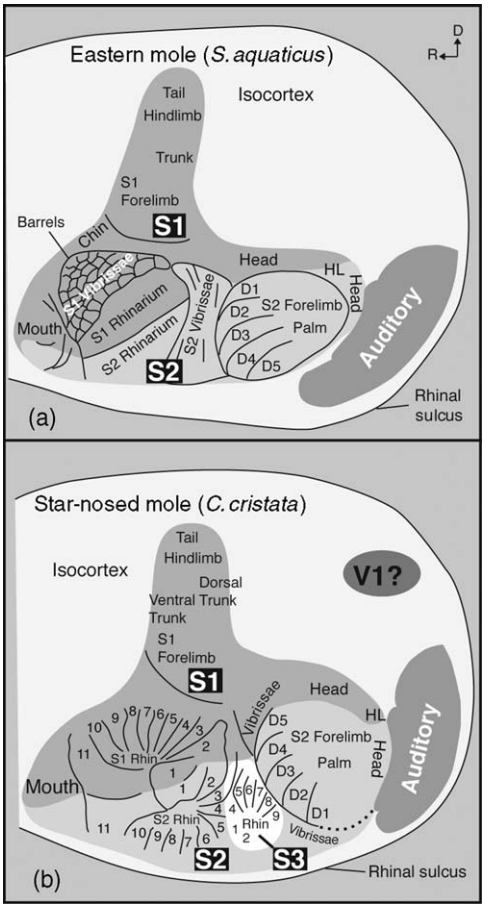

Figure 5 The results of recent investigations of cortical organization in moles. a, The eastern American mole has two somatosensory areas, primary (S1) and secondary (S2) somatosensory cortex, which include visible barrels much like those identified in rodent cortex. b, The star-nosed mole has three representations of the star (S1, S2, and S3). These areas are visibly reflected as a series of modules in flattened sections of cortex processed for cytochrome oxidase.

somatosensory areas, S1 and S2, is also found in other moles species (Catania, 2000c) and in the sister group to moles, the shrews (Catania *et al.*, 1999; see Figure 2). Thus, moles and shrews generally have two representations of the nose in lateral cortex. However, star-nosed moles have three representations of the star (Catania and Kaas, 1995) in lateral cortex (Figure 5b). The most parsimonious interpretation of these observations is that star-nosed moles have independently evolved an extra representation of the star.

This finding is from very closely related species that differ little in body weight and brain size, and it supports the conclusion that the addition of a new area to the cortical network is an important substrate for more efficient processing of sensory inputs. The most obvious difference between star-nosed moles and other moles is the elaboration of the somatosensory star with a corresponding increase in innervation density accompanied by more complex foraging behaviors (e.g., foveation movements of the star – this is discussed in Section 3.15.2.4). As a result, star-nosed moles are one of the fastest and most efficient of mammalian foragers (Catania and Remple, 2005) and the larger number of cortical representations of the star may facilitate this ability, perhaps through the parallel processing of different facets of touch information.

3.15.2.3 Behaviorally Important Areas Are Magnified in the Brain

Figure 6 illustrates cortical magnification of important sensory surfaces in the naked mole-rat and the star-nosed mole showing how the most behaviorally important sensory surfaces take up a disproportionate area of cortex. This feature of cortical maps has been documented since the pioneering studies of Adrian (1943) and Woolsey *et al.* (1942), in which it was noted that parts of the body that have the greatest tactile acuity have the largest cortical projection zones. Cortical magnifications have since been described for different sensory systems in diverse species, and this phenomenon makes for striking imagery. However, the relationship between sensory surface size and cortical representational area also raises important and fundamental questions about brain organization and evolution. Namely, how do the most important sensory surfaces acquire the largest territories in the brain?

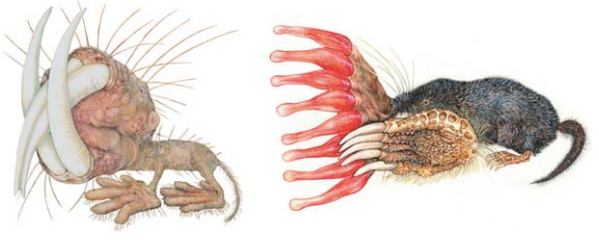

Figure 6 Cortical magnification in naked mole-rats and star-nosed moles. These schematics illustrate the relative proportions of the somatosensory cortex taken up by representations of different body parts in each species. Surprisingly, the naked mole-rat devotes much of its cortex (30% of S1) to the representation of the incisors. In contrast, star-nosed moles devote a huge portion of their somatosensory cortex to the representation of the star.

Early investigations of this relationship in rodent barrel cortex revealed a direct linear correlation between the size of a cortical barrel (the area representing a whisker) and the innervation density of the corresponding whisker (Welker and Van der Loos, 1986). This result suggested that cortical representational area could be, in general, proportional to the innervation density of the sensory surface projecting to any given area of cortex. Such a relationship would explain the expanded representations of important areas of the skin, retina, and cochlea that had been described in a number of species. At the same time, this finding suggested that there was no 'cortical component' to cortical magnification and that this parameter could be predicted without even examining the brain, simply by determining the relative innervation density of a sensory surface. Lee and Woolsey (1975) recognized this possibility and suggested that cortical representations are more appropriately described by a "peripheral scaling factor" than a "cortical magnification factor."

Of course, another possibility is that cortical representational area is not proportional to number of inputs from the periphery, and instead important sensory inputs could project to a larger area of cortex than less important inputs. This has been the subject of considerable historical debate in the visual system of primates, where some studies suggest that the large cortical representation of the retinal fovea simply reflects the number of retinal ganglion cells projecting from the retina (Drasdo, 1977; Wassle *et al.*, 1989, 1990), whereas other studies indicate that ganglion cells projecting from the fovea have a disproportionately large representation in cortex (Malpeli and Baker, 1975; Myerson *et al.*, 1977; Perry and Cowey, 1985; Silveira *et al.*, 1989). The weight of most recent evidence supports the contention that important inputs in the visual systems of primates are indeed overrepresented in the cortex (Azzopardi and Cowey, 1993). However, the few studies that have addressed this issue and the conflicting results from different studies in the

primate visual system highlight the difficulty of making these determinations in most sensory systems. This is a case where the particularly specialized sensory system of the star-nosed mole has provided new insights as a result of its anatomical specialization. But before describing how star-nosed moles can shed light on visual system organization, it is necessary to outline the parallels between the star-nosed mole's somatosensory system and the visual systems of sighted mammals.

3.15.2.4 A Somatosensory Fovea in the Star-Nosed Mole

Although the nose of the star-nosed mole is a tactile sensory surface, there are a number of behavioral and anatomical similarities between the mole's sensory system and the visual systems of other species. This is most obvious from observations of star-nosed mole behavior (Catania and Remple, 2004). The entire star is used for the detection of relevant stimuli in the environment, but once an object or food item of interest is detected, the nose is shifted in a saccadic manner for detailed investigations with the touch fovea. There are 11 finger-like appendages on each side of the star, and the ventral-most, 11th pair constitutes the fovea. The other appendages take up a much greater surface area and act as the 'tactile periphery' in a manner analogous to the peripheral visual receptors of the retina.

Because one small area of the skin surface is the behavioral focus of the star, we can address the question of whether the most important inputs from a sensory array are allocated extra territory in the cortex, or alternatively whether the sizes of each cortical representation are simply proportional to their innervation density. This question is relatively easy to answer in the star-nosed mole because of the favorable anatomical organization of the sensory system. It is possible to quantify three different parameters: (1) the number of sensory organs on the star, (2) the number of primary afferents innervating the each appendage of the star, and (3) the area of primary somatosensory cortex devoted to each appendage (Figures 7a–7c). It is also possible to accurately measure the cortical representation of the star because of the histologically visible reflection of the appendage representations as a series of modules in somatosensory cortex. This aspect of star-nosed mole brain organization is discussed in more detail in the next section.

Because these different parameters can be measured in star-nosed moles, a number of interesting comparisons can be made. First, it is possible to consider the relationship between innervation density (number of nerve fibers) and the number of sensory organs (Eimer's organs) on the skin surface of each appendage (Figure 7d). This comparison shows that the number of nerve fibers and the number of Eimer's organs co-vary almost precisely for appendages 1–9. However, for appendages 10 and 11, there are more fibers per sensory organ. This reflects the higher acuity of this behaviorally important sensory surface. But does this account for the cortical magnification of the fovea, as suggested by studies in rodent barrel cortex? Figure 7e shows this comparison (average area of cortex per afferent for each appendage of the star) clearly indicating that the higher innervation for the fovea area of the star does not account for the cortical magnification of the fovea. Instead, star-nosed moles devote a greater average area of cortex to the most important afferents from the 11th appendage of the star (the tactile fovea) and conversely a smaller average area of cortex to the representations of the afferents from remaining 10 appendages (Figure 7e). Thus, the favorable anatomy of star-nosed mole's sensory system has allowed for the quantification of variables that are difficult to measure in many species and these findings may reflect a common relationship between sensory surfaces and the cortex in mammals. For example, the degree of cortical overrepresentation of the inputs from the fovea of the star is similar to the degree of overrepresentation of the retinal fovea in primates (Catania, 1995; Azzopardi and Cowey, 1993).

Finally, the subdivision of the star-nosed mole's sensory system into fovea and periphery is a remarkable example of the convergent evolution of similar features across disparate sensory systems. It suggests this organizational scheme is a general solution to designing a high-resolution sensory system. The most familiar and common example of a fovea-periphery organization is of course found in many visual systems of diverse mammals; however, auditory systems can have an acoustic fovea as well. This has been demonstrated in a number of studies by Suga and colleagues (Suga and Jen, 1976; Suga, 1989) for mustached bats (*Pteronotus parnellii*). Mustached bats emit an echolocation call that includes a narrow frequency range around 60 kHz that is particularly important for detecting the acoustic evidence of wing-beats caused by flying insect prey. A large proportion of the hair cells in the bat's cochlea are tuned to this important echolocation frequency and a large territory of the bat's A1 is devoted to processing sounds at this frequency. Thus, mustached bats have an acoustic fovea, and they have the acoustic equivalent of a saccade as well. This is necessary because returning

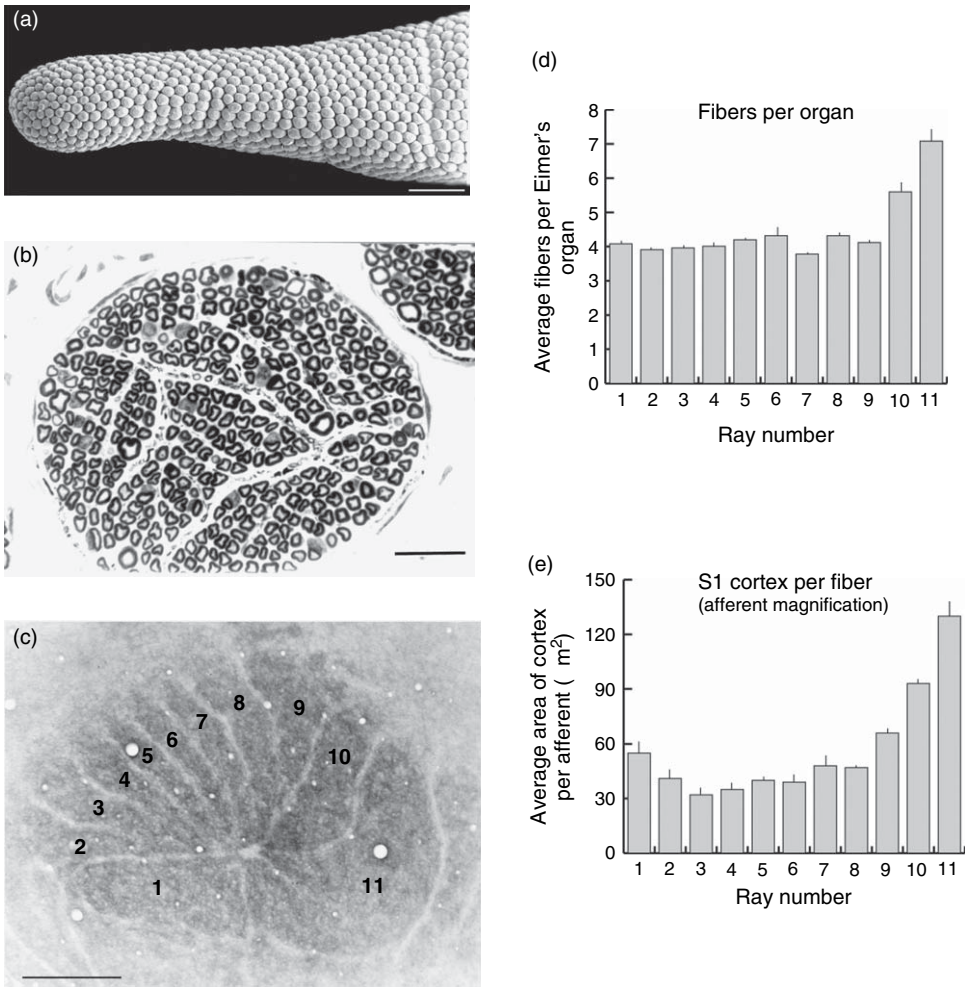

Figure 7 Quantification of the number of sensory organs, innervating nerve fibers, and representational area of the star in primary somatosensory cortex. a, A single appendage of the star under the scanning electron microscope showing the many visible sensory organs (Eimer's organs) covering the skin surface. b, A thin section of tissue showing a small portion of the many myelinated afferents supplying an appendage of the star. c, A potion of the cortex of a star-nosed mole that has been flattened and processed for cytochrome oxidase to reveal the primary somatosensory representation of the star. The area representing each appendage is visible as a separate subdivision. d, A graphic representation of the ratio of fibers (afferents) innervating each appendage per sensory organ on each appendage (or ray) of the star. e, The average area of cortex devoted to the primary afferents for each appendage (ray) of the star. Scale bars: a, 250 μm; b, 20 μm; c, 500 μm. Reproduced from Catania, K. C. and Kaas, J. H. 1997c. Somatosensory fovea in the star-nosed mole: Behavioral use of the star in relation to innervation patterns and cortical representation. *J. Comp. Neurol.* 387, 215–233.

echoes are often Doppler shifted to different frequencies depending on the speed of the bat and its target. To compensate for these Doppler shifts, bats are constantly shifting the frequency of their outgoing pulses to 'focus' the returning echo on the high-resolution area of the acoustic fovea. This behavior, called Doppler shift compensation (Schnitzler, 1968), is surprisingly similar to a saccade in the visual system.

The most well-developed visual systems, somatosensory systems, and auditory systems, all exhibit a fovea-periphery organization. An obvious benefit of this design is the conservation of neural processing area in the brain and innervating nerve fibers at the level of the sensory periphery. For example, making the entire sensory system high resolution would require a massive enlargement of the nerves carrying information to the brain, and a corresponding enlargement of the cortical areas processing the inputs. The ultimate result would be a staggering increase in brain size. It is far more efficient to devote a large part of the computational area of the brain to a small part of the sensory system (the retinal, tactile, or acoustic fovea) and then move that area around like a spotlight to analyze important stimuli (or in the case of bats, move the frequency of echolocation

pulses to ensure that Dopplar shifted echoes can be analyzed by the fovea).

3.15.2.5 Modules Represent Sensory Surfaces in Diverse Species

Woolsey and Van der Loos (1970) made the discovery of modules in the somatosensory cortex that represented the important facial vibrissae, or whiskers, in mice. They described cylindrical groupings of cells that were most easily seen in sections of the cortex cut parallel to the cortical surface. Electrophysiological recording of neuronal responses revealed that each barrel corresponded to the cortical representation of a single whisker on the face. This finding was remarkable because it revealed a visible reflection of a somatosensory map and at the same time provided a useful model system for exploring many details of mammalian brain organization and development. Cortical barrels were also considered to provide anatomical support for the columnar hypothesis of cortical organization, which suggests that cylindrical columns of interconnected neurons are the fundamental organizational unit of neocortex.

From the time since cortical barrels were first described, a number of investigations of cortex have revealed cortical subdivisions, or modules, related to sensory specializations in diverse species. Star-nosed moles provide one of the more dramatic examples of this relationship. Figure 8 shows details of star-nosed mole cortex. In the case of star-nosed moles, the receptors represented in cortex are part of an elongated skin surface, rather than a hair surrounded by a ring of mechanoreceptors as found in rats and mice (see Rice *et al.*, 1993). As described previously (Figure 5b) electrophysiological recordings from the cortex of star-nosed moles reveal three representations of the star in lateral cortex. When sections of the flattened cortex are cut parallel to the cortical surface and processed for cytochrome oxidase (Wong-Riley and Carroll, 1984) three different maps of the star are visible (Figure 8b). Each of these maps represents the entire contralateral star and each cortical module representing an appendage takes the from of elongated wedge.

The representations of the appendages of the star-nosed mole differ from cortical barrels of rodents in a number of ways. First, the representations of the appendages consist of elongated stripes of cortical tissue, rather than circular barrels. Second, the representation of the tactile fovea is greatly expanded in cortex relative to the size of this appendage on the star. As outlined above, the representation of this appendage reflects the behavioral importance of the fovea, rather than the innervation density of the sensory surface. Finally, in the star-nosed mole's cortex multiple maps of the sensory surface are uniquely visible. Three different somatosensory areas, S1, S2, and a new area we

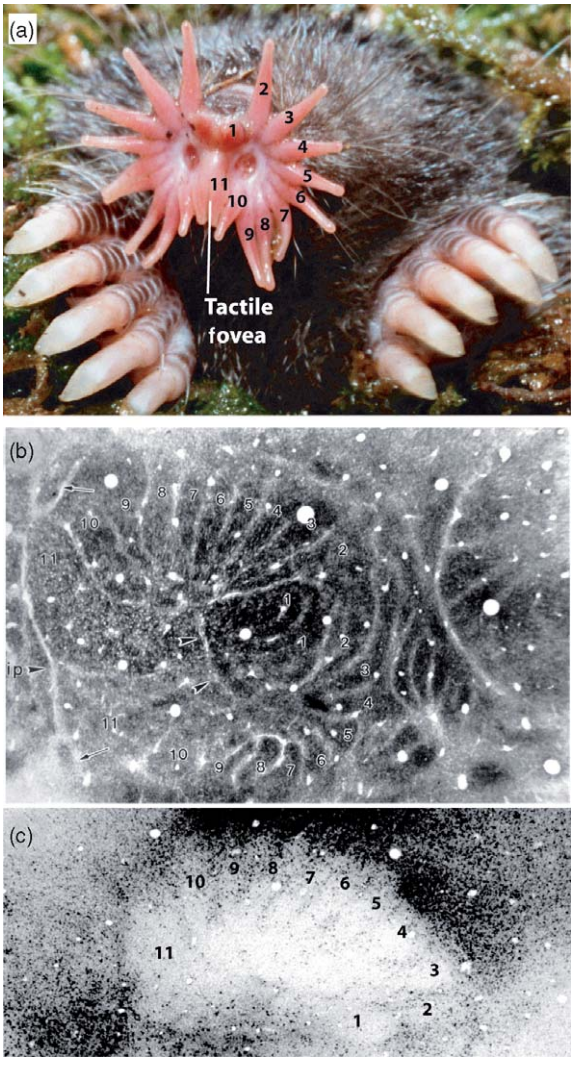

Figure 8 The unusual mechanosensory star and its corresponding cortical representation in the star-nosed mole (*C. cristata*). a, A star-nosed mole emerges from an underground tunnel showing its large forelimbs and the 22 fleshy appendages that surround each nostril. The 11th appendages on each side act as the somatosensory fovea and are used for detailed tactile investigations. b, A section of flattened cortex revealing all three cortical representations of the star (S1, S2, and S3 – see Figure 5b) visible as a series of modules, each representing an appendage from the contralateral star. c, An example of the specificity of callosal connections around the S1 star representation. Cells and terminals are concentrated in the septa between appendage representations and surrounding the star representation but are absent from the centers of each cortical stripe. Reproduced from Catania, K. C. and Kaas, J. H. 2001. Areal and callosal connections in the somatosensory cortex of the star-nosed mole. *Somatosens. Mot. Res.* 18, 303–311.

have termed S3, contain modules representing individual appendages.

From these observations, one can conclude that cortical modules are not constrained to form traditional columns, as suggested from barrels. It is also clear that insectivores may have exceptionally well-organized and complex cortical representations. This result is in stark contrast to results from early investigations of insectivores, including moles (Allison and Van Twyver, 1970), which suggested they had overlapping cortical areas with poorly defined topography. In this regard it is significant that the modules in the star-nose mole's cortex have different connections than the septa between modules. For example, tracer injections into the cortex reveal that callosal connections terminate selectively in the septa between cortical modules, whereas intercortical connections terminate primarily within modules (Figure 8c).

A different kind of modular representation of a sensory surface is found in the eastern American mole (*S. aquaticus*). This mole has an unusual and sensitive forelimb consisting of an oval palm and heavily clawed digits. In S2 of this species cytochrome oxidase processed sections of cortex reveal a modular reflection of the forelimb. This cortical pattern appears just like the large clawed hand that it represents (Figure 9). Tracer injections into the spinal cord of the eastern American mole show that the modular forelimb representation is also the location of dense areas of corticospinal projecting neurons (Catania and Kaas, 1997a). These examples of different kinds of connections to different parts of cortical modules in moles support the general conclusion that different parts of cortical modules may be the selective substrate for the distribution of specific cortical circuitry (Chapin *et al.*, 1987; Koralek *et al.*, 1990; Fabri and Burton, 1991; Hayama and Ogawa, 1997; Kim and Ebner, 1999).

In addition to cortical modules discussed above in rodents and insectivores, investigations of cortical organization in the duck-billed platypus have provided a different example of modules representing

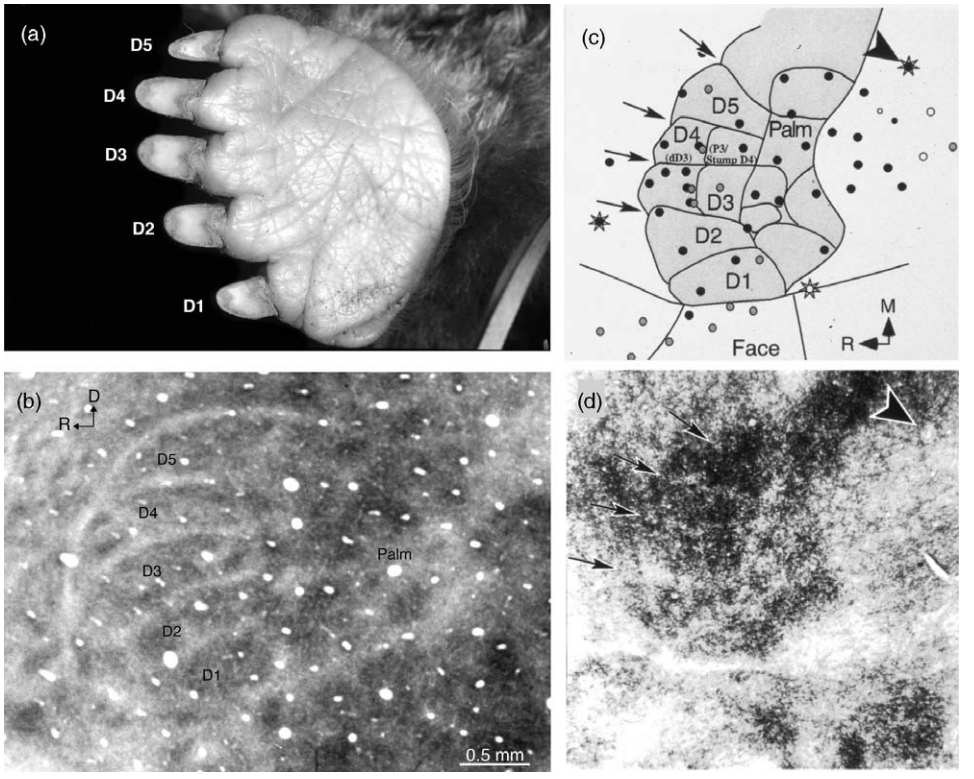

Figure 9 The representation of the eastern mole forelimb (*S. aquaticus*) and the hand of an owl monkey (*Aotus trivirgatus*). a, The large clawed forelimb of the mole. b, The cortical representation of the mole's forelimb as revealed by sections processed for cytochrome oxidase. The representation appears just like the large clawed hand it represents. c, A reconstruction of cortical recordings from an owl monkey showing the relative location of areas that responded to the digits (D1–D5) and the palm. d, Histological sections from the corresponding area of S1 (area 3B), in the same owl monkey, showing the cortical modules that represent the fingers and palm of the hand (arrowhead marks microlesions). b, Reproduced from Catania, K. C. and Kaas, J. H. 1997a. The organization of somatosensory cortex and distribution of corticospinal neurons in the eastern mole (*Scalopus aquaticus*). *J. Comp. Neurol.* 378, 337–353. d, Reproduced from Jain, N., Catania, K. C., and Kaas, J. H. 1998. A histologically visible representation of the fingers and palm in primate area 3b and its immutability following long-term deafferentations. *Cereb. Cortex* 8, 227–236.

sensory surfaces. The platypus bill contains tens of thousands of mechanoreceptors and electroreceptors (Manger and Pettigrew, 1996). Microelectrode mapping of the platypus somatosensory cortex has revealed a large S1 representation of the bill in lateral cortex (Krubitzer *et al.*, 1995). Flattened sections of cortex processed for cytochrome oxidase reveal alternating stripes of cortical tissue with dark and light regions representing higher and lower amounts of chronic neuronal activity. The dark areas represent the projection zones for mechanosensory information whereas the light zones represent the projection zones for combinations of mechanosensory and electrosensory information. Thus, S1 in the platypus contains receptor specific subdivisions very similar to the alternating bands of cortex representing rapidly adapting and slowly adapting mechanoreceptors in S1 of primates (Sur *et al.*, 1981), cats (Stretavan and Dykes, 1983), and raccoons (Rasmusson *et al.*, 1991). This anatomical arrangement of different sensory inputs in the platypus cortex is also reminiscent of ocular dominance columns representing inputs from the different eyes in primate area 17 (Hubel *et al.*, 1976).

The examples of cortical modules described above are from a range of particularly specialized mammals, and this raises the question of how common such representations of tactile sensory surfaces are across species and whether such findings have implications for primate and human brain organization. Relatively recent findings in primates suggest there are similar organizing principles for mechanosensory inputs across these diverse species. Jain *et al.* (1998) examined flattened cortex of three different primate species processed for myelin (Gallyas, 1979) and identified myelin-dense cortical modules representing the mechanoreceptors of the digits and palm in S1 (Figures 9c and 9d). Thus, the cortical representation of the primate hand, like the representation of rodent whiskers and the mole's star, is visibly reflected in flattened sections of cortex (see also Qi and Kaas, 2004). These findings indicate that large- and small-brained mammals share common developmental principles that segregate maps in similar ways. They also suggest there is a ubiquitous instructional role for the sensory periphery in guiding the formation of central representational maps.

3.15.2.6 The Sensory Periphery Guides Aspects of Cortical Development

The finding of histologically visible cortical maps of sensory surfaces that reflect the details of mechanoreceptor topography raises the question of how somatosensory areas become matched to the sensory periphery. Because the development of the somatosensory system begins with the skin surface and ends at the cortex (see Killackey *et al.*, 1995) there is opportunity for the sensory surface to instruct the cortex. Evidence for such an instructive role of the sensory periphery comes from the somatosensory system of rodents where it has been shown that early damage to a whisker disrupts the formation of the corresponding cortical barrel (Andres and Van der Loos, 1985; Woolsey, 1990).

A different but related kind of evidence comes from strains of mice bred for variations in the whisker pattern. Van der Loos and Dorfl (1978) noted that strains of mice born with extra whiskers on the face also developed extra barrels in the cortex in the appropriate topographic location (see Epigenetic Responses to a Changing Periphery – Wagging the Dog). They argued that it was unlikely for a single mutation to have simultaneously altered the entire sensory system from whisker to barrel, but rather a mutation acting at the level of the early developing skin surface was more likely to have been communicated to the subcortical nuclei and then to the developing cortex. Similar results have more recently been reported in star-nosed moles, where wild-caught animals have an unusually high rate (5%) of extra or missing nasal appendages. The different nose configurations are invariably reflected in the cortical maps (Catania and Kaas, 1997b).

Although Van der Loos and Dorfl made a compelling argument, they could not entirely rule out the possibility of a single genetic modification simultaneously and independently altered the brain and the whiskers of mice. Recently, however, their interpretation of an instructive role for the skin surface has received strong support from investigations in which altered whisker patterns were induced during embryonic development by transfecting the epidermis of mice with a virus containing the patterning gene Sonic hedgehog (Shh). This manipulation resulted in the formation of extra whiskers on the face, and later extra barrels in the cortex (Ohsaki *et al.*, 2002). However, in this case the genetic change was clearly restricted to the skin surface, supporting the hypothesis that the skin surface instructs the later-developing cortex.

Another possible role for the periphery in guiding the formation of cortex may be found in the timing of developmental events. For example, the retinal fovea in primates develops earlier than the peripheral retina, and inputs from the fovea have a preferentially magnified representation in cortex (as previously described). Similarly, the tactile fovea in star-nosed moles develops earlier than the more peripheral parts of the star. This can be

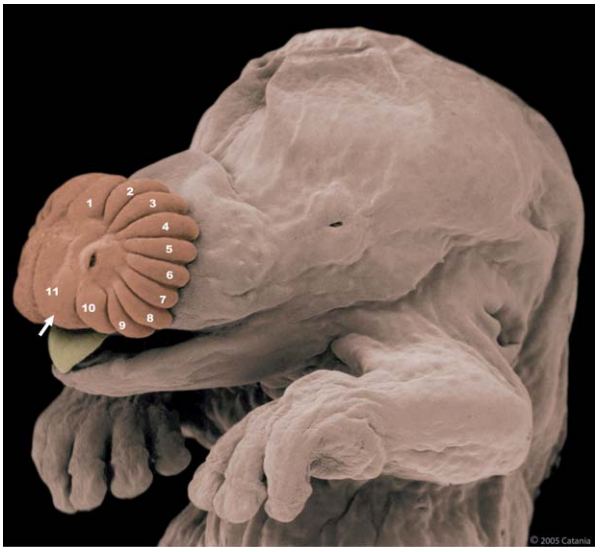

Figure 10 An embryonic mole showing the developing star. The appendages are numbered 1–11, as in adults. Note however, the relatively much larger area of the star taken up by the 11th, foveal appendage (arrow) at this early stage of development compared to appendage 11 in adults (see Figure 8a). Examination of this development sequence (Catania, 2001) reveals that the fovea leads the development of the star, and this may allow afferents from the developing fovea to capture a larger area of cortex (e.g., Figure 7e) in a competition for cortical territory. Photo copyright 2005 Catania.

appreciated by examining embryonic (Figure 10) and adult (Figure 8a) star-nosed moles and comparing the size of the 11th appendage (the tactile fovea) at these different stages. The 11th appendage takes up a far greater proportion of the star in embryos than it does in adults. More detailed investigations of this relationship (Catania, 2001) reveals that the tactile fovea leads the development of the star, such that it grows large early, has the largest innervated sensory surface in embryos, and develops sensory organs (Eimer's organs) before the peripheral appendages of the star (appendages 1–10). Yet later in development the peripheral appendages grow larger than the fovea, until in adults the 11th appendage is dwarfed by the rest of the star (Figure 8a).

The early development of these important sensory surfaces may give them an advantage in a competition for cortical territory during development. Evidence for this possibility comes from studies of the primate visual system. When one eye is sutured shut and deprived of visual input during critical periods of development, ocular dominance columns related to that eye are greatly reduced in size compared to the open eye (Hubel *et al.* 1977). Activity dependent expansions have also been documented for the somatosensory system, where the most active regions of barrel cortex undergo the greatest amount of growth during development (Riddle *et al.*, 1993; Purves *et al.*, 1994). These studies suggest that the most active inputs during critical periods of development have a competitive advantage in capturing representational space in the cortex.

So far, I have highlighted some of the evidence for changes that may have commonly occurred in the course of the evolution of the somatosensory system. These include the magnification of behaviorally important areas of sensory maps, the addition of new areas to cortical networks, the formation of a fovea-periphery organization for high-resolution sensory systems, and the subdivision of areas into modules representing segregated sensory surfaces in the periphery. In this last section I will outline some ideas for potential mechanisms by which some of these changes may occur. Additional details may be found in Epigenetic Responses to a Changing Periphery –Wagging the Dog.

3.15.3 What are the Mechanisms of Evolutionary Change?

3.15.3.1 Levels of Organization

The examples outlined above for the somatosensory system suggest two different levels of organizational change in the evolving neocortex that may be altered by two different mechanisms. The first level involves alterations of details of cortical representations that stem from the developmental link between the sensory periphery and the brain. Evidence for this possibility comes from a number of sources as outlined in the previous sections, including surgical alterations to the whiskers that change barrel patterns in mice, strains of mice bred with supernumerary whiskers that have extra barrels in the cortex, wild-caught star-nosed moles with extra appendages on the star and extra representational stripes in the cortex (indicating this occurs in natural populations), and evidence that changes in the timing of developmental events at the sensory surface may have an important impact on cortical development.

A second level of organizational change is the addition of completely new areas to the cortex, in the form of new maps of the sensory periphery. Evidence for this kind of change comes from comparative studies that illustrate the variation in numbers of cortical subdivisions in differently specialized species. The extra somatosensory area in star-nosed moles (Figure 5) compared to other mole species provides one example that can be

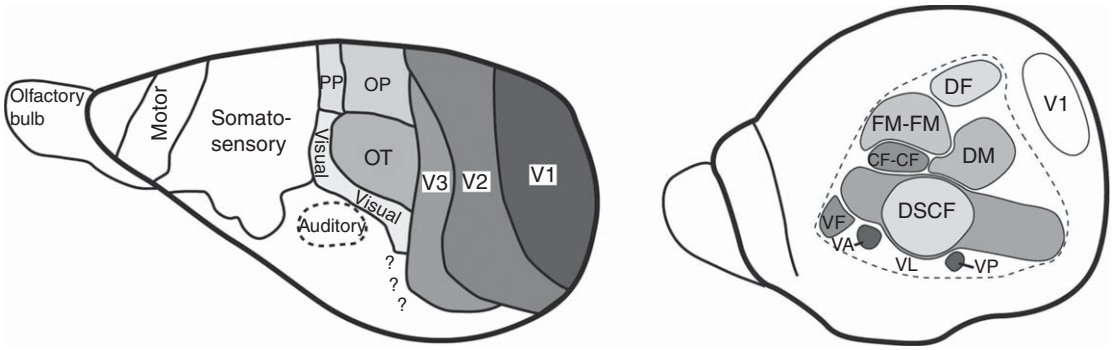

Figure 11 Cortical organization in megachiropteran and microchiropteran bats, demonstrating visual and auditory specializations, respectively. a, Summary of cortical areas in the megachiropteran flying fox (*Pteropus poliocephalus*). This fruit-eating species relies heavily on vision and this is reflected in the proportion of cortex devoted to vision and the number of corresponding visual areas. Roughly half of the cortex is taken up by a series of at least six visual areas (shaded areas) and a number of additional areas are likely to be found in more rostral-lateral cortex. b, Summary of cortical areas in the microchiropteran mustached bat (*Pteronotus parnellii*). In contrast to megachiropteran bats, microchiropteran bats have reduced visual systems and depend heavily on echolocation to navigate and locate flying prey. This is reflected in the organization of their neocortex which is dominated by a network of eight or more auditory areas (shaded areas) that largely process information in the frequency range of returning echolocation pulses. These closely related species provide an example of how cortex has evolved in parallel with the more complex visual and auditory abilities of each respective species. a, Data from Rosa, M. G., Krubitzer, L. A., Molnar, Z., and Nelson, J. E. 1999. Organization of visual cortex in the northern quoll, *Dasyurus hallucatus*: Evidence for a homologue of the second visual area in marsupials. *Eur. J. Neurosci.* 11(3), 907–915. b, Data from Suga, N. 1989. Principles of auditory information-processing derived from neuroethology. *J. Exp. Biol.* 146, 277–286.

confidently attributed to the elaboration of the somatosensory system. Other examples include comparison of the many visual areas in highly visual megachiropteran bats to the few visual areas in echolocating microchripteran bats, and conversely comparison of many auditory areas for processing echos in the microchiropteran bats to the few auditory areas in nonecholocating, megachropteran bats (Figure 11).

3.15.3.2 Potential Mechanisms of Change

As described above, the intimate developmental relationship between receptor arrays and cortical maps suggests that many changes to cortical areas in the course of evolution may initially occur simply by altering the body. It seems likely that cortical and subcortical areas of the brain are flexible enough to accommodate changes to the sensory periphery that may provide a selective advantage. For example, the expansion of a sensory surface allows for a greater area of the environment to be investigated per unit time. This is presumably the selective pressure that drove star-nosed moles in the direction of enlargement of their mechanosensory snout relative to other species. In support of this possibility, star-nosed moles eat relatively small prey items compared to other species of moles, and this requires locating more prey per unit time to satisfy metabolic requirements (Catania and Remple, 2005). The evidence of supernumerary appendages in some moles suggests a simple mechanism by which such an expansion of the sensory surface can occur – that is, change the star locally and the sensory processing areas will accommodate the alterations through a developmental cascade.

Yet changes to cortical areas to accommodate different configurations of a sensory surface may have important, negative consequences for sensory processing (Figure 12). In this respect, a cortical area may be challenged in the same general ways that have been outlined for increasing the size of the entire brain (Deacon, 1990; Kaas, 2000). One problem is the lengths and numbers of interconnections within a cortical area. As neurons become more widely separated, the diameters of their axons and dendrites must become greater to maintain similar conduction times between neurons (Ringo *et al.*, 1994). This in turn typically requires increases in the size of the supporting neuronal cell body in order to supply the metabolic requirements of the neurites. In addition, as the number of neurons in larger areas increases, the number of connections between neurons must increase drastically to maintain a similar degree of global connectivity between neurons within the area (Deacon, 1990). All of these changes require more space in the cortex, which compounds the problem. Thus, increasing the size of a cortical area could result in a suboptimal processing area and set the stage for the adaptive benefits of adding a new area to the cortex.

Figure 12 provides a schematic outline for how some of these changes may occur. The progressive

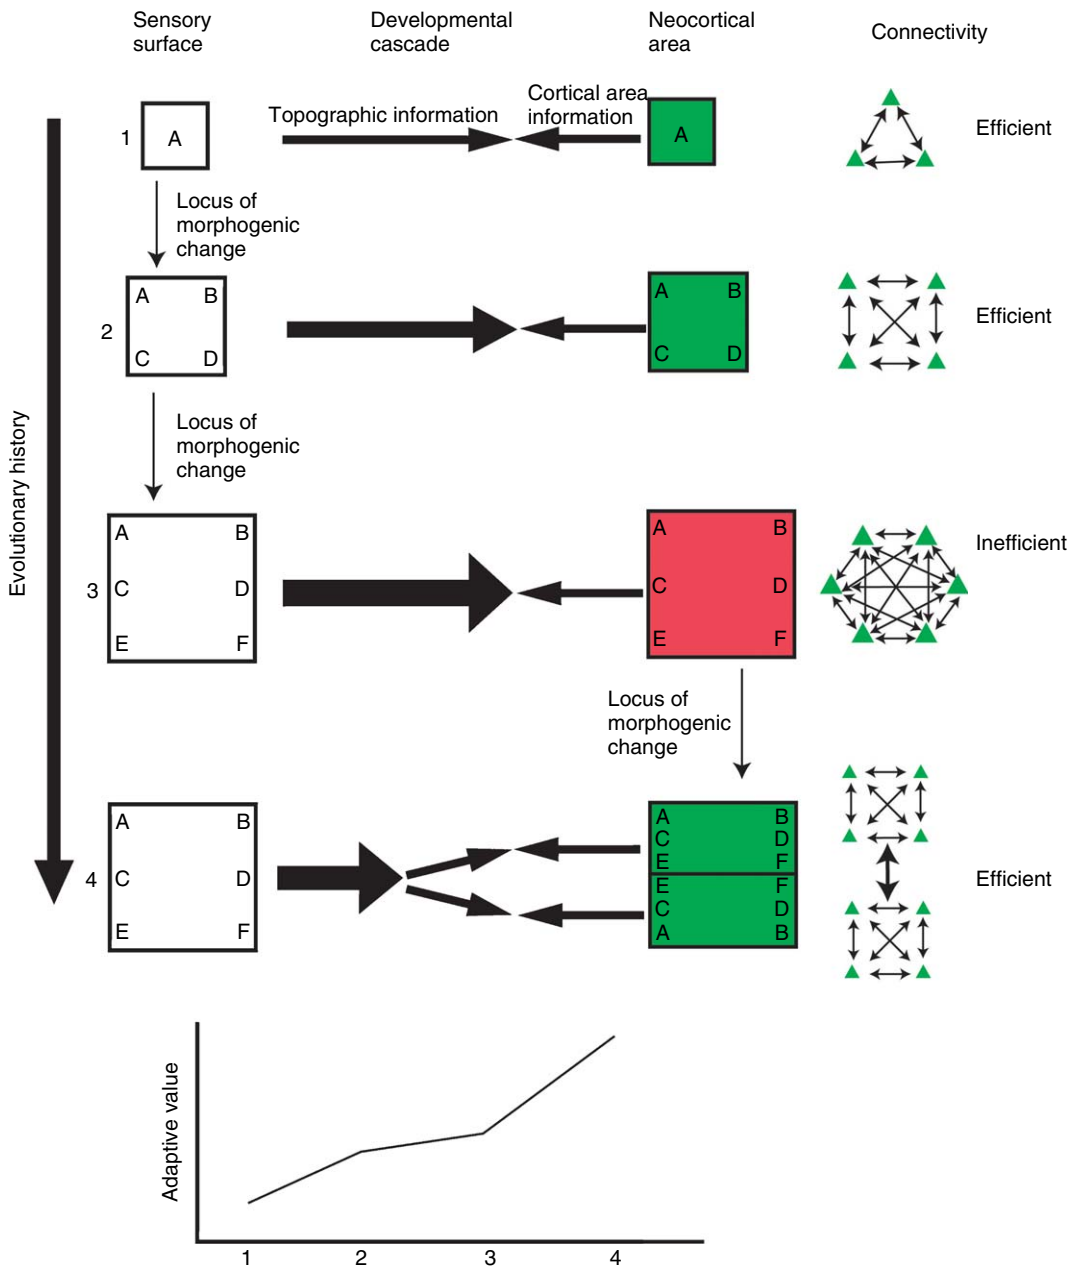

Figure 12 Schematic illustration of possible steps in the progressive evolution of a more complex cortex with new areas. Steps 1–4 represent a progression of changes in the species over successive generations. The graph at the bottom represents the proposed adaptive value of each evolutionary change for steps 1–4. In this proposal, the sensory surface leads the evolutionary process of brain reorganization through a cascade of developmental events in steps 1–3. This begins with the expansion of the sensory surface and a corresponding expansion of the representation of the sensory surface in cortex. The far right side represents the level of connectivity between neurons needed for sensory processing. Although each step is presumed to provide a net advantage (lower panels), by step 3, the cortical processing area is strained and no longer processing the information at peak efficiency. This sets the stage for step 4, during which the cortical area is duplicated (through developmental mechanisms centers in the cortex – see text for example) allowing for the two smaller areas to efficiently process information. Although not illustrated, the two areas are now free to specialize in processing different facets of sensory information and this is considered to be part of the adaptive value of this step (lower panel).

evolution of a sensory system is illustrated from top to bottom of the figure. The initial stages (1–3) reflect the progressive elaboration of the sensory surface (left side) and the corresponding expansion of the representation in cortex (right side) through a developmental cascade. The graph at the bottom illustrates the proposed adaptive value of each change. Initially the developmental changes to the sensory surface are accommodated by the later-developing brain, and there is a steep rise in adaptive

value (1–2). However, at some point (3) the cortical area is no longer at an optimal size for processing information from the sensory surface (as illustrated in red). Although the expansion of the sensory surface has still resulted in an increased net adaptive value for the sensory system as a whole (bottom panel), the stage is now set for the addition of a cortical area to optimize sensory processing. With the addition of a cortical area (4) there is another steep rise in adaptive value of the sensory system (4). Although not illustrated, the ability for the two daughter areas to specialize for processing different facets of sensory information may provide the most important advantaged for sensory processing.

There seems to be ample evidence from both experimental manipulations of development and naturally occurring variants that steps 1 and 2 can occur. That is, changes to the sensory system localized to the sensory periphery may cause alterations of the representations in the CNS. However, evidence for variation in the number of cortical areas is much less obvious, and must usually be inferred and reconstructed from comparative studies across species. Although there may be some ongoing variations in numbers of cortical areas in a given species, so few brains are processed and examined in detail for any species that the chances of such variants being identified are small. This can be contrasted with variants in body parts and sensory systems that can be readily identified by simply examining an animal's body (e.g., Van der Loos and Dörfl, 1978). As a result, the potential mechanisms for altering cortical area number are most readily deduced from laboratory investigations of patterning-gene expression.

Recent investigations and manipulations of gene expression patterns in developing mouse cortex suggest some of the mechanisms that control cortical area position, orientation, and number (Cecchi, 2002; Fukuchi-Shimogori and Grove, 2001; Ohsaki *et al.*, 2002; O'Leary and Nakagawa, 2002). These investigations have revealed graded expression of patterning proteins in the developing cortex that can be manipulated to cause predictable alterations in the positions of entire cortical subdivisions. One growth factor in particular – FGF8 (a member of the fibroblast growth factor family) – has been the focus of a number of recent studies. FGF8 is normally expressed at the rostral pole of the developing neocortex. In a landmark experiment, Fukuchi-Shimogori and Grove (2001) introduced a second source of FGF8 at the caudal pole of developing mouse neocortex. When they later examined the adult somatosensory cortex in these mice, some individuals had generated a partial mirror-image duplication of the S1 barrel field (Figure 13) that presumably was supplied by its own set of thalamocortical axons (O'Leary and Nakagawa, 2002).

This experiment has profound implications because the generation of a new, mirror-image representation of a sensory surface has clearly occurred many times in the course of mammalian brain evolution. Thus, addition of a new FGF8 source to developing cortex produces a phenotype in the laboratory that mimics a common product of cortical evolution.

Long before genetic manipulation of patterning genes was possible, previous investigators of mammalian cortical diversity had suggested that sudden duplications of cortical areas might occur as

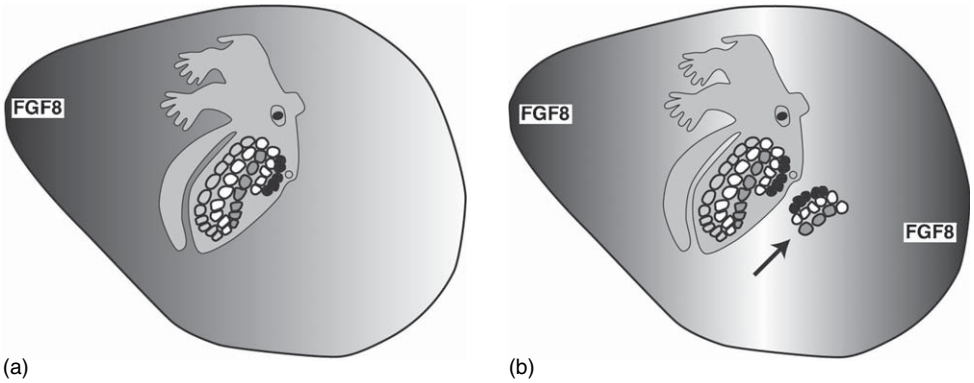

Figure 13 Schematic illustration of recent experiments that have induced the partial duplication of the cortical barrel field by adding a new source of FGF8 to the caudal part of developing cortex. a, FGF8, a member of the fibroblast growth factor family, is normally expressed rostrally in developing cortex. b, When a second source of FGF8 was introduced by electroporation during fetal development, adults were later found to have a partially duplicated barrel field (arrow). This results suggests a mechanism by which mirror image duplications of a cortical area might occur in the course of mammalian evolution. Reproduced from Fukuchi-Shimogori, T. and Grove, E. A. 2001. Neocortex patterning by the secreted signaling molecule FGF8. *Science* 294, 1071–1074.

mammalian brains evolved (Allman and Kaas, 1971; Kaas, 1982). The idea was that a new area could then become specialized to perform new functions while releasing the original area from some of its functions. There are a number of attractive features to this theory of cortical elaboration. Meristic changes – or alterations to a standard part – are a common mechanism of evolutionary change that has been well documented from the level of genes (see Ohno, 1970) to entire body parts (Raff, 1996). That this can occur for cortical areas seems likely in light of the recent findings of Fukuchi-Shimogori and Grove (2001).

In addition to this recent evidence from FGF8 expression, there are a number of considerations related to cortical area organization that suggest duplication of an area may be an efficient mechanism for expanding cortical functions. For example, such a mechanism (dependent on chemical gradients) would likely result in mirror-image maps (see Figure 13b and Catania, 2004), as observed for the supernumerary barrel representation in mice with an extra FGF8 source. Most adjacent cortical areas are mirror images of one another and share a congruent border (Kaas, 1982). This results in areas that are more topographic as a group, than non-mirror-image areas (i.e., neighbor relationships are maintained at, and across the congruent border between areas). It seems likely that such topographic representations are a particularly efficient configuration of cortex. Such an organization groups neurons that interact together, reducing fiber lengths and minimizing conduction delays. Topographic representations may also facilitate detection of movement and the refinement of acuity through center-surround receptive field configurations.

An alternative possibility for cortical elaboration is that cortical areas slowly fission by gradual separation. However, this seems less likely, as the result would be two daughter areas with the same (non-mirror image) orientation – and this is seldom observed. In addition, areas that gradually separate from one another would pass through a very nontopographic and presumably less efficient intermediate stage. Finally, if chemical gradients play a major role in the positioning and orienting of cortical areas during development, gradual separation of two areas may be difficult to achieve and the resulting, non-mirror-image representations may be difficult or impossible to code with chemical gradients (Catania, 2004).

3.15.4 Conclusions

Investigations of specialized mammals reveal a number of clear trends in mammalian brain evolution. This includes the expansion of the representations of behaviorally important sensory surfaces, the subdivision of cortical areas into modules representing parts of a sensory surface, and the addition of entirely new cortical areas to the processing network. Surgical alterations of sensory surfaces during development and the discovery of natural variations in sensory arrays suggests that many of the changes to the representations in the cortex may occur simply as a result of changes to the sensory surface that are communicated centrally by a developmental cascade. However, larger-scale changes in brain organization, such as the addition of new cortical areas to the processing network, require alterations of gene expression that are centered in the developing brain. The most recent advances in manipulating the expression of patterning genes in the cortex suggest mechanisms by which areas may be added to the cortex. These findings support some long-standing theories for how the brains of ancestral mammals may have evolved to produce the diversity of cortical configurations observed in modern mammalian lineages.

3.16 Somatosensory Specializations in the Nervous Systems of Manatees

R L Reep and D K Sarko, University of Florida, Gainesville, FL, USA

Glossary

oral disk	The expanded mystacial region of the sirenian face that contains bristle-like hairs used in tactile investigation.
oripulation	Use of the perioral bristles for prehensile grasping and directed movements.
perioral bristles	Prominent facial vibrissae used in feeding and investigative behavior.
Rindenkerne	Aggregations of neurons found in layer VI of some cortical areas; may be analogous to barrels associated with vibrissae in other taxa.

3.16.1 Introduction

Florida manatees are large-bodied, fully aquatic herbivorous mammals that are members of the order Sirenia, which has a fossil record that can be traced back to a four-legged ancestor that lived approximately 50 Mya (Domning, 1994, 2001a). Within the Sirenia, the trichechids (manatees) diverged from the dugongid lineage (dugongs) 25–40 Mya. Manatees in their modern form are a relatively recent offshoot, having evolved in the Amazon basin about 2 Mya (Domning, 2001b). They are currently represented by three species, found in Florida and the Caribbean (*Trichechus manatus*), South America (*Trichechus inunguis*), and West Africa (*Trichechus senegalensis*).

