1.27 Aggression in Invertebrates: The Emergence and Nature of Agonistic Behavioral Patterns

E A Kravitz, Harvard Medical School, Boston, MA, USA
R Huber, Bowling Green State University, Bowling Green, OH, USA

1.27.1 Introduction

The study of behavior generally begins with watching. It is hard to say it better than Yogi Berra in his famous quote "You can observe a lot just by watching!" With repeated observations of social rituals, patterns often emerge that are easily recognizable and highly stereotypical. However, like the digits on a hand that differ from each other even though all are called fingers, behavioral patterns differ each time they are performed depending on the social context. In addition, variability exists in (1) when during social rituals patterns appear and (2) how one pattern links to the next. Despite such variability, statistical techniques can reveal behavior's inherent structure and show when patterns are most likely to appear and how predictably they link to each other. But is all behavior of all animal species modular and does this extend to human behavior? Moreover, if behavior is modular, how do patterns of this sort get established within nervous systems and what rules govern the likelihood that one will transition to the next? Modular construction implies that superimposed on the hard wiring diagrams of nervous systems, codes exist specifying that particular combinations of neurons and neuronal circuits transiently link together to form recognizable behavioral patterns at appropriate times during behavioral rituals. The observed behavioral patterns overlap each other, can utilize identical sets of muscles in different ways, are species- and/or genus-selective, and must be understandable by conspecifics in communicating with each other. In this article, we examine studies of aggression using invertebrate models: (1) to illustrate the highly organized nature of this complex behavior, (2) to explore the roles of neurohormones such as amines in the behavior, and (3) to begin an exploration of the role of specific genes in establishing behavioral patterns in nervous systems. A comprehensive review of aggression in invertebrates has appeared recently (Kravitz, and Huber, 2003; see also Cognition in Invertebrates, Sleep in Invertebrates). In this article, therefore, the focus will be solely on studies with fruit flies and with two decapod crustacean species, crayfish and lobsters.

1.27.1.1 A Short History: Nature versus Nurture

Although the presence of stereotyped elements in behavior has been recognized for more than 50 years, the interpretation of how these come about has given rise to acrimonious debate. The presence of stereotyped behavioral elements and their formation became an ultimate battleground when it became inextricably linked with the dispute over nature versus nurture. Early ethologists noticed that many distinct, species-specific displays appear to develop fully intact, even in individuals raised without access to tutors (cf. Heinroth and Heinroth, 1933; Lorenz, 1941). They attributed the action of inherited developmental programs to

fixed action patterns and argued that such behavior would lend itself to phylogenetic analysis, akin to the use of morphological or physiological characteristics. Lehrman (1953) delivered a stinging critique, arguing that any discussion about the genetic basis of behavioral traits is a distraction from learning more about the developmental processes that produce them. Subsequently, the emergence of any sort of comprehensive view with respect to behavioral phenomena was held up for decades by this dispute. J. P. Scott's work on the roles of genetic components in mammalian social behavior highlighted the genetic contributions to core processes in behavior and helped to establish the field of behavioral genetics (Scott and Fuller, 1965). The practical solution now posits that behavioral development inevitably forms as a complex interchange of genes and environment and that the emergence of some traits may owe more to the contributions of one than the other. Attempts at an either/or classification between nature and nurture simply lack heuristic value due to the complexity of their entanglement (Marler, 2004). These notions have been adopted by researchers in evolution, genetics, and neuroscience with their fields moving on to more important questions. Studies of behavior in ethology, psychology, and sociology, however, are only now beginning to emerge from this counterproductive clash of extreme positions. The present review aims more to discuss the characteristics and functioning of stereotyped elements in behavior that occur linked to specific elements in the nervous system, and less to contributions of how these systems got there.

1.27.1.2 Why Aggression?

Intraspecific aggression is a behavior that is particularly well suited to a comprehensive examination of its component structure and underlying mechanisms. In many taxa, agonistic encounters are readily evoked in dyadic interactions, making possible studies ranging from behavioral through physiological and ultimately to molecular and genetic levels. Animals with no previous social experience or tutors often are able to perform and interpret agonistic behavioral patterns and their structure. With a clear ability to decode the communication components of the behavior, animals are effectively able to take part in coordinated, agonistic encounters. Even with these innate abilities, however, the behavioral patterns are malleable and can be molded by experience.

1.27.2 The Fruit Fly Model of Aggression

1.27.2.1 Characterization

Male and female fruit flies (*Drosophila melanogaster*) both show aggression. Ethograms of the behavioral patterns involved have been constructed and first-order Markov chain analyses have been performed to explore the dynamics of the fights (Chen *et al.*, 2002; Nilsen *et al.*, 2004). In comparing the patterns of fighting behavior between pairs of male and pairs of female flies, some of the patterns seen are the same in the male and female fights, whereas others appear selective to male or female fights (Figure 1; Nilsen *et al.*, 2004). Thus, certain

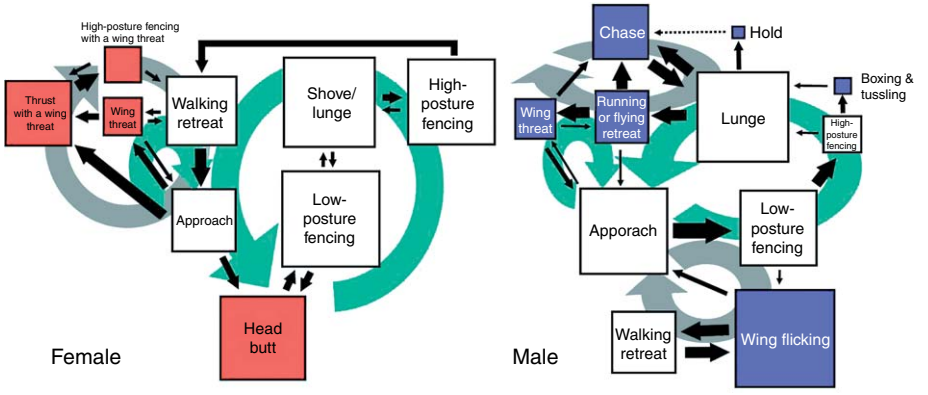

Figure 1 Behavioral patterns and transitions seen in fights between pairs of male and pairs of female *D. melanogaster*. Females and males share five common behavioral patterns (white boxes) while several gender-selective behavioral patterns also are seen (male (blue) and female (red) boxes). The box sizes represent the numbers of transitions to and from a pattern. The arrows between boxes represent the likelihood of transitions, with the addition that the dashed line between 'hold' and 'chase' in males illustrates a transition that approaches statistical likelihood. The large green arrows highlight similar transition loops, and the gray arrows highlight gender-selective transition loops. The female data is from 2597 behavioral transitions and the male data was collected from 2526 transitions from 376 encounters in 19 trials. Reprinted from Nilsen, S. P., Chan, Y. B., Huber, R., Kravitz, E. A. 2004. Gender-selective patterns of aggressive behavior in *Drosophila melanogaster. Proc. Natl. Acad. Sci. USA* 101, 12342–12347.

mid- or high-intensity components of fighting such as chasing, tussling, lunging, and boxing along with extended wing threats (greater than 2 s and up to several minutes) are seen predominantly in male fights, whereas head butting and very short wing threats (all under 2 s) are found mainly in encounters between females. Moreover, male fights are more likely to lead to hierarchical relationships than female fights (Nilsen *et al.*, 2004).

These patterns appear in full complexity without requiring a tutor, but also are malleable by experience. In all experiments, male and female flies are placed singly in isolation vials containing fly food when they first emerge as adults or as pupae that emerge as adults in isolation. Thus, the first time that these flies see another adult fly is when they are paired for fights, yet they use all the components that make up fighting behavior, they change intensity levels in appropriate ways in response to their opponents, and they establish hierarchical relationships (at least in males). This and genetic evidence suggest that the responsible neural circuits are established during embryonic, larval, or pupal life, and are already fully functional when flies emerge as adults. While the patterns are established early in development, they can be modified by experience that both alters the way male flies fight and changes the likelihood of their winning subsequent fights (A. Yurkovic, unpublished observations).

1.27.2.2 Genes and the Establishment of Behavioral Modules

In addressing the issue of how patterns of behavior get established in nervous systems, one approach is to ask how the patterns of female fighting behavior get established in female brains and the male patterns in male brains. Logical candidate genes for this purpose are the already established genes of the sex determination pathway (cf. Goodwin *et al.*, 1999; Baker *et al.*, 2001). The X-autosome ratio determines gender in fruit flies (females are XX and males XY), and early genes involved in the determination are: *sex lethal* (*sxl*), a splicing factor; *transformer* (*tra*), a second splicing factor that works in conjunction with a second transformer gene (*tra-2*), and *fruitless* (*fru*), a gene that codes for expression of members of the bric-a-brac-tram-trac-broad (BTB) complex family of zinc finger transcription factors (for reviews see Goodwin *et al.*, 1999; Baker *et al.*, 2001). The genes *sxl* and *tra* are transcribed and translated in females but not in males. This leads to splicing of *fru* to male- and female-specific transcripts, all of which are generated from the first of four promoter sites found in the gene. The male-specific transcripts generate FRU^M proteins, while no proteins are generated from the female-specific mRNAs (see Lee and Hall, 2000; Goodwin *et al.*, 2000). Mutant *fru* male flies cannot distinguish between male and female flies and will actively court both.

An indication that the emergence of behavioral modules might be influenced by genes is the report by Lee and Hall (2000), demonstrating enhanced levels of head-to-head interactions in *fru* mutant male flies. Such interactions are rarely seen in fights between pairs of wild-type male fruit flies, but they are commonly seen in fights between pairs of wild-type female flies (Nilsen *et al.*, 2004). Thus, it is possible that *fru* mutant male flies not only cannot distinguish between males and females during courtship rituals, but perhaps one of the behavioral patterns associated with female fighting behavior might have been introduced into the brains of male flies in the absence of *fru* transcripts. Recent studies by Nilsen (unpublished observations) suggest that *fru*-null male flies fight more like females than like males in that extended wing threats and mid- and high-intensity components of male fighting behavior are not observed in these animals, whereas head butting is common.

1.27.2.3 Genes and Mating Behavior

Mating behavior has been well studied in fruit flies, and as mentioned above, the genes of the sex-determination pathway have been defined (cf. Goodwin *et al.*, 1999; Baker *et al.*, 2001). Mating behavior also appears largely modular, with distinct recognizable components including approach and orienting, tapping, singing, licking, attempted copulation, and copulation taking place in a well-defined sequence that is compatible with a first-order Markov chain (Markow and Hanson, 1981). As mentioned above, *fru* mutant males cannot distinguish between males and females. The *fru* gene is expressed in about 20 groups of neurons in the fly brain and nerve cord (Goodwin *et al.*, 2000; Lee and Hall, 2000). Using an RNAi technique, Manoli and Baker (2004) eliminated the FRU^M protein isoforms in one subgroup of about 60 *fru*-expressing central nervous system neurons located in the subesophageal ganglion. These neurons send processes from that site in a major projection through the median bundle to terminate in the dorsal protocerebrum of the brain. The phenotype of the resultant male flies was that they attempted to court females, but the first two modules associated with courtship behavior were not observed (orienting and tapping): instead flies immediately began singing, licking females, and

attempting to copulate all at the same time and at an accelerated rate. These male flies were unsuccessful at copulating with females. In some thus far unknown way, the absence of FRU^M expression in this one subgroup of neurons leads to the absence of two of the early components of the courtship ritual, and the speeding up and disordering of the later ones.

1.27.2.4 Hormones and the Modulation of Behavioral Modules

Singing is usually not observed during aggression between pairs of males in *D. melanogaster*. In other species, however, such as *D. pseudoobscura*, singing is part of the fighting ritual (S. Nilsen unpublished observations). Singing also can be introduced into fights between male *D. melanogaster* by altering levels of the amine octopamine (S. J. Certel *et al.* unpublished observations). Using fly lines with mutations in the enhancer region for the gene tyramine-β-hydroxylase (the key enzyme in the biosynthesis of octopamine) generated by Monasterioti *et al.* (1996), it was found that flies with low or normal levels of octopamine would not sing during fights, while flies with double the level of octopamine would. This effect seemed related to selective effects of the amine on all modules of behavior associated with wing movements, as wing threats also increase in occurrence with increases in the levels of octopamine in the flies. These studies raise the interesting possibility that different neurohormones might have selective effects on different patterns of behavior and that switching between patterns during behavioral interactions might depend on the release of such substances associated with the social context at the time.

1.27.2.4.1 The role of genes, hormones, and experience in molding behavior in fruit flies There is little doubt that genes play an important role in laying down behavioral patterns in fruit fly central nervous systems. In addition, with fruit fly studies leading the way, much recent work has focused on defining the sequences of genes involved in specifying neuronal identity and in establishing pathways of neuronal connectivity in the developing nervous system (cf. Skeath and Thor, 2003). Much less work, however, has been done on the role of genes in establishing the behavioral patterns that are of concern here. Here again, however, elegant work with fruit flies is leading the way. For example, Bate and colleagues (Suster and Bate, 2002; Langraf *et al.*, 2003) have explored how the central pattern generator (CPG), which governs movements of larval fruit flies, gets established. Their findings are that rather than motor neuron cell body position determining the organization of these motor systems, the dendritic arbors of motor neurons appear to form a myotopic map within the larval ventral nerve cord. These endings form a central representation of the peripheral musculature and they do not require the muscles themselves, properly differentiated glial cells or sensory input to form their organizational domains. While sensory input is not required to form the central motor patterns, without sensory input the polarity of the movement patterns is abnormal. They found further that even though muscles are organized segmentally, the arbors of endings of the motor neurons are in the embryonic parasegmental organization lined up with the anterior margin of *engrailed* gene expression in the nervous system. They suggest that neurons of the ventral nerve cord can "differentiate autonomously to produce the CPG for larval peristalsis in Drosophila," and that this may be an essential feature of the formation of patterns within the fruit fly central nervous system (Suster and Bate, 2002).

1.27.3 Crustaceans as Model Organisms for the Study of Aggression: Exploring the Role of Amines in Aggression

1.27.3.1 Characterization of the System

Crustacean species, including crayfish and lobsters, represent excellent study systems to explore the structure of complex behaviors and their causation. Paired fighting between socially naïve animals features an exchange of highly stereotypical behaviors that escalate through different intensity levels and that ultimately result in a decision with behavioral consequences for both winners and losers (Bruski and Dunham, 1987; Huber and Kravitz, 1995; Pave and Fielder, 1996; Barki *et al.*, 1997). Quantitative analysis of agonistic (fighting) behavior in lobsters and crayfish allowed the construction of ethograms of the common behavioral patterns and their temporal structure (Huber and Kravitz, 1995; Huber *et al.*, 2004). Fighting proceeds according to strict rules of conduct. All animals exhibit a series of common behavioral patterns in a stereotypical manner. A temporal sequence of these patterns was evident, representing an increase in intensity during confrontations. The typical scenario of an encounter begins with extensive threat displays upon first contact, continues with periods of ritualized aggression and restrained use of the claws, and terminates in a brief session of unrestrained combat. Predictions of game theory

(i.e., assessment strategies) provide a useful framework for the understanding of fighting in lobsters (Parker and Rubenstein, 1981; Leimar and Enquist, 1984). The presence of a highly structured behavioral system may reduce the potential for damage in fights among conspecifics, and may prove useful in attempts to study the neurobiological causes of complex behavioral patterns such as aggression.

1.27.3.2 Neurohormones and Aggression

A common theme in these studies is that amines, peptides, and steroid hormones, substances that function as neuromodulators and as neurohormones, serve as important modulators of aggression at the behavioral level. Amine systems have been extensively studied in crustaceans. Beginning with studies showing that injections of octopamine and serotonin into animals triggered the appearance of opposing postures that resembled those seen in winning and losing animals during fights (Livingstone *et al.*, 1980), and continuing with demonstrations of the localization of amine neurons in the nervous system (Beltz and Kravitz, 1983; Schneider *et al.*, 1993), learning how these neurons function (Beltz and Kravitz, 1987; Ma *et al.*, 1992; Heinrich *et al.*, 2000; Kravitz, 2000), and recent demonstrations of changes in the functioning of these neurons with changes in social status (Yeh *et al.*, 1996, 1997; Edwards *et al.*, 1999), much has been learned about the functioning of amine neurons in aggression in crustacean systems. Several recent reviews describe the results of these experiments (Kravitz, 2000; Panksepp *et al.*, 2003; Kravitz and Huber, 2003; Huber *et al.*, 2004; Huber, 2005). The focus here, therefore, will be on the behavioral effects of amine infusion and/or on the consequences of pharmacological manipulations that alter amine levels in these species.

In one set of studies, fighting behavior has been examined in crayfish pairs with large size asymmetries (>30%), where the smaller (subordinate) animal received acute serotonin infusions via a fine-bore, fused silica cannula (Huber *et al.*, 1997a, 1997b; Huber and Delago, 1998; Figure 2). During such treatment, infused animals re-engaged their larger opponents, resulting in longer fights that reached higher levels of intensity compared with controls. Multivariate techniques (e.g., discriminant function analysis) revealed that serotonin treatment specifically altered the decision to retreat from an opponent, without affecting how likely the animal was to initiate fights, how individual fights progressed to higher intensities, or in the case of large size asymmetries, the eventual social rank that was achieved. In these studies, therefore, serotonin appears to act on key sites for agonistic decision making in the crayfish central nervous system. It is likely that serotonin reuptake mechanisms play an essential role in this behavioral change as the effects associated with acute serotonin infusion were significantly reduced in the presence of fluoxetine (Huber *et al.*, 1997a, 1997b; Huber and Delago, 1998). This finding suggests that a functional high-affinity serotonin reuptake mechanism (Livingstone *et al.*, 1981) is involved, and that serotonin-associated behavioral plasticity requires the reloading of synaptic terminals (which can be blocked by fluoxetine). Little information is available on the categories of serotonin receptors involved.

In studies with juvenile lobsters, although arriving at similar empirical outcomes after injections of serotonin, other investigators offered alternative interpretations of the observed effects, suggesting that an inhibition of retreat simply reflects global down-regulation of motor activity or motor coordination (see Peeke *et al.*, 2000). To address such criticism and to further distinguish between specific aggression-enhancing effects of serotonin and more global effects on motor activity or coordination, levels of activity, movement patterns, and space utilization were studied in crayfish receiving serotonin in ways that corresponded in dose, mode, site, and time course of infusion to those used in the earlier fighting studies. Under such conditions and compared with controls, acute serotonin-infusion neither altered absolute levels of locomotion nor movement patterns (Huber, 2005).

Subsequent work using chronic augmentation or disruption of serotonin function explored to what degree considerations of timescales and dynamic properties enhance understanding of the links between amines and behavior. Pharmacological interventions that alter serotonin–neuron function appear to be accompanied by the rapid induction of compensatory mechanisms that counteract such treatments. Thus, the differences in fighting behavior resulting from chronic infusions of serotonin were initially accompanied by the anticipated effects on behavior, but these were followed by a steady decline in effectiveness of the amine (Panksepp and Huber, 2002; Panksepp *et al.*, 2003). Infusions from silastic tube implants containing serotonin (Panksepp and Huber, 2002) and lasting up to several weeks initially boosted absolute amine levels in the nervous system. Within a week, however, it appeared that adaptations took place in the system that counteracted the effects of constant infusion and absolute levels of serotonin returned to pretreatment levels. Moreover, with continued serotonin

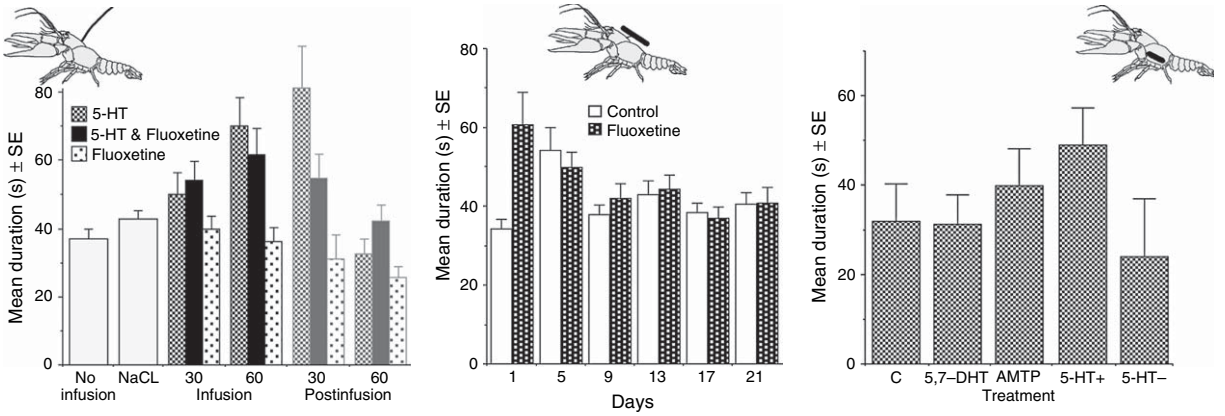

Figure 2 Composite figure illustrates differences in fight duration resulting from pharmacological manipulations of crayfish serotonin systems. Fight durations varied considerably with some lasting a few seconds and others several minutes. Encounters are graphed according to mean duration (in seconds) of fighting during the experimental period. a, Fine-bore fused silica capillaries were used to infuse serotonin, fluoxetine, or both substances together into freely moving, subordinate animals. Serotonin infusion (at 3 μg min^{-1}) resulted in longer fighting that persisted well after the infusion pump was turned off. Multivariate statistical techniques (i.e., discriminant function analysis) revealed that longer bouts of fighting resulted from a decreased likelihood of retreat. Infusion of fluoxetine alone did not enhance aggression, however, co-infused with serotonin resulted in a reduction of the fight-enhancing effects of serotonin. b, Chronic infusion of fluoxetine via osmotic minipumps increased duration of fighting during the early stages of treatment compared to animals receiving vehicle only. As with acute serotonin infusion, these differences in fighting were due to a decrease in the probability for retreat. c, Duration of fighting in animals that received chronic silastic implants containing either 5-HT synthesis inhibitors (5,7-dihydroxytryptamine or alpha-methyltryptamine) or serotonin at one of two different rates. No significant differences in fight duration existed among these groups. Reproduced from Huber, R., Panksepp, J. B., Yue, Z., Delago, A., and Moore, P. 2001. Dynamic interactions of behavior and amine neurochemistry during acquisition and maintenance of social rank in crayfish. *Brain Behav. Evol.* 57, 271–282, with permission from S. Karger AG, Basel.

infusion, some animals actually showed serotonin depletion likely resulting from overcompensation in the system. Such neuronal compensation could involve changes at many different levels, including altered synthesis (Stachowiak *et al.*, 1986; Sivam, 1995), amine release (Lent, 1984; Hall *et al.*, 1999), metabolic activity (Ase *et al.*, 2000), or receptor distribution or turnover (Patel *et al.*, 1996; Woo *et al.*, 1996). The studies utilizing chronic treatments did not generate increases in the aggression-enhancing effects of serotonin like those that result from acute infusions. Although this advises caution when discussing possible links between amines and behavior, it more likely reflects the constraints in working within a dynamic system in which critical components are the relative size of a signal relative to a given set point, and the timing of when a signal is triggered. Thus, the global systemic effects of pharmacological manipulations may be poor mimics of normal physiological processes in which neurons release neurohormones such as amines within nervous systems at precise times for actions on restricted sets of targets. To illustrate, raising or lowering levels of serotonin in lobsters by pharmacological manipulations generates the same behavioral phenotype of enhanced aggression (Doernberg *et al.*, 2001). It may well be that the more precise and selective control of amine neuron function that is available utilizing genetic methods such as the GAL4/UAS system (Kitamoto, 2001; Brand *et al.*, 1994), or recently developed methods for selectively activating neurons in behaving animals (Lima and Miesenbock, 2005), may provide more accurate information on how neurohormones function in complex behaviors such as aggression.

1.27.4 Summary

There is little doubt that in invertebrate animals, complex behavioral patterns exist that are stereotypical, recognizable by conspecifics, moldable by experience, and likely specified during development by genes. For the most part, there is little or no parental rearing in these species. Thus, as organisms emerge as adults, they must be fully capable of functioning on their own in order to survive and procreate. The fruit flies and crustacean species described in this article know all the rules of how to fight and make decisions the first time they meet a conspecific, and the decisions made as a result of agonistic interactions and probably other social experiences as well have profound consequences on their subsequent behavior. Neurohormonal substances such as amines serve important and essential roles in behaviors such as aggression in these species and much elegant experimental work has focused on

defining the roles served by these substances. In vertebrate species, with their extended periods of rearing, extensive learning or refining of behavioral patterns undoubtedly takes place shortly after pups emerge. How much of the rearing builds on patterns already defined, at least in outline form, by genes, during embryonic life, and how much defines new behaviors and patterns, remains an area of great contention. This discussion gets even more contentious when one relates it to human beings and to higher human functions such as cognition. Our goal is not to engage in this debate in this article. Instead, we aim to establish that there is much to learn from simpler forms such as invertebrates about important and essential processes that relate directly to human life and its complexities. Aggression is a serious problem in human society, a problem that undoubtedly has a biological basis. Invertebrate models offer insights into how complex behavioral patterns get established in nervous systems that are difficult to impossible when addressed in higher forms with the methodologies available at the present time, and offer elegantly detailed information on how social experience in turn molds behavior and the nervous system at levels of detail that are equally inaccessible with vertebrate studies. Those facts alone justify and warrant continuing studies of the amazing invertebrate organisms and the rich worlds in which they function and have functioned for far longer periods of evolutionary history than humans.

1.28 Sleep in Invertebrates

B van Swinderen, The Neurosciences Institute, San Diego, CA, USA

Glossary

arousal threshold	The level of stimulation required to elicit a behavioral response.
circadian rhythms	Daily patterns of behavioral activity.
homeostasis	Physiological balance for the purpose of survival.
LFPs	Local field potentials, recordings of summated brain activity.
MPC	Medial protecerebrum, part of the central brain of arthropods.
micro-behaviors	Movements of parts of the body, excluding locomotion.
phylogeny	The evolutionary relationships, through time, of all species.
quiescence	Behavioral immobility, awake or asleep.
unimodal	Described by a single peak.

1.28.1 Why Identifying Sleep in Invertebrates is Important

Sleep is universal among vertebrates, from fish to amphibians, reptiles, birds, and mammals (Campbell and Tobler, 1984). In these animals, sleep is regulatory in addition to being a behavioral state of quiescence. Similar evidence of sleep in invertebrates, on the other hand, was weak until fairly recently, partially because invertebrates have been relatively poorly studied experimentally for sleep criteria. It now appears the invertebrate realm may be partitioned between animals that require sleep and animals that do not sleep. For example, some invertebrates, such as flies, sleep as much as humans do, whereas others, such as certain nematodes, are never entirely quiescent. Although it is tenuous to make any premature claims about which invertebrates do not sleep (the case for flies sleeping is itself fairly recent; Shaw *et al*., 2000; Hendricks *et al*., 2000), one may predict more firmly that some invertebrates, perhaps certain jellyfish, roundworms, and sponges, among others, will be rigorously shown not to require any sleep at all. Much research in that realm remains to be done. Sleep has been rigorously demonstrated so far in only one class of invertebrates – arthropods.

Yet, deducing the phylogenetic emergence of sleep among invertebrates is interesting and important because it will immediately suggest which anatomical structures, neural systems, or behavioral repertoires are associated with sleep-like behavior. For example, is sleep associated with attention-like mechanisms or demonstrations of long-term memory? Is it associated with dopaminergic neurotransmitter systems? With a brain? These phenomena are all likely to have emerged within invertebrate evolution, alongside the need for sleep. Thus, by identifying sleep (or the lack thereof) in invertebrates, we are by the same token identifying which other aspects of their biology may be tied to sleep, thereby providing a valuable perspective on the possible function of sleep and its mechanism.

Sleep must accomplish an important function in both vertebrates and invertebrates: both flies and humans, for example, sleep on average a third of their life away, time during which they are highly unresponsive and cannot accomplish other behaviors which, during waking, are crucial to survival. This

function is most likely ancient and unrelated to the subjective, conscious associations we have with sleep in humans. Although our own sleep may be tied to altered conscious states, the formal demonstration of sleep relies purely on behavioral measures. These include observational studies, such as measures of daily cycles of quiescence as well as postural changes or sleeping sites. In addition, experimental studies probing the regulatory aspect of sleep include tests for behavioral responsiveness (arousal thresholds) as well as tests for increased sleep need following sleep deprivation. Finally, neural correlates of sleep can be identified in the brain activity of animals displaying the preceding behavioral states. Key invertebrates have been shown to demonstrate all of these criteria for sleep.

1.28.2 Gross Behavioral Measures

1.28.2.1 Quiescence

Behavioral immobility, or 'quiescence', is the most obvious predictor of sleep in invertebrates. The classical literature of invertebrate natural history provides a number of meticulous descriptions of behavioral states involving periodic quiescence in arthropods, annelids, and crustaceans (Rau and Rau, 1916). However, as we shall see in the following, these observations remain by and large insufficient for convincingly identifying sleep in these organisms. While some invertebrates seem to never stop moving for very long (e.g., certain nematodes and jellyfish), others become quiescent for hours at a time. Fruit flies and honeybees, for example, display long periods of immobility during the night, and cockroaches and scorpions are mostly immobile during daylight hours. Such daily cycles of activity, or 'circadian rhythms', have been well studied in model invertebrates such as fruit flies, and the underlying cellular processes controlling these rhythms are quite well understood (Hall, 2003). However, circadian rhythms alone do not necessarily reflect sleep processes. On shorter timescales (minutes or seconds), an immobile animal is not necessarily sleeping; it may be quietly vigilant. This is especially true for predatory arthropods such as scorpions and spiders, and may be general for any invertebrate capable of extended quiescence. Such immobility may also be an effective strategy for some invertebrates to evade predators, as in the case of camouflaged moths or stick-insects. Thus, immobility alone is not a sufficient criterion for sleep even if in the long term (days) circadian rhythms and sleep patterns do correlate.

1.28.2.2 Posture

Many invertebrates display a specific posture during periods of extended quiescence, and sometimes this occurs in specific sites as well. One striking example of a posture and a site associated with extended immobility is shown in Figure 1 for a species of solitary bees. These insects will seek out a twig at dusk and clamp on to its extremity with their mandibles, groom for a while, and then remain largely immobile, thus perched until the first rays of sunlight strike them the following morning. It is thought that this bizarre sleep position protects the bee while it is most vulnerable (asleep) by minimizing potential contact or detection by predators (Kaiser, 1995). Other solitary bee species sleep in the protective environment of burrows. Social honeybees sleep within their hive, where they retreat to the outer regions of the combs during the night. Fruit flies have been seen to sleep close to, but not on, food in constrained experimental settings, but in the wild they usually take refuge underneath leaves or such substrate. Scorpions, cockroaches, and spiders similarly seek burrows or find rocks or vegetation under which to retire, as do certain marine invertebrates such as *Aplysia* or cephalopods. Crayfish have been shown in the laboratory to display a typical sleep posture, lying immobile on their side just under the surface of the water, with chelae (pincers) extended (Figure 2). In each of the preceding examples of sleep posture or position, animals are almost completely immobile and (where it has been measured) display

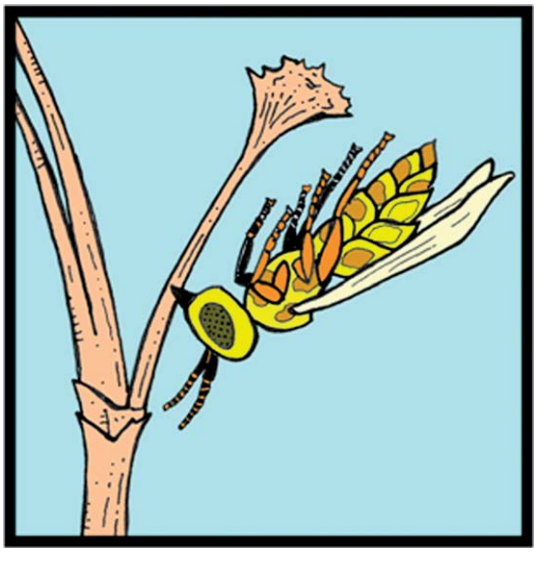

Figure 1 Sleeping posture in a solitary bee (*Nomada* sp.). At dusk, bees clasp twig extremities with their mandibles, usually with their head pointing downward and their legs off the substrate. They remain thus until the morning. Adapted from Kaiser, W. 1995. Rest at night in some solitary bees – a comparison with the sleep-like state of honeybees. *Apidologie* 26, 213–230, Elsevier.

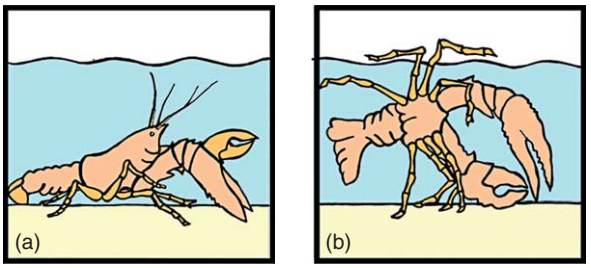

Figure 2 Sleep in the crayfish (*Procambarus clarkia*). a, Waking crayfish move, are upright, are responsive to mechanical stimuli, and display characteristic brain responses to visual stimuli. b, Sleeping crayfish lie on their side with appendages fully extended, are less responsive to mechanical stimuli, and display different levels of brain activity. Adapted from Ramon, F. *et al.* 2004. Slow wave sleep in crayfish. *Proc. Natl. Acad. Sci.* USA 101(32), 11857–11861. Copyright (2004) National Academy of Sciences, USA, with permission.

decreased muscle tone (Kaiser, 1988; Ramon *et al.*, 2004; Tobler and Stalder, 1988).

1.28.2.3 Arousal Thresholds

Still, postural immobility in itself is not a sufficient demonstration of sleep in invertebrates (as it should not be in humans either). The sleeping state can only really be put to the test by measuring behavioral responsiveness to stimuli – often irritating stimuli. During sleep, behavioral responsiveness (evidenced by movement or postural change) is always decreased (arousal thresholds are increased) compared to quiescent waking. Investigators have devised various methods of documenting increased arousal thresholds in immobile invertebrates, thereby formally associating the quiescent postural states with sleep. For example, an electric motor pounding on the thorax of a crayfish will require a stronger, longer on-time to evoke any movement while the crayfish is immobile in its sideways, extended posture (Figure 2), than when it is immobile but upright at the bottom of the observation tank (Ramon *et al.*, 2004). Arousal threshold studies in smaller invertebrates, such as flies, cockroaches, and scorpions, usually involve sporadically tapping or shaking the observation container housing the animal and quantifying subsequent whole-body movement by means of time-lapse video or infrared monitoring systems (see Cognition in Invertebrates, Aggression in Invertebrates: The Emergence and Nature of Agonistic Behavioral Patterns; Tobler, 1983). Although these studies have been relatively limited, considering arousal thresholds are the definitive indicator of sleep, they have all shown that a greater stimulus is required to evoke movement if a period of extended quiescence preceded the test stimulus. The amount of prior quiescence required for decreased behavioral responsiveness is probably variable for different invertebrates and has not been well examined. The most detailed, quantitative, studies to date on the relationship between arousal threshold and prior quiescence have been done in fruit flies, where it has been demonstrated that five minutes of immobility usually predicts decreased behavioral responsiveness, hence sleep (Shaw *et al.*, 2000; Huber *et al.*, 2004). This result argues for the possibility of a transitional state preceding sleep when the flies are still partially aroused, otherwise a shorter quiescent epoch might have been just as predictive of decreased responsiveness.

1.28.2.4 Sleep Homeostasis

The same methods which are used to test for behavioral responsiveness can also be used to deprive an animal of sleep. Sleep deprivation typically results in a 'sleep rebound' following the stimulation regime, where animals will enter extended quiescence with associated postures even during normal waking hours. Thus, a solitary bee deprived of twigs in a laboratory environment will lose sleep until it is provided with a twig, at which point it quickly engages in its bizarre sleep posture (Figure 1). In fruit flies, sleep rebounds are characterized by increased sleep intensity (higher arousal thresholds than usual) and fewer brief awakenings than are typical during a normal rest epoch. Crayfish deprived of sleep (by violently bubbling water) were shown to spend more time subsequently in their immobile 'sideways, floating' posture (Figure 2). Forced locomotion in cockroaches during the last three hours of their usual rest cycle enhanced immobility in the first four hours of the subsequent usual wake period (Tobler, 1983). Altogether, these experiments show that the regulatory or 'homeostatic' aspects of sleep common to vertebrates are present in invertebrates as well: sleep loss must be compensated by sleep recovery (Figure 3).

1.28.3 Micro-Behaviors During Sleep in the Honeybee

Studies of sleep and arousal in invertebrates have relied mainly on measures of whole-body movement, often for practical reasons since animals are mostly rather small. A few investigators have looked more closely at the micro-behaviors of individual body parts and aspects of invertebrate physiology during sleep, mainly in the honeybee. Several observations indicate that sleep in the honeybee is not a passive, homogenous state of continuous torpor-like immobility, but rather, is an active, dynamic process.

Close observation of marked individuals in a bee hive throughout the night revealed that honeybees

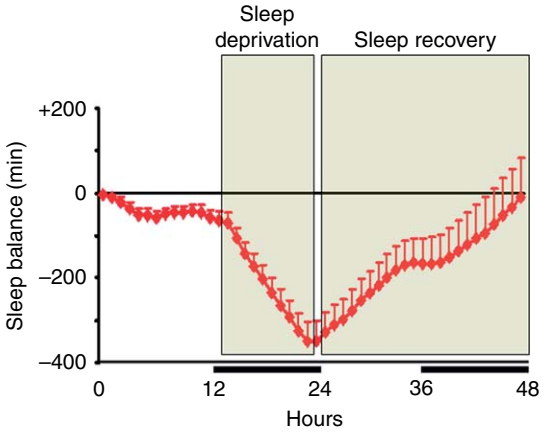

Figure 3 Sleep homeostasis in fruit flies. Cumulative rest is plotted for a population of *Drosophila melanogaster*, following a day of baseline activity (16 females, ± SEM). Fly activity is quantified by crossings of an infrared beam in a narrow tube containing food on one end. Cumulative rest (minutes of inactivity) is plotted for two days (a dark bar indicates night), during which flies are mechanically sleep-deprived during the first subjective night shown. Sleep recovery is evident in the following daylight hours, until all lost sleep has been recovered by the end of the second night, thus achieving sleep homeostasis. Data courtesy of Rozi Andretic.

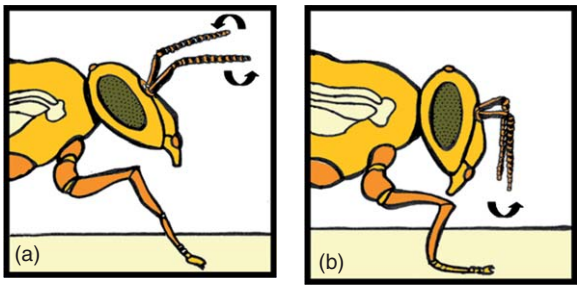

Figure 4 Micro-behaviors of sleep in the honeybee (*Apis mellifera*). a, In waking honeybees, the antenna move constantly by rotating (arrows) and orienting while the animal maintains an erect posture. b, During sleep, honeybees lose muscle tone in the neck and legs, but the antenna remain somewhat motile ('swaying', arrow) while pointing downward. Antennal motility gradually decreases until the middle of the night, when the antennas become mostly immobile. During this epoch, honeybees are most unresponsive to stimuli. Adapted from Kaiser, W. 1988. Busy bees need rest, too: Behavioural and electromyographical sleep signs in honeybees. *J. Comp. Physiol.* A 163, 565–584.

do not enter into a state of prolonged sleep immobilization, but instead show a gradual decrease in motility. Muscle tone in the legs is lost only late in the night, often culminating with the animal lying on its side in remote parts of the hive. Even closer observation achieved by video recordings of restrained bees tethered onto a treadmill further revealed that the antennas of bees show characteristic changes in motility and orientation during the night. Even while the insect is not moving its body, the antennas sway and rotate, typically ending in a downward-pointing orientation, whereupon the antennas themselves become immobilized (Figure 4). Overnight measures of antennal movement show that these appendages become gradually less motile until reaching a 'peak' of immobility in the middle of the night (hour 7 of the night cycle), thereby describing a unimodal behavioral dynamic. Arousal threshold and sleep-deprivation studies confirm that this peak of antennal immobility occurring in the middle of the bee's rest period represents the 'deepest' sleep state in the insect (Sauer *et al.*, 2003, 2004).

Additional observations of other honeybee micro-behaviors confirm that sleep is a dynamic and gradual process in this model invertebrate. Physiological recordings show that respiration, cardiac pulses, and neck muscle tone decrease gradually during the night, while behavioral measures indicate that various body parts (scape, flagella, and head) assume characteristic positions during deepest sleep. These physiological measures and body part positions all appear to co-vary significantly with antennal dynamics. Furthermore, the dynamics of some measures, such as the time between ventilatory cycles, follows exactly the same unimodal behavior as antennal immobility, centered with a peak in the middle of the night. Such comparable dynamics, as well as the co-variance among other behavioral and physiological measures, suggests that sleep in the bee is controlled by one process only. It is likely that a closer observation of micro-behaviors in other invertebrates will reveal that the dynamic, active, correlative aspects of rest in the honeybee are a general feature of sleep processes which have just never been investigated in other small invertebrates (Kaiser, 1988).

1.28.4 Electrophysiology of Sleep in Invertebrates

There are few studies of brain recordings during sleep (or wake) in invertebrates, even though this measure has become central to identifying sleep in humans (e.g., large-amplitude slow-EEG potentials are a signature of deep sleep in many mammals). Some probable reasons for the scarcity of brain activity recordings in invertebrates is their small size, the lack of neuroanatomical correlates or landmarks, and the fact that most larger invertebrates are water-dwelling, thus complicating electrophysiological recording paradigms. Sleep has nevertheless been examined in some brain recordings of insects and crayfish.

1.28.4.1 Crayfish

During epochs when crayfish are immobile and least responsive to arousing stimuli, floating sideways just beneath the water surface (see Figure 2), recordings of brain activity from their medial protocerebrum display a very regular 8 Hz oscillation. As the crayfish brain has little neuroanatomical homology with the mammalian brain, it is intriguing that any sleep-related oscillation occurs at all, even if it is not strictly 'slow'. Perhaps more relevant (than the exact frequency range of this signature) is the possibility that such a strong oscillation effectively reduces the complexity of recorded brain activity in the sleeping crayfish. Human slow waves are also less information-rich than waking brain activity.

In addition to spontaneous brain activity, the crayfish brain's responsiveness to visual stimuli was also measured during sleep. In vertebrates, trains of light pulses (e.g., 10 Hz) during waking evoke characteristic potentials upon stimulus termination, called 'omitted stimulus potentials' (OSPs), which have been described as a cognitive effect tied to expectancy. OSP amplitude in the crayfish was found to follow a diurnal cycle correlated with sleep. Behaviorally unresponsive crayfish floating on their side fail to elicit OSPs in their recorded brain activity. These evoked potentials immediately recover, however, when the crayfish is awakened by mechanical stimuli (Ramon *et al*., 2004).

1.28.4.2 Honeybees

Responsiveness to visual stimuli was also demonstrated to be dynamically tied to sleep in recordings from single neurons in the honeybee brain. 'HR' neurons in the optic lobes of insects typically respond to motion in a specific direction, by increased firing of action potentials. These neurons were found to respond much less (often not at all) to motion during the bee's rest cycle, compared to waking epochs. The spontaneous, unstimulated rate of firing also displayed a small rise and fall coinciding with wake and sleep. Critically, the neurons' responsiveness level during sleep could be 'awakened' by arousing stimuli such as air puffs or light flashes to the opposite eye. The rapid reversibility of neuronal unresponsiveness coinciding with wakefulness in the honeybee resembles similar effects found in crayfish brain recordings. The demonstration that other (nonvisual) modalities could instantly reset the responsiveness of a specific visual neuron suggests the existence of a 'general' arousal system in some invertebrates. This view is also consistent with behavioral studies in the bee showing that different sleep micro-behaviors, such as breathing and antennal immobility, seem to be under common control. The responsiveness of certain neurons in the brains of arthropods are thus tightly matched to behavioral responsiveness in general. These neurons may form part of a central system governing arousal, where an endogenous state prevents external stimuli from evoking full-fledged responses during sleep (Kaiser and Steiner-Kaiser, 1983).

1.28.4.3 Fruit Flies

Local field potential (LFP) recordings from the brains of tethered, yet intact and behaving fruit flies have further confirmed that neural correlates of sleep can indeed be identified in some invertebrates. Unlike crayfish recordings, no specific oscillations were observed in the medial protocerebrum of sleeping flies. Instead, brain activity was uniformly decreased across all frequencies measured (1–100 Hz) when flies were immobilized by sleep and showing decreased responsiveness to mechanical or visual stimuli. Similar to the crayfish OSP attenuation and the honeybee's HR neurons decreased responsiveness during sleep, a characteristic 20–30 Hz response to visual stimuli in the fly was found to be significantly attenuated during epochs of extended quiescence (Nitz *et al*., 2002; van Swinderen and Greenspan, 2003).

Similar to sleep in honeybees, sleep in fruit flies also appears to be a dynamic process marked by changes throughout the rest cycle. Correlation levels between ongoing brain activity and fly movement were found to change during the night, often decreasing to the lowest level in the middle of the night when brain activity became completely uncorrelated with any movements displayed by the insect (flies, like honeybees, move sporadically throughout the night). Furthermore, epochs of extended quiescence in the fruit fly were preceded by a few minutes of decreased correlation between brain activity and movement, providing some evidence that sleep processes may involve transitional states in these insects as well. Finally, such decreased correlation, or uncoupling, between brain and body measures of activity were associated with decreased behavioral responsiveness to a similar degree as extended quiescence itself (van Swinderen *et al*., 2004).

1.28.5 Conclusions

It is now undeniable that some invertebrates sleep. Combined data from behavioral and electrophysiological studies done almost exclusively in

arthropods (insects, arachnids, and crayfish) show that sleep is likely to be a central process in the brains of these simple animals. It is a dynamic process rather than just a state of inactivity, ultimately characterized by decreased behavioral responsiveness. As such, sleep in invertebrates is perhaps better described by an 'uncoupling' between the brain and external stimuli, instead of by single observations alone, such as brain signatures, behavioral postures, or even immobility. Taken together though, these disparate observations make a compelling argument for invertebrate sleep being a distinct behavioral state analogous to sleep in other animals. The function of sleep is likely to be the same in all animals, and perhaps the mechanism will be found to be similar as well.

The fruit fly *Drosophila melanogaster* has been pushed to the forefront as a model system in which to study sleep mechanisms and function since it is amenable to genetic analysis. Recent genetic and pharmacological studies in the fruit fly have suggested that similar neurotransmitter effects, such as neuromodulation by dopamine, may be central to controlling sleep processes in all animals. Combined with electrophysiological and behavioral data from flies and other simple arthropods, it is conceivable that invertebrates will provide valuable insights on the function and mechanisms of sleep applicable to all animals. Since invertebrates are likely to include a number of members which do not sleep, this sub-kingdom may prove to be a key resource to eventually understanding the phenomenon of sleep.

1.29 Gene Expression in the Honeybee Mushroom Body and Its Gene Orthologues

H Takeuchi, The University of Tokyo, Tokyo, Japan

Glossary

cDNA microarray method — A powerful tool to analyze transcription levels of thousand of genes (~20 000) between different biological conditions with a few repeated experiments. cDNA microarray is the method to use cDNA clones fixed on a glass slide in an ordered two-dimensional matrix as probes. The transcription levels of each gene can be calculated by the intensity of hybridized targets (RNA, cDNA), which are derived from tissues of interest and labeled with florescent dye.

differential display method — A method to identify genes transcribed differentially between different biological conditions. The RNAs are prepared from tissues of interest and RT-PCR is performed using short primers (10 mers). By analysis on a sequencing gel, RT-PCR products derived from a gene of interest can be detected as a band, which shows different intensities. By subcloning of the RT-PCR product, partial cDNA sequences (~300–900 bp) of the genes are determined. As this method often generates false positives (over 50%), it is necessary to confirm the differential expression using other methods (Northern hybridization method, real-time RT-PCR method, or *in situ* hybridization).

in situ *hybridization* — A method to visualize the location of nucleic acid (RNA or DNA) in the cell or tissues. Using this method, a cell expressing a gene of interest can be identified in a tissue. To visualize transcripts of interest, the fixed tissues are prepared as sections or whole-mounted. The tissues are then hybridized to a labeled RNA or DNA probe, which has complimentary sequences to the transcripts. Finally, the labeled probe can be detected using antibody against it.

matrix-assisted laser desorption/ ionization with time-of-flight mass spectrometry (MALDI-TOF MS) — A powerful tool to determine molecular masses of biomolecules, such as proteins, peptides, and oligonucleotides. As it is a very sensitive method, low (10^{-15}–10^{-18} mole) quantities can be detected. It is also applied for analysis of a mixture of samples and can be used for direct analysis of peptide profiles from small pieces of dissected tissue and makes it possible to demonstrate the expression of bioactive peptides.

1.29.1 Introduction

The honeybee is a eusocial insect and the honeybee colony is comprised of three types of adults. Male honeybees are drones, whereas female honeybees have a genetically equal potential to differentiate into two castes, which is determined by nutritional factors: queens (reproductive caste) and workers (labor caste) (Winston, 1987). In the honeybee colonies, queens and drones are fed by the workers and have unique specializations, particularly in association with reproduction. Worker bees are sterile and perform diverse tasks to maintain colony activity. The life span of a worker bee is usually 30–40 days and their role changes depending on their age after eclosion (age-polyethism). Young workers (nurse bees)

labor at in-nest jobs such as cleaning the comb and nursing the brood, while older workers (forager bees) forage for nectar and pollen (Figure 1). A returning forager bee communicates by dance to inform other workers in the hive of the direction and distance of food. The molecular basis of honeybee social behavior, however, is largely unknown.

Mushroom bodies (MBs) are paired structures in the insect brain that are important for memory formation and are involved in higher-order processing for different sensory modalities (Heisenberg, 1998; Rybak and Menzel, 1998; Strausfeld, 2002). The MBs of the aculeate Hymenoptera, including the honeybee, are more prominent compared with most other insects (Mobbs, 1982, 1984) (Figure 2). In the honeybee, each MB has two calyces composed of 170 000 Kenyon cells, the intrinsic MB neurons (Mobbs, 1982) (Figures 2 and 3). In contrast, fruit fly MBs have only approximately 2500 Kenyon cells each (Balling *et al.*, 1987). Honeybee MBs are composed of two morphologically distinct, large (6–7 μm in diameter) and small (4–5 μm in diameter), Kenyon cells. The somata of the large-type Kenyon cells are located on the inside edges of each calyx. The small-type Kenyon cells are subdivided into two classes: the somata of class I Kenyon cells are located on the inner core of each calyx and those of class II Kenyon cells are located in the outer-bottom region of each calyx (Strausfeld, 2002; Farris *et al.*, 2004; Figure 3). The dendritic projection patterns also differ among the Kenyon cell types. The large-type Kenyon cells receive projections from olfactory and optic neurons at the lip or collar zone, respectively, of the calyces (see The Loss of Olfactory Receptor Genes in Human Evolution). The class I small-type Kenyon cells receive projections at the basal ring and collar zones, and the class II Kenyon cells receive sensory afferents from the entire calyx. Honeybee MBs have a high degree of structural plasticity and the volume of the neuropil varies according to the division of labor and sex (e.g., see Mobbs, 1985; Withers *et al.*, 1993; Durst *et al.*, 1994; Robinson *et al.*, 1997; Figure 1). These observations suggest that MB function is closely related to honeybee social behavior.

To identify genes involved in intrinsic MB function, some genes expressed preferentially in the MBs of the worker honeybee brain were identified using molecular biologic techniques (e.g., differential display method, cDNA microarray, and matrix-assisted

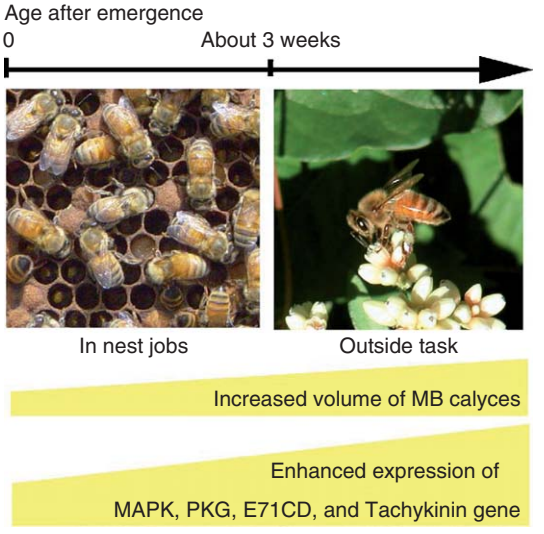

Figure 1 Age-based division of labor and gene expression in the worker brain. The many tasks required to maintain the hive are divided among worker bees in an age-based manner. Individual bees perform the tasks in an age-specific order (age-polyethism). Young bees clean the hive and nurse larvae in the nest. At around 3 weeks, the bees stand guard at the hive entrance, and after a few days the bees begin to collect pollen, water, and honey outside of the hive. The expression of some genes encoding mitogen-activated protein kinase (MAPK), methionine sulfoxide reductase, guanosine monophosphate-dependent protein kinase (PKG), and neuropeptides (tachykinin) are enhanced in forager bees, compared with nurse bees. Methionine sulfoxide reductase is encoded by an ecdysone-inducible gene, *E71CD* (Ben-Shahar *et al.*, 2002; Whitfield *et al.*, 2003; Takeuchi *et al.*, 2003). In the honeybee brain, the MBs undergo internal reorganization according to the division of labor, with the calyx volume increasing markedly between nursing and forager bees (Wither *et al.*, 1993). Photograph courtesy of T. Kubo.

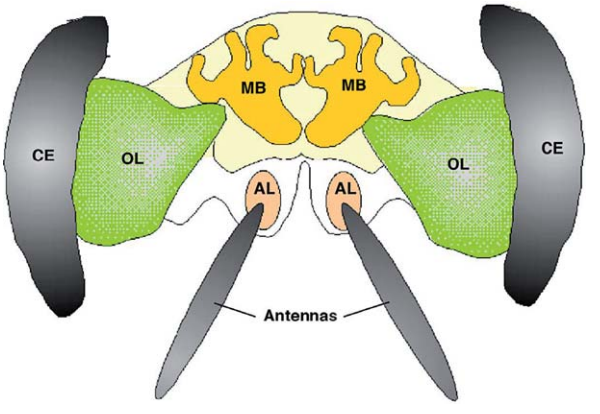

Figure 2 Schematic illustration of the front view of the honeybee brain. Honeybee brain consists of approximately 1 million neurons. The ratio of MB volume to the whole brain is approximately 12% (Mobbs, 1985). The MBs, paired protocerebral neuropils that receive processed sensory input from optic lobes (OL) and antennal lobes (AL), are thought to receive multiple inputs and have an important role in learning and memory.

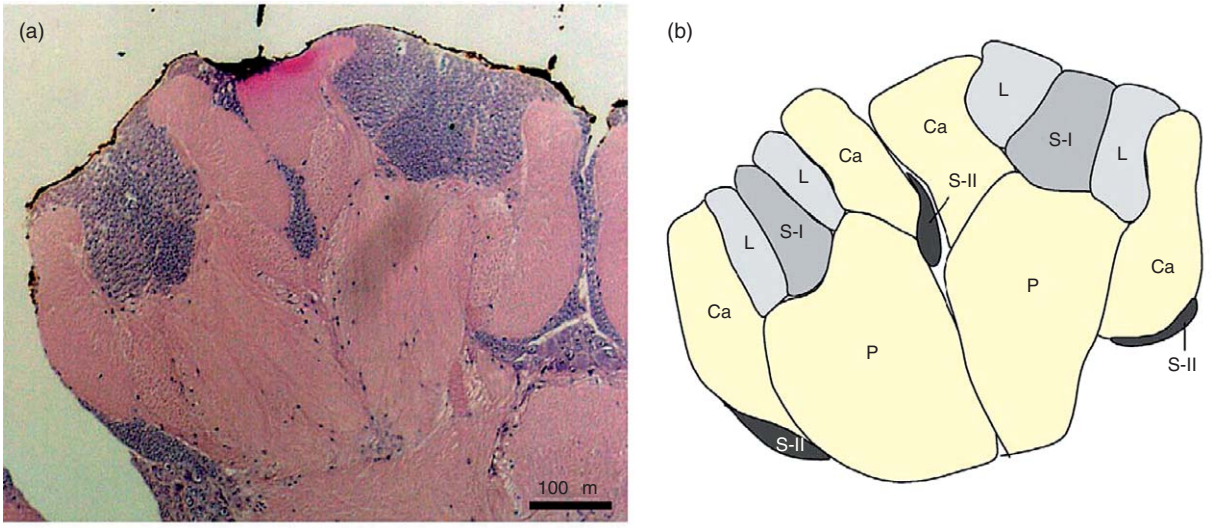

Figure 3 Honeybee MB structure. a, The left MB section with hematoxylin eosin staining. Each MB has two calyces composed of 170 000 intrinsic neurons of similar architecture called Kenyon cells (Mobbs, 1982); b, Organization in the MB. Dendrites of Kenyon cells compose the calyces (Ca), which comprise the lip (receives olfactory information from the antennoglomerular tracts), collar (receives projections from the visual medulla and lobula), and basal ring (receives dual olfactory and visual input). Kenyon cell axons compose the peduncles (P), which provide both the MB efferents and afferents (for review, see Strausfeld, 2001). Kenyon cells can be subdivided into two types: large (6–7 μm diameter) and small (4–5 μm diameter) Kenyon cells. The small-type Kenyon cells are subdivided into two classes: class I and class II (Strausfeld, 2002). In this figure, clusters of large type, and class I and class II small-type Kenyon cell bodies are indicated by L, S-I, and S-II, respectively. Farris *et al.* (1999) used another terminology to denote these main Kenyon cell subtypes: class I small-type Kenyon cells, inner compact cells (ICCs); Class II small-type Kenyon cells, outer compact cells (OCCs); large-type Kenyon cells, noncompact cells (NOCCs) (for review, see Robinson *et al.*, 1997). a, Modified from Takeuchi, H., Kage, E., Sawata, M., *et al.* 2001. Identification of a novel gene, Mblk-1, that encodes a putative transcription factor expressed preferentially in the large type Kenyon cells of the honey bee brain. *Insect Mol. Biol.* 10, 487–494, with permission from Blackwell Publishers Ltd.

laser desorption/ionization with time-of-flight mass spectrometry (MALDI-TOF MS)). In this chapter, the expression of these genes in the honeybee brain is described and their possible functions in honeybee MBs are discussed.

1.29.2 Expression of Genes for Ca^{2+}-Signaling Pathway Proteins in the MBs of the Honeybee Brain

To identify genes expressed preferentially in honeybee MBs, the differential display methods (Figure 4) and cDNA microarray methods were used to compare gene expression between the MBs and optic lobes, which were used as control tissue to detect genes expressed ubiquitously in neural tissues (see Genetic Analysis of Neural and Non-Neural Co-Evolution). Two genes were identified; one encoded an inositol 1,4,5-triphosphate (IP_3) receptor orthologue (Kamikouchi *et al.*, 1998) and the other a type I IP_3 5-phosphatase orthologue (Takeuchi *et al.*, 2002). *In situ* hybridization indicated that both of these genes were selectively expressed in the large-type Kenyon cells in the honeybee brain (Figures 5a and 5b). In mammalian brain, the IP_3 receptor is an endoplasmic reticulum protein required for mobilizing Ca^{2+} in response to IP_3-mediated extracellular signals (Mikoshiba, 1993) and type I IP_3 5-phosphatase is the major IP_3-hydrolyzing isoenzyme (De Smedt *et al.*, 1996). Thus, the function of IP_3-mediated Ca^{2+} signaling might be enhanced in large-type Kenyon cells in the honeybee brain (Figure 6).

In mammalian brain, the IP_3 receptor and type I IP_3 5-phosphatase genes are also co-expressed in cerebellar Purkinje neurons (Maeda *et al.*, 1990; De Smedt *et al.*, 1994). In Purkinje cells, some synaptic neurotransmitter receptors combine with G-proteins to activate phospholipase C (Figure 6). Phospholipase activity produces a pair of second messengers, diacylglycerol and IP_3. IP_3 mobilizes Ca^{2+} from the endoplasmic reticulum via IP_3 receptors and diacylglycerol activates protein kinase C (PKC) (Figure 5). The mammalian PKC family consists of 11 isoforms, at least 8 of which are expressed in cerebellar Purkinje cells (Barmack *et al.*, 2000).

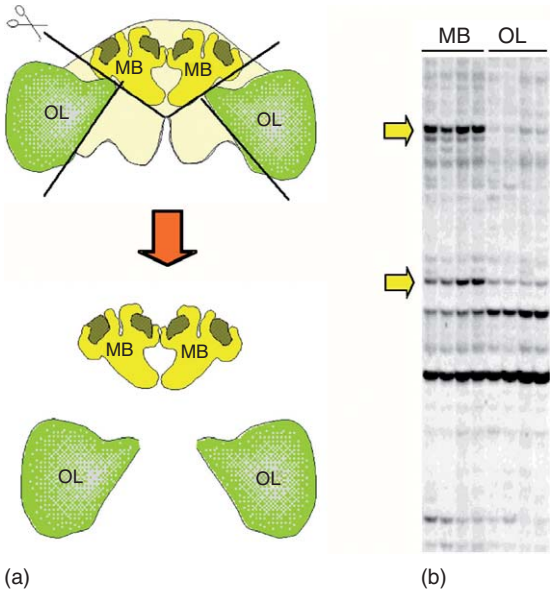

Figure 4 a, The dissection strategy used to isolate tissue prior to RNA extraction for differential display. Honeybee MBs can be easily dissected; b, Using the differential display method, the expression of each gene is detected as a band on a sequencing gel. Comparing bands in the MBs with those in the optic lobes, genes expressed preferentially in the MBs are identified as MB-selective bands as indicated by the arrows. a, Modified from Takeuchi, H., Kage, E., Sawata, M., *et al.* 2001. Identification of a novel gene, Mblk-1, that encodes a putative transcription factor expressed preferentially in the large-type Kenyon cells of the honey bee brain. *Insect Mol. Biol.* 10, 487–494, with permission from Blackwell Publishers Ltd.

PKC catalyzes the phosphorylation of various cellular proteins to affect both short-term biologic responses, such as synaptic modification, and long-lasting neuronal responses that require changes in gene expression (for review, see Clapham, 1995). In the cerebellum, the postsynaptic cascade in Purkinje cells is involved in synaptic plasticity (long-term depression), which occurs in certain forms of motor learning, such as associative eyelid conditioning and adaptation of the vestibulo-ocular reflex (for review, see Hansel *et al.*, 2001).

Therefore, the expression of other genes for proteins involved in the Ca^{2+} signaling pathway might also be enhanced in honeybee MBs. Consistently, the honeybee gene orthologues for Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) and PKC are predominantly expressed in the MBs (Figures 5c and 5d). In particular, the CaMIIK gene is preferentially expressed in the large-type Kenyon cells. Furthermore, the enzymatic activities of CaMKII and PKC are higher in the MBs and central bodies than in the optic and antennal lobes of the worker bee brain (Figures 5e and 5f). In mammalian brain, CaMKII is a leading candidate as a synaptic memory molecule because it is persistently activated after the induction of long-term potentiation and because mutations that block this persistent activity prevent long-term potentiation and learning (for review, see Lisman *et al.*, 2002). Given that CaMKII is important for synaptic and behavioral plasticity, these findings strongly suggest that the genes for proteins involved in synaptic plasticity and/or behavioral plasticity are enhanced in honeybee MBs.

In fruit fly brain, the *dunce*, *rutabaga*, and *DCO* genes, which are necessary for olfactory learning, are preferentially expressed in the MBs. The *dunce*, *rutabaga*, and *DCO* genes encode cAMP phosphodiesterase, adenylyl cyclase, and a catalytic subunit of cAMP-dependent protein kinase A (PKA), respectively, all of which are involved in the intracellular cAMP signaling pathway (Figure 6). In fruit fly, mutations in the *dunce*, *rutabaga*, and *DCO* genes influence olfactory learning (for review, see Davis, 2004). PKA is also preferentially expressed in honeybee MBs, and the downregulation of PKA during olfactory learning using an antisense technique impairs long-term memory formation (Müller, 1997; Fiala *et al.*, 1999; Eisenhardt *et al.*, 2001). Thus, the expression of some genes involved in synaptic plasticity is enhanced in insect MB neurons. The fruit fly genes for IP_3 receptors and PKC, however, are not reported to be predominantly expressed in the MBs, unlike in the honeybee. The gene (*itp-r*) encoding fruit fly IP_3 receptors is a single copy gene and its expression occurs throughout the cortex of the brain (Hasan and Robash, 1992). Similarly, there are three isoforms of PKC (53E, 53(ey), and 98F) in fruit fly and their expression pattern differs from those of the honeybee orthologue (Rosenthal *et al.*, 1987; Shaeffer *et al.*, 1989). Thus, the expression pattern of some genes involved in Ca^{2+} signal transduction might be associated with the evolution of honeybee MB function. Although the role of Ca^{2+} signal transduction in the MBs is unknown, the function of Ca^{2+} signal transduction might be involved in synaptic plasticity in the honeybee MBs, based on the function of the mammalian and fruit fly orthologues.

What synaptic receptors modulate cAMP or Ca^{2+} signal transduction in the honeybee Kenyon cells? In the honeybee, there are genes for nicotinic acetylcholine receptor α-subunits (Thany *et al.*, 2005), metabotropic glutamate receptors (Funada *et al.*, 2004), dopamine receptors (Humphries *et al.*, 2003), tyramine receptors (Mustard *et al.*, 2005), and octopamine receptors (Farooqui *et al.*, 2004). In honeybees and fruit flies, octopamine and dopamine stimulate adenylyl cyclase via G-protein-coupled receptors (for review, see Davis, 2004). In honeybee, orthologue genes for fruit fly dopamine

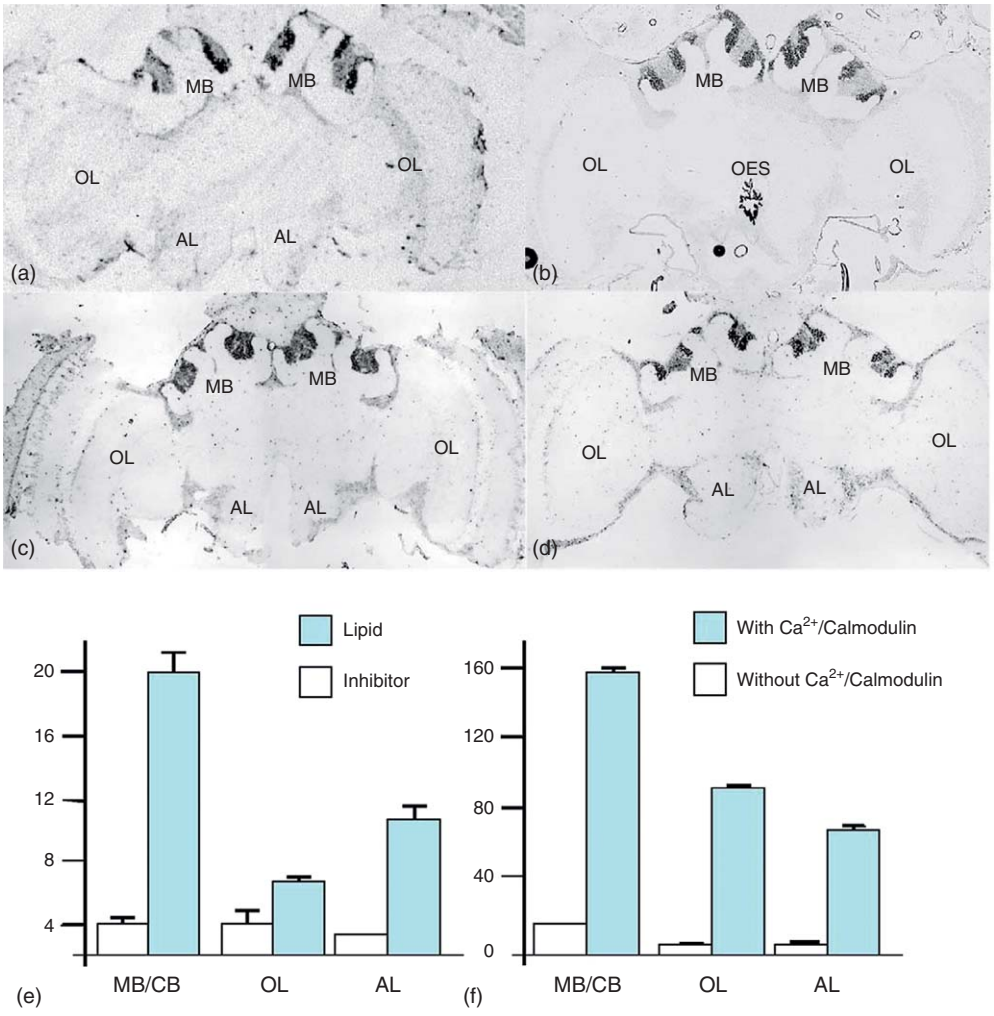

Figure 5 The expression pattern of genes for proteins involved in the Ca^{2+} signaling pathway in the honeybee MBs. a–d, *In situ* hybridization analysis was performed using frozen sections of worker bee brains with a DIG-labeled anti-sense RNA probe. Expression of genes encoding IP_3 receptors (a), IP_3 phosphatase (b), PKC (c), and CaMKII (d) was observed preferentially in the MBs. Furthermore, the expression of genes encoding the IP_3 receptor, IP_3 phosphatase, and CaMKII was observed preferentially in large-type Kenyon cell bodies, which are located at both inside edges of each calyx. e and f, Enzymatic activities of PKC and CaMKII in various regions of the worker bee brain. The *y*-axis indicates units per microgram protein. Enzymatic activities were determined using synthetic oligopeptides as specific substrates for these enzymes. The bars indicate duplicate values of the activities. The activity of PKC in the MB/central bodies (CBs) was higher than that in the optic lobes (OLs) (7.1 times) and antennal lobes (ALs) (2.5 times; e). Similarly, the activity of CaMKII in the MB/CBs was higher than that in the OLs (1.6 times; f) and ALs (2.2 times). These results indicated that the enzymatic activities of PKC and CaMKII are also enriched in the MB/CBs of the worker bee in comparison to other regions of the brain. a, Modified from Kamikouchi, A., Takeuchi, H., Sawata, M., Ohashi, K., Natori, S., and Kubo, T. 1998. Preferential expression of the gene for a putative inositol 1, 4, 5-trisphosphate receptor homologue in the mushroom bodies of the brain of the worker honeybee *Apis mellifera* L. *Biochem. Biophys. Res. Comm.* 242, 181–186, with permission from Elsevier. b, Reproduced from Takeuchi, H., Fujiyuki, T., Shirai, K., *et al.* 2002. Identification of genes expressed preferentially in the honeybee mushroom bodies by combination of differential display and cDNA microarray. *FEBS Lett.* 513, 230–234, with permission from Elsevier. c–f, Modified from Kamikouchi, A., Takeuchi, H., Sawata, M., Natori, S., and Kubo, T. 2000. Concentrated expression of Ca^{2+}/calmodulin-dependent protein kinase II and protein kinase C in the mushroom bodies of the brain of the honeybee *Apis mellifera* L. *J. Comp. and octopamine receptors are also expressed in the MBs (Figure 5). Thus, the major components of the cAMP signaling system seem to be conserved between the two insects. To compare the molecular basis underlying MB functions between honeybee and other insects, it will be important to identify receptors that activate phospholipase C in the honeybee Kenyon cells.

1.29.3 Ecdysteroid Regulated Genes (*Mbk1-1/AmE93* and *AmE74*) in the MBs

A novel gene, *mblk-1* (mushroom bodies large-type Kenyon cells preferential gene -1) encoding a transcription factor was identified as a MB-preferential gene using the differential display method (Takeuchi *et al.*, 2001). *Mblk-1* is preferentially

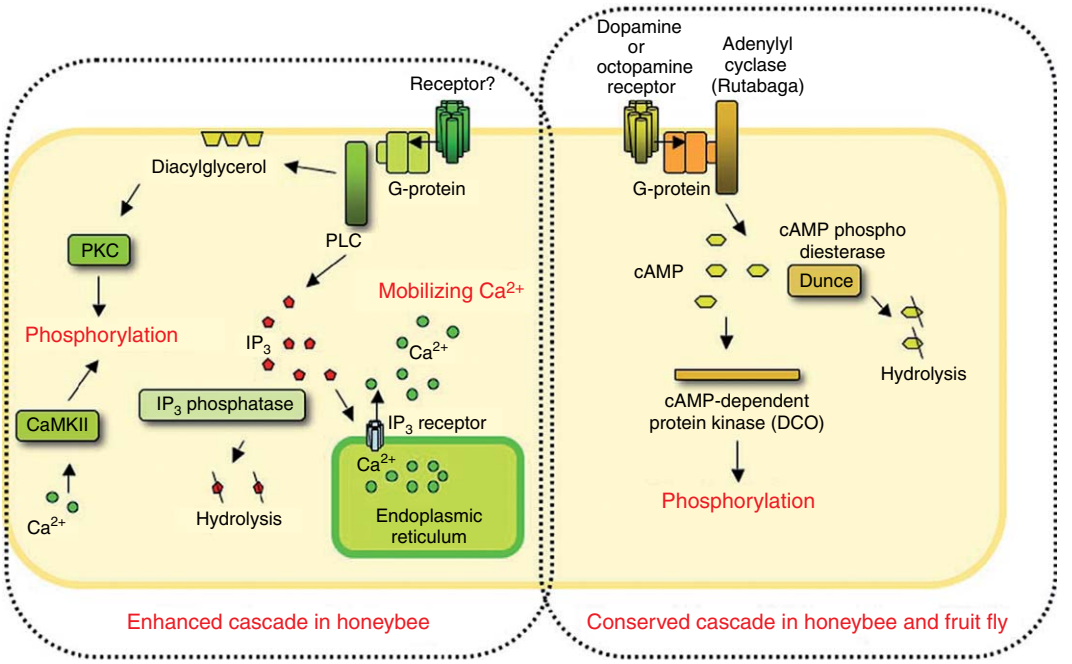

Figure 6 A possible molecular and cellular model as mediated by honeybee Kenyon cells. In fruit fly, plasticity of MB neurons, which underlies olfactory memory, requires the cAMP signaling pathway. Mutants and dominant negatives for the genes *dunce*, *rutabaga,* and *DCO* all had impaired olfactory memory. In the fruit fly, these genes are expressed predominantly in the MBs (for review, see Davis, 2004). The cAMP signaling pathway might be stimulated by neuromodulatory inputs from G-protein-coupled receptors, including dopamine D1-like receptors and octopamine receptors. In both honeybee and fruit fly MBs, PKA gene expression is enhanced. (Müller, 1997). In contrast, the expression of genes encoding PKC, CaMKII, IP_3 receptor, and IP_3 phosphatase are concentrated in the honeybee MBs. Thus, the function of the Ca^{2+} signaling pathway might be enhanced in the honeybee Kenyon cell.

expressed in the large-type Kenyon cell bodies of the MBs (Figures 7a and 7b). Mblk-1 encodes a novel transcription factor, which contains two helix-turn-helix DNA-binding motifs (Figure 8a). Park *et al.* (2002, 2003) demonstrated the biochemical properties of the honeybee Mblk-1. Honeybee Mblk-1 preferentially binds specific DNA sequences (MBE) and transactivates promoters containing MBEs (Park *et al.*, 2002, 2003). Furthermore, mitogen-activated protein kinase (MAPK) phosphorylates recombinant Mblk-1 at Ser-444 *in vitro* (Figure 8b) and Mblk-1-induced transactivation is stimulated by phosphorylation of Ser-444 by the Ras/MAPK pathway in the luciferase assay using insect culture cells (Figure 8c). Interestingly, MAPK gene expression changes according to the division of labor in worker brains (Figure 1). MAPK expression is increased over twofold in foragers compared to nurses (Whitfield *et al.*, 2003). Therefore, it is plausible that Mblk-1 functions as a transcriptional factor in the MB neuronal circuits and that its transcriptional activity might be regulated according to the division of labor (Figure 8d).

There are Mblk-1 orthologue genes in various animals, including fruit fly, nematode, mouse, and human (Figure 8a). Although orthologue genes in these species are also expressed in the nervous system, the involvement of these genes in neurons has not been characterized. In fruit fly and human, the orthologue genes are involved in steroid signaling. In fruit fly, an increase in steroid hormone (ecdysteroid) triggers metamorphosis and induces cell proliferation, cell death, and cell differentiation. The fruit fly orthologue gene of *mblk-1* (E93) is involved in programed cell death in the salivary gland in response to ecdysteroid (Baehrecke and Thummel, 1995; C. Y. Lee *et al.*, 2000). The human orthologue of Mblk-1 (LCoR) binds to the steroid hormone receptor via a LXXLL motif and the steroid hormone-receptor complex represses steroid-induced promoter activity (Fernandes *et al.*, 2003).

What is the expression pattern of other ecdysteroid-regulated genes in honeybee brain? Interestingly, the honeybee orthologue gene of fruit fly *E74* is also preferentially expressed in worker bee MBs, but in the type I small-type Kenyon cells (Figures 7c and 7d). Fruit fly *E74* encodes a transcriptional factor containing Ets DNA-binding domains and its expression is activated by ecdysteroids during metamorphosis. Like

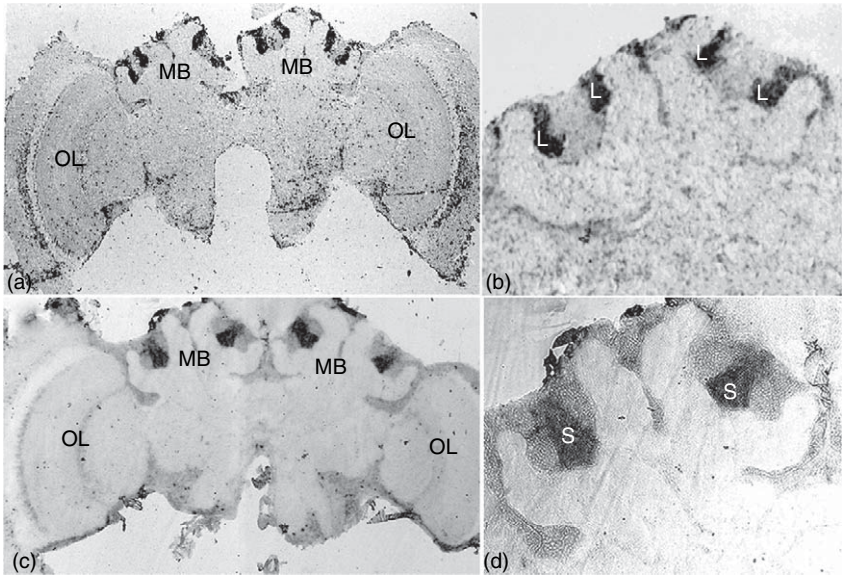

Figure 7 Kenyon cell subtype-selective expression of ecdysteroid-regulated genes (*Mblk-1/E93* and *E74*) in the honeybee MBs. In the worker brain, two ecdysteroid-regulated genes are expressed preferentially in a subset of Kenyon cells; *E74* is expressed selectively in the class I small-type Kenyon cells (S), while *Mblk-1/AmE93* is expressed selectively in the large-type Kenyon cells (L). *Mblk-1/E93* expression is shown in (a) and (b). *E74* expression is shown in (c) and (d). In fruit fly, both *E93* and *E74* are ecdysone-regulated genes, which are necessary for the regulation of ecdysone-triggered programmed cell death during metamorphosis. a and b, Modified from Takeuchi, H., Kage, E., Sawata, M., *et al.* 2001. Identification of a novel gene, Mblk-1, that encodes a putative transcription factor expressed preferentially in the large-type Kenyon cells of the honey bee brain. *Insect Mol. Biol.* 10, 487–494, with permission from Blackwell Publishers Ltd. c and d, Reproduced from Paul, R. K., Takeuchi, H., Matsuo, Y., and Kubo, T. 2005. Gene expression of ecdysteroid-regulated gene E74 of the honeybee in ovary and brain. *Insect Mol. Biol.* 14, 9–15, with permission from Blackwell Publishers Ltd.

E93, *E74* is also required for programed cell death in salivary glands (Lee *et al.*, 2000). In large-type Kenyon cells in the honeybee MBs, the expression of some genes for proteins involved in the Ca^{2+}-signaling pathway IP_3 receptor, IP_3 phosphatase, and CaMK II is enhanced (Figure 5). In the class I small-type Kenyon cells, the cGMP-dependent protein kinase (PKG) gene is preferentially expressed (Ben-Shahar *et al.*, 2002). Thus, some ecdysteroid-regulated genes (*AmE93* and *AmE74*) might regulate the transcription of genes preferentially expressed in a neural subtype-selective manner: *Mblk-1/E93* in the large-type Kenyon cells and *Am*E74 in the type I small-type Kenyon cells.

The endocrine system is important for modulating social status in eusocial Hymenoptera, including the honeybee. In the honeybee, juvenile hormone (JH) has a crucial role in caste differentiation. JH also has a role in age-polyethism of workers and acts as a behavioral pacemaker, modulating task transition (for review, see Robinson *et al.*, 1997). In contrast to the extensive studies of the effects of JH, little attention has been paid to ecdysteroids with respect to their possible involvement in regulating social behavior in the honeybee (Hartfelder *et al.*, 2002). In the honeybee, makisterone A is the principal ecdysteroid involved in molting and metamorphosis (Feldlaufer *et al.*, 1986). The hemolymph ecdysteroid titer is transiently elevated in young workers (Hartfelder *et al.*, 2002). Interestingly, the expression of the ecdysone-inducible orthologue gene *Eip71CD*, which encodes methionine-S-oxide reductase, is significantly enhanced in foragers compared to nurses (Figure 1). Thus, it is possible that ecdysteroid-regulated genes respond to ecdysteroids in the worker brain at a young age to alter neural function in adult worker honeybees. In some insects, ecdysteroids regulate insect neuronal remodeling (for review, see Tissot and Stocker, 2000). For example, in fruit fly brain, the projection of a subset of Kenyon cells changes during metamorphosis and the molecular mechanism underlying MB remodeling has also been characterized. A gene encoding an ecdysteroid receptor isoform (EcR-B1) is specifically expressed in Kenyon cells destined for remodeling, and mediates morphologic changes of the Kenyon cell axons during metamorphosis (T. Lee *et al.*, 2000; Zheng *et al.*, 2003). It might be possible that honeybee genes, whose orthologues are involved in neuronal remodeling

during metamorphosis in other insects, regulate the MB neuronal remodeling underlying the division of labor during the adult stage. Another possibility is that ecdysteroid-regulated genes (*Mblk-1/E93*, *E74*) function independently of ecdysteroids in the adult brain, as the hemolymph ecdysteroid titer of adult workers is much lower than that during metamorphosis.

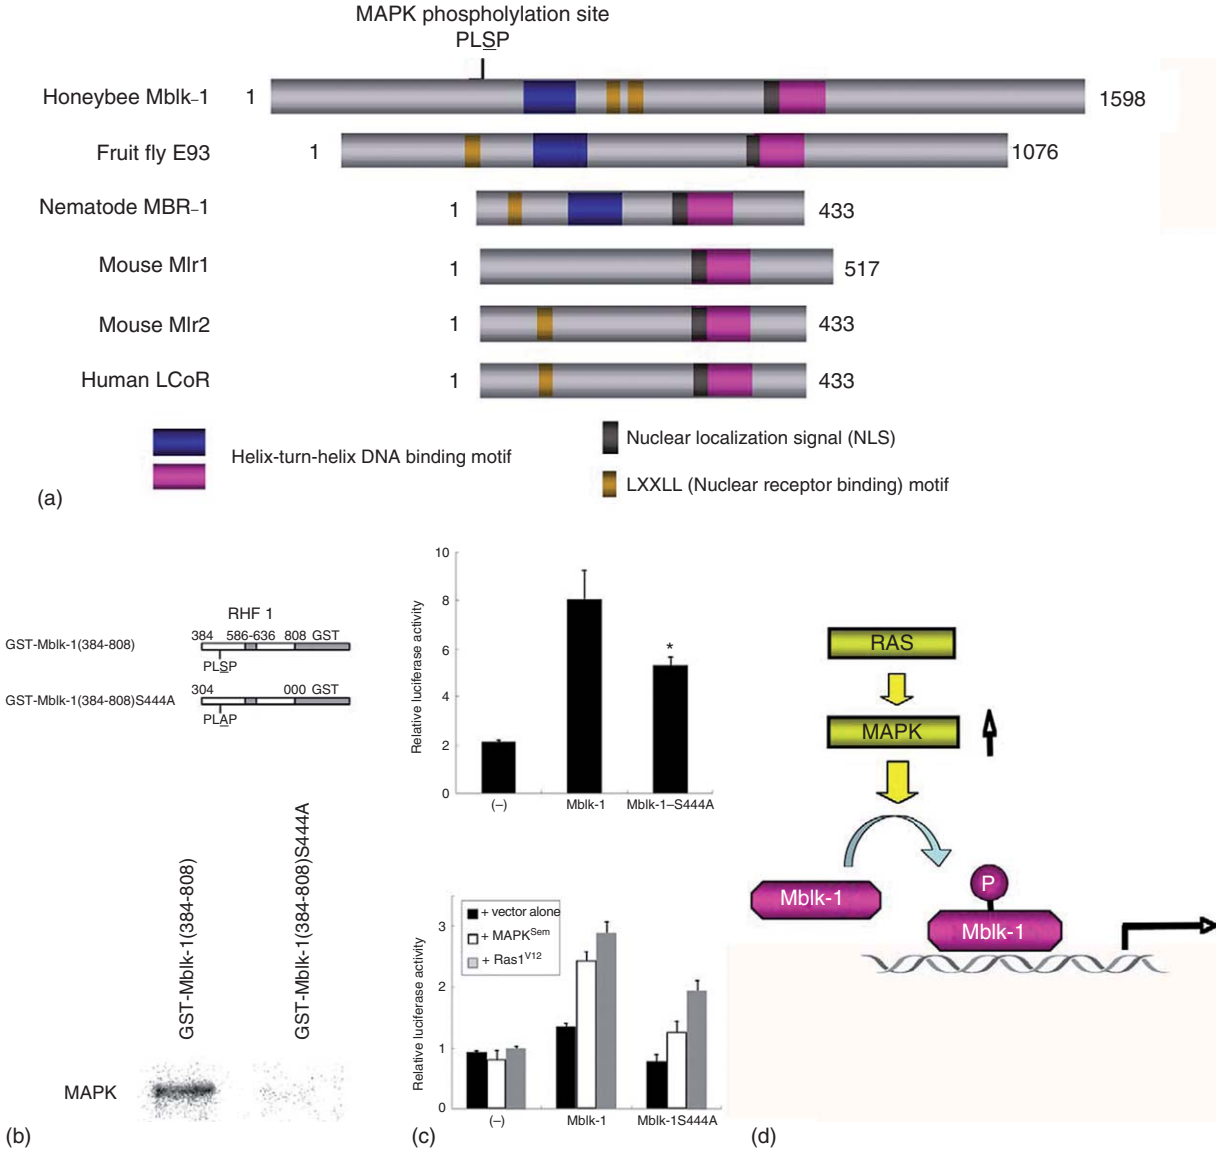

Figure 8 *Mblk-1* encodes a novel transcription factor. a, Comparison of the domain structures of Mblk-1 orthologues. The helix-turn-helix DNA binding motif of Mblk-1 has significant similarity with those of fruit fly E93 (Baehrecke and Thummel, 1995), nematode MBR-1 (Kage *et al.*, 2005), mouse Mlr1 and Mlr2 (Kunieda *et al.*, 2003), and human LCoR (Fernandes *et al.*, 2003). Human LCoR can interact with nuclear receptors (estrogen receptor) via the LXXLL motif, and this motif is also conserved; b, Mitogen-activated protein kinase (MAPK) phosphorylated Mblk-1 at Ser-444 *in vitro*. Mblk-1 contains a single consensus phosphorylation sequence (P*X*(S/T)P) for MAPK. The phosphorylated or mutant residue is underlined. The truncated Mblk-1 (GST-MBlk-384-808) can be phosphorylated by MAPK, while the mutant protein (GST-MBlk-1 384-808 S444A, where a phospho-acceptor residue, Ser-444, is changed to Ala), is not phosphorylated by MAPK; c, Mblk-1-induced transactivation is stimulated by phosphorylation of Ser-444 by the Ras/MAPK pathway in the luciferase assay using *Drosophila* Schneider's line 2 cells. Luciferase activity increases for the reporter vector containing six MBE elements, when exogenous Mblk-1 is expressed. The enhanced luciferase activity is significantly reduced using mutant Mblk-1S444A protein (upper panel). Co-expression of $MAPK^{Sem}$ or the $Ras1^{V12}$ plasmid, which are activated forms of *Drosophila* MAPK or Ras1, respectively, increases the transcriptional activity of intact Mblk-1 approximately twofold; d, The possible function of Mblk-1 in the honeybee MBs. Mblk-1 is a transcription factor that might function in the MBs neuronal circuits downstream of the Ras/MAPK pathway in the honeybee brain. As the expression of a gene encoding MAPK is enhanced in the forager bee, the Mblk -1 transactivation might be regulated according to the division of labor. b and c, Reproduced from Park, J. M., Kunieda, T., and Kubo, T. 2003. The activity of Mblk-1, a mushroom body-selective transcription factor from the honeybee, is modulated by the ras/MAPK pathway. *J. Biol. Chem.* 278, 18689–18694, with permission from American Society for Biochemistry and Molecular Biology.

1.29.4 Gene Expression of Preprotachykinin Gene in the Honeybee Brain and Other Insects

In some animals, neuropeptides are important for modulating social behaviors (for review, see Robinson, 2005). For example, in voles, two neuropeptides are critical mediators of partner-preference formation: oxytocin and arginine vasopression (for review, see Insel and Young, 2001). In nematode, social feeding is associated with the G-protein-coupled receptor NPR-1, which is activated by FMRFamide-related neuropeptide encoded by *flp-18* and *flp-21* (Rogers *et al.*, 2003).

What are the endogenous neuropeptides that function in the honeybee MBs? To determine the synthesis and expression of bioactive peptides in the honeybee MBs, the combined techniques of MALDI-TOF MS, molecular cloning, and online capillary reverse-phase high pressure liquid chromatography/quadrupole orthogonal acceleration time-of-flight (Q-Tof)-MS were applied. MALDI-TOF is a powerful tool for direct analysis of peptide profiles from small pieces of dissected tissue (for review, see Li *et al.*, 2000).

To identify neuropeptides from the honeybee MBs, MALDI-TOF MS was directly applied to slices of worker honeybee brain (Takeuchi *et al.*, 2003). Some peptides were detected as major peaks from the MB area. Based on Q-Tof MS/MS analysis, the sequence of a peak at mass *m/z* 994 was assigned as APMGFQGMRamide (Figure 9), which is a honeybee tachykinin-related peptide homologue (*Apis mellifera* tachykinin-related peptide, abbreviated AmTRP). cDNA cloning revealed that AmTRP is synthesized from precursor molecules that contain six forms of AmTRP. TRPs have been identified in various insects (for review, see Nässel, 1999, 2002). Although TRPs have neuromodulatory actions on central nervous system interneurons in locust (Lundquist and Nässel, 1997), the *in vivo* function of insect TRPs remains unclear. In blowfly, locust, cockroach, and *Drosophila*, mapping of TRP-immunoreactive neurons suggests a role for TRPs in central nervous system interneurons and in some other neurons that might regulate hormone release (for review, see Nässel, 1999). *In vitro* experiments indicate that most insect TRPs have a myostimulatory role in visceral (hindgut and oviduct) muscle (Kwok *et al.*, 1999).

In situ hybridization of the *AmTRP* gene revealed that the prepro-AmTRP gene is expressed preferentially in the honeybee MBs (Figure 9b). There are no reports of TRP-expression in the MB neurons (Kenyon cells) of other insect brains (Nässel, 1993, 1995; for review, see Nässel, 1999, 2002) Thus, prepro-TRP gene expression in Kenyon cells might be characteristic of the honeybee. In the MBs, the prepro-AmTRP gene is strongly expressed in the small-type Kenyon cells and weakly expressed in some of the large-type Kenyon cells with somata located at the inside edges of each calyx (Figure 10). Other than MBs, AmTRPs are expressed in the honeybee brain in a pattern that is similarly conserved among insect species (Nässel, 2002). In cockroach and locust brain, the TRP-immunoreactive neurons are interneurons that

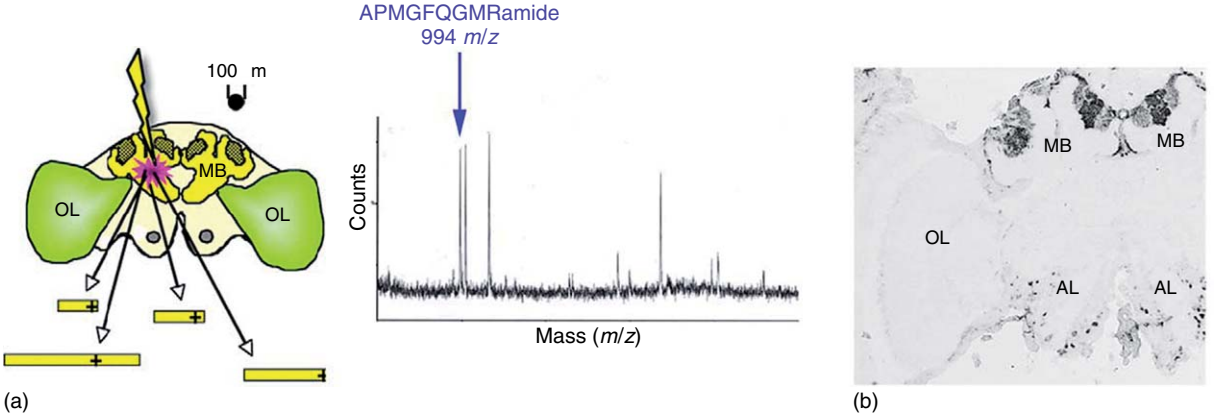

Figure 9 a, MALDI-TOF MS was directly applied to slices of worker honeybee brain. The matrix-coated brain section was mounted on a MALDI plate that can be moved within the MALDI source to expose the area of interest to the fixed position of the laser beam. Based on Q-Tof MS/MS analysis, the sequence of one of these peptides (mass *m/z* 994) was assigned as APMGFQGMRamide. Tachykinin-related peptides are characterized by the preserved C-terminal portion as FX1GX2Ramide (X1 and X2 are variable residues). As the extent of the laser beam is 100 μm, which is indicated by the black closed circle, the peptide profile from the MBs can be analyzed using this method; b, *In situ* hybridization indicates that the expression of the gene encoding the peptide is enhanced in the honeybee MBs.

have neurites projecting toward the antennal lobes, optic lobes, and central bodies. In the moth, TRPs are expressed in the cerebral neurosecretory cells (Kim *et al.*, 1998). The prepro-*Am*TRP gene is also expressed in the optic lobes, antennal lobes, and subesophageal ganglion, suggesting that the expression of TRPs in these brain regions is also conserved in the honeybee (Figure 10).

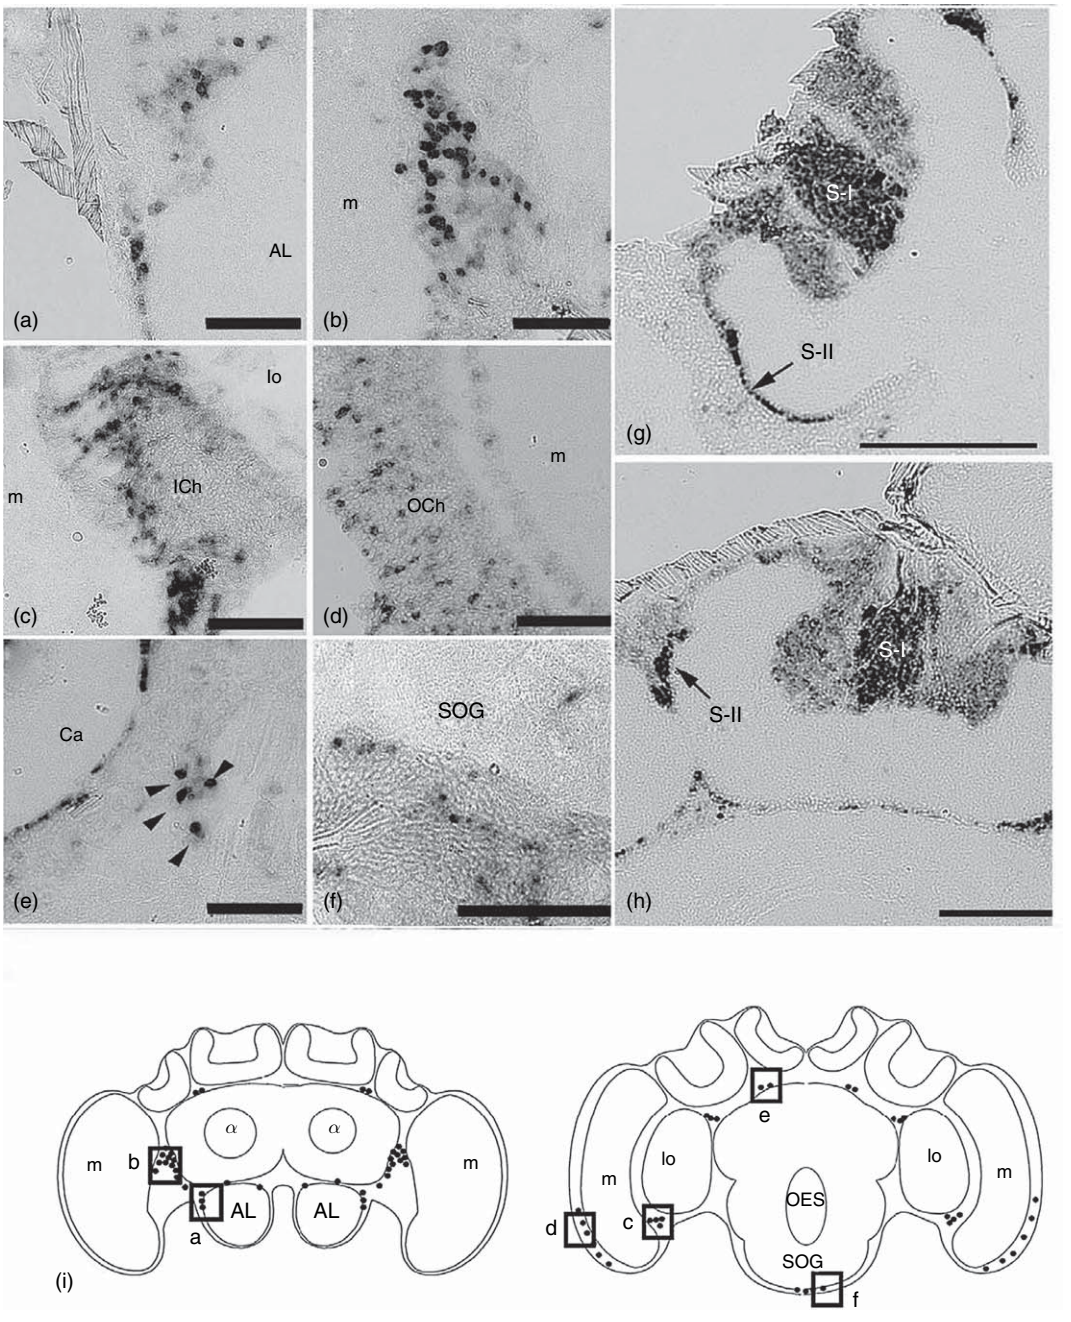

Figure 10 Expression of the tachykinin gene in the honeybee brain. S-I, somata of class I small-type Kenyon cells; S-II, somata of class II small-type Kenyon cells. Bars indicate 100 μm; i, Schematic illustration of honeybee brain section (left, anterior part; right, posterior part) to show brain regions (a–f). a–i, Reproduced from *Cell Tissue Res.*, vol. 316, 2004, pp. 281–293, Prepro-tachykinin gene expression in the brain of the honeybee *Apis mellifera*, Takeuchi, H., Yasuda, A., Yasuda-Kamatani, Y., *et al.*, figures 2 and 3. With kind permission of Springer Science and Business Media.

How does *AmTRP* expression change according to age/division of labor, caste, and sex in honeybees? *In situ* hybridization indicates that there is no difference in *Am*TRP-expressing cells among worker, queen, and drone brains, suggesting that the cell types that express the prepro-*Am*TRP gene do not change according to division of labor, caste, or sex (Takeuchi *et al.*, 2004). Northern blot analysis of RNA from the head of nurse and forager bees, however, indicates that *AmTRP* expression in the head changes depending on age/division of labor and sex of the honeybees, suggesting that the AmTRP peptide functions as a neuromodulator associated with sex-specific or age/division of labor-selective behavior (Figure 1). Considering that *Am*TRP gene expression is enhanced in the MBs, which are believed to be associated with social behavior, *Am*TRP is a strong candidate neuropeptide involved in the social behavior of honeybees. In the honeybee, PKG gene expression is enhanced based on the division of labor of the workers, like the AmTRP gene, and enhanced PKG activity induces foraging behavior (Figure 1) (Ben-Shahar *et al.*, 2002). Interestingly, in honeybee MBs, the PKG gene is also selectively expressed in the small-type Kenyon cells (Ben-Shahar *et al.*, 2002). AmTRPs might be involved in the division of labor, associated with PKG function, in the small-type Kenyon cells.

1.29.5 Discussion and Future Prospects

In this article, the identification and expression of some genes expressed preferentially in honeybee MBs are described. These are strong candidate genes that are associated with honeybee social behavior and the evolution of honeybee MB function. Recently, analysis of honeybee molecular biology has greatly progressed and the Human Genome Sequencing Center at the Baylor College of Medicine is currently sequencing the honeybee genome, which has allowed us to identify more MB-preferential genes. For example, genome-wide screening of the genes of interest using DNA microarray is in progress (Takeuchi *et al.*, 2002; Whitfield *et al.*, 2003; Robinson *et al.*, 2005). The honeybee genome project has also helped to identify possible *cis*-regulatory elements involved in MB-selective expression, which could unveil the molecular mechanisms underlying transcriptional regulation of these genes. One possible strategy to investigate honeybee MB evolution is to compare the promoter regions of these genes with their orthologues in other insects and to identify the genomic regions underlying the unique expression pattern of genes for the Ca^{2+} signaling pathway and/or tachykinin in the honeybee brain.

Further studies are needed to clarify the molecular functions of MB-preferential genes in honeybees. Gene manipulation techniques such as RNA interference (Farooqui *et al.*, 2003, 2004) and in *vivo* electroporation (Kunieda and Kubo, 2004) can be applied to bees. A combination of behavioral and neurobiologic methods will contribute to clarifying the molecular mechanisms underlying honeybee social behavior. A comparison of the functions and expression patterns of the MB-preferential genes with their orthologues among insects will contribute to a better understanding of the evolution of honeybee brain and behavior.

Acknowledgments

Most studies described here were performed in Prof. Takeo Kubo's laboratory (The University of Tokyo), which were mainly supported by the Program for Promotion of Basic Research Activities for Innovative Bioscience (PROBRAIN). I would like to express my sincere gratitude to Prof. Kubo and his collaborators: Drs Kazuaki Ohashi, Takekazu Kunieda, Miyuki Sawata, Azusa Kamikouchi, Eriko Kage, Jung-Min Park, Rajib Kumar Paul, Tomoko Fujiyuki, and Kenichi Shirai; Ms. Maya Ohara and Matsuo Yuko for their collaborations. My special thanks are for Drs Akikazu Yasuda, Yoshimi Yasuda-Kamatani, and Terumi Nakajima (Suntory Institute for Bioorganic Research), and Ms. Akiko Wakamoto (DNA Chip Research Inc.) for their collaborations on MALDI-TOF/MS and cDNA microarray experiments, respectively. Finally, I would like to express my deepest gratitude to Prof. Nicholas J. Strausfeld (The University of Arizona) for providing me the opportunity to write this manuscript.

2.01 Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes

B Fritzsch, Creighton University, Omaha, NE, USA
J C Glover, University of Oslo, Oslo, Norway

Glossary

acrania	A chordate with no obvious head (such as the lancelet, Amphioxus).
axon	Neuronal process typically involved in emitting output.
BF1 (Foxg1)	Brain forkhead gene 1 (forkhead gene g1).
bHLH	Basic helix-loop-helix gene (transcription factors such as Atoh1, Neurog1).
BMP	Bone morphogenic protein.
cephalochordate	Animals in which the notochord extends throughout the body, including the most rostral of head part (see acrania).
chordate	Deuterostome animals with a notochord.
coelenterate	Radial symmetric, diploblastic animals (jellyfish, corrals, cnidarians).
craniate	A chordate with fully developed head (cyclostomes and gnathostomes).
cyclostomes	Jawlesss with a circular mouth (lampreys and hagfish).
dendrite	Neuronal process(es) typically involved in receiving input.
deuterostomes	Animals in which the invaginating gastroporus becomes the anus.
Dmbx	Diencephalon/mesencephalon homeobox 1.
ecdysozoans	Animals that use ecdyson for molting.
En	Engrailed gene.
FGF	Fibroblast growth factor.
GABA	Gamma-amino-butyric acid.
Gbx	Gastrulation brain homeobox gene.
genotype	The sequence of all or of specific genes.
gnathostomes	Jawed vertebrates (sharks, bony fish, tetrapods).
hemichordates	Animals with a notochord equivalent.
hodology	Connections between a complex set of neuronal entities.
Hox	Homeobox gene.
lophotrochozoans	Animals that develop larvae with a lophotroch.
MHB	Midbrain/hindbrain boundary.
nerve	Bundle of nerve fibers in the PNS.
Otx	Orthodenticle homologue gene.
Pax	Paired box gene.
phenotype	The endproduct of all genes.
progenitor(s)	An incompletely committed cell or population of cells.
protostomes	Animals in which the invaginating gastroporus becomes the mouth.
rhombomere	Compartment of the hindbrain.
topology	The position of structures such as nerve centers in a defined spatial relationship.
tract	Bundle of nerve fibers running in the CNS.

transcription factors	Proteins that bind to DNA to regulate gene transcription.
urochordates	Animals in which a notochord exists only in the tail (tunicates, ascidians).
Wnt	Wingless-type MMTV integration site family member.