Because they are herbivorous and are not preyed upon, manatees lack the rapid movements and complex behaviors associated with predation and predator avoidance (Hartman, 1979). They are relatively slow-moving, usually reside in turbid, shallow water habitats, have greatly reduced visual systems (Marshall and Reep, 1995), poor visual acuity (Bauer *et al.*, 2003), do not appear to utilize echolocation (Gerstein *et al.*, 1999), and exhibit reduced chemosensory systems (Reep *et al.*, 1989). Under these circumstances, details of the near-field environment become significant, and it can be advantageous for an aquatic animal to maximize somatosensory acuity (see Evolution of the Somatosensory System – Clues from Specialized Species). Behavioral and anatomical evidence suggests that sirenians have done just that, as have the platypus (Manger and Pettigrew, 1995) and river dolphin (Layne and Caldwell, 1964).

Manatees eat a wide variety of aquatic vegetation. Food is gathered via modified perioral vibrissae that are used in a prehensile grasping fashion to oripulate food and bring it into the oral cavity. This behavior may be optimized to increase the efficiency of food gathering, because manatees forage for a significant amount of time daily and consume an amount equivalent to as much as 10% of their body weight per day. This manner of feeding and the use of vibrissae to grasp objects are both unique to sirenians (Marshall *et al.*, 1998a).

Manatees perform tactile investigations of novel objects or potential food items using the vibrissae of the oral disk, the expanded central mystacial region of the face (Figure 1) (Hartman, 1979; Marshall *et al.*, 1998a; Bachteler and Dehnhardt, 1999). Interestingly, prior to contact, manatees often close their eyes, perhaps to improve tactile discrimination. Tactile acuity using the oral disk vibrissae is comparable to that of the Asian elephant using its trunk (Bachteler and Dehnhardt, 1999).

3.16.2 Tactile Hair

Among the many unusual anatomical features of sirenians, one of the most significant for

Figure 1 Manatee face. The oral disk (od) is flared and its bristle-like hairs are everted in this side view of a manatee face. The large perioral bristles of the U2 field on the upper lip (U2) are withdrawn into their fleshy pad.

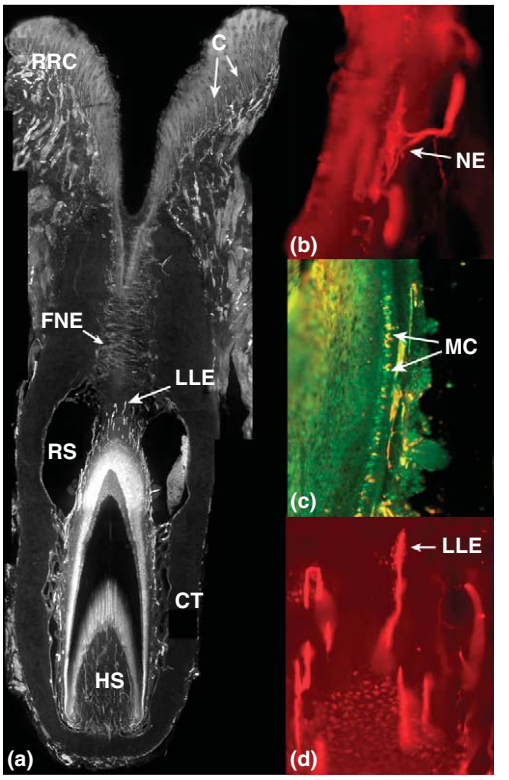

Figure 2 Follicle morphology and innervation. Panel a presents a longitudinal section of a U2 follicle, illustrating the prominent ring sinus (RS), connective tissue capsule (CT), and base of the hair shaft (HS). Dermal papillae underlying the epidermis of the circumferential rete ridge collar (RRC) are innervated by C fibers (c). At the inner conical body level, circumferential free nerve endings (FNEs) are present, as are novel endings (NEs in panel b). At the level of the RS, dense aggregations of Merkel cells (MCs in panel c) and longitudinal lanceolate endings (LLEs in panel d) are evident.

neurobiological function is the presence of true vibrissae (tactile hair) on the entire body, and the absence of pelage hair (Dosch, 1915; Reep *et al.*, 1998, 2001, 2002). Sirenians are the only mammals known to exhibit this condition, although fossorial naked molerats possess nonvibrissal hairs that mediate orientation to tactile stimuli (Crish *et al.*, 2003). Manatees possess approximately 5300 vibrissae, distributed about 30 times more densely on the face than on the postcranial body. The face contains approximately 2000 vibrissae, innervated by approximately 110 000 axons, whereas the postcranial body contains roughly 3300 smaller vibrissae innervated by approximately 100 000 axons.

The facial region of sirenians is highly modified in association with its use in feeding behavior (Reep *et al.*, 1998; Marshall *et al.*, 1998a, 1998b). The facial vibrissae are organized into nine distinct fields that vary according to location, size, and stiffness. Six of these fields comprise the perioral bristles on the upper and lower lips (~224 total), utilized during feeding behavior. These are the largest and stiffest vibrissae (hence the term 'bristle', coined by Murie, 1872), and are also the most heavily innervated (61–254 axons per follicle). The oral disk (Figure 1) contains approximately 600 bristle-like hairs, vibrissae that are intermediate in stiffness and innervation (49–74 axons per follicle) between the perioral bristles and postcranial vibrissae. The oral disk is usually flaccid, but in preparation for tactile scanning it flattens and expands, causing the bristle-like hairs to evert (Figure 1). The remainder of the face (chin and supradisk region around the nostrils) is invested with finer vibrissae that are not actively moved or everted, and these are similar in stiffness and innervation (~34–48 axons per follicle) to the postcranial hairs.

All facial follicles have the anatomical attributes of follicle–sinus complexes, including a circumferential blood sinus, dense connective tissue capsule, and substantial innervation. In addition, the facial follicles possess a ring sinus, defined as a distinctly enlarged nontrabeculated region located between upper and lower trabeculated cavernous sinuses. Preliminary analysis of a facial vibrissa immunolabeled for PGP 9.5 (protein gene product 9.5, a universal cytoplasmic protein) and NF200 (a 200 kDa neurofilament subunit) revealed that the dermal papillae of the rete ridge collar were densely innervated by C fibers (Figure 2a). This innervation may facilitate accurate assessment of water temperature, which is critical for the Florida manatee's survival in winter. Immunofluorescence also

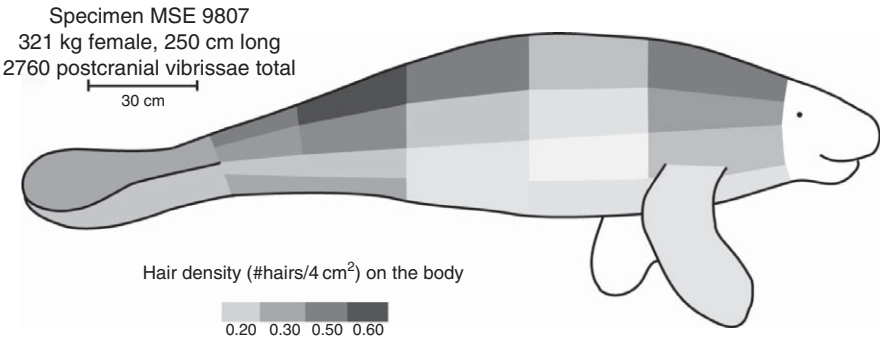

Figure 3 Distribution of postcranial vibrissae. Vibrissae are present over the entire body (facial distribution not shown in this figure). Growth produces an expansion of girth in the midsection, which results in lower density of vibrissae in this region. Adapted from figure 2 of Reep, R. L., Marshall, C. D., and Stoll, M. L. 2002. Tactile hairs on the postcranial body in Florida manatees: A mammalian lateral line? *Brain Behav. Evol. 59*, 141–154.

revealed that the inner conical body region in the manatee follicle lacks transverse lanceolate endings thought to be associated with whisking behavior in rats (Ebara *et al.*, 2002), but is supplied with novel large endings (Figure 2b). At the level of the ring sinus, the outer root sheath of the follicle was richly supplied with Merkel cells and longitudinal lanceolate endings (Figures 2c and 2d). Merkel cells represent slowly adapting, low-threshold receptors that, in the rat and cat, appear to provide directional sensitivity at the level of the ring sinus due to the terminal arbor from each afferent being restricted along one margin of the follicle (Ebara *et al.*, 2002). Finally, whereas each follicle–sinus complex is penetrated by a single deep vibrissal nerve (DVN) in rats and cats (Ebara *et al.*, 2002), manatee vibrissae appear to be innervated by several nerve bundles branching from the DVN (Reep *et al.*, 2001).

Vibrissae of the postcranial body (Figure 3) are 2–9 mm in length and are distributed fairly sparsely (~25 mm apart), except in specialized regions such as the edge of the fluke and the perivulvar area (Reep *et al.*, 2002). Unlike in the face, there are no obvious regional differences in postcranial follicle structure, suggesting that to a first approximation these follicles represent a distributed system of repeated modules. Postcranial follicles are markedly smaller than those of the perioral bristles and bristle-like hairs of the face, and are similar in size and innervation to those of the chin and supradisk region. They exhibit an elongated circumferential blood sinus, dense connective tissue capsule, and substantial innervation (21–47 axons per follicle). Rather than a ring sinus, most postcranial follicles exhibit a dorsal enlargement in the sinus, but retain connective tissue trabeculae that span the width of the sinus.

The presence of vibrissae on the entire body constitutes a distributed three-dimensional somatosensory array potentially capable of encoding the intensity and direction of water displacements and low-frequency vibrations associated with significant environmental stimuli, such as approaching conspecifics and other animals, water currents, and tidal flows. Therefore, this system may be used for touch at a distance, analogous to the lateral line system in fish. Gerstein *et al.* (1999) proposed that this system of hairs might also detect low-frequency acoustic energy in the form of near-field particle displacements. In a psychophysical study of manatee hearing, they noted that improvement in detection at low frequencies occurs within the range of frequencies (0.1–0.2 kHz) that correspond to lateral line detection in fish.

3.16.3 Central Somatosensory Regions

The brainstem, thalamus, and cerebral cortex all exhibit anatomical features suggestive of specializations associated with processing the large amount of information emanating from approximately 210 000 axons innervating the vibrissae on the body of a manatee (see The Development and Evolutionary Expansion of the Cerebral Cortex in Primates).

3.16.3.1 Brainstem

The brainstem nuclei most relevant to the manatee somatosensory system include Bischoff's nucleus, the trigeminal nucleus, and the cuneate–gracile complex. Bischoff's nucleus is present in many tailed animals (Ariens Kappers *et al.*, 1936; Johnson *et al.*, 1968), and through electrophysiological experiments it was shown to represent the tail and to project heavily to the somatosensory thalamus in raccoons (Ostapoff and Johnson, 1988). This distinct group of cells at the midline of the caudal medulla has also been identified in the manatee (Figure 4) and constitutes the presumptive fluke representation. In manatees, fine movements of the fluke are used to adjust the position of the body while moving, and presumably this

involves a significant amount of sensory feedback via Bischoff's nucleus.

Manatees have large trigeminal nerves and well-developed trigeminal and somatosensory nuclei, but reduced visual thalamic and brainstem nuclei (Welker *et al.*, 1986; Johnson *et al.*, 1986; 1987; Reep *et al.*, 1989). These anatomical observations are also reflected in sirenian behavior, particularly in the case of the trigeminal nerve system, which is extensively involved when the face is used for tactile exploration. Given its level of behavioral importance, it is no surprise that recent analysis of the trigeminal nucleus has revealed an organized, parcellated nucleus (Figure 5). This may indicate a topographical relationship linking each subdivision to functionally significant regions of the face such as the nine follicle fields mentioned above, and may be comparable to the barrelettes discovered to correspond to individual vibrissa follicles in the principle sensory nuclei of other species. The cuneate–gracile complex, which represents the forelimb flippers as well as the upper and lower body of the manatee by extrapolation from other species, also exhibits notable parcellation indicative of functionally segregated and organized cutaneous inputs (Figure 5). Presumably, a large proportion of the compartmentalization seen in the trigeminal and cuneate–gracile nuclei represents the segregated processing of inputs from the tactile hairs.

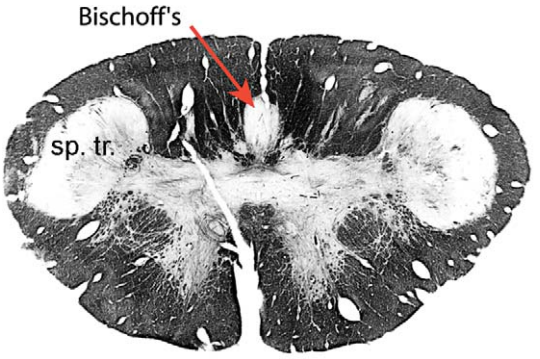

Figure 4 Bishcoff's nucleus. This site of representation of somatosensory afferents from the fluke is visible in the caudal brainstem as a prominent midline structure. Spinal trigeminal nucleus = sp. tr. Myelin stain, coronal section.

3.16.3.2 Thalamus

The principle somatosensory nucleus in the thalamus is the ventroposterior (VP) nucleus, with a ventral posterolateral (VPL) component representing the body and a ventral posteromedial (VPM) portion representing the face and most of the head. Given the manatee's reliance on haptic input, VPL and VPM would be expected to constitute a large proportion of the thalamus, and this does appear to be the case. Nucleus VP stains positively and rather uniformly for cytochrome oxidase (Figure 6). Acetylcholinesterase histochemistry produces a dark reaction product in the lateral portion of VP, suggesting that this corresponds to VPL, whereas the lighter-stained medial component corresponds to VPM, as in some other taxa (Bennett-Clarke *et al.*, 1999). The large size of the presumptive VPM suggests that the face and head are represented by a disproportionately large region within VP, consistent with the fact that manatees make extensive use of the bristles and bristle-like hairs of the face and oral region during a variety of behaviors. Cytochrome oxidase staining has not revealed the presence of barreloids in the manatee VPM. These are the thalamic counterparts to brainstem barrelettes, and are

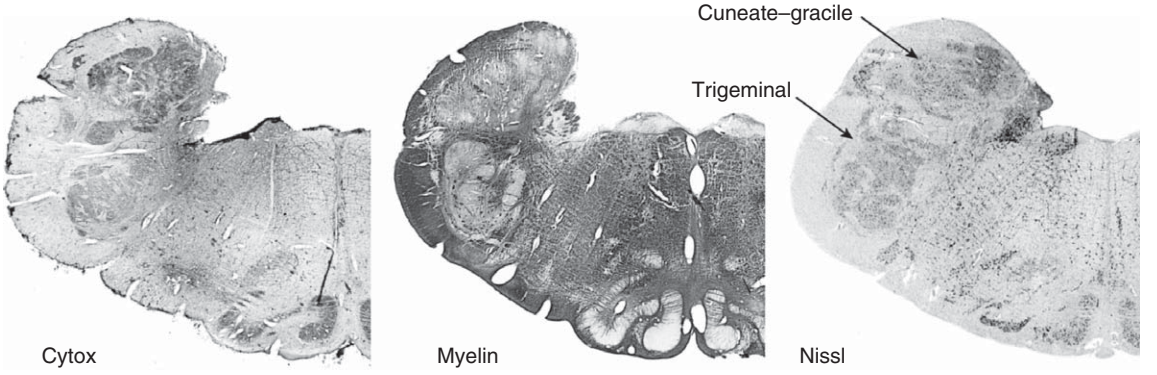

Figure 5 The brainstem contains large, partitioned somatosensory nuclei. Three coronal sections at approximately the same level reveal prominent bands in the cuneate–gracile complex, indicating a detailed organization of cutaneous inputs from the forelimb flippers as well as the upper and lower body. The trigeminal nucleus exhibits a similar parcellated organization, presumably related to the well-developed tactile sensitivity of the manatee face. Sections were stained for cytochrome oxidase (cytox), myelinated axons (myelin), or cell bodies (Nissl).

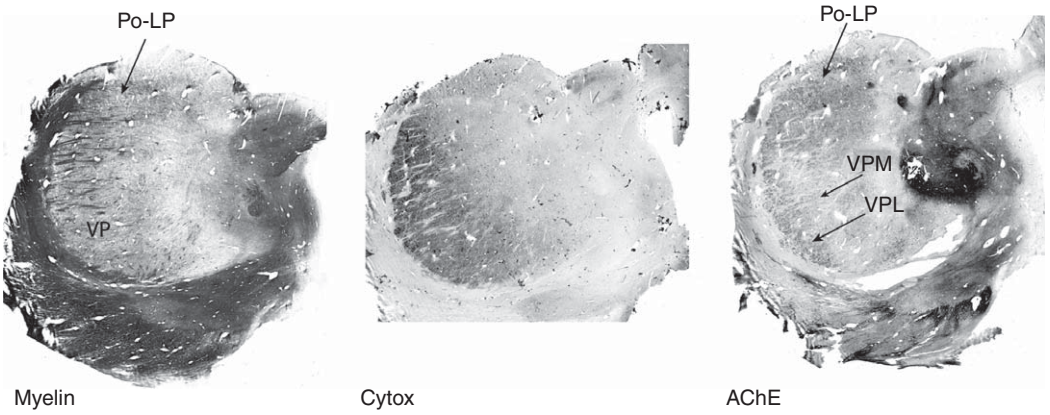

Figure 6 The thalamus exhibits large somatosensory nuclei. The general location of the VP nucleus is apparent on sections stained for myelinated axons (myelin) or cytochrome oxidase (Cytox), and VP is bounded dorsally by the posterior nucleus (Po-LP). Acetylcholinesterase staining distinguishes the VPL subnucleus as a dark-staining region, and the VPM subnucleus as a zone of light staining. The VPL–VPM complex is relatively large, consistent with the importance of somatic sensation in manatee behavior.

somatotopically organized regions related to vibrissal input in some other taxa (Jones, 1983).

3.16.3.3 Cerebral Cortex

The presumptive somatosensory cortex consists of areas CL1, CL2, DL1, and DL2. It was first identified on the basis of its location and cytoarchitectural characteristics (Reep *et al.*, 1989; Marshall and Reep, 1995). More recently we have discovered that portions of this region stain positively for cytochrome oxidase and are richly supplied with myelinated axons (Sarko and Reep, 2004), as is the case for somatosensory cortex in other taxa (Krubitzer, 1995). This can best be seen in flattened cortex preparations that reveal four distinct patches in the neonate (Figure 7), corresponding to the presumptive forelimb flipper, face, body, and tail representations (Sarko and Reep, 2003). There are only three distinct patches in juvenile and adult specimens (Sarko and Reep, 2004), and this may represent modification and refinement of sensory inputs as manatees develop.

As first noted by Dexler (1913), some areas of the sirenian cerebral cortex contain Rindenkerne (cortical nuclei), clusters of neuron cell bodies in layer VI (Figure 8). Rindenkerne may be specializations akin to the barrels seen in layer IV of the primary somatosensory cortex of other taxa having specific cortical representations for vibrissae (Rice, 1995). Like barrels, Rindenkerne react positively for cytochrome oxidase and some also stain positively for acetylcholinesterase (Reep *et al.*, 1989; Marshall and Reep, 1995). The presumptive face representation consists of the far lateral areas CL1 and CL2 (Figure 7). Area CL1 contains the largest

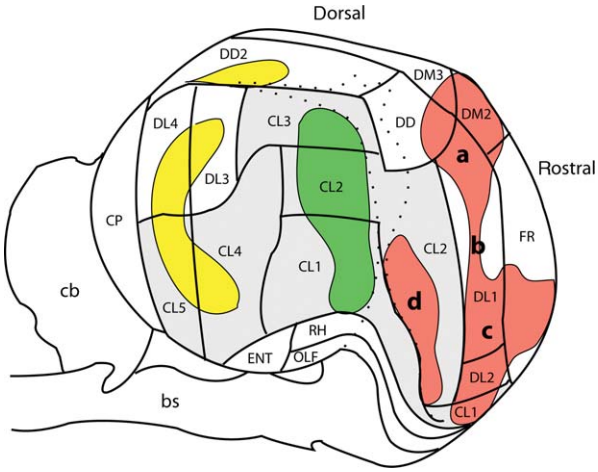

Figure 7 Sensory areas of cerebral cortex. Overlay of cytochrome oxidase staining pattern onto a cytoarchitectural map of the right hemisphere of specimen TM 0310, viewed laterally. Colored areas represent presumptive sensory cortex: orange, somatosensory; green, auditory; yellow, visual. Cortical areas containing Rindenkerne are shaded gray. Within somatosensory cortex are indicated the presumptive representations for the fluke (a), forelimb flipper (b), perioral face (c), oral disk and postcranial body (d). Dotted lines represent the vertically oriented lateral fissure; bs, brainstem; cb, cerebellum.

Rindenkerne (0.4–1.0 mm in diameter), whereas those found in area CL2 are about half this size and are often located more superficially in layer VI (Reep *et al.*, 1989). We hypothesize that the large Rindenkerne in area CL1 are related to the perioral bristles, whereas the smaller Rindenkerne of area CL2 are related to the bristle-like hairs of the oral disk and the postcranial vibrissae. This hypothesis is consistent with the finding that in mice the largest vibrissae are represented by the largest barrels (Woolsey and Van der Loos, 1970). However, if

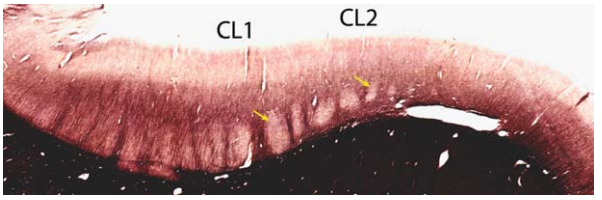

Figure 8 Rindenkerne in the CL1/CL2 transition area. Rindenkerne are clusters of neuron cell bodies that appear as light ovoid regions (arrows) in layer VI in this myelin-stained section. Larger clusters define cytoarchitectural area CL1, whereas smaller clusters mark the transition into area CL2.

the presence of Rindenkerne in the CL fields implies vibrissae representations, why does presumptive primary auditory cortex (see Figure 7) occupy territory in the CL fields? One possibility is that the somatosensory and auditory representations overlap. This would be consistent with a functional continuity between the perception of sound by the auditory system and processing of hydrodynamic stimuli by the vibrissae.

Marshall and Reep (1995) identified three additional cortical areas (CL3–CL5) containing small Rindenkerne. These areas may represent an expanded somatosensory representation for the postcranial vibrissae, but they overlap with the presumptive auditory and visual representations (Figure 7). Furthermore, their location caudal to the lateral fissure (i.e., temporally, given the ventralward rotation of the sirenian brain) argues against this. If these small Rindenkerne do represent vibrissae, then areas CL3–CL5 may be multisensory areas analogous to PV (parietal ventral area) or VS (ventral somatosensory area) (Kaas and Collins, 2001).

3.16.4 Summary

The somatosensory specializations present in manatees appear to be associated with adaptation to aquatic herbivory. Similar specializations are present in the other extant sirenians (Marshall *et al.*, 2003) and have likely been present for millions of years, at least since the divergence of the manatee and dugong lineages. Pronounced somatosensory specializations also exist in the platypus, an aquatic monotreme, and the star-nosed mole, a fossorial insectivore. Unusual cases such as these are important because they represent the range of variation present in sensory systems and their central representations, and thus the known extent of evolutionary potential.

3.17 Somatosensory Adaptations of Flying Mammals

J M Zook, Ohio University, Athens, OH, USA

Glossary

boundary layer	In reference to the airflow around a wing or airfoil, the thin layer of air immediately adjacent to the surfaces where air speed is reduced by surface drag.
camber	Cross-sectional profile of an airfoil with a convex curve to upper surface that provides lift.
homunculus	Schematic, two-dimensional presentation of body surface representations mapped in mammalian somatosensory neocortex.
interfemoral membrane (IFM)	The segment of wing membrane between a bat's legs.
neuroethology	The study of the nervous system in context with the natural behaviors and functional requirements of an organism.
radiohumeral membrane (RHM)	The segment of wing membrane in front of a bat's arm and forearm.

3.17.1 Introduction

As bats represent the only mammals with true powered flight, most of this article considers the bat somatosensory system. Although bat flight has long been observed and studied, surprisingly few data exist on sensory adaptations for flight. The oversight may result from the fact that the bat's somatosensory system has seldom been considered from an ethological viewpoint and almost never considered in terms of the unique capabilities and limitations of the bat hand-wing or how the somatosensory system might support bat flight or flight-related behaviors.

Bat flight has a highly acrobatic quality based on a wing that is largely made up of an elaborated hand (Chiroptera, the order of bats, translates as hand-wing). Figure 1 shows the basic pattern of the bat wing with a membrane of thin skin stretched between body wall with elongated forelimb arm and digits that act as wing-supportive struts. In most bats, a continuation of the wing membrane stretches between the legs (the interfemoral membrane or IFM). In the transformation into an airfoil, the bat hand has become functionally closer to a quadriped's hand than a biped in the sense that the hand-wing is almost entirely used to support the body (at least during flight) with little apparent ability to grip, carry, or manipulate objects. In other mammals, dense or specialized tactile innervation is generally associated with dexterity and a need for feedback in the fine control of manipulation and grip. Surprisingly, there is considerable evidence (from studies beginning over 140 years ago) that the bat wing is densely innervated with a number of potential tactile specializations. Only in the past 20 years, however, have these features been considered in terms of their role in a hand that is specialized for flight rather than manipulation. Before reviewing the earlier and recent studies of the bat somatosensory system, it is useful to consider some of the unique characteristics and challenges of flight and foraging with a hand-wing and specific roles for tactile feedback from the wing (Zook and Fowler, 1982, 1986; Zook, 1985, 2005, 2006; see The Evolution of Neuron Classes in the Neocortex

3.17.1.1 Wing Camber, Boundary Flow, and Lift

Although the dexterity of the bat hand-wing is limited, the bat's limbs and hands retain sufficient joint mobility for a flying bat to adjust the overall shape of the hand-wing airfoil, or even the shape of separate wing segments. With this articulated airfoil, a flying bat can continually adjust its wings to fine-tune the lift properties of wing to enhance control of wing aerodynamics, providing for a level of maneuverability unmatched by most birds.

The shape of an airfoil is critical for generating and sustaining lift properties (specifically the camber of the airfoil, the cross-sectional contour of the wing between leading and trailing edges). (For more complete treatments of bat-wing aerodynamics, see Rayner, 1987; Norberg, 1990; Altringham, 1996.) Figure 2a shows a simplified pattern of the airflow around a cambered airfoil. The parallel lines above and below the wing represent the pattern of laminar flow found within the boundary layer of air that lies next to the wing. Lift is based on the fact that air in the boundary layer must travel farther and thus faster over the top of the airfoil than below the airfoil. With this velocity difference, air pressure above the airfoil is reduced relative to below, and lift is created. When other factors are constant (air speed, angle of wing attack, drag), lift can be amplified by increasing airfoil curvature (camber), but only as long as boundary layer flow is able to follow the curved surface. Figure 2b shows the condition of boundary layer

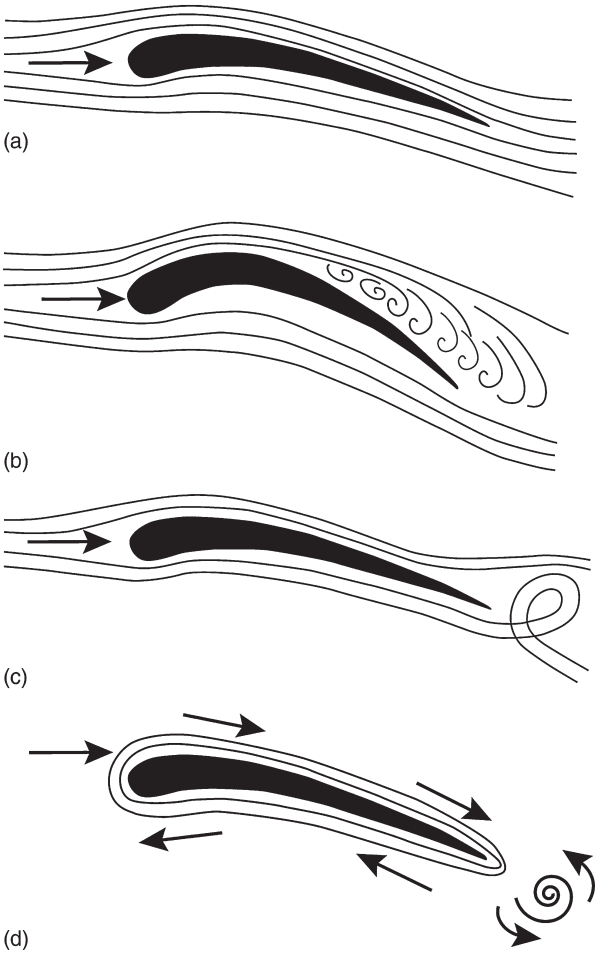

Figure 2 Boundary layer airflow patterns. The curved profiles represent a cross-sectional shape of a typical airfoil (camber), leading edge to left, trailing edge to right. a, Parallel lines represent the typical pattern of laminar airflow in the boundary layer next to wing surfaces. b, Boundary layer separation and boundary turbulence result when airfoil curve or camber is increased past the point where boundary flow can follow the curve. c, Flapping is thought to set up vortex wake patterns which develop and are shed from wing tips or from the trailing edge as shown here. d, During the wing-beat cycle, vortex theory suggests that boundary layer flow will circulate around the wing.

separation, where camber has been increased beyond the point where boundary flow can no longer follow the airfoil surface. Separation results in local turbulence in the flow and a sudden loss of lift (the wing stall point). The bat's control of wing shape allows it to adjust camber to optimize lift (and reduce stall speed). Unfortunately, the complex variables that affect boundary flow in flapping flight make estimation of boundary flow, camber, and stall difficult to judge or predict (Norberg, 1990; Altringham, 1996).

In flapping flight, the wings must provide propulsion as well as lift through changes in wing shape and angle of attack throughout the wing-beat cycle.

Vortex wake theory applied to a flapping airfoil predicts that the boundary layer flow will be pulled into the wing. Rotational currents are set up along wing surfaces, generating local vortex eddies which tend to be shed off the trailing edge of the wing (Figure 2c) or off the wing tips (Rayner, 1987; Altringham, 1996). During all or part of the wing-beat cycle, pressure gradients cause boundary flow to circulate around the wing (Figure 2d) which affect ongoing lift, drag, and propulsive forces acting on the wings (Rayner, 1987; Altringham, 1996; Norberg, 2002). The proposed somatosensory specializations of the bat wing may provide necessary feedback regarding wing lift by monitoring boundary layer flow, turbulence, circulation, and wake patterns (Zook, 1985, 2005; Zook and Fowler, 1986). The basic data to support this theory are reviewed here along with recent physiological and behavioral experiments from our lab (Zook, 2005, 2006).

3.17.1.2 Wing Capture of Active Prey

Although well adapted for flight (Swartz, 1998), the hand-wing's dexterity is limited by the extreme attenuation of its membrane-bound digits as well as the reduced strength and number of intrinsic muscles (Swartz *et al.*, 1996; Norberg, 2002). This functional tradeoff between flight and manipulation abilities presents a real challenge for most foraging behaviors and especially for the midair capture of flying insects. Bats may occasionally use their jaws to snatch insects out of midair, but such direct mouth capture is seldom a real option, given the size of a typical bat's mouth, the size of most prey, and the relative three-dimensional motion between pursuer and evasive prey (Webster and Brazier, 1965; Kalko and Schnitzler, 1998). While wing digits cannot be used to pick insects out of the air, the wings can be cast like nets to sweep a targeted insect out of the air (Vaughan, 1970; Kalko, 1995; Kalko and Schnitzler, 1998).

Once an insect is swept from air to the wing surface, there is still the challenge of transferring prey from the wing to the bat mouth without the ability to grasp the struggling insect during transfer (Webster and Griffin, 1962; Webster and Brazier, 1965; Zook, 2006). Furthermore, since capture generally takes place at night, and wing-gathered insects are too close for effective echolocation, transfer from wing to mouth must take place without either visual or echolocative cues (Fenton, 1990). Despite these challenges, foraging can be quite efficient, with some estimated capture rates greater than 90% (Kalko, 1995; Acharya and Fenton, 1999; Rydell *et al.*, 2002; Surlykke *et al.*, 2003). Feedback from wing cutaneous receptors could play a major role in this remarkable foraging efficiency (Zook, 2005, 2006).

3.17.2 Innervation of the Bat Wing

3.17.2.1 Early Neurohistology

As appropriate neurohistological techniques became available around the turn of the nineteenth century, a number of studies focused on the innervation of the wing (Schöbl, 1871; Sabussow, 1910; Ackert, 1914; see Griffin, 1958; Quay, 1970b, for reviews). These early studies and all that followed noted a particularly dense innervation of wing membranes, with nerve fibers concentrated along the bundles of elastin–collagen fibers that form a weblike network of prominent bands within all membranes, as shown in Figures 1 and 3 (Gupta, 1967; Holbrook and Odland, 1978). Most observers have commented on the regular series of raised domes distributed in the skin over the membrane bands. As shown in Figures 3 and 4, each dome is marked by a central hair follicle that is surrounded

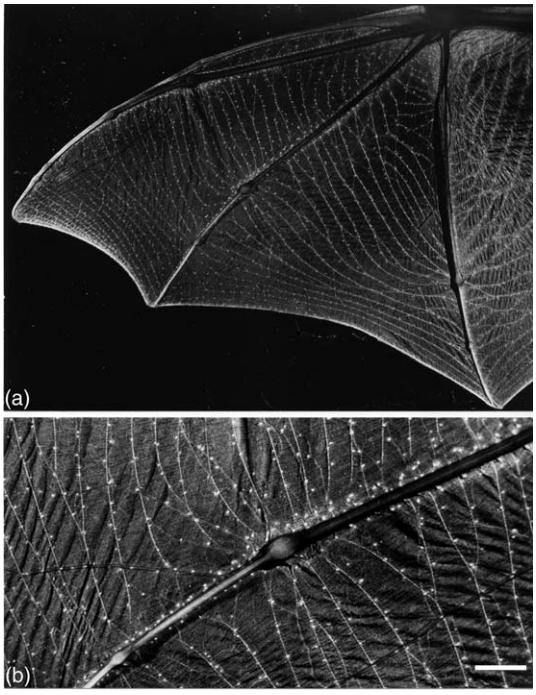

Figure 3 Photographs of transilluminated wing membranes from an *Antrozous pallidus* wing. a, Low-magnification photograph of the distal wing segments. b, Close-up view of the finger joints of the fourth digit shown in (a). Note the weblike pattern of membrane elastin–collagen bands that span the wing with a tendency to converge at wing joints. Both photographs also show the typical wing pattern of single domes spaced along the bands as well as the tendency for domes to be concentrated near digits and joints. Scale bar: 2 mm. Reproduced from Zook, J. M. and Fowler, B. C. 1986. A specialized mechanoreceptor array of the bat wing. *Myotis* 23, 31–36, with permission.

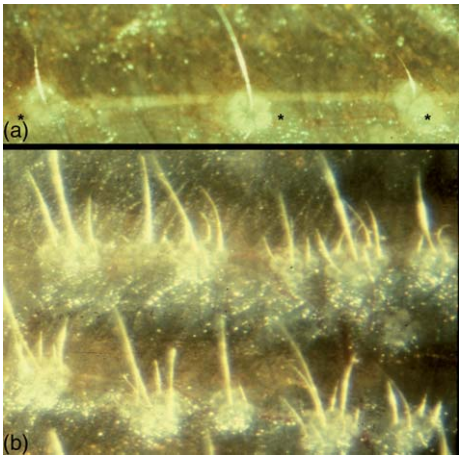

Figure 4 High-magnification photomicrographs of wing membrane domes from an *Antrozous pallidus* wing. a, A close-up view of the main wing pattern of single domes spaced along a membrane band. Asterisks mark the shadows of transilluminated domes positioned on the opposite membrane surface. b, A view of band-associated arrays of dome clusters found on both surfaces of the IFM. The average diameter of domes are 100 μm (a) and 250 μm (b).

by prominent sebaceous and apocrine glands (Schöbl, 1871; Ackert, 1914; Gupta, 1967; Quay, 1970a; Zook and Fowler, 1986; Crowley and Hall, 1994). Studies with a neurohistological focus consistently noted concentrations of nerve fibers and endings within the domes' dermis, basil epidermis, and at the hair follicle (Schöbl, 1871; Ackert, 1914; Quay, 1970b). In several microchiropteran species, free nerve endings and a number of possible terminal specializations were also reported in association with wing domes (Sabussow, 1910; Ackert, 1914).

Largely for historical reasons, none of the wing studies published before the 1980s had made an association between the rich innervation of the bat wing and possible sensory demands of flight and wing foraging. Before 1930, studies of the bat wing were dominated by the curious, but prevailing, theory that bats were able to navigate and forage in the dark due to a special tactile sixth sense of their wings. This tactile-navigation theory had been promoted by Georges Cuvier and others from the end of the eighteenth century. Touch remained the predominant explanation for the bats' blind-navigation skills for over a century, even though the Italian scientist, Lazzaro Spallanzani, had reported compelling experimental evidence of the role of bats' ears in distance navigation as early as 1795 (for reviews, see Dijkgraaf, 1949; Griffin, 1958; Neuweiler, 2000). The wing tactile theory persisted largely because, before the discovery of ultrasound and echolocation, no one could see how the ears could provide the distance sensing necessary for navigation.

In 1908, Walter Hahn came closest to associating wing tactile receptors with flight (and bat ears with navigation) when he observed that bats with grease-coated wings had trouble flying while bats with earplugs could fly but had trouble avoiding obstacles (Hahn, 1908). Hahn's mixed results did not deter Maxim (1912), who, in an attempt to improve ship navigation, came up with the most concrete mechanism for a tactile-based navigation sense. Maxim proposed that the bat's own wing beats generated a series of propagating, low-frequency waves – waves that could be reflected back from obstacles and processed by cutaneous receptors of the bat's wing (and face). The bat illustrated in Figure 1 appeared in Maxim's (1912) *Scientific American* article, where he introduced his design for a ship-based iceberg detector derived from the bat's supposed tactile navigation. Maxim's original caption noted: "This bat furnishes us with a very good illustration of the sensitive wing that enables a bat to send out vibrations and to receive the echo. The spots on the wing probably represent nerve centers." Although his first conjecture was off the mark, his second observation has proven quite prophetic.

Prior to these early wing studies, Merkel (1875) and Pinkus (1905) had separately described raised dome structures with a potential sensory function in other mammalian skin. These touch domes were named for their concentration of nerves and specialized terminal cells, Merkel cells, in the dome's basal epidermis (Iggo and Muir, 1969; Halata *et al.*, 2003). Merkel cells and their associated nerve terminals have come to be recognized as one of the four basic classes of mammalian tactile receptors (Smith, 1967; Iggo and Muir, 1969; Johnson, 2001; Halata *et al.*, 2003). Although not noted until later (Zook and Fowler, 1982), the bat domes bear a close resemblance to a less common form of touch dome–Merkel cell complex, a Haarscheibe, distinguished from other touch domes by a central or peripherally placed hair follicle (Pinkus, 1902; Smith, 1967).

Following the discovery of echolocation, the bat's wing received less attention, considered mainly in terms of the thin membrane's value for study of neurovascular, glandular, or lymphatic systems (reviewed in Quay, 1970a). Although the few additional histological studies mentioned the innervation of wing in passing, none directly addressed the possibility of a sensory role of the wing in flight and flight behaviors (Schumacher, 1932; Gupta, 1967; Quay, 1970b). It was not until almost 50 years later, in light of new attention on bat somatosensory neocortex in the 1980s, that wing innervation and wing domes were to be

considered in terms of flight (Zook and Fowler, 1982; Calford *et al.*, 1985).

3.17.2.2 Studies of the Somatosensory Central Nervous System

These cortical studies began with electrophysiological mapping of bat wing and body representation in primary somatosensory cortex (S1), and were mainly driven by evolutionary, comparative interests (Calford *et al.*, 1985; Wise *et al.*, 1986; Krubitzer, 1995). Most have been extensively reviewed elsewhere (Krubitzer *et al.*, 1993; Krubitzer, 1995) and will be summarized here only to the extent that they are relevant for flight adaptations. The majority of these studies were undertaken in species from the nonecholocating, frugivorous megachiropteran suborder of bats. The megachiropterans possess well-developed visual and olfactory systems useful for diurnal fruit foraging. As fruit eaters, their flight is not as finely tuned as it is in Microchiroptera, and tactile specializations may be less elaborate, particularly in comparison to insectivorous species which must actively pursue evasive prey in the night air. It is worth noting here that all of the primary studies reported large central neural representations of the hand-wing in Megachiroptera (Calford *et al.*, 1985; Krubitzer *et al.*, 1993; Martin, 1993; Manger *et al.*, 2001a, 2001b) as well as Microchiroptera (Zook and Fowler, 1982; Wise *et al.*, 1986).

3.17.3 Somatosensory Receptors of the Wing

3.17.3.1 Surface Features

Re-examination of the somatosensory periphery initially focused on the wings of the microchiropteran bat, *Antrozous pallidus*, and quickly began to reveal new details of the wing somatosensory system (Zook and Fowler, 1982, 1986). As *A. pallidus* is specialized as a gleaning/terrestrial foraging insectivore, two additional species were added to these studies, *Pteronotus parnellii* (an aerial/gleaning feeder) and *Eptesicus fuscus* (an aerial feeder).

The domes found on the bats' wing membranes were both more numerous and more highly organized than the Haarscheibe observed in other species (Smith, 1967). Similar to the earlier wing descriptions, domes in these species were distributed in regular arrays spaced out along wing elastin–collagen bands (Figures 3 and 4a), with additional concentrations grouped along the edges of wing bones (Figure 3). Individual domes were often spaced along the leading and trailing edges of the wing and scattered over limb bones and digits. In all three species, the density of domes per unit area varied between wing segments with a general increase toward the leading and trailing edges as well as wing tips. While dome distribution patterns were similar across the wings of all species, there is variation in dome diameter (100–400 μm), hair size, and hair length as well as specialized regional distributions (see discussion of the IFM, below). The largest domes were found in *A. pallidus*, most likely a byproduct of the exceptionally large, dome-associated glands in this desert-dwelling species.

In all species examined, domes appear to be distributed over the two sides of each wing membrane in almost mirror-image patterns. This can be appreciated in Figure 4a (*A. pallidus*), where each dome and hair projecting from the ventral surface is almost always closely opposed to a dome on the dorsal side (asterisks in Figure 4a).

The IFM was distinguished by a very different pattern, with small clusters of domes spaced out along the elastin–collagen bands of the membrane. This cluster pattern was particularly distinct over the dorsal and ventral surfaces of the IFM in *A. pallidus* (Figure 4b). Light microscopy and scanning electron microscopy showed that each IFM cluster consisted of a large, central dome with an unusually long hair surrounded by five to six smaller domes, each with a shorter, smaller-diameter hair (Zook and Fowler, 1982, 1986). The IFM clusters were also seen in the other species examined, but these were generally more randomly organized.

In their histological examination of the megachiropteran wing, Crowley and Hall (1994) found similar dome structures on the wing surfaces of several megachiropteran species. The megachiropteran domes differed in size of dome and diameter of dome hairs (respectively 2× and 5× larger) and in dome distribution across wing membranes. Although the megachiropteran wing membranes have similar elastin-band arrays, Crowley and Hall reported that megachiropteran domes were neither specifically associated with wing elastin bands nor regularly distributed across wing surfaces. There did not appear to be any special dome clustering or dome distribution on the megachiropteran IFM. Crowley and Hall did note that megachiropteran domes were particularly concentrated in lines running over elevated or projecting features of the wing, such as the larger membrane blood vessels, membrane-bound muscles, and wing bones. These particular locations may improve the mechanical isolation of domes from the surrounding wing membranes or could raise domes and dome hairs away from the wing surfaces to sample better specific regional boundary layer flow patterns.

3.17.3.2 Dome Neurohistology and Primary Afferent Recordings

Preliminary studies of bat wing with modern histological techniques (Zook and Fowler, 1982, 1986) revealed a large population of presumptive Merkel cells (arrowheads, Figure 5) concentrated at the basement membrane along the dome surface and surrounding the hair follicle. Following the classic description of Merkel cells (Pinkus, 1905; Smith, 1967; Halata *et al.*, 2003), these dome cells were typically large, clear cells with lobulated nuclei restricted to the epidermal basal lamina. This identification has been supported by more recent histology (Zook, 2005) showing a positive staining of these cells with both Merkel-specific quinacrine fluorescence (Nurse *et al.*, 1983) and a cell-specific antibody to the cytokeratin protein, CK20 (Moll *et al.*, 1995). Nerve fibers within the dome complex can be traced to individual Merkel cells, although free nerve endings and as yet unidentified specialized nerve terminals were identified around the dome hair follicle.

Preliminary recordings of wing dome primary afferent nerves have been made in the microchiropteran species, *A. pallidus* and *E. fuscus* (Zook and Fowler, 1986; Zook, 2005). These studies used suction and hook electrodes to isolate and record single afferent fiber activity from either a main limb nerve or from a smaller membrane nerve bundle isolated within the proximal wing membranes. Recorded afferents generally showed low-threshold responses to light touch or air-puff stimuli and could be characterized as either slowly adapting (SA) or rapidly adapting (RA) units. Both SA and RA responses could be associated with tactile stimulation of specific domes or wing regions. Afferent SA responses could be elicited by direct contact with an individual dome or from a small cluster of domes. Responses generally could not be elicited from light touch of the wing membrane surrounding a responsive dome or in between domes. Such response patterns are typical of Merkel cells in other mammals which are distinguished by their mechanically isolated, SA response patterns (Iggo and Muir, 1969; Halata *et al.*, 2003). In some wing afferent recordings, SA responses could be elicited by contact or movement of the dome hair. Still other dome-associated afferents showed primarily RA responses to hair movement. These latter afferents were particularly sensitive when air puffs were used to move dome hairs.

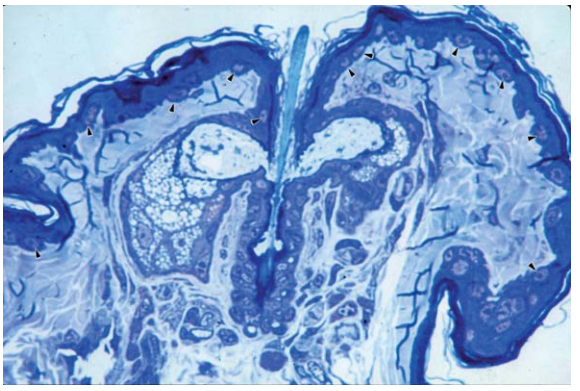

Figure 5 A high-magnification photomicrograph of a wing membrane dome in cross section. Methylene blue stain from *A. pallidus*. The darkly staining epidermis contains a number of clear cells, Merkel cells, along the boundary with the lighter-staining dermal layer. Concentrations of Merkel cells are also found encircling the centrally placed hair follicle above and below the dome's large sebaceous glands. The cross-sectional width of this dome is 120 μm.

The large-nerve recordings revealed another population of less selective RA afferents with a generalized response to membrane contact or membrane stretch. These afferents were characterized by medium to large receptive fields involving substantial portions of a membrane segment and often including a portion of a neighboring arm or digit. In many cases, these stretch-responsive afferents showed eccentric receptive fields with a point of greatest sensitivity near the convergence of multiple elastin bands at joints of the digits, wrist, or arm with a larger, less sensitive response field extending out from the side of the joint toward the middle of an adjacent wing membrane (Zook, 2005, 2006). Primary afferents serving cutaneous receptors in the IFM have not been examined.

Perhaps these studies' most interesting observation was the degree to which responses to threshold stimulation were confined to one or the other surface of a wing membrane. In other words, a given afferent might respond vigorously to the slightest contact with the dorsal membrane surface while remaining silent with even major deflections of the opposing ventral membrane surface. This surface-specific response was quite unexpected, given the extremely thin wing membrane skin that ranges in thickness from less than 0.03 mm in aerial-feeding insectivores to around 0.06 mm in many terrestrial-feeding microchiropteran species (Studier, 1972). megachiropteran species can have somewhat thicker membranes up to around 0.25 mm (Crowley and Hall, 1994). Given these dimensions, it is difficult to see how these receptors on opposing wing surfaces could be both sensitive to surface contact yet mechanically isolated from stimulation of the opposing surface.

The surface-specific response phenomenon was most dramatic in the case of the broadly sensitive,

large-field, stretch receptor population. Although afferents associated with stretch receptors responded to the slightest surface contact within its receptive field, almost all were markedly insensitive to gross stimulation of the opposite membrane surface, including gross physical deformations. The smaller receptive fields associated with dome and dome hair receptors were also more mechanically isolated from stimulation of the membrane surface directly opposing the dome than to the surrounding membrane on the same side as the dome. This uncoupling of membrane surfaces could be useful for selective discrimination of different airflow patterns over dorsal and ventral surfaces or may even be useful for improving the detection and localization of insect prey in contact with a wing surface.

The structural and physiological bases of this surface-specific receptor sensitivity have yet to be explored. It would seem likely that the limited mechanical isolation between surfaces could be enhanced by some form of mutual, contralateral inhibition within the local receptor population (Zook, 2005). Among the topics yet to be explored are the suggestion of afferent responses to directional stimulation of dome hairs and dome clusters, and the possibility of selective response of dome hairs to specific airflow or turbulence patterns.

Different types of wing hairs and pelage hair distributions have been observed over the wings of some microchiropteran species. While the forearm bones in most bats project above the membrane surface, such drag-inducing protrusions may be smoothed out by a tapered pattern of surrounding pelage hairs observed in some species, most notably in the swifter-flying Microchiroptera, where drag is a major factor (Vaughan and Bateman, 1980). A similar tapered extension of pelage hairs may smooth the transition between body and dorsal IFM (Vaughan, 1970). For slow-flying species, Vaughan and others have suggested that the projecting forearm bones or other hair patterns might be used to induce a measured degree of turbulence into the boundary air layer as a means of reducing flow separation from the wing reducing drag (Vaughan, 1970; Hill and Smith, 1984; Norberg, 2002).

3.17.3.3 Possible Roles of Tactile Receptors in Flight

The observed wing stretch receptor population has the most obvious potential role as a means of monitoring wing and wing membrane strain during sudden turns or extreme flight maneuvers (Zook, 2005). A number of studies have noted the fine balance struck by the wing between the need to conserve flight mass and the requirements for structural support (Studier, 1972; Swartz *et al.*, 1996; Swartz, 1998; Norberg, 2002). The ability to gauge relative strain on delicate wing elements during flight would seem crucial for all bats. A possible secondary role for stretch receptors in foraging (Zook, 1985, 2005, 2006) will be covered in the next section.

Domes and dome hairs show a number of characteristics that would make them suitable for monitoring boundary layer airflow, such as their ordered distribution across all wing surfaces as well as their mechanical isolation from the membrane and sensitivity to air stimuli. A preliminary survey across species suggests that the greatest variation in dome distributions may be found between species specialized for either slow or fast flight, which may have different requirements for monitoring boundary flow or wing vortex patterns (Zook and Fowler, 1986).

One preliminary behavioral study explored the potential role of dome hairs in flying bats (Zook, 2005). Several bats of the species *A. pallidus* and *E. fuscus* were flown in a lab setting after a depilatory cream was used to remove dome hairs from all wing surfaces. Flying bats without dome hairs showed no obvious difficulties during straight flight or when performing shallow turns. Flight performance, however, was clearly affected during sharp-angle turns. Although there were wide variations between tests and among bats, all showed abnormally large changes in flight elevation during most turns, often taking the form of an oscillating pattern of elevation changes. Following regrowth of dome hairs, normal turning behavior was re-established in each test bat, marked by a gradual rise during entry into the turn and a smooth transition through the turn (Aldridge, 1987).

Sharp turns are among the more complex of flight maneuvers, involving sudden braking, loss of air speed, and major changes in wing position and conformation (Norberg, 1985, 1990; Aldridge, 1987). Although preliminary, these hair ablation experiments suggest that dome hairs may be particularly involved in complex flight maneuvers that require rapid and precise adjustments of wing camber to maintain optimal lift. Similar wing-spanning sensory arrays would presumably be useful for birds, but in a feathered wing, sensory feedback for lift control may be obtained from extracutaneous receptors, specifically from muscle spindle populations in the avian forearm (Brown and Norberg, 1997). In bats, similar proprioceptive-based feedback could be provided by the muscle spindle afferents of the intrinsic membrane, striated muscles found within the proximal wing of many bats (Schumacher, 1932; Gupta, 1967; Crowley and

Hall, 1994). While the main role of these membrane-bound muscles may be for shaping or tensioning the membrane during flight (Swartz *et al.*, 2004), their spindle afferents might also signal local membrane disturbances, such as the ripples or fluttering that would result from boundary layer turbulence (similar to the lufting motion of a poorly trimmed sail).

Apart from a potential role in monitoring boundary flow, the clustered domes of the IFM are particularly intriguing in light of the proposed roles of this membrane in flight and aerial stability. Although the IFM is not present in all species and thus may not be essential for flight (Vaughan, 1970; Hill and Smith, 1984), it does add an additional lift surface and may aid in flight maneuvers such as an air brake during turns or as a flap for adjusting longitudinal stability (Vaughan, 1970; Norberg, 1985). Since bats have a short fuselage and lack long tails, pitch control may have to be actively maintained, possibly by curving the IFM either upward or downward to counterbalance shifts between a bat's center of mass and center of lift during different parts of the wing-beat cycle (Vaughan, 1970; Rayner, 1987). The IFM's elaborate dome arrays may provide feedback to optimize vestibulomotor reflexes controlling longitudinal stability (Zook, 2005). Wing dome hair arrays and their regional patterns need to be explored in terms of their potential interaction with vestibular and motor control of flight and flight stability in all dimensions (Horowitz *et al.*, 2004).

3.17.3.4 Possible Roles for Wing Receptors in Foraging

All or part of the wing receptor array could be used for locating, tracking, and assisting transfer of wing-gathered prey from initial contact point to mouth. Given their distribution, response patterns, and mechanical isolation, wing domes and dome arrays could provide fairly accurate positional feedback to aid in locating prey during manipulation and transfer (Zook, 2005, 2006). Insect movement and direction of movements across the wing surfaces could be tracked from a sequential stimulation of individual domes, dome hairs, or dome hair arrays.

The IFM is a favored site for capture in all kinds of foraging (Webster and Brazier, 1965; Arlettaz, 1996; Kalko and Schnitzler, 1998). While the IFM can be cupped more than the other wing membranes, struggling prey still cannot be pinned in place. Tactile feedback from IFM dome clusters might provide even more feedback on prey contact points or the direction of prey movement than the spaced dome arrays of the main wing. The main wing membranes of the forearm are the second most common sites for prey contact during aerial foraging. While the forearm and digits provide a longer reach for sweeping in prey than would be possible with the IFM, the forearm wing cannot be cupped for containing prey to the degree possible with the IFM (Arlettaz, 1996; Zook, 2005, 2006).

Forelimb sweeping motions may offer another advantage during capture. By continuing the wing's sweeping motion through the contact point, a bat may use the wing's acceleration and the insect's inertia to stick the insect to the wing membrane. Such an inertia-pinned insect would be easier to control during the short but critical transfer from wing to mouth. While the large receptive fields of the stretch receptors may not be useful for precisely locating wing-gathered prey, they could provide a means to monitor where the insect first contacts the wing membrane (Zook, 2005, 2006) and how well the insect is pinned to the wing contact point.

3.17.4 Central Somatotopic Representation of the Bat Wing: A Neuroethological Perspective

The observed peripheral tactile specializations provided an impetus for examining neocortical somatotopic representations of the wing in *A. pallidus* (Zook and Fowler, 1982). At the same time, a series of other studies were begun that mapped somatotopic representations of wing and body in several megachiropteran species, focusing primarily on the comparative and evolutionary implications of these cortical maps (Calford *et al.*, 1985; Wise *et al.*, 1986). As with most central sensory maps, these somatotopic maps generally reflect the relationships and proportions of the related sensory surface, in this case skin tactile receptors, with a disproportionate representation of peripheral structures that have particularly rich innervation. Figure 6 shows comparable schematic representations (homunculi) of bat somatotopic maps from primary neocortical area S1. Figure 6a is a homunculus redrawn from Zook and Fowler (1982), while Figures 6b and 6c represents homunculi respectively from a different microchiropteran species and a megachiropteran species (Wise *et al.*, 1986). A rat homunculus is included for comparison (Figure 6d).

Focusing on the wing representations, all four bats showed an enlarged representation of the hand with a disproportionate representation of the thumb, the only free digit of the hand-wing. All the bat maps contain representations of the remaining digits and

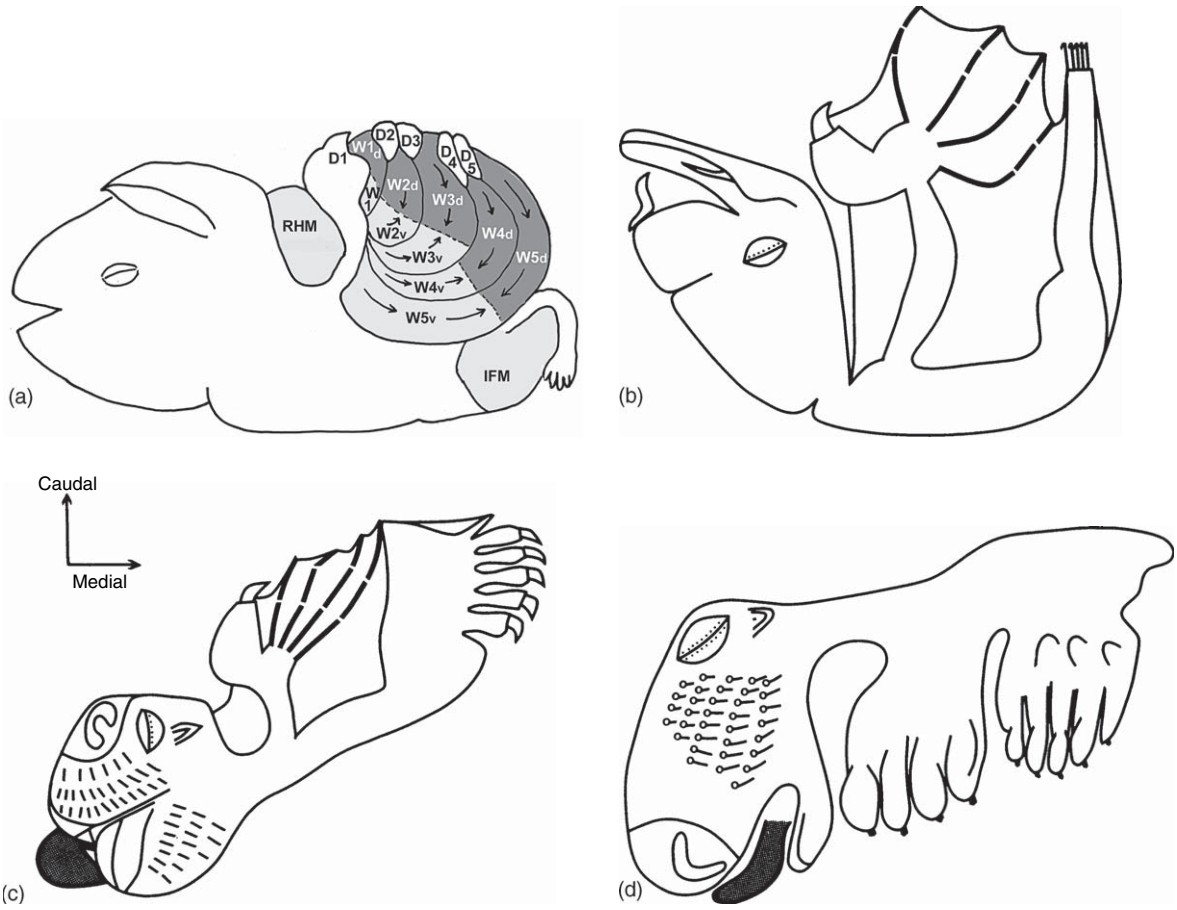

Figure 6 Schematic representations of the body surface (homunculi) from mapping studies of primary somatosensory cortex (S1) from two microchiropteran bats: a, *Antrozous pallidus* data (partly) from Zook and Fowler (1982); b, *Macroderma gigas* from Wise *et al.* (1986); and c, the microchiropteran bat *Pteropus poliocephalus* from Calford *et al.* (1985). A homunculus from the rat is shown in (d). Maps are not to scale, but are all oriented to match the position of the original cortical recordings on the surface of the cortical hemisphere. As indicated by the marker, the right side of each map is closest to the cortical midline, the left (face) side of each map is toward the lateral side of the hemisphere, while the top of each map is oriented toward the caudal pole of the brain. The bottom of each map is oriented toward the rostral pole of the brain. In map (a), the wing membranes (dark and light gray shading, labeled W1–W5) were represented somewhat separate from the digits (digits 1–5 labeled D1–D5) with a separate representation of each membrane surface (ventral=light gray, dorsal=dark gray). Each membrane surface representation was internally consistent, but flipped along the trailing edge (dashed lines). The arrows point the membrane maps' progression in the representation from leading to trailing edges. The ventral surface leading edge begins near the palm/D1 while the dorsal surface leading edge begins near the digits D2–D5, with both representations converging into the single trailing edge representation. RHM, radiohumeral membrane; IFM, interfemoral membrane. b–d, Reproduced from Somatosensory cortical representation in the Australian ghost bat, *Macroderma gigas*, *J. Comp. Neurol.*; Wise, L. Z., Pettigrew, J. D., and Calford, M. B.; Copyright © 1986, Wiley-Liss. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

wing membranes. In the Zook and Fowler map, however, membrane segments are partially segregated from the digits and include separate representations of the dorsal and ventral forelimb membrane surfaces. The other bat-wing representations report a single wing surface with digits positioned between wing segments. It is not clear whether surface-specific responses were encountered in these latter studies.

The difference between results in the different bats may be a matter of the different techniques or species used. Most somatotopic mapping studies depend almost exclusively upon surface-stimulating probes to elicit a standard response over all skin regions and across species. In order to elicit surface-specific responses from the wing membranes, the Zook and Fowler studies used a combination of tactile probe and air-puff stimulation. Air puffs may have selectively stimulated a subset of skin tactile receptors, imposing a modality bias on the cortical maps. In other species, when the different submodalities of tactile sensation are independently mapped on cortex, the somatotopic patterns can be quite different from the more standardized, probe-based map (Dykes, 1983; Friedman *et al.*, 2004). It is also

possible that the dual-surface pattern is unique to a subset of microchiropteran bats with specific flight or foraging requirements. Of the two microchiropteran species represented in Figure 6, *A. pallidus* is a gleaning and terrestrial insectivore known for the use of passive sound localization and highly maneuverable flight (Fuzessery *et al.*, 1993), while *Macroderma gigas* is an exceptionally large carnivorous bat with a well-developed visual system and less acrobatic flight (Wise *et al.*, 1986).

One of the most striking aspects of the surface-specific membrane representation in *A. pallidus* is the internal consistency within the two membrane surface maps. The ventral surface map reflects the hand and membrane pattern seen in the other bats in Figure 6, with the membrane segments extending caudally from the hand and thumb (D1) representations. At the trailing edge of the ventral surface representation, the membrane map flips to begin representing the dorsal surface, progressing from trailing to leading edge (arrows in the two membrane surface maps begin near the representation of the leading edge and point toward trailing edge representation where the surface maps converge). The fact that peripheral separate-surface response patterns are retained to the level of S1 may indicate a degree of independent processing of the two surfaces' receptor populations.

These wing-specific features aside, the general pattern of cortical body maps were otherwise quite consistent among these bat species (Wise *et al.*, 1986; Krubitzer, 1995). The greatest variation appears in the hindlimb placement, which may reflect the difficulty in mapping this underrepresented area (Calford *et al.*, 1985). Compared to S1 cortical maps in other mammals, however, the mapped position of the bat forelimb was strikingly different. In the general mammalian pattern, the representation of the limbs projects rostrally in the brain (see the orientation bars in Figure 6) and is mapped on the homunculus ventral from the trunk and below the head with the digits projecting rostrally (Figure 6d). In the bats (Figures 6a–6c, the forelimb and digital representation extended toward the caudal brain so that the homunculi map's arm and wings project dorsally away from the trunk and above the head. This partial map reversal was first noted by Calford *et al.* (1985) and has been consistently observed in all species examined (Zook and Fowler, 1982; Calford *et al.*, 1985; Wise *et al.*, 1986; Krubitzer *et al.*, 1993). Comparisons of bat and general mammal somatosensory pathways and subcortical maps have shown that the limb reversal is set up through a series of transformations between the sensory periphery, dorsal column nuclei, and somatosensory thalamus (Martin, 1993; Manger *et al.*, 2001a, 2001b).

Calford and others have suggested that the digital reversal may be a cortical reflection of the manner that bats' hands are held at rest with digits positioned caudal to the hand and arm (Calford *et al.*, 1985; Wise *et al.*, 1986). While there is no direct evidence to support this habitual position theory, it is intriguing, as it implies a major proprioceptive influence in the ordering of these somatotopic maps. Joint proprioceptive, muscle spindle, and other extracutaneous somatosensory modalities have not been examined in bats but may all play a role in facilitating the exquisite vestibulomotor control exhibited by night-flying and night-foraging bat species (Horowitz *et al.*, 2004). Proprioceptive somatosensory modalities are likely to play a central role in night navigation, and may be critical for the bat's extraordinary ability to memorize and navigate complex flight paths without echolocation or other sensory guidance (Möhres and Oettingen-Spielberg, 1949; Griffin, 1958).

3.17.5 Future Prospects for Somatosensory Study of the Bat Wing

The study of the somatosensory system in mammalian flight has a history of misdirection, neglect, and lack of clear focus. Hopefully this article has given a sense of the possibilities for future study and the potential of the neuroethological approach that has proven so successful in the exploration of bat echolocation. While the focus here has been on the bat wing, cutaneous receptors of the head and face may offer an even greater range of specializations, for example, the thermal and tactile receptors in vampire bats (Kürten and Schmidt, 1984; Kürten, 1985). With regard to the wing, more data are needed, focusing on a comparative neurohistology of the chiropteran wing and a closer examination of cortical representation of the wing in a broader range of representative species. With regard to broader comparisons, there may be some interesting similarities between bat dome arrays and the manatee's array of tactile body hairs (see 00068). The manatee hairs appear to function as a mammalian lateral-line system for the detection of water currents and other near-field phenomena (Reep *et al.*, 2002). In a manner similar to Maxim's proposed tactile sixth sense, a manatee's tactile hairs could serve as part of an active, remote-sensing system capable of detecting and interpreting echo patterns from pressure waves set up by the manatee's own movements.

Further study of both peripheral and central adaptations needs to establish behaviorally

appropriate stimuli to explore proprioceptive as well as cutaneous somatosensory receptor populations in terms of flight and flight-related behaviors. Although interesting in themselves, the wing dome arrays and the uncoupling of wing membrane responses and representations suggest that the main somatosensory adaptations for flight may lie in the population responses, the interplay of feedback from cutaneous and extracutaneous receptors, and their integration within the motor and vestibulomotor reflexes that optimize flight control (Horowitz *et al.*, 2004). This broader perspective of the role of somatosensory specializations in mammalian flight could lead to a greater appreciation of the sensorimotor mechanisms involved in vertebrate flapping flight as well as the role of feedback in the design and optimal control of micro air vehicles (Shyy *et al.*, 1999; Norberg, 2002).

3.18 Evolution of Pain Pathways

A D Craig, St. Joseph's Hospital and Medical Center, Phoenix, AZ, USA

Glossary

ACC	The anterior cingulate cortex (a portion of limbic motor cortex), where the behavioral motivations associated with homeostatic emotions are represented.
dpIns	The dorsal posterior insular cortex (a portion of limbic sensory cortex), where the representations of pain, temperature, itch, and other interoceptive sensations are located in primates.
homeostasis	The ongoing dynamic neural processes that maintain the physiological condition of the body.
insular cortex	The viscerosensory or limbic sensory cortex, which is called the insula, or island, because in the human brain it is buried inside the folds of the lateral sulcus.
interoception	Used here to mean the sense of the physiological condition of the body.
lamina I	The most superficial layer of the spinal (and trigeminal) dorsal horn.
MDvc	The medial thalamic nucleus that relays lamina I spinothalamic projections to anterior cingulate cortex in primates.
spinothalamic tract	The ascending pathway from the spinal cord to the thalamus.
VMpo	The lateral thalamic nucleus that relays lamina I spinothalamic projections to insular cortex in primates.

3.18.1 Introduction

Pain has traditionally been classified as an aspect of somatic sensation, for the obvious reason that pain is, first of all, a physical sensation we feel from our bodies. Accordingly, it was thought for many years that pain is represented within the same somatosensory system that represents the exteroceptive sense of touch and the proprioceptive sense of limb movement (the dorsal column – medial lemniscal system). The highly organized somatotopic maps of the body in the somatosensory cortices of mammals (see Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications) were thought to be necessary to explain the fact that pain, like touch, is a discriminative sensation that can be localized quite well on the skin surface.

Nevertheless, as we all recognize, pain can originate from any part of the body (that is, not just skin) and it has a strong emotional quality – a motivational affect – and other mystifying qualities (sensitization, radiation, wind-up, persistence, and so on) that make it quite different from touch and other classical senses like hearing and vision. Furthermore, the presumption that the somatosensory cortices have a critical role in pain is strongly contraindicated by the repeated observations that lesions and stimulation of the somatosensory (or perhaps better, sensorimotor) cortices, which definitively alter mechanoreception and proprioception, rarely have any affect on pain, temperature, itch, and other feelings from the body.

Although many textbooks today still describe pain as an aspect of the somatosensory system, recent functional anatomical evidence demonstrates that human pain sensation is subserved by a novel, unforeseen sensory pathway that is a phylogenetically distinct extension of an ancient, hierarchical

system that conveys ascending afferent activity associated with homeostasis – the maintenance of the physiological condition of the body. In primates, this system provides the basis for a high-resolution, modality-specific sense of the condition of the body (interoception redefined). In humans, higher-order re-representations of this system provide a substantive basis for the subjective awareness of the material me, that is, how you feel. These re-representations, as it turns out, are involved in all subjective feelings and emotions, consistent with the James–Lange theory of emotion and Damasio's somatic marker hypothesis of consciousness.

The homeostatic afferent (or interoceptive) system conveys afferent activity associated with all feelings from the body other than discriminative mechanoreception (touch) and proprioception (limb movement); these feelings include hot, cold, and mechanical pain, innocuous thermal sensations (warm, cool), itch, muscle burn, ache and cramp, visceral movement and cramp, visceromotor flush, and even sensual (C-fiber-mediated) touch. The essential psychophysiological distinction between these somatic feelings and the sensations of mechanoreception and proprioception is that these feelings all relate the physiological condition of the body, which is reflected in their association with an immediate affect (pleasantness, unpleasantness) that is the perceptual correlate of the homeostatic behavioral motivation they drive. For example, the sensation of muscle burn relates the deficient metabolic condition of the muscles (hypoxia, hypercapnia, and increased lactate) to the forebrain limbic behavioral control systems. The essential neurobiological distinction between these somatic feelings and the sensations of touch and limb movement is that they are all subserved by small-diameter afferent fibers and provide the afferent information required for homeostatic control of smooth muscle, whereas mechanoreception and proprioception are subserved by large-diameter afferent fibers that provide afferent information required for control of skeletal muscle. This fundamental functional distinction is made early during the ontogeny of the dorsal root ganglia and the spinal cord, and in primates this fundamental distinction is maintained in distinct patterns of thalamocortical organization. Thus, the cortical representation of these feelings from the body is located in a region associated with autonomic control rather than musculoskeletal control.

The evidence for these concepts has been described in detail in several recent reviews (e.g., Craig, 2002, 2003). In the following, I describe the organization of the human pain pathway, I discuss the comparative anatomy of the pain pathway in subhuman mammals, and then I address the evolutionary pressures that can be inferred to have led to the development of this system in the human brain. Because this system is more accurately termed a homeostatic afferent pathway, it should only nominally be called a pain pathway.

3.18.2 The Human Pain Pathway

Considerable clinical evidence documents the statement that lesions that alter or interrupt pain sensation occur in the anterolateral spinal cord, the posterolateral thalamus, the posterior parietoinsular cortex, or the anterior cingulate cortex (ACC). Similarly, stimulation in each of these regions can cause pain. Activation in the posterior parietoinsular and ACCs is also found in all evoked potential and functional imaging studies of pain. The anatomical substrate responsible for these findings is the lamina I spinothalamocortical pathway, as described in the following text.

3.18.2.1 Primary Afferent Connections

Small-diameter (A-delta and C) primary afferent fibers that report all aspects of the physiological status of all tissues of the body (which include nociceptors, thermoreceptors, osmoreceptors, and metaboreceptors from skin, muscle, bone, and viscera) terminate monosynaptically on neurons in lamina I of the spinal (and trigeminal) dorsal horn. Lamina I neurons provide the output of the superficial dorsal horn, which otherwise contains local interneurons. During development, the large-diameter primary afferents from mechanoreceptors and proprioceptors arrive in the dorsal horn first and contact the deep dorsal horn cells. Then the entire dorsal horn rotates ventromedially, and the small-diameter primary afferents arrive in a second wave that is genetically coordinated with the arrival of lamina I neurons. The lamina I neurons originate from progenitors of autonomic interneurons (in the lateral horn) and migrate to the top of the dorsal horn (carried along by its rotation), arriving precisely when the small-diameter afferents arrive. This exquisite developmental coordination indicates that together the small-diameter afferents and the lamina I neurons form a coherent system for homeostatic afferent activity. Small-diameter afferents that innervate visceral organs by way of the cranial parasympathetic nerves terminate similarly in the nucleus of the solitary tract in the medulla.

3.18.2.2 Lamina I Spinal and Bulbar Projections

The projection targets of lamina I neurons in the spinal cord and brainstem are all associated with autonomic control, indicating that lamina I provides the central continuation of the small-diameter afferent pathway conveying homeostatic sensory activity. The lamina I neurons project strongly to the autonomic cell columns of the thoracolumbar and sacral spinal cord, where sympathetic and parasympathetic preganglionic motor neurons are located. This provides the substrate for spinospinal somatoautonomic reflexes. In the brainstem, lamina I neurons project to all of the major homeostatic integration sites, which also receive parasympathetic afferent activity by way of the solitary nucleus, and are heavily interconnected with the hypothalamus and amygdala; these sites include the caudal and rostral ventrolateral medulla, catecholamine cell groups A1–2 and A5–7, parabrachial nucleus, and periaqueductal gray. These brainstem regions contain premotor autonomic neurons that have descending projections to spinal autonomic regions, as well as neurons with descending projections that modulate activity in the dorsal horn. The lamina I projections to the brainstem provide the substrate for the modality-selective somatoautonomic spinobulbospinal reflexes activated by spinal small-diameter afferents, which are critical mechanisms for homeostatic function. Lamina I also receives descending modulation not only from these brainstem preautonomic sources, but also selectively from descending fibers from the hypothalamus. Thus, the hierarchical lamina I spinal and bulbar projections provide the long-missing central afferent limb of the efferent autonomic nervous system. As far as I am aware, the homeostatic afferent pathway formed by small-diameter afferents and lamina I neurons is present in fish, lizards, birds, and mammals.

3.18.2.3 Lamina I Projections to the Forebrain

In subprimates, the integration of ascending homeostatic afferent activity from lamina I occurs mainly in the brainstem. There, the parabrachial nucleus at the junction of the pons and midbrain receives dense input from both lamina I and the nucleus of the solitary tract, and it projects densely to the hypothalamus and the amygdala. The parabrachial nucleus is thus the main homeostatic afferent integration site of the supraspinal autonomic control regions. In rats and cats, there are additional, weak rostral projections from lamina I that can be regarded as primordial evolutionary attempts at more direct forebrain integration; these include direct spinal projections to a variety of preautonomic (limbic) cortical regions, as described in the section on comparative anatomy below. By contrast, in primates there are direct, well-organized homeostatic afferent projections to sensory relay nuclei in the thalamus, and thence to cortex, from both lamina I and the nucleus of the solitary tract. The homeostatic afferents from parasympathetic nerves, which terminate in the nucleus of the solitary tract of the brainstem, and the homeostatic afferents from sympathetic and somatic nerves, which terminate in lamina I of the spinal (and trigeminal) dorsal horn, activate dorsal posterior insular cortex (dpIns) by way of direct ascending projections to the basal (parasympathetic) and posterior (sympathetic) parts of the ventromedial nucleus of the thalamus (that is, VMb and VMpo). These are modality-specific, topographically organized projection pathways that are phylogenetically distinct to primates and enormously well developed only in humans. The dpIns contains representations of all interoceptive afferent activity from lamina I and the solitary nucleus. (For illustrations of these projections, see Craig, 2002, 2003, 2004a.)

In humans, this interoceptive cortical field engenders several sensations, or feelings, associated with the homeostatic condition of the body. Functional imaging studies provide convergent evidence confirming the role of dpIns as the primary sensory cortex involved in pain, temperature, itch, muscle burn, sensual touch, hunger, thirst, cardiorespiratory activity, etc. (see Craig, 2002, 2003). Notably, these include well-localized, discriminative sensations that traditionally have been associated with the classical somatosensory system.

For example, dpIns is the only site in the contralateral cortex that evinces linear activation correlated with the temperature of a graded innocuous cooling stimulus. This activity corresponds directly with the linear activation of thermoreceptive-specific lamina I spinothalamic neurons. The dpIns is also the only cortical site where lesions produce thermanesthesia, and only stimulation in VMpo and dpIns can produce graded, well-localized sensations of cooling, whereas lesions or stimulation of parietal somatosensory areas do not affect thermal sensation. Thus, this cortical site is the representation of discriminative innocuous thermal sensation. This conclusion is confirmed by recent functional imaging evidence that thermosensory activation of dpIns is somatotopically organized (Figure 1; Hua *et al.*, 2005). The available anatomical tracing and functional imaging data indicate that the representation of painful stimuli in dpIns is also graded and somatotopographically organized; thus,

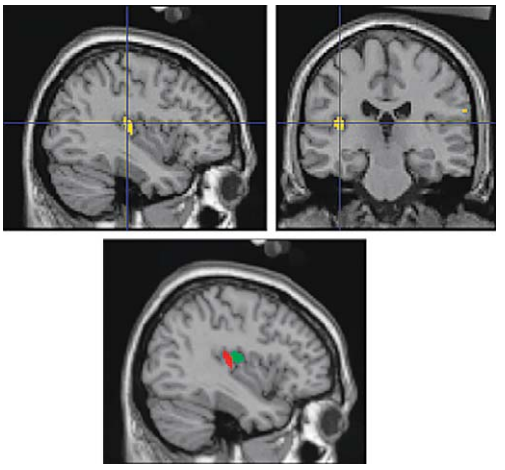

Figure 1 A composite showing the localization in dpIns of activation by graded innocuous cooling stimulation obtained using fMRI. The top panels show the location of activation correlated with stimulus temperature on the hand, and the bottom image shows the anteroposterior somatotopographic organization of activation from the hand (red) and the neck (green). Reproduced from Hua, L. H., Strigo, I. A., Baxter, L. C., Johnson, S. C., and Craig, A. D. 2005. Anteroposterior somatotopy of innocuous cooling activation focus in human dorsal posterior insular cortex. *Am. J. Physiol. Regul. Integr. Comp. Physiol.* 289, R319–R325, with permisson from the American Physiological Association.

it can subserve the haptic aspects of temperature and pain sensations that were formerly considered exteroceptive aspects of somatosensation.

The organization of the topographic maps in dpIns provides strong support for the fundamental distinction between these interoceptive cortices and the exteroceptive (or, sensorimotor) cortices that receive lemniscal input. In contrast to both S1 and S2, which are organized mediolaterally, the interoceptive cortical areas are organized in the orthogonal, anteroposterior direction. Thus, in S1, the foot is represented in the medial postcentral gyrus and the hand and face are represented progressively more laterally, and in S2, the foot is represented in the medial part of the parietal operculum and the hand and face are represented progressively more laterally (see Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications). In stark contrast, the anatomical tracing and the functional imaging evidence indicate that in both the cooling thermosensory representation and the noxious heat (pain) representation in dpIns, the foot is represented posterior and the hand and face are represented progressively more anterior (Figure 1; Hua *et al.*, 2005; Brooks *et al.*, 2005). This matches the orthogonal neighborhood relationship of the interoceptive and exteroceptive maps in the thalamus (that is, between VMb/VMpo and VPM/VPL), which are joined at the representation of the mouth, the embryological junction of the inside and the outside of the body. This organization validates the neuroanatomical and neurochemical distinctness of interoceptive modalities, important for homeostasis and autonomic activity, from the exteroceptive and proprioceptive modalities of touch and limb position, important for somatic motor control.

The ascending lamina I pathway in primates also activates the ACC (i.e., limbic motor cortex) by way of the ventral caudal portion of the medial dorsal thalamic nucleus, or MDvc. In addition, it activates a portion of sensorimotor cortex, area 3a, that is intercalated between the primary somatosensory area and the primary motor area by way of a collateral projection from VMpo. The anterior cingulate projection is directly associated with the affective motivation, the unpleasantness, of pain. The area 3a projection is likely involved with cortical control of the reflex motoric action of pain, that is, sensorimotor integration. This is consistent with the projection of vagal and other visceral afferent activity to anterolateral area 3a. Nevertheless, a role for this area 3a input in perception (e.g., the exteroceptive capacity of cutaneous pain) should still be considered. (Area 3a is the probable source of activation often interpreted as S1 in functional imaging studies of pain. A similar source of confusion in many functional imaging studies of pain is the nomenclative misidentification of dpIns as S2.)

3.18.2.4 Significance of the Homeostatic Afferent Representation for Emotion

In macaque monkeys, the interoceptive representation in dpIns projects directly to the orbitofrontal cortical regions that are associated with hedonic evaluation and emotional regulation of behavior (Carmichael and Price, 1996). In humans and humanoid primates, on the other hand, there are multiple re-representations of interoceptive afferent information, first in the middle insula (which also aggregates activity from the amygdala and from other cortical sensory regions) and then in the most anterior insula. The anterior insula seems to provide a meta-representation of the state of the body that is associated with subjective awareness of the material self as a feeling (sentient) entity across time, that is, emotional self-awareness, consistent with the ideas of James and Damasio (Craig, 2002, 2004b). These pathways become clearly lateralized as they progressively activate higher-order homeostatic afferent re-representations in more anterior portions of the human insula. This lateralization in humanoid primates makes the relevant homeostatic afferent

representations coincide with the asymmetric sympathetic and parasympathetic efferent control regions on the right and left sides of the forebrain. In other words, the feelings represented in the right anterior insula seem to be associated predominantly with sympathetic activity, and thus with arousal, danger, negative affect, withdrawal (aversive) behavior, and individual-oriented (survival) emotions. The feelings represented in the left anterior insula seem to be associated predominantly with parasympathetic activity, and thus with nourishment, safety, positive affect, approach (appetitive) behavior, and group-oriented (affiliative) emotions. This neuroanatomical model can explain the wealth of psychophysiological evidence indicating that the forebrain representation of emotion and affective style is asymmetric (Craig, 2005). The phylogenetic emergence of these anatomical pathways in humanoid primates corresponds well with the stark qualitative distinction between humanoid and subhumanoid primates in terms of self-recognition and emotional communication; thus, humanoid primates recognize themselves in the mirror test, whereas other primates do not, and humanoid primates use intentional gestures for communication, whereas other primates do not (MacPhail, 1998; De Waal, 2003). This phylogenetic progression also matches well the unique appearance of large spindle neurons in anterior insula and anterior cingulate cortices of humanoid primates (Craig, 2004b; Allman *et al.*, 2005).

3.18.2.5 Physiological Identification of the Lamina I Homeostatic Afferent Pathway as the Pain Pathway

Spinal and trigeminal lamina I neurons comprise several modality-selective, morphologically distinct classes of neurons that each receive selective input from particular subsets of afferents. These classes correspond with distinct feelings from the body (including first (sharp) pain, second (burning) pain, cool, warm, itch, sensual touch, muscle burn, etc.). The lamina I spinothalamic tract (STT) neurons project their axons to contralateral thalamus in the lateral STT, precisely where cordotomy lesions interrupt these feelings. The distinct role of lamina I STT neurons in sensation is convincingly demonstrated by the selectively histamine-responsive cells that correspond uniquely with the sensation of itch. Whereas lamina I is usually related to pain and temperature, its role in homeostasis is underscored by the neurons that respond selectively to small-diameter muscle afferents, which subserve ongoing cardiorespiratory adjustments to muscular work but when strongly activated signal muscle burn and pain.

In particular, single-unit recordings from monkey STT neurons reveal that the responses of nociceptive-specific lamina I STT cells correspond precisely with the human psychophysiological profile of stinging (first) pain, whereas the polymodal nociceptive lamina I STT neurons correspond with the profile of burning (second) pain. Definitive evidence for these associations is provided by use of a graded series of mechanical probes and use of the repeated brief contact heat test, which selectively elicit sensations of stinging and burning pain (Craig, 2003).

In stark contrast, the large lamina V wide-dynamic-range (WDR) neurons studied by many investigators show response patterns to these tests that are significantly different from the profile of human pain. This is an important distinction because the proponents of the widely held pattern/intensity concept of pain sensation (so-called gate control theory) profess that WDR lamina V STT neurons are pain transmission cells that are necessary and sufficient for all types of pain sensation (Willis and Westlund, 1998; Price *et al.*, 2003). However, the inherent modality ambiguity of lamina V WDR cells, their high ongoing discharge rate, their musculotopic receptive field organization, their interpolation in the flexor reflex motor pathway, and their distinct responsiveness to proprioceptive input are all features consistent with a role in sensorimotor integration, rather than pain sensation. They provide input to sensorimotor cortex. Contrary to the common presumption that the topographic maps of somatosensory cortices are necessary for pain localization, the somatotopically organized and modality-selective representation of different types of pain in the primate lamina I spinothalamocortical pathway to dpIns can explain the haptic characteristics of pain sensation quite well. Furthermore, this association emphasizes the fundamentally important distinction that pain is an evolutionarily emergent aspect of homeostasis, not an aspect of sensorimotor integration.

3.18.3 Comparative Neurobiology of the Pain Pathway

The lamina I projection system provides a homeostatic afferent pathway that conveys modality-selective sensory information on the physiological condition of all tissues of the body. Lamina I neurons project at the spinal level directly to the intermediolateral and intermediomedial cell columns that contain autonomic motor neurons, and

they project at the brainstem level selectively to homeostatic integration and control regions that contain autonomic premotor neurons. A parallel projection system conveys vagal and glossopharyngeal afferent input to such sites by way of the projections of the nucleus of the solitary tract.

Comparative analyses (mainly in rat and cat; for detailed references, see Craig, 2004a) suggest a possible archetypical mammalian pattern in the telencephalic projections of this system and highlight the phylogenetic novelty of the direct lamina I projections to VMpo and MDvc in primates. These analyses indicate that, in subprimates, the telencephalic extension of the spinal and brainstem lamina I projections appears to provide a medial thalamic pathway for autonomic control and a lateral thalamic pathway for viscerosomatic control. In primates, however, phylogenetically novel direct projections to both medial and lateral thalamus are present that are enormously expanded in humans (Craig, 2002, 2004a).

3.18.3.1 An Overview

In cat, trigemino- and spinothalamic projections occur mainly in the ventral aspect of the ventral tier nuclei, the motor thalamus, the intralaminar nuclei, and the submedial nucleus. Within this distribution, lamina I projections in cat are concentrated in three main sites: the submedial nucleus, the ventral aspect of the ventral tier (including VMb and VPI), and the dorsomedial aspect of VPM.

In rat, trigemino- and spinothalamic projections occur mainly in VP, the posterior nucleus, the overlying VP, and the intralaminar nuclei, as well as a variety of extrathalamic regions (hypothalamus, amygdala, septal and pallidal nuclei, and limbic cortices). Within this distribution, lamina I projections in rat are concentrated in VP, the posterior nucleus, and the posterior triangular nucleus, with weak terminations in the parvicellular part of VPM (VPMpc; equivalent to VMb in the present terminology) and the submedial nucleus.

A parsimonious interpretation of these data is that all mammals have a dual lamina I projection to medial (limbic) thalamic circuits and to lateral (sensorimotor) thalamic circuits, albeit with differing routes in different species. A dual projection is consonant with the global view that small-diameter homeostatic afferents from the entire body activate pathways (by way of lamina I and the nucleus of the solitary tract) that are important, first, for homeostatic and autonomic processing (i.e., control of smooth muscle) and, second, for viscerosomatic sensorimotor processing (i.e., control of striate muscle). Evidence in other mammals is consistent with this interpretation (e.g., hedgehog, opossum, and bush baby; Hazlett *et al.*, 1972; Pearson and Haines, 1980; Kunzle, 1998).

3.18.3.2 The Medial Lamina I Pathway

The data suggest that the direct lamina I projection to MDvc in the primate can be viewed as a phylogenetically novel route to ACC that has a potential evolutionary basis in an ancient mammalian homeostatic medial thalamic pathway that was directed in primordial species to more primitive telencephalic autonomic control regions.

The medial lamina I pathway in both rat and cat effectively targets MD-related, autonomic control regions in orbital and infralimbic cortices, either directly or by way of the submedial nucleus or the parabrachial complex. In cat, in contrast to rat, there are few extrathalamic projections and no direct cortical projections, yet the medial lamina I pathway similarly targets orbital cortex by way of the submedial nucleus.

In both cat and rat, the developmental origin of the submedial nucleus from the ventral caudal portion of the medial pronucleus suggests an evolutionary kinship with the primate MDvc (in fact, there is an identical posterior-to-anterior topography in both sites), albeit with a fundamentally different cortical target. This highlights the shift in primates to anterior cingulate. Notably, the medial (limbic) homeostatic afferent pathway in rat seems to reach the ACC (i.e., limbic behavioral motor cortex) only by way of parabrachial input to medial thalamus. In cat, homeostatic afferent lamina I activity similarly attains anterior cingulate mainly by way of the parabrachial input to medial thalamus, although curiously, in cat there is also lamina I input to anterior cingulate by way of the ventral aspect of the ventral tier nuclei of lateral thalamus.

3.18.3.3 The Lateral Lamina I Pathway

The data suggest that the direct lamina I projection to VMpo in the primate can be viewed as a phylogenetically novel route to insular cortex that has a potential evolutionary basis in an ancient mammalian homeostatic lateral thalamic pathway that was directed in primordial species to sensorimotor regions, but that in primates became redirected to limbic sensory cortex.

The lateral pathway in subprimates is directed mainly to sensorimotor cortex. In rat this projection ascends by way of VP and in cat by way of the ventral margin of the ventral tier nuclei (especially VPI).

In rat there is little differentiation in this pathway (VP supplies input to the overlapping sensory and motor cortices), but in cat both the lamina I and the vagal afferent projections seem to target area 3a, the transitional region between the primary motor and somatosensory cortices that also receives proprioceptive and vestibular inputs. Similarly, in primates a corollary lamina I projection by way of VMpo and a parallel vagal afferent projection by way of VMb also target area 3a. These observations support the interpretation that the archetypical ascending homeostatic afferent pathway by way of lateral thalamus provides a substantive basis for a generalized role in viscerosomatic sensorimotor integration.

The predominant lateral thalamic homeostatic afferent pathway in primates is the lamina I projection to VMpo and the parallel direct pathway to VMb from the nucleus of the solitary tract. This provides a novel modality-selective, topographic interoceptive sensory representation in insular cortex that is distinct from the primordial sensorimotor pathway. A rudimentary homologue of the lamina I projection to VMpo appears to exist in cat, but in rat this pathway is only tenuously present, if at all. Thus, in cat there is a moderately dense, weakly topographic lamina I projection to the ventral aspect of VMb. This appears to be homologous to VMpo, because it also projects to insular cortex adjacent to gustatory cortex and it is significant (though not critical, in sharp contrast to primates) for thermosensory behavior. Similarly, in rat a few trigeminal and spinal lamina I fibers terminate in the ventral and medial aspects of VPMpc, the parabrachio-recipient gustatory nucleus that is equivalent to VMb, but apparently no solitary nucleus fibers do so. A few neurons in this locus reportedly project to a small portion of rostral agranular insular cortex adjacent to gustatory cortex that is important for nociceptive behavior, and this area may respond to somatic C-fiber, vagal, and thermosensory inputs.

The primordial role of the insular cortex seems to be modulation and telencephalic control of brainstem homeostatic integration sites, such as the parabrachial nucleus, where its descending projections terminate. It is associated functionally with the autonomic nervous system, because stimulation of insular cortex affects cardiorespiratory, gastrointestinal, and thermoregulatory activity, and because it is closely interconnected with hypothalamus, amygdala, and ventral striatum. It can be regarded as limbic sensory cortex, whereas anterior cingulate can be regarded as limbic motor cortex. Thus, the encephalized representation of the condition of the body in primates and humans appears to have emerged evolutionarily from the afferent limb of the hierarchical homeostatic system. Activity that produces pain in humans ascends in the telencephalic extension of a pathway whose primary role has been homeostasis for hundreds of millions of years.

3.18.3.4 Summary

The comparative analyses indicate that the homeostatic afferent lamina I projections to MDvc and VMpo in the primate can be described as phylogenetically novel pathways that produce direct activation of ACC and the interoceptive representations in insular cortex. These pathways appear to signify fundamental primate innovations on the archetypical mammalian pattern of dual telencephalic pathways for autonomic and sensorimotor control. The most significant innovation appears to be the emergence of a primary limbic sensory representation of the physiological condition of the body as an extension of a primordial pathway for telencephalic control of mesencephalic and hypothalamic homeostatic integration.

3.18.4 Evolution of the Human Pain Pathway

The findings summarized in the above text indicate that pain in humans is a homeostatic emotion that consists of a feeling (a discriminative sensation engendered in dpIns) and a motivation (a behavioral drive engendered in ACC) that reflects an adverse condition in the body requiring a behavioral response. It is subserved by phylogenetically novel ascending pathways to the thalamus (to VMpo and MDvc) that are not present or, at best, are primordial in subprimates. It is associated in particular with progressive re-representations of the interoceptive afferent inflow in the anterior insula that are present only in humanoid primates. These functional anatomical findings have several implications.

First, these observations imply that subprimates cannot experience feelings of pain in the same manner as humans, because they do not have the same neuroanatomical substrates. Assumptions that animals can feel pain without the direct interoceptive sensory representation in dpIns and the progressive re-representations in the anterior insula that humans use are simply examples of anthropomorphism. On the contrary, survival behaviors elicited by homeostatically challenging stimuli (including thermal and noxious stimuli) are naturally emitted by invertebrates as well as vertebrates.

Second, these observations imply that the neural separation of skeletal and smooth muscle afferent

control systems, which is embedded in the development of the spinal cord, is evolutionarily ancient. The archetypical mammalian homeostatic afferent spinothalamic projections seem to reflect this basic functional division, with a pathway to the medial thalamus for limbic integration and a pathway to the lateral thalamus for viscerosomatic sensorimotor integration. The appearance of the high-resolution interoceptive representation in primate limbic sensory cortex, distinct from sensorimotor cortices, conforms with this fundamental functional distinction as well.

Third, these observations imply that the primate innovation of direct ascending homeostatic afferent input to limbic sensory and limbic motor cortices provided a profound evolutionary advantage. This is consistent with the view that encephalization in primates enabled more refined telencephalic control of hierarchical processing and enhanced postprocessing in all neural systems. The encephalized representation of the condition of the body in primates enabled modality-selective and topographically organized descending control of homeostatic integration in the brainstem, hypothalamus, and ventral striatum. This certainly had profound effects on adaptability. For instance, it seems reasonable to infer that the incredibly complex homeostatic adjustments (i.e., thermoregulatory, vestibuloautonomic, cardiorespiratory, etc.) that were necessary for the development of upright, bipedal locomotion must have required refined control capability. It is also noteworthy that the facial (branchiomeric) expression of emotion, an essential feature of mammalian reproductive and social interaction, became graded in primates (De Waal, 2003), and this evolutionary advancement in conspecific communication must have been greatly enhanced by the high-resolution homeostatic afferent representation in primates.

A clear example of the survival value of the direct, high-resolution interoceptive sensory representation in primates is provided by the owl monkey (Craig *et al.*, 1999). This New World primate is the only nocturnal monkey known, and accordingly it has several beneficial evolutionary adaptations. For example, its visual system is highly adapted for movement detection in the dark over a broad field of view, appropriate for its appetite for moths and other insects that fly at night. The owl monkey is also highly osmotic and has a greatly enhanced ability to use olfactory cues for orientation and food localization. In particular, these animals use scent markings for navigation and trail marking in the rain forest at night, when the humid air is cold and still – a significant aid to its nocturnal foraging. Notably, the cold night air also provides the appropriate condition for enhanced thermal discrimination of warm scent markings, and owl monkeys have a specialized thermosensitivity focused at the nose that inherently provides a valuable accessory signal when sampling olfactory cues during nocturnal foraging (or perhaps when another animal is near in the dark). This capability is provided by a highly developed lamina I trigeminothalamic thermosensory pathway to dpIns that is not present in other monkeys. An enhanced discriminative thermosensory capability for detecting the warmth or freshness of a scent trail must have considerable survival value for a small nuclear family of owl monkeys trying to follow one another, in pitch darkness, along an arboreal foraging trail through the rain forest (where separation can mean fatal exposure to felid predators). One can easily infer that this pathway evolved as an adaptive adjunct to nocturnal olfactory behavior by virtue of the refined thermosensory capability provided by the direct interoceptive cortical substrate in this primate.

Finally, these observations imply that humanoid primates benefited from an enormous evolutionary advantage due to the alignment of the homeostatic afferent representation in the insular cortex with the asymmetric autonomic efferent representation that had been present there in all mammals. In other words, the lateralized re-representations of parasympathetic feelings (e.g., taste) in the left anterior insula and of sympathetic feelings (e.g., pain) in the right anterior insula aligned these homeostatic afferent systems with the parasympathetic cardiac drives in the left insula and sympathetic drives in the right insula that are apparent even in rodents, which probably emanate anatomically from the inherent asymmetry in peripheral cardiac innervation. I infer that this adaptation in humanoid primates enabled numerous qualitatively significant adaptive refinements in conspecific emotional communication, including subjective self-awareness across time, empathy, and music (Craig, 2004b, 2005). The concomitant evolutionary development of the ability to feel pain from psychic (emotional) as well as physical causes, of course, has its disadvantages as well.

3.19 Visceral Afferents

K Bielefeldt and G F Gebhart, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Glossary

nociceptor(s) — A sensory receptor for which the adequate stimulus is one that damages or threatens damage (to skin; Sherrington, 1906). The adequate stimuli for activation of visceral nociceptors include distension of hollow organs, ischemia, inflammation, and traction on the mesentery.

nocifensor (nocifensive behavior) — Lewis (1936; see Lewis, 1942; LaMotte, 1992 for discussion) termed as nocifensor a system of 'nerves' associated with local defense against injury. The term has since expanded to describe behaviors associated with protection against insult and injury. Nocifensive behaviors are more complex than simple withdrawal reflexes initiated by activation of a nociceptor(s). Nocifensive behaviors produced by visceral stimulation are also considered pseudaffective (Sherrington, 1906; pseudoaffective) because responses to visceral stimulation are organized supraspinally.

polymodal nociceptor — A nociceptor that responds to multiple modalities of stimulus energies (i.e., thermal, chemical, and mechanical). Most (and perhaps all) visceral nociceptors are polymodal in character.

3.19.1 Introduction

Responses to wide-ranging stimuli characterize living organisms as simple as a single cell, which reacts to environmental cues and is attracted by chemical signals (chemotaxis). The molecular mechanisms linking an environmental stimulus or chemical signal to a cellular response (e.g., movement) may be similar across a wide range of organisms. Ion channels, such as the degenerins or members of the TRP (transient receptor potential) channel family, exhibit a high degree of structural homology between invertebrates and vertebrates, revealing evolutionary conservation of successful strategies. These highly conserved mechanisms for stimulus transduction are found in many cells in addition to neurons, a specific group of which are the focus of this article. Complex organisms have developed specialized organs serving diverse functions from gas exchange to nutrient absorption and excretion of toxins or waste products. Despite differences in structure and function, all contribute to maintaining an internal milieu (homeostasis) that is essential for survival of the organism.

As the complexity of organisms increases, the nervous system plays a greater role in the integration of information and maintenance of homeostasis. For example, feedback circuits evolved for controlling and adjusting homeostatic functions, including the regulation of visceral function. The innervation of the viscera ensures rapid and targeted transfer of

information, including flexible processing of this information, and triggers responses in and by effector organs. Interestingly, overlapping nervous systems developed in the viscera, not only in organs such as the heart, but importantly in groups (systems) of organs such as the gastrointestinal tract. In the gastrointestinal tract, an intrinsic (enteric) nervous system contains all the elements necessary to regulate basic functions such as absorption, secretion, motility, and blood flow. The enteric nervous system is modulated by various levels of extrinsic nervous control, characterized by neurons located outside of the gut wall in prevertebral ganglia, the spinal cord or brainstem and higher centers within the central nervous system. Figure 1 schematically illustrates several characteristics of visceral innervation and interaction, employing the gastrointestinal tract as representative of the viscera. The characteristics and functions of the extrinsic visceral innervation (visceral afferents) are considered below.

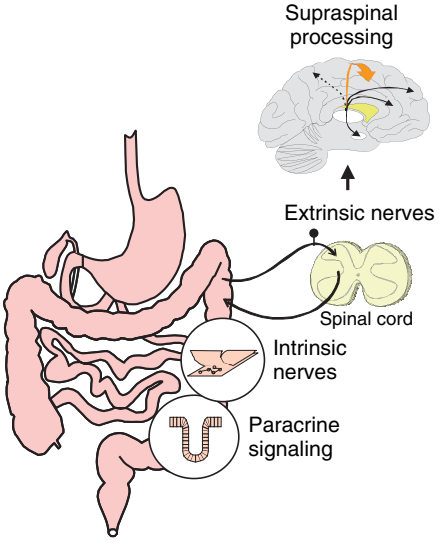

Figure 1 Diagrammatic illustration of visceral innervations and signaling, employing the gastrointestinal tract as the example. Extrinsic nerves convey information to the spinal cord (spinal afferents) and brainstem (vagal afferents, not shown; see Figure 2), which forwards visceral sensory information to supraspinal sites. As detailed in the text, most visceral input to supraspinal sites does not lead to conscious appreciation of visceral events, but is important to maintaining homeostasis by virtue of interacting with regulatory systems important to many visceral functions. The viscera are also innervated by an intrinsic nervous system, which interacts with nerve terminals of the extrinsic innervation in ways not fully understood and contribute to local events. Finally, the epithelium of all hollow viscera have the ability to secrete bioactive substances that can influence activity of either or both the intrinsic and extrinsic innervations of the organ, indicated here as a paracrine mechanism of signaling.

3.19.1.1 Activation-Sensation

When discussing the function of visceral afferents, it is essential to distinguish between activation of primary sensory neurons (or higher order visceroceptive sensory neurons) from activation of cortical structures. Cortical activation is necessary, but not sufficient for cognitive processes such as conscious perception of visceral stimulation. In humans and likely many other mammals, sensory input from skin, eyes, ears, or the olfactory system generally leads to activation of cortical structures and conscious perception of the event. Similarly, visceral input reliably activates central nervous system neurons, but only infrequently leads to awareness of the input in higher mammals. The most commonly perceived visceral events are either uncomfortable (e.g., bloating, over filling, gas, nausea) or painful, and visceral pain is relatively rare in health. By far, most visceral afferent activity conveyed to the central nervous system goes unnoticed. For example, the regularly beating heart and resulting pulsatile flow in arteries activates stretch receptors in cardiac and vessel walls, but despite this almost constant barrage of visceral afferent input, humans do not sense their heart as beating or register cyclical blood pressure changes. The exceptions confirm the rule; laypersons and physicians talk about palpitations as an unusual perception of the heartbeat.