2.01.1 Introduction

Multicellular animals other than sponges, coelenterates and some other basic taxa have a sizable portion of their nervous system grouped into a more or less continuous tissue aggregate, referred to as the central nervous system (or CNS: comprising the brain and spinal cord in vertebrates, the preoral and postoral chain of ganglia in invertebrates). Evolution of this centralized nervous system from a diffuse epidermal nerve network such as is present in more primitive taxa requires a reorganization or elaboration at two basic levels. First, patterning of the developing embryo must establish the position and size of the CNS anlage within the ectoderm, possibly by co-opting existing genes into a new developmental module. Second, the specification of neuronal phenotypes (which in taxa without a CNS is limited predominantly to simple neurosensory and neuromuscular cells whose connections provide limited integrative capacity) must provide molecular diversity to develop an expanded interneuron population that permits the sophisticated sensorimotor processing and integration necessary to govern the more complex motor repertoires exhibited by animals with a CNS.

Although some rudiments of the relevant molecular developmental modules are traceable to taxa without a CNS (Martindale *et al.*, 2004), the evolutionary elaboration has reached paramount status in animals in which the two basic levels have become interdependent features of an integrated process of neural patterning. In these animals, the developmental process that creates the neuronal phenotype diversity has become integrated into the patterning process to generate specific neurons in the correct places, to specify their migratory pathways and their dendritic and axonal growth patterns (in an interaction with environmental influences) to form a characteristic pattern of tracts and nerves, and to regulate proliferation and survival so that the appropriate adult number of neurons is established and maintained (Ghysen, 2003). The evolutionary transformation of a distributed subectodermal nerve net into a highly patterned CNS with numerous compartments, each containing a rich variety of characteristic neuronal types, must be explained as a well-coordinated progression of cell specification at the global and local levels. Moreover, evolution of the structure of the CNS also has to be integrated with the evolution of more sophisticated sensory apparatuses. Combination of the two would facilitate the extraction of more specific sensory information and its utilization to govern more graded and detailed motor responses, thus endowing the bearer of a given modification with enhanced survival.

A narrative of brain evolution can be assembled through a deconstruction process in which various nervous systems of extant animals are compared and a common set of principal features, or Bauplan is deduced. The validity but also the limitations of this approach are discussed in recent reviews (Butler and Hodos, 1996; Nieuwenhuys *et al.*, 1998). While successful at the level of the CNS of craniate vertebrates, it has only limited analytic power at the level of animals without a CNS such as coelenterates and basic bilaterians. Ultimately, the insights gained by this approach have to be related to the developmental patterning mechanisms that regionalize the neural anlage and specify the various populations of neurons within it (Puelles and Rubenstein, 2003). At the core of any model of brain evolution must therefore be the evolution of the transcription factors and intercellular signaling molecules that govern the patterning events necessary for CNS development (Ghysen, 2003; Holland, 2003; Lowe *et al.*, 2003; Meinhardt, 2004) and cell type-specifying transcription factors that govern the evolution of unique cell fates in specific locations (Bermingham *et al.*, 2001; Ghysen, 2003).

In this review we will outline first the basic brain organization of a cyclostome to highlight the differences from the epithelial nerve net found in hemichordate taxa (Figure 1), an outgroup of chordates among deuterostomes. We then briefly compare the major organizational differences in the CNS of adult chordates and other deuterostomes, and highlight what we consider to be the minimal steps in development necessary to generate a craniate nervous system. We then provide an overview of our understanding of the developmental patterning events that underlie CNS regionalization in major deuterostome phyla and then highlight the molecular interactions between regional patterning and neuronal phenotype determination. Finally, to underscore the importance of functional context in brain evolution, we briefly outline how the evolution of the CNS might be related to evolution of the peripheral nervous system (PNS), in particular the evolution of major sensory systems.

We hope that this review, as incomplete a snapshot of our current insight and ignorance as it is, will nevertheless provide a basis for critical and fruitful discussion of the hypotheses and ideas presented.

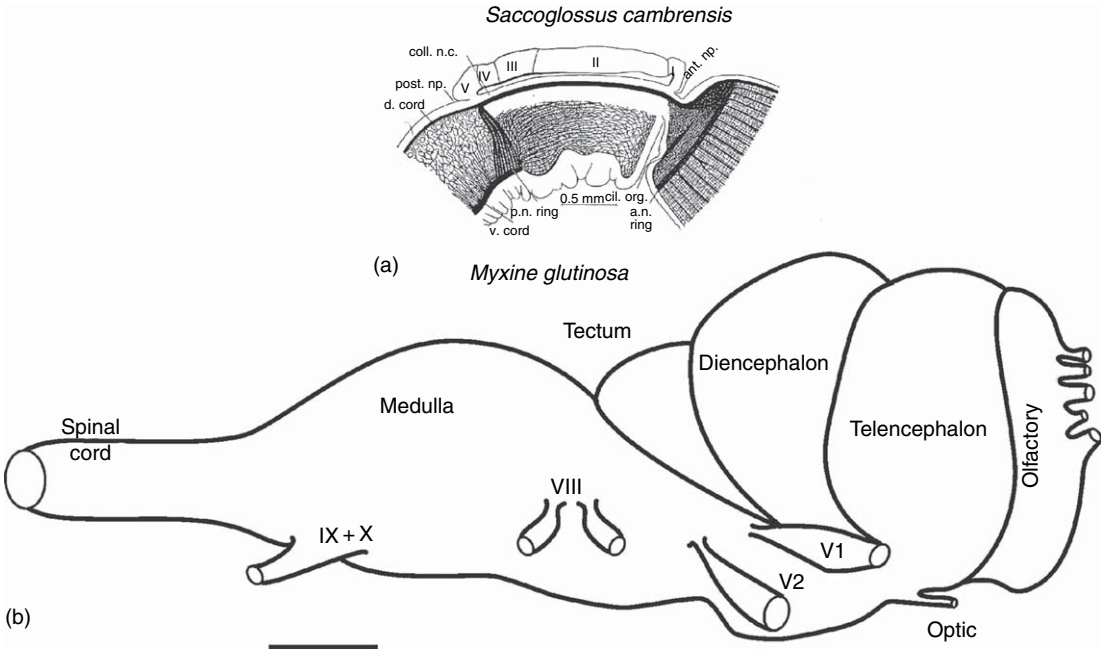

Figure 1 A hemichordate (a) and craniate (b) CNS compared at the same scale. Enteropneust hemichordates have an epidermal nerve network that shows condensations in certain areas. At the base of the proboscis is an anterior nerve ring (a.n. ring) that is next to the ciliary organ (cil. org), which is adjacent to the oral opening (org). The collar region has a collar nerve cord (coll. n.c.), an invaginated part of the epidermis with anterior and posterior neuropores (ant. np., post. np.) that lies dorsal to the buccal cavity. At the third body division, the metasome, the collar nerve cord becomes confluent with the dorsal nerve cord (d. cord) and, through the posterior nerve ring (p.n. ring), with the larger ventral cord (v. cord). Neither true nerves nor major sensory organs are apparent in this simple epithelial nerve net. In contrast, craniates (here shown is a hagfish) have a typical craniate brain that develops from invaginated ectoderm that becomes completely transformed into nervous tissue but remains confined within the former epithelial basement membrane. Only numerous distinct nerves pass through the basement membrane to connect the brain with various multisensory organs that provide chemical (olfaction and taste), mechanical (touch and vestibular sense), and visual (eyes) input for the brain to integrate into a motor output that is elicited via the brainstem and spinal cord. Adapted from Bullock and Horridge (1965) and Nieuwenhuys *et al.* (1998).

2.01.2 Cladistic Analysis of Major Differences in the Deuterostome Metazoan CNS

Analysis of CNS morphology has to be rooted in an independently corroborated cladistic analysis of the taxa to be investigated, for example, based on gene sequence data (Figure 2). Such analysis exists for only some genes, including the 18s ribosomal DNA, and relationships are likely to change as more data are considered. It should be stressed that the most recent molecular analysis has strongly supported the grouping of all extant jawless craniates into a single taxon, the cyclostomes (Winchell *et al.*, 2002; Takezaki *et al.*, 2003). This analysis also supported the sister taxon relationships of hemichordates and echinoderms and of cephalochordates and craniates. However, it only weakly supported a coherent chordate taxon, indicating that the apparent morphological similarities among chordates are imposed on deep divisions among extant deuterostome taxa (see Origins of the Chordate Central Nervous System: Insights from Hemichordates, Evolution of the Amphibian Nervous System).

Obviously, characters should be grouped to fit to such cladograms with minimal additional assumptions. Given that these separations in deuterostome phyla are approximately 600 million years old, it is to be expected that none of the crown taxa will in actuality reflect the ancestral features but rather will represent each its own idiosyncratic mix of characters retained in nearly ancestral states, characters transformed, and characters evolved anew. Such assumptions are warranted as genetic analysis has shown that about 30% of the genes of mammals are not shared with insects and likely arose after the split of protostomes from deuterostomes (Venter *et al.*, 2001). This split also led to an increase in the number of genes including generation of multiple orthologues (Wada *et al.*, 1998; Meinertzhagen *et al.*, 2004).

2.01.2.1 Principles of Comparative Neuroanatomy

Chordate brains are basically two-dimensional sheets of epithelial cells that have been folded during

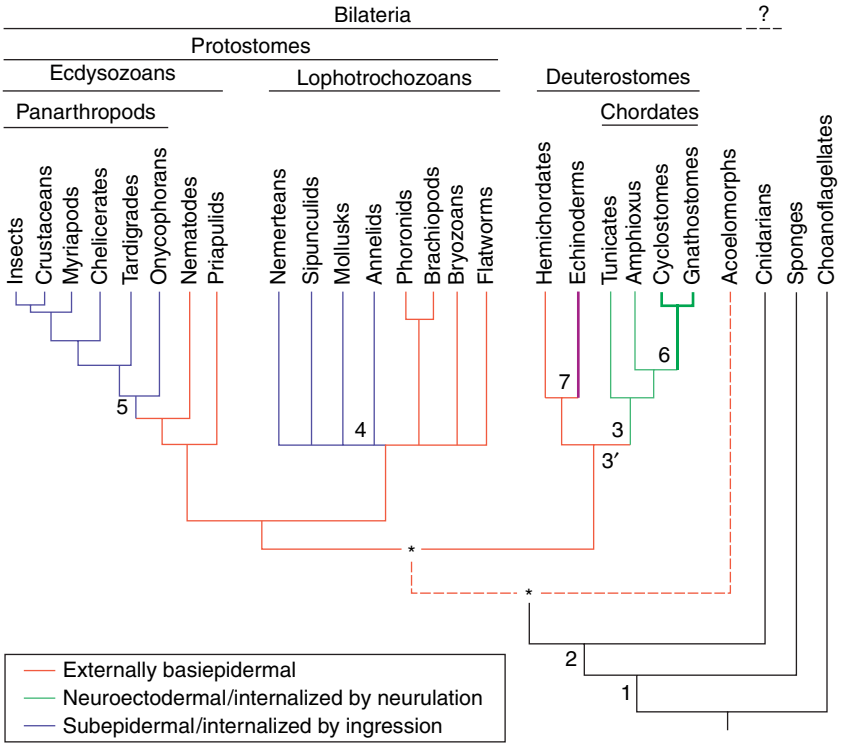

Figure 2 This cladogram of animal relationships shows major evolutionary steps in the generation of the nervous system. Outgroup comparison suggests that ancestral deuterostomes had an epidermal nerve plexus. Formation of a dorsal hollow nerve tube characterizes chordates (3), but a hollow epithelium with an epithelial nerve plexus is also found in hemichordates, suggesting that invagination of ectoderm may be primitive for deuterostomes (3′). Transforming the neural tube into a brain coincides with the formation of all craniate sensory systems, the eyes, ears, olfaction, taste, and lateral line (6). Clearly, under any scenario, the pentameric nervous system of echinoderms is considered as secondarily derived (7). Other major steps in evolution of the brain were the formation of interneurons (1) and the formation of a basiepithelial nerve net (2). Internalized nervous systems evolved independently in lophotrochozoans (4) and ecdysozoans (5). Asterix indicates uncertainty for the position of the common ancestor of deuterostomes and protostomes. Note that some data question the coherence of the taxon chordates (Winchell *et al.*, 2002). Adapted from Holland, N. D. 2003. Early central nervous system evolution: An era of skin brains? *Nat. Rev. Neurosci.* 4, 617–627.

development in various ways, have translocated below the epidermis and have differentially increased in thickness. Within this tissue sheet, connections are established that provide highways for information flow from sensory inputs, such as the eye, to motor outputs, such as spinal motoneurons. Comparative neuroanatomy tries to unravel the basic organizational principles of neuron populations and fiber tracts, whereas comparative embryology tries to relate species differences in this organization to developmental modifications, and ultimately to alterations in genes or gene expression (Fritzsch, 1998; Nieuwenhuys *et al.*, 1998; Nieuwenhuys, 2002). Essential for this approach is that the sameness of a given structure has to be established to verify homology. Two principal criteria have been used to identify homologous structures in the brain: topology and hodology. Topological analysis compares the relative positions of structures and neuron groups, preferably tracing them back to their origins in the proliferative centers at the ventricles (Bayer *et al.*, 1993). This approach can lead directly to the definition of a blueprint of clonal origin of neurons that can be related to transcription factor expression at the start of brain development and can therefore be integrated with known alterations in the sequences (both coding and regulatory sequences) and expression patterns of genes (Shubin *et al.*, 1997; Puelles and Rubenstein, 2003). Once completed, this approach will allow for establishing homology of a given neural structure across phyla using both topological and genetic criteria (Holland *et al.*, 1992; Takahashi and Holland, 2004). Such a phylogenetic definition of homology for the nervous system will have to face issues of homoplasy, deep homology, and serial homology, all problems already raised for the evolution of other systems (Figure 3).

A second approach to generating a blueprint of vertebrate and invertebrate brains is through hodological analysis of connections (Herrick, 1948; Butler and Hodos, 1996). Ideally, connections

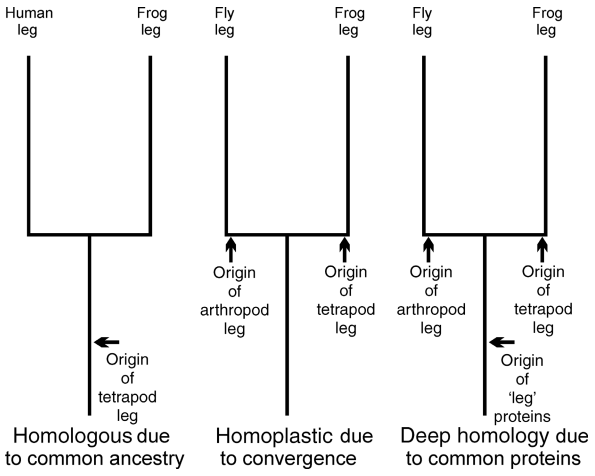

Figure 3 The basic problem of evolutionary homology is depicted. Homologous structures, such as various tetrapod appendages, are considered homologous because they all derive from the ancestral tetrapod limb. In contrast, homoplastic characters are independently derived from an ancestor that had no legs. Deep homology is rooted in molecular mechanisms as well as morphological similarity. For example, recent data shows that the proteins governing leg development are conserved across phyla, indicating that the molecular evolution predated the morphological evolution. Cases for which deep homology (also known as homocracy; Nielsen and Martinez, 2003) has been argued include the legs of arthropods and vertebrates, and the eyes and ears of multiple phyla. Whether this is also the case for brains remains more controversial (Arendt and Nubler-Jung, 1999; Lowe *et al.*, 2003; Meinhardt, 2004). Modified from Arthur (1997), Fritzsch and Beisel (2004), Kozmik *et al.* (2003), and Shubin *et al.* (1997).

between topologically identifiable neuron populations should exhibit a substantial degree of conservation through evolution, because the molecular basis for the homology of neuron populations is also likely to be involved in guiding axon pathway selection by the neuron populations that are specified. Indeed, numerous pathway selection genes appear to be conserved across phyla, suggesting that pathway selection molecules arose early in metazoan evolution (Ghysen, 2003). Nevertheless, the only existing direct analysis that compares cytoarchitectonic and hodologic approaches shows limited congruence between the two blueprints (Diaz *et al.*, 2003). In addition, despite the absence in animals such as salamanders of recognizable neuronal condensations that can be identified cytoarchitectonically, these brains nevertheless exhibit distinct fiber projections that allow for hodological comparisons across phyla in adults (Herrick, 1948; Nieuwenhuys *et al.*, 1998) and during development (Rettig *et al.*, 1981). Hodology may therefore provide a stronger basis for comparison than cytoarchitectonics, even if it does not derive from cytoarchectonically distinct groups of neurons, the so-called nuclei.

The analysis provided below will follow both of these approaches (topological and hodological), keeping in mind that topological relationships can be complicated through postnatal migration, modifications of input and output relationships, and alterations in absolute positions owing to intercalation of different cellular masses (Glover, 2001).

2.01.2.2 Comparative Appearances of Brains, Spinal Cords, and Nerves

2.01.2.2.1 Craniates (cyclostomes and gnathostomes)

The jawless cyclostomes, lampreys and hagfish, constitute a basic clade of craniates that shows the major features of brain organization also found in gnathostomes (jawed vertebrates). Externally, the brain of extant cyclostomes consists of a bilaterally symmetric rostral enlargement, the forebrain (telencephalon). This is composed of an olfactory bulb and a cerebral hemisphere (Figure 4). Each hemisphere is connected to the single, bipartite diencephalon. The diencephalon gives rise to a number of neural appendages. Ventrolaterally are located the paired optic nerves leading to the lateral eyes. Dorsally lies a single enlargement, the habenula, that in lampreys, but not hagfish, has an attached pineal organ (Pombal *et al.*, 1999). Ventrally is located the pituitary gland. The central ventricle of the diencephalon is continuous with the ventricle in the midbrain, the hindbrain, and the central canal of the spinal cord, all of which are greatly reduced in hagfish (Nieuwenhuys *et al.*, 1998). Lampreys have a dorsal central opening in the midbrain that is covered by a choroid plexus, a uniquely derived feature of lampreys not shared by other craniates. Lampreys have an oculomotor nerve leaving the midbrain ventrally, which hagfish do not possess. Likewise, the next more caudal nerve found in lampreys, the trochlear nerve, exiting lateral to the cerebellum, is not found in hagfish. Caudal to the small cerebellum in lampreys is the rhombencephalon (hindbrain) with a large choroid plexus covering the IVth ventricle. A small ventricle is also found in hagfish but there is no trace of a choroid plexus and the presence of a cerebellum has been questioned (Nieuwenhuys *et al.*, 1998). Whether the absence of a choroid plexus in hagfish is primitive and related to the unusual isotonicity of hagfish to seawater (Griffith, 1987) remains unclear.

As discussed previously (Fritzsch and Northcutt, 1993), lampreys have all the hindbrain nerves found in gnathostomes (trigeminal, abducens, facial, otic or statoacoustic, glossopharyngeus, and vagus), with the possible exception of the hypoglossal

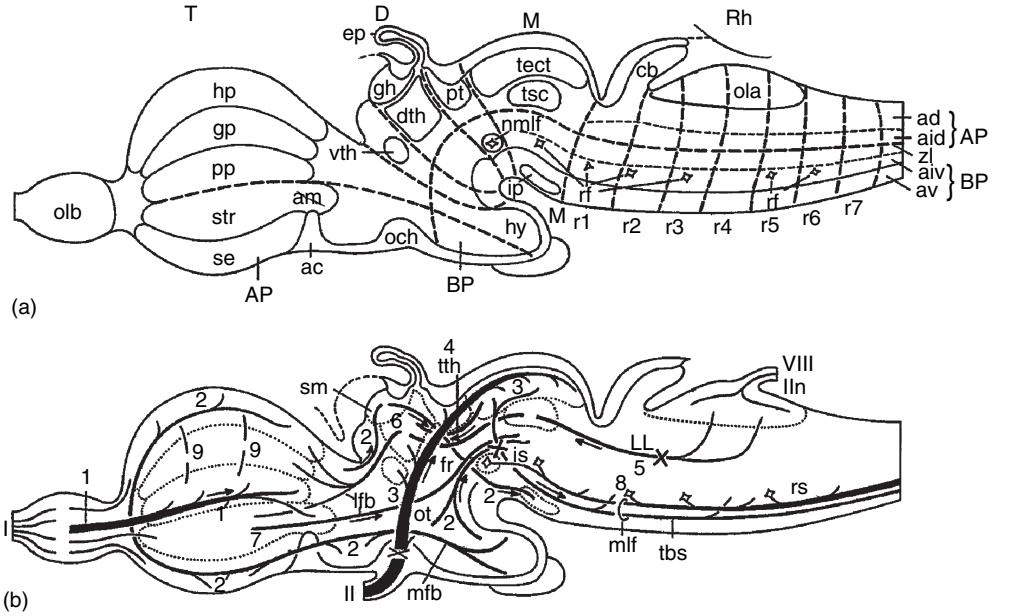

Figure 4 Basic organization (a) of a craniate brain (T, telencephalon; D, diencephalons; M, mesencephalon; Rh, rhombencephalon) and fiber tracts (b) are shown. Longitudinal divisions are the alar plate (AP) and basal plate (BP), which are separated by the sulcus limitans (zl). Each of these plates is subdivided into two areas (ad, area dorsalis; aid, area intermediodorsalis; aiv, area intermedioventralis; av, area ventralis). The rhombencephalon has approximately seven rhombomeres (r1–r7) with motoneurons and the reticular formation (rf) deriving from the basal plate and the octavolateral area (ola) and cerebellum (cb) from the alar plate. The midbrain has the tectum (tect), torus semicircularis (tsc), and interpeduncular (ip). Several prosomeres are shown in the diencephalon that extend from the hypothalamus (hy) to the pallium (hp, hippocampal pallium; gp, general pallium; pp, piriform pallium) and basal telencephalon (str, striatum; am, amygdale; se, septum). Several neuronal masses differentiate in the diencephalon (gh, habenula; pt, pretectum; nmlf, nucleus of the medial longitudinal fascicle; vth, ventral thalamus). The olfactory tract (1) originates from the olfactory bulb (olb) that receives the olfactory input (I). Secondary olfactory fibers reach various areas of the telencephalon, including the dorsal (sm, stria medullaris) and ventral thalamus (2). The fasciculus retroflexus (fr) relays information to the ip. Retinal axons (II) project through the optic chiasme (och) to the dorsal thalamus and optic tectum (3). The midbrain receives fibers from the octavolateral area via the lateral lemniscus (LL, 5), which projects (4) to the dorsal thalamus (6), which in turn projects to various parts of the telencephalon. Fibers descend via the lateral forebrain bundle (lfb) to the midbrain. Fibers from the interstitial nucleus of the medial longitudinal fascicle (mlf) (is), the tectum (tbs) and the reticular formation form together the mlf (mlf, 8) as well as the reticulospinal (rs) and tectobulbospinal (tbs) tracts. Association fibers (9) interconnect pallial areas. Modified from Nieuwenhuys, R. 2002. Deuterostome brains: Synopsis and commentary. *Brain Res. Bull.* 57, 257–270.

nerve (but see Kuratani *et al.*, 2002), the relative positions and fiber compositions of these nerves are very similar but not identical in cyclostomes and gnathostomes. For example, the abducent nerve root is almost integrated into the trigeminal nerve root in lampreys, whereas it is always a separate ventral nerve root at a more caudal level in gnathostomes. Moreover, gnathostomes have three distinct motoneuron populations in the brainstem, each innervating a different type of peripheral target: the somatic motoneurons that innervate somitomere-derived musculature, the branchial motoneurons that innervate branchial arch-derived musculature, and the visceral motoneurons that innervate neural crest-derived parasympathetic ganglia of the head and body. In contrast, cyclostomes as a group lack the somatic motoneurons of the hypoglossal nucleus and have no visceral motoneurons as no cranial parasympathetic ganglia are known to exist (Fritzsch and Northcutt, 1993; Nieuwenhuys *et al.*, 1998). To emphasize differences between gnathostomes and cyclostomes, the hagfish hindbrain, while recognizable as such, is unusually shaped, which relates to differences in its internal organization (Nieuwenhuys *et al.*, 1998). The organization of cranial nerves in hagfish, other than the apparent absence of the entire extraocular muscle-related nerves, shows a number of deviations from gnathostome vertebrates. Hagfish have three completely segregated parts of the trigeminal nerve, two otic (statoacoustic) nerves, no recognizable vagal ganglion, and a facial nerve that exits dorsal to the otic nerves (Figure 1). The composition and evolution of cranial nerves will be discussed below and compared with other deuterostomes (see Section 2.01.2.3).

The spinal cord in craniates is a continuous extension of the neural tissue of the hindbrain. Adult

cyclostomes have unusually shaped spinal cords that are dorsolaterally flattened and have ventral and dorsal nerve roots. Lampreys have separated dorsal and ventral roots that do not form mixed spinal nerves and are asymmetric between the left and right side. Similar organizations of spinal nerves are noted for cephalochordates (Bone, 1960) and have been suggested to be primitive for chordates as this pattern is also found in hagfish and some gnathostomes (Fritzsch and Northcutt, 1993). Hagfish have, like gnathostomes, fused dorsal and ventral nerve roots except in the tail. It is believed that having fused dorsal and ventral roots is a derived feature of gnathostomes and that the superficial similarity of this feature in hagfish is independently derived (Bone, 1963; Nieuwenhuys *et al.*, 1998). As we will see below, the overall fiber composition of spinal nerves is highly variable among cyclostomes and fits neither the cephalochordate nor the basal gnathostome composition. Consequently, the analysis of character polarity of such basic issues as cranial and spinal nerves, their composition and their relationship to nerves of cephalochordates and urochordates is problematic (Fritzsch and Northcutt, 1993). We will revisit this issue after the internal organization of deuterostome nervous systems and nerves has been described (see Section 2.01.2.3).

2.01.2.2.2 Cephalochordates The central nervous system of cephalochordates is a simple tube that does not show any obvious enlargement at the rostral pole that can be compared with the brain of craniates (Figure 5), hence the alternate name acrania for this taxon. The hollow tube has a central canal that shows a vesicular enlargement at the anterior pole. The open neural canal of this vesicle has processes of the frontal eye sensory cells extending into it (Lacalli, 2004). Like craniates, cephalochordates and urochordates have a unique structure that extends throughout the central canal, Reissner's fiber (Figure 5). However, cephalochordates show a number of obvious topological differences from craniates with respect to apparently similar structures. For example, in craniates the notochord ends at the level of the hindbrain, whereas the notochord extends in cephalochordates beyond the rostral aspect of the neural tube. The notochord is now known to have a major inductive influence on brain formation through diffusible proteins such as sonic hedgehog (Shubin *et al.*, 1997; Litingtung and Chiang, 2000) and thus this influence would likely be different in cephalochordates and craniates.

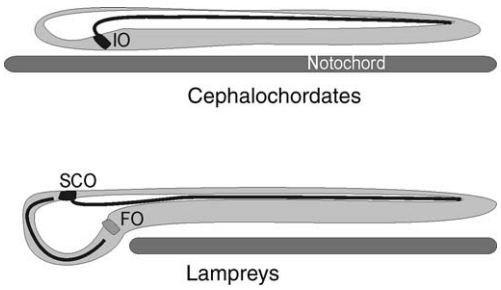

Figure 5 The different position of the origin of Reissner's fiber can be partially reconciled through developmental switches, as described in a single species of bony fish (Olsson, 1993). In principle there are three solutions: (1) Reissner's fiber is not homologous. (2) Despite the topographical differences of the organs that produce it, Reissner's fiber is homologous and is related to the apparently homoplastic structures through a deep homology for which no molecular evidence exists at the moment. (3) The infundibular (IO) and the subcommisural organ (SCO) represent a split of a single original cell population, intercalating a novel population (black line). If this is accepted, than all the area between the subcommisural and flexural organ (FO) of craniates and the infundibular organ of cephalochordates could be viewed as a craniate neomorph, that is the entire telencephalon and large areas of the thalamus of craniates have no equivalent in cephalochordates, as previously suggested (Takacs *et al.*, 2002). Modified from Fritzsch and Northcutt (1993) and Olsson (1993).

Turning now to the cranial and spinal nerves of cephalochordates, it is obvious that they are difficult to compare with those of craniates. To begin with, they are distributed too far rostral (Northcutt, 2001), leaving virtually no space for what is typically considered the brain. There are no true ventral roots in the sense of bundles of motoneuron axons leaving the spinal cord (Bone, 1960) and the notochord is composed of muscle fibers that form a unique synaptic contact with the ventral part of the spinal cord (Holland, 1996). Moreover, there are no dorsal root ganglia anywhere along the neuraxis (Fritzsch and Northcutt, 1993; Lacalli, 2004). Lastly, there is only one true ventral nerve, the first nerve. Starting with the second nerve, all dorsal nerves are more and more caudal on the right than on the left side, an asymmetry that by far exceeds anything found in other chordates (Fritzsch and Northcutt, 1993; Nieuwenhuys *et al.*, 1998). Other features of the cephalochordate anterior neuraxis are the conspicuous lamellar body (present only in larvae) and the Joseph cells. More caudally, one can find individual ocelli that extend throughout the spinal cord (Nieuwenhuys *et al.*, 1998; Lacalli, 2004). How these features relate to hindbrain and spinal cord divisions is unclear, leaving the questions of the caudal boundary of the brain and of the existence of brain subdivisions open (Northcutt, 2003). Paired sensory organs are

conspicuously absent in cephalochordates. However, certain primordia of mechanosensors and chemosensors may be present among the numerous single or multicellular organs (Fritzsch, 1996; Lacalli, 2004; Mazet *et al.*, 2004; Holland, 2005).

2.01.2.2.3 Urochordates In contrast to the rather uniform appearance of the neuraxis of cephalochordates, the developing urochordate CNS can be easily divided into a tripartite structure (Figure 6) that has long been recognized (Bone and Mackie, 1982). These divisions are (1) a rostral ganglion (totaling roughly 215 cells in *Ciona* and approximately 75 cells in *Oikopleura*), which contains sensory receptor structures, (an ocellus and/or an otolith), followed by (2) a caudal ganglion (containing approximately 45 cells in *Ciona* and approximately 25 neurons in *Oikopleura*), from which extends a caudal nerve cord (roughly 65 cells, mostly ependymal, in *Ciona*, and roughly 30 neurons and 25 support cells in *Oikopleura* (Meinertzhagen *et al.*, 2004; Søviknes *et al.*, 2005)). In addition, a slender neck region containing six cells lies between the two ganglia in *Ciona*. Each of these anteroposterior subdivisions of the ascidian CNS is itself patterned along the dorsoventral axis, a patterning that is revealed by the expression of specific marker genes. Other urochordate taxa seem to have primarily variations in size, not in structure (Meinertzhagen *et al.*, 2004). The ganglia of adult urochordates have the organization of an invertebrate ganglion, with cell bodies at the periphery and the neuropil in the center (Bullock and Horridge, 1965). Several nerves that vary considerably between species have been traced from adult ganglia, reaching up to 75 nerves in certain salps. These nerves appear to be mixed sensory and motor nerves and are asymmetric in several species, potentially related to the overall body asymmetry. The organization of motor projections varies among urochordates. In the *Ciona* larva, all the motoneurons are located in the caudal (visceral) ganglion and project along the aneural nerve cord and on to the peripheral muscle (Katz, 1983). In *Oikopleura*, the nerve cord contains motoneurons, which project directly laterally to the peripheral muscle (Bone, 1992). It is noteworthy here that comparisons between urochordates and cephalochordates claim similarities in the internal sensory organs, in particular the infundibular sensory cells and otolith (Nieuwenhuys, 2002; Lacalli, 2004). However, the interpretation of various sensory cells and organs outside the CNS is controversial with respect to vertebrate homology (Burighel *et al.*, 2003; Lacalli, 2004; Mackie and Singla, 2004; Holland, 2005). Some adult urochordates have fairly complex eyes attached to the cerebral ganglion. Modern tracing studies to unravel the details of neuronal connections within urochordate ganglia have yet to be conducted (Bullock and Horridge, 1965; Meinertzhagen *et al.*, 2004), but some are on their way.

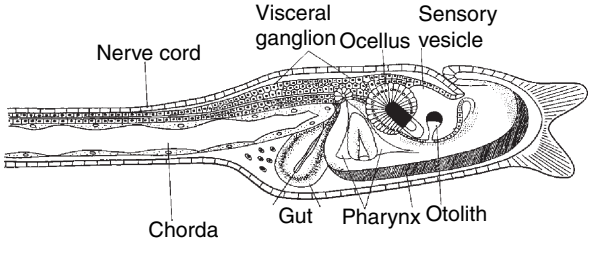

Figure 6 Simplified scheme of the urochordate *Ciona* larva. The nerve cord of *Ciona* consists only of epithelial cells (whereas in the appendicularian *Oikopleura* it contains neurons). In *Ciona*, the visceral (caudal) ganglion contains the motoneurons and is separated by a small neck from the sensory vesicle (rostral ganglion) that contains a rostral otolith and a caudal ocellus. The pharynx has gill slits.

2.01.2.2.4 Hemichordates Whether the simple nervous system of hemichordates should be referred to as a CNS is unclear (Bullock and Horridge, 1965). The overall organization is that of a basiepithelial plexus that shows regional concentrations in the three parts of the body, the protosome (the preoral proboscis), the mesosome (the postoral collar), and the metasome (or trunk, with rostral gill slits). The intraepithelial nerve plexus is well developed on the basement membrane but remains epithelial even in the invaginated collar region, which is hollow and opens through two neuropores (Figure 1). Concentrations of longitudinal strands of cells and fibers exist also on the trunk, where they form a dorsal and a larger ventral cord. The proboscis has a well-developed nerve plexus and numerous sense cells. A gut diverticle, the stomochord (which shares anatomic features with the notochord; (Welsch and Storch, 1970) but is different in its molecular organization (Shubin *et al.*, 1997)), extends into the proboscis. Except for the preoral ciliary organ with its abundance of sensory cells, there are no specialized sense organs. Concerning nerves, it appears that muscles are supplied by nerve fibers that cross the basement membrane singly and diffusely without forming obvious peripheral nerves.

2.01.2.2.5 Echinoderms The nervous system of echinoderms is interesting in its own right (Bullock and Horridge, 1965), but is likely of limited significance for chordates, as this would require the

transformation of a pentameric organization into the dorsal hollow nerve chord. While this cannot be ruled out, we assume for the sake of simplicity that echinoderms are derived and not directly related to the chordate ancestor. It needs to be stressed, however, that tremendous progress has been made in the study of sea urchin embryogenesis and these insights have recently been extended to nervous system development (Poustka *et al.*, 2004). However, the most detailed analysis seems to be concentrated on endoderm, ectoderm, and mesoderm formation (Davidson *et al.*, 2002). This analysis has revealed a complex network of gene interactions, many of which are conserved across phyla and are thus likely to be at least equally complex in other deuterostomes. It is important to understand that these data show that patterning genes function in networks and their function needs to be understood in the context of other genes with which they are co-expressed.

In summary, the CNS of deuterostomes shows a variety of forms, from a hardly specialized basiepithelial nerve plexus (hemichordates), to a few small ganglia with a tail nerve cord (urochordates; or a tailless head in adult sessile urochordates), to a swimming spinal cord with a hardly recognizable cerebral vesicle (cephalochordates), to a fully developed brain and spinal cord (craniates). Despite these overall differences, similarities related to a certain degree of rostrocaudal and dorsoventral patterning are present. These may be directly related to the overall rostrocaudal patterning of the body and to the fact that the neural tube evolved only once in ancestral chordates (Meinhardt, 2004) and has maintained a molecularly identical dorsoventral patterning scheme (Wada and Satoh, 2001). These issues will be revisited in a later section once we have introduced the transcription regulating genes that are involved in such patterning.

2.01.2.3 Organization of Identified Neuron Populations and Projections

Cytoarchitectonic specializations akin to cortical layers and aggregations of neurons into nuclei have not been observed in any deuterostome animal below the level of craniates. However, neuron populations can be identified throughout the animal kingdom on the basis of unusual size or through the use of specific markers.

2.01.2.3.1 Large neurons Particularly large neurons are a common feature of both invertebrate and vertebrate nervous systems. In many chordates, large neurons with descending axons have been identified in the rostral region of the neuraxis. Using cytological criteria, one can identify certain large reticulospinal neurons in the rhombencephalon of lampreys (the Muller and Mauthner cells) that have long descending axons that extend the length of the spinal cord (Nieuwenhuys *et al.*, 1998). Similar neurons are found in hagfish, but Mauthner cells cannot be identified among them and whether the other large cells are homologous to Muller cells is unclear. In the rostral neuraxis of juvenile cephalochordates, two pairs of larger interneurons with descending axons have been identified and termed ventral giant cells of the primary motor center. Similar large neurons have been serially reconstructed from electron micrographs in larval cephalochordates (Lacalli, 1996). These are potentially homologous to the reticulospinal neurons of cyclostomes. The axons of cephalochordate motoneurons also descend along the cord for unknown distance, however, and thus could be mistaken for reticulospinal neurons. Assessment of neurotransmitter phenotype could resolve this question, as motoneurons are expected to be cholinergic (see Section 2.01.2.3.2).

Cephalochordates are well known for another system of large neurons, the Rhode cells (Bone, 1960; Nieuwenhuys *et al.*, 1998). These cells are situated dorsally in the spinal cord starting at nerve VI in juveniles and somewhat more rostrally in adults (Ekhart *et al.*, 2003). Neurons with somewhat similar characteristics have been described in various craniates (Harper and Roberts, 1993) and may be a common feature of cephalochordates and craniates (Fritzsch, 1996).

No large neuronal elements have been described in urochordates (Bullock and Horridge, 1965), but large neurons have been described in hemichordates, clustered in the caudal part of the collar cord and also scattered in more rostral and caudal areas. Some of these neurons have uncrossed or crossed axons that extend toward the ventrolateral longitudinal muscles and therefore may be motoneurons (see below). Others have been compared to the Mauthner and Muller cells of craniates (Bullock and Horridge, 1965). However, independent confirmation of similarities with other deuterostome neurons needs to be established using immunocytochemistry or *in situ* hybridization for molecular markers, as in recent analysis of the urochordate ocellus (Sun *et al.*, 2003). At the moment, all the above anatomical similarities are tentative and more work combining tract tracing with assessment of gene expression is needed in more deuterostomes to substantiate potential homologies.

2.01.2.3.2 Motoneurons Motoneurons can be compared easily across deuterostomes for the following reasons. First, motoneurons are cholinergic in echinoderms, urochordates, cephalochordates, and craniates, and this may constitute a conserved feature of deuterostomes (Holland, 1996). Second, all motoneurons constitute efferent populations that target structures outside the CNS. However, these targets may be mesoderm-derived muscle fibers, neural crest-derived autonomic ganglia, or placode-derived hair cells (Fritzsch, 1999).

In hemichordates, motoneurons may be among the identified giant neurons, but details are unclear and no data on the cholinergic nature of these neurons is available (Bullock and Horridge, 1965). In some urochordates (such as *Ciona*), motoneurons are found only in the visceral ganglion where three to five pairs of cells have been recognized. The axons of these cells extend down the nerve cord and then exit to innervate adjacent muscle fibers (Katz, 1983). In other urochordates, such as *Oikopleura*, motoneurons are additionally found in the nerve cord itself (Bone *et al.*, 1996).

Cephalochordates have three different types of contacts with muscle fibers (Bone, 1960; Bone *et al.*, 1996; Holland, 1996). Two of these contacts are from muscle fibers to the spinal cord forming ventral roots and medioventral roots with the axial musculature and the muscles of the notochord. The motoneurons supplying these muscle fibers have only been tentatively identified for axial musculature and appear to project axons for at least three segments rostral or caudal before exiting (Figure 7). Motoneurons are found throughout the spinal cord and as far rostral as the primary motor center between the second and third dorsal nerves. An additional set of motoneurons encompasses the so-called visceral motoneurons. These are the most ventral neurons in the nervous system, situated virtually at the floor plate (Bone, 1960). The axons of these cells exit through the dorsal roots and supply the pterygeal muscle with cholinergic endings (Bone, 1960; Bone *et al.*, 1996).

In cyclostomes, somatic motoneurons are present only in the spinal cord and in the oculomotor nuclei near the isthmus, whereas branchial motoneurons are only present in the brainstem (Fritzsch and Northcutt, 1993; Fritzsch, 1998). Absence of extraocular motoneurons in hagfish may represent a primitive condition and, at least for oculomotor and trochlear motoneurons, may be related to a different organization of the isthmus and the apparent absence of a cerebellum. We will discuss this issue below when we consider the evolution of the midbrain/hindbrain boundary (MHB). It is important to note that cyclostomes do not have autonomic ganglia and lack visceral motoneurons that innervate such ganglia. It appears that autonomic ganglia arose with gnathostomes and in association with the formation of preganglionic parasympathetic motoneurons in the head and the caudal part of spinal cord (the craniosacral parasympathetic preganglionic motoneurons) and preganglionic sympathetic motoneurons in the thoracic and lumbar spinal cord (Fritzsch, 1998).

In summary, the motoneurons of deuterostomes show certain basic similarities across taxa but also exhibit unique taxon-specific features that do not appear to follow a progressive evolutionary transformation but rather indicate independently derived transformations that may have a common root in the basiepithelial nerve plexus of other deuterostome taxa (Figures 7 and 8).

2.01.2.3.3 Sensory afferents We next turn to the distribution of afferents, a feature that is highly indicative of specific sensory modalities in craniates (Fritzsch and Northcutt, 1993). As outlined above, sensory input through cranial nerves in craniates can be simply summarized: all sensory systems, except for olfaction and the visual system, reach the brain through nerves that terminate in the rhombencephalon (Nieuwenhuys *et al.*, 1998). More precisely, all sensory input is into the alar plate of the rhombencephalon or the alar plate of the midbrain (vision) or the forebrain (olfaction). The only noncraniate deuterostomes for which a reasonably detailed knowledge of central sensory projections exists are the cephalochordates. In these animals, the central projections of rostral nerves and the first pair of dorsal nerves have been described using tract tracing (Fritzsch, 1996) and serial electron microscopic reconstruction (Lacalli, 1996, 2004). Both approaches show that the first pair of dorsal nerves passes ventrally along the lamellar body and derives from the organs of de Quatrefages as well as some of the numerous sensory cells of the rostrum. However, interpretations of the likely homology of this region differ substantially. The serial reconstruction data have been interpreted to indicate that cephalochordate larvae have a midbrain that receives not only the fibers from the rostral sensory cells and organs, but also from the frontal eye that is a likely homologue of the lateral eyes of craniates (Lacalli, 1996, 2004). In contrast, the tracing studies have been interpreted to show that the termination area near the lamellar body is homologous to the alar plate of the hindbrain (Fritzsch,

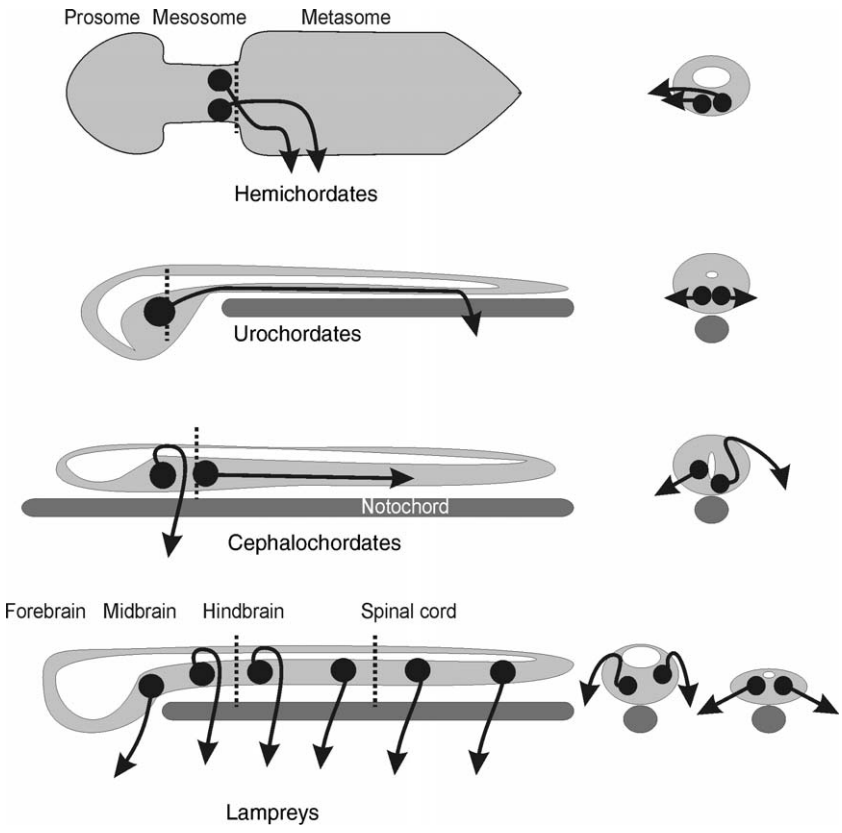

Figure 7 This scheme shows the distribution of motoneurons viewed from the dorsal aspect (Hemichordates) or lateral aspect (others) as well as in coronal sections at the levels indicated by the dotted lines. Motoneurons in hemichordates are predominantly located in the caudal half of the collar cord and their axons typically cross the basal membrane individually to reach muscle fibers. In some urochordate larvae, all motoneurons are concentrated in the caudal ganglion and project through the nerve cord to reach muscle fibers of the tail. In other urochordates, motoneurons are additionally present in the nerve cord and project directly to adjacent muscles (not shown). Cephalochordates have three types of motoneurons (only two are shown). One type is the somatic motoneuron that extends an axon along the spinal cord to innervate muscular processes that form synapses abutting the cord. The second type is the visceral motoneuron that projects through the dorsal root to innervate the pterygial muscle. Lampreys have in their spinal cord only somatic motoneurons whose axons project out through ventral roots, and in their hindbrain only dorsal exiting motoneurons, referred to as branchiomotoneurons because they innervate muscle derived from branchial arches. Lampreys have three populations of ocular motoneurons in the midbrain–hindbrain region, some of which have the appearance of somatic motoneurons. Modified from Bullock and Horridge (1965), Fritzsch and Northcutt (1993), and Fritzsch (1998).

1996). Under the second interpretation, cephalochordates lack a midbrain and hindbrain features start as far rostral as the first and second dorsal nerve. This interpretation was recently supported by an analysis of gene expression (Takahashi and Holland, 2004) and will be discussed below (see Section 2.01.3). Further studies as well as the clarification of the relationships of the various sensory organs of chordates across taxa is needed (Fritzsch and Beisel, 2004; Lacalli, 2004; Mackie and Singla, 2004; Mazet *et al.*, 2004; Holland, 2005). More molecular markers, in particular various transcription factors, need to be investigated to provide more plausibility to the various scenarios proposed.

Urochordates also have sensory input to their ganglia that is derived from cells that share certain developmental steps with the neural crest (Meinertzhagen *et al.*, 2004), but much more analysis is required in these species before arguments about homology can be made.

2.01.2.3.4 Immunocytochemically identified neuron populations We turn next to certain populations of immunocytochemically identified neurons in chordates. We will here focus only on three neuron types, those expressing the oligopeptide neurotransmitter FMRFamide, those expressing tyrosin hydroxylase (TH), the rate-limiting enzyme for synthesis of catecholamine neurotransmitters, and those expressing GABA, the principal inhibitory neurotransmitter. These examples are selected because the data are most revealing for the overall question of similarities and uniqueness of features across deuterostomes. We should emphasize, however, that

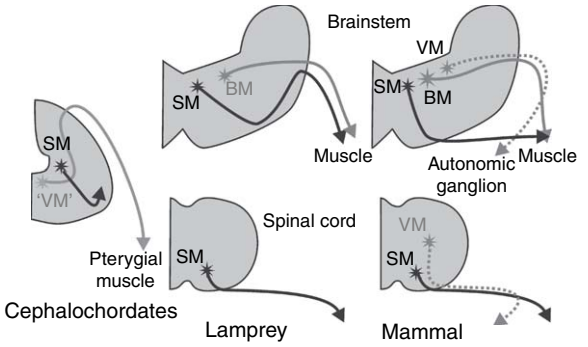

Figure 8 Motoneurons of craniates and cephalochordates are compared. Two motoneurons have been characterized in cephalochordates, the visceral motoneurons (VM) that innervate the pterygial muscle and exit through dorsal roots and the somatic motoneurons that do not exit the neural tube but rather form synapses with muscle processes at the lateral wall of the spinal cord. Lampreys have only somatic motoneurons that exit through the ventral root in the spinal cord. Mammals have evolved visceral motoneurons in the spinal cord that migrate into a distinct position and project to autonomic ganglia. The brainstem of lamprey has mainly branchiomotoneurons (BM) that project through the dorsal root. Whether the abducens motoneurons are somatic motoneurons (SM) in lampreys is unclear as they also project through the dorsal root. In mammals there are additionally visceral motoneurons in several cranial nerves that project to the parasympathetic ganglia. These visceral motoneurons can be regarded as special branchiomotoneurons. Modified from Fritzsch and Northcutt (1993) and Fritzsch (1998).

immunohistochemical identification of proteins (such as TH) in lower deuterostomes using antibodies raised against the craniate proteins should be regarded as tentative without independent confirmation using other molecular techniques.

2.01.2.3.4.(i) FMRFamide FMRFamide is widely distributed in the nervous system of invertebrates, including coelenterates (Katsukura *et al.*, 2003) and may be among the oldest neurotransmitters (Cazzamali and Grimmelikhuijzen, 2002; Seipel *et al.*, 2004). In deuterostomes, this small peptide has been demonstrated in echinoderms (Garcia-Arraras *et al.*, 1991) and immunoreactivity is abundantly present in the central and peripheral nervous system of cephalochordates (Uemura *et al.*, 1994; Bone *et al.*, 1996). In contrast, craniates seem to have only a few RFamide peptides (Hinuma *et al.*, 2000; Yano *et al.*, 2004), and the almost complete absence of FMRFamide in the peripheral nervous system and the gastrointestinal system of craniates stands in stark contrast to the abundant presence of this peptide in protostomes, coelenterates, echinoderms, and cephalochordates. This difference supports the notion that the enteric nervous system of the cephalochordate atrium is not related to the enteric system of craniates as has been previously suggested (Bone, 1961; Fritzsch and Northcutt, 1993). This may be related to a more recent evolution of the vertebrate enteric nervous system from the neural crest (Fritzsch and Northcutt, 1993).

In cephalochordates, the visceral motoneurons and possibly some of the somatic motoneurons are FMRFamide-immunoreactive (Pestarino and Lucaroni, 1996). No FMRFamide immunoreactivity has been reported for craniate motoneurons, indicating that the visceral motoneurons and some somatic motoneurons of cephalochordates may resemble a more primitive condition characteristic of coelenterates and protostomes. In this regard, it will be important to assess the expression of FMRFamide in urochordates and hemichordates.

2.01.2.3.4.(ii) Catecholaminergic neurons The TH gene has been sequenced in several deuterostomes and shown to be a single orthologue with high sequence similarity between cephalochordates and vertebrates and lower sequence similarity between either of these and the urochordates. Immunocytochemistry and *in situ* hybridization in cephalochordates shows a rostral and dorsal distribution near the anterior end of the neural tube and the first two dorsal nerves. This has been interpreted as indicating similarities with the di-, mes-, and rhombencephalic catecholaminergic neuron groups known in craniates. In this context, it is important to note that a genetic basis of the development of catecholaminergic and serotonergic neurons in mammals has been studied extensively and upstream regulators have been identified (Qian *et al.*, 2001; Brunet and Pattyn, 2002; Pattyn *et al.*, 2003a). Serotonergic neurons have been found to form through a positionally and temporally regulated fate switch of visceral motoneuron progenitors (Pattyn *et al.*, 2003b). If such developmental linkage is conserved, one would expect serotonergic neurons to form only near motoneurons, which closely fits the currently known distribution of serotonergic neurons near the first motor center in cephalochordates (Lacalli, 1996; Moret *et al.*, 2005). Most interesting is the case of catecholaminergic neurons related to the solitary tract in vertebrates (Qian *et al.*, 2001). These neurons form a longitudinal column in the hindbrain and depend on several transcription factors that are longitudinally expressed (Brunet and Pattyn, 2002). Interestingly, in cephalochordates a longitudinal column of putative catecholaminergic neurons is located adjacent to the fibers of sensory cells on

the rostrum that enter through the first nerves (Fritzsch, 1996; Lacalli, 1996). This molecular and topographic relationship could indicate that at least some of these fibers are chemosensory and that they terminate in the equivalent of the solitary tract. Given the paucity of data, other interpretations are possible.

In urochordates, a small population of dopamine+ and TH+ cells is found in the ventral region of the rostral ganglion in both *Ciona* (Moret *et al.*, 2005) and *Oikopleura* (Søviknes and Glover, unpublished data). Moret *et al.* (2005) surmise on the basis of this location that the ventral part of the rostral ganglion is homologous to the vertebrate hypothalamus, which also contains catecholaminergic neurons. As far as we know, catecholaminergic neuron populations have not yet been described in hemichordates.