The above emphasizes a unique aspect of the extrinsic (afferent) visceral innervation. The regulation of vital functions, such as respiration and blood flow, requires constant feedback from visceral afferent activity that is not consciously perceived. The afferent activity is critical to informing regulatory systems that are independent from intentional control mechanisms (hence the term 'autonomic nervous system'). As mentioned above, when visceral input is consciously perceived, it is often given special weight by the organism as a threat to vital functions, and therefore potentially to survival. However, there are notable and important exceptions. The proximal gastrointestinal tract is linked to digestion (and indigestion), and signals about its filling state are essential for the regulation of feeding behavior and the feeling of satiety. Conversely, the distal gastrointestinal tract and urinary bladder are important in storage and evacuation, which are linked to complex social functions (e.g., marking, appropriateness for defection) and thus require afferent input into higher brain centers.

Obviously, striking differences exist between the gills of fish and the lungs of mammals. Such differences multiply further if one includes invertebrates

in comparisons of organs serving similar vital functions (see Evolution of Visceral Control in Invertebrates). However, some similarities emerge when examining visceral structures responsible for gas exchange and their afferent innervation (Adriaensen *et al.*, 1998; Taylor *et al.*, 1999). It becomes more difficult to identify similarities or parallels between different species if one considers sensation as a feeling or perception, which requires some form of consciousness and relies on cortical structures. Using the musculocutaneous sensory system (commonly referred to as somatic, which is a misnomer given that viscera are part of the body) and the senses of vision, smell, and hearing as reference points, what are the unique aspects of visceral sensation? How do those unique aspects compare between different species? This article attempts to address these questions, primarily focusing on peripheral sensory mechanisms in the viscera. Because much of the research in neurobiology is driven by questions related to human disease, most studies have been performed in mammalian species, primarily mice and rats, thereby limiting our ability to compare detailed information about structure and function across the different branches of the phylogenetic tree.

3.19.2 Innervation of the Viscera

The innervation of the internal organs is uniquely associated anatomically with the autonomic nervous system (e.g., see Langley, 1921). Efferent fibers comprising sympathetic and parasympathetic divisions of the autonomic nervous system are contained in the same nerve bundles as are the afferent fibers that convey sensory information from the viscera to the central nervous system. Visceral afferents reach the central nervous system by two routes: cranial nerves directly enter the brainstem, primarily through the paired vagus nerves, the largest visceral sensory nerves in the body; a second group of afferents projects to thoracic, lumbar, and sacral dorsal root ganglia, conveying information to second-order neurons in corresponding segments of the spinal cord (Figure 2). Essentially all organs within the chest cavity and most of the gastrointestinal organs are innervated by both vagal and spinal afferents. Similarly, anatomically distinct nerves innervate the pelvic organs, conveyed in lumbar splanchnic (to thoracolumbar dorsal root ganglia) and pelvic (to lumbosacral dorsal root ganglia) nerves. Based on the anatomical organization and presence of efferent fibers in these nerves, an older nomenclature labeled these visceral afferents sympathetic ('afferent sympathetic fibers', Langley, 1921) and parasympathetic, respectively, analogous

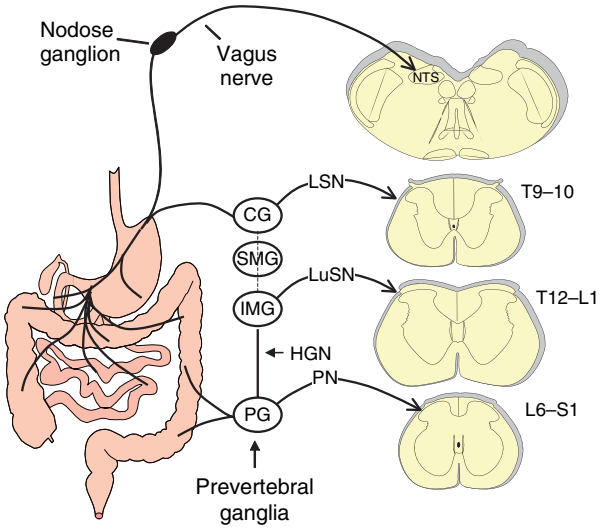

Figure 2 Diagrammatic representation of the extrinsic spinal and vagal innervation of the viscera. The diagram illustrates that each organ (e.g., distal colon, stomach, etc.) is innervated by two sets of nerves that terminate in different areas of the central nervous system. For example, the distal colon is innervated by the pelvic nerve (terminating principally in the sixth lumbar (L6) and first sacral (S1) segments of the rodent spinal cord) and hypogastric nerve (HGN)–lumbar splanchnic nerve (LuSN) (terminating in the 12th thoracic (T12) and L1 segments of the rodent spinal cord). Note that spinal visceral nerves pass through prevertebral ganglia, where they give off axon collaterals and interact with secretory and motor neurons in the ganglia, en route to the spinal cord. Note also the extensive innervation of the abdominal viscera by the vagus nerve, which terminates centrally in the nucleus of the solitary tract (NTS). The cell bodies of vagal afferents are contained in the nodose ganglia and those of spinal afferents in dorsal root ganglia (not shown).

to the dual efferent innervation of abdominal and thoracic viscera. Although Langley (1921) considered the presence of visceral afferents in autonomic nervous system nerves an important component of autonomic regulation, his and related terminology is confusing and the taxonomy has been largely abandoned.

There is no doubt that an important function of visceral afferents is to provide critical input to autonomic centers that modulate efferent outflow to the internal organs. Several lines of evidence suggest that these distinct pathways serve different functions. Interruption of spinal, but not vagal, afferents abolishes aversive responses to noxious mechanical stimulation of stomach, suggesting that spinal visceral afferents encode gastric nociceptive information (Ozaki *et al.*, 2002). This is consistent with the long-held notion that "visceral pain is transmitted to the spinal cord by afferent fibers traveling in sympathetic nerves" (Cervero and Foreman, 1990). However, growing evidence suggests that vagal afferents are also involved in

nociception, as they carry information about threatening conditions in heart and lungs, and may play a role in chemonociception within the gastrointestinal tract (Undem and Weinreich, 1993; Foreman, 1998; Schuligoi *et al.*, 1998; Benson and Sutherland, 2001; Lamb *et al.*, 2003; Kollarik and Undem, 2004). Taken together with the convergence of both pathways at the level of the brainstem and the significant overlap in functional characteristics, it is likely that vagal and spinal afferents both regulate visceral function in addition to their essential contributions to conscious perception of visceral events.

By far, most information about the function of visceral afferents has been derived from studies in mammalian vertebrates, and thus the information that follows is limited in an evolutionary context. Considerable attention, however, has been directed at the evolution and function (excitation, inhibition) of the autonomic nervous system (e.g., see Burnstock, 1969 for review), revealing that even though some features of the mammalian autonomic nervous system are represented in primitive vertebrates, there are striking variations in the function and autonomic innervation of organs in related species. Similarly, Walters (1994) has extensively studied and reviewed comparative and evolutionary features of nociceptor function, which although studied in leech, snail, and mollusk, in addition to vertebrates, addresses only surface (cutaneous) nociceptors. Given the importance of detecting injury and tissue damage from the viewpoint of survival, it is not surprising that there is considerable conservation of nociceptor function throughout animal evolution. A subset of visceral afferents are nociceptors, but stimuli adequate for activation of surface/cutaneous nociceptors (e.g., cutting, crushing, burning) are typically inadequate for activation of visceral nociceptors, which in mammalian vertebrates are activated most effectively by distension of hollow organs, ischemia, and traction on the mesentery (see Ness and Gebhart, 1990 for review). Although not the principal focus of the limited studies of which we are aware, work on frog (Tower, 1933) and toad (Niijima, 1960, 1961, 1967) support differences in adequate stimuli for surface nociceptors versus visceral nociceptors established in mammals. Thus, while extrapolation of information below to the general evolutionary trend may not be inappropriate, such extrapolation needs to be undertaken cautiously.

3.19.2.1 Sensory Endings

We have limited information about the structure of afferent nerve terminals within the viscera. The low innervation density of the viscera and the small size of these mostly unmyelinated fibers pose a significant challenge to direct examination. Much of our current understanding is derived from studies using tracer dyes, which stain both peripheral and central terminations after being transported distally and/or proximally from the injected site in the primary sensory ganglion. Current estimates suggest that less than 10% of neurons in spinal dorsal root ganglia project to a visceral target (McMahon, 1997). Even the most sophisticated tracing techniques will label only a fraction of these neurons, making direct studies of peripheral endings of spinal visceral afferents very difficult. While it has been generally assumed that most visceral afferents are unencapsulated, free nerve endings within their target tissues, recent reports have identified structural specializations on the terminals of some visceral afferent fibers that allow inference about their function. Current information remains largely restricted to vagal afferent nerve terminals in visceral organs, which have been described in some detail for the cardiovascular, respiratory, and gastrointestinal tract. However, a recent report suggests that pelvic afferents innervating the rectum form terminal specializations similar to those seen in some vagal afferent fibers projecting to the proximal gastrointestinal tract (see below).

In the gills or airways and in the gut, nerve endings can be found in close proximity to epithelial cells containing secretory granules at the basolateral site (Adriaensen *et al.*, 1998; Gershon, 1999; Taylor *et al.*, 1999; Brouns *et al.*, 2003). The close apposition between these specialized cells and nerve endings suggests that release of mediators from epithelial cells activates visceral afferent fiber terminals (i.e., paracrine signaling, Figure 1). Indeed, enteroendocrine cells isolated from the gut respond to appropriate stimuli and release mediators, such as serotonin or the neuropeptide cholecystokinin (CCK) (Kim *et al.*, 2001a, 2001b). Serotonin or CCK receptor antagonists block vagal responses to mucosal stimuli, such as flow of luminal contents, high luminal glucose or fat concentration, providing functional evidence for the indirect activation of neurons through epithelial chemical signaling (Davison and Clarke, 1988; Blackshaw and Grundy, 1990; Ladabaum *et al.*, 2001; Uneyama *et al.*, 2002; Li *et al.*, 2004).

Using anterograde tracers, more complex structural specializations of nerve endings have been described in the heart and the gastrointestinal tract. Within the tunica muscularis of the mammalian gut, some vagal afferents form two morphologically distinct endings in organ tissue: intraganglionic laminar

endings (IGLEs) and intramuscular arrays (IMAs) (Holst *et al.*, 1997). IGLEs are found in myenteric ganglia, a component of the enteric (or intrinsic) nervous system, at the interface between the circular and longitudinal muscle of hollow organs. Nerve fibers branch within these ganglia, surround one or many of the enteric neurons, and intercalate with the glial cells that form the scaffold of these ganglia. This structure prompted Phillips and Powley (2000) to speculate that IGLEs are activated by organ distensions, which passively distort (stretch) these structures. By combining physiologic studies with anterograde tracers, Zagorodnyuk *et al.* (2001) were able to show a close spatial relationship between the punctate receptive fields of mechanosensitive vagal afferent endings and IGLEs in the guinea pig stomach. Such a role in mechanosensation is further supported by experiments in genetically engineered mice lacking the gene for neurotrophin 4 (NT4). These knockout mice show a decrease in IGLE density within the proximal intestinal tract, and display an atypical eating behavior characterized by spurts of feedings, rapidly filling the stomach, interspersed with breaks (Fox *et al.*, 2001). These findings suggest that a satiety signal triggered by distension of the gastrointestinal tract is altered, possibly due to the change (reduction or absence) in peripheral mechanosensory elements. The close proximity between enteric neurons and vagal afferent fiber terminals certainly raises the question of whether and how the intrinsic and extrinsic afferent innervations of the gut interact. Inhibition of calcium-dependent transmitter release or the use of antagonists to neurotransmitters of enteric nervous system neurons, such as acetylcholine, did not affect vagal responses to mechanical stimulation, arguing against a sequential activation of enteric and – secondarily through synaptic transmission – vagal afferent fibers (Zagorodnyuk *et al.*, 2003).

Less information is available about IMAs, which are defined by branching fibers that run parallel to the smooth muscle cells within the circular or longitudinal muscle layers of the gastrointestinal tract (Wang and Powley, 2000). Interestingly, they are mostly found close to sphincteric regions, suggesting that they may provide important information about active tension generated by these muscles. While structure and distribution along the axis of the gut are consistent with IMAs functioning as tension receptors, no experimental evidence has directly shown the importance of IMAs in responses to muscle tension or stretch (Phillips and Powley, 2000).

Using anterograde tracers, several investigators have demonstrated that peripheral nerve terminals branch, at times forming hybrid endings in distinct areas, such as the myocardium and endocardium, or having endings with two distinct morphologies (Berthoud and Powley, 1992; Cheng *et al.*, 1997; Phillips and Powley, 2000). Consistent with such branching patterns, injection of different retrograde labels into distant areas of the same organ, such as the gastric fundus and pylorus, leads to double-labeling of a significant fraction of vagal and spinal neuron cell soma in nodose and dorsal root ganglia, respectively, suggesting that one neuron can innervate different areas of the same viscus (i.e., has multiple receptive endings or receptive fields in an organ; an example is given in Figure 3). That one visceral sensory neuron and its peripheral ending may have more than one receptive field is supported by nonanatomic, electrophysiological reports showing several distinct receptive fields, separated by as much as 3 cm, in about 10% of gastric or colorectal afferents (Berthoud *et al.*, 2001).

It is not unprecedented that a sensory neuron may have a widely branching terminal tree and multiple receptive fields in a tissue or organ. One defining characteristic of visceral pain is that it is referred to muscle and skin, and it has long been argued that a single visceral sensory neuron in the nodose or a dorsal root ganglion may give rise to axons that innervate different tissues (see Ness and Gebhart, 1990 for review). Although anatomical evidence in support of such dichotomizing afferents is limited and has been criticized methodologically in the past, several recent reports suggest that a single dorsal root ganglion neuron may give rise to axons that terminate in two different organs, such as urinary bladder and distal colon (Malykhina *et al.*, 2004).

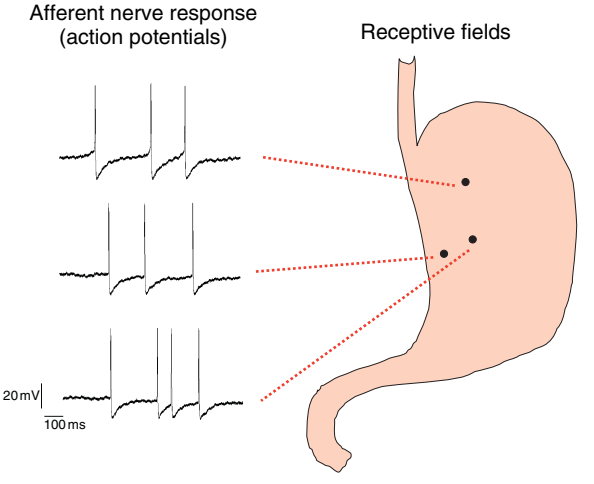

Figure 3 Example of a single visceral afferent with multiple receptive endings, or receptive fields, in an organ. In this example of a gastric vagal afferent, action potentials are shown to be evoked by probing at three different sites on the glandular portion of the rat stomach.

This observation raises the question of whether such promiscuous targeting of different organs is restricted to the pelvic organs and might be a phylogentic imprint of the cloaca. While physiologic studies have demonstrated the presence of two or more receptive fields within a single organ (Janig and Koltzenburg, 1991; Berthoud *et al.*, 2001), there is no complementary evidence showing that visceral afferents respond to stimulation of two anatomically distinct organs (Sengupta and Gebhart, 1994a, 1994b).

3.19.2.2 Sensory Axons

Electron microscopic and physiologic studies have demonstrated that virtually all visceral sensory neurons have unmyelinated or thinly myelinated axons (C and Aδ fibers), with a predominance of C fibers (Sengupta *et al.*, 1989, 1990; Berkley *et al.*, 1990; Undem and Weinreich, 1993; Sengupta and Gebhart, 1994a, 1994b; Navaratnam *et al.*, 1998). As metabolic demands increased in homeothermic animals, or visceral functions became linked to complex social function, more rapid sensory feedback became increasingly important. Myelination of neurons thus granted an advantage for survival. Changes in myelination of visceral axons also reflect phylogentic differences in vital organs, such as those for respiration, and their associated social function, such as vocalization. For example, the need for rapid adjustments of gas exchange during exercise requires monitoring of respiratory expansions of the lung. Consistent with these theoretical assumptions, most stretch receptors in the airways and lungs of mammals are associated with myelinated axons (Taylor *et al.*, 1999). Vocalization, in turn, relies on rapid changes in airflow, associated with movements of laryngeal, pharyngeal, and/or oral structures (Canning *et al.*, 2004). This evolution of afferent pathways with distinct conduction velocities fits with a phylogenetic tree described by Porges, who proposed that increasingly complex metabolic and social demands led to the evolution of more rapidly adjusting control mechanisms for autonomic function (Porges, 1998, 2003).

3.19.2.3 Central Terminations

As mentioned above, the central terminations of visceral afferent neurons project into the brainstem or spinal cord. Vagal sensory neurons send their central endings to the ipsilateral nucleus of the solitary tract and – for some gastrointestinal afferents – the area postrema. The terminals branch along the rostrocaudal axis of the brainstem and may even cross the midline, making connections with several second-order neurons (Altschuler *et al.*, 1989). Some visceral input from the cardiovascular system and upper respiratory tract, most notably the larynx, projects to the nucleus ambiguus, the main sensory ganglion of the glossopharyngeal nerve, allowing the integration of afferent information from pharynx and larynx, which is important for the regulation of deglutition and vocalization (Taylor *et al.*, 1999; Saper, 2002). Despite the tremendous differences in brain structures between fish and mammals, this basic organizational structure can be found in all vertebrates.

Within the mammalian spinal cord, most visceral sensory neurons project via the dorsal roots to superficial laminae I and II of the dorsal horn, with some extending to laminae V and X. Unlike spinal patterns of termination of cutaneous afferents, which are circumscribed in area and limited largely to a single spinal segment on the side ipsilateral to the input, the spinal terminations of visceral afferents spread rostrocaudally above and below the spinal segment of entry into the spinal cord and also cross to the contralateral spinal dorsal horn (Sugiura and Tonosaki, 1995). Visceral afferent terminals in the spinal dorsal horn are further distinguishable from cutaneous afferent terminals ultrastructurally in that they possess a greater number and density of terminal swellings, suggestive of a greater number of synapses and thus potentially greater and more diffuse input (Sugiura and Tonosaki, 1995).

In the sacral spinal cord, many visceral afferents terminate in the intermediolateral region and provide important input to the sacral parasympathetic nucleus, a component of the autonomic nervous system that sends preganglionic efferents out of the ventral roots of the spinal cord (Vizzard *et al.*, 2000). As already mentioned for visceral afferents projecting to the brainstem, spinal afferents that terminate within the lumbosacral cord form synapses with many second-order neurons over several segments within the rostrocaudal direction. This spread of central terminations may be important in responses requiring coordination of different organ functions. For example, micturition generally inhibits defecation in mammals (Pezzone *et al.*, 2005). However, the interactions with several central neurons also contribute to the poor ability to precisely locate and/or discriminate visceral stimuli.

3.19.3 Neurochemical Properties of Visceral Sensory Neurons

The expression of surface markers, structural proteins, ion channels, or transmitters has enabled us to

identify subgroups of sensory neurons, which may serve distinct functions. While helpful in the study of cutaneous sensory neurons, the utility of such surrogate markers appears to be limited in visceral sensory neurons. For example, the heat- and acid-sensitive ion channel TRPV1 (capsaicin receptor) is primarily expressed by small-diameter dorsal root ganglion neurons, which cannot be stained with neurofilament antibodies, a surrogate marker for myelination (Michael and Priestley, 1999; Zwick *et al.*, 2002; Yoshimura *et al.*, 2003). Based on physiological studies, most of these cells likely function as polymodal nociceptors (Perry and Lawson, 1998; Fang *et al.*, 2005a). However, this classification does not hold for visceral sensory neurons. Cough receptors in the extrapulmonary airways by definition respond to irritants (i.e., potentially noxious substances). However, many of these neurons are capsaicin-insensitive (Carr *et al.*, 2003; Kollarik and Undem, 2002, 2004; Canning *et al.*, 2004; Undem *et al.*, 2004). Conversely, nearly all colon sensory neurons show immunoreactivity for TRPV1 or respond to capsaicin (Robinson *et al.*, 2004; Sugiura *et al.*, 2004). Finally, while virtually all gastrointestinal sensory neuron axons in mice conduct in the C fiber range, about 30% of nodose neuron axons exhibit neurofilament immunoreactivity commonly associated with myelination (Ruan *et al.*, 2004). These findings highlight our still limited understanding of visceral sensory innervation.

It is generally held that groups of neurons with distinct functions and, therefore, also distinct anatomical and neurochemical markers likely exist. This assumption is supported by two neurochemical markers, which do provide some important information. The presence of immunoreactivity for substance P or calcitonin gene-related peptide (CGRP) is restricted to a small number of vagal sensory neurons, most of which innervate the upper airways and have their cell bodies in the proximal (jugular) portion of the ganglion (Altschuler *et al.*, 1989; Ruan *et al.*, 2004; Undem *et al.*, 2004; Thai Dinh *et al.*, 2005). Both neuropeptides are also found in greater numbers of spinal visceral sensory neurons (Vizzard, 2001; Robinson *et al.*, 2004). Their afferent terminals in organs may also have an effector function in their target area, as these neurons can release substance P or CGRP from both central and peripheral terminals (Fischer *et al.*, 1996; Castagliuolo *et al.*, 1997; Grady *et al.*, 2000). Significant activation of the nerve terminal or invasion of action potentials past branch points with propagation into other terminals (axon reflex) may trigger such peripheral release of substance P or CGRP. Both neuropeptides affect smooth muscle function, attract and activate immune cells, most notably mast cells, thereby contributing significantly to the development of neurogenic inflammation (Heiman and Newton, 1995; Riegler *et al.*, 1999; Theodorou *et al.*, 1996; Renzi *et al.*, 2000; Willis, 2001).

3.19.4 Functional Properties of Visceral Afferents

The preceding section emphasizes that visceral sensory neurons within a single species do not constitute a homogeneous population, making it difficult to discuss the function of these neurons across different species. In vertebrates, most viscera receive a dual sensory innervation, with vagal and spinal afferents having distinct functional properties, further confounding this picture. Despite these limitations, many recent studies have shed significant light on the functional properties of visceral sensory neurons.

3.19.4.1 Molecular Mechanisms of Signal Transduction

Visceral sensory neurons in dorsal root ganglia express many of the known ion channels involved in the transduction of mechanical, thermal, and chemical stimuli. Different members of the TRP channel family provide a molecular basis for thermosensation (McCleskey and Gold, 1999; Zhang *et al.*, 2004). This includes the capsaicin receptor TRPV1, which can be found in about half of all nodose ganglion neurons and most spinal dorsal root ganglion neurons innervating the colon (Michael and Priestley, 1999; Robinson *et al.*, 2004; Sugiura *et al.*, 2004, 2005). The functional importance of these results is supported by single-fiber recording studies showing that gastrointestinal afferent endings respond to heat and/or cold stimuli (El Ouazzani and Mei, 1982; Kang *et al.*, 2004). TRPV1 is expressed widely, particularly in sensory neurons, where it is considered by some to designate a neuron as a polymodal nociceptor (McCleskey and Gold, 1999). Although TRPV1 has been extensively studied, knowledge about its role in visceral sensation and nociception is limited. Significantly, TRPV1 is expressed in the bladder, including the urothelium, and bladder function is significantly altered in TRPV1 knockout mice, leading to the suggestion that TRPV1 is important in detecting bladder stretch (Birder *et al.*, 2001, 2002; Dang *et al.*, 2005a).

Vagal and spinal visceral sensory neurons also express acid-sensitive ion channels (ASIC), which are related to the degenerin/ENaC super family of voltage-insensitive, amiloride-sensitive Na^+ channels, a family of mechanosensitive ion channels

identified in *Caenorhabditis elegans*. ASICs are encoded by four different genes and ASICs 1–3 are expressed, typically as heteromers, in sensory neurons (Kellenberger and Schild, 2002). The name ASIC was chosen based on proton sensitivity of these ion channels. However, these channels are also activated by stretch. Consistent with a potential contribution of these channels in visceral mechanosensation, experiments in ASIC3 knockout mice revealed differences in afferent fiber activation during visceral distension (Jones *et al.*, 2005). However, a complex picture is emerging with respect to the role(s) of ASICs in mechanosensation. Some knockouts (ASIC1) exhibit increased mechanosensitivity rather than decreased sensitivity to visceral distension, which has been attributed to different contributions of various subunits forming the multimeric ion channel pore (Page *et al.*, 2004).

As described above, mechanical or chemical stimuli can also trigger the release of various mediators from specialized epithelial cells, which in turn then interact with ionotropic and/or metabotropic receptors on the peripheral terminals of visceral afferents (Figure 4). A different interaction between epithelial cells (urothelium) and the urinary bladder has been demonstrated in mammals, where no specialized paracrine cells have been identified within the epithelium. Despite the absence of cells with special endocrine activity, bladder distension triggers ATP release from urothelial cells, which activates purinergic receptors (P2X receptors) on bladder afferent terminals, potentially triggering micturition and/or sensation (Cockayne *et al.*, 2000, 2005; Vlaskovska *et al.*, 2001). Seven P2X receptors have been cloned ($P2X_{1–7}$), all of which are permeable to monovalent cations and several of which, either as homo- or hetero-oligomers, have been implicated in visceral function and sensation (Burnstock, 2001). $P2X_2$, $P2X_3$, and $P2X_{2,3}$ receptors are expressed in small- to medium-diameter sensory neurons (Petruska *et al.*, 2000) and in the micturition reflex pathway (Zhong *et al.*, 2003). Mice with engineered deletions of $P2X_3$ receptors exhibit bladder hyporeflexia, thereby demonstrating the physiologic importance of urothelial ATP release in bladder function (Vlaskovska *et al.*, 2001). It is unclear whether epithelial ATP release similarly affects gastrointestinal or respiratory function. Vagal and spinal neurons innervating the gut also express P2X receptors and respond to purinergic receptor agonists (Robinson *et al.*, 2004; Dang *et al.*, 2005b). However, P2X receptor antagonists do not alter responses of vagal afferents to esophageal stretch (Zagorodnyuk *et al.*, 2003). Considering the distinct microscopic structure of the esophageal epithelium (squamous epithelium), it remains to be seen if mechanical or chemical stimuli trigger epithelial ATP release in other areas of the gastrointestinal tract or in the airways.

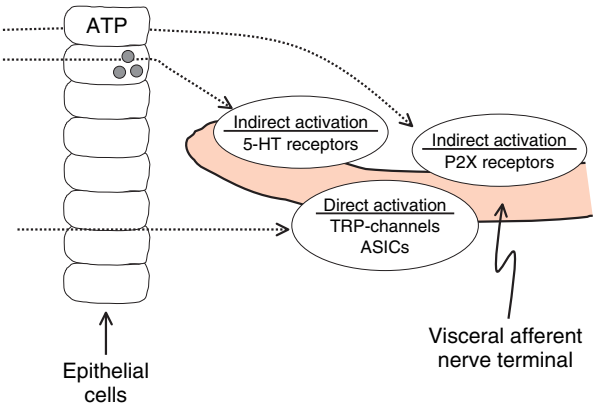

Figure 4 Diagrammatic illustration of direct and paracrine-like signaling in the viscera. Illustrated is a visceral afferent nerve terminal that is directly sensitive and activated by protons (e.g., ASIC and/or TRP channels) or thermal stimulation (TRP channels) applied to the organ. Other stimuli release bioactive substances (e.g., serotonin, 5-HT, or ATP) from epithelial cells which in turn activate visceral afferent nerves, an indirect action of a visceral stimulus.

3.19.4.2 Functional Characterization of Visceral Afferents

The function of visceral afferents has been studied extensively *in vivo* and *in vitro*, however almost exclusively in mammals. Most of the detailed information is derived from single-fiber recordings. The distal end of the cut nerve is split into small filaments, which are placed on a recording electrode to monitor action potentials in response to stimulation of a target organ (e.g., stomach). As most fibers in a given nerve filament will not innervate this target organ, recordings generally reflect the activation of a single nerve fiber. This approach requires a search stimulus to determine whether a fiber bundle contains processes projecting to the organ of interest. The choice of search stimulus, however, obviously biases results in favor of sensitivity to the search stimulus. Accordingly, claims of response specificity must be evaluated carefully.

Using the single-fiber recording method, early investigators functionally characterized mucosal, muscle, serosal, and mesenteric receptors based on responses to chemical and principally mechanical stimuli. Unlike the structural elements discussed previously (IGLEs and IMAs), the designations 'receptor' and further specifications, such as 'mucosal' or 'serosal', were based solely on

functional characterization in the absence of anatomical evidence.

Mucosal receptors were identified on the basis of rapid adaptation to mechanical stimulation and apparent selective chemosensitivity, both of which were absent after the mucosa was carefully scraped away, confirming a location in the mucosa (e.g., Iggo, 1957; Paintal, 1957; see Sengupta and Gebhart, 1994c for review). Whereas nutrient chemosensitivity of mucosal receptors was an early focus of study (e.g., glucose, lipid, and amino acid sensitivity), most recent studies used mechanical stimuli to functionally characterize muscle, serosal, and mesenteric receptors. Mechanical stimuli, such as blunt probing, tissue compression, traction on the mesentery, or hollow organ distension, have the experimental advantage that they can be easily and repeatedly applied. Single-fiber recordings from different species generally show punctate or narrowly circumscribed receptive fields for most mechanosensitive fibers. However, some visceral neurons may have two or more receptive fields, which can be located in anatomically distinct areas of an organ, such as the fundus and distal corpus of the stomach in mice (see Figure 3) (Berthoud *et al.*, 2001).

Most investigations have studied afferent fiber responses to distension, corresponding to different filling states and/or intraluminal pressures. That distension-sensitive visceral afferent fiber endings are located in organ muscle has been demonstrated by removal of mucosal, submucosal, and serous membranes of organs without compromising fiber responses to distension (see Sengupta and Gebhart, 1994c). All hollow organs contain muscular elements, and thus two distinct mechanisms are conceptually possible: stretch and tension (Phillips and Powley, 2000). Using the orientation of muscle cells as reference, stretch receptors are in parallel with muscle cells and will be activated by organ distension, such as propelled chyme or – under experimental conditions – inflation of a balloon. Contraction of the muscle running in parallel should cause a shortening in length and thus decrease firing of these receptors. In contrast, tension receptors are located in series with muscle cells. Therefore, muscle contractions will activate tension receptors even in the absence of changes in length. This model is borrowed from analogous structures involved in the regulation of skeletal muscle function (muscle spindle and Golgi tendon apparatus).

Sustained hollow organ distension typically triggers a slowly adapting response of visceral afferents. The response profiles of mechanosensitive visceral afferents to balloon distension have not yet convincingly demonstrated the existence of distinct receptors that distinguish between stretch or tension in hollow viscera. The best, but still controversial experimental evidence relates to mechanoreceptors in the atria (Taylor *et al.*, 1999). The type B receptor is activated by filling during the first part of diastole, associated with small pressure changes (V-wave of the pressure profile); the type A receptor is activated in response to atrial contraction at the end of diastole (A-wave of the pressure profile), associated with a second and higher pressure increase (Paintal, 1973). Most fibers identified based on their stretch sensitivity (i.e., volume change) also respond to muscle contraction (tension). This may in part be due to technical limitations, such as difficulty in achieving truly isometric (only tension changes) or isotonic (only stretch changes) conditions in viscera. In addition, the deformation associated with filling of a hollow organ may generate passive tension, which further blurs the distinction between stretch and tension (Lynn *et al.*, 2005; Zagorodnyuk *et al.*, 2005).

As already indicated, most investigators use graded distension of hollow organs with balloons or fluid when studying mechanosensitive visceral afferent fibers. Despite some variation between different organs and species, the results generally reveal that mechanosensitive visceral afferents dynamically encode stimulus intensity over a wide range. Under normal conditions, luminal pressures remain well below 20 mmHg in the urinary bladder and gastrointestinal tract. However, localized pressures can briefly exceed 100 mmHg during muscle contractions. Most healthy human volunteers perceive luminal pressures exceeding 30 mmHg as uncomfortable or painful (Corsetti *et al.*, 2004; Mayer, 1994). Consistent with these findings, distension pressures of 30 mmHg and higher trigger aversive, pseudaffective, and/or autonomic responses in experimental animals (Ness *et al.*, 1991; Ozaki *et al.*, 2002; Ness and Elhefni, 2004). Interestingly, a relatively small proportion of mechanosensitive fibers (~20–25%) require distending pressures of at least 25 mmHg for activation (Sengupta *et al.*, 1989, 1990; Sengupta and Gebhart, 1994a; Ozaki *et al.*, 1999; Ozaki and Gebhart, 2001). Such high-threshold fibers have only been found in spinal, and not vagal afferents, corresponding to the widely held importance of spinal sensory pathways in nocifensive reactions to noxious stimuli, discussed above (Cervero and Foreman, 1990; Cervero, 1994; Cervero and Laird, 1999). This prompted speculations that high-threshold mechanoreceptive fibers function as nociceptors in the viscera (specificity theory). Opponents of this interpretation point to the fact that low-threshold

mechanosensitive fibers also encode stimulus intensity well into the noxious range and thus contribute to nociception (intensity theory). Using the human percept as an indirect means to resolve this controversy, Tack *et al.* (2004) demonstrated that changes in descriptors for nonpainful sensations change over a wide range of stimulus intensities, described as a stimulus-response function, which shifts in parallel with that of painful sensations when visceral sensation is altered using pharmacological interventions. These findings support a model with high- and low-threshold visceral mechanosensitive pathways, both contributing to pain and the defensive responses triggered by the organism.

In addition to response threshold, temporal changes in response to a persistent stimulus are an important physiologic property, potentially allowing identification of distinct subgroups. Afferent fiber responses to organ distension or stretch generally show slow adaptation. Differences in time course and degree of adaptation have led, at times, to complex classification schemes, although the impact of these different firing patterns on visceral sensation or regulation of visceral function remains undefined. The very rapidly adapting stretch receptors described in stomach and colon may be an exception, as these afferents are activated by light mucosal stroking, suggesting that they have receptive endings in the mucosa and sense luminal flow (Page and Blackshaw, 1998; Lynn and Blackshaw, 1999; Page *et al.*, 2002). A similar response profile has also been described for irritant receptors of the airways (Paintal, 1973), which can also be activated by chemicals and are involved in triggering the cough reflex.

3.19.4.3 Functional Characterization of Chemosensitive Visceral Afferents

As mentioned previously, relatively little information exists about chemosensitive visceral afferents. A small number of afferents innervating the small bowel can be activated by luminal perfusion with different nutrients (Jeanningros, 1982; Mei, 1985). It is likely that most nutrients activate specialized epithelial cells, triggering the release of CCK and/or other mediators, which, in turn, depolarize afferent fiber terminals. Consistent with this interpretation, enteroendocrine cells of the small intestine express bitter receptors that have been identified in taste buds of the tongue. Exposure to cycloheximide increases the intracellular calcium concentration in these enteroendocrine cells, thereby initiating a cascade of events that ultimately leads to mediator release (Wu *et al.*, 2002). The activation of afferent neurons through such paracrine cells provides the body with dual and overlapping feedback regulatory mechanisms. The local release may affect neighboring structures and regulate or modulate their function, such as increasing blood flow or altering secretion or motility. The parallel activation of neuronal circuits, intrinsic and extrinsic, may further optimize digestion by rapidly and effectively modifying organ function locally and/or by affecting distant organs, such as activating pancreatic secretion or slowing the further delivery of luminal contents by inhibiting gastric motility. At the same time, extrinsic afferent fiber activity may alter the organism's behavior, decreasing food intake and/or even more complex actions required for procurement of food, such as foraging or hunting (Berthoud, 2004). At first glance, it seems counterintuitive that visceral, specifically vagal afferent input, which presumably goes largely unnoticed, may have such a profound effect. However, circumstantial evidence derived from clinical data and some experimental results support this interpretation. As already described above, a decrease in mechanosensory elements (IGLEs) within the gastrointestinal tract of NT4 knockout mice changes patterns of food intake (Fox *et al.*, 2001). Initial results suggest that electrical stimulation of the stomach nonselectively activates gastric vagal afferents, decreases food intake, and shows positive effects in the treatment of obesity (Xu *et al.*, 2005). Direct vagal nerve stimulation reportedly improves depression and is beneficial in the treatment of refractory epilepsy, presumably by inhibiting areas in the medial areas in the forebrain (see below) (Zagon, 2001).

While it is not known whether such specialized enteroendocrine cells can be found in close proximity to visceral sensory nerve terminals within the gut of species as different as fish and mammals, neuroepithelial signaling is an evolutionarily old signal. Glomus cells, which sense oxygenation and signal through the ninth and/or tenth cranial nerve, affect respiratory effort in organisms from elastomeres to humans (Taylor *et al.*, 1999). Despite this parallel, significant differences in sensory feedback that regulates gas exchange emerge, when comparing lung breathers with fish or tadpoles, which rely on gills for this function. With the development of lungs, the main signal driving respiration is hypercapnia and the associated drop in pH, sensed by central chemoreceptors located mainly on the floor of the fourth ventricle in the brainstem (Paintal, 1973). Amphibians apparently recapitulate this switch during metamorphosis. In early larval stages, acidification does not alter the rhythmic discharge of cranial nerves involved in respiratory efforts. With the onset of lung breathing, a slight

decrease in pH significantly enhances neuron bursting patterns.

Not all chemical stimuli activate visceral afferents indirectly through specialized epithelial or other non-neuronal cells. As discussed earlier, neurons express proton-sensitive ion channels (ASIC and TRPV1). Acid exposure can directly activate cardiac, gastrointestinal, bladder, and pulmonary neurons *in vitro* and *in vivo* (see Figure 4) (Benson *et al.*, 1999; Kollarik and Undem, 2002; Kang *et al.*, 2004; Sugiura *et al.*, 2004, 2005). Studies of cardiac afferent fibers suggest that such acid-sensitive receptors sense ischemia, as oxygen-deprived tissue relies on anaerobic metabolism, which generates lactate and rapidly decreases tissue pH (Benson and Sutherland, 2001). Similarly, irritant or cough receptors within the respiratory tract are likely activated by direct interaction between some irritants and the nerve terminal (Moore *et al.*, 2000; Kollarik and Undem, 2002; Canning *et al.*, 2004; Undem *et al.*, 2004). Ischemia-sensitive fibers and irritant receptors both trigger defensive responses to ensure the survival of the organism.

3.19.4.4 Polymodal Character of Visceral Sensory Neurons

Under normal conditions, sensory neurons respond to specific stimulus modalities, thereby allowing meaningful decoding of messages by higher-order sensory neurons in the central nervous system. Such modality specificity has also been described for afferents innervating different viscera. However, many visceral afferents are polymodal and respond to two or even three distinct stimulus modalities (Blackshaw and Grundy, 1989; Lynn and Blackshaw, 1999; Ozaki *et al.*, 1999; Ozaki and Gebhart, 2001; Berthoud *et al.*, 2001; Page *et al.*, 2002). Most chemosensitive visceral mucosal afferents and the majority of mechanosensitive visceral afferents conduct in the C-fiber range. Based on conduction velocity and lack of modality specificity, most visceral afferents resemble polymodal nociceptors that innervate the skin (Fang *et al.*, 2005b). However, it is unlikely that all or even most polymodal visceral afferents function as nociceptors in the viscera, thus leaving uncertain the physiological relevance of their polymodal character. Because the density of visceral innervation is low, and the rostrocaudal spread of visceral input within the spinal cord and brainstem is great, the polymodal character of visceral sensory neurons may further contribute to the poor ability of humans to discriminate and localize stimuli within the gut lumen. We also know that thermal or chemical stimuli can acutely alter excitability of mechanosensitive gastric vagal afferents (Kang *et al.*, 2004). Accordingly, sensitivity of visceral afferent ending to other modalities of stimuli may alternatively represent local modulatory influences on sensory feedback that can regulate food intake or satiety.

3.19.4.5 Sensitization

Sensitization is an increase in response magnitude of a sensory afferent fiber to an applied stimulus, frequently associated with a decrease in response threshold. Although initially introduced to describe the increase in excitability of cutaneous nociceptors following tissue injury (see Perl, 1996 for review), sensitization is now recognized as a representation of plasticity of neural function, and a property that defines most mechanosensitive visceral afferent fibers. Studies investigating sensitization of visceral afferents typically induce acute or chronic inflammation in hollow organs. These experimental forms of gastritis, colitis, or cystitis are associated with behavioral changes, such as increased micturition frequency or nocifensive reactions, as well as increased responses of afferent fibers innervating the organ. Detailed physiological studies show that both low- and high-threshold mechanosensitive visceral afferents sensitize, suggesting that both can contribute to visceral pain (because sensitization is a property unique to nociceptors in skin; see above). However, sensitization of visceral afferents has only been studied for mechanical stimuli. Considering the polymodal character of most visceral afferents, it is highly likely that responses to other stimuli are similarly sensitized, which may have implications beyond the development of visceral discomfort and/or pain. Accordingly, functions such as secretion and motility may be enhanced and play an important role in infections or parasitic infestations, where more rapid clearance of luminal contents may increase the chance for recovery and survival (e.g., intestinal infection).

3.19.5 Central Projections of Visceral Afferents

In vertebrates, the cranial (or oral) end of the organism is also the business end for key vital functions: gas exchange (gills and lungs), food intake, and – in fish – also electrolyte and fluid exchange (gills). Sensory input relevant for regulation of these functions is processed in the brainstem, where input from the vagus and

glossopharyngeal nerves to the nucleus of the solitary tract and the nucleus ambiguus is integrated with afferent information from other cranial nerves, triggering appropriate adjustments in visceral function and/or behavior (Paintal, 1973; Taylor *et al.*, 1999). Vagovagal reflexes execute relatively simple responses, such as gastric accommodation (Zhang *et al.*, 1998; Chang *et al.*, 2003; Travagli *et al.*, 2003). More complex responses rely on central pattern generators in the brainstem, which can also be activated by corticobulbar projections. The swallowing reflex is a good example of such a patterned response; it is triggered by pharyngeal stimulation, but can certainly also be initiated volitionally without such a peripheral stimulus (Goyal *et al.*, 2001).

Transneuronal tracing studies using viral vectors reveal projections of visceral afferent neurons to many structures in the brainstem, midbrain, diencephalon, and forebrain, including the rostral ventrolateral medulla, reticular formation, locus coeruleus, mesencephalic tegmentum, hypothalamus, thalamus, and amygdala (illustrated in Figure 1) (Marson, 1997; Valentino *et al.*, 2000; Vizzard *et al.*, 2000; Cano *et al.*, 2001; Rinaman and Schwartz, 2004). Many of these structures play a role in the regulation of autonomic function or are important relay stations for sensory input. Interestingly, several of these areas are involved in arousal and alertness. Vagal stimulation can trigger lasting inhibition of locus coeruleus neurons, a potentially important adaptive response that promotes rest and decreases energy expenditure when food intake reaches satiety levels (Zagon, 2001).

With the development and increasing size of forebrain structures, the processing of information that relates to interaction between the organism and its surroundings (external environment) – touch, sound, light – occurs primarily in the enlarging cortical mantle structures. Afferents providing information about volitionally controlled aspects of visceral function such as deglutition, defecation, or vocalization, similarly project to these mantle structures. However, most visceral input (interoception) activates deeper brain structures closer to the midline, including regions often referred to as the limbic system (evolved from the entorhinal cortex), which processes olfactory signals and plays an important role in emotional responses (Vogt, 2005). The integration of visceral input with information about smell and taste and centers controlling emotion has several potential implications. A bitter taste and/or foul smell trigger disgust, an aversive reaction, which will stop the organism from ingesting possibly poisonous or spoiled material. The opposite will be true for tastes or smells that are perceived as pleasant, which will promote food intake (Berthoud, 2004). Another implication relates to consciously perceived visceral input. Psychophysical research has demonstrated that visceral stimuli are generally more strongly linked to affective dimensions than is cutaneous sensory input (Strigo *et al.*, 2002, 2003). Considering that affect does not simply define states, such as happiness, but constitutes a strong drive (emotive function of sensory input or pain), the more significant emotional impact of visceral stimuli may represent a protective mechanism for vital functions, increasing the likelihood of survival.

3.19.6 Conclusion

The study of visceral sensation across a wide range of species reveals specializations of structure and/or function that reflect gradual adaptation of sensory mechanisms during the evolution from aquatic to terrestrial animals, from poikilothermic to homeothermic organisms. The findings described in this article suggest a gradual development that increases speed and precision of information transfer, enabling more rapid and targeted regulation of visceral function and/or animal behavior. The associated decrease in metabolic costs, and more effective adjustments to changing environmental conditions, likely enhanced survival chances for the organism (see Table 1).

Table 1 Characteristics of visceral afferent (extrinsic) innervation

Anatomically associated with the autonomic nervous system
Unmyelinated (C) and thinly myelinated (Aδ) axons
Myelination of visceral afferents is largely restricted to areas requiring rapid sensory feedback and visceral functions that are part of social interactions
In mammals, organs are innervated by two sets of nerves, each with different function(s)
Medium-sized cell soma in vagal nodose or spinal dorsal root ganglia
Less than 10% of spinal afferent inflow arises from viscera
Intraspinal arborization of spinal afferent terminals is extensive
Most, if not all, are polymodal (thermo-, chemo-, and/or mechanosensitive)
Endings in all different layers of organs with some structural (and likely functional) specialization
Neuroepithelial signaling plays an important role in chemosensation and contributes, at least in the mammalian bladder and intestine, to mechanosensation
They sensitize (an increase in response magnitude, i.e., excitability)

3.20 Evolution of Sound Localization in Mammals

S J Sterbing-D'Angelo, Vanderbilt University, Nashville, TN, USA

Glossary

binaural	With both ears.
contralateral	On the opposite side.
exteroceptive	Perception of external objects.
fossorial	Adapted to digging and underground life.
inferior colliculus	Midbrain nucleus of the ascending primary auditory pathway.
interaural	Between both ears.
isocortex	Top layer of the cerebral hemispheres in mammals (= neocortex).
lemniscal pathway	Pathway that involves the lateral lemniscus in the brainstem.
marsupials	Mammals in which the female typically has a pouch (marsupium), in which it rears its young through early infancy.
mesencephalic	Located in the midbrain.
monaural	With one ear.
monotremes	Egg-laying mammals.
Placentalia	Mammals that rear young through early infancy with a placenta.
sauropsids	Birds and reptiles.
taxon (plural taxa)	Taxonomic unit, a grouping of organisms.

3.20.1 Introduction

The ability to localize sound sources in a complex environment is of paramount importance for orientation in a biological habitat, and intraspecies as well as interspecies communication. The accurate localization of an approaching predator or competitor can be a matter of life or death. This topical essay discusses the major features of the evolution of sound localization in mammals in terms of the physical cues for sound localization, the major brain structures involved, and behavioral measures of localization acuity across taxa. Sound localization in mammals builds upon similar systems shared by lower vertebrates that utilize bilateral hearing, and adds unique abilities arising from the development of the external ear and from the development of the isocortex (neocortex). The evolution of sound localization in mammals is not characterized by a straightforward sequence of changes in the underlying brain structures concomitant with an improvement in ability but rather is more related to the ecological niche of each species. Different habitats and different behavioral strategies for survival require different solutions for sound localization. Many species from a variety of taxa have developed a remarkable acuity for localizing sounds, which comes close to or matches human localization acuity. However, while acuity may be similar, for example, across echolocating bats (microchiroptera), homologous brain structures involved in sound localization can be anatomically or functionally different.

3.20.2 Cues for Sound Localization

The cues for sound localization comprise interaural cues, which are based on the information derived from both ears, and monaural cues, which are caused by the filtering of each external ear, the pinna (for overview see Blauert, 1997). The interaural cues are used for lateralization, that is, the left/right discrimination of sound. The monaural cues give additional information on the elevation of a source and allow front/back discrimination. All vertebrates that have bilateral hearing use binaural cues to some extent (e.g., frogs, reptiles, and birds). For low-frequency sounds from the side, the time of arrival of the sound waves differs between the two ears. This is the interaural time difference (ITD). If the sound source direction is located along the mid-line axis, for example, front, rear, or directly above, the ITD would have the value zero, because the sound wave reaches both

ears at the same time. For lateral incidence angles, the sound travels around the head and the body of the animal on various paths to reach the far ear, that is, the ear opposed to the sound event. The physiologically relevant ITD range depends on head size, head geometry, and pinna shape. A common measure to estimate the physiological range of ITDs in a species has been to simply measure the distance between the ear canal openings. However, depending on the angle of incidence and the shape or body position of an animal, sound has to travel on complicated paths around the animal. The ITDs in the fine structure of a sound can be detected up to ~2.5 kHz in many mammalian species. For both low and high frequencies, the ITDs in the envelope of a sound, for example, the onset slope or amplitude modulations, can also be utilized (Joris, 2003). For high-frequency sounds the head shadow attenuates the sounds at the far ear. This interaural cue is called the interaural intensity difference (IID). The IID for low frequencies is relatively small (a few dB), but for high frequencies it can be as large as 20–30 dB for certain directions, depending on the head size.

In contrast to amphibians, reptiles, and birds, most nonaquatic and nonsubterranean mammals possess a pinna of varying complexity in shape and mobility. The resulting pinna cue is what distinguishes the localization ability of the mammals. The angle of sound incidence upon the ridges and folds of the pinna causes certain frequencies to be amplified while others are attenuated. Therefore, the pinna cues provide information about the location of sound in space. Many mammals can move the pinna. Others, for example some primates, cannot. It is of paramount importance to emphasize that ITD, IID, and the monaural spectrum always vary together in a natural acoustic environment. Because of the influence of the pinna, the magnitudes of the IID and the ITD can vary nonmonotonically with frequency and direction, especially for high frequencies. For natural broadband sounds delivered in an ecologically valid environment, the left and right ear will have a spectral transfer function at each azimuth and elevation, and the differences between the ears lead to an interaural difference spectrum (for review see Blauert, 1997). The implication is that the advanced localization system of mammals can make use of the combined cues to achieve the highest possible acuity in all spatial dimensions. However, many fossorial species, for example the pocket gopher, show little ability to localize sounds, which is explainable by the lack of spatial cues in their subterranean habitat (Heffner and Heffner, 1990).

3.20.3 Brain Structures for Sound Localization

The brain receives acoustic information via only one row of inner hair cells located in the cochlea of the inner ear. Unlike the retina, which is a two-dimensional structure, no spatial information is inherent in the pattern of activation of the receptors. Hence, the spatial position of a sound source has to be computed by the auditory structures of the brain. Solving this complex computation has resulted in a variety of evolutionary adaptations. I will restrict the discussion of the role of brain structures for the evolution of sound localization to a couple of nuclei in the superior olivary complex, the auditory midbrain (inferior colliculus), and the auditory cortex, although other brain structures are also involved in sound localization. To describe them all would exceed the scope of this topical essay (see Encephalization: Comparative Studies of Brain Size and Structure Volume in Mammals, The Effects of Domestication on Brain Size, Cetacean Brain Evolution).

3.20.3.1 Brainstem

The superior olivary complex (SOC) is a group of auditory nuclei in the brainstem of amphibians, reptiles, and mammals. One major function of the SOC is to encode the cues that contribute to sound lateralization on the basis of convergent binaural ascending inputs arising from both ventral cochlear nuclei. The SOC consists of several nuclei. Of major interest for sound localization are the lateral superior olivary nucleus (LSO) and the medial superior olivary nucleus (MSO). The LSO is involved in the coding of IIDs (Boudreau and Tsuchitani, 1968) and envelope ITDs (Joris and Yin, 1995). The MSO processes ITDs in the fine structure of predominantly low-frequency sounds (Yin and Chan, 1990). The range of the interaural disparity cues increases with head size. A large head is especially advantageous for the use of fine structure ITDs. Hence, it is not surprising that mammalian species with large heads have a pronounced MSO and often a smaller LSO, while species with small heads have a relatively smaller MSO and a large LSO. However, a large-sized LSO does not necessarily indicate superior IID coding. For example, some hoofed species like the horse, are apparently not able to use IIDs to localize high-frequency tones, although they possess a well-developed LSO (Heffner and Heffner, 1986). The basic neuronal properties of the LSO appear to be similar across taxa (Tollin, 2003, review): most LSO neurons are excited by the ipsilateral ear and inhibited by the contralateral ear. In contrast, MSO neurons are excited by both ears in

the cat and many other mammals. Individual MSO neurons are tuned to a certain range of ITDs (Yin and Chan, 1990). There is some weak evidence that the neurons of the mammalian MSO are spatially arranged in a manner that is consistent with a 'delay line', the anatomical basis of a coincidence detector (cross-correlation) model of ITD processing (Yin and Chan, 1990) as proposed by Jeffress (1948). Although, in the barn owl, the delay line in the nucleus that corresponds to the mammalian MSO (nucleus laminaris, NL) appears to be more clearly developed than in mammals (Kubke *et al*., 2002; Carr and Konishi, 1988), the function shows strong similarities. Neurons of both the NL and the MSO time-lock to monaural and binaural stimuli, and respond maximally when time-locked spikes from each side arrive simultaneously, that is, when the difference in the spike conduction delays compensates for the ITD (Goldberg and Brown, 1969; Carr and Konishi, 1988; Yin and Chan, 1990). The homology between the mammalian MSO and the nucleus laminaris was accepted for decades but has recently been questioned (Carr and Soares, 2002, review). However, it is clear that the mammalian MSO appears to be a less ideal cross-correlator than the owl's NL (Batra and Yin, 2004), and additional mechanisms of ITD processing via inhibitory processes within the MSO have been proposed (Brand *et al*., 2002). These inhibitory mechanisms could actually improve the cross-correlator, and might therefore be an evolutionary step.

Until recently, the fossil finds of early, mesozoic mammaliformes and mammals included only small, shrew to rat-size species, for example, *Morganucodon*, whose head was only about 20 mm long. The average small size of these fossils suggested that those early mammals were nocturnal insectivores, and possibly specialized to hear predominantly high frequencies like extant small insectivores and many rodents. The finding that some insectivores, for example some bat species, have a predominantly monaural MSO (Covey *et al*., 1991) prompted the theory that the mammalian MSO was initially a monaural structure which became binaural when the early nocturnal insectivorous mammals explored more ecological niches and evolved into larger species after the decline of the dinosaurs (Grothe, 2000, review). However, other bat species possess a binaural or mixed binaural/monaural MSO (Harnischfeger *et al*., 1985), or a binaural MSO that resembles the MSO of nonecholocating mammals (Grothe and Park, 1998). This diverse functional organization, and especially monaural characteristic might reflect an adaptation for certain echolocation strategies in the different bat species rather than a primitive feature. More research in primitive nonecholocating insectivores is needed to evaluate this theory. The first true mammals were probably represented by *Hadrocodium*, *Repenomamus*, and *Gobiconodon* species, which would fill an intermediate position between the reptile-like *Morganucodon* and the earliest therian (therians = marsupial and placental mammals), *Triconodon*, a species whose cranial endocast morphology places it at the time of origin of the mammalian isocortex (Rowe, 1996). *Triconodon* was quite large, and was about the size of a Virginia opossum. However, recent fossil finds indicate that some of the early mammalian *Repenomamus* species were considerably larger, for example *Repenomamus giganticus*, which had estimated bodyweight of 12–14 kg, a skull length of 160 mm, and overall body length of more than 1 m. It has been proposed that *R. giganticus* was a carnivore (Hu *et al*., 2005). The apparently larger diversity in body size of those early mammals provokes the question whether some bigger species were sensitive to lower sound frequencies, and used the ITDs provided by their larger heads, and whether they possibly had a binaural MSO. A definite answer to this question cannot be provided by the fossils, because soft tissues are not preserved. In many primitive mammals, like monotremes and some insectivores the middle ear cavities are not bony, but in part covered by cartilage and connective tissue. What these species have in common is that their low-frequency hearing is poor independent of head size (Masterton *et al*., 1969; Aitkin and Johnstone, 1972; Gates *et al*., 1974). Hence, the evolution of the MSO and ITD coding in the brainstem remains an open question.

3.20.3.2 Midbrain

The central nucleus of the inferior colliculus (IC) is an obligatory station of the primary ascending auditory pathway. The neuronal sensitivity to ITDs was first described by Rose *et al*. (1966) for the ICC of the cat, and further examined by Goldberg and Brown (1969) for the beagle. In the mammal IC the processing of combined interaural and spectral cues requires convergence of monaural and binaural inputs and across-frequency integration. The neuroanatomical aspects of this convergence in the IC have been studied using simultaneous tracer injections in different monaural and binaural lower brainstem nuclei (Oliver, 1987; Oliver and Shneiderman, 1991; Oliver *et al*., 1997; Loftus *et al*., 2004). Further anatomical evidence for across-frequency interaction within the ICC was provided by

Malmierca *et al*., (1995). They found that distant isofrequency layers are interconnected in the ICC of the guinea pig. Some neurophysiological aspects of this convergence have been revealed for the ICC of the rabbit by combining the ITD with monaural amplitude modulation (D'Angelo *et al*., 2003). It became evident that most neurons integrate ITD and monaural information to a varying degree. Chase and Young, (2005) as well as Sterbing *et al*. (2003) found evidence for the integration of different localization cues in the ICC of the cat and the guinea pig, respectively. Therefore, the mammalian ICC is a potential source of substantial monaural and binaural integration in the lemniscal pathway of a variety of mammals, which exceeds the function of the auditory midbrain in lower vertebrates.

3.20.3.3 Isocortex

The origin of the mammalian isocortex, in which the auditory cortex is located, has been subject of contradicting studies (for review, see Aboitiz *et al*., 2002). In the past it was regarded as a homologue to a structure named the 'dorsal ventricular ridge' in reptiles, which receives thalamic auditory and visual inputs. However, recent studies suggest that the mammalian isocortex arose from the dorsal pallium, which is predominantly visual and somatosensory in reptiles. This suggestion is supported by molecular and developmental evidence (for a review on the evolution of the isocortex, see Aboitiz *et al*., 2002). As a result, the mammalian isocortex would be a new evolutionary target for auditory thalamic projections. The development of the isocortex is accompanied by a gradual expansion of the brain, which is evident from fossil skull endocasts of early mammals, for example, *Hadrocodium* and *Morganucodon*. While the mesencephalic sensory pathways are the main processors of topographically organized exteroceptive information in sauropsids, and the lemniscal and collicular pathways are largely separated in sauropsids, this is not the case in mammals. In the mammalian isocortex both pathways are integrated, and might therefore implement more ascending information. The enlargement of the isocortex has been associated with the development of a 'modern' middle ear, which makes the transmission of sound more effective. However, while most early mammals with an enlarged isocortex have a fully evolved middle ear, the reverse is not true. Not every mammal with a modern middle ear has an enlarged isocortex. This makes a theory that the enlargement of the isocortex occurred to process sounds inconclusive.

While there is consensus from lesion studies that at least parts of the auditory cortex (AC) are necessary for sound localization, it is unclear whether different fields of the AC contribute differently to or are specialized exclusively for sound localization. Unilateral lesions of the AC in carnivores and monkeys result in deficits of localization of exclusively contralateral sounds (Jenkins and Masterton, 1982; Jenkins and Merzenich, 1984). The only exception from this finding is the human, which might be caused by our hemispheric specialization (Zatorre and Penhune, 2001). If the inactivation is confined to certain fields of the auditory cortex of the cat, either a contralateral deficit or no deficit occurs (Malhotra *et al*., 2004). A deficit occurs for the tonotopically organized fields A1 (primary auditory cortex), PAF (posterior auditory field), as well as, for the nontonotopic multisensory field AES (anterior ectosylvian sulcus), but no deficit was found following inactivation of the tonotopical field AAF (anterior auditory field), nontonotopic A2 and other multisensory fields. These lesion studies prompted the question whether different fields of the auditory cortex contribute differently to sound localization in different species. As described above, monaural and binaural information converge in the ICC, where the majority of neurons are spatially tuned. One could assume that the actual processing of auditory space is complete at this level, and that the role of AC is to distribute this preprocessed information to higher-order areas (Schnupp *et al*., 2001; Kowalski *et al*., 1995). However, the auditory cortex offers new substrates for further processing. The first would be the connection between the cortical hemispheres (corpus callosum) in higher mammals (Placentalia) (for review, see Aboitiz and Montiel, 2003). Since monotremes and marsupials lack the corpus callosum, the placental mammals have the evolutionary advantage of an additional layer for the processing of spatial information. Unfortunately, the possible role of transcallosal projections for sound localization especially under evolutionary aspects is not understood yet.

The second new substrate would be additional thalamic inputs that bypass the primary auditory cortex, but target certain secondary areas. In primates, for example, the secondary caudo-medial area (CM), which is known to be in part serially activated by A1 (Rauschecker *et al*., 1997), receives – in contrast to A1– additional lemniscal and extralemniscal projections from other parts of the auditory thalamus than the ventral medial geniculate body (MGv). These derive, for example, from the dorsal and medial part of the MG (for review, see Jones, 2003). These additional inputs might indicate a specialization of this area for the processing of

certain sound attributes. Based on anatomical studies on the topography in the connections of the lateral belt and parabelt (Romanski *et al.*, 1999; Hackett *et al.*, 1998a, 1998b, 1999a, 1999b), and preliminary electrophysiological studies, it has been proposed that area CM is specialized to code for sound location (Tian *et al.*, 2001; Recanzone *et al.*, 2000). From these findings, a model for two, separate 'what' and 'where' streams of cortical auditory processing was introduced by Romanski *et al.* (1999) in analogy to the processing streams in the visual system (Mishkin and Ungerleider, 1982).

However, despite the fact that the architecture and connections of the different auditory cortical fields have been well described in the macaque (Hackett *et al.*, 1998a, 1998b, 1999a, 1999b), their functional specialization for sound localization remains largely unknown. Even if many areas were coding for sound location, there might be differences in the processing of spatial information. For the cat, the work of Middlebrooks and co-workers on field PAF suggests that in this area, in contrast to A1, the acoustic space is coded in the form of response latency and patterns of trains of action potentials, rather than the rate of action potentials (Furukawa *et al.*, 2000; Furukawa and Middlebrooks, 2002; Stecker *et al.*, 2003).

To summarize, the relative contribution of different fields of the AC has not been studied in enough species to clearly reveal an evolutionary trend of specialization of certain fields/areas for sound localization. However, all mammalian species studied so far (carnivores, rodents, bats, and primates) have in common that the AC can be divided in a core of 2–3 and a belt of additional areas. This seems to be the basic organization retained from a common ancestor. Because of the remarkable differences in the number of fields, their relative location, their connections, and different physiological properties in different species, it is likely that the complex cortical processing system has developed in a quite independent fashion across mammalian taxa, and is therefore an example for niche evolution.

3.20.4 Behavioral Measures of Sound Localization

The variations of the organization of the auditory pathway involved in sound localization between mammalian species raises the question whether this variation is correlated with sound localization acuity. One might further assume that a bigger head, that is, a larger interaural distance, might improve the performance in localizing sounds. The acuity of sound localization has been examined behaviorally in a wide variety of mammalian species. Most information is available on the 'minimum audible azimuth angle' (MAAA) which is defined as the minimum angle for which the animal (or a human listener) perceives two separate sound sources instead of only one fused sound source. However, this measure does not represent a sound localization task, for which an animal would have to point to a perceived invisible/unknown sound source, but a sound source discrimination task. The methods used to assess the MAAA varied, but in most cases some kind of operant conditioning was used. To allow comparison, only studies that used broadband signals in an operant conditioning setup in air (not under water) were included in the following analysis. The head width was plotted against the MAAA for 18 mammalian species (Figure 1). Surprisingly, the minimum audible angle does not clearly depend on the interaural distance of the animal ($R = -0.39$). Very small species, for example, echolocating bats, can have quite small MAAAs despite their specialization for high frequencies, suggesting that ITDs do not play a major role for this sound-source discrimination task in these species. On the other hand, rodents with comparable headsize can have MAAAs ranging from 12° to 27°.

For comparative behavioral measures of sound localization acuity Heffner and Heffner (1992) pointed out an important problem: parameters unrelated to the auditory system might affect sound source localization behavior. Mammals that have a visual streak, that is, a horizontally enlarged area of highest visual acuity, might only orient their head up to a position where the acoustic target reached the boundary of the visual streak, while animals with a small visual fovea, for example primates, would have to direct their gaze toward an acoustic target within a much smaller area of vision. The disparity between the 'localized' and physical position of the sound source would naturally be expected to be greater for mammals with a visual streak than for mammals with a small fovea. The actual sound localization acuity on the basis of the physical sound localization cues, however, might very well be comparable, but hard to test in an experimental setup.

In summary, it is compelling how many factors affect sound localization. It appears to be difficult if not impossible to correlate certain parameters, like head size, pinna shape, or middle ear volume with localization acuity. The evolution of sound localization in mammals is a multifaceted aspect that is driven by ecological needs independent of taxon and common ancestry.

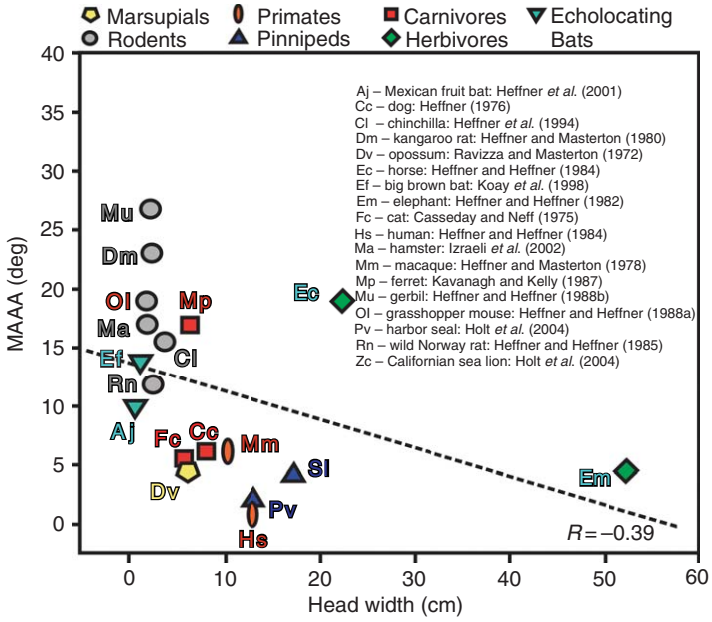

Figure 1 MAAA plotted against head width for 18 mammalian species. Only studies that used broadband signals in an operant conditioning setup in air (not under water) were included.

3.21 Cetacean Brain Evolution

L Marino, Emory University, Atlanta, GA, USA

Glossary

encephalization	An evolutionary increase in brain size relative to body size.
Mysticeti	The modern suborder of baleen and rorqual whales.
Odontoceti	The modern suborder of cetaceans consisting of dolphins, toothed whales, and porpoises.

3.21.1 Cetacean Evolution, Phylogeny, and Ecology

The origin and evolutionary history of the Cetacea represents one of the most dramatic physiological and behavioral transformations in the biological record. The first suborder, Archaeoceti, contained approximately 25 (known) genera (Thewissen, 1998) and derived from near-shore Indo-Pakistani locales (Thewissen *et al.*, 1996). Archaeocetes shared a common ancestry with modern Artiodactyla (the even-toed ungulates) over 60 Mya (Thewissen *et al.*, 2001) and survived until the late Eocene, around 37 Mya (Barnes *et al.*, 1985) when the modern suborders, Mysticeti (comprising 13 species of baleen and rorqual whales) and Odontoceti (comprising 67 species of toothed whales, dolphins, and porpoises) appeared (Barnes *et al.*, 1985).

Today, modern cetaceans have large brains and are streamlined predators that are widely diversified, inhabiting all oceans and many rivers. Their dietary strategies range from straining of krill to predation on other marine mammals. Their social groups span from two or three individuals to herds of thousands. They are long-lived with relatively long juvenile periods, are wide-ranging, and have complex social structures. Furthermore, in odontocetes a sophisticated echolocation system has evolved.

3.21.2 The Cetacean Brain as an Alternative Route to Complexity

Cetaceans are a highly divergent order that has not shared a common ancestry with our own order, Primates, for at least 92 My (Kumar and Blair Hedges, 1998). Modern cetacean brain structure is extremely different from that of other large-brained mammals, including primates. Yet, despite these neuroanatomical differences, there is growing evidence for a striking degree of cognitive and behavioral convergence between cetaceans and primates in such domains as social complexity, cognition, and self-awareness (Marino *et al.*, 2002, for a review of this literature). Therefore, the study of cetacean brains offers a unique opportunity to address questions about how complex behavior based on very different neuroanatomical substrates can evolve independently. Cetacean brains and primate brains are arguably most meaningfully conceived as alternative evolutionary routes to neurobiological and cognitive complexity.

3.21.3 Increases in Absolute Brain Size and Encephalization

Archaeocete brains changed surprisingly little over the 15 My it took for these ancient whales to became fully aquatic. Archaeocete brain mass varied from about 290 to 2240 g (Marino *et al.*, 2004). At first glance, the higher values in the upper range might imply that archaeocete brains were elaborated relative to other mammals. But brain size

scales allometrically with body size, and when the enormous body sizes of the archaeocetes are taken into account, the brain weight/body weight ratios plunge into the range from 0.0003 to 0.001 (compared to a mean ratio of 0.02 in humans). But ratios of brain weight and body weight overestimate relative brain size in very small animals and underestimate relative brain size in very large animals. Although not a flawless measure, encephalization quotient or EQ corrects for this nonlinearity by using a regression line that represents the overall parameters of the whole sample of brain weight and body weight data. (Throughout this article, reported EQ values will be based on the equation: EQ = brain weight/0.12 (body weight)$^{0.67}$, from Jerison, 1973.) When EQ is applied, the below-average range for archaeocetes, from 0.3 to 0.6, reiterates the conclusion from brain-weight/body-weight ratios that this early suborder did not possess a highly elaborated mammalian brain (Marino *et al.*, 2004). Moreover, the last group of archaeocetes from the late Eocene possessed EQs no higher than those of the earliest archaeocetes (Marino, 2004), disproving the notion that the process of adapting to the aquatic habitat *per se* involved selection for brain enlargement in cetaceans.

Recent studies of the pattern of EQ in cetacean evolution over the past 47 My shows that there were two significant increases in mean EQ among odontocetes (there are insufficient data for mysticetes at this time) (Figure 1). A major increase occurred about 37 Mya with the emergence of the first odontocetes, who were significantly more highly encephalized than the Eocene archaeocetes from which they are derived. The mean EQ grew from 0.5 in archaeocetes, i.e., well below average, to 2.0, in early odontocetes, i.e., significantly above average, with no overlap in the range of values (Marino *et al.*, 2004). By the mid-Miocene period, approximately 15 Mya, almost the full range of modern

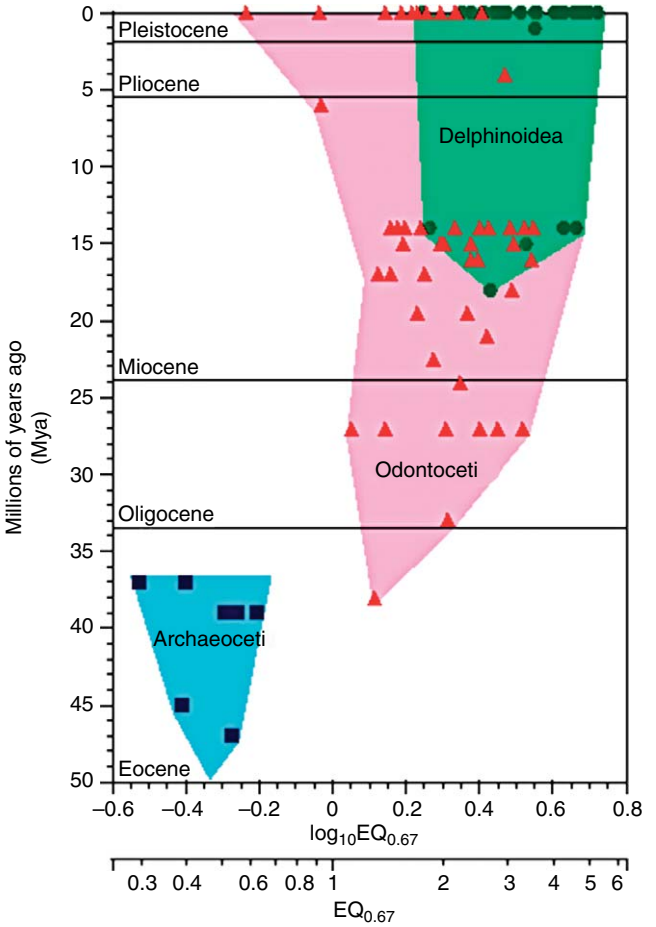

Figure 1 Mean encephalization quotients ($EQ_{0.67}$) of archaeocete and odontocete cetacean species over time. Scales for both raw $EQ_{0.67}$ and $\log_{10} EQ_{0.67}$ are shown across the bottom. Archaeocetes are shown in blue squares; delphinoid odontocetes are shown in green circles; nondelphinoid odontocetes are shown in red triangles. Timescale is in millions of years (My). Note the large shift in EQ at the origin of Odontoceti, and that the Delphinoidea form the upper range of odontocete EQ values from the middle Miocene to Recent. From Marino, L., McShea, D., and Uhen, M. D. 2004. The origin and evolution of large brains in toothed whales. *Anat. Rec.* 281A, 1247–1255.

odontocete EQ values had been achieved. The upper boundary in this period is occupied exclusively by members of the Delphinoidea superfamily (Delphinidae + Phocoenidae + Monodontidae). These mid-Miocene delphinoids enjoyed a second significant increase in EQ over their Oligocene ancestors but no significant change since then. Today, all odontocetes possess above-average EQs. Many modern species, with EQs ranging up to 4 and 5, possess encephalization levels second only to modern humans and significantly higher than any other animals (Marino, 1998; Marino *et al.*, 2004).

3.21.4 Changes in Major Neuroanatomical Structures

Archaeocete brains were characterized by small tubular cerebral hemispheres ending rostrally in relatively large olfactory peduncles and bulbs (Edinger, 1955). These features are further evidence that although some archaeocete brains were large in absolute size, they did not possess morphological characteristics of a highly elaborated mammalian brain such as an enlarged neocortex. But the brains of the earliest representatives of the odontocete and mysticetes that appeared in the late Eocene/early Oligocene did manifest the early stages of several neuroanatomical trends that culminate in the characteristics observed in modern cetaceans. Therefore, modern cetacean brains are not only different from those of other 'mammals' but are vastly divergent from the brains of their Eocene ancestors. These major morphological trends include the expansion of the cerebral hemispheres, the enlargement of auditory structures, the reduction of olfactory structures, the reproportioning of the limbic system, and the emergence of an unusual neocortical architecture.

3.21.4.1 Expansion of Cerebral Hemispheres

The cetacean telencephalon is arranged into three concentric tiers of limbic, paralimbic, and supralimbic tissue. The high degree of cortical gyrification and resulting expansive surface area of approximately 3745 cm^2 is unsurpassed among mammals, including humans (Ridgway and Brownson, 1984). Yet the cetacean neocortex is relatively thin, with a width between 1.3 and 1.8 mm, as compared with 3.0 mm in humans (Ridgway and Brownson, 1984). Cerebral enlargement in cetaceans occurred most exuberantly in the parietal and temporal regions. The frontal lobes, in particular, remain relatively hypoplastic. Whereas primate brains feature large frontal lobes, no homologous frontal lobe region in the cetacean brain has been identified, leading many investigators to substitute the term 'orbital lobe' for 'frontal lobe' when referring to these modest, ventrally oriented hemispheric regions (Morgane *et al.*, 1980).

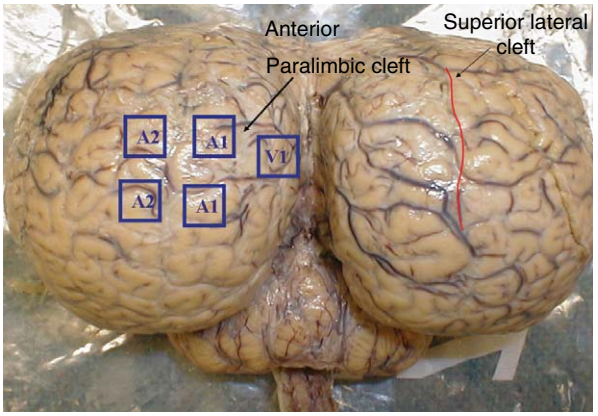

Figure 2 A dorsal view of a brain from an adult Blainville's beaked whale (*Mesoplodon densirostris*) showing the locations of the primary visual cortex (V1), primary auditory cortex (A1), and secondary auditory cortex (A2).

The idiosyncratic pattern of elaboration of the neocortex in cetaceans has resulted in a highly unusual configuration of sensory–motor projection zones. Electrophysiological mapping of cetacean cortex places primary visual cortex on the vertex of the hemisphere in the lateral gyrus and the primary auditory cortex lateral and directly adjacent to it in the suprasylvian gyrus. Secondary auditory cortex lies lateral to the primary auditory field in the medial ectosylvian gyrus (Supin *et al.*, 1978; Figure 2). Somatosensory and motor cortices lie immediately adjacent and rostral to the visual and auditory regions (Ladygina *et al.*, 1978). Therefore, all of the projection zones of the cetacean brain are confined to one region of the overall surface with a vast expanse of remaining nonprojection cortical tissue that can be tentatively described as integrative or associative. This is a highly unusual arrangement for large mammals in general.

3.21.4.2 Enlargement of Auditory Structures

Cetaceans are highly reliant on audition and use this special sense in an extremely complex and multifaceted manner. (Elaboration of auditory structures in cetacean brains has not been accompanied by reduction in visual structures or function, with the exception of the almost-blind river dolphins.) Generally, auditory structures are relatively larger in odontocetes than mysticetes because of the odontocete ability to echolocate. The vestibulocochlear nerve in cetaceans is immense in diameter and is

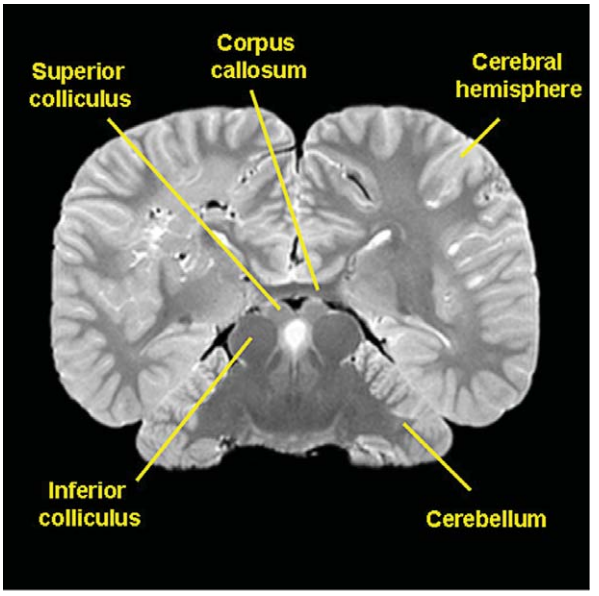

Figure 3 Labeled coronal magnetic resonance image of adult bottlenose dolphin (*Tursiops truncatus*) brain showing that the inferior colliculus is much larger than the superior colliculus. This reflects the emphasis in dolphins on processing auditory information.

composed of relatively more auditory than vestibular fibers (Oelschlager and Oelschlager, 2002). The ventral cochlear nucleus, trapezoid bodies, lateral lemniscus, and inferior colliculi (auditory tectum) are all greatly enlarged in comparison with terrestrial mammals. Whereas in mysticetes the inferior colliculus can be larger or smaller than the superior colliculus (visual tectum), in odontocetes the inferior colliculus is always larger than the visual tectum and can be at least four times the size of the superior colliculus (Marino *et al.*, 2003; Figure 3). The auditory tectum projects to a large medial geniculate nucleus in the massive thalamus.

Likewise, the primary and secondary auditory projection zones on the cerebral surface are extensive (Ladygina *et al.*, 1978; Supin *et al.*, 1978) but are not apparently the entire reason for the great expansiveness of the total neocortical volume in cetaceans. Auditory information is undoubtedly processed at higher integrative levels in other hemispheric regions, as is the case in all mammals. The fact that cetaceans possess such a large expanse of integrative neocortex is consistent with the experimental literature showing very sophisticated general cognitive processing capacities (Herman, 2002).

3.21.4.3 Reduction of Olfaction

Olfaction has been completely lost in adult odontocetes. Fetal odontocetes possess small olfactory structures (Buhl and Oelschlager, 1988; Marino *et al.*, 2001) that regress completely by birth. Infrequently, a short olfactory peduncle remains in adult sperm whales (*Physeter macrocephalus*) and northern bottlenosed whales (*Hyperoodon ampullatus*) (Oelschlager and Oelschlager, 2002). Adult mysticetes, while possessing a vastly reduced olfactory system, have maintained small olfactory bulbs, a thin olfactory peduncle, and an olfactory tubercle (Oelschlager and Oelschlager, 2002). Interestingly, both cetaceans and primates (albeit less extensively) underwent a reduction of olfaction during their evolution. But whereas this has led to a reduction in the hippocampal formation in cetaceans (see below), in primates the hippocampus remains well developed.

3.21.4.4 Reproportioning of the Limbic System

The reduction of olfactory input has resulted in a reproportioning of the limbic system in cetaceans. Notably, the cetacean hippocampus (archicortex), fornix, and mammillary bodies are all highly reduced (Jacobs *et al.*, 1979; Morgane *et al.*, 1980). On the other hand, the amygdala is large and well-developed in cetaceans (Schwerdtfeger *et al.*, 1984), reflecting the maintenance of substantial nonolfactory sources of input to this structure. An interesting corollary feature to the small limbic system is the extremely well-developed cortical limbic lobe (the periarchicortical field above the corpus callosum and the entorhinal cortex) in cetaceans (Oelschlager and Oelschlager, 2002; Marino *et al.*, 2003). This juxtaposition of a vastly reduced archicortex and a highly elaborated periarchicortical/entorhinal zone leads to intriguing questions about whether there was a transfer of learning and memory functions from the olfactory-based hippocampal domain to other cortical, including periarchicortical and entorhinal, regions.

3.21.5 Cortical Architecture

The neocortex of primates (and many other mammals) consists of six well-defined layers. Main input from the thalamus is to granular layer 4 with feedback from layer 6. Layers 2 and 3 output to other parts of the cortex and layer 5 to subcortical structures. Pyramidal cells, with apical dendrites oriented perpendicularly to the neocortical surface, span much of the cortex and end in layer 1 (Allman, 1999). Although stellate and pyramidal cells dominate, other kinds of cellular morphotypes are clearly distinguishable and there is a considerable

amount of heterogeneity (Swanson, 2003). In contrast, cetacean neocortex possesses mainly five layers. It is characterized by a very thick layer 1 that contains apical dendrites of extraverted pyramidal cells from a highly accentuated layer 2 (Glezer *et al.*, 1988; Morgane *et al.*, 1988). Glezer *et al.* (1988) and Morgane *et al.* (1990) suggested that in cetaceans the entirety of thalamocortical afferents feed into the thick layer 1 and through the extraverted neurons of layer 2 to deeper levels.

One of the most salient features of cetacean neocortex is the general lack of granularity in layer 4. Morgane *et al.* (1988) identified two types of visual cortex in the bottlenose dolphin. Heterolaminar cortex contains a very meager layer 4, which is entirely absent in homolaminar cortex. The general lack of layer 4 in cetaceans has important implications for afferentation patterns. In primates and other mammals, some afferent connections come through layer 1 to dendritic connections from layer 2 neurons, whereas other specialized thalamocortical afferents synapse directly on neurons in layer 4. In cetaceans, the majority of afferents appear to go through the very thick layer 1 to synapse en passage on extraverted neurons of layer 2 (Glezer *et al.*, 1988). A small portion of afferents go to layers 3 and 5 as well (Revishchin and Garey, 1990). Some investigators view the segregation of afferents to layer 4 and 1 to be a later evolutionary development than the pattern evinced in cetacean neocortex (Morgane *et al.*, 1986; Glezer *et al.*, 1988; Morgane *et al.*, 1990), further adding to the notion that the cetacean neocortex has expanded on a highly conserved theme that essentially bypasses an entire stage of neocortical granularization found in many other mammals.

Despite the general lack of granularity, there is evidence for considerable cytoarchitectural heterogeneity in many cetacean cortical regions. Morgane *et al.* (1988, 1990) reported the presence of highly conserved cytoarchitectonic vertically oriented columns in both homolaminar and heterolaminar visual cortex of the striped dolphin, *Stenella coeruleoalba*. Also, in a study of insular cortex in the bottlenose dolphin, Manger *et al.* (1998) reported cellular clumps or modular subdivisions that are distinct from the vertical columns noted by Morgane and his colleagues. Furthermore, Glezer *et al.* (1999) reported the prevalence of calretinin and calbindin-immunoreactive neurons over parvalbumin-immunoreactive neurons in dolphin neocortex and noted that, given the role of calretinin and calbindin neurons in inhibiting intracolumnar signals, the preponderance of vertical flow of inhibition along the columnar axis over laminar flow is a chemoarchitectural indicator of strong verticality in cetacean neocortex. The expansive surface area may indicate an extreme multiplication of vertical functional units that provides an intriguing dimension of processing complexity in cetacean brains.

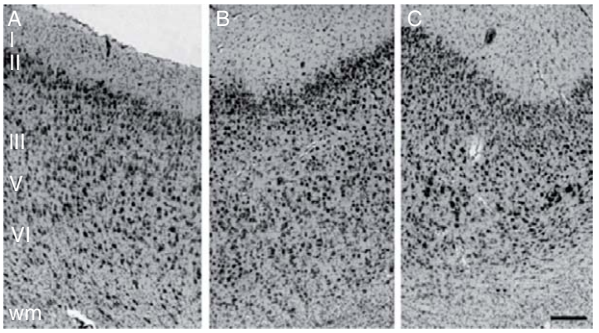

Figure 4 Examples of cytoarchitecture in the frontal cortex of the bottlenose dolphin. A, Lateral orbital gyrys; B, posterior level of the gyrus proreus; C, cortex on the lateral bank of the cruciate sulcus possibly corresponding to a motor field. Layers are indicated by Roman numbers. wm, white matter. Scale bar (on C): 100 μm. Reproduced from Hof, P., Chanis, R., and Marino, L. 2005. Cortical complexity in cetacean brains. *Anat. Rec. (Special Issue: Nature's experiments in brain diversity)* 287A, 1142–1152, with permission from John Wiley & Sons.

Very recent work has added to the view that cetacean neocortex is more complexly organized and diverse than previously thought. For instance, the frontal region of the cetacean brain is very different from that of other mammals, but it is characterized by a well-defined laminar pattern with considerable heterogeneity across regions (Hof *et al.*, 2005; Figure 4). Other areas of the cetacean brain, such as the insular cortex, the sensory cortices, and the posterior polar region, possess well-differentiated groupings of cells and vertically oriented modules. These characteristics provide the neurobiological substrate for the considerable behavioral complexity in many cetaceans (Marino, 2002).

3.21.6 Summary

The study of cetacean brains provides a unique opportunity to examine how large complex brains evolve outside of the primate lineage. Our present knowledge of cetacean brain evolution and modern neurobiology indicates that cetacean brains began a process of substantial elaboration in size and organization approximately 35 Mya with the emergence of the first odontocetes and mysticetes. Today many cetaceans possess encephalization levels exceeded only by modern humans. The highly expanded cetacean brain, however, is characterized by very different neuroanatomical trends and cytoarchitectural organizational themes than other

large mammal brains, i.e., primates. This juxtaposition of similar encephalization levels in cetaceans and primates and highly divergent neuroanatomical trends presents an intriguing picture of alternative neurobiological routes to cognitive and behavioral complexity and a unique opportunity to examine convergent behavioral and cognitive processes.

3.22 The Evolution of Visual Cortex and Visual Systems

D C Lyon, University of California, Irvine, CA, USA

Glossary

architecture The internal structure of a cortical area may contain unique histological features relative to adjacent cortical areas. There are several features that might distinguish an area. Two widely used histological markers result from (1) differences in metabolic activity of neurons driven by inputs from the thalamus or (2) by the degree of myelination of intrinsic axons.

cortical layers Neocortex is commonly portrayed as having six layers, although these layers can be divided into additional sublayers depending on the cortical area. Layer 1 sits at the pial surface of cortex, whereas layer 6 is the deepest layer.

extrastriate Refers to all of visual cortex outside of V1, as V1 is commonly referred to as striate cortex.

neuroanatomical tracing Because they are available in several colors, fluorescent tracers are particularly useful at retrogradely labeling multiple populations of neurons. Injected extracellularly in small volumes (0.2–1.0 μl) the tracer is taken in at synaptic sites of axon terminals over a relatively small region of cortex, spanning a half of a millimeter or less. Over a period of several days the fluorescent tracers are transported back along the axon to the cell body. In this way one is able to trace the origins of inputs to a particular cortical region.

3.22.1 Differences in Visual Cortex Complexity

Confronting the evolution of visual cortex is appealing in that it is perhaps the most dominant sensory system in humans, as evidenced by the large expanse of cortex devoted to visual processing. We have relatively big brains, so perhaps it is not surprising that we have a lot of visual cortex. Yet, compared to other sensory modalities, vision has a far greater representation in our cortex. Presumably our expanded visual system affords us a richer view of reflected light than animals with less cortex devoted to vision. Though our visual processing capabilities are due in part to a more elaborately constructed

retina, the visual thalamic relay stations and cortical areas in species with complex visual systems provide much more than a one-to-one correspondence of retinal ganglion cell output. The expanded size of our visual cortex can be used to infer an increased capacity for visual processing as size of mammalian cortex is often attributed to greater cognitive abilities. In line with such reasoning, comparisons of cortical sizes between several species of mammals are useful for determining a first approximation of the variability of cortically driven features. This is particularly informative when studying extinct species where sizes of brain endocasts can provide insights into cortical evolution (see What Fossils Tell Us about the Evolution of the Neocortex). But, the size of visual cortex in different mammals does not allow us to infer much about visual system complexity.

In addition to overall size, we know that mammalian cortex is subdivided into areas, or 'organs' of the brain (Brodmann, 1909). In the shrew, there is only one discernable visual area in cortex (Catania *et al.*, 1999). It is difficult to know what the shrew sees with that one area, but based on models of neuronal interconnectivity, the processing of visual features would be limited (Kaas, 2000; Mitchison, 1991; Ringo *et al.*, 1994). In mammals with greatly expanded visual cortex, such as carnivores and primates, as many as 19–40 visual areas have been proposed, based on anatomical and functional investigations (Felleman and Van Essen, 1991; Kaas, 1989b, 1997a; Sereno and Allman, 1991; Van Essen, 2004). The utility of having multiple visual areas is that each can be specialized for certain aspects of visual processing. By compartmentalizing there is a reduced need for intercommunication between all neurons, and thus fewer connections are required to process the information (Changizi and Shimojo, 2005; Kaas, 2000, 2002; Koulakov and Chklovskii, 2001; Mitchison, 1991; Ringo *et al.*, 1994). Areas can be further compartmentalized into processing modules, creating another level of complexity. Modular organization is more commonly reported in mammals that are considered to have moderate to high numbers of visual areas. Interestingly, while squirrels and tree shrews appear to have a similar, moderate numbers of visual areas, at least six (Kaas, 2002), they do not share the same level of modular organization (Bosking *et al.*, 1997; Van Hooser *et al.*, 2005a). Thus, one level of complexity, number of areas, does not necessarily lead to higher complexity of other levels, modularity.

We know that the numbers of cortical areas and degree of modularity within these areas varies across studied species (Kaas, 1989a, 2002). In the framework of cladistics, we can compare similarities in cortical organization across sister groups, and contrast with more distantly related species to determine what structures within the visual system represent the basic mammalian plan and from where features of more complex brains may have evolved (Kaas, 1995, 2002, 2004b; Striedter, 2005). However, sweeping comparisons are made difficult by the small number of examined species. Particularly lacking is a more detailed description of the number of visual areas, their functions, and modular organization. We have some evidence as to the number of cortical areas, their architecture and connection patterns in species from a handful of orders, but functional modular organization has been studied in detail in only a few species, namely monkeys, prosimians, cats, ferrets, tree shrews, and squirrels. Modular organization can and has been studied at the anatomical level in more species and this information, though less descriptive, is useful for making comparisons across several sister groups (Kaas, 2002). Another hindrance to species comparisons is that researchers who do study the organization of visual cortex in various mammals do not always agree with each other's interpretation of the evidence. Even in macaque monkeys, probably the most commonly studied animal for visual cortex organization, it has taken over 30 years to agree on the existence of the third visual area, V3 (Lyon and Kaas, 2002b; Van Essen, 2004; Zeki, 2003). Yet issues with V3 and the 20 or so other poorly defined areas remain, limiting our ability to make comparisons to other primates such as New World monkeys and even humans (Felleman and Van Essen, 1991; Kaas and Lyon, 2001; Rosa and Tweedale, 2005; Sereno and Tootell, 2005).

The goal of this article is to provide a reasonable interpretation of the available evidence on the organization of visual cortex and underlying structures in species from several mammalian orders (see Figure 1). Comparisons of the organizational schemes between species are made, highlighting several issues. How many visual areas were present in the earliest mammals? Have rodents diverged from the common mammalian plan? What are the organizational similarities and differences in species with moderate visual systems? How similar are the complex visual systems of cats and primates? Are any higher-order areas homologous? To address these questions, a focus is placed on a cladistic approach to species comparisons, but an emphasis is also made on similarities between distantly related species. The consolidation within this article of a wide body of comparative evidence on visual cortex organization should serve as a useful template for investigators probing cortical evolution.

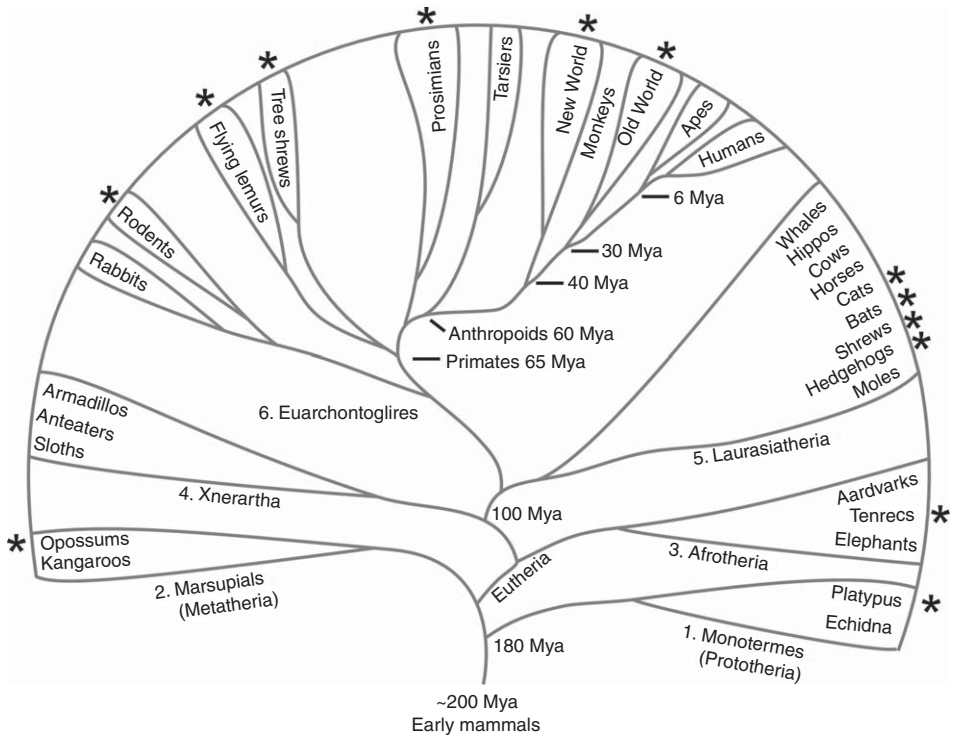

Figure 1 Phylogenetic relationships of the six mammalian superorders based on recent molecular studies (Murphy *et al.*, 2001). Early mammals diverged into prototherian monotremes, metatherian marsupials, and four superorders of eutherians. The organization of visual cortex in 13 taxa from five of the six superorders is covered in this article. * Species covered in text. Adapted from Kaas, J. H. 2005a. From mice to men: The evolution of the large, complex human brain. *J. Biosci.* 30, 155–165.

3.22.2 The Basic Mammalian Plan

3.22.2.1 Identification of V1 and V2

With perhaps only a couple of exceptions, mammals have at least two visual areas (Kaas, 1987; Kaas and Krubitzer, 1991; Krubitzer, 1998; Rosa and Krubitzer, 1999). An obvious exception would be mammals with vestigial eyes, such as subterranean species – the common mole (Catania and Kaas, 1995) and the naked mole rat (Catania and Remple, 2002) – where perhaps no visual cortex is present. Another exception can be found in the very small brains of the shrew where only a single visual area is present (Figure 2b; Catania *et al.*, 1999). Nevertheless, most mammals studied have at least two distinct visual areas. And, observed similarities in myeloarchitecture, subcortical inputs, and retinotopic organization across species have led to the generally accepted conclusion that the primary visual area (V1) and the secondary visual area (V2) are homologous across mammals (Kaas, 1987; Krubitzer, 1995; Krubitzer and Kahn, 2003).

V1 is typically found at the caudomedial extreme of neocortex and has several hallmarks of a primary sensory area that have been revealed through three basic techniques used for the study of cortical organization, namely architecture, connections, and retinotopic mapping (Kaas, 1987; Van Essen, 1979). The most conspicuous architectonic feature of V1 is the dense myelination of axons that can be revealed through a silver staining procedure (Gallyas, 1979). V1 also stains darkly for the metabolic enzyme cytochrome oxidase (CO; Wong-Riley and Carroll, 1984). Particularly when applied to flattened cortical preparations, these staining methods have proved very effective in identifying V1 in many species, from marsupials to monkeys (Kaas, 1987; Krubitzer, 1995), and have served as a useful landmark for further examination of the characteristics of V1.

Beyond the architecture, much of what we know about V1 in the majority of studied mammals comes through neuroanatomical tracing techniques and electrophysiological mapping of the representation of the contralateral visual hemifield. Through neuroanatomical tracing, we know that the primary retinal ascending pathway to V1 is relayed by the lateral geniculate nucleus (LGN) to the middle cortical layer, layer 4 (Jones, 1985; Steriade *et al.*, 1997). In most mammals, the LGN projects heavily to V1, and less so, if at all, to the remainder of visual cortex. Superficial layers 2 and 3 in V1 in turn project to layer 4 of V2. This basic cortical

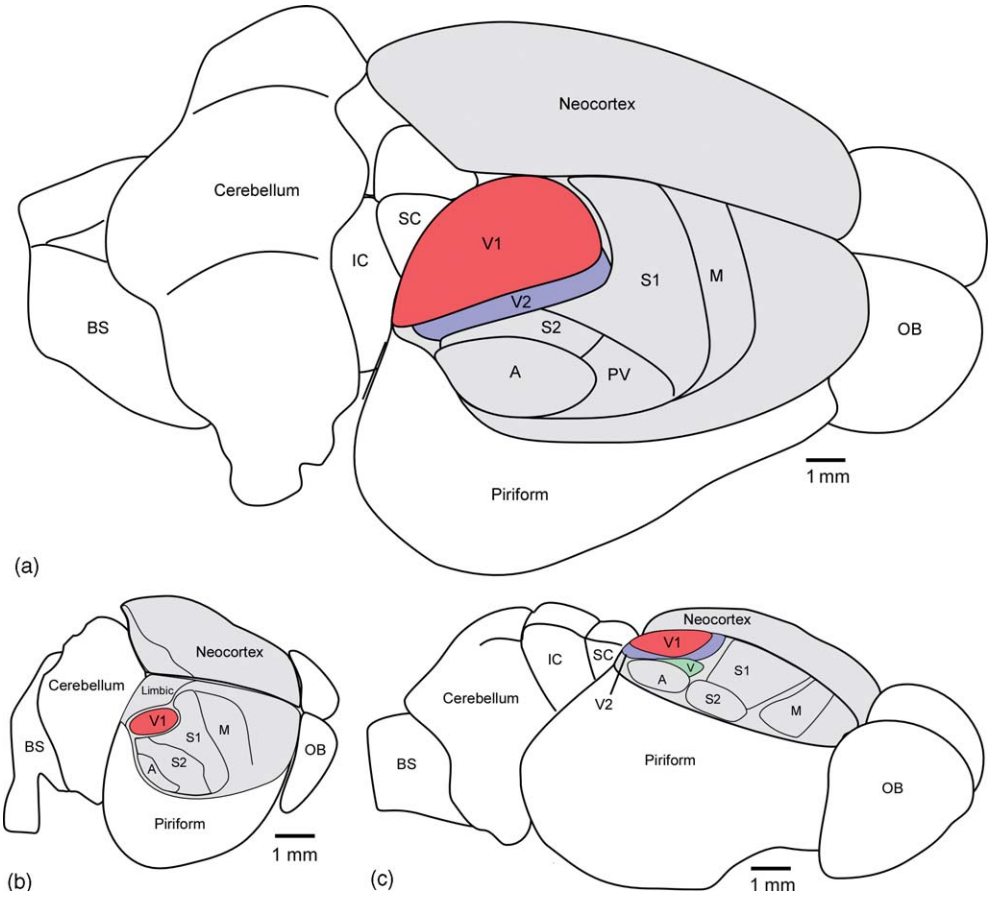

Figure 2 Visual cortex organization in small nonvisual mammals shown on whole-brain drawings. Based on similarities of several features, including brain sizes, insectivores (hedgehogs and shrews; (a and b) and tenrecs (member of the Afrotheria superorder; (c)) may have a cortical organization similar to the earliest mammals. Neocortex is relatively small and dominated by somatosensory areas 1 (S1) and 2 (S2), with a third area, parietal ventral (PV), found in the larger insectivore, the hedgehog. In insectivores, at most, only two visual areas are present, the primary (V1) and secondary (V2), with only a single area present in the smallest insectivores, the shrews. A third, visually responsive region (V) has been reported in the tenrec. Auditory (A) and motor cortex (M) are also present. Phylogenetically older piriform cortex is quite large. Likewise, the superior and inferior colliculi (SC and IC), the cerebellum, olfactory bulbs (OB), and brainstems (BS) are also relatively large. a, Data from Catania, K. C., Collins, C. E., and Kaas, J. H. 2000. Organization of sensory cortex in the East African hedgehog (*Atelerix albiventris*). *J. Comp. Neurol.* 421, 256–274. b, Data from Catania, K. C., Lyon, D. C., Mock, O. B., and Kaas, J. H. 1999. Cortical organization in shrews: Evidence from five species. *J. Comp. Neurol.* 410, 55–72. c, Data from Krubitzer, L., Kunzle, H., and Kass, J. 1997. Organization of sensory cortex in a Madagascan insectivore, the tenrec (*Echinops telfairi*). *J. Comp. Neurol.* 379, 399–414; and Kaas, J. H. 2002. Convergences in the modular and areal organization of the forebrain of mammals: Implications for the reconstruction of forebrain evolution. *Brain Behav. Evol.* 59, 262–272.

projection pattern is the early part of a general 'hierarchical' progression of areas within the visual system (Rockland, 1997). We also know that a secondary pathway provides less direct retinal input to cortex, by transmitting through the superficial layers of the superior colliculus (SC) to the pulvinar (also referred to as the lateral posterior nucleus, LP) and then to superficial layers of cortex. In contrast to the LGN, the pulvinar not only projects heavily to V1, but also provides large numbers of inputs to all areas of visual cortex (Casanova, 2004; Kaas and Huerta, 1988; Stepniewska, 2003).