2.01.2.3.4.(iii) GABA GABA is the principal inhibitory transmitter in vertebrates and is also a major inhibitory transmitter in invertebrates. It therefore appears to be a common currency for inhibition throughout the animal kingdom. In invertebrates, GABA-immunopositive neurons typically occupy specific locations within ganglia either as distinct single neurons or clusters of neurons (reviewed in Søviknes *et al.*, 2005). In vertebrates, GABA-immunopositive neurons have widespread distributions and nearly all regions of the brain are replete with GABA-immunopositive terminals (Anadon *et al.*, 1998a; Melendez-Ferro *et al.*, 2000, 2002, 2003). However, the developmental origins of mammalian GABA-immunopositive neurons are much more discrete, with subsequent migration giving rise to their far-flung positions (Stuhmer *et al.*, 2002a, 2002b).

In the lamprey, the earliest GABA-immunopositive neurons appear in late embryos in the basal plate of the isthmus, in the caudal rhombencephalon, and in the rostral spinal cord (Melendez-Ferro *et al.*, 2002, 2003). Somewhat later, GABA appears in the prosencephalon, first in the diencephalon and later in the cortex. GABA neurons then appear elsewhere, but with distinct regional differences in distribution.

In the urochordate *Oikopleura*, GABA-immunoreactive neurons also originate at discrete sites within the CNS, both in the rostral ganglion and in the caudal ganglion (Søviknes *et al.*, 2005). GABA-immunoreactive neurons are not found, however, in the nerve cord, in contrast to the extensive population of GABA neurons in the spinal cord of vertebrates. Thus, GABA neurons appear to be regionally patterned in both urochordates and vertebrates, but there seems to be an increasingly broader distribution of GABA neurons in higher taxa, perhaps in conjunction with an increasing demand for local inhibitory inputs to provide finer regulation of sensory and motor information traffic.

In summary, comparative analysis of common neuronal cell types indicates a variety of patterns of topology and homology. Enough similarities exist to suggest that most of the apparent differences can probably be interpreted as variations on a theme that may already have been set up in the last common ancestor of all deuterostomes.

2.01.3 Making and Placing Neurons: The Evolution of Cell Fate and Regional Patterning

The expression of multiple genes in a nested anteroposterior pattern in the basiepithelial nerve plexus of hemichordates (Holland, 2003; Lowe *et al.*, 2003), combined with the presence of neuron-specific patterning genes and transcription factors in coelenterates (Seipel *et al.*, 2004) make it likely that ancestral deuterostomes had a skin brain that was regionally patterned by virtue of specific gene expression. Obviously, this basiepithelial nervous system had no dorsoventral patterning, since this would first arise in chordates in conjunction with the process of invagination of the neural plate into the neural tube. It has been noticed in both protostomes and deuterostomes that many genes governing the processes of invagination and of dorsoventral patterning are different (Arendt and Nubler-Jung, 1999). It seems therefore plausible that both processes were derived independently from an organism that already had evolved anteroposterior patterning. This would explain the utilization of two different sets of similar genes to regulate the two different processes (Meinhardt, 2004). It is fair to say that the relationship of most of the patterning genes to cell fate-determining genes and, ultimately, to neuronal organization is largely unknown. Thus, understanding how these genes relate within the context of the ancestral basiepithelial nerve net may provide insight into their functional relationships in the context of the brain of higher taxa. Examples such as otx, which helps specify the forebrain as an element of anteroposterior patterning in gnathostomes but is also expressed regionally in the brainless coelenterates (Ghysen, 2003), illustrate the possibility of an ancestral role that presumably was co-opted along with the neurogenic genes into the process of forming and patterning the brain *per se*.

In recent years, a number of cell fate determining genes have been identified in the nervous system and their functions experimentally determined (Lee, 1997; Anderson, 1999; Bermingham *et al.*, 1999; Brunet and Pattyn, 2002). Many of these patterning genes code for basic helix-loop-helix (bHLH) transcription factors. Much recent work has shown that the bHLH genes are ancient and are found not only in bilaterians, but also in coelenterates (Muller *et al.*, 2003; Seipel *et al.*, 2004). These findings begin to shed light on a major question in neurobiology: what is the origin of the neuron, the basic building block of any brain or nerve net? We propose here that the evolution of cellular diversification is closely associated with the evolutionary divergence of the bHLH genes and their restricted expression in the peripheral and central nervous system (Figure 9). The evolutionary expansion of this gene family as well as the currently known expression patterns of its members is consistent with a previously proposed hypothesis of cellular diversification as the basis for brain evolution (Mackie, 1990).

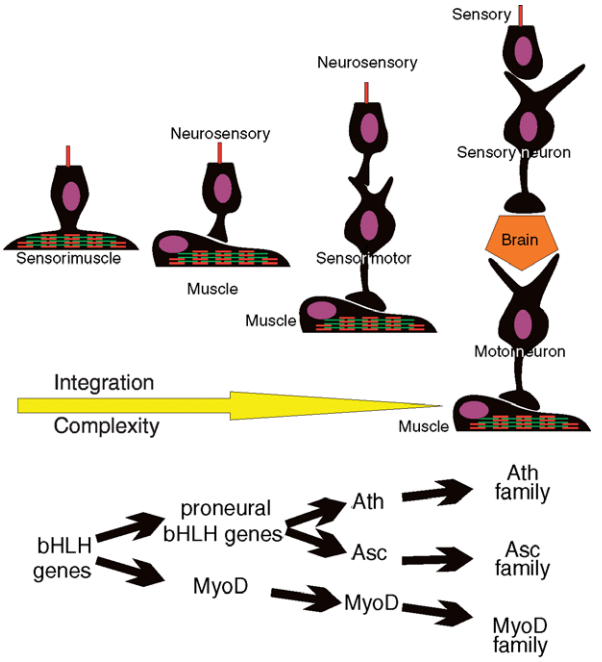

Figure 9 The proposed co-evolution of cellular complexity and expansion of the bHLH gene family that guides development of cellular diversity. It is hypothesized that the original neuronal cell type was a sensorimuscle cell that had both sensory capacity and contractile capacity. As the *bHLH* gene family expanded by generation of additional paralogous family members, the repertoire of neuronal cell types increased. Eventually, specialized sensorimotor cells that interconnected pure neurosensory cells and pure muscle cells evolved, thus providing the basis for integration of input from multiple sensory cells to govern the activity of multiple muscle fibers. These sensorimotor neurons ultimately diverged to give rise to the entire interneuronal compartment of the brain, an evolution that occurred in parallel with the increased specialization and diversification of sensory organs to govern more complex motor output. Modified from Mackie (1990) and Seipel *et al.* (2004).

Essential for the formation of any CNS is the specification of a neural cell fate in the developing ectoderm: cells have to be diverted from an epidermal fate to a neural fate, which is to say into neurons instead of skin cells. This fate switch is likely to be triggered by activating the bHLH genes that specify neuronal fate. We therefore turn our attention now to the question of how neuronal induction might have evolved.

Over the last 10 years, the predominant view has been that Spemann's organizer generates signals that can change cell fate from epidermal to neuronal through the generation of bone morphogenic proteins (BMP) antagonists (De Robertis *et al.*, 2000; Munoz-Sanjuan *et al.*, 2002). Based on several transplantation and *in vitro* experiments, it has been proposed that neuronal induction is a direct consequence of BMP inhibition in the ectoderm and that the neural fate can be considered to be a ground state that is revealed in the absence of the instructive (negative) BMP signals and the ectopic expression of proneural bHLH genes (Ma *et al.*, 1996; Lee, 1997). One possibility is that in the ancestral deuterostome, BMP expression was suppressed, or at least downregulated, in a scattered pattern, thus triggering neurogenesis at the scattered locations characteristic of the basiepithelial nerve net. bHLH genes evolved already in coelenterates, where they are involved in specifying neuronal precursors in the ectoderm and endoderm (Seipel *et al.*, 2004).

In the chicken, Spemann's organizer, but not previously defined BMP inhibitors, leads to neurogenesis, and it has been claimed that it is FGF signaling that is elicited by the organizer and that antagonizes BMP signaling (Munoz-Sanjuan *et al.*, 2002). However, recent data from ascidian embryos suggest that FGF signaling alone, without acting through BMP inhibition, is a direct inducer of early neurogenic genes (Bertrand *et al.*, 2003). More recent work seems to generate a unified position and suggests that FGF is not only inhibiting BMP signaling, but also has an independent and direct neural inductive capacity possibly conserved among chordates (Delaune *et al.*, 2004; Kuroda *et al.*, 2005). Specifically, it now appears that FGFs can directly activate neuralization through the MAPK pathway rather than by overriding the BMP-mediated inhibition (Kuroda *et al.*, 2005). Unfortunately, the function of FGFs in the context of neural induction in other deuterostomes has not been fully analyzed

(Davidson *et al.*, 2002). It is important to note that a cooperative FGF/BMP signaling system also exists in insects, but not in connection with CNS development. The FGF pathway is used for branching morphogenesis of trachea (Sutherland *et al.*, 1996) and null mutants of the single known *Drosophila* FGF ligand (branchless) do not show overt brain development deficits (Hirth *et al.*, 2003). This difference is significant, as in the past it appeared that both insect and vertebrate neural induction relied on BMP/dpp suppression (Urbach and Technau, 2004). Now it appears that either chordates have evolved the new feature of FGF involvement, or, conversely, that FGF involvement in neural induction was lost in insects. Clearly, the emerging issues regarding phylogenetic differences in the signaling that underlies neural induction support the model that neurulation in protostomes and deuterostomes may have evolved independently (Lowe *et al.*, 2003; Meinhardt, 2004). These divergent views need to be reconciled by more detailed analysis of nonchordate deuterostomes. Such data could help to resolve the basic question of conservation of neural induction across phyla, which as of this writing is controversial.

Upon invagination, the vertebrate neural tube becomes patterned in the transverse plane according to an intricate process involving multiple transcription factors (Figure 10). In a simplified version, the dorsoventral expression domains of these transcription factors are established by a bipolar gradient of diffusible signaling molecules that act in concert (Sander *et al.*, 2000; Vallstedt *et al.*, 2001; Maklad and Fritzsch, 2003; Pattyn *et al.*, 2003b), a fact that can be unmasked if one pole of the gradient is experimentally abolished (Litingtung and Chiang, 2000). Several of these patterning genes have been identified across deuterostome phyla (Wada and Satoh, 2001). However, it is also clear that factors such as the Wnts are expressed differently in cephalochordates and craniates (Holland *et al.*, 2000; Schubert *et al.*, 2001), suggesting that certain aspects of dorsoventral patterning may not be fully conserved across deuterostomes. Clearly, more work on other relevant dorsoventral patterning genes is needed in more deuterostomes before any firm conclusion can be drawn.

One specific brain region that has attracted intensive studies and has generated a large set of comparative gene expression data is the MHB (Figure 11). The formation of the MHB has been shown to be critically dependent on several transcription factors that interact with each other to stabilize the boundary (Wang and Zoghbi, 2001). If any of these genes is mutated, the boundary does not form and nearby neuron populations, including certain extraocular motoneurons, fail to differentiate (Fritzsch *et al.*, 1995). Certain genes expressed in this region, such as Pax2/5/8, can be used as markers to delineate the MHB (Wada *et al.*, 1998). It is interesting that no midbrain seems to exist in noncraniate deuterostomes in the sense of the specific overlapping gene expression patterns that are found in gnathostomes. Likewise, it is unclear whether a true isthmus region with the organizer capacity of gnathostomes exists in any nonvertebrate deuterostome (Figure 11). Given that the MHB is so important for cerebellar, oculomotor motoneuron, and trochlear motoneuron development, it is conceivable that the absence of a cerebellum as well as of all extraocular motoneurons in hagfish may reflect a primitive absence of a true MHB. Likewise, the absence of a mesencephalic root of the trigeminus nerve in cyclostomes may be related to a different pattern of gene expression in this region.

Another long-standing comparative issue is the number and significance of neuromeres and how they relate to gene expression domains and neuronal differentiation. Based on gnathostome data, it appeared that most cranial motoneuron nuclei showed a simple relationship to specific rhombomeres in a pattern that was reasonably well conserved across gnathostome phyla (Fritzsch,

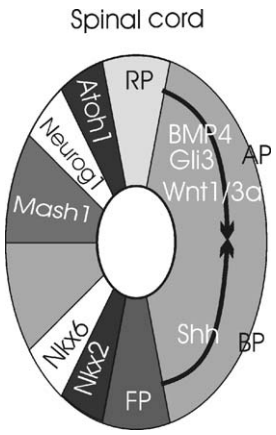

Figure 10 Genes involved in the dorsoventral patterning of the neural tube. The floor plate produces sonic hedgehog (*Shh*), which diffuses through the basal plate (BP) to interact with GLI-Kruppel family member 3 (*Gli3*). Opposing diffusion gradients are set up by bone morphogenic factor 4 (*BMP*4) and wingless-type MMTV integration site family member 1/3a (*Wnt1/3a*). The interaction of these gradients sets up domains of transcription factor expression that govern more directly the cell fate of neurons developing in their expression area. For example, the expression of NK6 transcription factor related, locus 1 (*Nkx6.1*) is essential for the formation of somatic motoneurons. Modified from Sander *et al.* (2000), Vallstedt *et al.* (2001), Maklad and Fritzsch (2003), and Pattyn *et al.* (2003b).

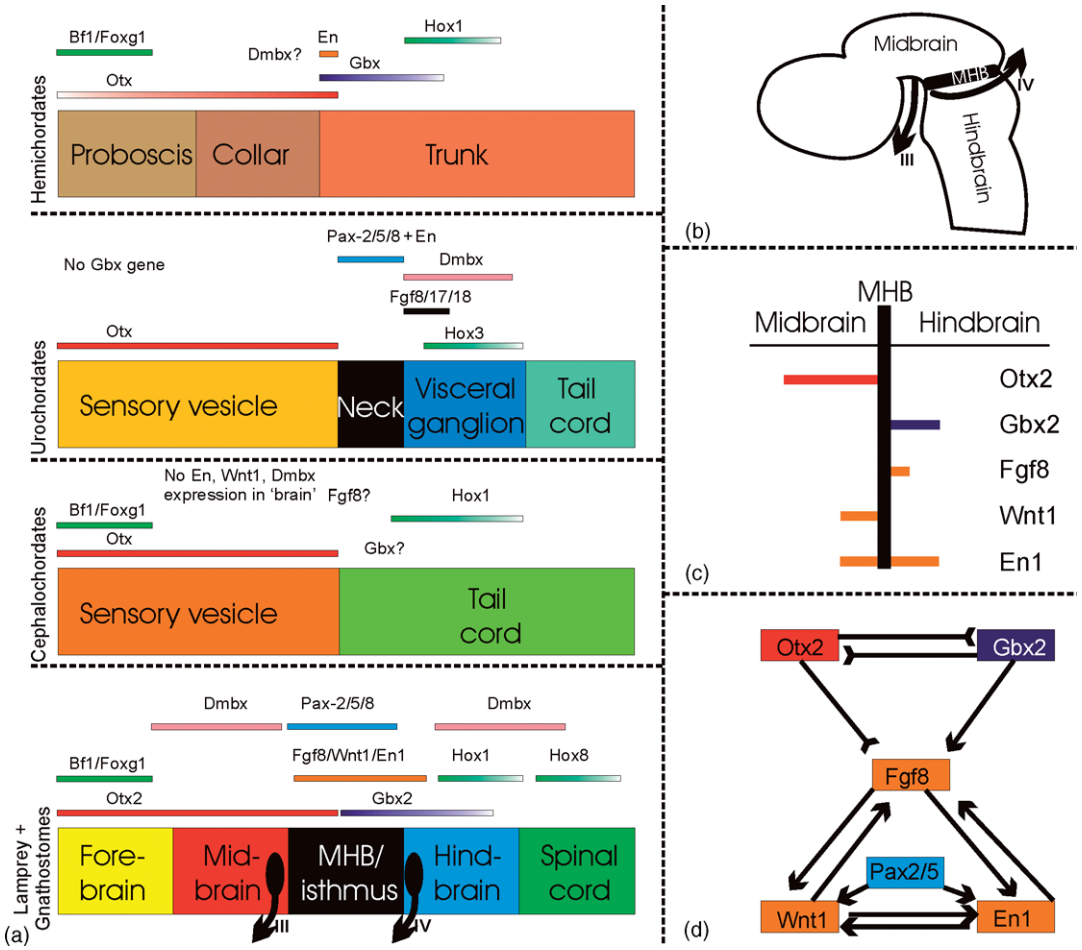

Figure 11 The evolution of gene expression at the MHB is shown for deuterostomes. The MHB forms in gnathostomes where *Otx2* and *Gbx2* expression is abutting. This stabilizes the expression of *Fgf8*, which in turn stabilizes the expression of *Wnt1* and *En1*. Mutation of *Otx2*, *Gbx2*, *Fgf8*, or *Wnt1* eliminates the MHB. *Pax2/5/8* are also expressed at the MHB, whereas the expression of *Dmbx* occurs immediately rostral to the MHB and later in the hindbrain and spinal cord. Cephalochordates have *Dmbx*, *Wnt1*, and *Engrailed* genes, but these are not expressed in any close relation to the *Otx* expression domain. The expression of *Fgf*s and *Gbx* has not yet been characterized in cephalochordates. Urochordates lack a *Gbx* gene and have nonoverlapping *Pax* and *Fgf* expression domains meeting between the visceral ganglion and the neck, with *Dmbx* expression caudal to *Pax* expression as opposed to rostral to *Pax* expression as is seen in gnathostomes. Hemichordates have overlapping expression of *Gbx*, *Otx*, and *En* in the rostral trunk. Outgroup data suggest that coelenterates have a *Dbmx* orthologue, thus raising the possibility that hemichordates also have a *Dmbx* gene, but neither this gene nor the *Fgf* and *Pax* genes have been characterized in terms of expression pattern in hemichordates. Together these data show that certain gene expression domains are topographically conserved (*Hox*, *Otx*), whereas others show varying degrees of overlap. It is conceivable that the evolution of nested expression domains of transcription factors is causally related to the evolution of specific neuronal features such as the evolution of oculomotor and trochlear motoneurons around the MHB. Modified from Fritzsch (1996), Wang and Zoghbi (2001), Lowe *et al.* (2003), and Takahashi and Holland (2004).

1998; Glover, 2001; Murakami *et al.*, 2004; Kiecker and Lumsden, 2005). However, a number of exceptions have been noted among cyclostomes in the organization of hindbrain motor nuclei compared to mammals (Figure 12). These data suggest that while the formation of rhombomeres might be a constant feature of craniate hindbrains (with the possible exception of hagfish) the content of rhombomeres is not stably conserved. The distribution of motoneurons in the adult hindbrain is complicated by longitudinal and radial migrations that make comparison among craniates somewhat tentative. For example, facial motoneurons migrate in hagfish and mammals, whereas they remain near their ventricular origin in lampreys. Rhombomeric differences in the distribution of craniate motoneurons have recently been analyzed during development in cyclostomes and correlated with gene expression patterns (Murakami *et al.*, 2004). Beyond the branchiomotor neurons analyzed in this study, the abducens nucleus has also been found not to have boundaries coinciding with rhombomere

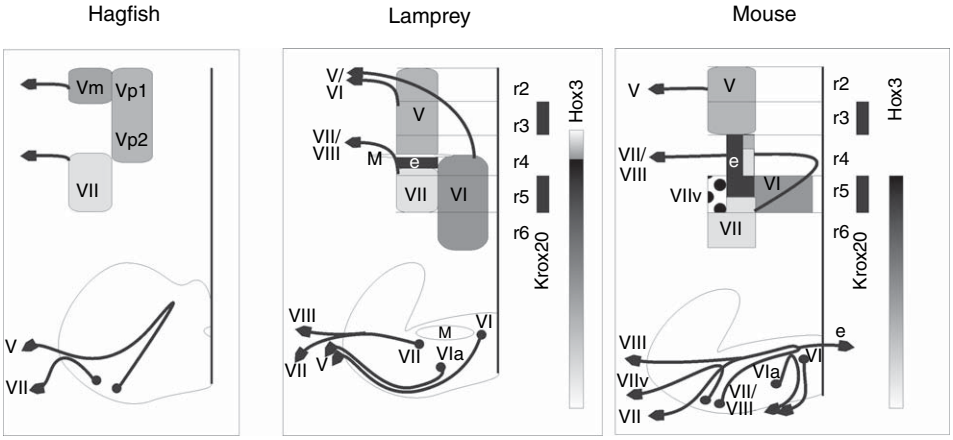

Figure 12 The distribution of motoneurons relative to rhombomeres is shown for three adult craniates in combination with gene expression in a dorsal view (top) and a coronal section (bottom) of the left half of a hindbrain. Hagfish and lampreys have a much larger contingent of trigeminal (V) than facial motoneurons (VII). Hagfish are unusual in the trajectories taken by their motoneuron axons, a feature that is related to the overall unusual organization of the hindbrain. In lampreys, the abducens (VI) and facial motoneurons (VII) originate from rhombomeres 2.5 and 1.5, respectively, and trigeminal and facial motoneurons approximate each other in the middle of rhombomere 4 near the Mauthner cell (M) and the inner ear efferents (e). Lampreys have two adjacent populations of motoneurons that each innervates distinct ocular muscles. Fibers of the abducens exit through the trigeminal nerve (V). In mice, the facial branchial (VII) and visceral (VIIv) motoneurons originate in rhombomeres 4 and 6, respectively. The facial branchiomotor neurons migrate during development from rhombomere 4 to 6, trailing their axons behind them. Each of the three motoneuron types generated in rhombomere 4/5 has a distinct exit either bilaterally through the octaval nerve (VIII) for efferents (e) or through the intermediate nerve for facial visceral motoneurons (VIIv) or through the facial nerve for facial branchiomotoer neurons (VII). Note that abducens fibers exit in mammals as a ventral root (VI). Gene expression studies show that rhombomeres 3 and 5 are characterized across phyla by the expression of *Krox20*, whereas *Hox* expression changes from a midrhombomere 4 expression in lampreys to a rhombomere 4/5 boundary expression in mice. No expression data exist on hagfish. Modified from Fritzsch (1998), Glover (2001), and Murakami *et al.* (2004).

boundaries (Fritzsch, 1998). This detailed analysis has confirmed earlier assessments of motoneuron distribution and shows a correlation of motoneuron populations not with rhombomeric boundaries *per se* but with Hox gene expression domains, as had previously been hypothesized for craniates in general (Glover, 2001). Indeed, the details of distribution of motoneurons generated in a given rhombomere are not stable across craniate evolution, as illustrated by the formation of a visceral motor component in rhombomere 5 of the mammalian hindbrain, a motoneuron population that is entirely missing in cyclostomes. Experimental manipulation of gene expression is now needed in lampreys to show that the boundaries of motoneuron domains are specified by *Hox* gene expression.

Overall, these data show that rhombomeres are not fully invariant with respect to motoneuron composition, and similar conclusions have been reached with respect to reticulospinal and vestibulospinal neurons (Auclair *et al.*, 1999; Diaz and Glover, 2002; Diaz *et al.*, 2003; Maklad and Fritzsch, 2003). This instability in detail relates to the unresolved problem of the origin of neuromeres. While past research assumed that this might have happened early in deuterostome evolution and may have been related to segmentation from a hypothetical common urbilaterian ancestor (Arendt and Nubler-Jung, 1999), more recent data based on the study of the *Krox20* gene suggests that neuromeres evolved first among craniates. This conclusion is warranted, as in null mutants of that gene there is selective disappearance of rhombomere 3 and 5 (Voiculescu *et al.*, 2001). Genetic analysis has shown that in the absence of *Krox20* the remaining cells of rhombomeres 3 and 5 acquire rhombomere 2 or 4 identities, demonstrating that *Krox20* is essential for odd- and even-numbered territories in the hindbrain. *Krox20* is not expressed in the brain of cephalochordates, thus indicating that rhombomere formation probably evolved after *Krox20* was co-opted into hindbrain patterning (Knight *et al.*, 2000).

In summary, these data indicate a promising beginning but also show, despite their current paucity, that gene expression domains do not constitute a magic bullet that reveals the basic homology of neuromeres across phyla. Evolutionary alterations of gene expression and/or neuronal population differentiation patterns within any given neuromere will make the road ahead as difficult as the road was until here. Still, experimental manipulation of the emerging framework of nested gene expression through gain and

loss of function studies, combined with more sophisticated tracer studies, should reveal the origins of region-specific neuronal phenotypes and their relationships to specific gene expression domains.

2.01.4 Multiplying and Diversifying Sensory Systems for More Detailed Sensory Analysis and More Appropriate Motor Responses: The Conundrum of the Co-Evolution of Ever More Sophisticated Input, Processing, and Output Processes as a Basis for a Runaway Selection

The chicken and egg question to be addressed next is the co-evolution of sophisticated sensory systems and the brains necessary to process the information they provide. As with the evolution of brain regionalization outlined above, it is likely that the evolution of genes predated the evolution of sensory systems, which, in turn, predated the evolution of sophisticated brains. We base this assertion on the simple fact that even animals with a basiepithelial nerve plexus, like some jellyfish, may have both eyes and ears (Kozmik *et al.*, 2003). Conversely, to date, no animal is known that has a sophisticated brain but lacks sensory inputs entirely. Indeed, in animals in which a specific sensory system becomes the leading sensory input, the brain areas dedicated to this input tend to increase in absolute size and complexity (Nieuwenhuys *et al.*, 1998). Clearly, among deuterostomes the degree of development of sensory systems and brain go rather well with each other. For example, no specialized sensory system is known for hemichordates or echinoderms (Bullock and Horridge, 1965). Urochordates have some specialized systems associated with water intake (Mackie and Singla, 2004) and have two simple receptors in the rostral ganglion (Meinertzhagen *et al.*, 2004). The most sophisticated sensory system of cephalochordates encompasses the organs of de Quatrefages and their function is still unknown (Lacalli, 2004). This raises the problem of ancestral craniate senses that are causally linked to the progressive evolution of the brain. Judging from the central representation size and abundance of receptors, it appears that chemical sense and tactile sense are the dominant sensory inputs to the hagfish brain (Braun, 1996, 1998), but it remains unclear whether this is a primitive or a derived condition. Overall, craniate evolution is clearly correlated with greater sophistication of eyes and ears. We therefore provide below a brief comparison of these two organs in craniates and gnathostomes.

2.01.4.1 Eyes

Vertebrate eyes have long been regarded as uniquely derived features that are homoplastic to arthropod eyes. This is related to the unusual development as an evagination of the forebrain not found in any other phylum. However, recent years have highlighted a number of transcription factors and, more recently, opsin proteins that are related across phyla (Kozmik *et al.*, 2003; Arendt *et al.*, 2004). Indeed, a molecular link between the photoreceptors and opsins of invertebrates and vertebrates was recently proposed (Arendt *et al.*, 2004) and may be extendable to deeper evolutionary connections between eyes and mechanoreceptors (O'Brien and Degnan, 2003; Fritzsch and Beisel, 2004; Niwa *et al.*, 2004; Piatigorsky and Kozmik, 2004). Minimally, this raises the possibility that at least the molecular building blocks of eyes are homologous across phyla and arose already in coelenterates, thus indicating a deep homology of all eyes. While it cannot be excluded that hemichordates and echinoderm ancestors had more sophisticated eyes, it seems more plausible to assume that lack of eyes in these two taxa is primitive. If so, eye evolution would begin in deuterostomes with the chordates. It has been proposed that the frontal organ of cephalochordates is homologous to the lateral eyes of craniates and this suggestion is backed by some connectional data as well as by the expression of Pax6 (Lacalli, 2004). Furthermore, some data suggest that all retinal neurons may be directly related to the sensory receptors (Arendt, 2003) and past differences perceived in opsins among metazoans have recently been reconciled (Arendt *et al.*, 2004).

This may be so, but we want to explore here the basic organization of cyclostome retinas that appears to be primitively different from gnathostome retinas in several respects (Figure 13). First, like the submeningeal layer of the brain, the vitreal part of the lamprey and hagfish retina is devoid of nerve fibers, which run instead at the level of the inner nuclear layer. Second, most of the ganglion cells are located within the inner nuclear layer and do not form a distinct ganglion cell layer. Last, but not least, cyclostome eyes receive a proportionally large GABAergic retinofugal input from apparently homologous efferent nuclear centers in the midbrain (Fritzsch and Collin, 1990; Fritzsch, 1991; Nieuwenhuys *et al.*, 1998) and this input develops before receptor cells mature (Fritzsch, 1991; Anadon *et al.*, 1998b). These data suggest that cyclostome retinas are only partially transformed from their original neuroectoderm-like cell and fiber layering. The organization of the gnathostome

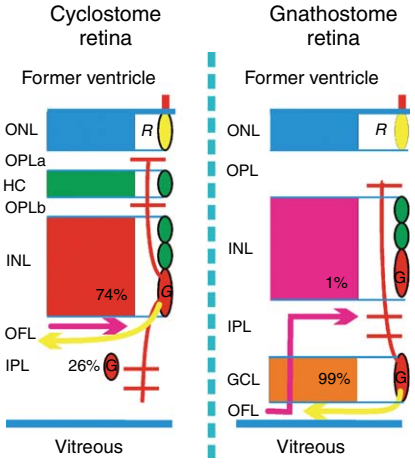

Figure 13 Differences in the fiber and cell layers of the cyclostome and gnathostome retinas. Note that the receptor processes of the outer nuclear layer (ONL) protrude into the former ventricle. In lampreys, horizontal cells are separated from the ONL and inner nuclear layer (INL) by two sublayers of the outer plexiform layer. Lampreys have about 74% of their ganglion cells (G) located in the INL, whereas only 1% of ganglion cells of jawed vertebrates are found in this layer, with 99% being in the ganglion cell layer (GCL). Afferent (yellow) and efferent (lilac) fibers project in lamprey along the INL. In jawed vertebrates, such fibers run in the outer fiber layer (OFL) at the vitreous. It is conceivable that the formation of myelin necessitated a different distribution of myelinated fibers near the vitreous and farther away from the receptors in jawed vertebrates. Reorganization of ganglion cells into the IPL to eventually form the ganglion cell layer may have been a consequence of this fiber reorganization. HC, horizontal cell; IPL, inner plexiform layer; OPLa, outer plexiform layer a; OPLb, outer plexiform layer b. Modified from Fritzsch (1991) and Anadon *et al.* (1998b).

retina seems to be a transformation of this ancestral pattern (Figure 13). It is important here to realize that the eye of cyclostomes is moved by a different organization of eye muscles and that the pattern of innervation of these eye muscles is also different from gnathostomes (Fritzsch, 1998). In addition, lampreys lack a ciliary muscle and accommodation must happen by other means, potentially related to the triangular shape of the lens. Overall, these data on the eye support the monophyly of cyclostomes and show a radical reorganization of retina organization and eye muscles in gnathostome vertebrates.

2.01.4.2 Ears

Like the eye, the ear has been proposed as an example of deep homology with several transcription factors shared between deuterostomes and coelenterates (Kozmik *et al.*, 2003; Fritzsch and Beisel, 2004; Seipel *et al.*, 2004; Fritzsch and Piatigorsky, 2005). Comparable to the retina, the ear of cyclostomes also shows an apparently primitive organization different from gnathostomes: cyclostome ears have only two canal cristae, lacking the horizontal canal and crista, and they have only a single otoconia-bearing epithelium (Fritzsch and Beisel, 2004). It has been suggested that a gene otherwise related to the forebrain is causally linked to the evolution of the horizontal canal (Cantos *et al.*, 2000; Fritzsch *et al.*, 2001). *Otx1* appears in the gnathostome lineage through duplication and has acquired a novel expression and function in the ear that is not shared by *Otx2* (Morsli *et al.*, 1999). Moreover, several other genes discussed above in the MHB context (see Section 2.01.3) all appear in the ear, again emphasizing that evolutionary change in expression, multiplication of an ancestral gene, and acquisition of a novel function need to be considered when gene expression is to be related to evolutionary alterations. In this context, the evolutionary relation with structures in other deuterostomes that show expression of *Pax2* also have a phenotype in *Pax2*-null mutants (Burton *et al.*, 2004). *Pax 2* has been discussed as a major factor relevant for ear evolution (Wada *et al.*, 1998; Mazet *et al.*, 2003) and has been used to suggest homologies across phyla. However, this idea should be regarded at the moment as tentative and requires support through the expression of other genes (Fritzsch and Beisel, 2004; Holland, 2005). It is fair to say that the ear can be viewed as a miniature problem of craniate head evolution and unraveling the molecule basis of its evolution might pave the way for furthering our understanding of head evolution in general.

Overall, the sensory systems reviewed here show a remarkable progression between cyclostomes and gnathostomes and indicate that these sensory systems present unique components of cyclostomes that set them apart in a likely primitive way from gnathostomes. More detailed understandings of the molecular alterations underlying jaw formation (Shigetani *et al.*, 2002) need to be revealed and related to the sensory and motor reorganizations of the cyclostomes. At the moment, it is safe to say that we do not understand the molecular basis of these changes in enough detail. More experimental work is needed to support the current notion of nested gene expression patterns and their potential evolutionary significance.

2.01.5 Summary and Conclusion

Attempts at linking the evolution of organisms and organs to the evolution of transcription factors that direct developmental processes are greatly complicated by the multitude of poorly understood transcriptional regulatory networks. Emerging issues are the apparent pleiotropic effects of many

transcription factors, the modularity of development, and the evolution of *cis*-acting regulation of transcription factors (Carroll *et al.*, 2005). Conflicts between morphology and genetics, such as the many examples of morphological divergence arising from apparently identical transcription factor expression across taxa, are bound to leave conclusions on molecular and developmental homologies controversial for the near future. For example, recent progress in the long-standing issue of the molecular basis of organ formation has shown that certain *Pax* genes are relevant for the formation of eyes (*Pax6*) and ears (*Pax2*) across many phyla and have evidently arisen from an ancestral *Pax2/6* gene, *PaxB*, that is found in cnidarians (Sun *et al.*, 1997). Moreover, *PaxB* is expressed in the eye and statocyst of cubomedusan jellyfish, cnidarians that already contain these sophisticated organs for vision and mechanoreception (Piatigorsky and Kozmik, 2004). This suggests that evolution may have used paralogues of a single ancestral *Pax* gene to organize the development of both of these peripheral organs, no matter what shape, cell types, and transducer molecules are involved (Kozmik *et al.*, 2003; Piatigorsky and Kozmik, 2004). Since *PaxB* is also expressed in sponges (Hoshiyama *et al.*, 1998), its involvement in sensory development may even have predated the formation of a central nervous system (Lowe *et al.*, 2003; O'Brien and Degnan, 2003; Piatigorsky and Kozmik, 2004; Fritzsch and Piatigorsky, 2005). Such ideas imply that *Pax2/6* expression in the brain and the use of *Pax2/5/8* in the MHB is a secondary co-option of these genes from their original involvement in sensory organ development. As an extension of the principles governing the determination of organs, the fates of individual cells within organs have to be similarly directed. Much as with *Pax* genes, a number of common cell fate-determining transcription factors are co-utilized in the eyes and ears of different species. Examples include the *bHLH* gene *atonal/Atoh1/Atoh5* (Ben-Arie *et al.*, 2000; Niwa *et al.*, 2004), and the Pou domain factor *Pou4f3* (Liu *et al.*, 2001; Wang *et al.*, 2002). It is noteworthy that the selective co-expression pattern of these genes, which appear to be situated downstream of the *Pax2* gene regulating development of the optic nerve and ear (Torres *et al.*, 1996), suggests their specialization for the specification of cells within these two sensory organs. Another example is the *Eya1/Six1* signaling system, which is essential for development of the vertebrate and insect eye and the vertebrate ear (Zou *et al.*, 2004) as well as being used in other aspects of development (Piatigorsky and Kozmik, 2004). Extending this line of inquiry into the CNS, several examples exist of transcription factors controlling the same neuronal phenotype across taxa, such as the *Islet/LIM* genes, which are involved in specifying the motoneuron phenotype in urochordates as well as vertebrates (Price and Briscoe, 2004; Katsuyama *et al.*, 2005), and the *Unc30/Pitx2* gene, which has been shown to control the determination of the GABAergic phenotype in vertebrates as well as the nematode *C. elegans* (Westmoreland *et al.*, 2001). Clearly, a number of the transcription factors and developmental cascades that determine cell fates are shared across phyla and across sensory organs and the CNS. Assuming that these similarities are more than coincidental and in fact indicative of a co-evolutionary history of eyes, ears, and brains, the present challenge is to trace the common origins of these structures to conserved developmental programs. In keeping with the recently emerging concept of a second code for gene regulation (Pennisi, 2004), namely the *cis*-acting regulatory elements, it is possible that enhancers orchestrating the development of specific structures in different species share motifs and properties that have led to the modular use of common transcription factors during the evolution of those structures. One of the challenges ahead is therefore the careful mapping of regulatory elements associated with the transcription factor genes that play pivotal roles in such modules. Obtaining an overarching conceptual framework of the molecular characterization of brain development is likely to provide more than unifying insight into the evolution of the brain and senses. Evolutionary molecular neurobiology is likely also to provide novel insights into human diseases common to such apparently dissimilar organs as the eye and ear, such as Usher syndrome (Fritzsch and Beisel, 2004), myosin IIIa-associated nonsyndromic hearing loss, and retinal degeneration (Walsh *et al.*, 2002), choroideremia (Starr *et al.*, 2004), and Norrie disease and exudative vitreoretinopathy (Xu *et al.*, 2004). Understanding the regulation of common transcription factor modules, and linking this to their expression in topographically distinct contexts, may ultimately lead to a better understanding of the causes and differential penetrance of such inherited diseases.

Acknowledgments

This work was supported by grants from NIH (RO1 DC005590; BF), NASA (NAG 2-1611; BF), and the European Union (QLG2-CT-2001-01467; JG). This investigation was conducted in a facility constructed with support from Research Facilities Improvement Program Grant Number 1 C06 RR17417-01 from

the National Center for Research Resources, National Institutes of Health. We wish to dedicate this chapter to Ted Bullock, a great mentor and friend.

2.02 Origins of the Chordate Central Nervous System: Insights from Hemichordates

C J Lowe, University of Chicago, Chicago, IL, USA

Glossary

amphioxus	Belongs to the cephalochordates, and is the most basally branching node of the chordates.
direct developer	Animals that form an adult body plan from the embryo without an intervening larval stages.
hox *genes*	Homeodomain transcription factors arranged in clusters in the genome that have conserved roles in patterning a range of axial elements in animals.
indirect developer	Animals that employ a discrete feeding larval stage before metamorphosis into an adult.
larvacean	A nonvertebrate chordate closely related to ascidians.
life history	The variety of developmental and behavioral strategies utilized by animals and plants to maximize reproductive success.

2.02.1 Introduction

The origin of the chordate body plan and its unique nervous system has been debated for over a century. The early part of the twentieth century was a particularly active period of speculation, when many of the most influential hypotheses were proposed, but in the latter part of the century the issue stagnated through a lack of new data. The early evolution of deuterostomes has proven to be a particularly problematic node to reconstruct, and remains largely unresolved (Gee, 1996; Lowe *et al.*, 2003; see Evolution of the Deuterostome Central Nervous System: An Intercalation of Developmental Patterning Processes with Cellular Specification Processes, Gene Expression in the Honeybee Mushroom Body and Its Gene Orthologues). There are a variety of factors that contribute to difficulties in addressing this issue, but probably the two most challenging obstacles have been, and continue to be, the uncertainty of deuterostome relationships and the large morphological disparity between extant deuterostome phyla. This has been compounded by a poor fossil record and, by the end of the 1970s, the issue of chordate origins had essentially reached an impasse. The last 20 years have seen a surge in new data with the advent of molecular systematics and molecular developmental genetics. These new data are radically beginning to reshape both our understanding of comparative body plan specification and development, but also, just as importantly, the phylogenetic relationships between the deuterstome phyla (Field *et al.*, 1988; Lake, 1990; Adoutte *et al.*, 2000). Deuterostome phylogeny is currently a very active area of research and will likely be largely resolved at the level of the relationships between the major phyla, as more basal deuterostome genomic data sets become available for more comprehensive molecular phylogenetic analysis. The application of comparative molecular genetics to characterize the development of poorly described groups at critical phylogenetic positions, within the deuterostomes, is beginning to enhance our understanding of the early steps in deuterostome evolutionary history (Holland, 2002; Lowe *et al.*, 2003). We are currently amidst a new wave of discovery in deuterostome evolution as many of the phylogenetically key genomes are now either sequenced or are currently being sequenced. A recent, radical revision to the phylogenetic relationships based on a large genomic data set suggests that there are still plenty of surprises ahead (Delsuc *et al.*, 2006).

In this article, I focus on the insights gained into the origins and evolution of the vertebrate nervous system by the characterization of early development of the nervous system of a bilateral phylum closely related to vertebrates, the hemichordates. The nervous system has been characterized as barely more complicated than that of cnidarians (Bullock and Horridge, 1965) yet the expression of a large suite of transcription factors with critical and conserved roles in anteroposterior patterning and brain regionalization in vertebrates shows unprecedented similarities in relative expression topology in the ectoderm of the developing embryos of hemichordates (Lowe *et al.*, 2003). I discuss the implications of this data for the understanding of early deuterostome evolution and the evolution of vertebrate brains.

2.02.2 Deuterostome Phylogeny and Hemichordate Biology

The phylum Hemichordata is a bilateral phylum of animals, the sister group of echinoderms, and closely related to the chordates. Along with the newly reclassified marine worm, *Xenoturbella bockii*, these four groups constitute the deuterostomes (Figure 1).

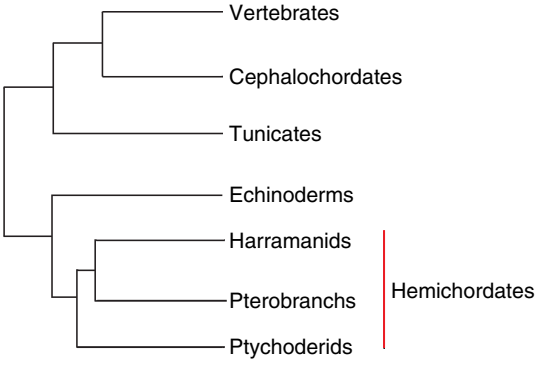

Figure 1 Deuterostome relationships based on 18S RNA. After Cameron, C. B., Garey, J. R., Swalla, B. J. 2000. Evolution of the chordate body plan: New insights from phylogenetic analyses of deuterostome phyla. *Proc. Natl. Acad. Sci. USA* 97, 4469–4474.

Deuterostome phylogeny has been revised many times over the past few years, which has played a major role in refining hypotheses on early deuterostome evolution and the origin of chordates. The first major reorganization occurred with the advent of molecular systematics and resulted in the reclassification of five phyla into the protostomes, leaving only three deuterostome phyla (Field *et al.*, 1988; Lake, 1990) in a topology that has generally been well supported by subsequent studies (Adoutte *et al.*, 2000; Cameron *et al.*, 2000; Bromham and Degnan, 1999). Recently, an obscure, rare, and morphologically unremarkable marine worm, *Xenoturbella,* was reclassified into the deuterostomes with an as yet uncertain phylogenetic position within the lineage. The phylogenetic relationships are continuing to be refined, with some potential for yet more dramatic reorganization as new genomic data sets are generated and phylogenetic methods continue to improve. A new study utilizing new, large genomic data sets from amphioxus, tunicates, and sea urchin challenges the topology established from 18S RNA studies (Delsuc *et al.*, 2006). These results support the sister taxon status of tunicates and vertebrates and are statistically robust. Even more surprising is the grouping of amphioxus with echinoderms (Figure 2b). This node has weaker support, and the analysis lacks sequence data from hemichordates and *Xenoturbella*. If this topology holds up to future analysis, it has sweeping consequences for our understanding of chordate origins and nervous system evolution as it implies the ancestral deuterostome already possessed the fundamental features of the chordate body plan such as somites, notochord, gill slits, and the dorsal centralized nervous system.

Of all the nonchordate deuterostome phyla, the hemichordates are the most promising for addressing issues of chordate origins and the early evolution of the deuterostomes (Lowe *et al.*, 2003).

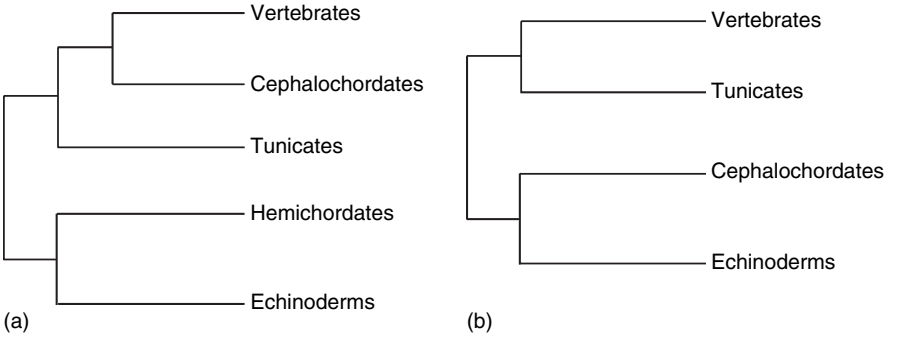

Figure 2 Deuterostome relationships from different molecular data sets. a, 18S RNA (Cameron *et al.*, 2000). b, 146 genes gathered from the genome of a range of deuterostome organisms (Delsuc *et al.*, 2006).

While basal chordates such as amphioxus and ascidians have been key for understanding the diversification of the basic chordate body plan, understanding the origins of the chordate body plan can only be addressed by using outgroups. There are limited options within the deuterostomes for informative outgroups, and the issue of divergent morphologies plays a large role in guiding appropriate choices. The most familiar deuterostome outside chordates is the echinoderms. While a fascinating group, their adult body plan is highly derived (Lowe and Wray, 1997) and difficult to compare directly with the chordate body plan. *Xenoturbella* is rare and poorly characterized so far, which leaves the hemichordates as the only other bilaterian phylum closely related to chordates. Zoological descriptions of hemichordates by Morgan (1894) and Bateson (1885, 1886) recognized their promise for addressing issues of chordate origins and the origin of the chordate central nervous system. As a result of proposed morphological affinities with the chordates, they were originally classified as a subphylum of the chordates and it was not until the 1940s that they were reclassified into their own phylum (Hyman, 1940).

The phylum is divided into two major classes: the pterobranchs and the enteropneusts. The pterobranchs are poorly characterized, in part due to their sparse distribution (having only been described in a few specific locations) and their small size. Their life history is largely colonial, with a few exceptions, and they are all direct developers, each zooid producing only small numbers of oocytes. The enteropneusts are all solitary marine worms, with a broad biogeographic range and habitats from the intertidal down to deep waters and hydrothermal vents. They range in size from a few centimeters up to 2 m and form U-shaped burrows, feeding by ingesting particles and filtering phytoplankton from the seawater. The phylogenetic relationships of the various groups within the hemichordates are currently uncertain, but are beginning to be resolved by molecular analyses (Cameron *et al.*, 2000; Winchell *et al.*, 2002). Currently, phylogenies based on 18S and 28S RNA phylogenies conflict in their placement of the pterobranchs (Winchell *et al.*, 2002). The topology shown in Figure 1 is based on 18S data.

Of the two lineages of enteropneust worms, there is a clear division in life history strategy: in the Harramanid lineage, all species are characterized by direct development, whereas in the other lineage that includes the Ptychoderids, all species have complex life cycles with a prolonged larval period (Cameron *et al.*, 2000; Lowe *et al.*, 2004).

The continued interest in this group is largely a result of proposed morphological affinities of these worms to the chordates. Figure 3b shows the characteristics of the external and internal hemichordate body plan, and Figure 3a shows a photomicrograph of an early juvenile of the Harramanid *Saccoglossus kowalevskii*. The animal has a classic deuterostome tripartite body plan with an anterior proboscis used for burrowing and feeding, a collar or mesosome, and trunk or metasome.

The mouth opens on the ventral side between the collar and proboscis. The metasome or trunk is very long in the adult. Gill slits are another key feature and are located in the anterodorsal region of this body region and occur paired, in large numbers in adults. From a morphological perspective, the gill slits resemble those of amphioxus quite closely and both morphological analysis and molecular analyses suggest that they may represent true homologues (Ogasawara *et al.*, 1999; Okai *et al.*, 2000; Lowe *et al.*, 2003; Rychel *et al.*, 2006). An anterior projection from the gut called the stomochord supports the heart–kidney complex and has been classically compared to the notochord. However, more recently, both morphological and molecular studies have failed to find support for this homology (Ogasawara *et al.*, 1999; Peterson *et al.*, 1999; Okai *et al.*, 2000; Lowe *et al.*, 2003; Ruppert, 2005).

2.02.3 Morphological Characteristics of the Hemichordate Nervous System

Our understanding of hemichordate nervous system organization and structure is based heavily on studies that all date back to before the 1960s. The first person to describe the nervous system of the hemichordates was Spengel (1877). His description of the major elements and organization of the enteropneust nervous system has been borne out by further detailed analysis in the 1940s and 1950s, notably by Bullock (1945), whose reinvestigated the general organization of balanoglossids in his classic paper. In addition, he investigated the giant axon system in 1944 (Bullock, 1944) and the general function of the nervous system in 1940 (Bullock, 1940). The last comprehensive study of the nervous system of this group was by Knight-Jones (1952), further developing the work of Bullock. Silen (1950) also contributed to the body of work, but some of his data and interpretations have been questioned by both Knight-Jones and Bullock. While the basic descriptions are clearly established, there remain

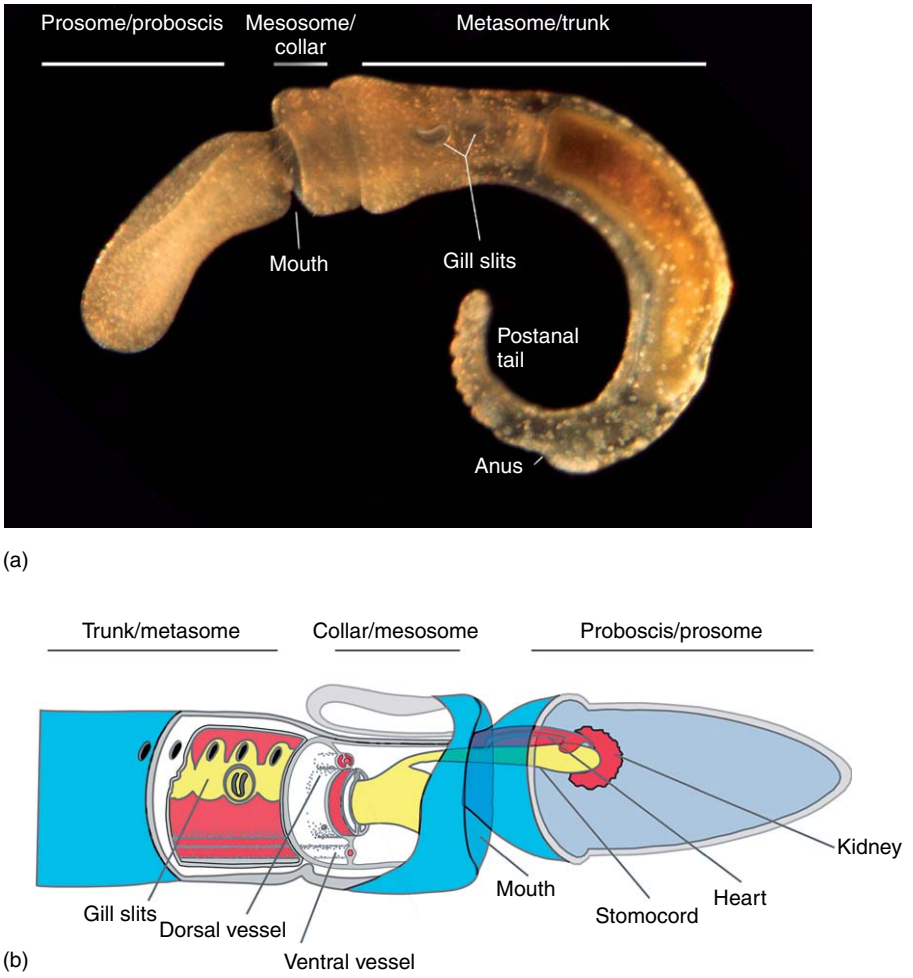

Figure 3 Structure and organization of the enteropneust hemichordate body plan. a, A 13-day-old *Saccoglossus kowalevskii* juvenile. b, Model of the anterior-most region of an enteropneust. Blue, ectodermal derivatives; yellow, endodermal derivatives; and red, mesodermal derivatives.

many unresolved issues in the structure and function of the nervous systems that would benefit greatly from a molecular characterization.

The major organizational feature of the nervous system is a basiepithelial plexus: there is no central nervous system. Cell bodies are scattered throughout the epithelia of the body, with a few exceptions, such as the intestine and gill slits. A mat of axons is spread out along the basement membrane of the epithelia, which is thickened in certain areas of the ectoderm, such as at the base of the proboscis, along the anterodorsal region of the body in the mesosome, and in both the dorsal and ventral midlines of the metasome (Figure 4).