Another basic tool for the examination of visual cortex is mapping of the visual topography (Allman and Kaas, 1971b; Gattass and Gross, 1981; Hubel and Wiesel, 1965; Kaas, 1997b; Kaas *et al.*, 1970; Rosa, 1997; Tusa *et al.*, 1979). By presenting isolated spots of light to different regions of the retina, the so-called retinotopic mapping has revealed a first-order map of the contralateral visual hemifield that is coextensive with architectonically defined V1 (Rosa and Krubitzer, 1999). Though the progressive placement of a microelectrode at sites traversing across the surface of V1 to determine the receptive fields of local neurons is painstaking, what emerges is an inverted map with the upper visual quadrant represented ventrally and the lower quadrant dorsally (for examples, see Figures 3–5; also, see

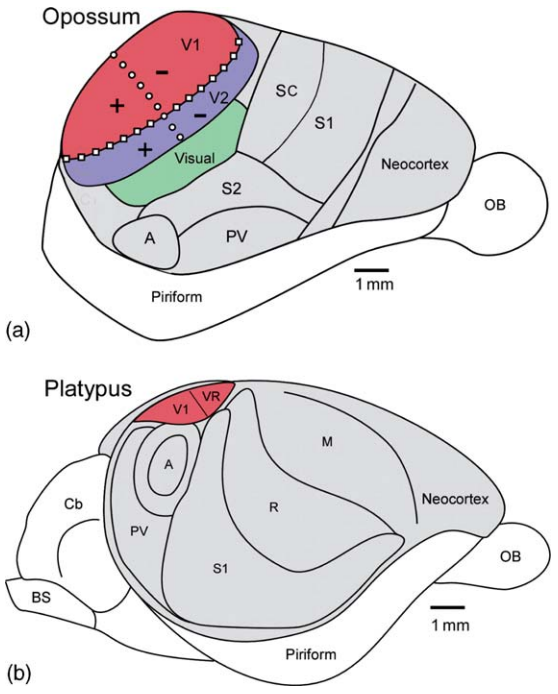

Figure 3 Visual cortex organization in nonplacental mammals, marsupials (a) and monotremes (b), shown on whole-brain drawings. a, The cortical organization of the opossum is typical of most small marsupials. Like the hedgehog, there are three large somatosensory areas, S1, S2, and PV, and a small auditory region as well as an additional caudal somatosensory area (SC) (A). However, unlike insectivores and tenrecs, visual cortex in opossum has expanded with comparatively large areas V1 and V2, and a large third region that contains visually responsive neurons. Areas V1 and V2 are both retinotopically organized (see schematic of visual hemifield in Figure 4a), with the representations of the upper (+) and lower (−) visual fields located ventrally and dorsally, respectively. The + and − visual field representations are bisected by the representation of the horizontal meridian (line of circles), while the representation of the vertical meridian (line of squares) separates areas V1 and V2, resulting in mirror-image representations of the visual field. b, In contrast to the marsupials, cortical organization in monotremes is dominated by three large somatosensory areas, S1, PV, and the rostral area (R), as shown in platypus. Motor cortex (M) is also quite large, and auditory cortex is comprised of at least two areas, a primary (A) and surrounding belt. Visual cortex is relatively small in monotremes. Though the evidence is limited, the caudal region of visual cortex may be homologous to V1 of other mammals, while the rostral visual area (VR) may represent a second visual area. a, Data from Beck *et al.* (1996), Rosa *et al.* (1999), and Kahn *et al.* (2000). b, Data from Krubitzer *et al.* (1995) and Krubitzer and Kahn (2003).

schematic in Figure 4a). The two visual quadrants are separated by the representation of the horizontal meridian (shown as a line of circles in several figures) which bisects V1. The representation of the vertical meridian (shown as a line of squares in several figures) is found at the rostral or anterior border of V1. Many more details of cortical organization are known from retinotopic mapping, such as variability in receptive field sizes, and in most species the magnified representation of central vision (see Allman and Kaas, 1971b; Rosa, 1997; Van Essen *et al.*, 1984). In addition to microelectrode mapping, the more recently developed techniques of intrinsic signal optical imaging and functional magnetic resonance imaging (fMRI) have been used to obtain retinotopic maps of large regions of cortex, making for easier comparisons across cortical areas (Sereno and Tootell, 2005). While retinotopic maps provide basic organizational information, neurophysiological studies describing the functional properties of V1 neurons have been reported for relatively few species, but they have provided for useful comparisons.

In most cases, the mammalian cortex also contains V2, located along the anterior border of V1. Characteristic of a nonprimary cortical area, V2 stains less darkly than V1 for CO and myelin (Krubitzer, 1995), receives feed-forward projections from V1 (Rockland, 1997), and receives its main subcortical retinal relays through the pulvinar, rather than the LGN (Jones, 1985; Steriade *et al.*, 1997). In addition, because V2 is substantially smaller than V1, it contains a compressed representation of the contralateral visual hemifield (see Rosa, 1997; Rosa and Krubitzer, 1999). The V2 retinotopic map can be distinguished from V1 by matching with CO and myeloarchitecture, but also because as the receptive fields for recording sites cross from V1 to V2 over the vertical meridian, the receptive field positions flip to form a rough mirror image of the representation in V1. The retinotopic organization of V2 has been revealed through microelectrode mapping and through connections with retinotopically defined regions of V1. Most evidence revealed through these techniques shows a similar organizational scheme for V2 in all mammals (see Rosa and Krubitzer, 1999).

3.22.2.2 Visual Cortex of Insectivores and Nonplacental Mammals

While most mammals have ample cortical space for more than two visual areas (Kaas, 1989b; Kaas and Krubitzer, 1991), certain constraints in the smallest mammals limit cortical representations to two or even only one visual area. Insectivores are notable for their small brain-to-body size ratio (Striedter, 2005), and in some species for small body size (Catania *et al.*, 1999). While the brain of a common laboratory rat may weigh as much as a few grams, the entire body weight of the smallest insectivore, the least shrew, is only 5 g. The extremely small size of the shrew brain is compounded further by the

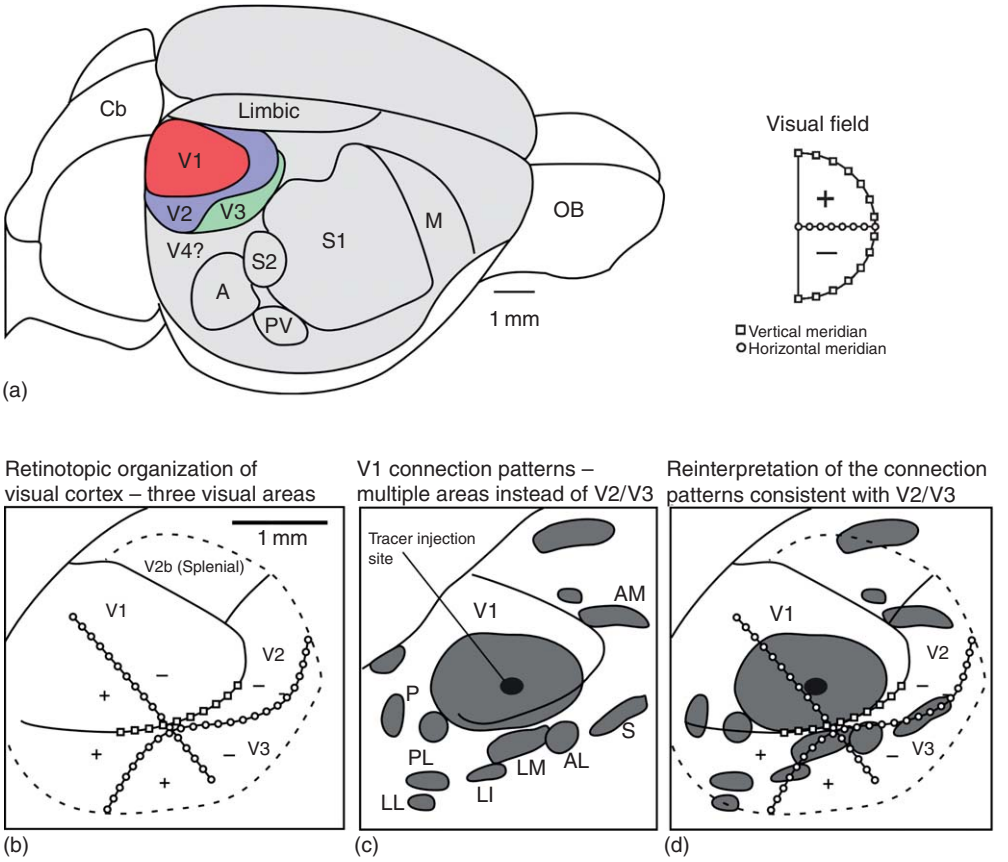

Figure 4 Visual cortex organization in a nonvisual rodent, the common mouse, shown on a drawing of the whole brain. a, Despite the somatosensory (S1, S2, and PV) dominance of cortical space, the mouse has at least three distinct cortical visual areas (V1, V2, and V3) and a fourth region (V4) that contains visually responsive neurons (Wagor *et al.*, 1980; Kaas and Krubitzer, 1991). b, While the visual areas are relatively small, V1, V2, and V3 are retinotopically organized (Wagor *et al.*, 1980; see schematic of the visual hemifield in panel a). c, In contrast, alternative schemes of the organization of visual cortex in nonvisual rodents propose as many as eight extrastriate areas in place of V2 and V3 (Olavarria and Montero, 1989). These results are based primarily on the multiple patches of neurons labeled from tracer injections in V1. In this example, a V1 injection was placed near the representation of the horizontal meridian. d, While several distinct clusters of labeled neurons are found in extrastriate cortex, these clusters are not inconsistent with the retinotopic organization of V2 and V3, and do not unequivocally support the proposal of eight extrastriate areas. For example, the majority of patches of labeled neurons can be found along the proposed V2/V3 border, which represents the horizontal meridian, and matches the retinotopic location of the injection site in V1. See Section 3.22.3 for abbreviations.

small size of neocortex relative to the rest of the brain, and further still by the majority of cortex representing somatosensory receptors, leaving little cortex representing vision (see Figure 2b; Catania *et al.*, 1999). With the larger shrews weighing upwards of 50g, these insectivores provide a close approximation to the size constraints presented to our earliest mammalian ancestors, which are estimated to have weighed ~30g (Allman, 1999). In addition to body and cortical size constraints, insectivores in general are considered to have retained many other structural features of the first mammals and to occupy similar habitats (see Kaas *et al.*, 1970). Because of these similarities to early mammals, the organization of visual cortex in shrews and other insectivores is likely to have diverged little from the original mammalian plan.

In five species of shrew, only a single visual area is present (Figure 2b; Catania *et al.*, 1999). It has the characteristic dark CO staining of mammalian V1, its neurons respond robustly to flashes of light presented to the eyes, and it receives projections from the LGN. Other insectivores, such as the European hedgehog (Figure 2a) and the tenrec of Madagascar (Figure 2c), do not fair much better than the shrew in terms of the amount of visual representation in cortex. However, there is a V2, present in these species. The hedgehog is much larger than the shrew, weighing about 1000g. Both V1 and V2 have been demonstrated through microelectrode mapping, with V2 forming a mirror representation of V1 (Kaas *et al.*, 1970). Indicative of a V1, hedgehog V1 stains very darkly for myelin and CO (Catania *et al.*, 2000; Kaas *et al.*, 1970; Krubitzer,

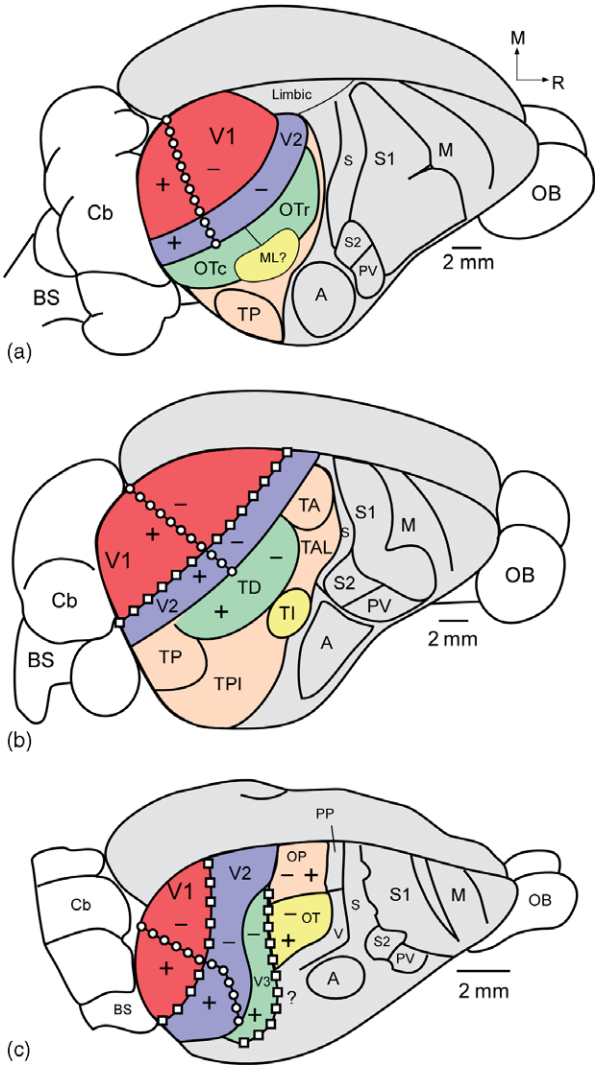

Figure 5 Visual cortex organization in species with moderately complex visual systems: squirrels (a), tree shrews (b), and flying foxes (c). At least half of cortex in these three highly visual species is devoted to vision (colored shading). In all three species, V1 and V2 are retinotopically organized and quite large, comprising nearly half of visual cortex. A V3-like region is found in all three species as well (green shading), with a fourth region (yellow shading) that in limited ways resembles area MT in primates (see Figures 12–14). Overall, several visual areas comprise the cortex. At least six visual areas have been defined in squirrels (Kaas *et al.*, 1989; Paolini and Sereno, 1998) and flying foxes (Rosa, 1999), and eight in tree shrews (Lyon *et al.*, 1998). Additional visual areas may be present in rostral cortex which has been shown to be visually responsive. See Section 3.22.4 for explanation of visual areas and abbreviations.

1995) and receives projections from the LGN (Hall and Ebner, 1970). Because many characteristics of the hedgehog resemble that of some of our earliest mammalian ancestors, it is postulated that V1 and V2 likely represent the prototypical mammalian plan for visual cortex (Kaas, 2005a; Kaas *et al.*, 1970), and this is supported by the evidence that most mammals, including marsupials, also have a V1 and a V2 (Rosa and Krubitzer, 1999). While the organization of the tenrec and hedgehog visual cortex is very similar, this similarity may be more of a reflection of the limitations imposed by small cortical size, as recent evidence shows that tenrecs should not be considered insectivores (Murphy *et al.*, 2001). In fact, tenrecs are now considered part of the African superorder of mammals, Afrotheria (see Figure 1), which includes golden moles, elephant shrews, aardvarks, and even elephants and sea cows.

Metatherian mammals, or marsupials, diverged from an older common ancestor than insectivores, but nevertheless, by most accounts, all studied marsupials have a V1 and V2 (Figure 3a). In several small marsupial species V1 is clearly delimited through CO or myeloarchitecture (Beck *et al.*, 1996; Kahn *et al.*, 2000; Martinich *et al.*, 2000; Rosa *et al.*, 1999). In addition, an orderly retinotopic map is evident (Rosa *et al.*, 1999; Kahn *et al.*, 2000). The case for a marsupial V2 initially was less certain. For example, in an earlier study on the mouse opossum (*Marmosa elegans*) tracer injections in V1 resulted in several patches of labeled neurons in cortex adjacent to the anterior V1 border (Bravo *et al.*, 1990). In a manner similar to conclusions made in some rodent studies (see Section 3.22.3.1) it was proposed that each patch represented a separate visual area, rather than a single V2. However, subsequent experiments on V1 connectivity in other small marsupials showed connectivity with V2 that is more consistent with the concept of a single visual area, V2 (Beck *et al.*, 1996; Kahn *et al.*, 2000). The existence of V2 was confirmed through detailed retinotopic mapping (Rosa *et al.*, 1999).

Prototherian mammals, or monotremes, were the first to diverge from the mammalian line, having split perhaps as many as 180 Mya (Figure 1; Murphy *et al.*, 2001). In the cortex of monotremes, at least two visual areas have been described (Figure 3b; Krubitzer, 1998; Manger, 2005). However, there is some question as to whether they can be considered homologous to V1 and V2 of metatherian and eutherian mammals. As a result, rather than V1 and V2, they have been tentatively termed the caudal and rostral visual areas, or Vc and Vr. Krubitzer *et al.* (1995) described a region of dark CO and myeloarchitecture that is coextensive with both visual areas. While Vr is somewhat lighter in appearance, there is no sharp architectonic division between the two areas as between V1 and V2 in other mammals. Both regions contain fairly complete retinotopic maps, but Vc can be distinguished from Vr in that it responds more vigorously to visual

stimulation (Krubitzer, 1998). Because of the slightly darker architectonic features, more vigorous response properties, and the fact that the caudalmost area occupies cortical territory similar to that of mammalian V1, it is possible that Vc is homologous to V1. However, there is some evidence that visual cortex in monotremes receives ascending inputs from a secondary visual thalamic nucleus, rather than the LGN. Thus, while monotreme cortex contains at least two visual areas, they only partly resemble visual areas in other mammals. Largely because so few studies have been done on the visual system in monotremes, homologies to visual cortex in marsupials and eutherian mammals remain in doubt, and it is plausible that the basic mammalian plan for the visual system underwent several modifications after having split from the monotremes (see Krubitzer, 1998).

3.22.2.3 The Basic Mammalian Plan: One Area, Two, or Even Three?

From the cortical organization evidence in marsupials and insectivores, as well as the implication that most other eutherian mammals have a V1 and a V2, there emerge two approaches for reconstructing the cortical organization of the earliest mammals. These approaches are somewhat in conflict and result in different conclusions. On the one hand, shrews and other insectivores retain several anatomical features of the earliest mammals and would be under similar constraints brought on by a small cortex. This overwhelming similarity has led to the conclusion that insectivore cortical organization reflects the basic mammalian plan. On the other hand, shrews have one less visual area than other, larger insectivores (see Figure 2), and the argument that all other mammalian sister groups, including marsupials, have a V1 and a V2 is used to support the view that the common ancestor to marsupials and eutherians was likely to have a V1 and V2 as well. So, do we devise the basic mammalian plan based on similarities between shrews and early mammals, or common features across all mammalian sister groups? Or can we use both criteria?

While the proposal that similarities in body and brain sizes, other morphological characteristics, and habitat make insectivores an ideal candidate for the species most resembling early mammals is fairly supportable, it clashes with earlier conclusions derived from comparisons across all mammalian sister groups. In particular, though all studied mammals (other than shrews, and possibly monotremes) possess at least a V1 and V2, many insectivores tend to have fewer visual areas than most other mammalian orders, including marsupials, which have at least three (Figure 3a). The issue now becomes whether any of the three or more visual areas are homologous or evolved independently in separate orders. While some have made the argument for homologies of at least three visual areas – V1, V2, and V3 (Rosa, 1999; Rosa and Manger, 2005) – others conclude that V3 is not homologous (Kaas, 2002).

Let us assume that only two areas are homologous across eutherian mammals. Even so, is the hedgehog, with V1 and V2, more representative of the basic mammalian plan than the shrew, which only has a V1? The shrew having only a V1 can be explained through evolutionary digression to adapt to an extremely small body and brain size, where there just is not enough room for a second visual area. However, it is important to consider here that all species studied that do have a V2 are significantly larger than shrews, and these species are also significantly larger than the estimated size of the first mammals. Shrews, on the other hand, are about the same size as the earliest known mammals. Thus, it is not implausible that shrew cortical organization is most representative of the first eutherian mammals.

If we postulate that only a V1 was present in the earliest mammals, then this has implications for the evolution of subsequent visual areas – V2 and every other extrastriate area could have evolved independently in some or several mammalian orders. Whether these areas are homologous would depend on whether a pre-existing mechanism allowing for the emergence of multiple visual areas in a similar fashion was in place in the earliest mammals (see Striedter, 2005). However, such a viewpoint would represent an extreme. What we can say for certain is that shrews and larger insectivores possess a visual cortex that is minimal in design, possessing only one or two visual areas and occupying a relatively small portion of cortex compared to the somatosensory system. As the visual system has expanded in other orders that place a greater emphasis on visual processing, it is generally agreed that V1 and V2 have retained enough of their basic features to remain homologous across species.

3.22.3 Rodent Visual Systems: Simple or Complex?

3.22.3.1 Have Small Rodents Diverged from the Common Mammalian Plan?

If we conclude that the basic mammalian plan for visual cortex calls for, at most, two areas, V1 and

V2, and we know that most mammals have at least three visual areas and probably more, then it follows that cortical evolution has resulted in the addition of visual areas. There are several theories as to how cortical areas have increased in number (see Captured in the Net of Space and Time: Understanding Cortical Field Evolution; Allman, 1999; Allman and Kaas, 1971a; Kaas, 1989a; Krubitzer, 1995; Krubitzer and Kaas, 2005; Krubitzer and Kahn, 2003; Northcutt and Kaas, 1995; Rosa, 1999, 2002; Rosa and Krubitzer, 1999; Rosa and Tweedale, 2005; Striedter, 2005). Rodents provide a good example for both slightly and more moderately expanded cortex, as has been shown in mouse and squirrel, respectively (see Figures 4 and 5a). And, because rodents are the most abundant of the mammalian orders, insights into their organization are important for the study of cortical evolution. Despite using similar techniques, efforts over the past 30 years to determine the organization of visual cortex in rodents have led to two very different conclusions as to the organization of extrastriate cortex (see Sereno and Allman, 1991; Rosa and Krubitzer, 1999). Discrepancies in extrastriate organizational schemes begin as early as V2. As detailed by Rosa and Krubitzer (1999), opposing opinions relate to whether subsequent extrastriate areas have been added to a pre-existing V2 or whether pre-existing extrastriate cortex in an early rodent ancestor, instead of a V2, was already subdivided into several small areas. As we have seen in species that branched from earlier common ancestors – marsupials, tenrecs, and insectivores – only a single area V2 is present, if at all (Figures 2 and 3). Thus, multiple areas in place of V2 in rodents would represent a divergent path in mammalian visual cortex evolution.

The controversial conclusions stem from studies in mouse and rat. Building upon an earlier microelectrode mapping of rat cortex anterior to V1 (Montero *et al.*, 1973b), the patchy extrastriate connection patterns of V1 in mouse and rat were interpreted as support for several distinct visual areas (see Figure 2c; Olavarria and Montero, 1989), rather than a single V2 (Figures 2a and 2b), as postulated by others (Malach, 1989; Rumberger *et al.*, 2001; Wagor *et al.*, 1980). A subsequent study used two to three distinguishable tracer injections placed in different retinotopic locations of V1 in single animals (Montero, 1993) to further establish the retinotopic organizations of the multiple regions. The emergence of multiple distinguishable tracers has proved to be a useful tool for estimates of extrastriate cortex, as will be demonstrated more fully in subsequent sections. Retinotopic maps by others reported similar organizational schemes in rat and hamster (Espinoza *et al.*, 1992; Espinoza and Thomas, 1983). In addition, supporting evidence was derived from callosal connections used to approximate the vertical meridian borders of several of the proposed areas (Olavarria and Montero, 1981, 1989; Thomas and Espinoza, 1987). For example, Thomas and Espinoza (1987) proposed seven extrastriate visual areas, four of which border V1. The largest of these proposed areas, LM, contains a retinotopic map similar to that of V2. Other schemes have postulated as many as nine areas along the V1 borders (see Sereno and Allman, 1991). While it is not unreasonable to consider LM a V2 homologue (Rosa and Krubitzer, 1999), its truncated size leaves several areas adjacent to V1, a pattern not typically reported in other mammalian orders (Kaas and Krubitzer, 1991).

Despite several corroborating experiments, other results contradict the interpretation of multiple areas in place of V2. For example, an early anatomical study using lesions in V1 to look for degenerated neurons in extrastriate cortex, revealed only a single patch of connected neurons in extrastriate cortex nearest V1 (Montero *et al.*, 1973a). In addition, microelectrode mapping studies in the hamster and mouse supported a retinotopic organization more consistent with a single V2 along the lateral border of V1 (see Figures 4b and 4d; Tiao and Blakemore, 1976; Wagor *et al.*, 1980). Interestingly, these results are similar to those reported for lagomorphs (see Sereno and Allman, 1991), the closest relatives to rodents (Figure 1; Murphy *et al.*, 2001). More recently, intrinsic signal optical imaging in mouse visual cortex also yielded results consistent with a single V2 lateral to the V1 border (Kalatsky and Stryker, 2003).

Likely contributing to the differences in data on the retinotopic organization in small rodents are inherent logistical problems in obtaining a clean, detailed retinotopic map in a cramped cortical space while trying to stabilize the very small eyes (Rosa and Krubitzer, 1999; however, see Wagor *et al.*, 1980). In addition, a heavy reliance on callosal connectivity patterns to reveal multiple areas could be misleading in that callosal connections in species with a well-defined V2 extending the entire lateral border of V1, as found in primates, reveals a similar pattern as that seen in rat (Cusick *et al.*, 1984). Thus, callosal patterns are often irregularly distributed within single areas and give the impression of multiple areas if one assumes their location marks the vertical meridian. For these reasons, the use of callosal input patterns as a primary means of

delimiting borders between visual areas is questionable. In addition to the evidence in small rodents, results from brains of more visually dependent squirrels (see the discussion below), argue against multiple areas immediately outside of V1 in rodents, and point to a single V2 (Figure 5a), consistent with the common mammalian plan (Kaas and Krubitzer, 1991).

Before moving on, it should be noted that many rodent studies designate a separate V2, V2b, sometimes referred to as area 18b (Wagor *et al.*, 1980), that lies medial to V1. While the lateral area 18a (Wagor *et al.*, 1980), or LM (Espinoza and Thomas, 1983), is considered to be the homologue to V2 in other mammals, Rosa *et al.* (1999) contend that the medial region is similar to the splenial visual area of limbic cortex found in other mammals, including primates (Rosa *et al.*, 1997), and is not part of mammalian V2.

3.22.3.2 How Many Visual Areas in Rodent Cortex?

Most of the upwards of 12 extrastriate areas described in rodents are all located along the V1 border (Sereno and Allman, 1991), three along the medial border and six along the lateral border. But, as discussed above, alternative evidence concludes that the region immediately lateral to V1 comprises a single V2 (Wagor *et al.*, 1980; Kaas and Krubitzer, 1991), and the medial region may be more consistent with limbic visual cortex found in other mammals (Rosa and Krubitzer, 1999). Moving beyond the V2 controversy, we know that the rodent has additional cortex devoted to vision, and has presumably expanded from the basic visual plan found in insectivores. So, how many visual areas do rodents have?

If we jump ahead to results from more modern techniques, we find two retinotopically organized extrastriate areas outside of V2 in a mouse. Kalatsky and Stryker (2003) optimized visual display signals to avoid confounding biorhythms. In this manner, they were able to maximize intrinsic neuronal activity measured through optical imaging (movies of the activation of visual cortex as stimuli sweep across the visual field are available in their online supplemental material – see 'Relevant Website'). In all, four extrastriate areas were described – V2, V3, V4, and V5. V2 represents a condensed mirror image of the representation found in V1, while V3 mirrors V2, and likewise V4 mirrors V3. Area V5 is found medially in a similar location to V2b described above, and is probably the visual region of the limbic cortex (see Rosa and Krubitzer, 1999). The optical imaging measurements are consistent with earlier microelectrode maps in the mouse, where V1, V2, a V3 and an additional lateral region were reported (Figures 4a and 4b; Wagor *et al.*, 1980).

3.22.3.3 The Complexity of Squirrel Visual Cortex

Although mice have an expanded visual cortex compared to insectivores, they rely largely on somatosensation through vibrissa on the snout, and through their sense of smell. The importance of the somatosensory system is reflected by a cortex dominated by the barrel fields representing the vibrissa. This leaves little cortical space for visual areas, and subsequently as few as two extrastriate cortical areas outside of V2 have been reported (Figure 4a; Wagor *et al.*, 1980; Kalatsky and Stryker, 2003), as described in the previous section. In contrast, squirrels, which are diurnal, have retinas comprised primarily of cones, 90–95% (Jacobs *et al.*, 1980), and have an extremely high density of ganglion cells projecting to the LGN and SC (Johnson *et al.*, 1998; Major *et al.*, 2003) allowing for higher visual acuity. This increase in visual input is reflected in the greater expanse of cortex devoted to vision (Kaas, 2002), and an increased number of extrastriate visual areas (Figure 5a; Kaas *et al.*, 1989; Paolini and Sereno, 1998). Thus, the somatosensory subfield for the barrel field is one-third the size in squirrels than in rats, whereas striate cortex and extrastriate cortex are four and eight times larger, respectively, in squirrels (Paolini and Sereno, 1998).

An early study identified three retinotopically organized visual areas 17, 18, and 19 (Hall *et al.*, 1971), similar to V1, V2, and V3 found in other mammals. Like other rodents, V1 is easily distinguished through myelin staining (Kaas *et al.*, 1989; Paolini and Sereno, 1998). However, an advantage of studying squirrels over smaller, less visual rodents is that V2 is also distinguishable as a uniform darkly stained myelin region along the lateral border of V1. Consistent with the common mammalian plan, squirrel V1 receives topographic projections from the LGN (Kaas *et al.*, 1972a), whereas the main visual thalamic input to extrastriate cortex comes through the relatively large pulvinar (see Figure 6a; Robson and Hall, 1977). V2 and V3 in squirrels are also relatively large compared to the descriptions for mice (Figures 4a and 5b). Connection patterns from tracer injections placed in V1 and V2 of squirrels revealed several features of these large regions (Figure 7a; Kaas *et al.*, 1989). Similar to small rodent studies described above, patchy

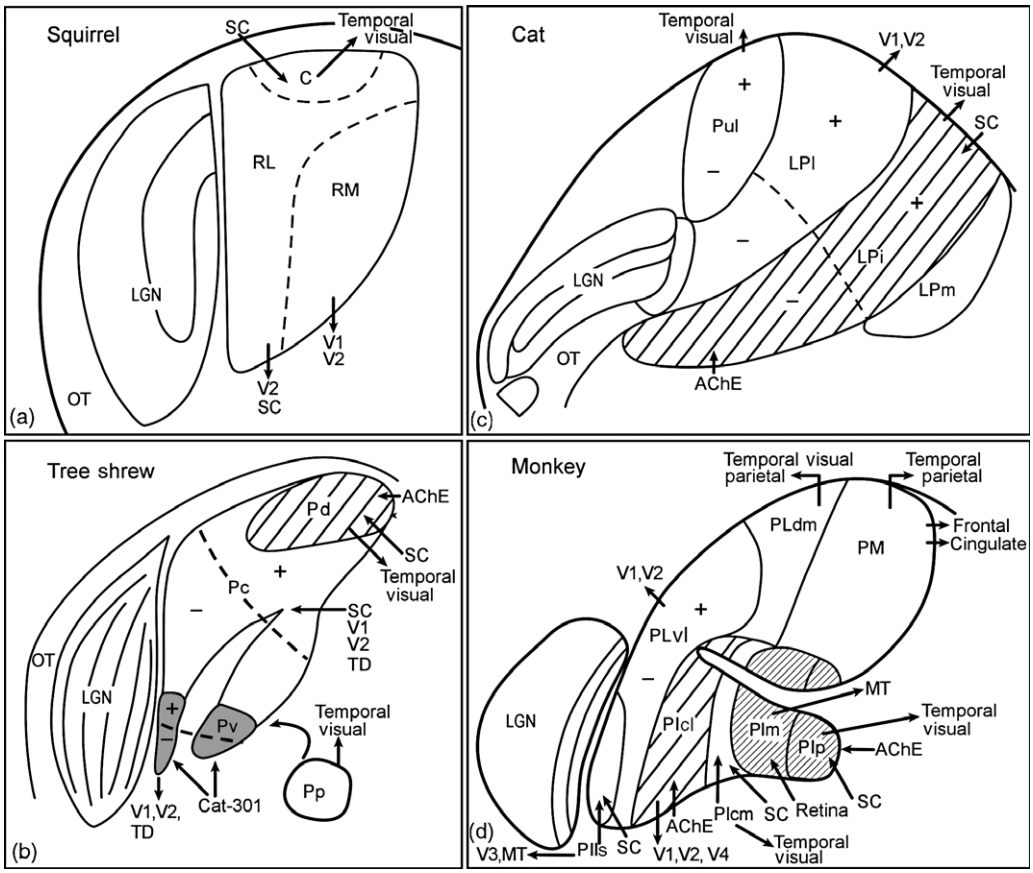

Figure 6 Organization and cortical connections of the pulvinar nucleus in four highly visual species. A thalamic nucleus relaying inputs from the superior colliculus (SC), the pulvinar receives feedback from and provides inputs to all of visual cortex. In highly visual species the pulvinar can be subdivided into distinct nuclei, each with a distinct pattern of connections to extrastriate visual cortex. a, There is evidence for three subdivisions in the pulvinar of squirrels, the rostrolateral (RL), rostromedial (RM), and caudal (C) divisions (Robson and Hall, 1977). RL receives projections from SC and projects to V2, whereas RM does not get SC projections but projects to both V1 and V2. The C subdivision is only found in the caudal extent of pulvinar, and is distinguished by SC inputs and connections with temporal visual cortex. b, Tree shrew pulvinar has four subdivisions distinguished through differences in architecture (Lyon *et al.*, 2003a), input from SC (Luppino *et al.*, 1988), and projections to visual cortex (Lyon *et al.*, 2003b). The central (Pc) is the largest subdivision. It receives inputs from SC and has retinotopic projections to V1, V2, and TD. The ventral subdivision (Pv) also provides retinotopic inputs to V1, V2, and TD, and can be distinguished through immunoreactivity to Cat-301 (gray shading). A dashed line in both Pc and Pv separates portions representing the upper (+) and lower (−) visual field representations in these subdivisions. The dorsal subdivision (Pd) with high levels of acetylcholinesterase (AChE; thatching) receives projections from SC and projects in turn to temporal visual areas. A posterior subdivision (Pp) is located in the posterior-most extent of the pulvinar and projects exclusively to temporal visual areas. c, The cat pulvinar is formed by the 'pulvinar' (Pul) and three subdivisions of the lateral posterior nucleus including lateral (LPl), intermediate (LPi) and medial (LPm; Casanova, 2004; Lyon *et al.*, 2003b). Inputs from SC and projections to distinct cortical visual areas are shown (based on Lyon *et al.*, 2003b; Casanova, 2004). For more details see Section 3.22.5.1. d, Monkey pulvinar has been split into at least eight subdivisions (Cusick *et al.*, 1993; Stepniewska, 2003). The inferior pulvinar is comprised of five subdivisions, the posterior (PIp), medial (PIm), central medial (PIcm), central lateral (PIcl) and lateral shell (PIls). The lateral pulvinar has been split into at least two subdivisions, the ventral lateral (PLvl) and dorsal medial (PLdm), while conservative estimates treat the medial subdivision as a single region (PM). Inputs from SC and projections to distinct sets of cortical areas are shown (Lyon *et al.*, 2005; Shipp, 2001; Stepniewska *et al.*, 2000; Stepniewska, 2003). In all panels, the dorsal lateral geniculate nucleus (LGN) and the optic tract (OT) are shown for reference. Modified from Lyon, D. C., Jain, N., and Kaas, J. H. 2003b. The visual pulvinar in tree shrews. II: Projections of four nuclei to areas of visual cortex. *J. Comp. Neurol.* 467, 607–627.

connections in V2 resulted from V1 injections. Furthermore, injections in V2 resulted in intrinsic long-range connections of up to 6 mm. In addition, callosal connections revealed a patchy pattern, much like that reported for rats (Gould, 1984). In conjunction with the myelin pattern and retinotopic maps, these patterns are taken to reflect modular organization within V2, rather

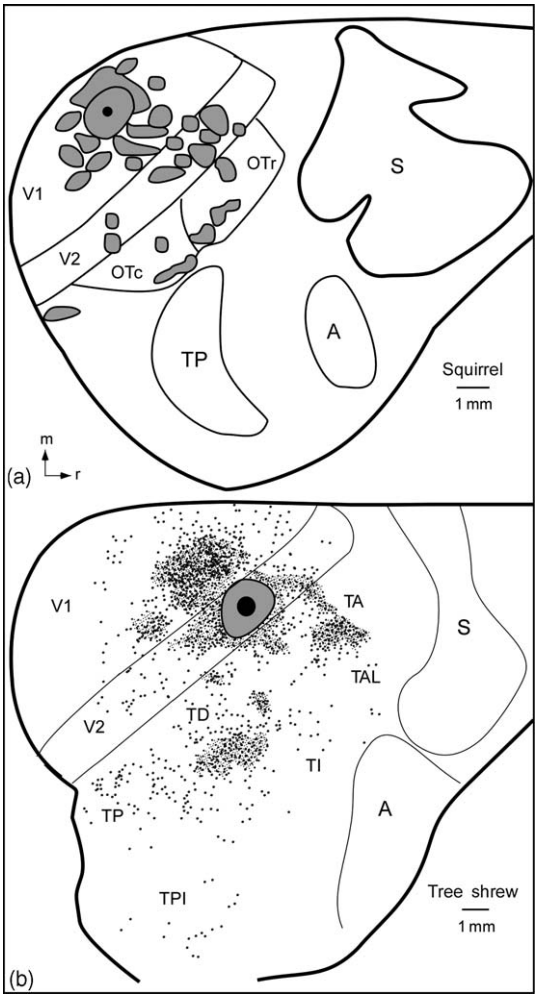

Figure 7 Connection patterns of early visual cortex are useful in identifying multiple extrastriate areas. a, An injection in V1 of squirrels results in a patchy pattern of label both intrinsically within V1 and in extrastriate cortex. In extrastriate regions, a wider displacement of these patches is attributed to separate cortical areas, OTc and OTr. b, In tree shrews, following a tracer injection in V2 the displacement of patches of labeled neurons in extrastriate cortex is more distinct, revealing several visual areas, TA, TD, TP, TPI. In both instances, these connection patterns can be used as guides for further exploration of extrastriate visual cortex, such as, targeting extrastriate areas for microelectrode recordings and further tracer injections. See Section 3.22.4 for abbreviations and more details. a, Based on Kaas, J. H., Krubitzer, L. A., and Johanson, K. L. 1989. Cortical connections of areas 17 (V-I) and 18 (V-II) of squirrels. *J. Comp. Neurol.* 281, 426–446. b, Modified from Lyon, D. C., Jain, N., and Kaas, J. H. 1998. Cortical connections of striate and extrastriate visual areas in tree shrews. *J. Comp. Neurol.* 401, 109–128, with permission from John Wiley & Sons.

than an indication of several distinct visual areas bordering V2.

Following V1 and V2 injections, patchy connections were also found in V3, termed the occipital–temporal zone (OT; Kaas *et al.*, 1989). However, because of widely spaced patchy connectivity it was proposed that V3 could be broken up into 2–3 areas labeled as rostral, middle, and caudal divisions of the occipital temporal cortex (OTr, OTm, and OTc; Kaas and Krubitzer, 1991; Kaas, 2002). Still, the connection patterns are somewhat consistent with a single area V3 (OT), if one considers multiple patches as a sign of modular organization as for V2, but in some cases the distance between patches in V3 is much larger than that found in V2 (Kaas *et al.*, 1989). In addition, earlier retinotopic maps of V3 were very limited (Hall *et al.*, 1971), leaving this region open to other interpretations. More conservative estimates split OT into two regions, OTr and OTc (Figures 5a and 7a; Kaas *et al.*, 1989; Kaas, 2002). Additional studies exploring the retinotopic organization with multiple tracer injections and retinotopic mapping would help determine whether OT is a single retinotopically organized region or actually comprised of 2–3 separate areas. As we shall see in the next section, the squirrel pattern of connectivity is similar to multiple divisions of V3 described for the highly visual tree shrew (Figures 5 and 7; Kaas and Krubitzer, 1991; Kaas, 2002).

The expanded temporal lobe of the squirrel provides additional space for two more large visual regions between OT and anterior cortex devoted to audition and somatosensation. These regions were identified as visual in nature through their connection patterns with V2. It is worth noting that tracing techniques, such as this, have proved to be a valuable technique for providing a first approximation of the number of extrastriate areas (see Kaas, 2004c). These visual areas have been termed the temporal posterior (TP) and temporal intermediate (TI). TP extends laterally from OTc, along the base of sensory cortex. TP stains very darkly for myelin and is sparsely interconnected with V2 (Kaas *et al.*, 1989). TI stains lightly for myelin and can be divided into at least two distinct regions based on interconnectivity with V2. Thus, outside of V2 and OT, the squirrel has at least three more extrastriate areas.

Based on response properties of neurons found in the OT visual region, Paolini and Sereno (1998) have designated two areas, the middle lateral (ML) and lateral (L). ML and L occupy territories similar to OTr and OTc. Further investigation revealed that ML and L are comprised of neurons selective for speed and the direction of moving stimuli (Paolini and Sereno, 1998).

The functional characteristics of neurons have been sparingly discussed up to this point. So, what

does it mean to find an area specialized for a visual feature? V1 neurons of rats, as well as squirrels, prefer particular aspects of features of a visual stimulus – orientation, direction, and length (Girman *et al.*, 1999; Ohki *et al.*, 2005; Van Hooser *et al.*, 2005b). However, V1 receptive field sizes are typically very small and thus will only respond to a stimulus presented in a very small portion of the visual field, but converging inputs to subsequent extrastriate areas enable neurons to respond to a larger region of the receptive field. In addition, particular features of a stimulus activate neurons in different extrastriate cortical areas to different degrees such that some areas may contain neurons that respond more vigorously to the motion of the object while being less influenced by the shape or color of the object, features which are important to neurons in other visual areas. While there are no reports of functionally specialized extrastriate areas in rats, a large body of evidence has detailed functionally selective areas in mammals with more complex visual systems, such as cats and primates (see Section 3.22.5).

With an extrastriate visual cortex eight times larger than the rat, and a conservative estimate of at least five extrastriate areas beyond V2, it seems clear that squirrel visual cortex is more complex than the rat or mouse, where likely only two more areas can be found beyond V2 (see previous section; Figure 4). This observation conflicts with a recent proposal that species within a particular order typically have the same level of cortical complexity (Manger, 2005). In support of similar complexity between rat and squirrel, one could argue that the multiple subdivisions proposed for V2 in rat and mouse increase the number of extrastriate cortex tremendously. Yet, this intricate pattern is not found in squirrels. Furthermore, if we give the rat nine visual areas along the V1 border, this would represent an organization more complex than visual cortex found adjacent to V1 in any other mammalian order, including primates.

3.22.4 The Moderate Visual Systems

In the species discussed thus far, we have seen as few as one visual area in the shrew, two in monotremes, hedgehogs, and tenrecs, two or three in some small marsupials, and perhaps as many as four in small rodents. While these species rely heavily on modalities other than vision, the number of areas jumps to at least seven in the more visually dependent squirrel. As we will see in this section, the number of visual areas is similar to that proposed for megachiropteran bats (flying foxes) and tree shrews, species that have been or still are considered close relatives of primates. These species, particularly tree shrews, are thought to have retained many of the features found in the common ancestor that led to primates, so an understanding of their cortical organization is essential for understanding the early evolution of the primate brain.

3.22.4.1 Visual Systems of the Tree Shrew and Flying Fox

Until recently, the superorder Archonta was used to group primates together with their three closest relatives – the gliding lemur, tree shrew, and flying fox. Two species of gliding lemur make up the order Dermoptera. While not actually a lemur, and despite having a rather large wing-like web of skin encircling its entire body, the gliding lemur resembles prosimian primates. In fact, recent DNA analysis indicates that gliding lemurs are indeed closely related to primates (Murphy *et al.*, 2001). The tree shrew, a squirrel look-alike, despite its name is more closely related to primates than shrews and other insectivores. Early classification based on brain similarities placed tree shrews within the primate order, though they have since been moved to their own order, Scandentia (see Martin, 1990). DNA evidence also supports a very close relationship between tree shrew and primates (Murphy *et al.*, 2001). The flying fox is the largest of the fruit-eating bats (Megachiroptera). While some unique anatomical similarities to primates led to the proposal that the flying fox should be classified separately from smaller, microchiropteran bats, and considered close relatives of primates (Pettigrew, 1986; Pettigrew *et al.*, 1989), more recent genetic evidence maintains bat monophyly (Van Den Bussche *et al.*, 1998) and has removed megabats from Archonta, claiming a closer relationship to cats than to either rodents or primates (Kaas, 2004b; Murphy *et al.*, 2001).

Despite the recent distancing of flying fox from tree shrew, neuroanatomical and physiological studies indicate some similarities in visual system organization (Figure 5). Both species are diurnal and boast retinas packed densely with ganglion output cells (Pettigrew, 1986; Kaas and Preuss, 1993) allowing for high visual acuity (Petry *et al.*, 1984). In thalamus there is a well-laminated LGN, which provides the main relay of retinal inputs to V1. Tree shrews have six architectonically distinct layers (Figure 6b), which segregate input from each eye and contain functionally distinct classes of neurons

(see Conley *et al.*, 1984; Jain *et al.*, 1994; Kretz *et al.*, 1986; Lyon *et al.*, 2003b; Wong-Riley and Norton, 1988). It has been suggested that the LGNs of the flying lemur and flying fox each have as many as six layers as well (see Kaas and Preuss, 1993), though only three layers are architectonically distinguishable in the flying fox (Ichida *et al.*, 2000; Manger and Rosa, 2005) and only Nissl stained sections, less than ideal for determining LGN layers, have been examined for the flying lemur (Kaas and Preuss, 1993). Thus, the similarity between the LGN of these species is uncertain. Furthermore, though these species show a relatively high number of geniculate layers compared to other species such as rodents, it has been argued that this feature is easy to evolve and has appeared several times through convergent evolution in distantly related species (Striedter, 2005).

As for most mammalian species, flying foxes and tree shrews have areas V1 and V2 that are clearly defined (Figure 5). Like the squirrel, these areas are fairly large, contain a retinotopic map of the contralateral hemifield (Kaas *et al.*, 1972b; Rosa *et al.*, 1993, 1994), and are easily distinguished through CO or myelin staining (Lyon *et al.*, 1998; Rosa *et al.*, 1994). While the LGN projects primarily to V1 in tree shrew, it provides a topographic but diffuse input to V2 (Lyon *et al.*, 2003b). A similar connection pattern appears to be present in the flying fox as well (Manger and Rosa, 2005). More detailed analysis of the tree shrew has also revealed several levels of modularity within V1 and V2 (Bosking *et al.*, 1997; Lund *et al.*, 1985; Lyon *et al.*, 1998), and these are described in Section 3.22.4.2.

Anterior to V2 in the flying fox, detailed microelectrode recordings revealed several fairly complete retinotopic maps (Figure 5c; Rosa, 1999). A V3 was identified adjacent to V2, as a narrower and shorter band of cortex representing a compressed mirror image of the retinotopic map of V2. Anterior to V3, two more retinotopically organized areas, the occipital temporal (OT) and occipital parietal (OP), were also identified. Anterior to OT was a narrow strip of cortex that contained visually responsive neurons. Because these neurons had large receptive field sizes, no retinotopic order was apparent. Anterior to OP, in the posterior parietal cortex (PP), just posterior to somatosensory areas S1 and S, neurons were responsive to both vision and touch. Uncharted cortex (?) ventral to OT and posterior to auditory cortex could also be part of visual cortex, as is the case for this region of cortex in squirrels (see previous section) and tree shrew (see below). In all, at least seven visual areas and visually responsive regions have been identified in the flying fox.

In tree shrews, injections of different, distinguishable tracers into different retinotopic locations of V1 and V2 (see Figure 7b) revealed several extrastriate visual areas lateral to V2 (Figure 5b; Kaas, 2002; Lyon *et al.*, 1998; Sesma *et al.*, 1984). In tree shrews, rather than a single V3 strip extending along the lateral border of V2, the existence of three separate areas has been proposed – the temporal anterior, dorsal, and posterior areas (TA, TD, and TP). The largest of the three areas, TD, is the most V3-like, in that it extends across much of the V2 border, and has retinotopic connections with areas V1 and V2. Areas TA and TP are found at the medial–anterior and lateral–posterior ends of TD. TA receives retinotopic inputs from V2, and interconnects with areas TD and TP. Likewise, TP receives crudely retinotopic projections from V2 and connects with TD and TA. The retinotopic pattern of connections with V2 and interconnections between areas TA, TD, and TP strongly support the proposal that a single, large V3 is not present in tree shrews (Lyon *et al.*, 1998). This conclusion may represent a divergence from the common mammalian plan wherein several species have an area resembling V3 (Rosa, 1999). Or, it may reflect the proposal that V3-like visual areas have evolved separately and are not homologous (Kaas, 2002). One suggestion is that a narrow strip more anterior in the temporal cortex, just adjacent to V2, could be homologous to a V3 (Rosa, 1999); however, retinotopic microelectrode maps of this region remain to be done. Alternatively, perhaps TD is homologous to V3, in that it is not unlike the proportions of V3 in the flying fox (Rosa, 1999) and compared to V2 it contains a condensed retinotopic map (Lyon *et al.*, 1998).

At least three more visual areas have been identified in cortex more anterior to TA, TD, and TP (Lyon *et al.*, 1998, 2003b). The temporal inferior area (TI) situated anterior–lateral to TD can be distinguished architectonically through staining for myelin and connections with TP. Interestingly, tree shrew TI is in a similar location to squirrel TP (see Figure 5) which also has some visual connections and stains darkly for myelin. Another extrastriate area in the tree shrew, TPI, lies lateral and inferior to TP with which, like TI, it is primarily connected. Lateral to TA, there is the temporal anterior lateral area (TAL) which receives input from both visual and somatosensory thalamus (Lyon *et al.*, 2003b) and is connected with visual and somatosensory cortex (Lyon *et al.*, 1998; Remple *et al.*, in press).

These bimodal anatomical inputs resemble the bimodal neuronal properties reported for OP of the flying fox (Rosa, 1999). In all, at least eight visual areas and regions have been identified in the tree shrew.

Both the tree shrew and flying fox also have an enlarged and subdivided pulvinar (Figure 6b; Luppino *et al.*, 1988; Lyon *et al.*, 2003a, 2003b; Manger and Rosa, 2005). This increase in pulvinar size is typically seen in species with a greater expanse of extrastriate visual cortex, including squirrels (Figure 6a; Robson and Hall, 1977). In addition, distinct subdivisions of the pulvinar project differently to regions of visual cortex, and evidence of these connection patterns is used as support for the existence of multiple extrastriate areas. In the flying fox, three architectonic subdivisions are discernible through CO staining, the lateral, intermediate, and medial (Pl, Pi, and Pm, respectively) (Manger and Rosa, 2005). Tracer injections across several areas in visual cortex, show that Pl, which is located adjacent to the LGN, projects strongest to V2, whereas subsequent subdivisions project more strongly to visual areas V3, OT, and OP, which are located progressively anterior in cortex (Manger and Rosa, 2005). In tree shrews, four pulvinar subdivisions have been identified through different connections to extrastriate cortex and through distinct architecture (Figure 6b; Lyon *et al.*, 2003a, 2003b). Adjacent to the LGN, is the largest, central subdivision, Pc, which projects topographically to V2 as well as to adjacent cortex in area TD. The ventral subdivision, Pv, stains darkly for the antibody to Cat-301, a marker for large diameter neurons, and projects topographically to V2 and TD, as well as to TA. The dorsal subdivision, Pd, stains darkly for acetylcholinesterase (AChe) and projects to posterior extrastriate areas TP and TPI. A posterior subdivision, Pp, projects exclusively to the most anterior extrastriate visual areas, TAL, TI, and also to TPI.

Despite the rather distant relationship between tree shrews and megachiropteran bats, these visually dependent species have a similar proportion of cortex devoted to vision, with a similar number of areas. Areas V1 and V2 are similar in size and retinotopic organization; there is a third visual area, V3 in the bat and TD in the tree shrew, that both have a compressed mirror image of the representation of the visual field in V2. Each species has two more visual areas that are retinotopically organized, OT and OP, in the bat, and TA and TP in the tree shrew. Additionally, a bimodal sensory zone, representing somatosensory and vision, is present in each species, OP in bat and TAL in tree shrew. While tree shrews are considered a good approximation of the primordial primate, the basic cortical organization seen in tree shrew has more in common with megabats, and even squirrels, than with extant primates. However, comparisons up to this point have only focused on the location, retinotopic organization, and connection patterns of visual areas. The modular organization within visual areas, both anatomical and functional, indicates that tree shrews are more primate-like than squirrel-like, as discussed below.