In the proboscis ectoderm, there is a particularly dense concentration of nerve cells that have been proposed to be primarily sensory (Figure 4b; Bullock, 1945; Knight-Jones, 1952). Around the base of the proboscis, there is a particularly dense aggregation of cell bodies. There do not generally seem to be any true sensory organs, but rather individual sensory neurons. One exception is possibly the ciliary organ at the base of the ventral proboscis (Brambell and Cole, 1939). The nerve plexus in the proboscis is particularly thick and axons are organized into lateral and longitudinal tracts that are thought to funnel back to the dorsal peduncle that connects to the collar, passing axons down to the rest of the body (Knight-Jones, 1952). The plexus of axons is particularly thick in this region around the base of the proboscis and forms the so-called anterior nerve ring. Figure 4a shows an updated version of the classic picture from Knight-Jones of the organization of the nerve plexus in hemichordates. A low-magnification confocal Z-series of a 13-day-old juvenile of *S. kowalevskii* following

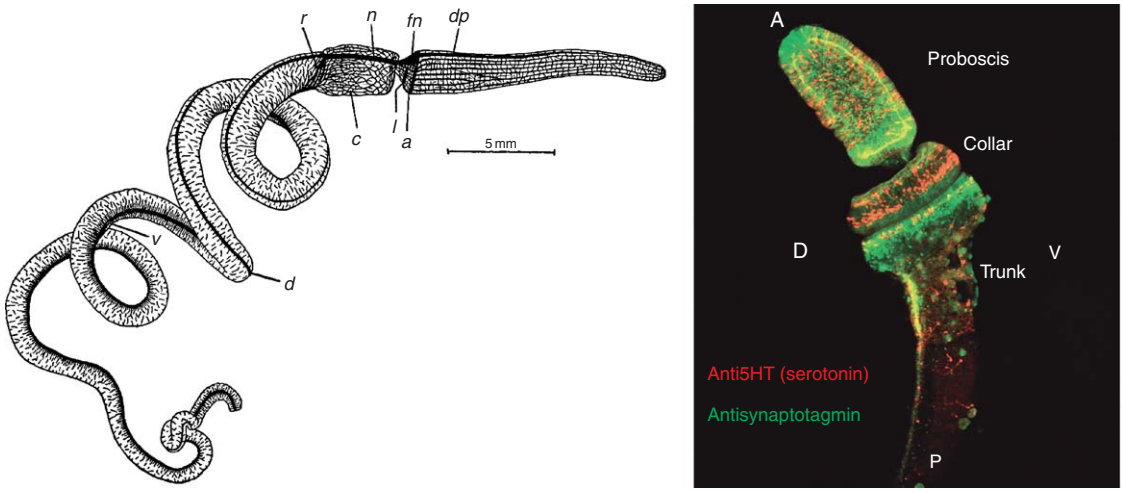

Figure 4 General organization of the nervous system of enteropneusts. a, Drawing from Knight-Jones (1952) of the nerve plexus of *Saccoglossus cambriensis*. d, dorsal cord; v, ventral cord; r, prebranchial nerve ring; c, collar; n, neurocord; fn, fan-shaped thickening of nerve fiber layer; l, ciliary organ; a, anterior nerve ring; dp, dorsal concentration of fibers on the proboscis. b, Confocal micrograph of 13-day-old juvenile of *S. kowalevskii*. Immunocytochemistry of antibodies against serotonin and synaptotagmin (monoclonal antibody courtesy of Bob Burke, University of Victoria). A, anterior; P, posterior; D, dorsal; V, ventral. a, Reproduced from Knight-Jones, E. 1952. On the nervous system of *Saccoglossus cambriensis* (Enteropneusta). *Philos. Trans. R. Soc. Lond. B: Biol. Sci.* 236, 315–354, with permission from The Royal Society. b, Lowe (unpublished).

immunocytochemistry against serotonin and synaptotagmin shows the broad distribution of cell bodies in the ectoderm, particularly densely packed in the anterior ectoderm, collar, and a dense mat of axons, particularly prominent in the base of the proboscis and throughout the proboscis ectoderm, lining the basement membrane (unpublished data).

Probably the most well-known aspect of hemichordate anatomy is the mid-dorsal region of the dorsal cord, or collar cord, which is internalized into a hollow tube of epithelium in some species within the Ptychoderidae and in one species of the Spengeliidae. However, in the other major enteropneust lineage, the Harramanids, there is no contiguous hollow tube, but scattered blind lacunae (Bullock and Horridge, 1965; Nieuwenhuys, 2002; Ruppert, 2005; Figure 5a). This structure has been widely compared to the dorsal cord of chordates due to the superficial similarities to the hollow ciliated nerve cord, and similarities in its morphogenesis with neurulation in vertebrates (Morgan, 1891). However, the similarities have generally been overemphasized as it seems to be more of a conducting tract rather than processing center (Ruppert, 2005), as evidenced by both ultrastructural (Dilly *et al.*, 1970) and physiological data (Cameron and Mackie, 1996). Another striking feature of the dorsal cord is the presence of giant axons (Figure 5b). The number is quite variable between different species, but they are always associated with the dorsal cord and are unipolar cells from 15 to 40 μm in diameter. The cell bodies project their axons across the midline and continue posteriorly within the collar cord. It is not known where the axons finally project: Bullock (1945) proposed that they innervate the ventrolateral muscles of the trunk and suspected that their primary function is to elicit a rapid contraction of the ventrolateral musculature.

In the metasome, the third body region, the most prominent features are the ventral and dorsal nerve cords, which are both thickenings of the nerve plexus. The dorsal cord is contiguous with the collar cord and projects down the entire length of the metasome. The ventral cord is comparatively much thicker, and more cell bodies are associated with the ventral cord, but both cords are interpreted as being through axon tracts. They seem to play a role in the rapid retreat of the animals following anterior stimulation (Knight-Jones, 1952; Bullock and Horridge, 1965). The collar cord seems to play a more minor role than the ventral cord in this response. Ruppert has proposed that the collar cord may be more associated with innervation of the collar musculature that is involved in retraction of the proboscis into the collar, thus sealing the mouth (Ruppert, 2005).

From these studies, there remain some quite fundamental and important questions about the organization of the nervous system. There are still discrepancies between the major texts in terms of the extent of neural plexus and the density of the cell bodies at various regions of the body (Bullock and

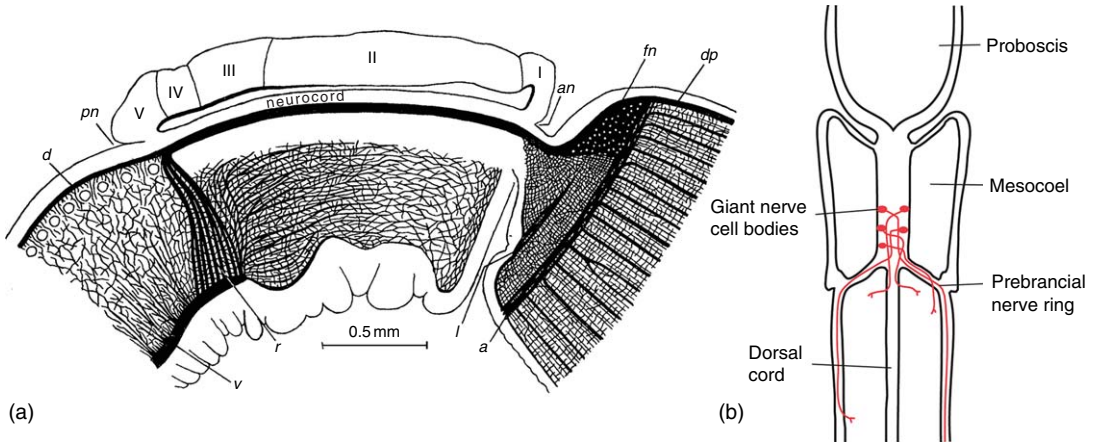

Figure 5 Nervous system of the enteropneust collar/mesosome. a, Drawing of a sagittal section of the enteropneust collar. a, anterior nerve ring; d, dorsal cord; pn, posterior neuropore; an, anterior neuropore; fn, fan-shaped thickening of the nerve fiber layer; v, ventral cord; r, prebranchial nerve ring; dp, dorsal concentration of fibers on the proboscis. b, Dorsal view of collar showing the arrangement of the giant axons. a, Reproduced from Knight-Jones, E. 1952. On the nervous system of *Saccoglossus cambriensis* (Enteropneusta). *Philos. Trans. R. Soc. Lond. B: Biol. Sci.* 236, 315–354, with permission from The Royal Society. b, Redrawn from Bullock, T. H. and Horridge, G. A. 1965. Structure and Function in the Nervous Systems of Invertebrates. W. H. Freeman.

Horridge, 1965). Of fundamental importance is to what extent the nerve plexus and cell bodies show functional differentiation. The classical papers have been unable to distinguish between motor neurons and interneurons, and there is disagreement over which of the ectodermal cells represent neurons, and which ones are glandular or more characteristic of epidermis. The extent to which the plexus shows differentiation along the anteroposterior and dorsoventral axis is also still an open question. Perhaps the most interesting question is whether a greater characterization of the development and differentiation of the nervous system of this group will shed light on the early evolution of the deuterostome nervous system and the evolutionary origins of the chordate central nervous system. Our understanding of the function and differentiation of this nervous system will greatly benefit from the application of basic molecular biological techniques, such as neuron back-filling to map the distribution of cell bodies and where they project their axons; and immunocytochemistry with antibodies raised against conserved neural markers and neurotransmitters to determine the extent of neural differentiation in the nerve plexus.

2.02.4 Proposed Morphological Homology between Vertebrate Central Nervous System and Hemichordate Nervous System

As discussed in the previous section, the classic papers on hemichordate development and evolution have emphasized the critical phylogenetic position of the hemichordates and their relevance for understanding the early evolution of the chordate body plan. Morphological studies have proposed hypotheses on the possible homologies of the enteropneust cords to the dorsal nervous system of chordates. The majority of the papers focus on the possible homology of the dorsal nervous system of chordates with the dorsal collar cord of the enteropneusts. However, more recently an alternative proposal was made that the ventral cord is homologous to the arthropod ventral cord, and the dorsal cord and proboscis plexus homologous to the dorsoanterior brain of arthropods (Nubler-Jung and Arendt, 1996). This would imply that the ventral side of hemichordates is homologous to the dorsal side of chordates. In all of these proposals, both molecular and morphological, the focus of comparisons has been on the axon cords. However, these cords are not the information-processing centers of animals with central nervous systems, but conduction tracts. Both Bullock (1945) and Ruppert (2005) favor homoplasy over homology when comparing the dorsal cord directly with chordates, and argue that the mere presence of a hollow tube is an unreliable character, having evolved independently in several lineages, such as in the cerebral ganglion of some ectoproct bryozoans and in ophiuroids. Other authors have reached the same conclusion (Nieuwenhuys, 2002). Knight-Jones (1952) supports cord homology and argues that the dorsal cord represents a degenerate structure, disagreeing with Bullock. In the next section, I will argue that the fundamental element of relevant comparison between chordates and hemichordates is not the two cords, but the entire basiepithelial nervous system.

2.02.5 Molecular Patterning Events in the Anteroposterior Patterning of the Hemichordate Nervous System

Molecular genetic studies carried out over the past 25 years have established some remarkable similarities in the suite of developmental genes involved in patterning both the dorsoventral and anteroposterior axis of chordates and arthropods and likely all bilaterian phyla (Krumlauf *et al.*, 1993; Arendt and Nubler-Jung, 1994; Finkelstein and Boncinelli, 1994; De Robertis and Sasai, 1996; Lowe *et al.*, 2003; Lichtneckert and Reichert, 2005). Many of the most striking similarities revealed have been during the patterning of the central nervous systems of these two groups (Figure 6). So similar are the relative expression domains of the orthologues of a range of transcription factors along the anteroposterior axis in the developing nervous system of flies and vertebrates that some authors have concluded that the ancestor of bilaterians must have already possessed a complex central nervous system, with an anterior brain already organized into a tripartite structure (Lichtneckert and Reichert, 2005). The plausibility of the arguments depends on this suite of genes being correlated with the development of central nervous systems. However, there has been little comprehensive study of neural specification of any phyla without a highly developed and centralized nervous system. Without comparative data sets in other phyla with more diffuse nervous systems, the hypothesis is difficult to test. The interpretation of this molecular genetic data set is clearly at odds with the classical zoological view of how nervous system evolution has occurred during the evolution of the bilaterian nervous system (Holland, 2003). The current molecular phylogeny of bilaterians most parsimoniously supports a reconstruction of a bilaterian ancestor with a modest nervous system organized as a basiepithlial nervous net, and not the complex, highly regionalized and centralized nervous system, as suggested by the molecular genetic data set.

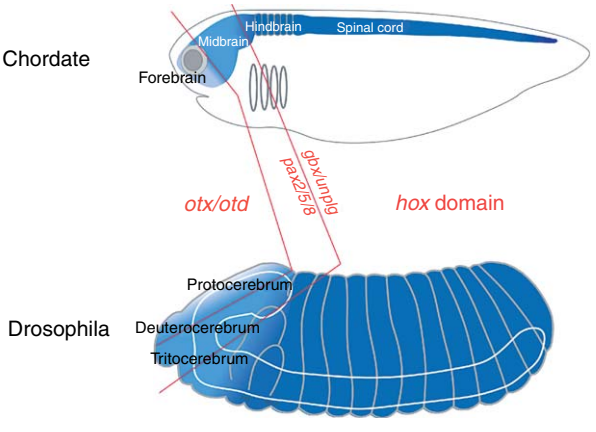

Figure 6 Conserved expression domains of transcription factors between vertebrates and chordates in the developing central nervous system.

We undertook a large comparative study to investigate the role of the transcription factors with conserved roles in anteroposterior patterning of arthropods and chordates during the development of the hemichordate *S. kowalevskii*. The study had two aims: (1) to test the hypothesis of a bilaterian nervous system evolution and (2) to investigate the relationship between the chordate and hemichordate nervous systems. Clearly these suites of genes are very useful axial markers in bilaterian phyla, and their relative expression domains can act as a basic means of comparing body plans of quite distantly related phyla with divergent morphologies (Lowe *et al.*, 2003). *S. kowalevskii* belongs to the Harramanids, which are all characterized by direct development (Figure 1): the adult body plan is formed directly from the egg without any intervening larval stages. We first investigated the observations of Bullock that the entire ectoderm of this animal is neurogeneic without contiguous areas of non-neurogenic ectoderm as in arthropods and chordates. The first group of genes described are all markers of neural differentiation, such as *sox1/2/3*, *musashi,* and *elv*. All of these genes are early markers of neural plate in vertebrates: the first two are early markers of proliferating neural precursors while *elv* is a marker of differentiating neurons (Kim and Baker, 1993; Kaneko *et al.*, 2000; Sasai, 2001). All three orthologues of these genes are expressed throughout the ectoderm of the developing embryos of *S. kowalevskii* from very early stages of gastrulation through to all stages examined. The expression of these genes begins broadly throughout the ectoderm, with expression uniform at early developmental stages. At later stages, expression in the prosome and mesosome is stronger than in the metasome. This observation generally correlates with the distribution of cell bodies described by Bullock (1945).

The remaining characterization of the expression of developmental transcriptional regulators describes the expression of genes involved in the anteroposterio patterning of the vertebrate neural plate. Twenty-two transcription factors with conserved roles in patterning the anteroposterior neuraxis of vertebrates were examined. The surprising result from the study was that the relative expression patterns of these genes in developing embryos of *S. kowalevskii* are highly correlated

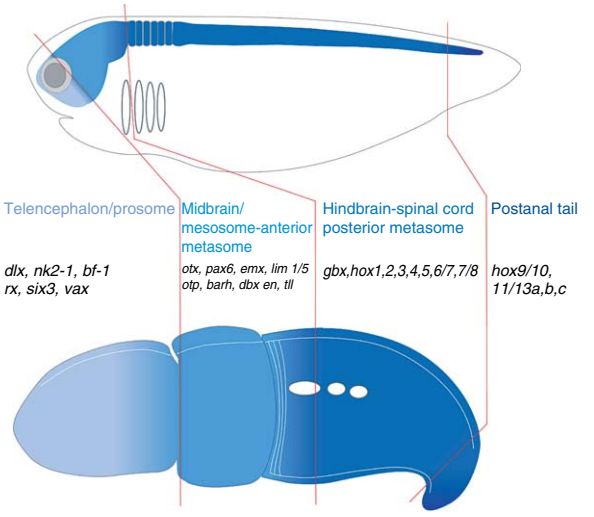

Figure 7 Model showing the similarities of expression domains between *S. kowalevskii* and vertebrates for conserved transcription factors with critical roles in patterning the brain and central nervous system of chordates.

when compared to those in vertebrates (Figure 7). The expression domains, however, were not restricted to either the dorsal or ventral side of the developing embryo, but were expressed in concentric rings in the ectoderm, reflecting the organization of the basiepithelial nerve net. The general domains of expression can be divided into three main fields. In the first, genes that are generally markers of vertebrate forebrain development (*retinal homeobox* (*rx*), *six3*, *nk2-1*, *brain factor-1* (*bf-1*), *distalless* (*dlx*), and *ventral anterior homeobox* (*vax*)) are expressed uniquely in the developing proboscis ectoderm.

In the second region, genes that are predominantly markers of the forebrain and midbrain show correspondingly further posterior domains of expression in the hemichordate embryo; their expression is detected in the more caudal region of the proboscis ectoderm and into the collar/anterior mesosome (*pax6*, *tailless* (*tll*), *emx*, *barH*, *dorsal brain homeobox* (*dbx*), *lim1/5*, *iroquois* (*irx*), *orthodenticle* (*otx*), and *engrailed* (*en*)). Again, their expression is detected in concentric rings in the ectoderm in patterns that approximate their relative expression domains in the midbrain and into the anterior hindbrain of vertebrates. Moving even further posterior in the vertebrate brain, into the hindbrain and spinal cord, in the most anterior domain at the midbrain–hindbrain boundary (MHB), *gbx* defines the limit of the midbrain and antagonizes the expression of *otx,* which is expressed rostrally. The mutual antagonism of these two transcription factors is involved in placing the MHB (Li and Joyner, 2001; Rhinn *et al.*, 2005). In hemichordates, there is a large degree of overlap in *gbx* and *otx* expression, suggesting that these genes may not have similar regulatory interactions in this group. Posterior to *gbx* is the expression of *hox* genes in the hindbrain and spinal cord. As has been well characterized, *hox* cluster members in the 3′ region of the cluster are expressed more anteriorly during embryonic development than cluster members located more 5′. A similar expression relationship is found in hemichordates, with *hox1* expressed just below the first gill slit and the remaining cluster members expressed increasingly more caudally in the ectoderm. This is a consistent pattern for *hox3, 4, 6/7, 7/8*, and *11/13c*. All the remaining *hox* members have been characterized (*hox 2, 5, 9/10*, and *hox11/13a, b*) and all members exhibit colinearity in the same way that other bilaterian groups do (unpublished data). The most posterior members of the hox cluster, *hox11/13, a, b,* and *c* are all expressed in the ventral postanal tail of the late juvenile (Figure 7).

The extent to which vertebrates and hemichordates share patterning similarities is work in progress and is clearly critical for establishing the early patterning systems of the deuterostome ancestor. My lab is investigating the role of signaling molecules with conserved roles in early neural patterning in vertebrates during the early development of hemichordates. The expression of the transcription factors described in the previous section is downstream of early patterning from signaling factors immediately following neural induction in vertebrate development. By the end of gastrulation, the neural plate has already become subdivided into the precursors of the fore-, mid-, and hindbrain (Rhinn *et al.*, 2006). Immediately following neural induction, the entire neural plate expresses *otx2* that in later stages becomes restricted to the fore- and midbrain. This suggests that, at neural induction, the entire neural plate is initially fated as anterior (Gamse and Sive, 2000). Posteriorization by transformation of anterior to posterior fates has been postulated to be the primary mechanism to achieve neural partitioning with candidate signaling from *wnt* (McGrew *et al.*, 1995; Fekany-Lee *et al.*, 2000; Kiecker and Niehrs, 2001), *fgf* (Kengaku and Okamoto, 1993; Lamb and Harland, 1995), and retinoic acid (RA) (Durston *et al.*, 1989; Sive *et al.*, 1990; Conlon, 1995), which are all present in the posterior region of the embryo. Following gastrulation, after the initial global action of *wnts*, *fgfs,* and RA, local signaling centers are set up in the neural plate that further refine the anteroposterior patterning established from earlier signals. These

centers are the anterior neural ridge at the far rostral tip of the neural plate (Shimamura and Rubenstein, 1997; Houart *et al.*, 2002), and the zona limitans intrathalamica at the boundary of prosomeres 2 and 3 (Kiecker and Lumsden, 2004). Further caudally is the MHB or isthmus, which maintains distinct cell fates between the midbrain and hindbrain (Wurst and Bally-Cuif, 2001; Raible and Brand, 2004; Nakamura *et al.*, 2005; Rhinn *et al.*, 2005), and at the far posterior is the tail organizer (Agathon *et al.*, 2003). Is there any evidence of either early action of *wnts*, *fgfs*, and RA in posteriorization of hemichordate ectoderm and nervous system? Is there evidence of signaling centers homologous to those found in vertebrate neural plate?

The evidence for a role of *fgf*, *wnt*, and RA in global posteriorization is mixed outside vertebrates. RA shows the strongest evidence for a conserved role in posteriorization by experiments carried out in both ascidians and amphioxus (Hinman and Degnan, 2000; Matsumoto *et al.*, 2004; Schubert *et al.*, 2004, 2005). There is strong evidence of a posterior organizing center in amphioxus, and weaker evidence in ascidians, but there is ample evidence to propose an ancestral posterior signaling center homologous to the tail organizer in vertebrates (Holland, 2002). However, the role of *fgf* in posteriorization is not well established outside the vertebrates. There are currently no *fgf* data from amphioxus, and data from ascidians showing some localized expression of *fgf8/17/18* in a region that loosely resembles an MHB (Imai *et al.*, 2002) but no functional data have yet been described. Beyond chordates, the evolutionary origins of these signaling factors in ectodermal patterning are not well characterized. RA metabolism has no published account outside chordates, and the role of *wnts* and *fgfs* in *Drosophila* does not support a conserved role in neural patterning homologous to that of vertebrates. The origins of the MHB are equally uncertain: outside vertebrates there is weak evidence for the presence of an MHB-like patterning cassette based on the profile of gene expression (Tallafuss and Bally-Cuif, 2002). Amphioxus perhaps shows the least amount of similarities to vertebrates and lacks many critical markers of this boundary (Takahashi, 2005). Within the urochordates, *Ciona intestinalis* exhibits the most likely candidate for an MHB. However, between species of ascidians, the domains shift quite significantly, and in the larvacean there is no good evidence for such a region (Cañestro *et al.*, 2005). Hemichordates, as an outgroup of chordates, offer an opportunity to investigate the origins of vertebrate neural patterning centers. We have some preliminary molecular evidence that the evolutionary origins of *wnts*, *fgfs*, and RA may be far more ancient than previously anticipated (Gerhart *et al.*, 2005, unpublished data). The localization of the expression of certain *fgfs*, *wnts*, and *wnt* antagonists in the ectoderm of the developing embryo of *S. kowalevskii*, when mapped onto the existing transcriptional map of conserved anteroposterior genes, shows remarkable topological similarities with the localization of their vertebrate orthologues during neural plate regionalization (unpublished data). From our expressed sequence tag (EST) data we have also cloned many members of RA metabolism, such as the receptors RXR and RAR, the enzyme Raldh2 that metabolizes retinol to produce RA (Conlon, 1995), and the enzyme cyp26 that breaks down RA (Ray *et al.*, 1997). Functional data will be required to test whether the early patterning events, following the induction of neural plate, have more ancient deuterostome origins than previously anticipated, but the data so far are very promising.

2.02.6 Evolutionary Interpretations of the Molecular Data from Hemichordates

The expression of the correlated suite of anteroposterior patterning genes with such conserved domains in the hemichordate ectoderm has many implications for our understanding of the evolution of deuterostome nervous systems, but also for how reliable body-patterning genes can be used for reconstructing ancestral neural anatomies of distantly related groups of animals. Do these data allow us to test hypotheses of morphological homology between hemichordates and other bilaterians? For example, a subset of the study genes from Lowe *et al.* (2003) has similar relative expression domains between arthropods and chordates. These similarities have been used to support the hypothesis that the ancestor of protostomes and deuterostomes must have already possessed a complicated and central nervous system (Lichtneckert and Reichert, 2005), as was discussed in an earlier section. However, the correlated expression domains of this suite of genes broadly in the ectoderm of hemichordates raises the possibility that this group of genes acts as a conserved regulatory suite for patterning all bilaterian nervous systems. The study establishes that these genes are not uniquely associated with central nervous system development. It is, of course, also possible that hemichordates lost centralization from a deuterostome ancestor with a central nervous system. However, even if this proves to be the case, correlated suites of developmental

genes expressed in similar topologies between distantly related groups are clearly deployed to pattern diverse types of neural architectures. Caution should therefore be used about using this suite of genes to test hypotheses of morphological homology of specific neuroanatomies.

Clearly the similarities in gene expression between vertebrates and hemichordates does not indicate any sort of morphological homology between regions of the vertebrate brain and the basiepithelial plexus of the hemichordates, so what exactly do these data allow us to compare between groups, and what do they tell us about the early evolution of the chordate nervous system? These data provide, for the first time, a transcriptional rationale or map with which to compare the body plans of vertebrates and hemichordates, and give some critical insights into the deterostome ancestor that gave rise to the chordates. While the details of the morphology of the nervous system (centralized, or diffuse) are difficult to reconstruct from this kind of data, the ancestor clearly used this group of genes to pattern its anteroposterior axis, and likely its nervous system. The various suites of genes involved in patterning the three regions of the vertebrate brain were already present in the deuterostome ancestor. This is a surprising finding based on the studies of similar genes from cephalochordates and urochordates (Takahashi and Holland, 2004; Cañestro *et al.*, 2005; Takahashi, 2005). Neither of these two groups exhibits the degree of similarity in the relative expression domains between vertebrates and hemichordates, suggesting that they have lost some of the complexity of the ancestral transcriptional network. Work from larvaceans, ascidians, and amphioxus has reached sometimes conflicting conclusions regarding the evolution and early chordate origins of the vertebrate brain. These issues have been extensively reviewed elsewhere (Wada *et al.*, 1998; Wada and Satoh, 2001; Mazet and Shimeld, 2002; Tallafuss and Bally-Cuif, 2002; Takahashi and Holland, 2004; Takahashi, 2005). Given the uncertainties of the neural organization of the deuterostome ancestor, searching for morphological homologues of vertebrate brain regions in the early chordates using gene expression as the primary data could lead to misleading conclusions.

2.02.7 Life History Considerations

A discussion of the origins of the chordate nervous system would not be complete without a discussion of life history issues and particularly the potential role of larval forms in the evolution of the chordate dorsal nervous system. As described earlier in this article, enteropeust hemichordates are divided into two major lineages characterized by divergent developmental strategies (Cameron *et al.*, 2000). Developmental studies have been carried out from species from both lineages (Lowe *et al.*, 2004). While *S. kowalevskii* is a direct developer, *Ptychodera flava* is an indirect developer and its early development is characterized by a prolonged larval period in the plankton before metamorphosis into a juvenile many months after fertilization (Tagawa *et al.*, 2001). The early larval development of hemichordates resembles the early larva of many echinoderm species and has been termed dipleurula-type. Study of *P. flava* allows for the investigation of the development of both the larval and the adult body plan of enteropneusts.

One of the most influential and enduring hypotheses on the origin of the chordate nervous system is from Garstang (1894, 1928). He proposed the auricularian hypothesis, which drew directly on the larval similarities between the echinoderms and hemichordates. While the adult body plans of hemichordates and echinoderms are highly divergent, the larval body plans are very similar. The key component of the hypothesis is that Garstang derived the chordate dorsal central nervous system by a dorsal migration of the lateral ciliated bands of an auricularian-type (dipleurula) larva, similar to the early larva of echinoderms and hemichordates. Garstang's hypothesis has been extremely influential on subsequent work in this area (Gee, 1996). There have been many modifications to the original hypothesis, but the essential elements remain the same: the adult body plan of chordates is derived by transformation of a larval life history stage. There are a range of reviews on the features of Garstang's original hypothesis (Lacalli, 1995; Nielsen, 1999), and I will only focus on the molecular genetic studies that are relevant to this hypothesis. There have been a series of papers over the past 10 years on the role of body-patterning genes in larval development relevant for testing the auricularian hypothesis (Lowe and Wray, 1997; Harada *et al.*, 2000, 2002; Shoguchi *et al.*, 2000b; Tagawa *et al.*, 2000; Lowe *et al.*, 2002; Taguchi *et al.*, 2002; Poustka *et al.*, 2004). Some of these studies propose molecular support for the auricularian hypothesis and show expression domains for developmental genes with conserved roles in the development of the central nervous system in chordates, as described in an earlier section. In order to argue compellingly for a molecular case to support this hypothesis, there should be evidence that the anteroposterior patterning domains, which show nested in the nervous system of chordates, have

similarly correlated domains during larval development. Not finding such domains does not disprove the auricularian hypothesis, but finding a correspondingly complex set of domains during the adult life history stage would argue quite strongly against Garstang's theory (Lowe *et al.*, 2003; Haag, 2005, 2006).

Of the genes so far studied, there is the most comparative information on *otx*, which has an anterior localization during the development of the vertebrate nervous system and likely plays a conserved role in the determination of the anterior region of all bilaterians (Finkelstein and Boncinelli, 1994). The expression of *otx* during the development of larvae shows a general association with the development of ciliated bands. There is not, however, any particular anterior bias, with quite a variation in detailed expression domains between larval types of hemichordate (Harada *et al.*, 2000) and holothuroid development (Lowe and Wray, 1997; Shoguchi *et al.*, 2000b; Lowe *et al.*, 2002). *t-brain* is a T-box gene with a largely conserved anterior domain of expression in the development of the forebrain of vertebrates (Bulfone *et al.*, 1995; Mione *et al.*, 2001). Tagawa *et al.* (2000) investigated the expression of the hemichordate orthologue of *t-brain* during early larval development in *P. flava* and detected its expression in the apical organ, at the very anterior tip of the larval ectoderm. They discussed the evolutionary implications of the data and raised the possibility of homology between the apical organ and vertebrate forebrain. However, in a similar study on asteroid larval development, whose early development resembles that of *P. flava* quite closely, there is no such expression detected in the apical organ, and it is confined to the blastopore and endoderm (Shoguchi *et al.*, 2000a). How does one resolve the variability in the expression domains of conserved developmental genes in similar larval morphologies? It is hard to draw firm conclusions when there is such variability in gene expression domains. The same observation is made when *Dlx* expression is examined across echinoderm larval types (Lowe *et al.*, 2002). There is quite a range of expression domains of *Dlx* throughout three different classes of echinoderms, and between different developmental modes during development. Expression in a range of holothuroid larval types is associated with cilia and ciliated bands. However, expression of *Dlx* is not detected in the ciliated bands of asteroid or echinoid larvae, and, unlike vertebrates, is not expressed anteriorly. Of particular note in this study was that, while larval domains of *Dlx* expression varied extensively, the expression domains during early adult body patterning is conservative, and is initially expressed at the onset of the adult body plan as the hydrocoel first begins to form five pouches – the first sign of the radial symmetry of the adult body plan. Perhaps the most telling study is of the expression of *hox* genes during the development of echinoid larvae (Arenas-Mena *et al.*, 2000). Very few *hox* genes are expressed during early development of the larva, and those that are, are expressed in a lineage-specific fashion and not in nested domains, as found in most other bilaterian groups. The first evidence of the expression of *hox* genes in a co-linear manner is late in larval development during the formation of the adult body plan, and expression is detected in the mesoderm rather than the ectoderm.

While a full characterization of body-patterning genes during the development of larval body plans is still lacking, the current evidence supporting larval origins of the chordate body plan is weak . Evidence from Lowe *et al.* (2003) in hemichordate adult patterning, and from limited data during adult body patterning of echinoderms (Morris and Byrne, 2005), support the alternative view that the most fruitful approach for understanding the early origins of the chordate body plan will come from the adult life history stage and not larvae (Lowe *et al.*, 2003; Haag, 2005, 2006). However, it is important to reiterate here that the search for morphological homologies between chordate central nervous system and either life history stage using molecular markers is unlikely to be informative, and even misleading, if gene expression is the only criterion to assess hypotheses of homology. Even similarities in suites of correlated expression domains, as found in Lowe *et al.* (2003), only allow for a reconstruction of the regulatory map that an ancestor must have utilized in early development. Additional data in the form of morphological or fossil data are also required to make strong conclusions about homology.

2.02.8 Future Directions

It seems likely that the story of the origins of chordates and the murky history of early deuterostome evolution is going to remain a topic of hot debate in the near future. The most significant advances will likely occur in the next few years, and most of the progress will be directly due to the completion in sequencing of several key genomes. The sea urchin and amphioxus genomes are close to completion and the genome for *S. kowalevskii* is also timetabled for completion this year. The phylogenetic issues raised in Delsuc *et al.* (2006) will begin to be

resolved one way or another with increased phylogenetic sampling to include additional hemichordates, echinoderms, and *Xenoturbella*. This study clearly shows how interpretation of the molecular genetic data is only as good as the phylogeny used to map the characters. One of the largest gaps in our understanding of body patterning in the deuterostomes is that of the echinoderms. There have only been a handful of studies investigating body patterning of the adult echinoderms, and mention of echinoderms in discussion of deuterostome body plans generally dismisses them as being too derived to give informative data for reconstructing early deuterostome evolution. It is still possible that the highly divergent symmetry system of echinoderms, and their odd morphologies, are still regulated by the conserved ectodermal transcriptional network as described in this review. Further work will be required to test this hypothesis. Ongoing research in my lab is investigating the similarities in nervous system patterning between vertebrates and hemichordates, and this work will help establish the extent to which transcriptional and signaling elements of vertebrate brain patterning were established early in deuterostome evolutionary history, and which ones evolved much later during chordate diversification.

2.03 Evolution of the Nervous System in Fishes

M F Wullimann and P Vernier, DEPNS – Institute of Neurobiology A. Fessard, CNRS, Gif sur Yvette, France

Glossary

actinopterygians	Sistergroup of sarcopterygians, include all ray-finned fishes, that is, bichirs (*Polypterus*) and the reedfish (*Calamoichthys*), together forming the cladistians, the sturgeons (chondrosteans), the gars (*Lepisosteus*; ginglymodes), and the bowfin (*Amia*; halecomorphs), as well as the manifold modern ray-finned fishes, the teleosts.
agnathan(s)	Descriptor for all jawless fishes; the two extant groups, lampreys (petromyzontids) and hagfishes (myxinoids) are not considered monophyletic here, since petromyzontids are more closely related to gnathostomes.
Bauplan	Set of ancestral characters shared by all organisms (or one of their organs; e.g., the brain) forming a given taxon.
chondrichthyans	Outgroup of remaining gnathostomes, including all cartilaginous fishes, that is, elasmobranchs (sharks, skates, and rays) and holocephalans (chimaeras).
cladogram	Branching diagram of taxa exclusively based on shared derived characters (synapomorphies).
gnathostomes	Vertebrates with true jaws (chondrichthyans, actinopterygians, sarcopterygians).
monophyletic group	Taxon that includes all descendants of a last common ancestor.
neuromeres	Transverse units (segments) of developing neural tube (rhombomeres, prosomeres).
neuromeric model	Assumes transverse (neuromeres) as well as longitudinal units (roof, alar, basal, floor plates) along the entire anteroposterior neural tube axis, and that their arrangement is guided by selective regulatory gene expression that allows for regionalized developmental processes.
organizing centers and patterning	Restricted regions of the embryo that secrete specific signalling molecules, responsible for specifying distinct domains (molecularly, anatomically, functionally distinct) in competent neighbouring tissues. This process is called patterning.
phyletic method	Uses cladistic methodology (cladograms, outgroup comparison) for establishing evolutionary polarity (i.e., ancestrality vs. derivedness) of characters.
sarcopterygians	Sistergroup of actinopterygians, including lobe-finned fishes, that is, *Latimeria* (actinistians) and the lungfishes (dipnoi), and all land-vertebrates (tetrapods).

2.03.1 Introduction: *Scala Naturae* Concept is Hard to Kill

The designation of fishes and amphibians as 'lower' vertebrates and of amniotes – or even mammals only – as 'higher' vertebrates expresses the pervasive

ladder concept of linear progress along the vertebrate phylogenetic tree (*Scala naturae*). Instead of considering the mammalian condition as the peak of vertebrate Bauplan perfection – a very idealistic viewpoint of the ladder of progress concept – Charles Darwin and his followers have argued that one should rather view the evolution of species in general, and the evolution of vertebrates in particular, as having occurred in a bush-like fashion (see Butler and Hodos, 2005 for recent review). Viewing evolution as a bush and not as a ladder implicates that each living species is neither 'higher' nor 'lower' than the others. Species simply diverged from each other at different time points during phylogenesis. This separation always included changes in early development, resulting in different animal forms and functions. Thus, many modern, derived features evolved independently in various vertebrate lineages, at the same time as many ancestral traits were shared by all vertebrates, representing the inheritance of their common ancestor. Most animal forms became extinct at some point or another, the extant species representing merely a relatively small selection of those forms that survived for reasons of adaptation or other factors, such as geographic isolation or escaping mass extinctions.

To reconstruct the evolution of the vertebrate brain, modern neurobiologists use the comparative (cladistic) method for establishing the evolutionary polarity of brain traits. This method analyzes single-organism characters instead of entire organisms or their brains, and allows to determine whether a neural character is ancestral (plesiomorphic) or derived (apomorphic) using well-supported cladograms (Figure 1). Cladograms are exclusively based on shared derived characters (synapomorphies). Sistergroups (e.g., sarcopterygians–actinopterygians in Figure 1a) are characterized by synapomorphies inherited from their last common ancestor, separating them from the outgroup taxa (e.g., cartilaginous fishes in Figure 1a). The outgroup comparison determines the evolutionary polarity of particular neural characters. If two conditions occur in sistergroups (evagination of telencephalic hemispheres in sarcopterygians; eversion in actinopterygians), the condition in the outgroups is investigated (evagination in cartilaginous fishes) which, for reasons of parsimony (i.e., principle of choosing the simplest explanation), is considered to represent the ancestral condition.

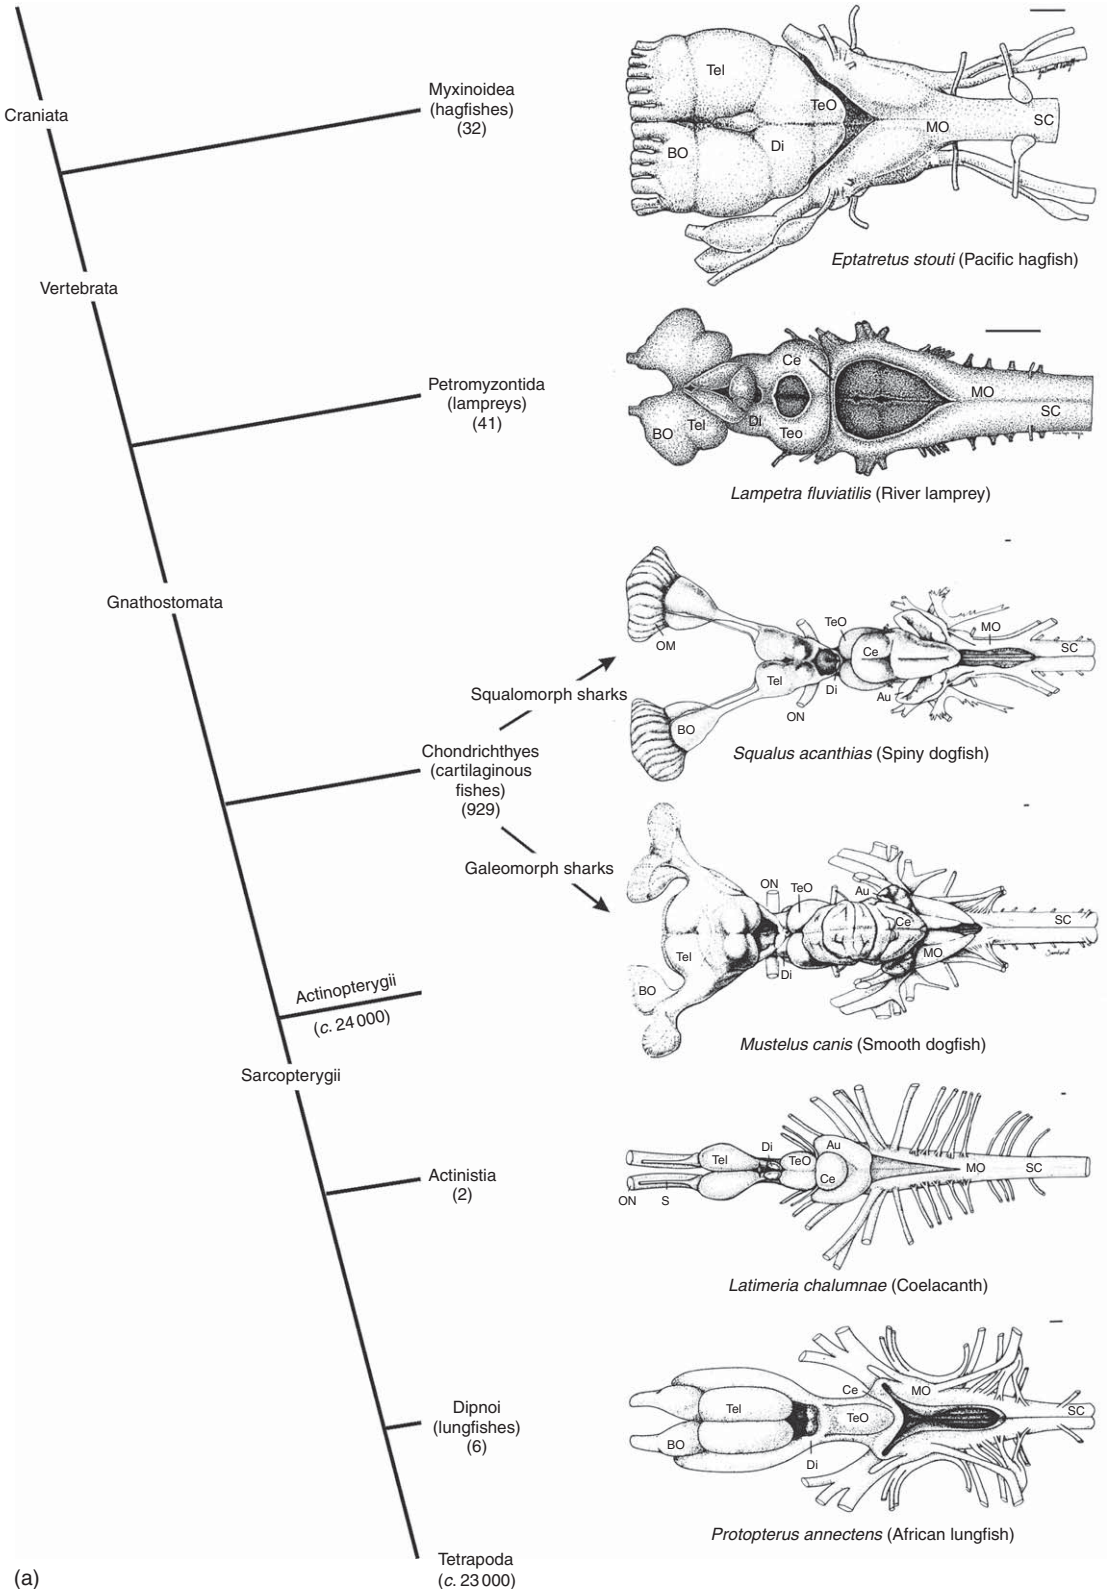
Despite this meanwhile well-accepted change of perspective brought about especially by the cladistic school in evolutionary theory, the metaphoric value of the *Scala naturae* concept is hard to kill. Especially the vertebrate brain evolution is still often viewed as proceeding from an assumed simple brain in various fish groups or amphibians to increasingly larger and more complex brains with greater capacity in turtles, lepidosaurs (lizards and snakes) and birds, with mammals being at the summit of the ladder, and this phenomenon is believed to be notable in the brain diversity of extant vertebrates. However, this view is highly biased by anthropocentric, teleological thinking. In the following, we discuss the notion of progress during vertebrate brain evolution, with special emphasis on fishes, and ask in particular whether *Scala naturae* thinking is supported by brain weight/body weight data or degree of histological and morphological complexity (see Section 2.03.2), by functional neuroanatomy (see Section 2.03.3), and by neurochemical brain organization (see Section 2.03.4).

2.03.2 Diversity and Bauplan of Fish Brains from Agnathans to Lungfishes

What are fishes? Fishes represent a way of life rather than a monophyletic craniate group (Figures 1a–1c). Extant fish groups include species such as the Comoran and Indonesian coelacanths (Actinistia; two species) and the lungfishes (Dipnoi; six species), both of which are sarcopterygians (lobe-finned fishes), the taxon that includes tetrapods (Figure 1a). Within the tetrapod radiation of approximately 23 000 species, amphibians amount to almost 4000 (18%), reptiles to more than 6000 (26%), birds to almost 9000 (38%), and mammals to slightly more than 4000 (19%) species.

The sistergroup of the sarcopterygians is comprised of the actinopterygians (ray-finned fishes, often regarded as the 'true fishes'). Actinopterygians are the most successful vertebrate radiation, since they represent half of all living vertebrate species (almost 24 000), forming a symmetrical dichotomy in vertebrate evolution. Thus, it is hard to argue objectively that there is a linear increase in evolutionary success going from fishes to mammals. The outgroup to sarco- and actinopterygians are the chondrichthyans or cartilaginous fishes (holocephalans, sharks, and batoids, i.e., rays and skates), a rather successful ancient gnathostome radation (around 1000 extant species). Two more outgroups to gnathostomes exist, namely the extant agnathan petromyzontids (lampreys; around 41 species), which constitute the vertebrates together with the gnathostomes and myxinoids (hagfishes; 32 species), which complement the vertebrates in the formation of the craniates (Figure 1a).

The craniate taxon indeed entails a large increase in anatomical and physiological complexity, as



(a)

Figure 1 (*Continued*)

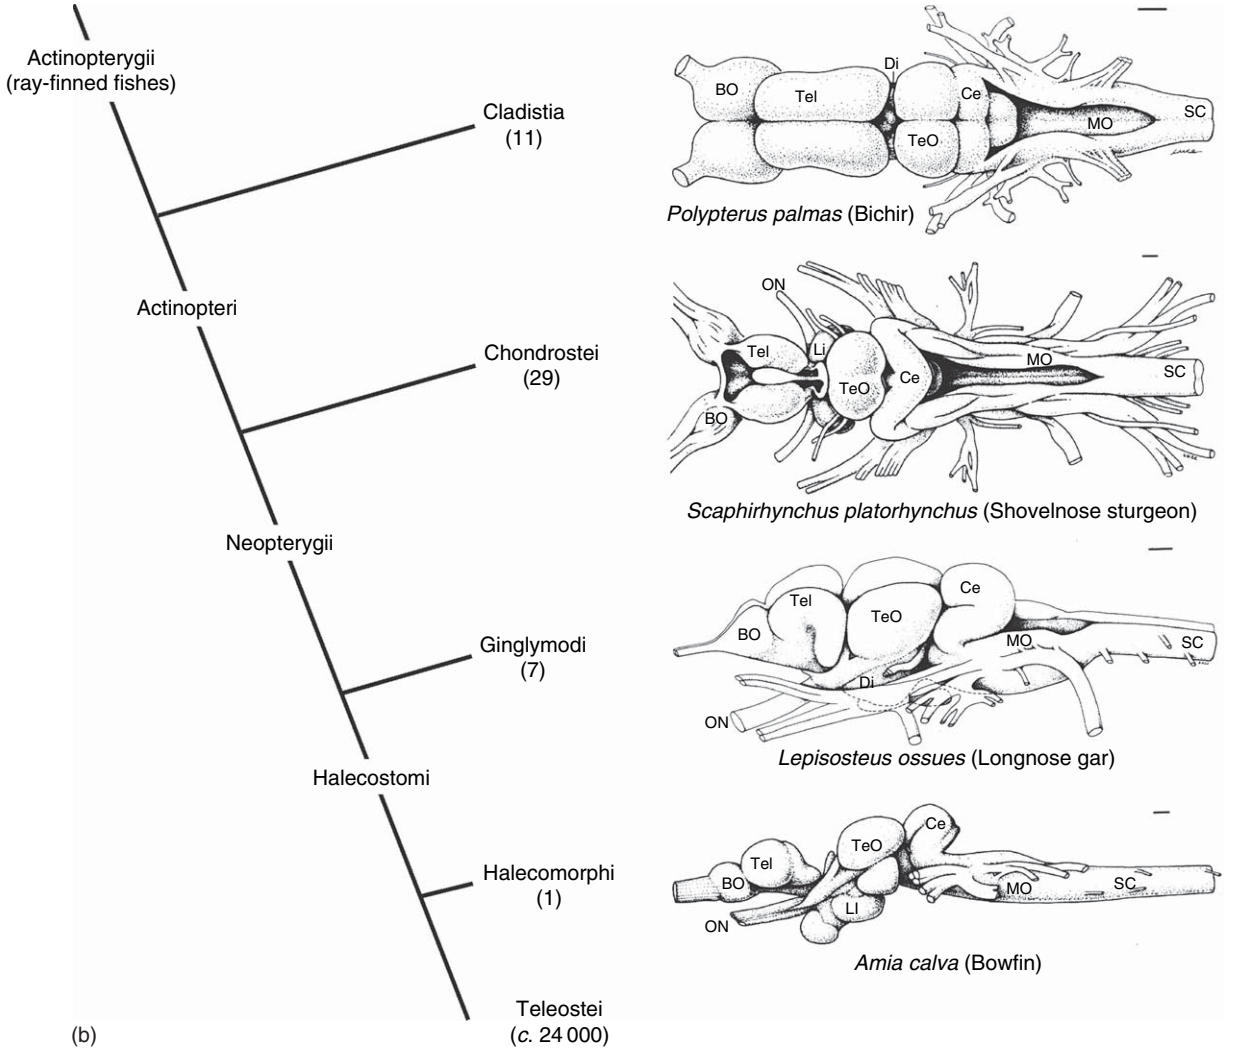


Figure 1 (*Continued*)

compared to its protochordate outgroups, that is, cephalochordates (amphioxus) and urochordates (ascidians). The recent advances of genome sequencing have rejuvenated the idea put forward originally by S. Ohno that the generation of craniate morpho-functional complexity relies upon the generation of a genetic complexity (Ohno, 1970). Indeed, craniates have on average 2 times more genes than protochordates, mainly resulting from the duplication of already existing genes (Furlong and Holland, 2002). Although no agreement has been reached on the mechanisms at the origin of this increased genetic complexity (Hughes and Friedman, 2003), a double duplication of the whole genome of a chordate ancestor (the 2R hypothesis) may have been instrumental in the emergence of craniates, more than 500 Mya (Lynch and Conery, 2000; Levine and Tjian, 2003).

Considering actinopterygians (Figure 1b), modern teleosts are as remote from their Paleozoic ray-finned fish ancestors as modern mammals differ from their Early Mesozoic sauropsid ancestors. Moreover, ray-finned fishes (actinopterygians) flourished several times in evolution (Carroll, 1988), first as chondrosteans (especially the palaeoniscoids) in the Paleozoic, and continuing with the (historically called) holosteans in the Mesozoic. These two actinopterygian radations independently generated many forms apparently adapted to all sorts of enviroments, probably from deep sea and free water to coral reefs. In contrast, the living descendants (i.e., cladistians, chondrosteans, gynglimodes, halecomorphs; Figure 1b) of nonteleost actinopterygians are small in species number.

Interestingly enough, the analysis of the whole genome of several teleost fishes, and gene data from

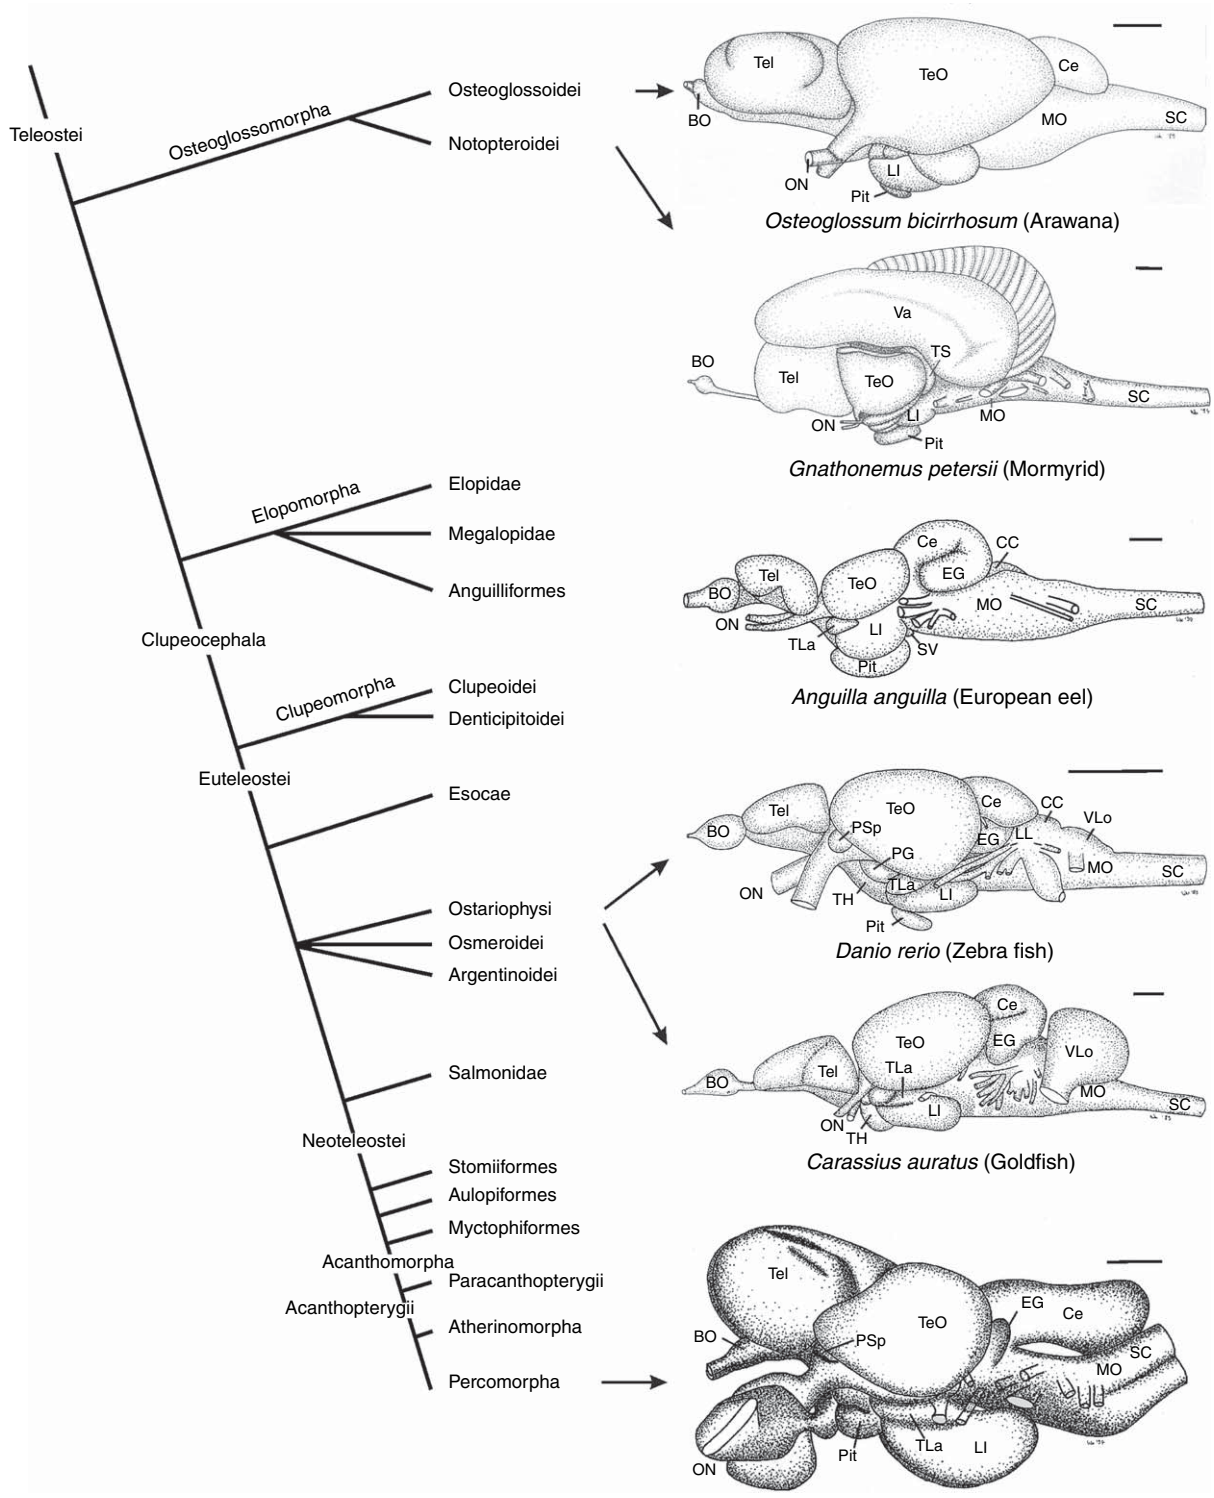

Figure 1 Cladograms depict systematics of extant a, craniate; b, actinopterygian; c, teleostean taxa. Lateral or dorsal views of representative brains are shown on the right side. Au, auricle; BO, olfactory bulb; CC, crista cerebellaris; Ce, cerebellum; Di, diencephalon; EG, eminentia granularis; LI, hypothalamic inferior lobe; LL, lateral line nerves; MO, medulla oblongata; OM, olfactory mucosa; ON, optic nerve; PSp, parvocellular superficial pretectal nucleus; Pit, pituitary; PG, preglomerular area; S, secondary olfactory peduncle; SC, spinal cord; SV, saccus vasculosus; Tel, telencephalon; TeO, optic tectum; TH, tuberal hypothalamus; TLa, torus lateralis; TS, torus semicircularis; Va, valvula cerebelli; VLo, vagal lobe. Scale bars: 1 mm. Adapted from Lauder, G. V. and Liem, K. F. 1983. The evolution and interrelationships of the actinopterygian fishes. *Bull. Mus. Comp. Zool.* 150, 95–197. Some drawings courtesy of Helmut Wicht (*Eptatretus*), Christoph Weigle (*Lampetra*) and R Glenn Northcutt (cartilaginous fishes, sarcopterygians, nonteleost actinopterygians). Species numbers according to Berra (1981), except cartilaginous fishes (Hamlett, 1999).

other groups of actinopterygians, has consistently shown that an additional round of genome duplication occurred between nonteleost actinopterygians and teleosts around 335–404 Mya (Hoegg *et al.*, 2004). Accordingly, teleost fishes have about 2 times more genes than the other craniate/vertebrate groups including mammals, a fact that also breaks the ladder of an assumed increasing complexity from fish to mammals. It is plausible that this genetic complexity of teleosts may have been critical for their tremendous species diversification, leading to the invasion of all aquatic environments covering 80% of the Earth's surface (Meyer and Van de Peer, 2005). The fossil origin of teleosts (Figure 1c) lies in the Early Mesozoic (Late Trias, as does that of mammals; Carroll, 1988), when teleosts started to form free water fish swarms (pholidophorids, leptolepids). But teleost speciation, in particular that of the acanthomorphs (which include the percomorphs), increased tremendously toward and after the cretaceous–tertiary boundary. Thus, acanthomorphs and placental mammals originate in the fossil record at around the same geological time.

2.03.2.1 Bauplan: The Shared Ancestral Brain Morphotype

Despite the apparent considerable diversity of general morphology (Figure 1) and internal organization of fish brains (see Sections 2.03.2 and 2.03.3), one can nevertheless establish a brain Bauplan or morphotype, that is, use the comparative method to demonstrate shared primitive characters that define the ancestral craniate or vertebrate brain (Northcutt, 1985; Wicht and Northcutt, 1992). Such a comparison makes clear that no stepwise addition of brain parts at the anterior pole of the neuraxis occurred during craniate evolution, as had been envisaged historically by E. Haeckel and followers (terminal addition and recapitulation; see Butler and Hodos, 2005, for review). Rather, it shows that most basic brain parts were initially present in craniate/vertebrate ancestors, with the possibility to develop novelties and peculiarities from a common morphotype, as originally proposed (in a different form) by von Baer (1928).

All gnathostome fishes exhibit the five conventionally recognized amniote brain parts (shown in Figure 2): from rostral to the caudal telencephalon, diencephalon (both together: forebrain), mesencephalon (midbrain), metencephalon (including the cerebellum), and myelencephalon (both together: hindbrain). The latter two, without the cerebellum, are often referred to as medulla oblongata. Classical embryology describes that the vertebrate brain develops from a three-vesicle stage (rhombencephalic vesicle including metencephalon and myelencephalon, mesencephalic vesicle, prosencephalic vesicle including diencephalon and telencephalon) into a five-vesicle stage (representing the primordia of the five adult brain parts mentioned). The rejuvenation of paradigms of neuromeric organization further suggests that the craniate rhombencephalon develops from seven to eight transitory neuromeres (rhombomeres), and that the prosencephalon does so from at least three more neuromeres and a less clearly segmented secondary prosencephalon (prosomeres; Puelles and Rubenstein, 1993, 2003; cf. the discussion of molecular data below). Neuromeres, originally described by von Baer (1928), are both morphologically defined entities, as well as territories of gene expression representing a useful framework to compare and interpret morphological observations from one species to another.

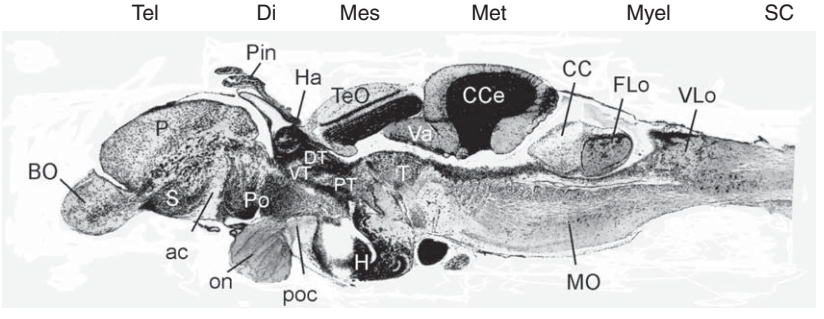

Figure 2 Sagittal section of adult zebra fish brain shows histology of major brain parts. ac, anterior commissure; BO, olfactory bulb; CC, crista cerebellaris; CCe, corpus cerebelli; Di, diencephalon; DT, dorsal thalamus; FLo, facial lobe; H, hypothalamus; Ha, habenula; Mes, mesencephalon; Met, metencephalon; MO, medulla oblongata; Myel, myelencephalon; on, optic nerve; P, pallium; Pin, pineal organ; Po, preoptic region; poc, postoptic commissure; PT, posterior tuberculum; S, subpallium; SC, spinal cord; T, tegmentum; Tel, telencephalon; TeO, optic tectum; Va, valvula cerebelli; VLo, vagal lobe; VT, ventral thalamus (prethalamus). Modified from Wullimann, M. F., Rupp, B., and Reichert, H. 1996. Neuroanatomy of the Zebrafish Brain. A Topological Atlas. Birkhäuser Verlag.

The vertebrate rhombencephalon is ancestrally characterized by its association with the majority of cranial nerves and their primary motor and sensory centers, that is, the trochlear (IV), trigeminal (V), abducens (VI), facial (VII), otic (VIII), glossopharyngeal (IX), and vagal (X) nerves, as well as the lateral line nerves (including a mechano- and an electroreceptive component).

The mesencephalon of vertebrate fishes includes dorsally an optic tectum (visual-multisensory; corresponding to mammalian superior colliculus) and a torus semicircularis (auditory-lateral line; corresponding to mammalian inferior colliculus) which may become somewhat ventrally displaced during ontogeny in certain taxa, as well as a ventral tegmentum which is dominated by motor structures, for example, oculomotor nerve (III) and nucleus.

Classically, the vertebrate diencephalon has been described in dorsoventral order to consist of epithalamus, dorsal thalamus, ventral thalamus, posterior tuberculum, and hypothalamus, with the pretectum intricately intermingled with diencephalic cell groups. The neuromeric model instead (Puelles and Rubenstein, 1993, 2003) proposes that pretectum, dorsal thalamus, and ventral thalamus (prethalamus) represent three transverse neural tube units or prosomeres along the longitudinal brain axis. The posterior tuberculum of fishes develops from the ventral portions of prosomeres 2 and 3, and the region of the nucleus of the medial longitudinal fascicle represents the ventral portion of prosomere 1. The optic nerve (II) enters the diencephalon at the ventral boundary region of preoptic region and hypothalamus.

The telencephalon of all fishes includes a pallium and a subpallium representing, together with the hypothalamus (as well as eminentia thalami and preoptic region), the most anterior, prechordal part of the neural tube (proposed to represent three prosomeres of the secondary prosencephalon; see the discussion above). Thus, the diencephalon gains a new meaning in the neuromeric model, since the classical dorsoventral order of diencephalic divisions transforms into a caudorostral sequence of the anterior neural tube. The olfactory nerve (I) enters the olfactory bulb at the anterior pallial pole of the telencephalon. The terminal nerve (0) is also associated with the telencephalon.

Most of the above-discussed vertebrate neural characters also apply to myxinoids (craniates). However, in contrast to gnathostomes, hagfishes have no recognizable cerebellum, and lampreys also only have a rudiment of it, lacking Purkinje cells or other major rhombic lip-derived elements. Interestingly, the lamprey rhombic lip region also lacks *Pax6* expression which is mandatory for the development of cerebellar structures in gnathostomes (Murakami *et al.*, 2005). Another novelty of gnathostomes is the presence of three semicircular canals in the vestibular inner ear, whereas hagfishes and lampreys have a simpler labyrinth. This is directly related to the absence of expression of one *Otx* gene in the otic placode of agnathans in contrast to gnathostomes (Germot *et al.*, 2001). Therefore, both agnathan groups offer no reasonable distinction between met- and myelencephalon.

Furthermore, myxinoids, but not lampreys, lack external eye muscles, as well as the associated cranial nerves and nuclei (e.g., III, IV, VI) and a terminal nerve, as well as the electroreceptive – but not the mechanoreceptive – component of the lateral line nerves (Braun, 1996; Wicht, 1996; Wicht and Northcutt, 1998). The absence of these and additional neural characters may be part of the ancestral condition for craniates, corroborating that myxinoids form the outgroup to vertebrates. Unfortunately, the lack of an appropriate outgroup to craniates prevents a test of an alternative explanation, namely that these myxinoid characteristics evolved as secondary reductions.

In any case, considerable evidence from modern developmental studies is in support of a basic craniate/vertebrate Bauplan just outlined.

2.03.2.2 Extension of Bauplan: Phylotypic Stage in Brain Development

Neuromeres are useful paradigms for comparing brain morphologies. They are also morphogenetic units resulting from the specification of the neural phenotype, which is an ongoing succession of cell-fate determination in spatially defined regions of the neuroepithelium. The conservation of neuromeres throughout the craniate taxon reflects major constraints on the development of the neural tube. During neurulation, the neural tube closes and becomes patterned along the anteroposterior axis (neuromeres) and along the dorsoventral axis (roof, alar, basal, floor plates). This patterning corresponds to the restriction of cell movements and to polyclonal cell divisions that become confined to a neuromeric unit.

A key feature of this cell patterning in the neural tube is that it also corresponds to gene patterning. In other words, morphogenetic units are also territories of defined gene expression. A probable proximal cause of this gene patterning is the existence of local sources of inductive signals located in the so-called organizing centers such as in the roof plate (members of secreted bone morphogenetic

proteins (BMPs) and wingless-related factors – WNTs) in the floor plate and zona limitans intrathalamica (ZLI) (secreted Hedgehog factors, Shh; induced after expression in notochord and prechordal plate), in the anterior neural ridge (ANR) or in the midbrain–hindbrain boundary (MHB), both secreting FGF8. The signals emitted by these centers coordinate the action of proliferation-related neurogenic or proneural genes at specific locations to maintain or inhibit proliferation of neural progenitors, leading to the formation of segments or neuromeres (Wurst and Bally-Cuif, 2001; Bertrand *et al*., 2002; Lekven *et al*., 2003; Buckles *et al*., 2004; Wilson and Houart, 2004; Figure 3). In addition to neurogenesis, local signals control the expression of other classes of genes, providing an identity, that is, a restricted fate of differentiation, to the precursor born in one of these neuromeres, and linking neurogenesis to neural differentiation.

Thus, there is a stage during neural development where the segmental or neuromeric organization of the neural tube is easy to recognize. During this stage, the acquisition of positional identity of neuroblasts under the control of signaling coordinates and specific genetic networks takes place. The important aspect of this paradigm is that neural determination and subsequent differentiation is acquired in a strict spatially defined manner, similar to the so-called phylotypic stage in the hourglass model of development by Duboule (1994) and Raff (1996). Before this phylotypic step, gastrulation and neurulation can significantly vary from one vertebrate species to another, provided they lead to a neural tube that is spatially organized into morphogenetic units, which may be neuromeres or finer units. The direct consequence of the phylotypic gene regulations is generation and differentiation of neural precursors in a time-and-space-defined manner within morphogenetic units. Neural precursors produced in a given morphogenetic unit will then proliferate, migrate, and establish connections with other brain parts, often losing their original spatial distribution. These events may differ from one species to another and render the neuromeric organization difficult to recognize at later stages of development or in adults.

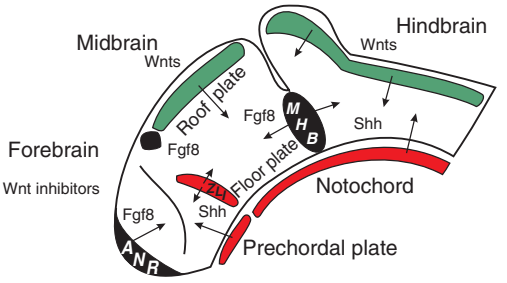

Figure 3 Schematic lateral view of early zebra fish brain with some major signaling centers indicated. Their activity underlies dorsoventral and anteroposterior regionalization leading to the formation of a Bauplan during the phylotypic brain development stage. ANR, anterior neural ridge; MHB, midbrain–hindbrain boundary; ZLI, zona limitans intrathalamica. Adapted from Buckles, G. R. Thorpe, C. J., Ramel, M.-C., and Lekven, A. C. 2004. Combinatorial Wnt control of zebrafish midbrain–hindbrain boundary formation. *Mech. Dev.* 121, 437–447 and Wilson, S. W. and Houart, C. 2004. Early steps in the development of the forebrain. *Dev. Cell* 6, 167–181.

Thus, this central nervous phylotypic stage results from tight constraints of neural differentiation, and certainly accounts for the striking conservation of the neuromeric organization of the neural tube in vertebrates, providing an easily recognizable framework for brain comparisons between species. From an evolutionary point of view, the phylotypic stage is also the developmental master theme on which many species-specific brain variations emerge depending on functional adaptation.

The best example of phylotypic structures is found in the neuromeric organization of the vertebrate rhombencephalon. Here, the combined action of proneural genes and positional cues, which depends on the spatially defined expression of *Hox* and *Nkx*-related genes (the so-called *Hox* code for acquiring positional identity), will, for example, specify the identity of motor neurons in the cranial nerve nuclei and of serotoninergic neurons in the reticular raphe nuclei (Cordes, 2001). In most vertebrates, the pattern of cranial nerves is highly similar, highlighting the power of segmental specification. Still, differences exist, such as the position of the trigeminal and facial nerve nuclei which are not in register with rhombomeres 2 through 4 in lampreys as they are in jawed vertebrates (Murakami *et al*., 2005). This is due to a rostral shift of *Hox3* expression in lampreys, revealing that positional information is retained, but in this case, independent of rhombomere segmentation.

Also in the forebrain, an astonishing degree of similarity of brain patterning has been described between zebra fish, *Xenopus*, and mouse at critical time point (zebra fish: 2–3 days postfertilization, *Xenopus*: stage 48, mouse: embryonic day 12.5/13.5). This morphogenetic pattern nicely corresponds to the differential presence of neurogenic and proneural gene expression, which later affects the differentiation of neurotransmitter phenotypes. For example, in the mammalian brain, γ-aminobutyric acid (GABA)-ergic cells are born and determined in the embryonic ventral subpallium (i.e., the medial ganglionic eminence), the determination of which depends on a genetic pathway that includes the regionalized expression of *Dlx1/2*, *Nkx21* and *Lhx6* and

of the proneural *Mash1* gene. A very similar situation is observed in *Xenopus* and zebra fish (Wullimann *et al.*, 2005; Mueller *et al.*, 2006). In the mouse, a large fraction of these ventrally born GABA neurons later migrate tangentially into the pallium, that is, the future cortex (reviewed in Wullimann and Mueller, 2004) where they become interneurons. In the zebra fish, migration of GABA neurons into the pallium likely also occurs (Mueller *et al.*, 2006), but the adult arrangement of interneurons in the zebra fish pallium remains to be described precisely. Interestingly, the absence of *Nkx2.1* expression in the lamprey subpallium correlates with the absence of GABA cells in the pallium (Murakami *et al.*, 2005). In contrast, the determination and differentiation of glutamatergic cells of the pallium (cortex) depends on the concerted activity of *Neurogenin1* and *NeuroD* in areas where *Pax6*, *Emx1/2*, *Tbr1*, and *Lhx9* are expressed in a regionalized manner (Wullimann and Mueller, 2004, and references therein).

These observations suggest that there are indeed strictly defined temporal and spatial requirements for a given neuronal phenotype to be differentiated (e.g., for GABAergic neurons), reflected in the strict spatiotemporal patterning of gene expression at the phylotypic stage. It is also the stage when proliferation of neural precursors is the most tightly regulated, affecting thereby relative final size of brain areas and total brain size as a consequence. Assuming comparable changes in cell cycle lengths during development of different species, the later the cell divisions stop the larger the brain will be. This requires that sufficient energy is produced by the organism to support brain metabolism, linking brain size to body size.

2.03.2.3 Brain Weight–Body Weight Data

How do vertebrate brain weights compare with a *Scala naturae* concept? All organs increase in size/weight with increase in body size. The brain does so at a coefficient of 0.66 of the body weight on average. In other words, the steepness of the regression line reveals a negative allometric growth of brain weight compared with body weight (van Dongen, 1998; Jerison, 2001). A common measure for relative brain size (degree of encephalization) is real brain weight over the expected brain weight. This value is 1.0 if a brain weight lies on the regression line. If the brain is twice the expected size, the value would be 2.0. In such a comparison, humans amount to 6.45, whereas the trout is at a value of 1.2. This may appear supportive of a linear increase in relative brain weight from fish to human and of *Scala naturae*. However, the goldfish amounts to 2.2 and the African electric fish *Gnathonemus petersii* reaches 5.5 (calculated based on brain weights/body weights given in Nilsson, 1996) Furthermore, within mammals, independent brain enlargement is seen in primates, carnivores, whales, and elephants (van Dongen, 1998). This clearly shows that there is independent increase in relative brain weight between and also within major vertebrate taxa and is in accord with a bush-like evolution of relative brain weight as discussed above.

Another way of looking at relative brain weight is to construct minimum convex polygons (Figure 4). It is true that, in such a comparison, the mammalian and bird polygons lie above agnathans, amphibians, and reptiles, that is, mammalian and avian brains are always much larger for a given body weight compared to these other three groups (Jerison, 2001) Interestingly, fossil information (endocasts) shows an increase in relative brain weight during geological times (i.e., tertiary) in mammals, but not in diapsid reptiles (van Dongen, 1998). A similar tendency of brain enlargement is seen in fossil versus extant birds. Thus, based on their evolutionary history of brain enlargement, mammals and birds might be considered 'higher' vertebrates. However, a large fraction of cartilaginous fish and certain teleost (i.e., mormyrid) brain weights overlap with the avian and mammalian polygons. The fact that the mormyrid data have only recently been added (Jerison, 2001) furthermore indicates that the values for ray-finned fishes may not be representative in the face of their large species number (see the discussion above). The fact that many extant cartilaginous fishes as well as at least the mormyrid fishes among ray-finned fishes lie in a range as to overlap with the mammalian or bird polygons also shows that there is no rule that keeps early diverging vertebrate groups intrinsically constrained by way of their systematic alliance to have small relative brain weights. Moreover, in contrast to the general belief that all brain parts increase to the same degree, relative brain enlargement in cartilaginous fishes and teleosts may largely be accounted for by disproportional growth of the cerebellum.

Consequently, these big-brained sharks, rays, and mormyrids would have to be considered as 'higher' vertebrates, together with mammals and birds, which is not useful. Clearly, brain weight–body weight data do not support the common ladder notion of *Scala naturae*, but rather show that independent cases of relative brain enlargement did occur in mammals, birds, cartilaginous fishes, and ray-finned fishes – several times in each –and, thus, represent cases of homoplastic (convergent) evolution of brain enlargement.

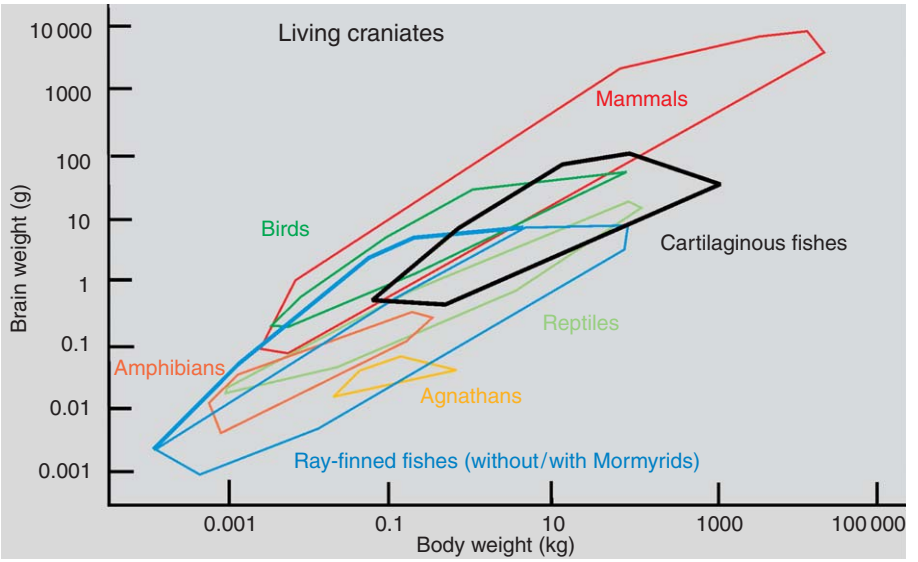

Figure 4 Brain weight/body weight relationships of living craniates. Note that both cartilaginous and ray-finned fish polygons overlap greatly with those of mammals and birds in comparable body size ranges. Adapted from Jerison, H. 2001. The evolution of neural and behavioral complexity. In: Brain Evolution and Cognition (*eds.* G. Roth and M. F. Wullimann), p. 523. Spektrum Akad Verlag/Wiley.

The analysis of environmental factors that may have guided the evolution of relative brain enlargement fits into this picture (van Dongen, 1998). The need for improved sensory and neural processing for finding and discriminating food has been suggested in primates and bats where fruit eaters have larger brains than herbivores/insectivores. Also, socially demanding environments for any given species generally seem to correlate with larger brain size (Striedter, 2005). Alternatively, the high-energy content of certain foods may allow for brain enlargement. Similarly, food-storing birds have a considerably larger hippocampus than closely related birds that do not store food. The degree of precociality at birth in birds – but interestingly not in mammals – is negatively correlated with brain size (van Dongen, 1998). The fact that apparently no general evolutionary factor does account for brain enlargement in mammals and birds, let alone in cartilaginous or ray-finned fishes, is in further support of the convergent nature of brain enlargement in various vertebrate taxa.

2.03.3 Functional Neuroanatomy of Fish Brains

2.03.3.1 How the World and Brain Interconnect: The Peripheral Nervous System

The peripheral nervous system of the head is represented by the cranial nerves. They connect the brain with the sensory and motor periphery and, thus, represent a natural starting point for understanding functional neuroanatomy. As already noted, myxinoids lack terminal, oculomotor, trochlear, and abducens nerves, as well as electrosensory (but not mechanosensory) lateral line nerves, while the situation in lampreys for sensory systems and cranial nerves is similar to gnathostomes in this respect. Therefore, here, we will describe only briefly the ancestral set of cranial nerves and sense organs that defines vertebrates (reviews: agnathans: Braun, 1996; teleosts: Wullimann, 1998; cartilaginous fish: Hofmann, 1999).

The relationship of cranial nerves and brain can only be understood in the larger context of how the vertebrate head is developmentally constructed (Northcutt and Gans, 1983). The interactions of the three embryonic germ layers during neurulation and their anatomical consequences are considerably more complex in the head than in the vertebrate body trunk (see Wilson and Houart, 2004; Butler and Hodos, 2005). For our purpose, it is important to keep in mind that in addition to neural tube (all somato- and visceromotor nerve components) and neural crest (sensory nerve components) – which are involved in spinal nerve development as well – a third set of neuroectodermal structures, namely the placodes, are involved in cranial nerve development. Placodes are embryonic epidermal thickenings representing neurogenic tissues that give rise to most special head sensory organs and – together with the head neural crest – to their innervating sensory ganglia and nerves.

Of the classical twelve cranial nerves recognized in human neuroanatomy, the hypoglossal (XII,

motor innervation of tongue) and spinal accessory nerve (XI, motor innervation of some neck and larynx muscles) are unique to tetrapods. The remaining ten nerves characterize all vertebrates and, thus, are present in lampreys and gnathostome fishes. The olfactory nerve (I) consists of primary sensory cells in the olfactory epithelium with an axon that projects to the olfactory bulb. In contrast, the terminal nerve (0) is formed by ganglion cells that often lie close to the ventral olfactory bulb and send a peripheral dendrite toward the olfactory epithelium and a central axon into the telencephalon beyond the olfactory bulb. The optic nerve originates from ganglion cells of the retina and is, thus, part of the central, not the peripheral, nervous system. The oculomotor (III), trochlear (IV), and abducens (VI) motor nerves innervate the extraocular eye muscles, with the oculomotor nerve including a parasympathetic component controlling pupillary light reflex. Branchiomeric nerves (V, VII, IX, X) are related to the innervation of one or more (only X) branchial arches or their derivatives (Butler and Hodos, 2005). The trigeminal (V) nerve is concerned with somatosensation of face and oral cavity. The facial (VII), glossopharyngeal (IX), and vagal (X) nerves all include a gustatory component innervating taste buds which may also lie outside the oral cavity on the body surface in fishes where they are always innervated by the facial nerve. Some teleosts have separate primary sensory facial and vagal lobes in the medulla oblongata (cf. Figure 2). All branchiomeric nerves in fishes have a motor contribution for innervating the jaw musculature (V), the hyoid arch (VII) or gill arch musculature (pharynx; IX, X), as well as a viscerosensory and parasympathetic component related to the innervation of head glands or viscera. Clearly, the ancestral vertebrate condition involves more than those ten cranial nerves just discussed. The lateral line nerves of vertebrate fishes – as many as six may be ancestral for gnathostomes (Northcutt, 1989) – innervate mechanosensory neuromasts (hair cell receptors) and electroreceptors on the body surface (Bullock *et al.*, 1983). Closely associated developmentally and functionally is the otic nerve (VIII) which innervates the mechanoreceptive hair cells of the labyrinth. Next to the vestibular sense, an auditory component is meanwhile assumed to be ancestral for vertebrates. Northcutt and various co-workers (summary in Northcutt and Bemis, 1993) furthered the comparative and embryological study of placodes, their developmental fate, and adult configuration of cranial nerves which resulted in a new understanding of the vertebrate head and its evolutionary history. This modern view gives a clear definition of sensory cranial nerves including a distinct placodal origin, the resulting peripheral ganglion and sensory receptor structures, and, most importantly, separate primary central nervous projection nuclei. This led to the falsification of the so-called octavolateralis hypothesis, which assumed that lateral line mechanoreceptors on the fish body surface were internalized in evolution into the labyrinth to serve tetrapod auditory function. The related concept of a primary sensory octavolateralis region in fishes where lateral line and otic nerve input forms an overlapping input is also factually false. The ancestral condition for vertebrate fishes is that they have, from dorsal to ventral, three separate sensory medullary columns dedicated to receive segregated lateral line electrosensory, mechanosensory, and otic nerve information (McCormick, 1992).

2.03.3.2 Sensory Systems from Primary Sensory to Higher Order Integrative Centers

There is a great general similarity in the synaptic relay from the primary sensory centers throughout the ascending neuraxis into the subpallium and/or pallium between amniotes and fishes.

2.03.3.2.1 Actinopterygians In teleosts, almost all sensory system pathways have been neuronally traced from primary sensory centers into the telencephalon (for detailed review of original literature, see Wullimann, 1998), which definitely receives largely nonoverlapping information from all sensory systems. Although the homology of sensory pathways between teleosts and tetrapods is not certain in each single case, the degree of similarity is nevertheless of great functional interest. Secondary olfactory input reaches a limited pallial territory in teleosts (in particular the posterior zone of the dorsal telencephalon, Dp, which is considered the homologue of the lateral pallium or olfactory cortex; Figure 5d) as well as most subpallial areas. The teleostean visual system has been described to display a direct retino-thalamofugal and an indirect retino-tecto-thalamofugal system with synaptic relays in the dorsal thalamus. In contrast to amniotes, both teleost visual pathways may be terminating in the subpallium and not in the pallium. However, tectofugal visual information reaches the pallium in certain teleosts via the preglomerular region, a complex of migrated nuclei lateral to the posterior tuberculum. The sensory systems which ascend multisynaptically in the lateral longitudinal fascicle via mesencephalic torus semicircularis and diencephalon to the pallium, that is, audition, lateral line mechanoreception, and electroreception,

are very comparable to the lateral lemniscal system of tetrapods. Gustation in teleosts reaches the diencephalon and telencephalon via a medullary secondary gustatory nucleus, which is comparable to the parabrachial nuclear region of mammals. Finally, teleosts possess a direct spinal ascending somatosensory system similar to the mammalian anterolateral (protopathic) system in addition to indirect spinal ascending projections which are relayed at the obex level, comparable to the mammalian medial lemniscal (epicritic) system.

A notable difference between teleost and amniote ascending sensory circuitry is that the predominant diencephalic targets of teleostean ascending sensory projections are not in the dorsal thalamus, but in the preglomerular nuclei located in the lateral periphery of the posterior tuberculum (Wullimann, 1998; Northcutt, 2006). Specific sensory preglomerular nuclei exist for the auditory, the lateral line mechanosensory, the electrosensory, and the gustatory systems (Figure 5e). There is also a preglomerular nucleus relaying visual information from tectum to telencephalon, at least in some teleosts. Finally, somatosensory information is relayed in the preglomerular region (Finger, 2000). Furthermore, these preglomerular nuclei – and not the dorsal thalamic ones – provide the major diencephalic input to the pallial zones of the area dorsalis telencephali (Figure 5d, left side). Also, the preglomerular nuclei in teleosts clearly display a higher degree of cytoarchitectonic differentiation and interspecific variation compared to the dorsal thalamus. Thus, the functional similarities between the teleostean preglomerular region and the amniote dorsal thalamus are striking: both make up a large proportion of the diencephalon, are subdivided into many nuclei associated with specific sensory systems, and most of them have reciprocal connections with the pallium.

The teleostean telencephalon is divided into a subpallial ventral telencephalic and a pallial dorsal telencephalic area (shown, for the zebra fish, in Figure 5d, right side). Teleostean pallial masses are topologically different from the usual vertebrate location of medial, dorsal, and lateral pallium resulting from evagination of bilateral telencephalic hemispheres (illustrated, for sharks, in Figure 5b). In teleosts, pallial masses are everted (Nieuwenhuys and Meek, 1990) and a recently proposed theory of partial eversion attempts to explain this topology by a developmental mechanism (Wullimann and Mueller, 2004). For our purpose, it is important to note that the posterior zone of the dorsal telencephalic area (Dp) is the major recipient of secondary olfactory input and is considered as the homologue of the lateral pallium (or olfactory cortex). The pallial lateral zone has been described as a visual area, the lateral, central, and medial zones as lateral line mechanosensory, the lateral and medial zones as auditory, the medial and central zones as somatosensory, and the medial zone as gustatory recipient zones in various teleosts species (for review of original literature, see Wullimann, 1998 and Northcutt, 2006).

2.03.3.2.2 Chondrichthyans Historically, the smell-brain theory suggested that the telencephalon of fishes is largely dominated by secondary olfactory input. Thus, ascending sensory systems reaching the telencephalon were believed to exclusively characterize amniotes, or even mammals only. However, the situation summarized above suggests that there is a pattern of ascending sensory pathways to the telencephalon common to tetrapods and actinopterygians. Since sarcopterygians include tetrapods and are the sistergroup of actinopterygians (Figure 1a), it is pivotal to analyze the information on cartilaginous fishes as an outgroup to reveal the ancestral condition of ascending sensory pathways and centers in gnathostomes.

We will first consider the location of diencephalic sensory targets in cartilaginous fishes (for original literature, see Smeets *et al*., 1983; Wullimann, 1998; Hofmann, 1999). Visual information reaches the dorsal thalamus both directly from the retina and via the optic tectum. It is unclear which diencephalic region is involved in chondrichthyan audition, although autoradiographic deoxyglucose data suggest that it is the dorsal thalamus. Cartilaginous fishes also have a lateral lemniscal system. The ascending lateral line mechanosensory information reaches the dorsal thalamus, as well as the region lateral to the posterior tuberculum. Electroreception, on the other hand, does not reach the dorsal thalamus, but is represented in a ventral nucleus, lateral to the posterior tuberculum and in a hypothalamic nucleus, and both nuclei project to the telencephalon (Fiebig and Bleckmann, 1989). Further, directly ascending spinal somatosensory pathways exist up to the dorsal thalamus in chondrichthyans, though the presence of an indirect somatosensory system relayed at the obex level is unclear in these fishes. Ascending gustatory pathways have not been investigated in cartilaginous fishes.

These data in cartilaginous fishes suggest that a dual innervation of the diencephalon (dorsal thalamus/posterior tubercular region) by at least some ascending sensory systems is the ancestral pattern

for gnathostomes. Furthermore, it may be a gnathostome plesiomorphy that hair cell sensory organs in the labyrinth (audition, vestibular sense) are represented in the dorsal thalamus and the remaining hair cell sensory organs (mechanoreception, electroreception) are present in the posterior tubercular region. If so, the evolutionary loss of the latter sensory systems in amniotes may directly explain the dominance of the dorsal thalamus as the diencephalic sensory region in amniotes.

We turn now to the question where sensory systems are represented in the chondrichthyan telencephalon. Cartilaginous fish display evaginated telencephalic hemispheres with medial, dorsal, and lateral pallial divisions located dorsal to the subpallium (illustrated, in the spiny dogfish, by Northcutt, 1981; Figure 5b, left side). As noted above, many cartilaginous fish species have relatively large brains (Figures 1a and 4). In fact, galeomorph sharks and myliobatiforms (stingrays) among batoids show independent brain enlargement, while holocephalans, squatinomorphs, and squalomorph sharks, as well as most skates and rays other than stingrays, remain modest in brain size (Northcutt, 1978; cf. Figures 1a, 5b, and 5c). Apart from the cerebellum (compare *Squalus* and *Mustelus* in Figure 1a), particularly the telencephalon is also enlarged in these groups. Galeomorph sharks (e.g., *Mustelus canis*, the smooth dogfish; Figure 1a) display for example a conspicuous large central nucleus in the dorsal pallium (Figure 5c). Pioneer discoveries by Ebbesson and co-workers (summarized in Ebbesson, 1980) revealed that the telencephalon of the (galeomorph) nurse shark (*Gynglimostoma cirratum*) receives only very restricted secondary olfactory projections from the olfactory bulb to pallial (lateral pallium) and subpallial territories (Figure 5c) and, furthermore, that the nurse shark central pallial nucleus receives substantial contralateral and the lateral dorsal pallium receives ispilateral dorsal thalamic input (unspecified modality). Later, the central pallial nucleus of the nurse shark has been demonstrated to be recipient of a retino-thalamofugal and a retino-tecto-thalamofugal system (Luiten, 1981). Electrophysiological evidence also indicates that visual, somatosensory, and lateral line information is processed in the nurse shark central pallial nucleus (Bodznick, 1991). Furthermore, the medial pallium of the squalomorph spiny dogfish (*Squalus acanthias*) also receives dorsal thalamic as well as posterior tubercular inputs and it has been identified electrophysiologically as a multisensory region (vision, electrosense; Figure 5b right side, Smeets and Northcutt, 1987; Bodznick, 1991). These findings falsify the smell-brain theory because they show that the ancestral situation for gnathostome vertebrates is already characterized by ascending pathways of most, if not all, sensory systems reaching the telencephalon.

2.03.3.2.3 Agnathans Finally, turning to petromyzontids and myxinoids, we shall focus on the forebrain (original literature cited in Braun, 1996; Wicht, 1996). Both subpallial and pallial divisions may be recognized in the myxinoid telencephalon (*Eptatretus stouti*; Figures 1a and 5a). However, the myxinoid pallium apparently does not show three pallial divisions typical of gnathostomes (see the discussion above), but is rather homogeneously organized as a cortex, exhibiting five distinct neuronal layers throughout (Wicht and Northcutt, 1998). Olfactory bulb input covers most of the mediolateral extent of the hagfish pallium, but this input remains restricted to two pallial layers (P1, P5; Figure 5a). Secondary olfactory projections are also extensive – although to a lesser degree – in the lamprey pallium (Polenova and Vesselkin, 1993). However, all hagfish pallial layers receive additional dorsal thalamic input (Wicht and Northcutt, 1998). Furthermore, there are reciprocal connections both with the olfactory bulb and, importantly, with the dorsal thalamus. Also, the lamprey pallium receives dorsal thalamic input (Polenova and Vesselkin, 1993). An outgroup comparison of these findings may indicate that early vertebrates and craniates possessed a more olfactory dominated telencephalon or pallium than early gnathostome vertebrates. However, this is not to revive the smell-brain theory for two reasons. First, extant agnathans are very different from their ancestors (Carroll, 1988) and their life habits are seemingly very specialized for olfactory orientation, possibly representing later adaptive specializations. Second, and more importantly, the fact that diencephalic sensory input reaches the pallium in both lampreys and myxinoids demonstrates that, also in these highly olfactory guided animals, the telencephalon (and pallium) is not exclusively of olfactory nature as the smell-brain theory would predict.

2.03.3.3 Integrative and Motor Systems

Regarding the functional organization of two additional major integrative centers next to the telencephalon, namely optic tectum and cerebellum, surprising similarity is seen between gnathostome fishes and tetrapods. Also, both extant agnathan groups have an optic tectum that shares various inputs and outputs with those of gnathostomes. It

is beyond the scope of this contribution to review this information (for details on all groups, see Nieuwenhuys *et al*., 1998; for cartilaginous fishes, see Northcutt, 1978; Smeets *et al*., 1983; Hofmann, 1999; for teleosts, see Wullimann, 1998). The cytoarchitectonic and modular organization of the craniate optic tectum, its segregated multimodal input, and the topographical representation of this input and output to the reticular formation provide very likely an ancestral neuronal machinery apparently exquisitely designed for integrative orientation tasks, such as object identification and location, and coordinated motor control.

As noted above, a very rudimentary cerebellum may be identified in lampreys, but not in myxinoids. However, gnathostomes clearly have ancestrally a large cerebellum that exhibits the typical three-layered cortex with comparable cell types and internal circuits. Also the afferent and efferent connections of the chondrichtyan and actinopterygian cerebellum are similar to tetrapods, and this suggests that the cerebellum may have ancestral functions in motor learning and coordination in all gnathostomes (see also Evolution of the Cerebellum).

What remains to be discussed is how the fish brain manages to access the efferent structures, that is, the primary motor nuclei of brain and spinal cord, for displaying a particular behavior. Except for the long palliospinal and palliopontine tracts, which represent independently evolved derived characters of (some) mammals and birds, also the motor (spinal and cranial nerve motor nuclei; see the above discussion) and premotor systems of gnathostome fishes resemble those of tetrapods. As in mammals, descending spinal projections in chondrichthyans (Smeets *et al*., 1983; Cruce *et al*., 1999) and actinopterygians (reviewed in Wullimann, 1998) originate in all divisions of the reticular formation, in the caudal (inferior) raphe region (but not in the superior raphe), in vestibular and sensory trigeminal nuclei, and even in a nucleus ruber. Furthermore, the nucleus of the medial longitudinal fascicle is the locus of an ancestral craniate premotor system descending to medullary and spinal levels. Also, in both agnathan groups, all parts of the reticular formation, as well as vestibular and sensory trigeminal nuclei, give rise to descending spinal projections (Ronan, 1989). However, they both lack a nucleus ruber, likely related to the absence of extremities.

As noted above, both optic tectum and cerebellum act on various premotor centers, in particular onto the reticular formation. However, the forebrain control centers of fish spinal descending systems are less well understood compared to tetrapods. Even more than in the case of the ascending sensory systems, studies in cartilaginous fishes and agnathans are urgently needed in order to understand the ancestral gnathostome and craniate condition of multisynaptically descending (extrapyramidal) systems.

2.03.4 Neurochemical Organization

The adult functional fish brain anatomy of excitatory neurotransmitters, such as glutamate and aspartate, as well as of inhibitory neurotransmitters GABA and glycine, remains to be described in detail, although these are certainly involved in sensory, motor, and higher-order circuitry just discussed. Recent descriptions of GABA systems in lampreys or teleosts basically show a similar degree of conservation as seen in the sensorimotor networks they contribute to form. A more complete picture may be drawn here on modulatory neuroactive substances of the fish brain, such as dopamine, noradrenaline, serotonin, histamine, and acetylcholine, with a particular focus on the involvement of these transmitters in the ascending modulatory systems.

2.03.4.1 Dopaminergic, Noradrenergic, Serotoninergic, Histaminergic, and Cholinergic Systems

The neurons that synthesize monoamines and acetylcholine in the craniate brain include the neuromodulatory systems, which regulate all basic functions of the central nervous system (i.e., many aspects of motor programming and sensory processing; Nieuwenhuys, 1985). They are also the main substrate of more specific behavioral processes such as reward and motivation, awareness, aggression or escape, sleep, or thirst and hunger. Accordingly, modulatory systems send most of their projections anteriorly in a very divergent manner, likely accompanying the evolutionary invention of the telencephalon of craniates. They act in target cells through activation of membrane receptors, which belong to different classes (see Kapsimali *et al*., 2003), and mediate different types of responses in the neural networks they control.

2.03.4.1.1 Actinopterygians Neurons synthesizing catecholamines (mostly dopamine and noradrenaline in craniates) were primarily studied by immunohistochemistry of tyrosine hydroxylase, the rate-limiting enzyme of catecholamine synthesis, and sometimes by direct analysis of dopamine or noradrenaline distribution in various

actinopterygian brains (for reviews, see Kaslin and Panula, 2001; Rink and Wullimann, 2001). Here, we will focus on the model animal zebra fish (*Danio rerio*), as there is complementary immunohistochemical information on the serotoninergic, histaminergic, and cholinergic systems, as well as on critical ascending modulatory forebrain and spinal connections.

The zebra fish noradrenergic system (Kaslin and Panula, 2001; Figure 6a) includes medullary cells close to the viscerosensory column/area postrema (comparable to mammalian groups A1/A2; Smeets and Reiner, 1994) and a locus coeruleus (mammalian A6). The other noradrenergic neurons corresponding to the A3–A5 and A7 groups of mammals are not distinguishable separately in the teleost brain. Neurons of mammalian A1/2 exert local control on the respiratory pacemaker and related functions (e.g., swallowing, response to pH changes). These mixed dopaminergic/noradrenergic neurons are highly conserved in vertebrates and probably induce very similar cell responses in a broad range of species. The axons of the zebra fish locus coeruleus (Figure 7b) mainly project anteriorly, with a smaller contingent going to the hindbrain and spinal cord (Ma, 1997). Anterior projections reach virtually all midbrain and forebrain structures as they do in other gnathostomes. In mammals, the locus coeruleus is crucial for two basic components of behaviors, namely arousal (as opposed to sleep or resting states) and awareness, the latter being necessary for focusing on specific aspects of sensory perceptions. Three receptor classes mediate the effect of noradrenaline, α_1, α_2, and β, each of which comprising typically 3–4 subtypes, highlighting the large variety of cellular actions promoted by this neurotransmitter. No precise distribution of all receptors are available yet in teleosts, although α_{2A} and β_2 receptors seem to be more concentrated in anterior pallial areas and β_1/β_2 receptors in pretectal and cerebellar target areas (Zikopoulos and Dermon, 2005). The remaining tyrosine hydroxylase positive cells rostral to the locus coeruleus in the zebra fish brain are dopaminergic (Ma, 1997; Kaslin and Panula, 2001).

Some dopaminergic cell clusters in the zebra fish posterior tuberculum with a ventral telencephalic (likely striatal) projection were recently proposed to be homologous to the most anterior part (now interpreted as basal diencephalic instead of mesencephalic) of the amniote substantia nigra/ventral tegmental area (mammalian A9/A10; groups 1, 2, 4 of Rink and Wullimann, 2001; Figures 6a and 7a). Posterior tubercular zebra fish dopamine neurons project to telencephalic ventral (septum) and dorsal (basal ganglia) divisions, but some projections from the posterior tuberculum may also reach dorsal (pallial) areas, as is the case in mammals and other amniotes. The action of dopamine on these structures is mediated by classes of receptors (D1 and D2), comprising also 2–4 subtypes. In subpallial structures, two receptor subtypes are mainly found, the D_{1A} and D_2 subtypes, which are located on different populations of neurons (Kapsimali *et al.*, 2003). They likely mediate integration of sensorimotor cues in automatic programs of movements (dorsal striatum), as in other gnathostomes. In contrast, the D_{1B} receptors are clearly present in an area located at the Dm–Dl junction, which has been proposed to be homologous to the mammalian hippocampus (Kapsimali *et al.*, 2000; Salas *et al.*, 2003). In addition, some dopaminergic cells in the zebra fish posterior tubercular area project to the spinal cord (McLean and Fetcho, 2004) and, thus, may correspond to A11. Other diencephalic zebra fish dopamine cells include a ventral thalamic group corresponding to mammalian zona incerta (A13; group 0 of Rink and Wullimann, 2001; Figure 6a). Preoptic zebra fish dopamine cells may partially correspond to group A14, as there are strong preoptic projections to the ventral telencephalon (likely to septum; Rink and Wullimann, 2004). Other preoptic dopamine cells in teleosts project on the GnRH producing cells of the ventral hypothalamus, where they exert a highly variable, mostly inhibitory effect on gametogenesis and ovulation via D_2 receptors (Dufour *et al.*, 2005). A homologue of A15 as seen in some mammals additionally in the preoptic region is doubtful in the zebra fish. As all vertebrates, teleosts possess olfactory bulb (A16) and retinal (A17) dopamine cells, where dopamine acts mostly on D2-like receptors likely to increase discrimination for the two sensory pathways as in amniotes.

Clearly, teleostean posterior tubercular and hypothalamic dopamine populations are more numerous (groups 3, 5–7, 9–11; Figure 6a) than those of amniotes and they include three distinct cell types. Liquor-contacting cells (zebra fish groups 3, 5, 7, 10; Figures 6a and 7a) are absent in mammals (but present in all other vertebrates). Zebra fish large pear-shaped dopamine cells are long-distance projections neurons (see above and Figure 7a). Thus, only small round dopamine cells remain as possible candidates for an A12 (mammalian hypothalamic dopamine cells) homologue. Accordingly, numerous nuclei in the ventral and dorsal hypothalamic regions are targets of dopamine neurons. In some teleosts, the D_{1A} and D_{1B}

receptor transcripts have been detected in preoptic nuclei and in the dorsal and ventral periventricular hypothalamic areas. In addition, the D_{1C} receptor, a dopamine receptor subtype which has been lost in mammals, is found in a few restricted areas of the dorsal hypothalamus, including the liquor-contacting cells. Pretectal dopamine cells (group 8; Figure 1a), which project to tectal layers where D_{1A} receptors are found, likely are ancestral for sarco- and actinopterygians, as they are absent in chondrichthyans and agnathans (and, again, absent in mammals). Telencephalic (subpallial) dopamine cells occur ancestrally in agnathans, chondrichthyans, and actinopterygians and are lost in tetrapods, while mammals appear to evolve convergently subpallial dopamine cells.

Turning now to serotoninergic zebra fish brain populations, there are also some striking correspondences to amniotes (Kaslin and Panula, 2001; Figure 6b). However, although the five classes of serotoninergic receptors, which have been isolated in mammals, also exist in teleosts, very few studies have addressed the relationship of serotonin projections and receptor localization. The large

serotoninergic population in the superior raphe, which has a telencephalic projection (Rink and Wullimann, 2004; Figure 7b), is almost certainly homologous to mammalian dorsal and central superior raphe nuclei (B6–8; Nieuwenhuys, 1985). The main target areas of these raphe neurons are probably hypothalamic nuclei where a high amount of receptor binding sites have been evidenced, as well as striatal and pallial areas. Serotonin cells in the zebra fish inferior raphe and in the more caudolaterally located reticular formation (both with spinal projections; Wullimann, 1998) may correspond to mammalian nucleus raphes magnus (B3) and nuclei raphes pallidus/obscurus (B1/2), respectively. There is a distinct population of serotonin cells in the posterior tuberculum, and two more in the hypothalamus of the zebra fish (Figure 1b). The situation in the amphibian posterior tuberculum and hypothalamus is similar (Dicke *et al*., 1997), and sauropsids – but not mammals – also have serotonin cells in the posterior tuberculum (Smeets and Steinbusch, 1988; Challet *et al*., 1996). The zebra fish hypothalamic intermediate nucleus exclusively exhibits serotonin cells, while the paraventricular organ as well as the caudal hypothalamus contain both dopamine and serotonin cells in the zebra fish (Figure 6b). Although absent in amniotes, serotonin cells seen in the teleost pretectum may be ancestral for vertebrates, as they occur in amphibians (Dicke *et al*., 1997), chondrichthyans, and lampreys (see the discussion below), but those in the pineal stalk may be unique to actinopterygians. As in tetrapods, histaminergic cell populations in the zebra fish brain are present exclusively in the most caudal hypothalamus (Kaslin and Panula, 2001; Figures 6b and 7e).