3.22.4.2 Building Levels of Complexity: Number of Areas and Functional Modularity in Tree Shrew and Squirrel Visual Cortex

While tree shrews are considered among the closest relatives to primates and interspecies comparisons can provide insights into the evolution of primate visual cortex, it is also useful to compare tree shrews to other species occupying a similar ecological niche (see Kaas, 2002). In the previous section, tree shrews were compared with the flying fox. These mammals shared many common organizational features of visual cortex. In addition, squirrels and tree shrews have many similarities in behavior, and in fact were considered squirrels by the local people in their native Southeast Asian habitat (see Martin, 1990). Both of these highly visual mammals have two types of cone photoreceptors in the retina allowing for some color vision (Jacobs *et al.*, 1980; Petry and Kelly, 1991), and have a high density of ganglion cell output (Kaas and Preuss, 1993). Furthermore, both species have a large and well-differentiated LGN (Figures 6a and 6b; Johnson *et al.*, 1998; Kaas, 2002), a large distinctive pulvinar (Figures 6a and 6b; Lyon *et al.*, 2003a), an unusually large SC (Kaas and Collins, 2001), and a moderate number of visual areas, seven or eight (Figures 5a and 5b). Finally, genetic studies have shown that tree shrews are more related to squirrels than bats (Figure 1; Murphy *et al.*, 2001).

An additional organizational component in mammals with expanded visual systems is that of anatomical and functional modules within early visual areas V1 and V2. At first glance, the organization of V1 and V2 between tree shrews and squirrels seems similar. In each species, the two areas can be identified through myelin staining and they have retinotopic maps that form mirror images. In addition, they show patchy intrinsic connection patterns. However, a closer examination reveals that the anatomical organization of visual cortex in tree shrews is much more elaborate than in squirrels (Bosking *et al.*, 1997; Fitzpatrick, 1996; Rockland and Lund, 1982; Rockland *et al.*, 1982;

Van Hooser *et al.*, 2005c). One distinguishing feature of tree shrews is the distinct ocular dominance layers of V1 (Hubel, 1975). These layers subdivide layer 4 and preserve the ocular segregation of the inputs from separate geniculate layers. While individual neurons in rodent visual cortex can receive relayed input primarily from one eye or the other, there is no evidence for structural preservation of ocular dominance. Ocular dominance is a prominent feature in ferrets, cats, and Old World monkeys, which take the shape of columns rather than layers. While ocular dominance is very distinctive in some highly visual species, it remains unclear whether a functional advantage can be attributed to these modules (Horton and Adams, 2005).

Anatomically, tree shrews and squirrels both exhibit long-range intrinsic connections (Figures 7a and 8a; Rockland and Lund, 1982; Kaas *et al.*, 1989). Yet, the pattern is patchy and more widespread in tree shrews (Figure 8a; Rockland and Lund, 1982; Rockland *et al.*, 1982; Lyon *et al.*, 1998; Van Hooser *et al.*, 2005c). Rockland and colleagues (1982) revealed several, fine 200μm wide bands of labeled cell bodies and axon terminations evenly distributed throughout a several millimeter wide region of V1 (up to 8mm) from a single tracer injection in V1. The size and periodicity of the bands resembled banding from 2-deoxyglucose (2-DG) uptake following full field visual stimulation of moving bars presented at a single orientation (Rockland *et al.*, 1982). In 2-DG experiments, radioactive glucose is introduced to the blood supply. Regions of the brain that are metabolically active will incorporate more of the 2-DG into the local neurons. Repetitively stimulating the visual field with bars of a single orientation will preferentially activate only those neurons that prefer that orientation. Thus, this experiment not only demonstrated that the tree shrew brain contains regularly distributed clusters of neurons preferring a similar orientation, it suggested that these regions are likely to be interconnected.

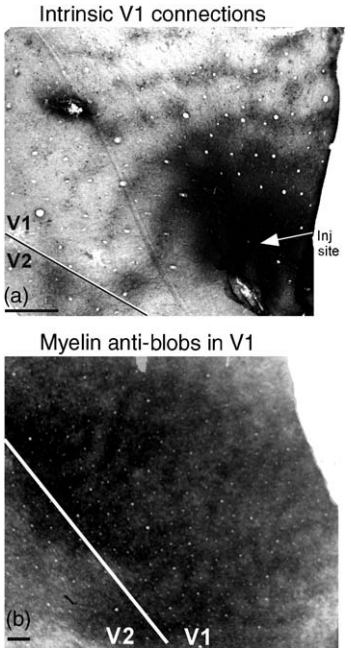

Figure 8 Anatomically defined modules in tree shrew V1. a, An injection of biotynilated dextran amine (BDA) reveals the intrinsic anterograde and retrograde connections of V1. Shown on a tangential section through cortical layer 3, a single injection resulted in a repeating pattern of regularly spaced clusters of labeled terminals and cell bodies within V1. b, Regularly spaced dense and light patches of myelin are also discernable across superficial cortical layers. Scale bar: 500μm. Reproduced from Lyon, D. C., Jain, N., and Kaas, J. H. 1998. Cortical connections of striate and extrastriate visual areas in tree shrews. *J. Comp. Neurol.* 401, 109–128, with permission from John Wiley & Sons.

Consistently with this prediction, recent studies using intrinsic signal optical imaging showed that the connections tend to link similar regions of cortex containing neurons that prefer similar orientations of a visual stimulus (Figure 9c; Bosking *et al.*, 1997). While presenting different oriented sinusoidal gratings to the tree shrew, intrinsic signals related to the neuronal activation were imaged optically and converted into a cortical map of orientation preference (Figures 9a and 9b). Similar maps are also a feature of primary visual cortex in ferret, cat, and all studied primates (see next section). When compared to patterns of connections from tracer injections placed into single orientation domains a high correlation between the location of axon terminals and similar preferred orientation was found (Bosking *et al.*, 1997). In contrast, recent work by Van Hooser *et al.* (2005a, 2005b) has shown that orientation domains are not present in the squirrel (Figure 10). In keeping with this observation, the intrinsic connectivity of squirrel V1 shows qualitatively only a limited patchy pattern (Figure 7a; Kaas *et al.*, 1989) and quantitatively this weak patchiness is not statistically significant (Van Hooser *et al.*, 2005c).

Other anatomical modules in tree shrew include the myelin dark 'anti-blobs' seen in V1 (Figure 8b; Lyon *et al.*, 1998) and the banding pattern of connections in V2 (Sesma *et al.*, 1984; Lyon *et al.*, 1998). While these features are not present in the squirrel, they are characteristics of primate V1 and V2. In tree shrew myelin patches are found in the superficial layers of V1. Such myelin patches have also been demonstrated in the superficial layers of primate V1, and they tend to occupy regions in-between CO blobs, hence the term 'anti-blob'. The functional significance of these myelin-dense patches remains to be determined, but axon

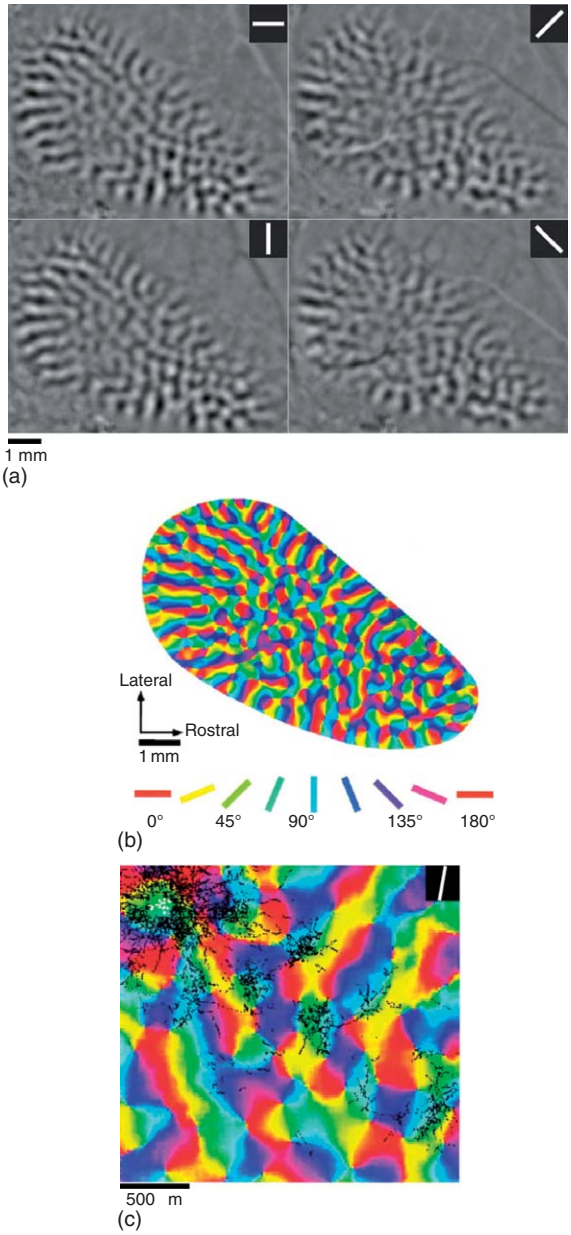

Figure 9 A regular pattern of functionally defined modules in tree shrew V1 can be revealed through intrinsic signal optical imaging. A major advantage of this technique is that it can simultaneously measure the responses of a large group of neurons over a wide area of cortex. a, Different populations of neurons are activated (black region) by a visual stimulus presented at one of four orientations (indicated in the upper right of each panel). Neurons preferring the same orientation are clustered together into modules, called orientation domains. b, A regular pattern of eight different orientation domains in V1 is apparent following stimulation with eight different orientated bars (below). The color-coding of the bars matches the color-coding of the domains. c, An anterograde neuronal tracer injected (white stipple) into a domain comprised of neurons preferring 45° (green) preferentially projects to like-domains. Reproduced from Bosking, W. H., Zhang, Y., Schofield, B., and Fitzpatrick, D. 1997. Orientation selectivity and the arrangement of horizontal connections in tree shrew striate cortex. *J. Neurosci.* 17, 2112–2127, copyright 1997 by the Society for Neuroscience, with permission.

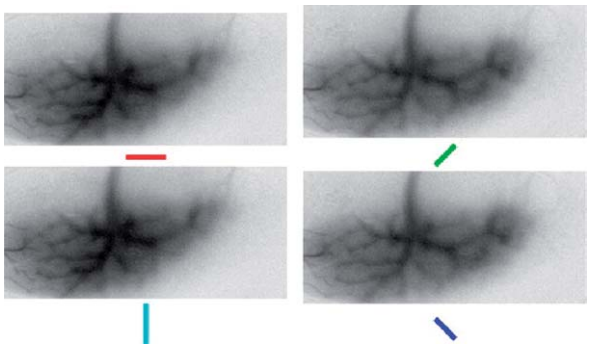

Figure 10 While intrinsic signal optical imaging of V1 in most highly visual mammals has revealed modular organization with respect to orientation processing (see Figure 9), orientation domains are not found in squirrels. These highly visual rodents, while having a comparable number of areas to tree shrews, exhibit less refinement of the internal structure of V1 and in this respect are similar to nonvisual rodents, such as mice and rats. Reproduced from Van Hooser, S. D., Heimel, J. A., Chung, S., Nelson, S. B., and Toth, L. J. 2005a. Orientation selectivity without orientation maps in visual cortex of a highly visual mammal. *J. Neurosci.* 25, 19-28, copyright 2005 by the Society for Neuroscience, with permission.

myelination is a key factor in increased conductivity speed so perhaps these clusters subserve some form of faster processing in V1.

The banding pattern in tree shrew V2 has been revealed through bidirectional tracers injected into V1 and V2. Terminals and cell bodies in V2 labeled by V1 tracer injections were arranged into several bands about 250–300 μm thick that extended from the V1/V2 border to the outer V2/TD border (Sesma *et al.*, 1984). Similar, but more constricted banding was observed following some individual V2 tracer injections, with the bands appearing up to 3 mm from the injection (Lyon *et al.*, 1998). These bands may be similar to bands found in primate V2 (see next section).

While tree shrews and squirrels have in common a moderate number of visual areas, the level of complexity in modular organization is very different. Functional and architectonic modular organization has not been demonstrated in V1 of squirrels, and the organization appears no different than V1 of mice and rats. In contrast, tree shrew V1 is highly modular and resembles many features found in V1 of carnivores and primates. Additionally, tree shrew V2 contains some of the modular anatomical features seen in primates. While the similarity in V1 and V2 between tree shrews and primates can be used to bolster their status as a close primate relative, the lack of modular organization in squirrels (Van Hooser *et al.*, 2005a, 2005b, 2005c) refutes the generally held belief that modularity and expanded visual systems come hand in hand. It may come as a

surprise that squirrels, with a relatively expansive visual system, lack modular organization, but, differences in modular organization in visual cortex between squirrels and tree shrews present an opportunity to explore the functional contributions of modular organization in otherwise similar complex systems.

3.22.5 Highly Complex Visual Systems in Carnivores and Primates

In contrast to the available data on the cortical organization of insectivores, rodents, bats, and tree shrews, the reported literature for cats and monkeys is vast, and includes detailed studies of functional characteristics of neurons while the animals are unanesthetized and performing visual tasks. The number of proposed visual areas in each taxa ranges from 15–19 in cats (Kaas and Krubitzer, 1991; Sereno and Allman, 1991; Payne, 1993) to 25 or more in monkeys (Kaas, 1997a; Van Essen, 2004; Rosa and Tweedale, 2005). While there is widespread agreement that monkeys and cats have a large number of visual areas, there has been less agreement as to each area's name, exact location, function, and even its very existence. In the first three sections here we will sample the available evidence to form a general overview of the organization of visual cortex in cats and ferrets, prosimian primates, and monkeys. In the subsequent sections, a more detailed description of certain cortical areas defined in primates – V1, V2, V3, and middle temporal (MT) – will provide the basis for comparisons with similar areas described in carnivores and other mammals.

3.22.5.1 Cat and Ferret Visual System

The cat as a model system for the study of visual cortex came into prominence through the early experiments of Hubel and Wiesel (1962, 1965, 1998). This seminal work was instrumental in developing an understanding of the receptive field properties of individual neurons in early cortical areas, identified as areas 17, 18, and 19 (but referred to here as areas V1, V2, and V3; see Figure 11). These three areas were considered to represent serial steps in a hierarchical progression where cells found early in the system were characterized as 'simple' and led to 'complex' and 'hypercomplex' cells at subsequent stages in visual cortex (see Payne and Peters, 2002). Though this description is oversimplified and there is a lot of mixing of simple and complex cells at early and later stages in the hierarchy, this organizational scheme set the stage for how mammalian visual cortex is viewed today, namely that visual processing becomes increasingly complex as it progresses across subsequent areas in visual cortex (see Bullier, 2004; Gross, 1997; Salin and Bullier, 1995).

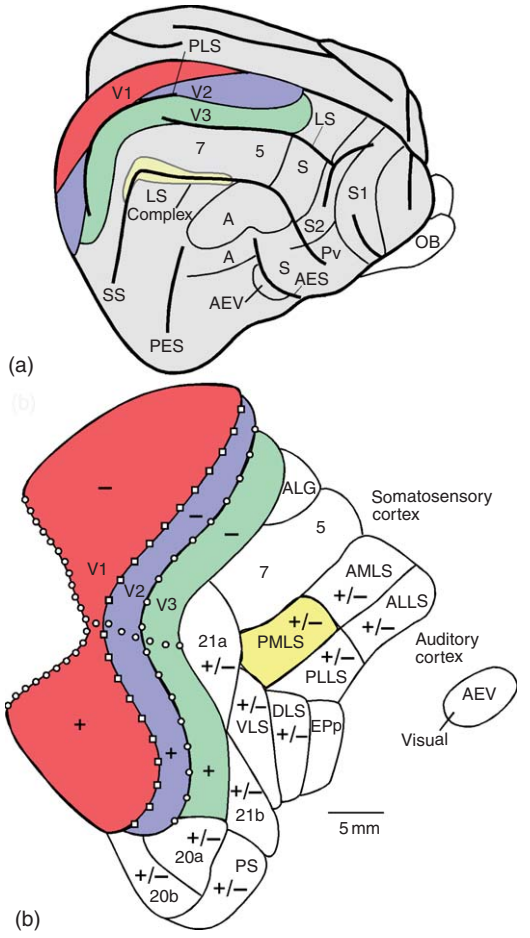

Figure 11 The organization of visual cortex in cats. a, Prominent visual areas, V1, V2, V3, and the LS complex (lateral suprasylvian) are shown relative to sulci, other visually responsive areas (5, 7, and anterior ectosylvian visual area (AEV)), and several nonvisual areas on the surface of an intact cortical hemisphere. Visually responsive areas occupy approximately half of the entire cortical surface. Anterior ectosylvian sulcus (AES); lateral sulcus (LS); posterior ectosylvian sulcus (PES); posterior lateral sulcus (PLS); suprasylvian sulcus (SS). b, A flattened cortical view of the relative sizes and locations of cat visual areas. Of the 19 visual areas shown, many are retinotopically organized (see schematic in Figure 4), though several of the higher-order areas contain incomplete representations of the contralateral visual field (see Kaas and Krubitzer, 1991). V1 (red) and V2 (blue) are considered homologous to early cortical areas found in most mammals. However, whether V3 (green) and PMLS (yellow) can be considered homologous to visual areas in other mammals, in particular areas V3 and MT in primates, remains a matter of debate (see Sections 3.22.5.5 and 3.22.5.6). See Section 3.22.5.1 for further description of cat visual areas and abbreviations. a, Based on Kaas and Krubitzer (1991) and Sereno and Allman (1991). b, Based on Sereno and Allman (1991) and Payne (1993).

As we have seen throughout this article, the earliest cortical stage in the visual system of mammals is V1, as it is the main recipient of the geniculate relay of retinal information. In addition to V1, cat V2 also receives direct projections from the LGN. While V2 in most mammals receives input from the LGN, the projections are less dense than those in cats, especially in other highly visual mammals, such as tree shrews (see Lyon *et al*., 2003b) and primates (Benevento and Yoshida, 1981; Bullier and Kennedy, 1983) – and somewhat less pronounced in the flying fox (Manger and Rosa, 2005). In cats, a large proportion of geniculate projections, stemming primarily from the Y-type ganglion cells (see Section 3.22.5.4.1), go directly to V2 (Stone *et al*., 1979). In this sense, V2 can be considered primary-like, an issue considered in great detail by Payne and Peters (2002). The specific projections of the Y cells directly to V2, provides a nonduplicative primary role for the region. As a result, cell properties in V2 reflect the fast conducting, transient response properties of the Y-cell inputs, whereas many of the V1 cells reflect the slower latency and sustained firing properties of the X-cell inputs. The lack of distinction between primary–secondary is also reflected in the myeloarchitecture of both cat and ferret cortex where, particularly in flattened preparations, there is no major differences between V1 and V2 at the border (Matsubara and Boyd, 2002; Olavarria and Van Sluyters, 1985; unpublished observations). Furthermore, CO blobs, a hallmark of primate V1 (Carroll and Wong-Riley, 1984; Horton and Hubel, 1981), are distributed evenly throughout V1 and V2 in the cat (Matsubara and Boyd, 2002).

Despite certain histological similarities between V1 and V2 in cats, differences in retinotopic organization can be used to reliably delineate the two areas. Through retinotopic microelectrode recordings pioneered by Hubel and Wiesel (1965), a stepwise progression from V1 to V2 revealed that these areas were split by the representation of the vertical meridian, whereas V2 and V3 were separated by the representation of the horizontal meridian. Subsequent studies exploring the retinotopic organization and connectional patterns of cat visual cortex revealed the size and extent of areas V1–V3 (see Figure 11; Tusa *et al*., 1978, 1979). As seen in tree shrew, bat, and squirrel visual cortex, nearly the entire laterorostral extent of V1 is bordered by V2. However, unlike these other species, cat V3 is substantially larger as it is nearly coextensive with the outer border of V2. As for other mammals, the lower visual field is represented dorsally, whereas the upper visual field is represented ventrally. One prominent feature of the retinotopy in these early areas in cats, which is even more pronounced in monkeys, is the greater representation through cortical magnification of the central visual field (see figure 1 in Payne, 1993).

In comparison to the mammals covered earlier in this article, cat cortex is quite expansive, and subsequently in this highly visual species there is room for a larger number of visual areas. Due to the overwhelming number of studies on the retinotopy of these areas and their interconnections, the focus here will be on presenting an overview of the relative locations of each area, while subsequent sections will highlight some of the characteristics of a few of these areas (for extensive reviews of extrastriate cortex in cat, see Payne, 1993; Payne and Peters, 2002; Rosenquist, 1985; Sereno and Allman, 1991; Tusa *et al*., 1981). Figure 11b, adapted and modified from Sereno and Allman (1991) and Payne (1993) shows 19 total visual areas on an unfolded, or flattened, cortical sheet. Beyond V3, as for the moderately complex visual systems in other species, the areas are substantially smaller, and contain complete or nearly complete representations of the contralateral visual hemifield. The relative locations of these areas to the two main sulci, the lateral and suprasylvian, are shown in Figure 11a. Naming of many of the extrastriate visual areas is based on their relative locations along or near one of these sulci. For example, dorsally, just adjacent to the peripheral lower field representation of V3, lies an area along the anterior lateral gyrus, area ALG (Symonds and Rosenquist, 1984). Other areas have been named as an extension of the alternative numbering scheme adapted from Brodmann (1909) that refers to areas V1–V3 as areas 17, 18 and 19 (see Payne and Peters, 2002). These areas, 20 and 21, are found adjacent to the middle and ventral parts of area 19 (V3), and have been split into two areas each – 20a, 20b, 21a, and 21b (Rosenquist, 1985; Tusa and Palmer, 1980). However, the liberal subdividing of these regions results in areas with only incomplete representations of the contralateral visual hemifield (see Kaas and Krubitzer, 1991). Just anterior to the two ventral areas, 20a and 20b, is the posterior suprasylvian area, PS, which also contains an incomplete retinotopic map in that it primarily represents the lower field (Updyke, 1986). While ALG, is among the smallest extrastriate areas described in cats, areas 5 and 7, which are also named based on similarities to architectonically defined regions of Brodmann (1909), are among the largest (after V2 and V3). Anterior to the dorsal portion of V3, in a similar region of posterior parietal cortex as visual areas reported in the flying fox (OP) and tree shrew (TAL; see Section 3.22.4.1),

areas 5 and 7 have only crude retinotopic organizations and contain bimodal neurons responding to visual and somatosensory stimulation (see Manger *et al.*, 2002b). Ventrally in the lateral suprasylvian sulcus is the aptly named area VLS, situated somewhat between areas 21a and 21b. On the opposite, dorsal bank of the suprasylvian sulcus, VLS is bordered by area DLS. While there is some evidence for retinotopic organization of VLS and DLS, area EPp, immediately anterior to DLS, is not retinotopically organized (see Payne, 1993).

Just medial to VLS and DLS, but still along the lateral suprasylvian sulcus there is a large complex of visual areas that roughly corresponds in location to the Clare–Bishop area, a region first identified as visually responsive over 50 years ago (Clare and Bishop, 1954). This complex has been split into as few as two areas (see Sherk, 1986a, 1986b; Shipp and Grant, 1991) and as many as four regions as portrayed in Figure 11 (see Rosenquist, 1985). The four areas are named PMLS, AMLS, PLLS, and ALLS, based on their posterior (P) or anterior (A) locations on the medial (M) and lateral (L) banks of the lateral suprasylvian (LS) sulcus. This region of extrastriate cortex, particularly PMLS, has been studied in detail and comparisons have been made to the direction selective MT, or V5, of primates (see Grant and Hilgetag, 2005; Payne, 1993; also see Section 3.22.5.6). Lastly, the anterior ectosylvian visual area (AEV), located several millimeters anterior to the nearest visual area is unique in that it sits surrounded by cortical areas responsive to modalities other than vision (see Sereno and Allman, 1991). Perhaps because of its unusual isolation, it is helpful to include visual as part of its name.

The cat also contains a rather large visual pulvinar complex in the thalamus (Figure 6c), as we have seen for other visual species. The large size of the cat pulvinar, or lateral posterior-pulvinar complex, reflects the expansiveness of extrastriate visual cortex with which it is extensively interconnected. The LP-pulvinar can be divided into subdivisions of the lateral posterior region including lateral (LPl), intermediate (LPi) and medial (LPm), and the pulvinar-proper (e.g., Hutchins and Updyke, 1989), based on connection patterns with visual cortex and differences in architecture (see Lyon *et al.*, 2003b; Casanova, 2004). The lateral subdivision of the lateral posterior region, LPl, is the only subdivision interconnected with early visual areas V1 and V2. It also connects with the complex of areas in and around the PMLS region, and areas 19, 20, and 21. The medial division, LPm (sometimes considered the inferior subdivision, LPi), also connects with areas 19–21, the PMLS region, as well as posterior parietal areas 5 and 7, and AEV. Likewise the pulvinar-proper connects to the same areas as LPm, but does not connect with AEV. LPi has been distinguished architectonically from LPm as staining darkly for both substance P (Hutsler and Chalupa, 1991) – a marker associated with SC inputs – and AChE (Graybiel and Berson, 1980). This dark staining for AChE is similar to the dorsal subdivision of the tree shrew pulvinar (Figure 6b; see Lyon *et al.*, 2003a).

Other than the multiple areas forming the PMLS complex, the majority of the extrastriate areas in cat, have been identified in their mustelan cousin, the ferret, in a series of retinotopic mapping experiments by Manger and colleagues (Innocenti *et al.*, 2002; Manger *et al.*, 2002a, 2002b, 2004). However, it has been suggested that areas similar to those found in the cat PMLS complex are also present in ferrets (Manger, 2005), so the two species appear to share the same number of cortical visual areas. Because there is a rather substantial overall difference in brain size between the two species, it is perhaps surprising that the number of extrastriate visual areas is comparable. Manger (2005) has used these observations as support for the idea that, within orders, there is little interspecies variability in cortical organization. However, we have already seen substantial differences between squirrels and smaller, less visual rodents (see Section 3.22.3). Yet, rodent species vary significantly in their emphasis on vision, and it can be argued that the entire carnivore order is highly visual, as visual cortex is also large in other carnivore species such as the mink (see McConnell and LeVay, 1986). Perhaps, this is what drives the similarity in visual cortex organization in carnivores. Another issue to consider is that V1 and V2 in both cats and ferrets is highly modular as revealed through connectivity patterns and optical imaging (Gilbert and Wiesel, 1983; Kisvarday *et al.*, 1997; Weliky *et al.*, 1996; White *et al.*, 1999). Yet, one of the more striking anatomical modules found in cats and primates, the CO blobs in V1, are not present in ferret V1. Perhaps at this level, cats and ferrets differ in complexity as differences in V1 modular organization exist between tree shrews and squirrels as well (see Section 3.22.4.2).

3.22.5.2 Prosimian Visual System

Prosimian primates – lemurs and lorises – having split over 50 Mya from other primates are considered to have retained many early primate features (see Fleagle, 1988). Thus, understanding prosimian cortical organization provides insights into the organization that may have been present in the earliest primates. Only a few prosimian species have been

studied, with the galago or bush baby (*Otolemur garnetti*) examined in the most detail. As we have seen for the mammals covered previously in this review, V1 is easily distinguishable as a large, densely myelinated region in the caudal-most portion of the prosimian cortex. As in cats, staining for the metabolic enzyme, CO, reveals regularly distributed blobs throughout V1 (Casagrande and Kaas, 1994). Earlier reports found a lack of CO blobs in certain prosimian species (see Sereno and Allman, 1991). Because CO blobs are present in all studied monkeys and apes, but not in every prosimian species, this left open the possibility that blobs evolved independently in monkeys and prosimians (see Preuss and Kaas, 1996). However, the absence of CO blobs in earlier preparations may have been due to technical difficulties, as subsequent studies demonstrated that CO blobs are a common feature in prosimian V1 (Preuss and Kaas, 1996).

In galagos, retinotopic maps of V1 show an orderly representation of the contralateral visual hemifield, with a larger portion of cortex representing central vision (Rosa *et al.*, 1997). In addition, galago V1 exhibits intrinsic patchy connectivity (Cusick and Kaas, 1988b; Preuss *et al.*, 1993; Lyon and Kaas, 2002c) and contains an orderly orientation preference map (Xu *et al.*, 2005). Immediately adjacent to V1 lies V2 (see Figure 12), which can be identified through myeloarchitecture as well (Krubitzer and Kaas, 1990; Collins *et al.*, 2001; Lyon and Kaas, 2002c). Galago V2 resembles V2 in other species as it represents a compressed, rough mirror image of the representation of the visual field in V1 (Rosa *et al.*, 1997), and receives feedforward inputs from and sends feedback to V1 (Collins *et al.*, 2001; Symonds and Kaas, 1978; Tigges *et al.*, 1973).

A second extrastriate cortical area common to all primates is the MT area (see Kaas and Lyon, 2001). First described in New World monkeys (Allman and Kaas, 1971b), homologous area was subsequently identified in prosimians using similar criteria (Allman *et al.*, 1973; Tigges *et al.*, 1973; Symonds and Kaas, 1978). Whether a homologous area is present in other mammals is a matter of debate (see Section 3.22.5.6; Payne, 1993; Kaas, 2002; Rosa and Tweedale, 2005).

In prosimians, as many as 12 more extrastriate visual areas (Figure 12) are discernable through feedback connections to V1 (Cusick and Kaas, 1988b; Krubitzer and Kaas, 1993; Lyon and Kaas, 2002a; Preuss *et al.*, 1993), V2 (Collins *et al.*, 2001), and MT (Krubitzer and Kaas, 1990). One of these 12 extrastriate areas, V3, had not been identified in prosimians (Allman *et al.*, 1979; Beck and Kaas, 1998a; Collins *et al.*, 2001; Rosa *et al.*, 1997) until recently, when several tracer injections placed in estimated retinotopic locations of V1 proved instrumental in dividing extrastriate visual cortex of the galago (Lyon and Kaas, 2002a). As a result, for example, the dorsal medial area, DM, originally identified through microelectrode mapping of retinotopy (Allman *et al.*, 1979, Rosa *et al.*, 1997), has

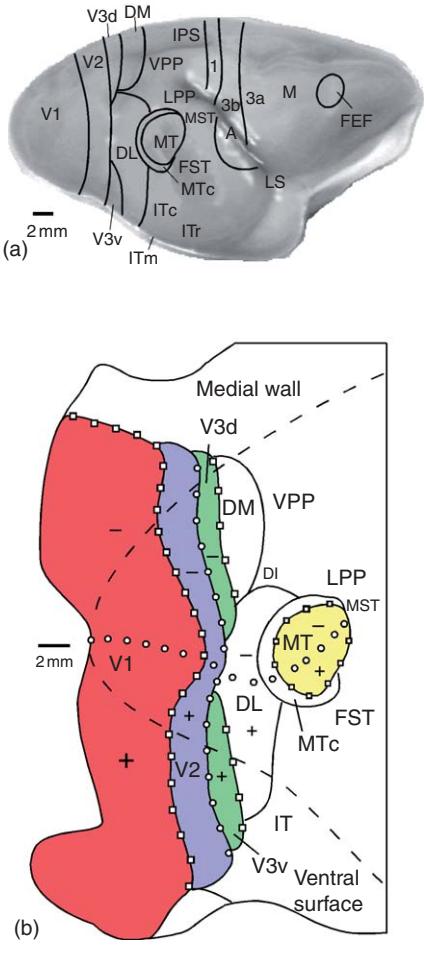

Figure 12 The organization of visual cortex in prosimian primates. a, The locations of several visual and nonvisual areas are shown on a digital photograph of the cortical surface of an intact galago brain. The intraparietal (IPS) and lateral (LS) sulci are clearly visible, while the superior temporal sulcus is present as a slight dimple ventral to MT. b, A flattened cortical view of the relative sizes and locations of galago visual areas. V1 (red) and V2 (blue) are likely homologous to similar areas present in other mammals, while primate areas V3 (green) and MT (yellow) may be unique to the primate order. The homology of primate V3 and MT to areas present in nonprimates is a matter of debate (see Sections 3.22.5.5 and 3.22.5.6). Nevertheless, the existence of V3 and MT, as well as several other visual areas (DL, DM, DI, MTc, MST, IT) in prosimian primates indicates that these areas were present early in primate evolution. For abbreviations and detailed descriptions of galago visual areas see Section 3.22.5.2. a and b, Modified from Lyon, D. C. and Kaas, J. H. 2002a. Connectional evidence for dorsal and ventral V3, and other extrastriate areas in the prosimian primate, *Galago garnetti*. *Brain Behav. Evol.* 59, 114–129.

been slightly displaced by V3 from its original location adjacent to the anterior border of dorsal V2 (see Figure 12; Lyon and Kaas, 2002a). Anterior to DM and dorsal to MT, at least two more areas have been identified the lateral and ventral areas of posterior parietal cortex, LPP and VPP (Beck and Kaas, 1998a; Lyon and Kaas, 2002a). Ventral to DM, along the anterior border of the ventral two-thirds of V3 is the dorsal lateral visual area, DL (Cusick and Kaas, 1988b), a possible homologue of macaque monkey V4 (see Stepniewska *et al.*, 2005). Some studies suggest that prosimian DL can be split into caudal and rostral subdivisions as proposed for both New and Old World monkeys (Cusick and Kaas, 1988a; Lyon and Kaas, 2002c; Stepniewska *et al.*, 2005). Anterior to the ventral half of DL, at least three areas in inferior temporal cortex (IT) can be distinguished based on clusters of labeled cells in different relative locations – the caudal (ITc), medial (ITm), and rostral (ITr) areas, as described for New World monkeys (Weller and Kaas, 1987). Surrounding MT, three more areas, the MT crescent (MTc), the area of the fundus of the superior temporal sulcus (FST), and the medial superior temporal area (MST) are also distinguishable.

Some of the available evidence suggests that galagos and perhaps prosimians in general represent a scaled-down version of the organization of monkey visual cortex (see Kaas, 2004a, 2004b). For example, monkey V1 is larger and contains a greater representation of central vision (Van Essen *et al.*, 1984; Gattass *et al.*, 1987; Rosa *et al.*, 1997). Furthermore, while both monkeys and prosimians have CO blobs in V1, the monkey – but not galago – V2 also contains distinct cytoarchitectonic bands (see Sections 3.22.5.3 and 3.22.5.4; however, see Preuss and Kaas, 1996). In addition, the pulvinar nucleus, which is a distributor of visual information to all of visual cortex, is larger in monkeys than in prosimians and can be divided into several subcompartments based on architectonic criteria and cortical projection patterns (Beck and Kaas, 1998b; Stepniewska, 2003). Despite these differences, the number and locations of visual areas described for prosimians is very similar to those described in monkeys (see Figures 12 and 13; Kaas, 1997a, 2004a, 2004b; Kaas and Lyon, 2001; Van Essen, 2004; Rosa and Tweedale, 2005).

3.22.5.3 New World and Old World Monkey Visual Systems

Several species of New World monkeys have been examined from the very small 300g marmoset monkey and moderately sized 1kg squirrel monkey, to the large, macaque-sized cebus monkey. Various species of the macaque monkey genus have been the Old World monkey of choice. Weighing as much as 15kg and boasting a brain size as large as 10 times that of the tiny marmoset (80g vs. 8g; see Rosa and Tweedale, 2005), macaques are used as the primary model for comparisons to the human visual system (Brewer *et al.*, 2002; Fize *et al.*, 2003; Orban *et al.*, 2004; Sereno and Tootell, 2005; Tootell *et al.*, 2003; Van Essen, 2004). Emphasis on the macaque monkey as a human model is due in part to historical factors and the ready availability of this species (Rosa and Tweedale, 2005). Yet, despite the size differences and the 10 million years of evolution that separate the New World and Old World monkey lineages, several studies indicate that the organization of their visual cortex is quite similar (Casagrande and Kaas, 1994; Lyon and Kaas, 2002b, 2002c; Lyon *et al.*, 2002; Rosa and Tweedale, 2005). This is particularly true for the early, caudal visual areas that have been studied in more detail in both New and Old World species (see Kaas and Lyon, 2001; Kaas, 2004a). Therefore, this section will review studies on visual cortex organization in both New and Old World monkeys.

Monkey visual areas V1 and V2 are well established as the two largest visual areas in primate cortex (see Figures 13 and 14). V1 and V2 are found at the caudal end of cortex and are likely homologous to V1 and V2 of all mammals (see Sections 3.22.2 and 3.22.5.4). Of all the remaining extrastriate visual areas proposed to exist in monkeys, area MT (see Section 3.22.5.6) is the only one that is unanimously accepted (see Felleman and Van Essen, 1991; Kaas and Lyon, 2001). MT, also referred to as V5, was first described as a densely myelinated retinotopically organized region located several millimeters anterior to V2 in the middle temporal lobe of New World owl monkeys (Allman and Kaas, 1971b) and as a region on the posterior bank of the superior temporal sulcus (STS) in macaque monkeys that received direct projections from V1 (Zeki, 1971). Subsequently, MT of macaques was also shown to be retinotopically organized (Gattass and Gross, 1981; Van Essen *et al.*, 1981). Additional work demonstrated that MT is likely to be a common primate feature (see Kaas and Lyon, 2001; Kaas, 2004a). Whether primate MT evolved from an area common to nonprimates is a matter of debate (Kaas, 2002; Rosa and Tweedale, 2005; see Section 3.22.5.6.1). Studies on the functional properties of MT show that it plays a major role in the processing of binocular

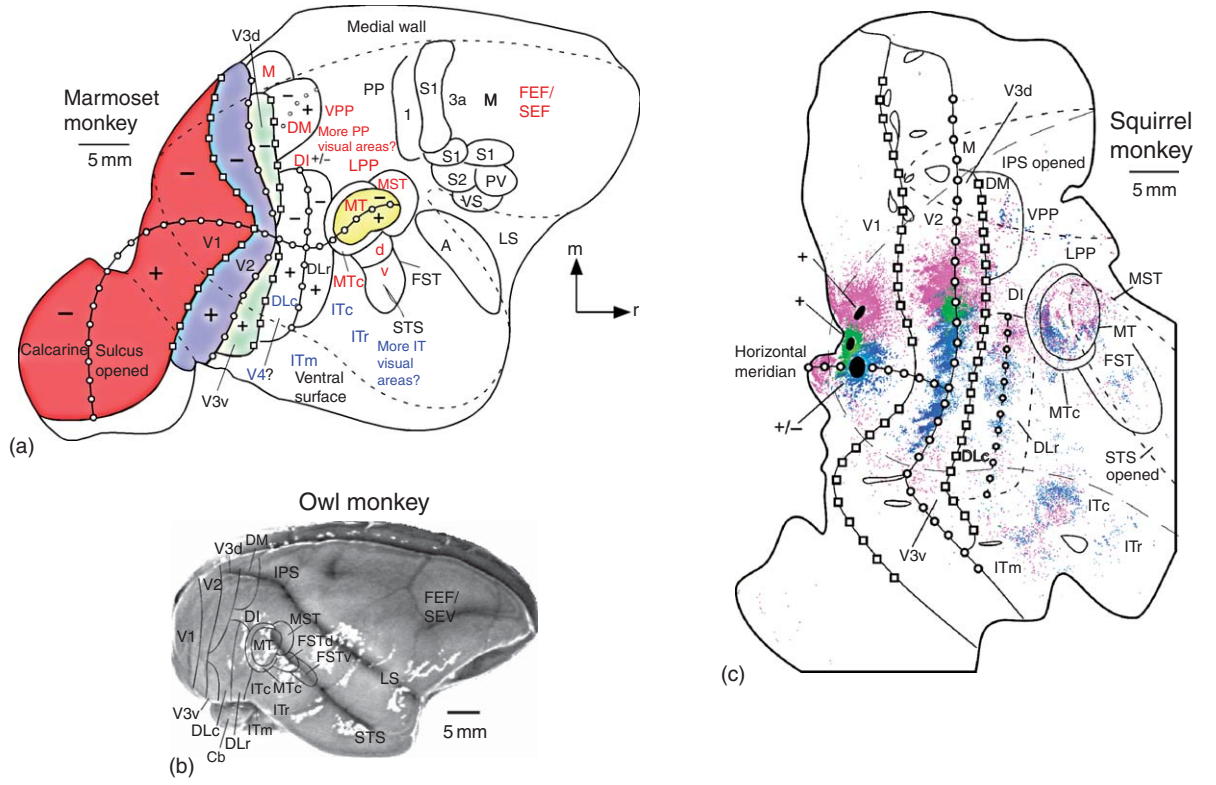

Figure 13 The organization of visual cortex in New World monkeys. a, The locations and sizes of visual areas in New World monkeys are shown on a flattened sheet of an entire cortical hemisphere from a marmoset monkey. Like other highly visual species V1 (red shading) and V2 (blue shading) are quite large, and retinotopically organized (see schematic in Figure 4a). V3 (green shading) is present as two distinct dorsal (d) and ventral (v) divisions, each representing a compressed mirror image of the retinotopic organization in dorsal and ventral portions of V2. Several more retinotopic areas (DLc, DLr, DI, DM, and MT) are present in extrastriate cortex (indicated by +/–). Areas lettered in red, fed predominantly through feed-forward projections from direction selective area MT, are thought to comprise the dorsal stream of visual processing related to motion and spatial processing, whereas areas lettered in blue, fed predominantly by V4 (Dlc/DLr), are related to the processing of color and form (see Section 3.22.5.3). SEF, supplementary eye field; FEF, frontal eye field. b, The positions of several areas relative to the sulcus pattern on the cortical surface are shown on a digital photograph of an owl monkey brain. Intraparietal sulcus (IPS), lateral sulcus (ILS), superior temporal sulcus (STS). c, The pattern of retrogradely labeled neurons following injections (black ovals) of three tracers into different retinotopic locations of V1 in a single case is shown on a flattened reconstruction of the caudal half of squirrel monkey cortex. Colored dots represent individually labeled neurons from the corresponding tracer injection. An injection of fast blue (blue) was made on the representation of the horizontal meridian (line of circles, see schematic in Figure 4a), thus labeled neurons in extrastriate cortex were found near known locations of the horizontal meridian. For example, the horizontal meridian is located at the V2/V3 and DLc/DLr borders, as well as the caudal border of MT. Injections of diamidino yellow (green) and cholera toxin subunit-b (CTB; purple) were placed near the horizontal meridian, but slightly medial, in cortex representing progressively more peripheral vision. As a result, the labeled cells in extrastriate cortex from each of the two injections were located progressively more medial along the horizontal meridians at the V2/V3 and DLc/DLr borders. Interestingly compared to the smaller marmoset monkey V3 which is split into dorsal and ventral divisions (a), V3 in squirrel monkeys is a continuous strip. Additional retrogradely labeled neurons were found in several other cortical areas, indicating that a wide region of visual cortex provides feedback to V1. For abbreviations and detailed description of the organization of New World monkey visual areas see Section 3.22.5.3. a, Modified from Lyon, D. C. and Kaas, J. H. 2001. Connectional and architectonic evidence for dorsal and ventral V3, and dorsomedial area in marmoset monkeys. *J. Neurosci.* 21, 249–261. b, Modified from Lyon, D. C., Xu, X., Casagrande, V. A., Stefansic, J. D., Shima, D., and Kaas, J. H. 2002. Optical imaging reveals retinotopic organization of dorsal V3 in New World owl monkeys. *Proc. Natl. Acad. Sci. USA* 99, 15735–15742; Based on data from Lyon, D. C. and Kaas, J. H. 2002c. Evidence from V1 connections for both dorsal and ventral subdivisions of V3 in three species of New World monkeys. *J. Comp. Neurol.* 449, 281–297. c, Modified from Lyon, D. C. and Kaas, J. H. 2002c. Evidence from V1 connections for both dorsal and ventral subdivisions of V3 in three species of New World monkeys. *J. Comp. Neurol.* 449, 281–297, with permission from John Wiley and Sons.

disparity and the direction and speed of visual stimuli (Albright, 1984; Born and Bradley, 2005; Felleman and Kaas, 1984; Maunsell and Van Essen, 1983b), and is likely a primary source of input to the motion and spatial processing areas in the dorsal stream of visual processing (Maunsell and Van Essen, 1983a; Shipp and Zeki, 1995; Ungerleider and Desimone, 1986).

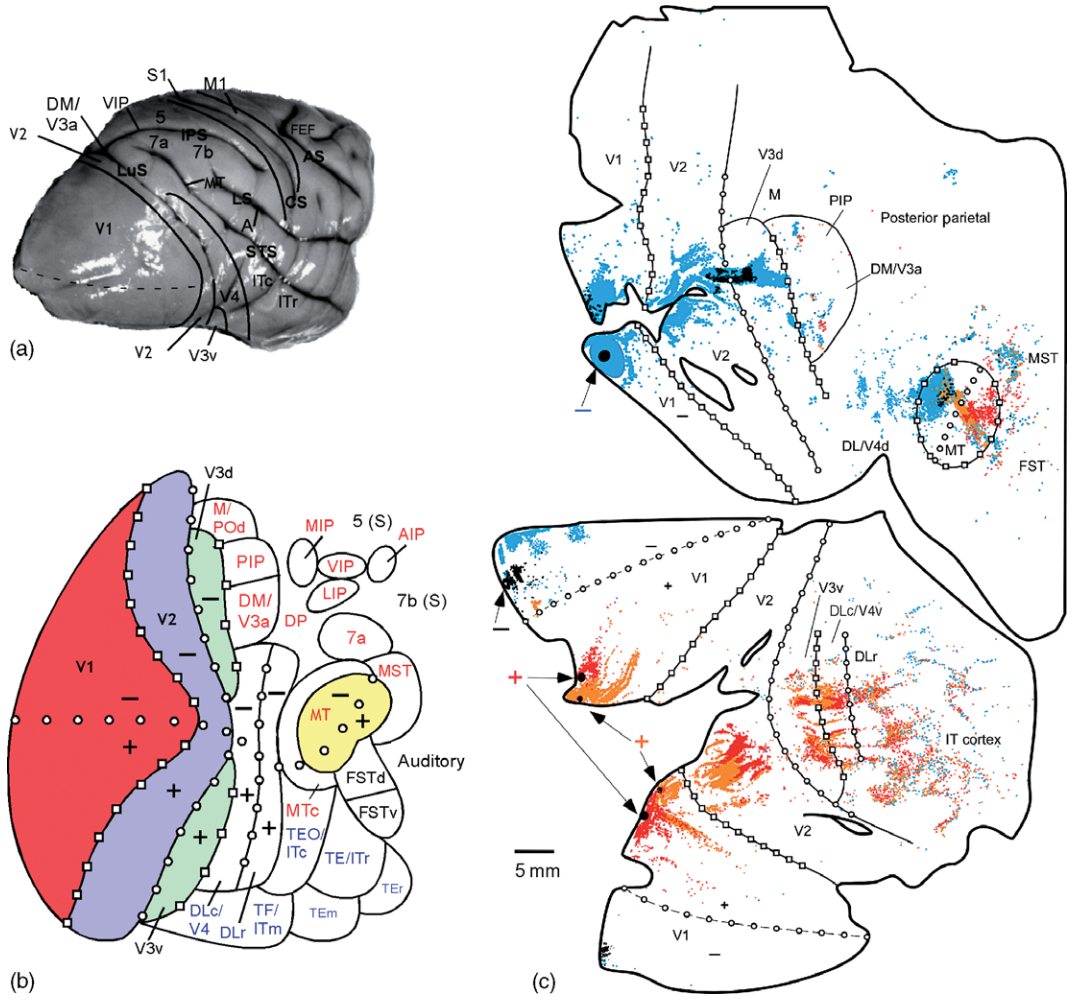

Figure 14 The organization of visual cortex in Old World macaque monkeys. a, The positions of several areas relative to the sulcus pattern on the cortical surface are shown on a digital photograph of a macaque monkey brain. The majority of V2, all of V3 and V3a, are buried within the lunate sulcus (LuS). Area MT and its satellites are buried within the dorsal extent of the superior temporal sulcus (STS), whereas much of the higher-order ventral stream areas in inferotemporal cortex (IT) are located within the ventral extent of the STS. Higher-order dorsal stream areas such as the ventral intraparietal area (VIP) are buried within the intraparietal sulcus (IPS). AS, arcuate sulcus; CS, central sulcus; FEF, frontal eye field. b, The relative locations and sizes of visual areas in macaque monkeys are shown on a flattened representation of the caudal half of cortex. Many visual areas reported for the macaque are likely homologous to those proposed for New World monkeys (see Figure 13), especially in the caudal extent of visual cortex, including areas V1, V2, V3, V4 (DLc/DLr), MT, MTc, MST, FSTd/v, DM (V3a), POd (M), DP (DI). However, several more areas have been described in the higher-order stations of the dorsal and ventral processing streams. It is uncertain whether these areas represent an expansion of visual cortex in Old World monkeys because (1) similar areas have been described in larger New World cebus monkeys (see Rosa and Tweedale, 2005) and (2) few studies have looked at the detailed organization of higher-order visual cortex in the more commonly studied smaller New World monkey species. TE, temporal cortex; TEm, middle subdivision of TE; TEr, rostral subdivision of TE; TEO, temporal occipital cortex. c, The pattern of retrogradely labeled neurons following injections (black ovals) of four tracers into different retinotopic locations of V1 in a single case is shown on a flattened reconstruction of the caudal half of macaque cortex. Colored dots represent individually labeled neurons from the corresponding tracer injection. Two injections were placed in the upper visual field representation in ventral V1, one (orange) nearer the representation of the vertical meridian (line of squares) found at the V1/V2 border, and the other nearer the representation of the horizontal meridian (line of circles; see schematic in Figure 4a). In adjacent ventral cortex, a series of mirror reversals of the retinotopic locations of the V1 injections was found in the pattern of retrogradely labeled cells in extrastriate areas V2, V3, DLc (V4), and DLr. A similar pattern of labeled cells resulted in dorsal visual cortex following two tracer injections in the lower visual field representation of dorsal V1. Retinotopic patterns of retrogradely labeled cells from the dorsal and ventral V1 injections were found in MT as well. A crude retinotopic pattern of connections with MST was also present. Labeled neurons in areas V3a and PIP were sparse, yet indicated a crude retinotopy. Few cells, if any, were labeled in PP, indicating that higher-order dorsal stream areas do not provide feedback to V1. In contrast, numerous cells were labeled in IT cortex (nonretinotopically), indicating that, like New World monkeys, higher-order ventral stream areas provide feedback to V1. For abbreviations and detailed description of the organization of macaque monkey visual areas see Sections 3.22.5.2 and 3.22.5.3. c, Modified from Lyon, D. C. and Kaas, J. H. 2002b. Evidence for a modified V3 with dorsal and ventral halves in macaque monkeys. *Neuron* 33, 453–461, with permission from Elsevier.

Probably the greatest factor contributing to the establishment of V1, V2, and MT as valid visual areas is that these are the only areas that can be reliably identified through architectonic criteria, such as stains for myelin and CO (see Figures 15 and 16). The numbers, locations, and sizes of the myriad of remaining, proposed extrastriate visual areas in monkey cortex remain uncertain. In some cases it is simply a difference in area size and terminology (DL vs. V4; see Stepniewska *et al.*, 2005), while in other cases it is a reported difference in connectivity and function (dorsal V3 vs. ventral V3; see Section 3.22.5.5). As a result, several different organizational schemes of monkey visual cortex have been proposed (see Kaas, 1997a; Rosa, 1997; Van Essen, 2004). Methods used to identify areas play a large role in the observed variability. For example, fine-scale methods such as microelectrode mapping have been used to demonstrate several retinotopically organized areas in the third tier of visual cortex (Allman and Kaas, 1975; Rosa and Schmid, 1995); conversely a single area, V3, is revealed through techniques capable of measuring activity of larger regions of cortex simultaneously, such as intrinsic signal optical imaging (Lyon *et al.*, 2002; Xu *et al.*, 2004) and fMRI (Brewer *et al.*, 2002; Fize *et al.*, 2003). While others have provided comparisons of the many proposals of monkey visual cortex organization (Kaas, 1997a; Rosa, 1997; Van Essen, 2004), the goal of this section is to present a composite representation (see Figures 13 and 14) of the various versions to allow for straightforward comparisons of New and Old World monkeys, and to provide a scheme that can be readily compared to those presented for other mammals.