Also the cholinergic system of the zebra fish easily reveals great similarity to the amniote pattern (Figure 6c; for discussion see Mueller *et al*., 2004). First, all motor cranial nerve nuclei (as discussed above) expectedly are cholinergic. Second, there are cholinergic subpallial as well as brainstem neurons possibly corresponding to amniote cholinergic basal forebrain (Figure 7d) and ascending reticular (i.e., pedunculopontine-laterodorsal tegmental; Figure 7c) systems. Also, the zebra fish secondary gustatory nucleus is at least partially cholinergic and projects to the hypothalamus. Furthermore, a cholinergic isthmic nucleus (comparable to the mammalian parabigeminal nucleus) projects to the optic tectum.

2.03.4.1.2 Chondrichthyans The noradrenergic system of cartilaginous fishes also exhibits rhombencephalic groups including cells close to the viscerosensory column and a locus coeruleus (summarized by Smeets and Reiner, 1994). Chondrichthyan dopamine cells are present in olfactory bulb, subpallium, preoptic region, zona incerta, posterior tuberculum, and hypothalamus, where the situation is very comparable to actinopterygians (Smeets and Reiner, 1994). However, elasmobranchs (sharks and skates/rays) have large dopamine cell groups in the mesencephalic tegmentum resembling the amniote substantia nigra/ventral tegmental area. In contrast to all elasmobranchs investigated, *Hydrolagus collei* (a holocephalian, the sistergroup of elasmobranchs) lacks basal mesencephalic dopamine cells (Stuesse and Cruce, 1991); such cells are restriced to the directly adjacent posterior tuberculum (similar to actinopterygians) and this possibly represents the ancestral vertebrate condition (see discussion below). Unfortunately, there is practically no functional information on this system in cartilaginous fishes. Interestingly, chondrichthyans exhibit dopamine cells in the pallium and habenula, features they share (apparently convergently) only with mammals (pallial cells also with some reptiles).

Chondrichthyan serotoninergic cells are abundant in the extensive raphe region and reticular formation (Stuesse *et al*., 1990, 1991; Stuesse and Cruce, 1991). Also, similar to actinopterygians, posterior tuberculum and hypothalamus contain many serotonin cells. The pretectum contains serotonin in some, but not all, chondrichthyan species. There is no report on histamine in chondrichthyans.

The cholinergic system in chondrichthyans (summarized by Rodríguez-Moldes *et al*., 2002) shares many ancestral features with that in actinopterygians, that is, the motor nuclei, potential cholinergic basal forebrain (subpallial) cells, brainstem reticular ascending cholinergic system, an isthmic nucleus, and a possible secondary viscerosensory nucleus. Interestingly, there are pallial cholinergic cells in chondrichthyans, otherwise only seen in mammals.

2.03.4.1.3 Agnathans Noradrenergic cells in lampreys are definitely present in a brainstem group (corresponding to a locus coeruleus) that projects to the telencephalon (nucleus reticularis medius; Pombal *et al*., 1997). The dopamine system of lampreys includes retinal, olfactory bulb, preoptic, and possibly some subpallial cells (Pombal *et al*., 1997). The pattern in the posterior tuberculum and hypothalamus is similar to that in chondrichthyans and actinopterygians. In particular, a projection of dopaminergic posterior tubercular cells to the striatum has been shown, supporting the ancestral presence in vertebrates of a diencephalic homologue of the substantia nigra/ventral tegmental area, as

also seen in some chondrichthyans and all actinopterygians investigated.

In hagfishes, tyrosine hydroxylase containing cells are present in a brainstem group, likely representing a noradrenergic locus coeruleus, as well as in hypothalamic and posterior tubercular positions, presumably representing dopaminergic cells (Wicht and Northcutt, 1994).

The serotoninergic system in lampreys (Pierre *et al.*, 1992) and hagfishes (Kadota, 1991) includes neuronal groups apparently corresponding to raphe nuclei, posterior tubercular, and hypothalamic populations; lampreys also contain a pretectal one, as seen in other vertebrates.

Histaminergic neurons in lampreys have been reported in the hypothalamus and, unlike all other vertebrates, in the midbrain–hindbrain boundary region (Brodin *et al.*, 1990).

Regarding cholinergic systems in the lamprey brain, they also exhibit many ancestral characteristics, that is, motor nuclei of cranial nerves, nucleus isthmi, possibly a secondary viscerosensory population, and even a small cholinergic basal forebrain group (Pombal *et al.*, 2001).

2.03.5 Conclusions

Modern comparative research in developmental biology, functional neuroanatomy, and neurochemical central nervous system organization has fundamentally changed our view of vertebrate brain evolution. The metaphor of the vertebrate brain climbing slowly up the ladder of progress from fish to human has been replaced by the common theme of a largely conservative Bauplan of vertebrate brain organization, upon which uncounted variations are independently generated along various major phylogenetic lines.

2.04 Evolution of the Amphibian Nervous System

U Dicke and G Roth, University of Bremen, Bremen, Germany

Glossary

basal optic neuropil (BON) Situated in the ventral tegmentum. It obtains afferents from all quadrants of the retina. Neurons of the BON are sensitive to horizontal and vertical direction of stimulus movement and, together with the thalamus and pretectum, constitute the circuitry for optokinetic responses.

basolateral amygdala It is disputed whether amphibians possess an amygdalar complex homologous to the mammalian basolateral amygdala of pallial origin.

bed nucleus of the stria terminalis (BNST) Part of the extended central amygdala.

central amygdala Occupies the caudal ventral telencephalon around the ventricle medial to the caudal pole of the striatopallidum in frogs. In salamanders, it is located more rostrally extending ventral to the striatopallidum. It is characterized by reciprocal connections with visceral-autonomic brain centers.

cerebellum Composed of the corpus cerebelli, the auricular lobes, and the cerebellar nucleus. A mossy fiber and a climbing fiber system are present. The cerebellar nucleus is considered homologous to the deep cerebellar nuclei of mammals. Like that of other vertebrates, the cerebellum is involved in sensorimotor integration and motor coordination.

dorsal column nucleus (DCN) Situated in the transition zone between the medulla oblongata and medulla spinalis. It receives somatotopically organized input from the skeletal system. The ascending tracts reach ipsi- and/or contralateral mesencephalic and diencephalic structures.

dorsal pallium Forms the dorsal part of the telencephalon and consists of a dorsomedial and a dorsolateral portion. Neurons of both portions display only intratelencephalic projections. It has associative-limbic functions.

dorsal striatopallidum Occupies the ventrolateral wall of the telencephalic hemisphere; its neurons resemble the medium-spiny neurons of the mammalian caudate-putamen. The rostral portion of this complex is now regarded dorsal striatum proper and the caudal portion dorsal pallidum.

hypothalamus Part of the diencephalon consisting of a preoptic and an infundibular region, which

have wide connections with nuclei of the limbic system and brainstem nuclei. It consists of the preoptic region, the partly cholinergic magnocellular preoptic nucleus, the suprachiasmatic nucleus, the posterior entopeduncular nucleus, the periventricular dorsal, ventral and lateral nucleus, the posterior tubercle, and the periventricular organ.

isthmic nucleus Situated in the caudal tegmentum and essential for object localization and selection. It is homologous to the parabigeminal nucleus of mammals. Retinotectal transmission is facilitated by a cholinergic isthmotectal projection, which is topographically organized and in register with the retinal map.

lateral line system Present in fully aquatic species and in species with biphasic lifestyle during larval stages, but absent in direct-developing or life-bearing taxa. It is involved in directional current detection and current-related postural adjustments.

lateral pallium Occupies the dorsolateral portion of the telencephalon. It is divided into a rostral-intermediate, precommissural, and a caudal postcommissural part. Neurons of the former portion project to the medial, dorsal, and ventral pallium and to the main olfactory bulb, while those of the latter portion send their dendrites and axons along the olfactohabenular tract to the dorsal and medial pallium and to the septum.

main olfactory amygdala Region in the ventrolateral part of the caudal pallium dorsolateral to the vomeronasal amygdala. It is connected to olfactory structures and to the hypothalamus.

medial pallium Occupies the dorsomedial portion of the telencephalon. The dorsal portion of the medial pallium is considered homologous to the mammalian Ammon's horn and the ventral portion to the subiculum; a dentate gyrus seems to be absent. It is believed to be involved in learning and memory formation.

motor nuclei Classically divided into viscero-, branchio-, and somatomotor nuclei. Motor pools display a somatotopic organization and form a medial and a lateral column in the spinal cord of most amphibian species.

nucleus accumbens/ventral striatopallidum Found in the rostral ventromedial telencephalon. It extends caudally to what is now considered the ventral pallidum.

nucleus of the diagonal band of broca Situated ventral to the medial septal nucleus and now believed to be part of the medial septal complex.

pallidum The caudal part of the dorsal striatum is now considered the dorsal pallidum. The ventral pallidum is situated in the ventromedial telencephalon. It is a shell-like caudal continuation of the nucleus accumbens/ventral striatum.

parabrachial nuclei The nucleus visceralis secundarius of amphibians is considered homologous to the parabrachial nuclei of amniotes.

pedomorphosis A form of heterochrony, in which traits that characterize larvae or juveniles of ancestral taxa are maintained in the adult stage of descendant taxa. It involves different degrees of retardation, reduction, or absence of traits in otherwise fully developed organisms.

posterior tubercle Situated in the caudal ventral diencephalon. It contains dopaminergic cells and is homologous to the mammalian substantia nigra pars compacta.

preoptic area/region See hypothalamus.

pretectum Transition zone between diencephalon and mesencephalon (also called synencephalon). Deep and laterally migrated neurons are distinguished with reciprocal connections with other visual centers. Neurons are directionally selective and involved in optokinetic nystagmus.

raphe nuclei Situated along the ventral midline of the entire brainstem. They have extensive ascending projections to all parts of the brain. The exact contribution of

the different raphe nuclei for targets in the forebrain is unknown.

reticular formation — Situated in the brainstem and composed of a median, medial, and lateral zone. These zones differ in the distribution of neurotransmitters. Numerous descending pathways converge onto the zones. Nuclei of the amphibian reticular formation are assumed to correspond to that of mammals.

rostral pallium — Occupies the rostral pole of the pallium and projects to all other pallial regions and, like the ventral pallium, to the dorsal edge of the striato-pallidum.

secondary simplification — Arises from pedomorphosis. A mosaic of fully adult, weakly expressed and missing traits appears at terminal ontogenetic stages. Accordingly, brains have fewer cells, a lower degree of morphological differentiation and reduced cellular migration, but retain the plesiomorphic organization found in other vertebrates.

septum — Located between medial pallium and nucleus accumbens. A medial complex including a ventrally situated nucleus of the diagonal band of Broca, a lateral, and a central complex are now distinguished.

solitary tract — Runs inside the dorsolateral medulla oblongata and receives general and gustatory viscerosensory fibers from the IXth and Xth cranial nerves. It is accompanied by the nucleus of the solitary tract.

striatopallial transition area (SPTA) — Located dorsal to the striato-pallidum. It is considered as part of the ventral pallium. Projects to the (lateral) vomeronasal amygdala and hypothalamus.

tectum mesencephali — Laminated structure forming the dorsal midbrain. It is the main center for visual perception and visuomotor functions. It possesses neuronal types with specific connections to the forebrain and/or brainstem. Here, like in amniotes, object recognition is based on population coding and occurs in a parallel-distributed fashion.

tegmentum mesencephali — Forms the ventral mesencephalon and consists of a dorsal and ventral part with a classical distinction of tegmental nuclei comparable to mammals.

thalamus — The dorsal thalamus contains an anterior, central, and posterior periventricular and an anterior and posterior lateral nucleus. Sensory afferents terminate in the ventral thalamus consisting of a periventricular nucleus and a number of migrated nuclei. In contrast to mammals, the dorsal thalamus does not process unimodal sensory (lemnothalamic) information. The anterior dorsal nucleus combines traits of the mammalian anterior, dorsomedial, midline, and intralaminar nuclei. The central dorsal nucleus of amphibians is regarded homologous to the nucleus rotundus of reptiles and birds.

torus semicircularis — Consists of a principal, laminar, and magnocellular nucleus. It is the major audiomotor interface and the center of convergence of ascending auditory, vestibular, somatosensory, and lateral line pathways as well as descending pathways from the forebrain.

ventral pallium — Situated between lateral pallium and striatopallidum and includes the SPTA. It projects to the accessory olfactory bulb, the vomeronasal amygdala and preoptic region, and hypothalamus.

vestibular nuclei — Situated in the medulla oblongata and divided into four nuclei, which receive projections from sensory epithelia of the canal ampullae, utriculus, sacculus, and lagena of the inner ear.

vomeronasal amygdala — Situated in the caudal ventrolateral telencephalon. It is continuous with the SPTA covering the area formerly called 'lateral amygdala' and is characterized by its massive input from the accessory olfactory bulb and its projections to the preoptic area and hypothalamus via the stria terminalis.

2.04.1 Introduction

In this article, we give an overview of the central nervous system (CNS) (see Basic Nervous System Types: One or Many?, Origin and Evolution of the First Nervous System), i.e., spinal cord and brain, of amphibians in a comparative and evolutionary context. A comprehensive description of sense organs and the CNS of amphibians is beyond the scope of this article, and we restrict a more detailed description to those parts of the CNS that are best studied and of greatest interest for a comparative and evolutionary approach, namely (1) the visual system including retina, optic tectum, pretectum, and thalamus; (2) thalamotelencephalic pathways; (3) telencephalic pallial regions; and (4) telencephalic limbic centers including the basal ganglia. For a more extended overview of the amphibian nervous system, the reader is referred to volume 2 of Nieuwenhuys *et al.* (1998). However, in our article, we include substantial data from more recent studies.

2.04.2 Phylogeny of Amphibians

Modern amphibians, the *Lissamphibia*, form the three orders Anura (anurans: frogs and toads; presently 29 families, about 5086 species), Urodela (urodeles: newts and salamanders; 10 families, about 545 species), and Gymnophiona (caecilians; six families, 170 species) (Frost, 1985; Duellman and Trueb, 1986; Amphibiaweb, 2006). Members of the order Anura are distributed worldwide; those of the order Caudata are found in the northern hemisphere of Eurasia as well as in North America, Central America, and the northern part of South America; and the order Gymnophiona is restricted to the tropics and subtropics of the Old and New World.

Most authors now assume that lissamphibians form a monophyletic group, but a minority assumes a polyphyletic origin for the three orders (cf. Pough *et al.*, 2001). It is assumed that the lungfishes (Dipnoi, six species) are the living sister group to tetrapods and the closest nontetrapod relatives of modern amphibians (Zardoya *et al.*, 1998; Tohyama *et al.*, 2000; Brinkmann *et al.*, 2004).

The earliest limbed vertebrates, the labyrinthodontids (stegocephalians), appeared in the Upper Devonian. Living amphibians have ancient roots and each may have originated in the Paleozoic (San Mauro *et al.*, 2005). Different authors consider them to be either a sister group or descendants of the temnospondyls (living about 340 Mya) (Ruta *et al.*, 2003) or the even more ancient microsaurs (Laurin, 1998a, 1998b). Most temnospondyls were clumsy-looking animals, up to several meters long with a thick, scaly skin, but some, the dissorophoids, were small and gracile and thought by some to be ancestors of the lissamphibia. Modern amphibians are mostly small to very small animals with thin, mostly smooth skin allowing cutaneous respiration: hence the name Lissamphibia (i.e., amphibians with smooth skin). They exhibit many additional traits that distinguish them from their paleozoic ancestors; this suggests that they have undergone substantial evolutionary transformation in the process of pedomorphosis, as will be discussed below.

The relationship between the three amphibian orders is still controversial, but most authors adhere to the hypothesis that salamanders and caecilians are more closely related to one another than to frogs (cf. Pough *et al.*, 2001). Despite their presumed monophyly, the three amphibian orders differ greatly in skeletal structure and way of life. While urodeles retained much of the bodily appearance of ancestral amphibians, anurans have a greatly reduced vertebral column and strongly developed hind limbs. Caecilians, finally, evolved a highly ossified skull and lost their limbs. The ancestors of amphibians most probably underwent metamorphosis including an aquatic larval stage, but many taxa from all three orders developed direct development (i.e., loss of a larval stage), and some of them developed viviparity (Duellman and Trueb, 1986).

2.04.3 Structure and Function of the Amphibian CNS

The CNS of amphibians consists of the spinal cord and the brain, which is divided into five parts, i.e., medulla oblongata, cerebellum, mesencephalon, diencephalon, and telencephalon, as indicated in Figure 1.

2.04.3.1 Spinal Cord

2.04.3.1.1 Gross morphology The amphibian spinal cord possesses cervical and lumbar enlargements characteristic of tetrapods. In transverse sections, the gray matter of the spinal cord typically has an H shape in frogs and a compact, oval appearance in salamanders (cf. Figure 2). The frog spinal cord is divided into a dorsal, lateral, central, ventromedial, and ventrolateral field; the spinal cord of salamanders consists of dorsal, intermediate, and ventral zones. In frogs, the dorsal horns are separated by dorsal funiculi; the substantia gelatinosa is difficult to delimit within the dorsal horn. In salamanders, the dorsal horn mainly consists of the

Scale bar: 500 μm.

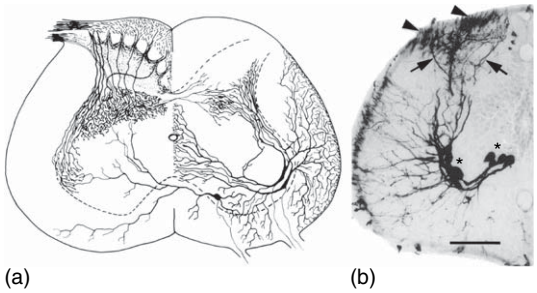

Figure 2 a, Schematic representation of a cross section through the lumbosacral region of the spinal cord of the frog. Motor neurons (right side) belong to the dorsolateral and ventromedial group of spinal motor neurons; their dendrites constitute spatially separate dendritic arrays. On the left side, the projection of dorsal root fibers is illustrated. A lateral bundle of fibers descends into the ventral horn, and establishes contact with motor neurons. The dotted area of the dorsal horn represents the substantia gelatinosa. b, Microphotograph of a transverse section through the spinal cord of *Plethodon jordani* at the level between the third and fourth spinal nerves. After HRP labeling of the superficial ramus of the brachial nerve, motor neurons (asterisks) and sensory fibers are stained. Some primary dendrites (arrows) extend to the dorsal or dorsolateral sensory fiber bundles (arrowheads). Scale bar: 100 μm. a, Reproduced from Frog Neurobiology, 1976, pp. 765–792, Organization of locomotion, Székely, G. and Czeh, G. With kind permission of Springer Science and Business Media. b, From Dicke, U. and Muhlenbrock-Lenter, S. 1998. Primary and secondary somatosensory projections in direct-developing plethodontid salamanders. *J. Morphol.* 238, 307–326.

substantia gelatinosa. The ventral zone comprises the motor neurons, which are arranged in motor columns along the rostrocaudal axis. Ependymal cells line the central canal, and radial glial cells send processes toward the pia. These types of cells are present throughout the CNS; inside the brain, they constitute the layer lining the ventricles.

2.04.3.1.2 Primary afferents Afferent fibers originate from end organs in the skin, joints, and muscles, from free nerve endings of the skeletal system and the inner organs. Dorsal root fibers entering the spinal cord bifurcate into descending and ascending fiber bundles; a lateral division of sensory fibers runs in a bundle comparable to the Lissauer tract of mammals. In the cervical spinal cord, afferent fibers cross the midline and terminate in the corresponding contralateral gray matter. In frogs and salamandrid salamanders, primary afferents ascend to the hindbrain and enter the cerebellum, whereas in plethodontid salamanders they reach the rostral medulla oblongata (Antal *et al.*, 1980; Muñoz *et al.*, 1997; Dicke and Muhlenbrock-Lenter, 1998). A somatotopic arrangement has been described for primary afferents that terminate in the dorsal column nucleus (DCN) situated in the rostral spinal cord (Muñoz *et al.*, 1994a, 1995, 1998). In frogs, primary afferents of the somatosensory system constitute a tract with thick myelinated fibers running in the medial dorsal horn, while thin myelinated fibers run ventrally and laterally to the entrance of the dorsal root. Cutaneous afferent fibers run within the dorsal tract and form a dorsal neuropil, while muscle afferent fibers form a ventral neuropil of the ventral tract, which is contacted by dendrites of motor neurons (Figure 2a). In plethodontid salamanders, both types of afferents form a dorsal and dorsolateral tract and corresponding neuropils, which are both contacted by motor neuron dendrites (Figure 2b).

A variety of neuropeptides involved in transmission of somatosensory and/or nociceptive stimuli (opioids, tachykinins, and FMRFamides) as well as serotonergic, histaminergic, and catecholaminergic fibers have been demonstrated in primary afferent fibers and/or in the dorsal spinal cord of amphibians (Lorez and Kemali, 1981; Danger *et al.*, 1985; Adli

et al., 1988; Salio *et al.*, 2001; Sanchez-Camacho *et al.*, 2001b; Partata *et al.*, 2002; Chartrel *et al.*, 2002; Guedes *et al.*, 2004) (see Somatosensory Specializations in the Nervous Systems of Manatees).

2.04.3.1.3 Autonomic neurons Sympathetic preganglionic somata are situated dorsal to the central canal and form a continuous column between the level of the third and the seventh/eighth spinal nerves; parasympathetic preganglionic neurons are situated in the most caudal part of the spinal cord.

2.04.3.1.4 Motor neurons In most amphibians, motor neurons are arranged in a medial and a lateral column (Matesz and Székely, 1978; Wake *et al.*, 1988; Kim and Hetherington, 1993) (Figures 2, 3d, and 3e). Among salamanders, interspecific differences exist; in bolitoglossines, for example, a clear distinction of the two motor columns is absent (Figures 3e and 3h, right). The medial motor column consists of pear-shaped cells and the lateral one of spindle-shaped cells. Primary dendrites of the latter motor neurons extend to the dorsal horn and overlap with primary afferent fibers and their neuropils. Within the motor columns, motor pools innervating different muscles considerably overlap in the rostrocaudal axis and in the transverse plane. Nevertheless, motor pools show a somatotopic organization in the sense that more caudally located motor neurons innervate more distally located limb muscles. Spinal circuits form building blocks for movement construction and have been described as isometric force fields. During limb behavior, motor elements are combined in chains and in combination contingent on the interaction of feedback and central motor programs (Giszter *et al.*, 1993; Kargo and Giszter, 2000).

2.04.3.1.5 Secondary projections

2.04.3.1.5.(i) Descending projections from brain centers In all amphibian taxa, extensive descending pathways arise from the reticular formation, the octavolateral area, the locus coeruleus, the laterodorsal tegmental nucleus, the raphe nucleus, and sensory nuclei of the medulla oblongata. Descending projections from the cerebellum, mesencephalon (tectum, torus, and tegmentum), pretectum, posterior tubercle, ventral thalamus, hypothalamus, and the amygdaloid complex were likewise found (ten Donkelaar *et al.*, 1981; Luksch *et al.*, 1998; Dicke, 1999; Roth and Grunwald, 2000; Sanchez-Camacho *et al.*, 2001a, 2001b).

2.04.3.1.5.(ii) Ascending projections of the spinal cord Projections from the spinal cord ascend via the lateral and/or the ventral funiculus to the reticular formation, mesencephalon, and thalamus. Neurons of the DCN and the lateral cervical nucleus (LCN) form a contralaterally ascending ventral tract and an ipsilaterally ascending dorsal tract in frogs and in salamandrid salamanders. The contralateral tract reaches the level of the mesencephalon; the ipsilateral tract terminates at the level of the cerebellum in salamandrids and sparsely innervates mesencephalic and diencephalic structures in frogs. In plethodontid salamanders projections from the DCN and LCN ascend in three tracts, i.e., a contralateral ventral, a contralateral and an ipsilateral lateral one (spinal lemniscus), which ipsi- and contralaterally reach the cerebellum, tegmentum, torus, and tectum in the midbrain, posterior tubercle, pretectum, and ventral thalamus by a substantial number of fibers (Muñoz *et al.*, 1997; Dicke and Muhlenbrock-Lenter, 1998).

2.04.3.2 Medulla Oblongata and Cerebellum

2.04.3.2.1 Medulla oblongata

2.04.3.2.1.(i) The longitudinal zones In amphibians, as in other vertebrates, the medulla oblongata is an anatomically and functionally heterogeneous part of the brain. It contains primary and secondary relay stations for somato- and viscerosensory information as well as sensory input from the inner ear, and – when present – form the lateral line organs and ampullary organs (electroreception). Networks exist for the control of vital body functions such as respiration and blood circulation; the reticular formation is involved in the control of vigilance and attention. Finally, the medulla oblongata is the convergence zone of numerous descending pathways from all parts of the brain (for a synopsis of the sensory and motor cranial nerves and the reticular formation of vertebrates, see Butler and Hodos, 1996).

The division of the medulla oblongata of amphibians into four longitudinal zones is based mainly on the density and arrangement of cell masses and size and shape of somata, and this likewise holds for the division of the reticular formation into median, medial, and lateral zones. The existence of such longitudinal zones was demonstrated by characteristic differences in the distribution of neurotransmitters such as serotonin (raphe nuclei) or noradrenaline (locus coeruleus). Nuclei of the reticular formation were investigated by means of immunohistochemistry and tracer techniques in ranid frogs and assumed to be homologous to the classical distinction of reticular nuclei established in mammals (Marín *et al.*, 1996; Adli *et al.*, 1999; Stuesse *et al.*, 2001; Zhao and Debski, 2005). In salamanders, somata – except for giant cells such as Mauthner neurons – are more or less equal in size and rather evenly distributed throughout the cellular layer. However, tracer and immunohistochemical investigations of viscero- and somatomotor nuclei, sensory afferents, and transmitter-specific nuclei demonstrate that the longitudinal zones in the medulla oblongata of salamanders match those of other amphibian species (Dicke *et al.*, 1997; Landwehr and Dicke, 2005).

2.04.3.2.1.(ii) Motor nuclei The efferent system is situated in the basal plate of the medulla oblongata and consists of somatomotor and branchiomotor nuclei (Roth *et al.*, 1988b; Székely and Matesz, 1993) (Figures 3a–3c and 3f–3h). The hypoglossal nucleus and the motor nuclei innervating the external eye muscles (abducens nucleus, and the trochlear and oculomotor nuclei situated in the mesencephalon) constitute the somatomotor nuclei. Branchiomotor nuclei comprise the trigeminal and facial motor nuclei, the nucleus ambiguus (glossopharyngeal and vagal nucleus), and the accessory nucleus. The basic organization of the frog ambiguus nucleus is comparable to that of the rat, and differences in nuclear organization reflect differences in peripheral structures (Matesz and Székely, 1996). Motor neurons subserving different functions in tongue movements disclose characteristic morphological differences. Motor neurons innervating different groups of muscles involved in the movements of the tongue (protractor, retractor, and inner muscles) could be separated on the basis of the shape of dendritic arborization in the horizontal, frontal, and sagittal planes of the brainstem (Matesz *et al.*, 1999; Birinyi *et al.*, 2004).

2.04.3.2.1.(iii) Primary sensory afferents Cranial nerves V–XII terminate and/or originate in the rhombencephalon. The alar plate receives somatosensory fibers of the head, general visceral sensory and gustatory fibers, as well as afferents from the inner ear and the lateral line system (Fritzsch *et al.*, 1984; Kuruvilla *et al.*, 1985; Roth and Wake, 1985a; Fritzsch, 1989; Muñoz *et al.*, 1994b). The sensory fibers of the trigeminal nerve extend in the descending tract of the trigeminal nerve to the first and second spinal segment, where they cross to the contralateral side. Fibers and collaterals terminate continuously along the tract in an area containing small cells, i.e., the nucleus of the spinal trigeminal tract; gap junctional coupling was observed between fibers of the descending limb and their postsynaptic targets (Bacskai and Matesz, 2002). Primary afferents of the trigeminal nerve also terminate at the level of the obex in the principal sensory nucleus and in the mesencephalic nucleus of the trigeminal nerve. The latter nucleus is situated in the tectum mesencephali and is characterized by large, unipolar somata dispersed in the cellular layers. The solitary tract comprises mainly general and gustatory viscerosensory fibers of the IXth and Xth cranial nerves. This tract extends from the level of the trigeminal motor nucleus to the spinomedullary border and is accompanied by small, densely packed cells of the nucleus of the solitary tract. Afferents of the inner ear terminate at the level of the entrance of the VIIIth nerve in the dorsolateral nucleus, which is the first relay nucleus of the auditory system and homologous to the cochlear nucleus of mammals. Projections from sensory epithelia of the canal ampullae, utriculus, sacculus, and lagena of the inner ear reach the nucleus of the ventral octavus column, which in ranid frogs has been divided into four vestibular nuclei. GABA and glycine are the major inhibitory transmitters of neurons in the vestibular nuclear complex in frogs as well as in mammals (Reichenberger *et al.*, 1997). The lateral line system is present in fully aquatic species and in those with biphasic lifestyle during larval stages; it is lacking in direct-developing or life-bearing taxa. It is involved in both directional current detection and current-related postural adjustments in *Xenopus* (Simmons, 2004). Afferents enter via the VIIth and Xth cranial nerves (also via the Vth cranial nerve in urodeles) and bifurcate into descending and ascending branches within the medulla oblongata; collaterals terminate on a medially situated lateral line (octavolateral) column of cells that accompany the afferent tracts.

2.04.3.2.1.(iv) Afferents from other brain regions In frogs and salamanders, descending projections to the rostral medulla oblongata arise from at least 30 major cell groups situated in the telencephalon, diencephalon, synencephalon, mesencephalon, and cerebellum. The majority of afferent fibers originate from ipsilateral nuclei of these brain parts, and the white matter of the lateral and the medial medulla oblongata is reached by afferent fibers of different brain regions. Main afferents exclusively reaching the lateral white matter comprise fibers of the dorsal and ventral striatum and amygdalar nuclei of the telencephalon, the magnocellular nucleus of the preoptic area, the large neurons of the superficial pretectal nucleus, the mesencephalic nucleus of the trigeminal nerve, the red nucleus, and the cerebellar nucleus, while a substantial number of axons of the dorsal thalamus, lateral posteroventral thalamic nuclei, the dorsal hypothalamus, the nucleus of the longitudinal medial fascicle, and the superior and isthmic reticular nuclei exclusively descend to the medial white matter of the medulla oblongata. The lateral and the medial white matter receive extensive descending projections from the preoptic area, ventral thalamic and lateral posterodorsal thalamic nuclei, the deep pretectal nucleus, the tectum (see Section 2.04.3.4.9.(i)), the torus and tegmental nuclei, and the middle and lateral reticular nucleus. Fewer neurons of the ventral (ventral lateral) pallium, the central thalamic nucleus, the posterior tubercle, the nucleus Darkschewitsch and Edinger–Westphal likewise project to the white matter of the medulla oblongata (Naujoks-Manteuffel *et al.*, 1988; Dicke *et al.*, 1998).

2.04.3.2.1.(v) Ascending pathways of the medulla oblongata The raphe nuclei of the brainstem display extensive ascending projections to all brain parts, although the exact contribution of the different raphe nuclei, using combined immunohistochemistry and tracing, has mainly been studied in the mesencephalon and is lacking for targets in the forebrain. This also holds true for other reticular nuclei of the medulla oblongata (Dicke *et al.*, 1997; Stuesse *et al.*, 2001; Landwehr and Dicke, 2005; Zhao and Debski, 2005).

Second-order projections of the descending trigeminal nucleus reach the cerebellum, ventral mesencephalon, pretectum, and thalamus. The nucleus of the solitary tract projects to the nucleus visceralis secundarius (NVS) situated in the isthmic region and homologous to the parabrachial nucleus of mammals. The NVS/parabrachial nucleus in turn projects to the preoptic area, the amygdala, and ventral pallium (Moreno and González, 2004; Roth *et al.*, 2004). Second-order neurons of the auditory

pathway are situated in the contralateral dorsolateral nucleus, bilaterally in the nucleus of the superior olive and the torus semicircularis. Projections from the superior olive extend to the nucleus of the lateral lemniscus and to the torus, and some axons reach the posterior thalamus. The vestibular input is transmitted onto the vestibular nucleus complex with a remarkable specific convergence pattern, and a number of fundamental organization principles common to most vertebrates is found in the amphibian vestibular system (Straka and Dieringer, 2004). Ascending efferents from vestibular nuclei travel via the medial longitudinal fascicle to the cerebellum and to brainstem nuclei involved in oculomotor function. Projections from the lateral vestibular nucleus interconnect vestibular nuclei and reach tegmental nuclei, the nucleus of medial longitudinal fascicle and the anterior, central, and ventromedial thalamic nuclei (Matesz *et al.*, 2002). Neurons of the lateral line nucleus mainly project to the torus; in the aquatic toad *Xenopus*, the principal and magnocellular nuclei of the torus receive their major input from the lateral line nucleus (Edwards and Kelley, 2001).

2.04.3.2.2 Cerebellum Compared to that of most other vertebrates, the amphibian cerebellum is small, but exhibits the basic cerebellar circuitry typical of vertebrates. It is composed of the corpus cerebelli and the auricular lobes. The corpus cerebelli is the central part of the cerebellum and consists of a transverse plate, which contains a molecular and a granular layer; the Purkinje cells are aligned at the boundary between these two layers. The cerebellar nucleus, which is considered homologous to the deep cerebellar nuclei of mammals, is situated ventral to the corpus cerebelli. The granular layer contains the afferent fibers to and efferent fibers from the cerebellum. The mossy fiber-granule cell-parallel fiber system and the climbing fiber system are present and constitute excitatory input onto Purkinje cells. Somata of Purkinje cells and of stellate cells in the molecular layer are immunoreactive for GABA, and most of GABA-positive neurons in the granular layer appear to be Golgi cells. True basket cells are missing, stellate cells are fewer in number, and co-localization of GABA and glycine in Golgi neurons is encountered less frequently in frogs compared with mammals. In the bullfrog, Calbindin immunoreactivity (-ir) was observed in various populations of cells in the auricular lobe and interauricular granular band of the cerebellum, in the cerebellar peduncle, and in a bundle of interauricular commissural fibers. Cells in the granular layer of the ventral part (i.e., corpus cerebelli) of the cerebellar plate as well as fibers in the molecular layer of this region were not immunoreactive (Uray and Gona, 1999). The pattern of calbindin-ir in the auricular lobes and marginal part of the cerebellar plate differs distinctly in its origin, biochemistry, and connectivity from the corpus cerebelli.

The main input comes from the rhombencephalon and comprises fibers of the trigeminal and trochlear nerve, the vestibular nuclear complex, the glossopharyngeal-taste sensory system, the hypoglossal nerve (mediating sensory information of the tongue), the inferior olive, and primary and secondary afferents of the somatosensory system (Antal *et al.*, 1980; Amat *et al.*, 1984; Montgomery, 1988; Anderson and Nishikawa, 1997). The efferent cerebellar pathways extend to the lateral medulla oblongata and mainly reach the vestibular complex; they also descend to cervical and lumbar root fibers (Dicke *et al.*, 1998; Bacskai and Matesz, 2002). A small, distinct projection also reaches the ventral tegmentum at the level of the oculomotor nerve; reciprocal connections between the red nucleus and the cerebellum were described in frogs and salamanders (Montgomery, 1988; Naujoks-Manteuffel *et al.*, 1988; Larson-Prior and Cruce, 1992).

In *Rana pipiens*, a pathway from the hypoglossal motor nuclei to the cerebellar nucleus as well as an afferent projection from the peripheral hypoglossal nerve to the Purkinje cell layer of the cerebellar cortex was demonstrated by Anderson (2001). Anatomical convergence of these pathways in the medial reticular formation and a reciprocal connection between the trigeminal motor nuclei and the cerebellar nuclei as well as the medulla appear to be the anatomical basis for feeding reflex modulation. The neuronal circuitry for optokinetic responses includes both visual centers (thalamus, pretectum, BON) and the auricular lobe of the cerebellum (Fite *et al.*, 1992). In general, the cerebellum of amphibians, like that of other vertebrates, appears to be involved in sensorimotor integration and motor coordination.

2.04.3.3 Mesencephalon

2.04.3.3.1 Isthmic region and tegmentum The isthmic region (Figures 13c and 13d) is separated from the tegmentum by the sulcus isthmi, and the isthmic nucleus is situated ventral to the dorsocaudal end of the tegmentum, immediately rostral to the cerebellar corpus. The isthmic nucleus is a compact prominent nucleus; its dendrites extend laterally and form a conspicuous dendritic neuropil (see below for a more detailed description). The nucleus

visceralis secundarius, considered homologous to the parabrachial nucleus, is found dorsal to the isthmic nucleus, and neurons of the cholinergic laterodorsal tegmental nucleus are situated ventral to the nucleus isthmi (Marín *et al.*, 1997d). Neurons of the noradrenergic locus coeruleus are dispersed medially, ventrally, and/or caudally to the isthmic nucleus (Marín *et al.*, 1996). They have long processes directed ventrally or ventrolaterally and arborizing in the lateral reticular formation.

The tegmentum is divided into a dorsal and ventral tegmentum. The nucleus of the medial longitudinal fascicle is situated in the rostral dorsal tegmentum, while the dorsal tegmental nucleus is found throughout the rostrocaudal extent. The ventral tegmentum includes the oculomotor and trochlear motor nucleus and the accessory oculomotor nucleus Edinger–Westphal. The pedunculopontine tegmental nucleus is situated at the border of the dorsal and ventral tegmentum; its cholinergic part is present in frogs and plethodontid salamanders, but is absent in salamandrid salamanders (frogs and salamandrids: Marín *et al.*, 1997a; plethodontids: U. Dicke, unpublished data). The ventral tegmental nucleus is bordered by the ventrally located nucleus ruber, and the interpeduncular nucleus is situated in the median basal tegmentum.

The dorsal tegmental and the pedunculopontine tegmental nucleus have reciprocal connections with the tectum; neurons of the nucleus of the medial longitudinal fascicle and the nucleus ruber give rise to descending pathways to the medulla oblongata and rostral spinal cord (Naujoks-Manteuffel *et al.*, 1988; Dicke *et al.*, 1998). The interpeduncular nucleus receives olfactory input via the fasciculus retroflexus that descends from the habenula. Ascending and descending pathways of the brain run in the fiber layer of the dorsal and/or ventral tegmentum, and neurons of tegmental nuclei with their laterally directed dendrites are likely to receive input from a variety of brain regions. In general, the tegmental relay stations are poorly studied even though the tegmentum most likely constitutes a complex anatomical zone of interfaces, where the sensory, motor, and limbic systems of the brain meet.

2.04.3.3.2 Torus semicircularis The torus semicircularis is situated below the tectum. In frogs, it consists of three major auditory nuclei, the principal, laminar, and magnocellular nucleus (Potter, 1965). The laminar nucleus forms nearly a hemisphere and occupies the entire dorsal and rostral surface of the torus bordering the tectal ventricle (Figure 4). The somata of this nucleus are arranged in laminae (hence the name of the nucleus). The principal nucleus is situated caudally and ventrally of the laminar nucleus, which caudoventrally includes the magnocellular nucleus. In *Salamandra salamandra*, the subtectal dorsal tegmentum is divided into a dorsally located torus semicircularis and a ventrally situated dorsal tegmental nucleus. The torus of this species processes auditory and vibratory signals, and the hearing capabilities are comparable to those of anurans with extra-tympanic sound transmission (Manteuffel and Naujoks-Manteuffel, 1990).

The torus semicircularis is the center of convergence of ascending auditory (terminating primarily in the principal nucleus), vestibular (entire torus), somatosensory (lateral laminar nucleus), lateral line (if present, lateral principal nucleus) pathways and descending pathways from the forebrain, i.e., the central, ventromedial, and posterior thalamic nuclei, the anterior entopeduncular nucleus and suprachiasmatic nucleus terminating predominantly in the laminar and principal nucleus (Wilczynski, 1981; Feng and Lin, 1991; Matesz and Kulik, 1996; Edwards and Kelley, 2001). Weak descending afferents originate in the lateral septum and in the caudal striatopallidum (Marín *et al.*, 1997a; Endepols *et al.*, 2005).

Efferents from all toral nuclei run to the tectum, tegmentum, and isthmic nucleus; the principal nucleus projects to the posterior and central dorsal thalamic nuclei and the laminar and magnocellular nucleus to the telencephalon, predominantly to the striatopallidum (primarily the nucleus laminaris). All toral nuclei have descending projections to auditory brainstem nuclei (Neary, 1988; Feng and Lin, 1991; Luksch and Walkowiak, 1998; Endepols and Walkowiak, 2001).

The torus contains numerous neuromodulatory substances such as dopamine, bombesin, noradrenaline, enkephalin, substance P, somatostatin, neuropeptide Y, as well as steroid hormones (Endepols *et al.*, 2000). It contains neurons that either exhibit weak or no tonotopy and either simple or complex tuning curves (Walkowiak, 1980; Feng *et al.*, 1990). Whereas the majority of neurons can be driven by relatively simple auditory stimuli, some of them respond preferentially to complex sounds. In brief, the data underline the essential role of the torus semicircularis as the major audiomotor interface.

2.04.3.4 Neuroanatomy of the Retino-Tecto-Pretectal System

2.04.3.4.1 Retina The retina of amphibians, like that of other vertebrates, exhibits a typical five-layered

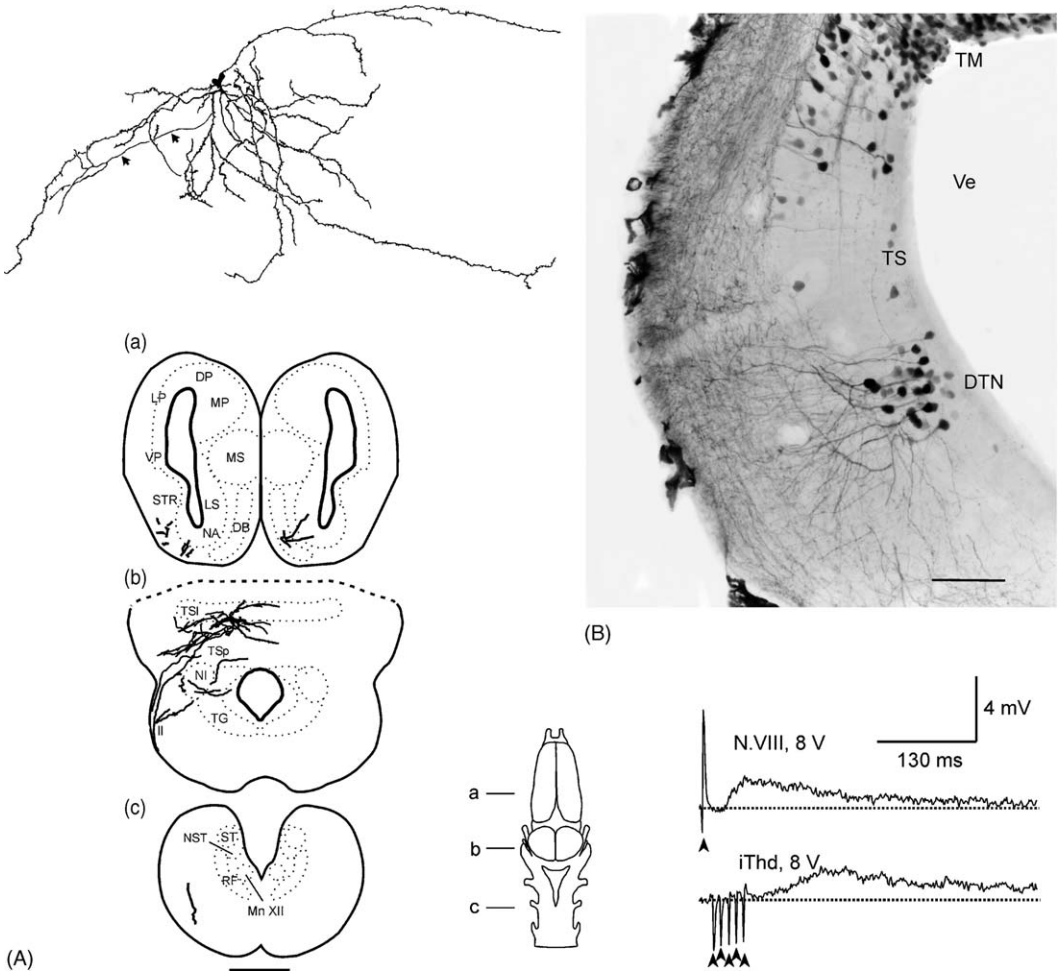

Figure 4 A, Reconstruction of two neurons in the torus of *Discoglossus pictus* recorded and subsequently labeled with neurobiotin. The reconstruction of the dendritic tree is shown at the top left; arrows point to the proximal part of an axon. Scheme of transverse sections (a–c): a, telencephalon showing the termination sites of two axons in its ipsi- and contralateral ventral part; b, location of the two neurons in the caudal laminar nucleus of the torus; the dorsal part of the tectum is cut off (broken outline); c, one axon descends laterally in the fiber layer down to the level of the obex. Responses at single stimulation of the contralateral auditory nerve (VIII) and repetitive stimulation of the ipsilateral dorsal thalamus (iThd) are given at the bottom right. Scale bar: 500 μm. B, Microphotograph of dorsal tegmental neurons of *Plethodon teyahalee* retrogradely labeled after tracer application to the tectum and forming a band extending rostrocaudally throughout the tegmentum. DP, dorsal pallium; LP, lateral pallium; VP, ventral pallium; STR, striatum; NA, nucleus accumbens; DB, diagonal band; LS, lateral septum; MS, medial septum; MP, medial pallium; TSl, laminar nucleus of the torus semicircularis; TSp, principal nucleus of the torus semicircularis; NI, isthmic nucleus; TG, tegmentum; II, XII, cranial nerves; NST, nucleus of the solitary tract; RF, reticular formation; Mn, hypoglossal motor nucleus; TM, mesencephalic tectum; Ve, ventricle; TS, torus semicircularis; DTN, dorsal tegmental nucleus. Scale bar: 100 μm. A, Reproduced from *J. Comp. Physiol. A*, Vol. 186, 2001, pp. 1119–1133, Integration of ascending and descending inputs in the auditory midbrain of a nurons, Endepols, H. and Walkowiak, W. With kind permission of Springer Science and Business Media.

structure. The outer and the inner nuclear layer and the layer of retinal ganglion cells (RGCs) are separated by the outer plexiform layer and the much thicker inner plexiform layer. The two plexiform layers are the main site of synaptic contacts between the five major types of retinal cells (photoreceptors, amacrine cells, bipolar cells, horizontal cells, and ganglion cells). The outer nuclear layer contains the inner segments of the photoreceptors and their nuclei. In most frog and salamander species, the rod nuclei in the outer nuclear layer are aligned at the distal side, and the cone nuclei are more proximal (Gordon and Hood, 1976). This is the contrary of the situation in most other vertebrates, in which the rod nuclei are vitread to the cone somata. Amacrine cells are concentrated at the vitread side of the inner nuclear layer, bipolar cells in the middle, horizontal cells at the sclerad side, and a few displaced RGCs at the vitread side. In most amphibians, the layer of RGCs contains more than one row of cells, and

axons of the RGCs bundle and constitute the optic nerve.

Amphibians have no specialized intraretinal structure like the fovea of primates or birds. However, in the frogs *Hyla raniceps* (Bousfield and Pessoa, 1980), *Heleioporus eyrei* (Dunlop and Beazley, 1981), and *Bufo marinus* (Nguyen and Straznicky, 1989), a streak of high cell density exists in the RGC layer along the nasotemporal meridian of the retina. The same is found in the inner nuclear layer (Zhu *et al.*, 1990) and the outer nuclear layer (Zhang and Straznicky, 1991). The increase in cell density is comparable to that of the visual streak in the reptilian retina (Wong, 1989; Wilhelm and Straznicky, 1992). In salamanders, differences in intraretinal cell density have not been found so far.

In plethodontid salamanders (Linke and Roth, 1989), four types of RGCs have been identified, while in frogs the number of RGCs varies among three major types (with 12 subtypes based on morphology of dendritic trees) in *Xenopus laevis* (Straznicky and Straznicky, 1988) and seven types in *R. pipiens* (Frank and Hollyfield, 1987).

The optic nerve contains myelinated and unmyelinated fibers. The highest number of optic nerve axons (and thus of RGCs) are found in anurans. In *Rana pipiens*, 470 000 fibers were counted, and the lowest number presently known among anurans was found in *X. laevis* with 68 000–80 000 fibers (Maturana, 1959; Dunlop and Beazley, 1984). On average, salamanders have 5–10 times fewer optic fibers. They range from 26 000 in *Batrachoseps attenuatus* (Linke and Roth, 1990) to 75 000 in the salamandrid *Notophthalmus viridescens* (Ball and Dickson, 1983). The percentage of myelination in adult amphibians is low compared to that of mammals; in *X. laevis*, the percentage of myelination is 11% (Dunlop and Beazley, 1984), whereas the lowest percentage is found in the plethodontid salamander, *B. attenuatus*, with less than 1% myelinated fibers (Linke and Roth, 1990).

2.04.3.4.2 Visual afferents to the brain The majority of fibers of the optic nerve cross in the optic chiasm and reach targets in the opposite diencephalon and mesencephalon (frogs: Lázár and Székely, 1969; Fite and Scalia, 1976; Montgomery and Fite, 1989; salamanders: Fritzsch, 1980; Rettig and Roth, 1986). Ipsilaterally projecting RGCs in *R. pipiens* include not more than 2.3% of the overall population in the ganglion cell layer and exist in the monocular as well as binocular parts of the retina (Singman and Scalia, 1990, 1991). Within the optic chiasm, a sequence of positional transformations occurs that result in the formation of multiple optic pathways (Montgomery *et al.*, 1998).

Staining of retinal afferents in frogs and salamanders reveals four thalamic neuropils: the neuropil of Bellonci (NB), the corpus geniculatum thalamicum (CGT) (Figures 5 and 6), the preoptic area, and the posterior thalamic neuropil. The latter neuropil is divided into a laterally situated pretectal neuropil and a medially situated uncinate field; in frogs the presence of such a division was reported in a study on *Rana* (Fite and Scalia, 1976). In the mesencephalon, the superficial and part of the deeper fiber layers of the tectum receive extensive visual afferents (Figure 7). A smaller number of RGCs projects to the basal optic neuropil (BON) situated in the tegmentum rostral to the root of the third cranial nerve. In salamanders, the neuropil of Bellonci can be clearly divided into a medial part and a lateral part (Figure 6) (Fritzsch, 1980; Rettig and Roth, 1986; Wiggers, 1999), and plethodontid salamanders have a substantial number of ipsilaterally projecting RGCs compared to other urodeles and anurans (cf. Figure 7a).

2.04.3.4.3 Organization of retinal projections In amphibians, the projection of RGCs is topographically organized onto diencephalic and mesencephalic targets. In the diencephalon, the topography of projections appears to differ in frogs and salamanders (Rettig and Roth, 1986; Montgomery and Fite, 1989; Montgomery *et al.*, 1998).