Other than areas V1, V2, and MT, a conservative estimate of the number of proposed visual areas in monkeys is slightly greater than 20 (see Figures 13a and 14b). Areas early in the cortical hierarchy located more caudally have been identified through similar methodologies in both New and Old World monkeys. Retrograde tracing studies that focused on the feedback connectivity patterns of these areas to V1 have served as a useful means for comparison across species, revealing many similarities in organization (see Figures 13c and 14c). On the other hand, cortical areas located more distantly from V1, for example in PP, have been studied more extensively in macaque monkeys (see Andersen, 1995; Andersen *et al.*, 1985b; Colby and Duhamel, 1991; Lewis and Van Essen, 2000a, 2000b), making comparisons with New World monkeys more difficult.

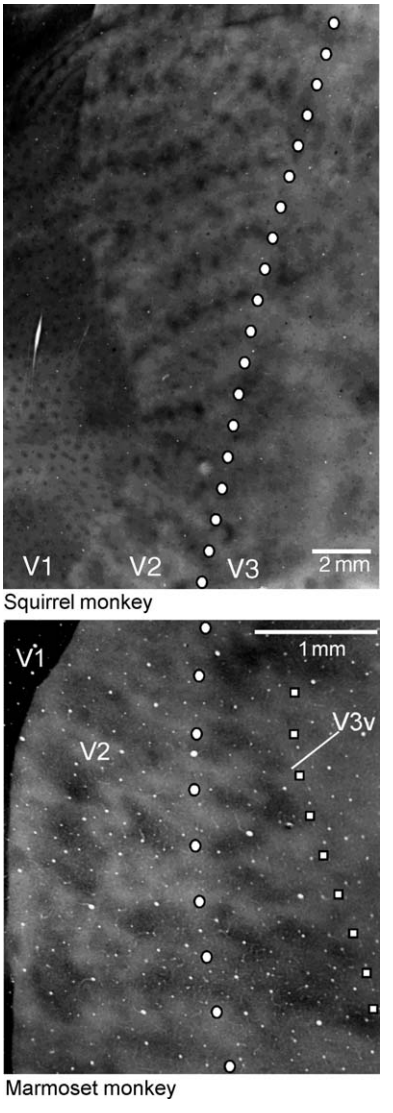

Figure 15 When processed for the presence of cytochrome oxidase (CO), cortex manually flattened and cut tangential to the cortical surface shows a regular pattern of dark (high concentration of CO) and light (low concentration of CO) modules in early visual areas of monkeys. As shown in squirrel monkey cortex (top panel), in V1, the dark CO patches form small, discrete blobs, whereas in V2 the blobs are strung together to form stripes, or bands. The V2 bands are characterized as either 'thick' or 'thin', and have been linked to the dorsal and ventral visual processing streams, respectively (see Section 3.22.5.4.1). Though less distinct than the bands in V2, dark CO bands are often visible in V3 (bottom panel). Whether these bands are associated to either of the visual processing streams remains to be determined, but it has been shown that band-like patches of labeled neurons become labeled in V3 following tracer injections into dorsal stream areas DM and MT (Lyon and Kaas, 2001). Squirrel monkey, reproduced from Lyon, D. C. and Kaas, J. H. 2002c. Evidence from V1 connections for both dorsal and ventral subdivisions of V3 in three species of New World monkeys. *J. Comp. Neurol.* 449, 281–297, with permission from John Wiley & Sons. Marmoset monkey, reproduced from Lyon, D. C. and Kaas, J. H. 2001. Connectional and architectonic evidence for dorsal and ventral V3, and dorsomedial area in marmoset monkeys. *J. Neurosci.* 21, 249–261, copyright 2001 by the Society for Neuroscience, with permission.

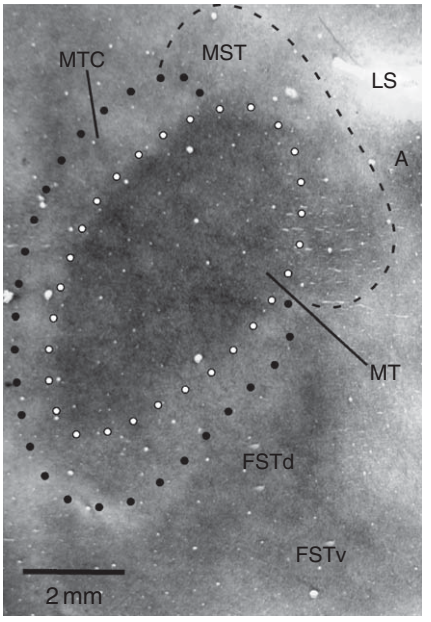

Figure 16 In flattened cortical preparations, dense myelination easily distinguishes primate area MT from surrounding cortical areas. Furthermore, in this section through the superficial layers of cortex dark and light patches within MT indicate a modular organization of dense and light myelination. In addition to differences in myelination, several forms of modular organization within MT have been revealed through a variety of techniques (see Sections 3.22.5.3 and 3.22.5.6 for more details of MT and surrounding cortical areas). Reproduced from Lyon, D. C. and Kaas, J. H. 2001. Connectional and architectonic evidence for dorsal and ventral V3, and dorsomedial area in marmoset monkeys. *J. Neurosci.* 21, 249–261, copyright 2001 by the Society for Neuroscience, with permission.

In addition to the identification of discrete cortical areas, primate visual cortex can be segregated into the dorsal and ventral streams of visual processing (see Figures 13a and 14b). The identification of these processing streams derives from lesion studies in cats and primates, including humans, revealing a segregation of function into separate cortical pathways (see Ungerleider and Mishkin, 1982; Ungerleider and Pasternak, 2004). Motion and spatial information are processed in a stream of neighboring visual areas found more dorsally within occipital and parietal cortex, the dorsal or parietal stream. Conversely, color and form processing is most pronounced in neighboring ventral regions within occipital and temporal cortex, the ventral or temporal stream. The higher-order areas comprising the two streams are fed in varying degrees by early caudal visual areas, V1, V2, V3, V4 and MT (Van Essen and De Yoe, 1995).

V3, considered a provider of inputs to both streams (see Gegenfurtner *et al.*, 1997), is located immediately adjacent to V2 as a narrower strip of cortex that was first identified through its connectivity with V1 (Cragg, 1969; Zeki, 1969). While a V3-like area has been identified in several other mammalian species as discussed throughout this article and elsewhere (see Rosa, 1999), the organization and even the very existence of primate V3 remains controversial (Kaas and Lyon, 2001; see Section 3.22.5.5). Monkey V3 has a retinotopic map representing a condensed mirror image of the visual field representation in V2 as revealed through microelectrode mapping (Gattass *et al.*, 1988), intrinsic signal optical imaging (Lyon *et al.*, 2002; Xu *et al.*, 2004), fMRI (Brewer *et al.*, 2002; Fize *et al.*, 2003), and connections with primary visual cortex (Lyon and Kaas, 2001, 2002b, 2002c). Importantly, V3 can be identified in flat mounted sections through myelo- and cytochrome architecture (Figure 15; Lyon and Kaas, 2001, 2002c; Sincich *et al.*, 2003; Xu *et al.*, 2004). In this regard, V3 joins the company of the three well-established areas – V1, V2, and MT. Though less reliably demonstrated, the CO architecture in V3 reveals modular light and dark bands. These bands are like those found in V2, yet thicker and less differentiated (Lyon and Kaas, 2001; Xu *et al.*, 2004). Connection patterns with well-established areas such as MT reveal a band-like pattern of modular organization in V3 as well (Lyon and Kaas, 2001).

Often associated with the ventral stream, V4, or DL, lies adjacent to V3. This region of cortex is less distinguishable through staining procedures, but has been identified principally through microelectrode mapping and connection patterns with well-established cortical areas (Gattass *et al.*, 1988; Piñon *et al.*, 1998; Stepniewska *et al.*, 2005). Issues as to the dorsal and ventral extents of DL/V4 remain unresolved. Some researchers have the area extending well onto the ventral cortical surface, adjacent to the entire extent of ventral V3 and even extending as far as the ventral extreme of V2 (Gattass *et al.*, 1988), whereas others have proposed a truncated version based on a change in connectivity patterns for tracers injected more ventrally (Stepniewska *et al.*, 2005). The ventral DL/V4 border illustrated in Figures 13 and 14 is intermediate to the proposals contrasted above. This border is derived from studies on the connection patterns from tracer injections placed in different retinotopic locations in V1 of New and Old World monkeys, including the peripheral representation of the upper visual quadrant, which is likely to be found near the ventral-most regions in areas V3 and V4 (Lyon and Kaas, 2002b, 2002c). As MT is often viewed as a distributor of feedforward inputs to dorsal stream

areas, V4 is considered to be a main distributor to ventral stream areas (see Figure 13a; Shipp and Zeki, 1995; Van Essen and De Yoe, 1995).

The dorsointermediate, dorsomedial, and medial areas (DI, DM, and M, respectively), are consecutively located dorsal to DL/V4. In the organizational scheme presented here, the dorsalmost area M lies adjacent to the dorsal-most portion of V2. Area M, first described in New World owl monkeys (Allman and Kaas, 1971a), may be a homologue of the dorsal parietal occipital area (POd) or the posterior intraparietal area (PIP) described in macaques (Colby *et al.*, 1988; Felleman and Van Essen, 1991). Ventral to M, areas DM and DI are displaced from the outer border of V2 by dorsal V3. Earlier descriptions based on studies of New World monkeys placed these areas immediately adjacent to V2 (Allman and Kaas, 1975; Rosa and Schmid, 1995); however, subsequent connectional and architectonic evidence has shown that these areas, particularly DM, are in the location of V3a as described in macaques (Lyon and Kaas, 2001, 2002b, 2002c; Van Essen and Zeki, 1978). Whether DI in macaques lies ventral to DM/V3a, or V3a can be split into two regions, the ventral of which may correspond to DI, is uncertain. Connections with V1 show separate clusters of cells in the dorsal and ventral halves of V3a, termed PIP or M dorsally and V3a (Figure 14c) or DM ventrally. However, it may be that the ventral portion corresponds to DI and the dorsal portion to DM/V3a. This interpretation is more consistent with results found in similar experiments of New World monkeys where connections between V1 and M were not found (Lyon and Kaas, 2002c).

In the vicinity of the dorsal extent of the STS (the exact location relative to the STS depends on the size of the monkey; see Figures 13b and 14a), MT is easily identified through its myelo- and cytoarchitecture (Figure 16). Particularly in flattened cortex preparations, MT serves as a reliable point of comparison for the examination of architecture, connection patterns, and microelectrode mapping of visual areas in the immediate vicinity. Sometimes referred to as the 'MT-satellites' several areas surrounding MT have been identified (Allman and Kaas, 1974; Desimone and Ungerleider, 1986; Kaas, 2004a; Krubitzer and Kaas, 1990; Rosa, 1997; Rosa and Elston, 1998). The MTc surrounds much of the dorsal, posterior, and ventral borders of MT (Allman and Kaas, 1974; Rosa and Elston, 1998) and can be differentiated from MT as a retinotopically organized arc of moderately myelinated cortex and through its unique pattern of connections with the ventral division of area FST (Kaas and Morel, 1993; Lyon and Kaas, 2001; Rosa and Elston, 1998). FST, first identified in macaques (Desimone and Ungerleider, 1986), extends from the ventral border of MT and MTc and can be split into separate dorsal and ventral areas, FSTd and FSTv (Krubitzer and Kaas, 1990; Kaas and Morel, 1993). The MST area is located adjacent to the representation of the peripheral visual field in MT, along its medial anterior border (Maunsell and Van Essen, 1983a; Desimone and Ungerleider, 1986; Ungerleider and Desimone, 1986; Rosa and Elston, 1998) and receives inputs from functionally distinct modules in MT (Berezovskii and Born, 2000).

Based on connectivity patterns (Felleman and Van Essen, 1991) and the evidence for roles in the processing of increasingly complex moving stimuli, such as spiral motion (Duffy and Wurtz, 1995), the MT satellites can be considered the second stages of the dorsal stream after MT. Dorsal to MT, areas in PP represent a third stage in the dorsal stream as they receive the bulk of their input from the MT satellites. In New World monkeys, based on feedback projections to V1, DM and the SC (Collins *et al.*, 2005; Krubitzer and Kaas, 1993; Lyon and Kaas, 2001, 2002c), only two areas within PP have been identified, LPP, located just dorsal to MT, and VPP, dorsal to LPP and just anterior to DM. Initial macaque monkey studies identified similar regions, area 7a (Andersen *et al.*, 1985a, 1985b; Motter and Mountcastle, 1981) just dorsal to MT, and the ventral area of the intraparietal sulcus, VIP (Maunsell and Van Essen, 1983a). Subsequent studies have proposed several more visual areas in PP. While none of these areas shows any precise retinotopic organization, contributing to the uncertainty, connection studies placing injections directly into different regions of the PP and functional mapping studies have led to the identification of at least four areas located medial, ventral, lateral, and anterior in the intraparietal (IP) sulcus – areas MIP, VIP, LIP and AIP (Figure 14b; see Colby and Duhamel, 1991; Andersen, 1995; Lewis and Van Essen, 2000a).

Despite uncertainty as to the exact number of areas in PP, this region seems greatly expanded compared to the amount of PP processing vision in the cat (see Payne, 1993). Neurons in this region of monkey cortex are highly selective for complex spatial perception (Siegel and Read, 1997) and are heavily involved in deciding where next to move

the eyes (Duhamel *et al.*, 1992) – cortex involved in eye movements is less prominent in cats (see Payne, 1993). Accordingly, these areas, as well as MT and some of its satellites, are heavily interconnected with eye movement fields in prefrontal cortex (FEF; Schall *et al.*, 1995). In addition, neurons in some areas are multimodal, responding to both visual and somatosensory stimuli (Duhamel, 2002), while neurons in AIP play a visual role in the guidance for the grasping of objects (Fogassi *et al.*, 1996; Jeannerod *et al.*, 1995) – a feature unlikely to be of as much use to carnivores.

Areas comprising the ventral stream are located ventral to MT in the IT, and have little interconnections with areas in PP (Baizer *et al.*, 1991). Like the areas in PP, retinotopic organization of areas in IT is coarse at best (Boussaoud *et al.*, 1991; Desimone and Gross, 1979). Even so, the IT region can be subdivided into at least four areas based on connectivity patterns and functional differences (see Figure 14b; Baizer *et al.*, 1991; Buffalo *et al.*, 2005; Distler *et al.*, 1993; Weller and Kaas, 1987). V4 at the head of the ventral stream is fed through V2 projections originating in CO light interbands and CO dark thin bands (Felleman *et al.*, 1997; Shipp and Zeki, 1995; Van Essen and De Yoe, 1995; Xiao *et al.*, 1999). In turn, V4 projects to adjacent area TEO/ITc (where TEO = temporal occipital cortex; Nakamura *et al.*, 1993). These areas can also be identified through direct feedback connections to V1 (Figure 14c; Lyon and Kaas, 2002b, 2002c; Rockland and Van Hoesen, 1994). The segregated V4 inputs are thought to give rise to the specialized object and color processing of cells in the ventral stream. TEO, for example, has been implicated in color selectivity (Tootell *et al.*, 2004) and the perception of objects (Brincat and Connor, 2006), while areas further anterior in the hierarchy are selective for complex objects such as faces (Perrett *et al.*, 1982, 1984).

3.22.5.4 V1 and V2 in Cats and Primates

As we have seen earlier in the article, V1 and V2 are present in most mammals and are considered to have been retained from an early common ancestor (see Section 3.22.2). And, as described for other highly visual mammals, such as tree shrews (see Section 3.22.4.2), cats, ferrets, prosimians, and monkeys have patchy, long-range, intrinsic connections within V1 and V2 (Rockland and Lund, 1982; Gilbert and Wiesel, 1983; Casagrande and Kaas, 1994). Also, as seen for tree shrews, correlation of the connection patterns to functional maps of orientation preference show that like-orientation domains are preferentially connected (Kisvarday *et al.*, 1997; Malach *et al.*, 1993; Schmidt and Lowel, 2002). While these features are found in tree shrews and ferrets, as well as primates and cats, V1 and V2 of the complex visual systems of cats and primates have independently evolved additional features of modular organization. Most notable is the regular distribution of CO blobs in V1 (Casagrande and Kaas, 1994; Horton and Hubel, 1981; Matsubara and Boyd, 2002; Murphy *et al.*, 1995).

While several features have been attributed to CO blobs, such as the processing of color in primates (Livingstone and Hubel, 1988, 1984), these interpretations remain controversial (see Sincich and Horton, 2005). The simplest explanation for blobs is that they arise from increased activity brought about by direct thalamic connections (Livingstone and Hubel, 1982), as CO is a marker for higher metabolic activity (Wong-Riley, 1979) and thalamic afferents provide strong driving inputs (Reid and Alonso, 1996). Blobs, which are most prominent in superficial layer 3, coincide with the termination zones of K cell geniculate afferents (Casagrande, 1994). The lighter interblob regions lack geniculate afferents. Consistent with the interpretation of thalamic afferents resulting in increased CO activity, layer 4C, the main geniculate input zone, receives dense nonpatchy geniculate afferents from M and P cells and as a result stains uniformly dark for CO. Patchy geniculate afferents in cat have also been correlated with the blobs (Matsubara and Boyd, 2002).

3.22.5.4.1 Early parallel processing From the early work in cats and primates, the concept emerged that three ganglion cell types (X, Y, and W) give rise to parallel processing streams relayed through the LGN – X, Y, and W geniculate cells in cats, and the P, M, and K geniculate cells in primates – to V1 (see The Evolution of Parallel Visual Pathways in the Brains of Primates; Stone *et al.*, 1979; Casagrande and Xu, 2004). In primates, the parallel channels remain segregated in their projections to V1 and this was thought to play a crucial role in the emergence of the dorsal and ventral processing streams in higher-order cortex (Livingstone and Hubel, 1988; Ungerleider and Mishkin, 1982; Ungerleider and Pasternak, 2004; Zeki and Shipp, 1988; see Section 3.22.5.3). M cells can be characterized by features that lead to motion and spatial perception – fast conducting axons, high temporal resolution, and sensitivity to low-contrast stimuli – characteristic

of visual areas in the dorsal stream. In contrast, P cells exhibit features that could lead to the perception of form and color (high spatial resolution and chromatic contrast), characteristics of the ventral stream. In cats, there is less segregation of the X and Y channels in V1 (Casagrande and Xu, 2004; Humphrey *et al.*, 1985; Payne and Peters, 2002). Nevertheless, there is support for dorsal and ventral streams in visual cortex of cats and ferrets (Lomber *et al.*, 1996a, 1996b; Manger *et al.*, 2002b, 2004; Payne, 1993).

While the parallel geniculate inputs to V1 in primates remain much more segregated than the geniculostriate projections of cats, there is clear evidence that mixing of the streams occurs at subsequent processing stages within V1 of primates (Callaway, 1998, 2005; Casagrande and Kaas, 1994; Merigan and Maunsell, 1993; Sincich and Horton, 2005). Thus, it is unclear whether the segregation of geniculostriate projections is relevant to subsequent outputs to the dorsal and ventral streams. This convergence within V1 is consistent with receptive fields becoming more complex as information flows through the visual hierarchy, but it leads to a complicated picture of the emergence of the dorsal and ventral streams (see Van Essen and De Yoe, 1995). Nevertheless, most evidence points towards some segregation of the functional streams – dorsal stream areas receive an M dominated relay, whereas the ventral stream receives a relay containing P and M signals. However, recent findings have shown a convergence of M and P geniculostriate projections that are in turn relayed directly to dorsal stream area MT, indicating that M and P signals are mixed even within the dorsal stream (Nassi *et al.*, 2006).

A major evolutionary modification present in V2 of monkeys, compared to cats, tree shrews, and prosimians is the three architectonically distinct bands, or stripes, that can be revealed through CO architecture (Krubitzer and Kaas, 1990; Livingstone and Hubel, 1982; Tootell *et al.*, 1985). These compartments have distinct connection patterns and functional selectivity of their neurons (see Sincich and Horton, 2005) that feed higher-order areas in the dorsal and ventral streams (see Section 3.22.5.3; Shipp and Zeki, 1995; Van Essen and De Yoe, 1995). The thick CO bands are reported to receive input from the M dominated stream in V1, whereas interbands and thin CO bands receive inputs from a mixture of M and P sources. The thick bands are thought to feed subsequent dorsal stream areas, whereas interbands and thin bands feed areas in the ventral stream. While the CO staining is a fairly reliable marker there is some question as to its functional relevance. While band location can be correlated with inputs from V1 and projections to areas V4 and MT, the dark CO bands in V2 may actually result from thalamic afferents arriving from the pulvinar nucleus (Levitt *et al.*, 1995).

3.22.5.5 The Controversy over Monkey V3

Is V3 a feature common to most mammalian visual systems? As we have seen for V2, the size, the relative position, feedforward projections from and feedback projections to V1, and a compressed mirror reversal of the retinotopic organization of V1 are the main reasons for considering V2 as part of the common mammalian plan. This is true even for cat and ferret V2, where, through divergent evolution, V2 has become more primary-like. Using the same criteria, a comparison across species shows that an area exists in a similar location, adjacent to the anterior border of V2, represents a compressed mirror image of the retinotopic organization of V2, and receives feedforward projections from V1 and V2, while providing feedback to these areas. While these criteria point toward a homology of V3 across mammals, there are some obstacles to overcome. While many of these obstacles have been addressed in earlier sections (3.22.2.3 and 3.22.4.1), a remaining obstacle in accepting V3 as a homologous region across most mammals, is that even in the most visually complex order, the primates, there is a debate over the existence of V3 (see the discussion below; Kaas, 2005b; Kaas and Lyon, 2001; Rosa and Manger, 2005).

Since the early retinotopic mapping experiments by Allman and Kaas (1975), the existence of a V3 in primates has been questioned (see Kaas and Lyon, 2001; Lyon and Kaas, 2002c). One issue, deriving from work on New World monkeys, is whether several visual areas, in place of a V3, can be found immediately adjacent to V2 (Allman and Kaas, 1975; Rosa and Schmid, 1995; Lyon and Kaas, 2001, 2002c; Lyon *et al.*, 2002; Rosa *et al.*, 2005). A second issue, derived from studies on Old World monkeys, is whether there are functional and connectional differences between the dorsal and ventral halves of V3 (Van Essen, *et al.*, 1986; Lyon and Kaas, 2002b), resulting in the identification of two separate areas.

In Old World monkeys the dorsal and ventral halves of V3, V3d and V3v, contain the representation of the lower and upper visual fields, respectively (Gattass *et al.*, 1988). A reported difference in the neuronal properties and projection patterns from

V1 led to a split of V3 into two separate areas (Burkhalter *et al.*, 1986; Felleman and Van Essen, 1987; Van Essen *et al.*, 1986). V3d became V3, representing only the lower visual quadrant, whereas V3v became the ventral posterior area, VP, representing only the upper visual quadrant. The functional properties of neurons may not be relevant to the homology of V3 in other species – as the function of V2 can differ between species. Nevertheless, it is unusual that functional properties such as chromatic sensitivity and direction selectivity would differ between the upper and lower visual fields of a single area. However, the functional characteristics of neurons in V3v have only been examined in one study (Burkhalter and Van Essen, 1986), so confirmation of the proposed differences in V3v and V3d neurons is needed. This is particularly important because several studies have yielded different characterizations of the response properties of neurons just within V3d (Baizer, 1982; Felleman and Van Essen, 1987; Gegenfurtner *et al.*, 1997; Zeki, 1978). Part of such differences in characterizations is due to different criteria used to define the characteristics of the neurons (see Gegenfurtner *et al.*, 1997), and part is likely due to the difficulty of accessing V3d in the macaque monkey, as it is completely buried within the lunate sulcus. It is also unusual for the connection patterns to differ between the two visual fields of a single area (see Kaas, 1996; Zeki, 2003). Accordingly, a re-examination of the connection patterns has revealed the missing connections. Whereas, initially, it was reported that V3d was interconnected with V1, but that V3v was not (Van Essen *et al.*, 1986), more recent work has revealed that both V3d and V3v are interconnected with V1 (Lyon and Kaas, 2002b). Thus, the controversy over V3 in Old World monkeys has become more settled (see Kaas, 2005b; Van Essen, 2004).

For New World monkeys, differences in interpretation over the size and location of V3 continues. The main issue in New World monkeys concerns the organization of cortex just anterior to the dorsal extent of V2. Early microelectrode mapping experiments in owl monkeys found the representation of the upper visual quadrant immediately adjacent to dorsal V2 (Allman and Kaas, 1975). As dorsal V2 represents the lower visual quadrant, the existence of an adjacent upper field representation argued against the idea of a V3 strip of cortex mirroring the V2 retinotopy. This new region was demonstrated to have a complete retinotopic map occupying cortex similar in size to area MT. Subsequent experiments in the smaller marmoset monkey also found an upper field representation immediately adjacent to dorsal V2, but the resulting DM contained an unconventional split representation of the horizontal meridian (Rosa and Schmid, 1995). More recently, however, connection patterns with V1 in four species of New World monkeys found no evidence for an upper field representation near the anterior border of V2 (Lyon and Kaas, 2001, 2002c). Instead, the observed connections from upper field V1 were displaced at least 1–2 mm anterior to the dorsal V2 boundary. Along with evidence from cytochrome and myeloarchitecture, dorsal V3 was identified as a strip of cortex displacing DM from dorsal V2. Counter to these connection patterns, however, a subsequent study placing injections anterior to dorsal V2 did show connections with the upper field representation in marmoset V1 (Rosa *et al.*, 2005). However, injection sites were centered nearly 2 mm from the outer V2 border. Thus, the upper field connections likely arose from the upper field location of DM.

In addition to the conflicting reports of the upper field connectivity of DM, it has been argued that the microelectrode maps of this dorsal region clearly demonstrate an upper field representation immediately adjacent to the dorsal V2 border (Rosa and Schmid, 1995; Rosa *et al.*, 2005; Rosa and Manger, 2005; Rosa and Tweedale, 2005). Yet, careful examination of the published data reveals some ambiguities, and there are additional results that are rather perplexing. First of all, the evidence for an upper field representation immediately adjacent to V2 (Rosa and Schmid, 1995) can be interpreted in another way, especially in light of more recent connection studies (Lyon and Kaas, 2001, 2002c). The receptive fields of recording sites considered as part of the upper field were centered very near the outer border of V2 representing the horizontal meridian, as a result much of the recorded receptive fields of individual neurons were found in the lower visual field as well the upper (Rosa and Schmid, 1995). As most of these recording sites were located near the V2 border they were taken as evidence for upper field representation immediately adjacent to V2. However, as the V2–V3 border represents the horizontal meridian it is not surprising that the receptive field would partially overlap with the upper field, and thus this evidence in itself cannot be used to argue against a V3.

While this issue is open to interpretation, there are other findings reported from the retinotopic maps of DM, such as an irregular progression from the central to peripheral visual field and the representation of two separate horizontal meridians (Rosa, 2002;

Rosa and Schmid, 1995), that lead one to question the reliability of the microelectrode technique as a means for such issues, especially in regions that have been difficult to define. Alternatively, techniques such as intrinsic signal optical imaging offer a fairly high spatial resolution but, unlike microelectrode mapping, allow the recording of neural activity from a large array of cortex simultaneously (see Figure 9). This procedure is helpful in reducing any ambiguities that may arise through the reconstruction of electrode tracks in several coronal or parasagitally cut sections. In owl monkeys, optical imaging of neural activity revealed only the representation of the lower visual field adjacent to V2 (Lyon *et al.*, 2002). The resulting retinotopic map revealed a slightly compressed mirror-image representation of the retinotopy in dorsal V2, consistent with a dorsal V3 (Figure 17). Also consistent with a dorsal V3, the V2–V3 border was marked by the representation of the horizontal meridian, while the outer V3 border was marked by the vertical meridian. These results are also consistent with the retinotopic connections of this region to V1 in owl monkeys, three other New World monkey species, and two species of Old World macaque monkeys (Lyon and Kaas, 2001, 2002b, 2002c). In addition, the observed retinotopy of dorsal V3 in owl monkeys is similar to the retinotopic organization revealed in macaque monkey V3 through microelectrode mapping (Gattass *et al.*, 1988) and fMRI (Brewer *et al.*, 2002; Fize *et al.*, 2003).

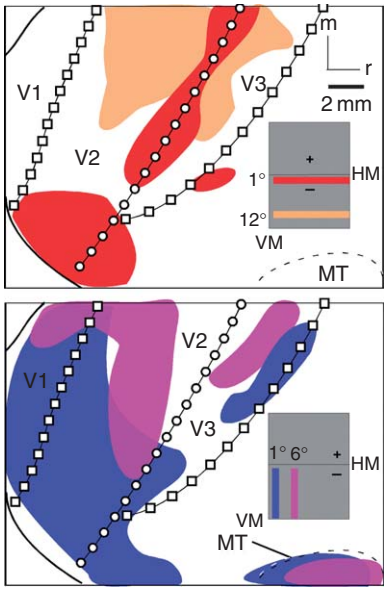

Figure 17 Reconstructions of the retinotopic organization of monkey V2 and V3. These summary diagrams are reconstructed from data in Lyon, D. C., Xu, X., Casagrande, V. A., Stefansic, J. D., Shima, D., and Kaas, J. H. 2002. Optical imaging reveals retinotopic organization of dorsal V3 in New World owl monkeys. *Proc. Natl. Acad. Sci. USA* 99, 15735–15742.

3.22.5.6 The Middle Temporal Area, MT

Primate area MT exhibits several features that make it the most prominent extrastriate area, outside of V2. As revealed through connection patterns, MT is strongly interconnected with V1, V2, and V3 (Born and Bradley, 2005; Lyon and Kaas, 2002b, 2002c; Shipp and Zeki, 1989a, 1989b), receiving inputs perhaps dominated by the M geniculate pathway (Merigan and Maunsell, 1993; Van Essen and De Yoe, 1995), but also inputs from the P pathway (see Nassi *et al.*, 2006). In addition, MT receives direct but sparse input from the K geniculate cells (Sincich *et al.*, 2004; Stepniewska *et al.*, 1999) and receives fairly dense disynaptic projections from the SC (Lyon *et al.*, 2005). In turn, MT is a primary provider of inputs to many of the areas in PP that form the dorsal stream of visual processing (Maunsell and Van Essen, 1983a; Ungerleider and Desimone, 1986; Shipp and Zeki, 1995). Another distinctive feature of MT is its dense and patchy myelination (Figure 16; Allman and Kaas, 1971b; Krubitzer and Kaas, 1990) and blob-like staining for the metabolic enzyme CO (Tootell *et al.*, 1985; Lyon and Kaas, 2001).

Functionally, MT contains a precise first-order representation of the contralateral visual hemifield (Allman and Kaas, 1971b; Rosa and Elston, 1998) similar to that found in V1 and a systematic representation of direction preference that is arranged in a columnar fashion (Albright *et al.*, 1984) that is in many ways similar to the orientation columns of V1 (see Albright and Desimone, 1987). Columns are also seen in MT architecture and connection patterns. V1 projections to MT terminate in a modular arrangement (Rockland, 1989) and MT cells projecting to other extrastriate areas, such as DM, FST, and MST, are also arranged in small, modular clusters (Kaas and Morel, 1993; Krubitzer and Kaas, 1993; Berezovskii and Born, 2000). The internal architecture of MT revealed through stains for CO (Tootell *et al.*, 1985) and myelin (Krubitzer and Kaas, 1990) contains intermittent dark and light regions comparable in size to MT functional columns. Interestingly, callosal projections from MT have been correlated with the myelin dark regions (Krubitzer and Kaas, 1990). Subsequent studies have indicated that similar functionally defined modules may be correlated to differences in MT architecture and patchy intrinsic connectivity (Born and Tootell, 1992; Malach *et al.*, 1997). More recently, Berezovskii and Born (2000) have

shown that MT regions responsive to local motion cues project preferentially to the dorsal half of MST, whereas MT regions more responsive to global motion cues project preferentially to the ventral half of MST and to FST.

3.22.5.6.1 Is MT found in other mammals? Whereas there is a similar V3-like area found in most mammalian species, it is even less certain whether there is an MT-like area across species. MT is a prominent region in primate visual cortex and thought to have emerged early in primate evolution. One theory suggests that tree shrew TD, rather than a V3-like area, is a potential MT homologue and that MT gradually drifted further anterior from the V2 border as cortex evolved in successive primate lines – prosimians, New World monkeys, and Old World monkeys (Northcutt and Kaas, 1995). Like MT, tree shrew TD shows an increase in myelination compared to surrounding regions and is heavily connected with V1. However, there are several extrastriate areas in primate that are connected with V1, including V3 which is also moderately myelinated (Lyon and Kaas, 2001). Additionally, there are several other extrastriate areas in the tree shrew that lie more anterior to V2 and could represent an MT-like area based on other criteria. The most prominent area, TI, is connected with V2 rather than V1, but it does stain conspicuously dark for myelin and lies very close to primary auditory cortex (Lyon *et al.*, 1998). The dark myelination of primate MT is probably its most distinctive feature, and like tree shrew TI, primate MT is found just posterior to auditory cortex (see Lyon and Kaas, 2001). What is sorely lacking is any evidence of functional similarities between MT and TD or TI, as in tree shrew there are no reports on the functional properties of neurons outside of V1.

In other species, areas in location similar to TD have also been proposed as MT homologues. A squirrel MT homologue, area ML-L, has been proposed on the basis of functional similarities to primate MT (Paolini and Sereno, 1998) and it is in a similar location to tree shrew TD. A region anterior to V2 in the flying fox has also been proposed as a homologue to MT based on its myelination, retinotopic organization, and input from V1 (see Kaas and Preuss, 1993). However, like the tree shrew, this proposed MT homologue has been considered a homologue to V3 in other interpretations (Rosa, 1999). While the data in support of an MT homologue is limited for these species, a significant body of evidence has implicated the cat PMLS complex as a homologue to MT and its surrounding satellites (see Grant and Hilgetag, 2005; Hilgetag and Grant, 2000; Payne, 1993). Indeed, PMLS and MT share many similarities. Both regions are located well anterior to V2 in temporal cortex and are comprised of neurons specialized for direction discrimination. In addition, they both have orderly retinotopic maps, stain darkly for myelin, receive feedforward projections from V1, V2, and V3, and provide feedforward projections from similar cortical layers to the surrounding motion processing areas. Furthermore, Matsubara and Boyd (2002) report similarities in the origin of the projections from V1 to the PMLS region in cat and MT in monkey, showing that cells located in CO blobs within the layer 4B project to these areas. Despite the great number of similarities, a cladistic approach makes it difficult to conclude that PMLS is an MT homologue because the evidence for an MT homologue in intervening species is so limited (Kaas, 2002). Nevertheless, MT-like regions have been proposed for species in sister groups to both cats (flying foxes) and primates (tree shrews and squirrels) leaving open the possibility that primate MT emerged from an area common to many mammals.

3.22.6 Conclusions

Despite detailed evidence reviewed here on the organization of visual cortex in several mammalian taxa, at this point we know very little about how differences in mammalian visual cortex organization evolved (see Streidter, 2005). As presented in this article, we can look at the organizational schemes of several different mammalian orders from the small nonvisual insectivores to the large and highly visual carnivores and primates. Still, because detailed evidence is lacking, we can say little about homologies between extrastriate visual areas. Should we care whether cat visual areas are homologous to the primate? Is an understanding of whether brain structures are homologous or homoplaseous critical to understanding how the brain functions? For, despite uncertainty of the homology between species, is it not unreasonable to use neuronal properties of, for example, cat PMLS to help us understand how monkey and human brains process motion? If area PMLS is homologous to MT, will that help us understand the brain any better? More likely, understanding the brain will help us determine whether areas are homologous.

3.23 The Evolution of Crossed and Uncrossed Retinal Pathways in Mammals

E Herrera, Instituto de Neurociencias (UMH-CSIC), Alicante, Spain
C A Mason, Columbia University, New York, NY, USA

Glossary

contralateral (crossed) axons	Retinal axons that cross the midline and project to higher targets on the opposite side of the brain from which they originate.
ipsilateral (uncrossed) axons	Retinal axons that do not cross the midline and that project to higher targets on the same side of the brain from which they originate.
optic chiasm	Retinal ganglion cell axons from each eye project through the optic nerves and make up this X-shaped commissure; here, fibers from each eye project to one or the other side of the brain and re-sort to form the optic tracts.
retinal axon decussation	Retinal ganglion cell axons from each eye diverge from one another in the optic chiasm, to cross or remain on the ipsilateral side of the brain.
retinal ganglion cells (RGCs)	The only cell class that projects axons from the retina to the brain, conveying information from the photoreceptors in the outer nuclear layer and from interneurons such as bipolar, horizontal, and amacrine cells in the inner nuclear layer. The axons of RGCs form the optic nerve.

3.23.1 Anatomical Basis of Binocular Vision

3.23.1.1 Types of Retinal Fiber Decussation in the Optic Chiasm of Vertebrates

Strictly speaking, all animals with two eyes have binocular vision, but the terms binocular vision and stereoscopic vision are usually reserved for animals that possess a large area of binocular overlap and this overlap is utilized to code depth. In animals with good binocular vision, the eyes are forward facing and each eye receives a slightly different perspective on a scene. Visual information from each eye is sent to both sides of the brain because retinal fibers from the nasal regions of the retina cross the brain midline and fibers from the temporal retina do not cross the midline and instead project to the same side of the brain. Once this information reaches the visual cortex, the two different images perceived by each side of the brain are integrated into one cohesive mental image. The differences in perspective transmitted through each eye allow the brain to triangulate distance much more accurately, resulting in improved depth perception (Bishop and Pettigrew, 1986; Figure 1; see The Role of Vision in the Origin and Evolution of Primates, The Evolution of Visual Cortex and Visual Systems).

Retinal ganglion cells (RGCs) are the last cells in the retina to collect visual information within each eye and then project their axons toward the main visual nuclei in the central nervous system, the lateral geniculate nucleus in the thalamus, and the superior colliculus, or optic tectum in lower vertebrates, in the midbrain (Figure 2). The structure in which RGC axons from each retina partially decussate or cross is the optic chiasm and it is located in the ventral diencephalon (Figure 2). Thus, one important function of hemidecussation is to obtain inputs from the same part of the visual field perceived by each retina and to transmit this

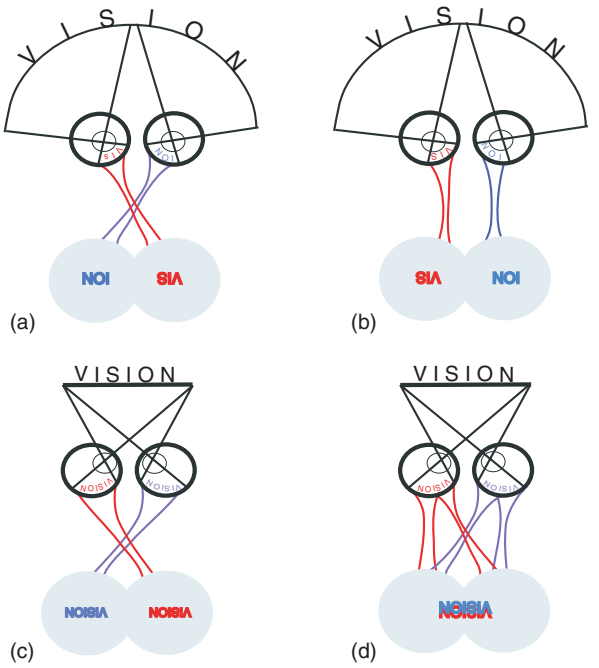

Figure 1 Crossed and uncrossed visual pathways. Images that form on the retina are inverted by the lens of the eye. In animals without stereoscopic vision, eyes placed more laterally allow panoramic view and predator scanning. Complete crossing of retinal fibers at the chiasm is necessary to restore a congruent image of the outside visual world (the word VISION is re-formed in (a)). b, If no fiber crossing occurs, IONVIS would be perceived. c, In animals with forward-facing eyes, if complete crossing occurs, as in lower vertebrates, stereoscopic information would be compromised, as in albino animals of many species. d, In most mammals, partial fiber crossing is necessary to fuse both retinal images homotopically in the brain.

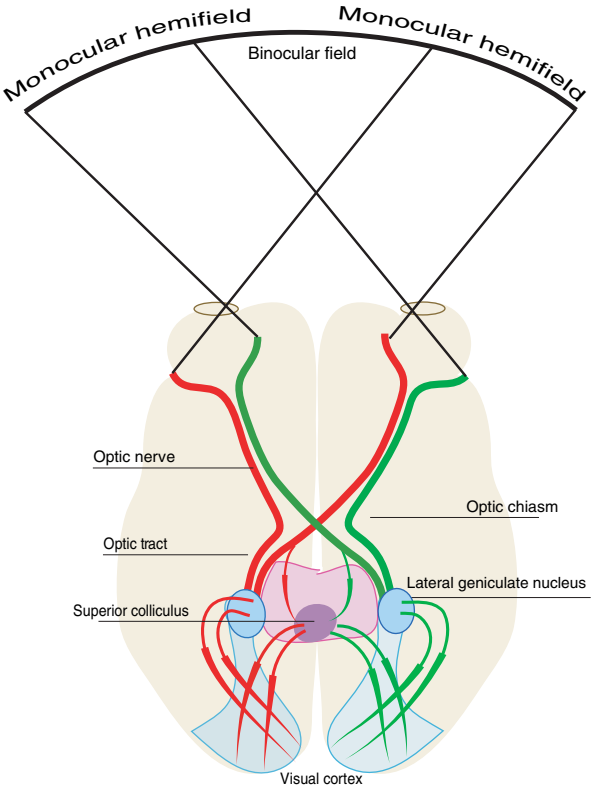

Figure 2 The visual pathway from retina to primary visual cortex, in human brain. The binocular field is that portion of the total visual field within which the monocular fields overlap. The higher visual centers in the brain – the superior colliculus, lateral geniculate nucleus, and visual cortex – in each hemisphere receive input from both eyes. Visual information is perceived by the two left halves of the retina (red) and ends up in the left half of the brain. In the same manner, axons from the right half of each eye (green) bring information to the right occipital lobe. This occurs because approximately half the optic nerve fibers cross at the chiasm and the remainder are uncrossed.

information to the same location in targets that are located further centrally.

Other optic decussations occur in lower vertebrates, for example, in the isthmus complex at the pontine–midbrain junction, interconnected with the optic tectum, and in the form of retinoretinal projections (Thanos, 1999). In amphibians and reptiles, the isthmic complex projects topographically to the contralateral as well as the ipsilateral tectal lobe. The isthmo-optic nucleus also projects centrifugally to the retina. This projection develops after birth, once visual activity has commenced, and appears to be required for the further refinement of tectal maps by sensory activity (Constantine-Paton and Cline, 1998; Schmidt and Edwards, 1983). The development of retinoretinal projections and the centrifugal projection from the isthmo-optic nucleus may be interdependent (Thanos, 1999).

In this article, we focus on the decussation of RGC axons in the ventral diencephalon during formation of the optic chiasm, a process that takes place during embryonic development and that is apparently independent of visual stimuli. Partial decussation of the fibers from each eye occurs in most mammals. The majority of RGC axons originating from the nasal retina cross the midline to enter the optic tract on the opposite side of the brain, whereas axons from the temporal or ventrotemporal (VT) segment of the retina, depending on the species, do not cross (Chalupa and Lia, 1991; Polyak, 1957; Stone *et al.*, 1973). The number of uncrossed fibers is proportional to the size of the binocular visual field, which in turn depends on the extent to which the eyes are located in a frontal position. In animals with frontally placed eyes, such as humans or monkeys, the uncrossed component reaches approximately 40% of all RGCs (Chalupa and Lia, 1991; Stone *et al.*, 1973). Cats, ferrets, horses, rabbits, and mice have different degrees of separation of the eyes in the head and show a gradually decreased uncrossed component, which ranges from 30% in cats to approximately

5% in mice, which have laterally placed eyes and poor binocular vision (Jeffrey, 2001). In lower vertebrates, amphibians such as the much-studied *Xenopus* are an interesting case, since a subpopulation of ganglion cells in the VT retina projects ipsilaterally beginning at metamorphosis, when the laterally located eyes become positioned frontally (Hoskins and Grobstein, 1985; Mann and Holt, 2001; see The Evolution of Vertebrate Eyes).

Birds and fish have laterally located eyes and panoramic vision and do not have an uncrossed projection except for a minor early ipsilateral projection that is transient (see The Role of Vision in the Origin and Evolution of Primates). The totally decussating fibers from each retina intercalate in the chick optic chiasm but the bundles of fibers from each eye overlay one another in fish (Drenhaus and Rager, 1992; O'Leary *et al.*, 1983; Polyak, 1957; Thanos *et al.*, 1984; Figure 3).

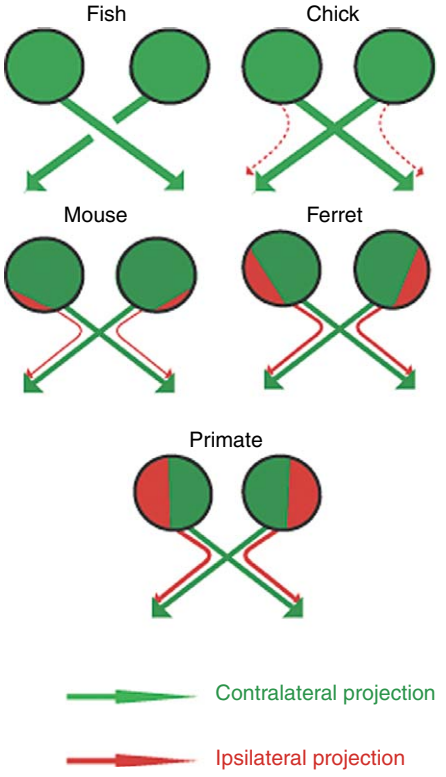

Figure 3 Crossed and uncrossed pathways throughout evolution. In fish, all RGCs project contralaterally and retinal axons do not intermingle at the chiasm. In chick and other birds, retinal axons project contralaterally but there is a small transient ipsilateral projection that disappears during maturation (red dashed lines). Binocular vision is partially developed in mammals such as mouse or ferret, with most of the retinal axons crossing the midline (green) but with an appreciable number of axons projecting ipsilaterally (red); binocularity is fully developed in those mammals with frontally located eyes, such as felines or primates. In this figure, line thickness approximates the proportions of fibers that project to ipsilateral or contralateral targets.

For many species of prey, such as cows or horses, the wider field of view provided by side-facing eyes and monocular vision provides better adaptation, reducing the chance that a predator could approach them unaware. In contrast, in many hunting animals, binocular vision is a common feature, as it is more important for predators to accurately determine the distance between themselves and their prey. Primates have good stereoscopic vision and rely on it when navigating complex three-dimensional environments. Most complex visual tasks, such as reading, detecting camouflaged objects, and eye–hand coordination, are performed more effectively with two eyes rather than with one, even when the visual display has no depth.

In sum, the retinal origin of the fibers that cross the midline or remain on the same side of the brain via the optic chiasm is relatively conserved across species, but the size of the uncrossed projection is related to the degree of binocularity, which, in turn, relates to the position of the eyes on the head.

3.23.1.2 Visual Defects Resulting from Anomalies in Optic Chiasm Formation

Albinos and individuals that suffer the nondecussating retinal–fugal fiber, or achiasmatic, syndrome represent interesting anomalies related to retinal fiber decussation. In general, the albino defect causes an approximately 50% decrease in the normal number of uncrossed axons, irrespective of the species (Jeffery, 1997; Rice *et al.*, 1995), whereas in achiasmatic individuals, all retinal axons are uncrossed (Victor *et al.*, 2000). The gene mutated in the most prominent form of albinism is tyrosinase, a key enzyme in melanin synthesis, but other gene mutations causing defects in melanin biosynthesis can also lead to the absence of pigment in the retinal pigment epithelium and subsequently a reduction of ipsilateral fibers (Incerti *et al.*, 2000). It is not understood how tyrosinase, or any other component of the melanogenic pathway, influences the projection of RGC axons. It has been shown that spatiotemporal aspects of neurogenesis are altered in albino mice; such alterations could influence the specification of the RGC projection phenotype (see below) (Rachel *et al.*, 2002). Interestingly, in achiasmatic humans, and to a lesser extent in albinos, the altered mapping and sensory input are almost corrected later in the visual pathways by interhemispheric communication (Victor *et al.*, 2000).

3.23.1.3 Optic Chiasm Development

Even with its very small ipsilateral component, the mouse is the most commonly used mammalian model for studying how the optic chiasm and the partial retinal decussation develop. The formation

of the optic chiasm in mouse occurs in two sequential steps. In a first phase, pioneer axons arising from the dorsocentral retina leave the optic cup through the optic disk at embryonic gestational day 12 (E12) and navigate into the optic stalk to enter the developing ventral diencephalon. The majority of these pioneering axons then cross the midline and grow in close relationship with an inverted V-shaped array of early neurons, establishing the position of the optic chiasm along the anterior–posterior axis of the brain (Figure 4). A small proportion of these axons continue to extend on the same side of the brain, distant from the midline, and form an early uncrossed projection that is thought to be transient. In a second phase, at approximately E14, retinal axons arising from the VT crescent in the retina arrive at the midline and turn back to the same side of the brain from which they originate, whereas axons from the rest of the retina cross the midline (Guillery *et al.*, 1995; Mason and Sretavan, 1997; Figure 4). It is unclear how the first step gives rise to the second phase, but ipsilateral axons from the peripheral VT retina generated in the second phase are considered to constitute the permanent uncrossed component. In a third and final phase, RGCs with an uncrossed projection cease to be generated after E17, and thereafter, until E19, RGCs born in the VT retina, as well as in the rest of the retina, tend to have a crossed projection (Dräger, 1985; Figure 4).

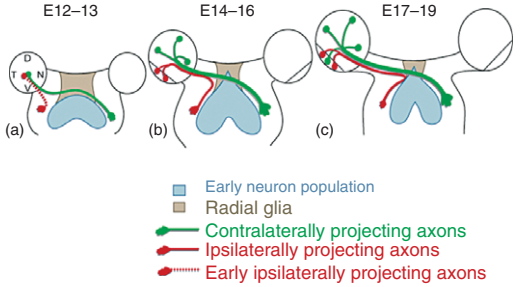

Figure 4 Development of the optic chiasm. The formation of the optic chiasm takes place in three phases. a, In an early phase of RGC axon out growth (E12–13), the earliest generated RGC axons originating from the dorsal-central retina grow in close relationship to the inverted V-shaped array or CD44 neurons (blue) at the developing ventral diencephalon and grow contralaterally across the midline. A population of RGC axons, thought to be transient, turn lateral to the early neurons and do not approach or cross the midline, but directly enter the optic tract. b, By E14–16, a group of RGC axons originating from the VT retina have reached the midline but they turn away from it to project into the ipsilateral optic tract, whereas axons originating from other regions of the contralateral retina have crossed the midline to project into the same optic tract. c, In a final phase, E17–19, axons from the VT quadrant remain as an ipsilateral projection, but additional RGCs intermingled with the uncrossed RGCs in the VT retina now project contralaterally. D, dorsal; N, nasal; T, temporal; V, ventral.

Several aspects of the course of retinal fibers deserve mention. Whereas fibers leave the retina and enter the optic nerve in a rough retinotopic organization, this order is lost and new rearrangements with reference to the topographic origin of retinal fibers occur near the chiasm (Chan *et al.*, 1999). Second, where the fibers rearrange, growing retinal axons shift from being organized by interfascicular glia to an environment populated by radial glia. Third, the youngest fibers to join the optic nerve and chiasm change their position at this glial transition, such that they grow among glial end-feet at the pial surface, in the lateral chiasm. At the midline region, growth cones extend dorsally to cross or turn away from the midline. The growth cones then grow ventrally again as they project into the optic tracts (Guillery *et al.*, 1995; Reese *et al.*, 1997).