In frogs, contralateral projections of the retina distribute as follows: the anterior CGT, NB, and pretectal neuropils receive afferents from the ventral and nasal quadrants of the retina. Axons from the ventral quadrant terminate in the dorsal and those from the nasal quadrant terminate in the ventral portion of the thalamic targets. In the posterior CGT, NB, and pretectum, retinal axons of the temporal and dorsal quadrants terminate in the dorsal and ventral portion of the targets, respectively. The rostral and central tectum receives retinal afferents from the temporal quadrant, the medial tectum is reached by retinal axons of the ventral quadrant, and afferents from the dorsal and nasal quadrant of the retina project to the lateral and caudal tectum, respectively. The BON obtains afferents from the entire retina; the major retinal projection is contralateral, but a small, ipsilateral component was described in *R. pipiens* (Montgomery *et al.*, 1981). The basal optic root consists of a lateral and a medial fascicle. In *R. pipiens*, the lateral fascicle innervates the entire terminal field of the BON, while the medial fascicle innervates only the central and mediodorsal portions. The ventrolateral portion of the BON is innervated only by the lateral

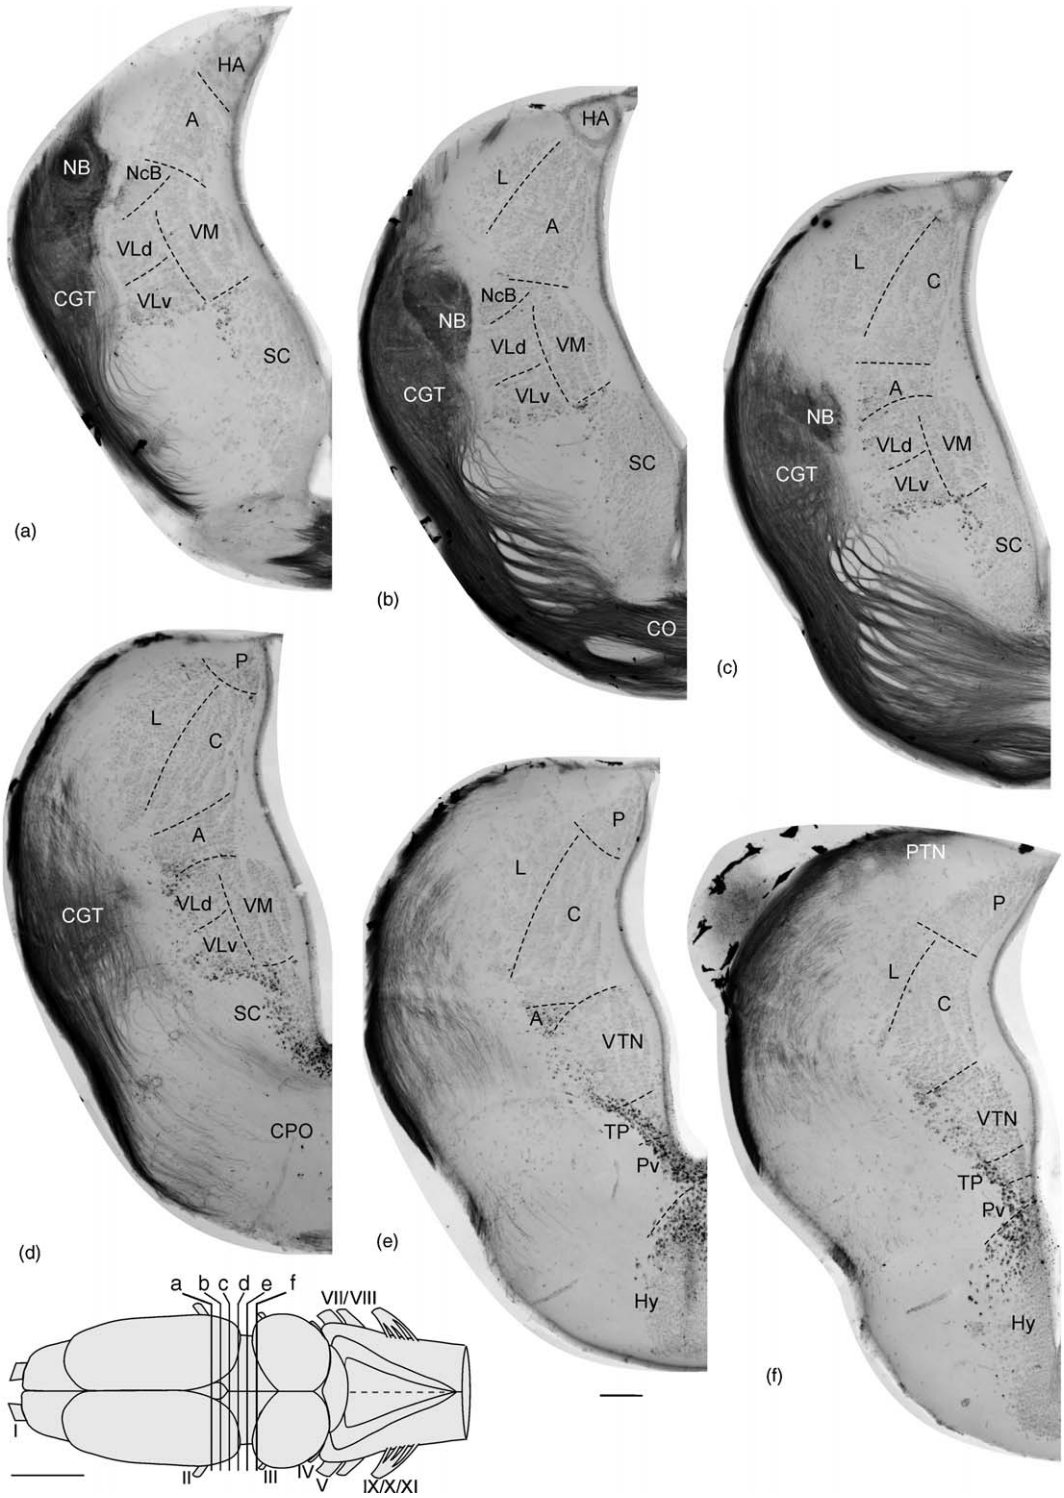

Figure 5 Microphotographs of transverse sections through the diencephalon of *Bombina orientalis* showing retinofugal neuropils (NB and CGT) revealed by anterograde tracing after application of biocytin to the optic nerve. Sites of sections are indicated in the inset. Scale bar: 100 μm. From Roth, G., Grunwald, W., and Dicke, U. 2003. Morphology, axonal projection pattern and responses to optic nerve stimulation of thalamic neurons in the fire-bellied toad *Bombina orientalis*. *J. Comp. Neurol.* 461, 91–110.

fascicle and the medial region by both fascicles (Fite *et al.*, 1988).

In salamanders, contralateral projections of RGCs are arranged such that afferents from the nasal quadrant terminate in thalamic and pretectal neuropils, while those from the ventral quadrant reach the medial portion of the CGT, lateral NB, and pretectal neuropils. RGCs in the dorsal quadrant of the retina project to the lateral portion of the CGT, lateral NB, and pretectum; in the latter, the entire uncinate field is reached. Afferents originating from RGCs of the temporal retina terminate in the caudal portions of the CGT and lateral NB, in the entire medial NB, the caudal pretectal neuropil and the entire uncinate field. The topography of retinal projections to the contralateral tectum is identical with that found in frogs. Also, the BON receives afferents from all quadrants of the retina. Ipsilateral projections of RGCs reach the rostral tectum; more extensive projections are found in bolitoglossines (Rettig and Roth, 1986). The RGCs project ipsilaterally to all targets in the thalamus and pretectum, but the topic arrangement has not been investigated with modern tracers, which label neuronal structures more intensely.

2.04.3.4.4 Projection specificity of retinal ganglion cells and morphology of terminal arbors In amphibians, the morphology of single terminal arbors was studied by means of intracellular labeling of RGCs and anterograde staining of the optic nerve (frogs: Stirling and Merrill, 1987; Hughes, 1990; salamanders: Wiggers, 1999). Axons of RGCs often have multiple terminal structures in the tectum and in the thalamic neuropils, while projections to the BON appear to originate from another type of RGC in plethodontid salamanders (Wiggers, 1999).

In frogs, terminal arbors of intracellularly HRP-labeled RGCs responding to the extinguishing of light were situated in the deep tectal fiber layers with a size of 400 and 200 μm in rostrocaudal and mediolateral axis, respectively. The axon gives off few branches to the pretectum before entering the tectum (Stirling and Merrill, 1987). In the Hughes (1990) study, HRP-labeled axons of RGCs were found in all superficial tectal fiber layers, but the

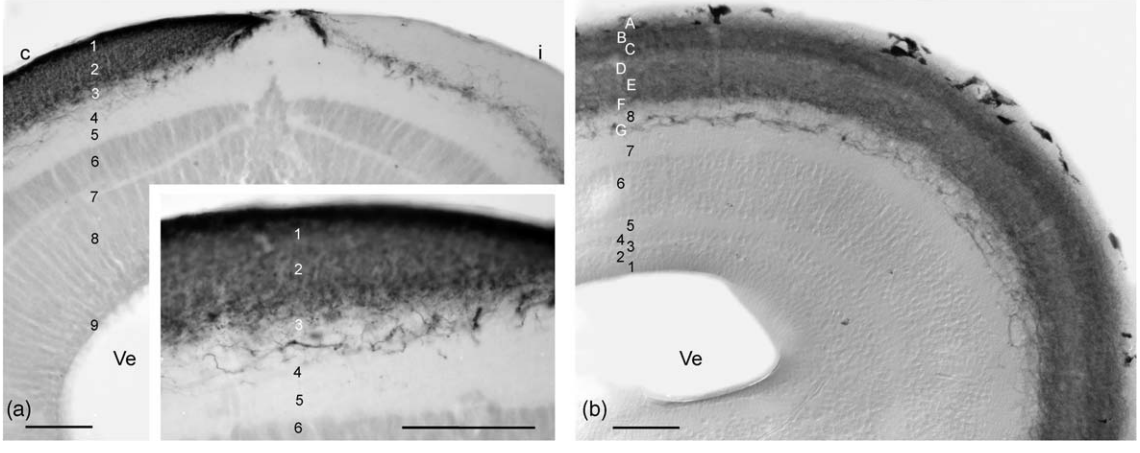

Figure 7 Microphotographs of transverse sections through the tectum of *Plethodon jordani* (a) and *Bombina orientalis* (b) showing retinal afferents after application of biocytin to the stump of the optic nerve. In (a), the contralateral afferents to the superficial tectal layers are shown on the left side and the ipsilateral afferents, mostly restricted to layer 3, on the right side. The inset shows the contralateral afferents at greater magnification. In (b), the contralateral afferents forming laminae A–G of layer 9 are shown. Ve, ventricle. Scale bars: 100 μm.

extent and morphology of arbors differed from layer to layer. Small and dense arbors with thin and beaded fibers were found in the superficial layer, whereas in the deep tectal fiber layer large arbors with sparse branching were labeled.

In a study on intracellularly biocytin-labeled RGCs of plethodontid salamanders by Wiggers (1999), the following types of projection pattern were frequently found:

1. RGCs with large terminal arbors and dense branching in thalamic neuropils (mainly in the medial NB) project to the deep tectal fiber layers with axons that are sparsely beaded and reveal no obvious terminal structures; pretectal neuropils are formed by sparse fields of axon collaterals.
2. RGCs with dense terminal arborization in the pretectal neuropils have additional sparse fields of collaterals in the thalamus, especially in the CGT and lateral NB; a projection to tectal fiber layers was not found.
3. RGCs with axons forming dense terminal arbors in the superficial fiber layer of the tectum reveal only few beads in the pretectal neuropils; neuropils in the thalamus were not found.
4. RGCs that have dense terminal fields in one of the two layers underneath the superficial tectal layer reveal additional sparse terminals in thalamic and pretectal neuropils. Axons of RGCs form terminals with moderate or sparse branching of collaterals in the CGT and in the lateral NB.

2.04.3.4.5 Cytoarchitecture of the tectum mesencephali In the tectum of frogs, nine layers are distinguished beginning from the ventricle (Potter, 1969) (cf. Figures 7b and 8a). Layer 1 contains ependymal glial cells with long processes extending toward the tectal surface, where they form the external limiting membrane. Cellular layers 2, 4, and 6 (stratum griseum periventriculare) together constitute the periventricular grey matter. These cellular layers are divided by deep fiber layers 3 and 5, consisting of unmyelinated afferent and efferent fibers and basal dendrites of the periventricular neurons. Fiber layer 7 (stratum album centrale) contains the bulk of efferent tectal fibers and a few scattered neurons. Layer 8 (stratum griseum centrale) consists of loosely arranged neurons embedded in a meshwork of dendrites of tectal neurons and afferent fibers. Layer 9 (stratum fibrosum et griseum superficiale + stratum opticum) contains relatively few neurons dispersed in the meshwork of retinal afferents and dendrites of tectal neurons. Layer 9 is further divided into seven laminae A–G. Lamina A (occurring only in the rostral tectum) and laminae B, D, and F plus lamina G in layer 8 contain myelinated and unmyelinated fibers (mostly retinal afferents), and C and E are cellular layers.

The tectum of salamanders, like that of caecilians and lepidosirenid lungfishes (Northcutt, 1977), shows an essentially two-layered structure consisting of a periventricular cellular layer and a superficial white matter consisting of dendrites of tectal neurons and tectal afferent and efferent fibers, in which only a few migrated neurons are dispersed. However, based on

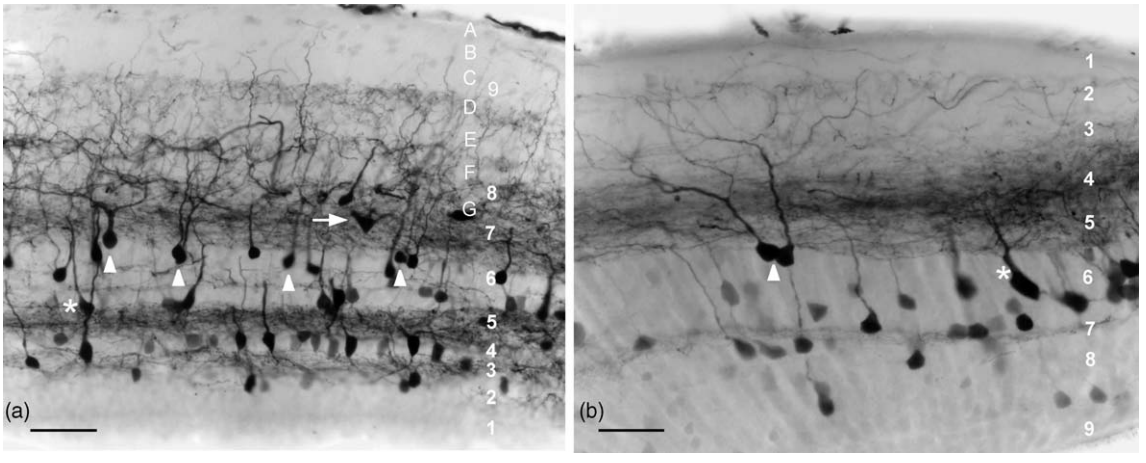

Figure 8 Microphotographs of tectal neurons type 2, 3, and 5 in *Discoglossus pictus* (a) and *Plethodon jordani* (b) labeled after injection of biocytin into the lateral medulla oblongata. The dendritic trees of neurons arborize in the middle layer of retinal afferents (arrowheads point to somata of the homologous type 3 of frogs and type 2 of salamanders) or in the deep, nonretinal afferent layers (asterisk indicates soma of type 5 in frogs and type 3 in salamanders). In (a), the arrow points to a spindle-shaped soma in layer 7; this type of neuron (type 2 of frogs) is only present in the frog tectum. Axons of the different types of neurons constitute the lateral uncrossed tectobulbospinal tract, and give rise to a nontopographic tectothalamic projection. From Dicke, U. and Roth, G. 1996. Similarities and differences in the cytoarchitecture of the tectum of frogs and salamanders. *Acta Biol. Hung.* 47, 41–59.

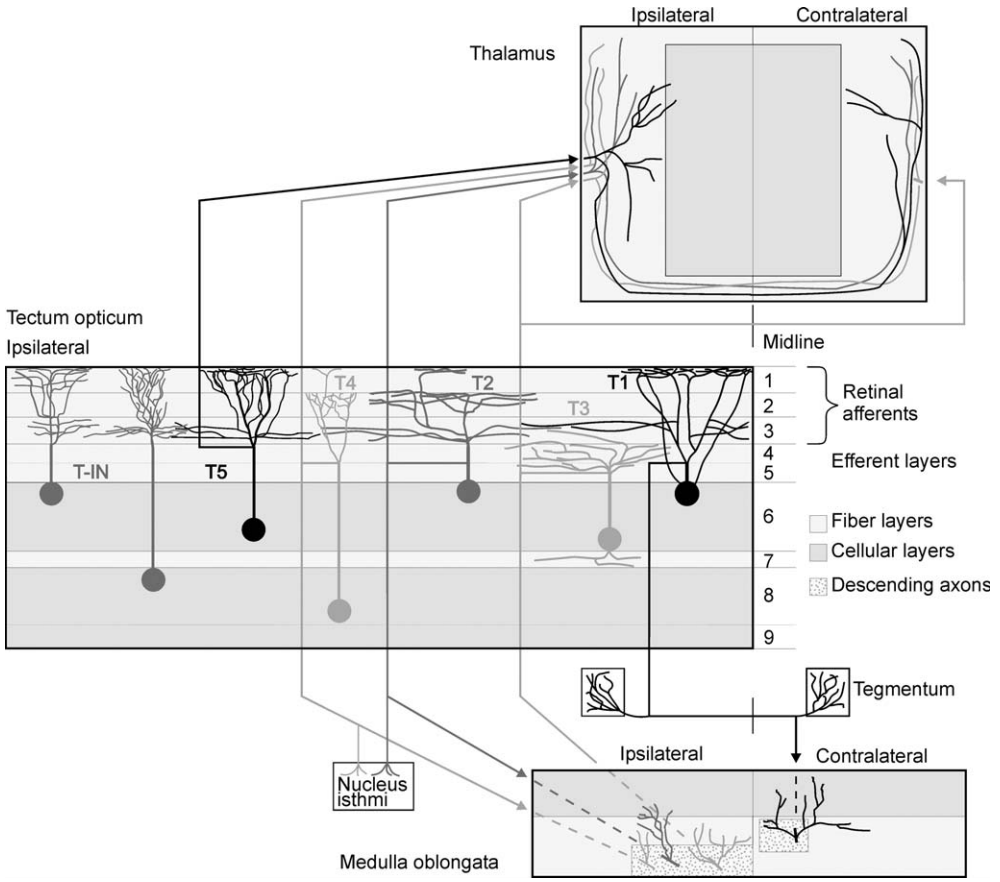

Figure 9 Schematic diagram of ipsilaterally and contralaterally ascending and descending tectofugal pathways constituted by different types (T1–T5) of neurons in salamanders. For further explanation see text. From Roth, G., Dicke, U., and Grunwald, W. 1999. Morphology, axonal projection pattern and response types of tectal neurons in plethodontid salamanders. II: Intracellular recording and labeling experiments. *J. Comp. Neurol.* 404, 489–504.

tracer experiments, the salamander tectum is divided from the surface to the ventricle into nine layers (Roth, 1987) (Figures 7a, 8b, and 9). Layers 1–3 contain retinal afferent fibers as well as afferents from other visual centers such as pretectum, thalamus, and isthmic nucleus; layers 4 and 5 contain efferent fibers and afferents from other senses, e.g. somatosensory, vestibular, and lateral line (if present). Layer 6 consists of the superficial cellular layer, while layer 7 (absent in miniaturized plethodontid salamanders) contains deep unmyelinated fibers. Layer 8 is the deep cellular layer, and layer 9 contains periventricular ependymal (glial) cells. In some salamanders, for example *Ambystoma mexicanum*, the periventricular grey matter regionally exhibits two to three sublayers.

On the basis of data from tracer studies on neuronal types (see below), tectal layers in salamanders and frogs can be homologized. Periventricular cellular and fiber layers 6–8 in salamanders are homologous to periventricular layers 2–6 in frogs, with cellular layer 6 being the most superficial of the periventricular layers in both groups. Dorsally, layer 6 is followed by the main efferent fiber layer(s), layers 4 and 5 in salamanders and layer 7 in frogs. Whereas in salamanders, only a few migrated neurons are found in the superficial part of the tectum (layers 1–3), in frogs such cells form a cellular band in layer 8 and are loosely arranged in layer 9. Retinal afferents terminate in layers 1–3 in salamanders and in laminae A–G of layers 8 and 9 in frogs.

2.04.3.4.6 Morphology and location of neuron types in the tectum A comparison of the morphology of dendritic trees of projection neurons and their targets in frogs and salamanders reveals that in both orders the same set of tectal projection neurons exists (frogs: Lázár *et al.*, 1983; Antal *et al.*, 1986; Dicke and Roth, 1996; salamanders: Roth *et al.*, 1990, 1999; Dicke and Roth, 1996; Dicke, 1999) (cf. Figures 8, 10, and 11). Types with descending axons are presented first and are ordered by their type of arborization from the superficial to the deeper fiber layers.

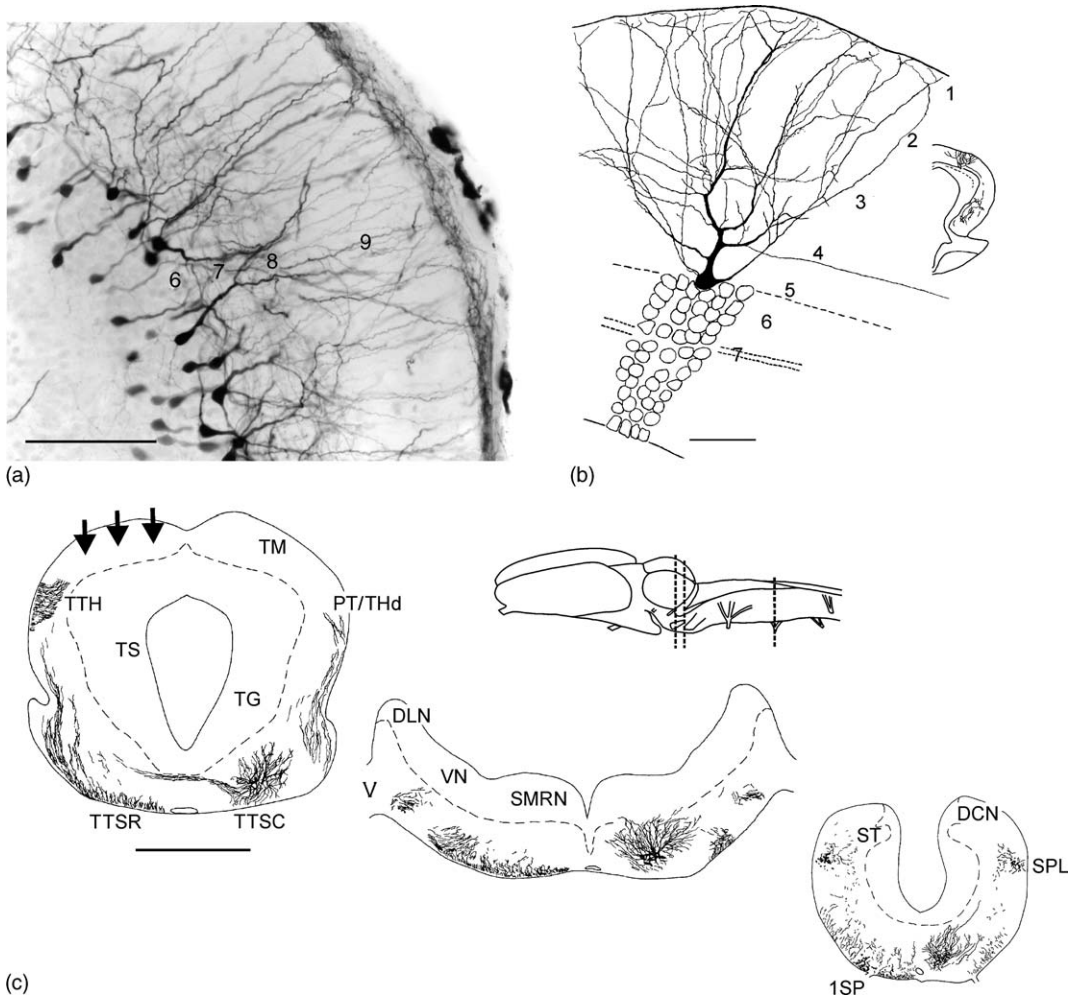

Figure 10 a, Microphotograph of the tectum of *Discoglossus* showing type-1 neurons labeled after application of biocytin into the medial medulla oblongata and projecting to the contralateral medulla oblongata. b, Camera lucida drawing of a type-1 neuron in *Plethodon jordani* labeled after application of biocytin into the medial medulla oblongata and projecting to the contralateral medulla oblongata. c, Drawing of descending tectobulbospinal tracts at levels indicated in the inset (tectum, level of Vth cranial nerve and 1st spinal nerve). Scale bars: 100 μm in (a, b) and 500 μm in (c). Modified from Dicke and Roth (1996); Dicke (1999), Roth *et al.* (1999).

In frogs, type-1 neurons with large pear-shaped or pyramidal somata situated in layer 6 and occasionally in layers 7 and 8 have candelabrum-shaped dendritic trees that arborize predominantly in lamina A. They closely resemble type-1 neurons of salamanders with somata situated in the superficial cellular layer 6 or in efferent layers 4 and 5; their likewise candelabrum-shaped dendritic trees extend into layers 1–3. Axons descend contralaterally to the medulla, where they constitute the crossed tectobulbospinal tract (Figures 10a and 10b).

Type-2 and type-3 neurons of frogs have the same pattern of descending and ascending axonal projections, but the former type of cells have spindle-shaped somata situated in or immediately above the large efferent layer 7 (Figure 8a). Two to several thick dendrites originate directly from the soma and branch into thick secondary dendrites, which extend obliquely to the surface. Smaller dendrites either terminate in lamina F and less frequently in laminae B and D or terminate in lamina B. This type of tectal neuron, with ipsilaterally descending axons, was not found in salamanders.

Type-3 neurons (pear-shaped or pyramidal cells) in frogs and type-2 neurons in salamanders (Figures 8a and 8b) can be regarded as homologous, because their somata are situated in the superficial layer of the periventricular gray. Both types have

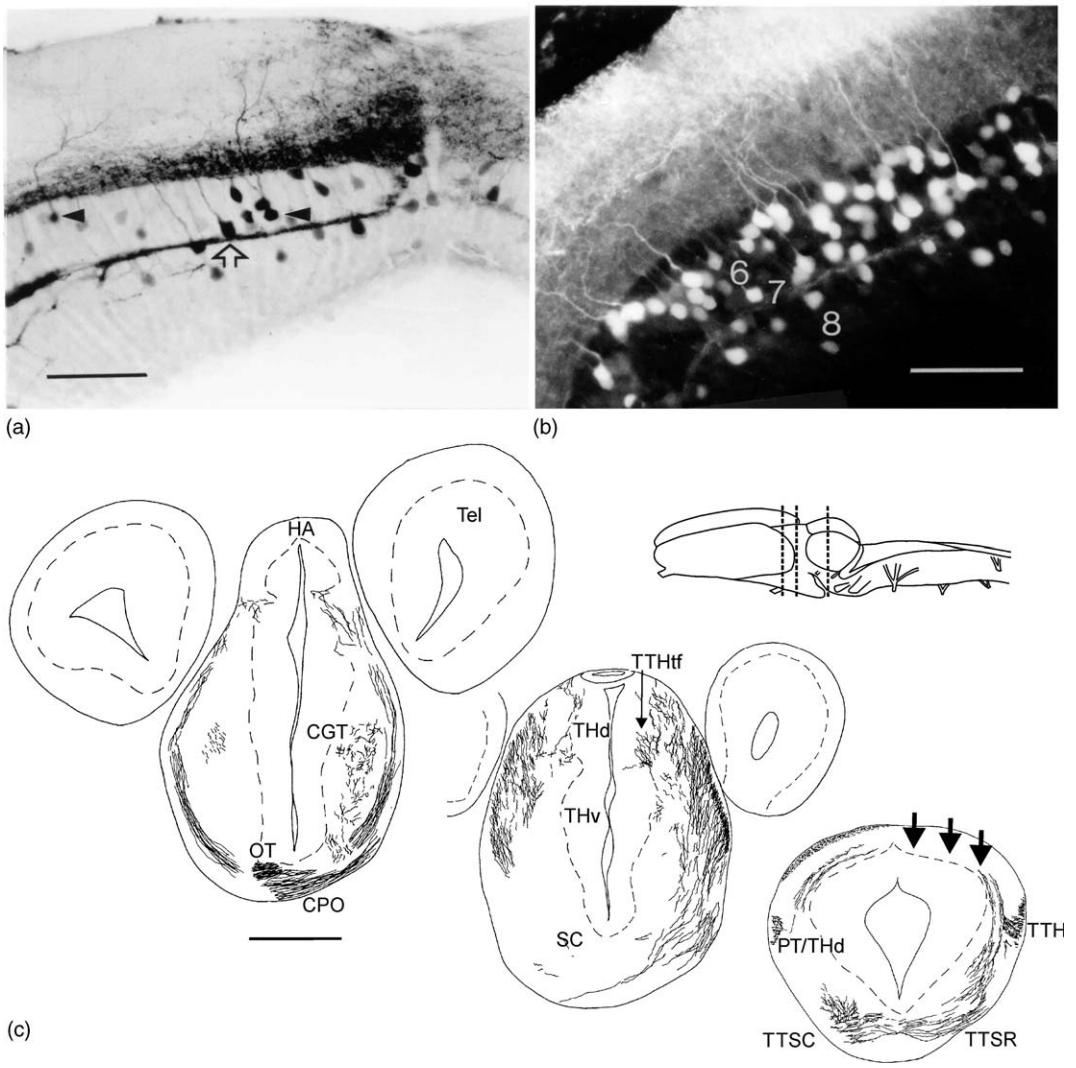

Figure 11 a, b, Microphotographs of transverse section showing tectal neurons labeled after tracer application to the postoptic commissure in *Plethodon jordani*. a, Type-3 tectal neuron (open arrow) and type-5 tectal neuron (black arrowhead) ipsilateral to the application site of biocytin. b, Type-5 neurons constituting the bulk of the ascending tectothalamic tract labeled ipsilateral to the application site of tetramethylrhodamine. c, Drawings of the ascending tectothalamic tract at levels indicated in inset. 6, 7, 8, ventricles; HA, habenula; CGT, corpus geniculatum thalamicum; OT, optic tract; CPO, postoptic commissure; Tel, telencephalon; TTHtf, terminal fields of tecto-thalamic tract; THd, dorsal thalamus; THv, ventral thalamus; SC, suprachiasmatic nucleus; PT/THd, descending tract of pretectum and thalamus; TTSC, crossed tecto-bulbo-spinal tract; TTSR, uncrossed tecto-bulbo-spinal tract; TTH, tecto-thalamic tract. Scale bars: 100 μm (a, b), and 500 μm (c). Modified from Dicke, U. 1999. Morphology, axonal projection pattern, and response types of tectal neurons in plethodontid salamanders. I: Tracer study of projection neurons and their pathways. *J. Comp. Neurol.* 404, 473–488.

wide to very wide dendritic trees, which arborize predominantly in the deeper retinorecipient laminae (lamina C or D in the frog, and layers 2 and 3 in the salamander tectum). In frogs, the somata are located in periventricular layers 2 and 4, a larger number in layer 6, and fewer in layers 7 and 8. In salamanders, somata are found in the upper part of layer 6. The axons of this type descend ipsilaterally, some of them forming contacts with the isthmic nucleus; in the medulla, axons run in a ventrolateral superficial position. They constitute the lateral part of the uncrossed tectobulbospinal tract. Axons ascend to the ipsi- and contralateral thalamus.

Type-5 neurons (pear-shaped cells) of frogs and type-3 neurons of salamanders can be considered homologous, because their somata are usually situated in the deeper part of the periventricular gray (Figures 8a and 8b). Their dendritic tree is flat and T-shaped and mostly confined to the efferent fiber layers (layer 7 in frogs, layers 4 and 5 in

salamanders). With their descending axons they either contribute to the lateral part of the uncrossed tectobulbospinal tract or constitute its medial part; they have ascending ipsilateral or bilateral projections to the pretectum and thalamus.

In frogs, the somata of the type-4 neuron (pear-shaped) are located in the deep cellular layer; their slender primary dendrite arborizes in lamina C. They resemble the rarely labeled type-4 neurons of salamanders with narrow dendritic trees arborizing predominantly in layer 2. Axons of this type descend ipsilaterally to the ventrolateral part of the rostral medulla oblongata; other axons or axon collaterals ascend to the ipsilateral thalamus.

In the frog tectum, cells with small pear-shaped somata situated in layer 8 and slender dendritic trees and arborizing either in lamina B or D were identified as rostrally projecting cells. They strongly resemble the slender type-5 neurons found in salamanders (Figures 11a and 11b). The somata of the latter are situated in layer 6 and less often in 8; the narrow dendritic trees arborize in fiber layer 1 or 2. Axons only ascend ipsi- and/or contralaterally to the pretectum and thalamus.

Interneurons are similar in the salamander and frog tectum. Their pear-shaped somata are situated mainly in the deeper part of the periventricular gray matter, and their dendritic trees are mostly very slender (Figure 9). The dendritic trees arborize in different retinorecipient laminae of the tectum. However, because of a much higher degree of cell migration in the anuran compared to the urodele tectum, in frogs many interneurons, i.e., small pear-shaped cells, occupy a superficial position. During ontogeny of the frog tectum, these neurons (like other tectal cells) originate in the periventricular germinal zone and then migrate toward the surface. In salamanders, this late ontogenetic migration process is either strongly reduced or completely abolished, with the consequence that cells remain within the periventricular cellular layer 6 (Schmidt and Roth, 1993).

2.04.3.4.7 The number of tectal neurons The salamander tectum comprises on average 100 000 cells; frogs possess 2–17 times more tectal cells (Roth *et al.*, 1995). The bulk of them is formed by interneurons; projection neurons make up roughly 5% independent of the absolute number of neurons (Dicke, 1999).

2.04.3.4.8 Nonretinal afferents The tectum mesencephali of amphibians, like that of other vertebrates, is a center for multisensory integration. It receives afferents from the thalamus and pretectum, which are also targets of primary visual afferents. In frogs, thalamic neurons projecting to the tectum were described recently in *Bombina* (Roth *et al.*, 2003). They are located in the dorsal portion of the ventral nucleus, the NB, and the central and posterior dorsal nucleus. Most of these neurons are characterized by a dendritic tree oriented dorsolaterally, sometimes also ventrolaterally entering the NB or the CGT neuropils. Their axons terminate in layer 7 of the tectum, the layer of tectal efferents. They are either restricted to the medial portion or extend throughout that layer and form collaterals. In the salamander *Plethodon*, the situation corresponds with that found in *Bombina* (Roth and Grunwald, 2000). Two groups of cells send axons to the tectum: one group of cells has its somata in the posterior dorsal thalamus around the sulcus medialis (corresponding to the central dorsal and posterior dorsal nucleus of frogs) and possesses a wide and flat dendritic tree that arborizes mostly in the medial white matter; dorsalmost dendrites reach the lateral surface. The other group consists of cells with somata in the ventral thalamus (ventral nucleus and NB in frogs), which forms relatively narrow dendritic trees extending laterally or ventrolaterally toward the surface. Neurons of the latter group constitute two nuclei, one at the level and another one ventrally to the sulcus medialis (Dicke, unpublished data) (Figure 12). In the three groups, terminals in the tectum are confined mostly to deeper tectal fiber layers 3–5 within the medial, intermediate, or lateral zone of the tectum. Furthermore, neurons of the pretectum project to the tectum (Marín *et al.*, 1997b); in salamanders, axons run ipsilaterally in the deep fiber layers of the tectum (Luksch *et al.*, 1998). Finally, afferents originate from a small number of neurons in the contralateral tectum.

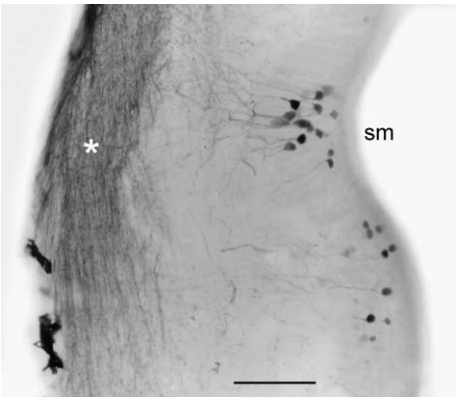

Figure 12 Microphotograph of ipsilaterally labeled ventral neurons in the mid thalamus of the salamander *Plethodon teyahalee* after application of biocytin to the tectum. Medial is to the right, dorsal is to the top. Asterisk indicates anterogradely labeled axons of tectal neurons as well as retinofugal axons of retinal ganglion cells that collateralize and run to the tectum and thalamus. Scale bar: 100 μm. sm, medial thalamic sulcus.

Neurons of the vomeronasal amygdala, dorsal tegmentum, isthmic nucleus, and medulla oblongata and spinalis project into tectal fiber layers; only few striatal neurons project to the deep fiber layers of tectum (Marín *et al.*, 1997c; Roth *et al.*, 2004). In *Rana*, there are mainly indirect connections of the striatum to the tectum constituted by pathways via the amygdala/entopecuncular nucleus, pretectum, and tegmentum (Marín *et al.*, 1997b; see also below).

A substantial tectal innervation arises in the dorsal tegmental nucleus, which projects ipsilaterally (entire nucleus) and contralaterally (only the posterior portion) to the tectum (Figure 4b); there is no information on the site of termination inside the tectum. In addition to retinal afferents from the retina, in amphibians as well as in other vertebrates, a major input to the superficial tectum originates in the isthmic nucleus (homologous to the parabigeminal nucleus in mammals). In frogs, neurons in the dorsal part of this nucleus project to the ipsilateral fiber layers 9 and 8 and those of the ventral part to the superficial contralateral fiber layer (Gruberg and Udin, 1978; Gruberg *et al.*, 1994). In salamanders, two subnuclei were likewise reported in a double-labeling study of Wiggers and Roth (1991), but intracellular labeling revealed that the majority of isthmic neurons project to both tectal hemispheres (Wiggers, 1998). However, an ipsilateral projection to several retinorecipient layers and a contralateral projection to only the superficial layer of retinal afferents is commonly found in all vertebrate tecta. The isthmotectal projection is topographically ordered and in register with the retinal map (Gruberg and Lettvin, 1980; Gruberg *et al.*, 1989; Wiggers 1998).

In amphibians as well as in all vertebrate species studied so far, neurons of the isthmic nucleus comprise acetylcholine as a major transmitter and are the principal source of cholinergic input to the tectum (Ricciuti and Gruberg, 1985; Wallace, *et al.*, 1990; Marín *et al.*, 1997a; Marín and González, 1999). In plethodontid salamanders and in the caecilian, *Dermophis mexicanus*, part of the cholinergic input to the tectum stems from tectal cells revealing ChAT-like immunoreactivity (-ir); their dendritic trees also reach superficial fiber layers (Wallstein and Dicke, 1998; Gonzalez *et al.*, 2002) (Figure 13). In frogs, the isthmic nucleus also contains GABA-ir somata, but the distribution varies among species. GABA-ir cells are evenly distributed in the isthmic nucleus of *R. pipiens* (Li and Fite, 1998), while in *Rana esculenta* the majority of them are found in the anterior one-third of the nucleus (0.5% of the total population), and a meshwork of GABA-immunostained fine-beaded axons fills the entire isthmic nucleus (Pollak *et al.*, 1999). Based on lesion experiments, it is assumed that the majority of GABA-positive fibers derives from local GABA-positive cells and the rest from tegmental GABAergic cells. In *Rana catesbeiana*, staining of GABA-ir cells is moderate to dense in the anterior and posterior part of the nucleus and absent in the central part, and the isthmic nucleus is sparsely GABA-immunoreactive in *X. laevis* (Hollis and Boyd, 2005).

Afferents from the medulla to the tectum include the auditory dorsal nucleus, the vestibular nucleus, the middle reticular nucleus and the raphe nuclei of the rostral medulla oblongata as well as nuclei of the medulla oblongata and spinal cord that mediate somatosensory information. Axons from sensory nuclei mainly innervate the contralateral tectum and run in the deep fiber layers containing efferent fibers of tectal neurons (layers 7 in frogs, and 4 and 5 in salamanders), whereas the majority of axons of the reticular nucleus ascend to the ipsilateral tectum and extend in all deep fiber layers of the tectum (3, 5, 7 in frogs; 3–5, 7 in salamanders). The distribution of transmitters in the nuclei with ascending projection was recently studied in the salamander, *Plethodon* (Landwehr and Dicke, 2005). Projection neurons of the dorsal and vestibular nucleus are glutamate-ir, and in the latter nucleus often reveal additional GABA- and/or glycine-ir. Projection neurons of the middle reticular nucleus reveal predominantly gly-ir, often co-localized with glu-ir; this nucleus appears to be homologous to the mammalian gigantocellular reticular nucleus (Figure 14b).

In salamanders, the serotonergic raphe nuclei strongly innervate the retinorecipient layers 2 and 3, and some axons of the raphe nuclei reach the efferent fiber layers 4 and 5 (Dicke *et al.*, 1997) (Figure 14a). In *Rana*, 5-HT is located in tectal layers 3, 5, 6, 7, and 9 (Liu and Debski, 1995), but the source of serotonergic innervation differs from that found in salamanders. The 5-HT-ir cells are labeled in cellular layers 2, 4, and 6 of the tectum and are assumed to contribute to the serotonergic innervation of the deeper fiber layers. The distribution of serotonergic neurons is most prominent in the lateral tectum and decreases significantly medially, but is largely constant in the rostrocaudal dimension (Debski *et al.*, 1995). The 5-HT-ir fibers in lamina A of layer 9 are mainly of retinal origin, while serotonergic fibers in the other laminae most likely originate from neurons in the midbrain tegmentum and the isthmic nucleus. The raphe nuclei of the reticular formation of the medulla project nontopographically to midtectal layers (Zhao and Debski, 2005). Neurons of the DCN and LCN situated in the caudal medulla oblongata and cervical spinal cord receive predominantly somatosensory

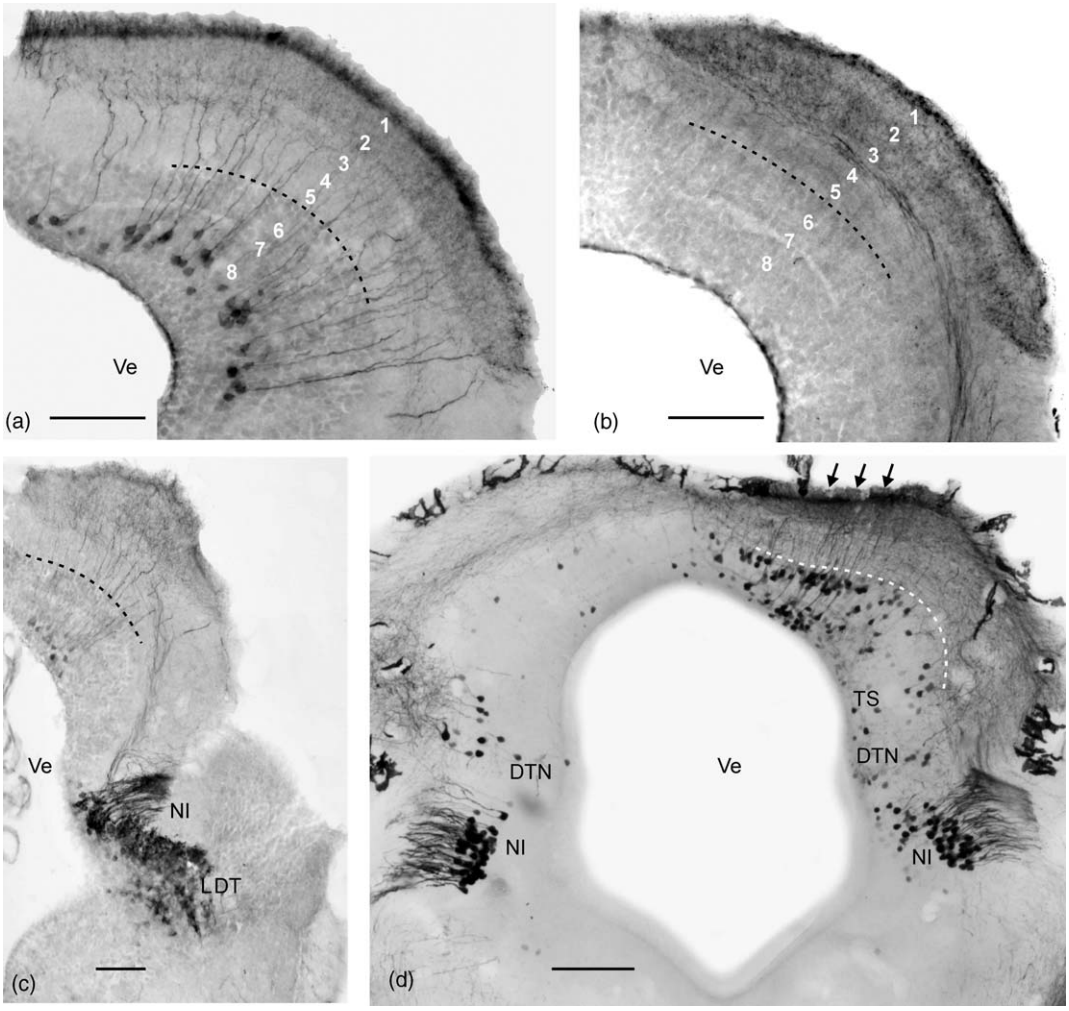

Figure 13 Microphotographs of ChAT-immunoreactive structures in the plethodontid salamander *Desmognathus ochrophaeus* ((a), (c)) and in the salamandrid *Salamandra salamandra* (b). In (d), retrograde labeling of bilateral tegmental and isthmic neurons after unilateral application of biocytin (black arrows) to the tectum is shown. Note that in *Desmognathus*, ChAT-ir tectal neurons are present that extend processes into the superficial layers, whereas in *Salamandra* only the isthmic neurons provide the tectal layers with cholinergic fibers. 1, 2, 3, 4, 5, 6, 7, 8, ventricles; Ve, ventricle; NI, isthmic nucleus; LDT, laterodorsal tegmental nucleus; DTN, dorsal tegmental nucleus; TS, torus semicircularis. Scale bars: 100 μm.

input. These neurons carry different sensory modalities and project to the tectum and the torus semicircularis. The pattern of ascending somatosensory projections differs between plethodontid salamanders on the one hand and *Pleurodeles waltl* and frogs on the other (Muñoz *et al.*, 1994a, 1994b, 1995, 1997; Dicke and Muhlenbrock-Lenter, 1998) (see Section 2.04.3.1.5.*(ii)* above). In the salamander, *Ambystoma tigrinum*, ipsi- and contralateral projections to the tectum have been reported (Gruberg and Solish, 1978; Gruberg and Harris, 1981).

In plethodontids, the tectum appears to be the main center for multimodal integration, while in frogs the torus is the main target of somatosensory afferents. The presence of a more elaborate secondary somatosensory system in terrestrial plethodontids compared to salamandrid salamanders with a larval stage as well as ranid and pipid frogs may be due either to phylogeny, differences in development (direct vs. biphasic), or functional adaptation (e.g., differences in quantity and distribution of transmitters in the tectum in the context of visuomotor and visual functions).

2.04.3.4.9 Tectal efferent pathways

2.04.3.4.9.(i) Descending pathways In order to elucidate descending tectal pathways, tracer studies have been carried out in frogs and salamanders using HRP or cobaltic lysine applied to the entire half of the medulla spinalis (ten Donkelaar *et al.*, 1981; Tóth *et al.*, 1985; Naujoks-Manteuffel and Manteuffel, 1988), and the existence of a crossed and uncrossed

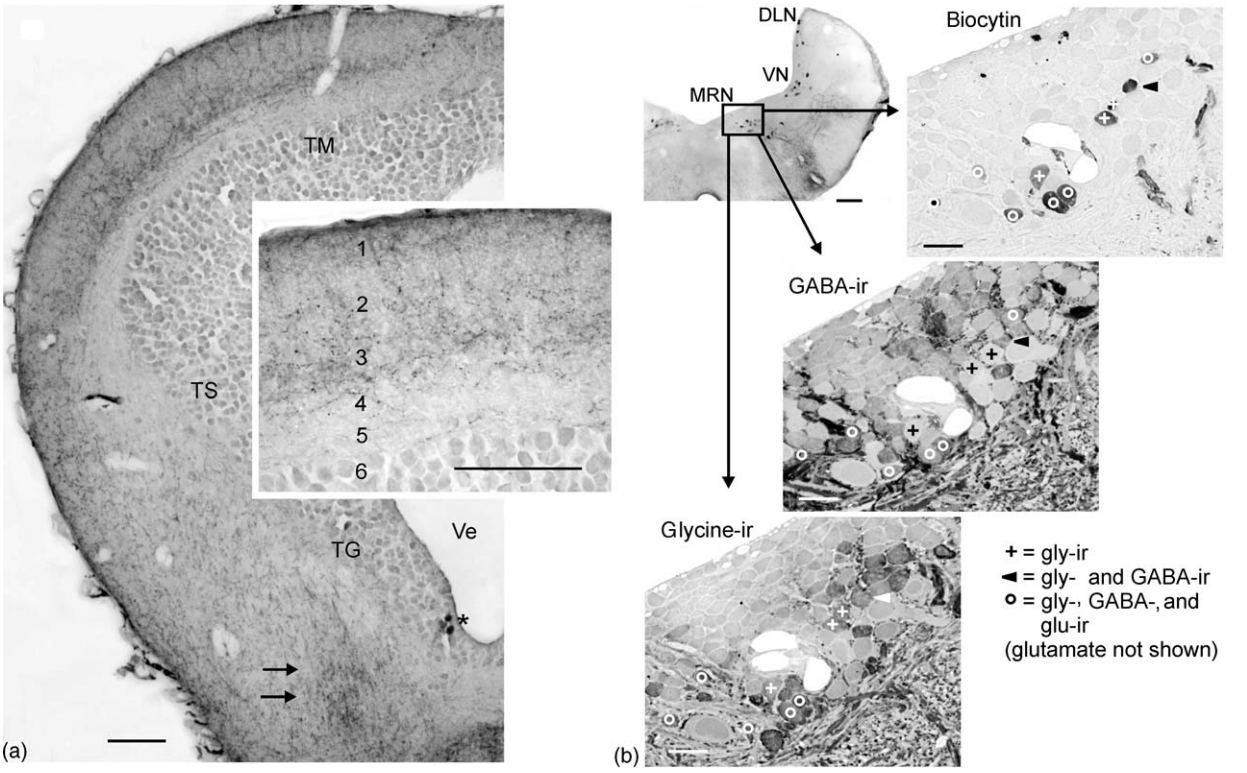

Figure 14 a, Microphotographs of transverse sections through the midbrain revealing 5-HT-immunoreactivity in the salamander *Plethodon jordani.* Arrows point to the ascending bundle and asterisk indicates labeled somata of the rostral raphe nucleus. Inset shows part of the tectum at higher magnification. b, Glycine-ir and GABA-ir in neurons of the middle reticular nucleus retrogradely labeled after biocytin application to the tectum. Consecutive semithin sections with cell bodies stained for the two transmitters and biocytin reveal that co-localization of transmitters occurs more frequently than previously assumed. Scale bar in (a) 100 μm and in (b) 50 μm for the section above left and 20 μm for semithin sections. a, Modified after Dicke, U., Wallstein, M., and Roth, G. 1997. 5-HT-like immunoreactivity in the brains of plethodontid and salamandrid salamanders (*Hydromantes italicus, Hydromantes genei, Plethodon jordani, Desmognathus ochrophaeus, Pleurodeles waltl*): An immunohistochemical and biocytin double-labelling study. *Cell Tissue Res.* 287, 513–523. b, Modified from Landwehr, S. and Dicke, U. 2005. The distribution of GABA, glycine and glutamate in neurons of the medulla oblongata and their projections to the midbrain tectum in plethodontid salamanders. *J. Comp. Neurol.* 490, 145–162.

tectal tract was consistently reported. Locally restricted application of biocytin to the ventromedial or ventrolateral medulla oblongata revealed that different populations of tectal neurons give rise to a crossed and one or two uncrossed descending tracts. In plethodontid salamanders, neurons in the ipsilateral tectum are labeled after ventromedial and ventrolateral tracer application, whereas in *Discoglossus* they are labeled only after ventrolateral tracer application (Dicke *et al.*, 1998; Dicke, 1999).

In plethodontid salamanders, the course of the descending axons and sites of collaterals to the medulla were investigated by biocytin application into the tectum as well as by intracellular biocytin injection into tectal neurons (Dicke and Roth, 1994; Dicke, 1999; Roth *et al.*, 1999) (Figures 10c and 9). The fibers of the crossed tectobulbospinal tract run to the ipsilateral ventral tegmentum and cross the midline in the rostral to caudal tegmentum. They further descend in the contralateral ventral tegmentum, where fibers form a neuropil extending inside the ventral white matter. In the medulla oblongata and spinalis, fibers run close to the midline within the ventral white matter below the surface. The tract thins out during its course to the spinal cord; axons terminate in the rostral medulla oblongata or reach at least the level of the third spinal nerve.

Axons of the uncrossed tract descend in the caudal tectum to the ventral tegmentum. During their course from the tegmentum to the ventral medulla, axons are distributed broadly in the medial white matter. More laterally, dense axon bundles are formed, which remain close to the lateral edge of the uncrossed tract inside the medulla; they originate from other types of neurons than the medially descending axons. In the medulla oblongata and spinalis, axons run in a superficial ventral position; in the transverse plane, they are distributed from the

midline to the ventrolateral part. The uncrossed tracts extend to rostral spinal cord levels, but only one-half to one-third of axons reach the level of the third spinal nerve.

During their course within the medulla oblongata and spinalis, axons of the descending tracts give rise to many fine collaterals that often carry boutons. Axons of single neurons give rise to a substantial amount of axon collaterals inside the medulla oblongata. The majority of collaterals extend inside the white matter. At the level of the IXth and Xth cranial nerves, prominent axon collaterals of the crossed tract extend dorsally and dorsolaterally into the gray matter; they often twist around each other. In the caudal medulla oblongata, some axon collaterals extend along the border of the gray matter to the dorsal side.

In salamanders as well as in frogs, the descending fibers of the crossed and uncrossed pathways show strong branching, but unlike in salamanders (and in other tetrapod vertebrates), in frogs only few contralaterally descending axons reach spinal levels. This may be a consequence of the condensation of the neck region and consequently of bulbar and cervical spinal motor nuclei that has occurred during the evolution of anurans.

2.04.3.4.9.(ii) Ascending pathways Systematic studies of the ascending axons of tectal neurons have been carried out in the frog *R. pipiens* and in the salamander *Plethodon jordani* (Montgomery and Fite, 1991; Dicke, 1999; Roth *et al.*, 1999). In *Rana*, the ascending projections from the dorsal mesencephalon to the thalamus and pretectum were investigated by means of HRP tracing. Axons of small pear-shaped neurons (type-5 in salamanders) in the superficial portion of tectal layer 8 exit the tectum through layer 9, travel in the superficial portion of the dorsal and ventral tectothalamic tracts, and innervate the nucleus lentiformis mesencephali (the large-celled part of the pretectal nucleus), the posterior lateral dorsal nucleus, and the CGT. Axons of small pear-shaped neurons in the lateral and caudal tectum ascend via the ventral tectothalamic tract, while those of neurons in the rostral and medium tectum run in the dorsal tectothalamic tract. Axons from pear-shaped neurons (type-5 of frogs homologous to type-3 in salamanders) in layer 6 and pyramidal neurons (type-3 of frogs homologous to type-2 in salamanders) in layer 8 leave the tectum through layer 7, travel in the dorsal or ventral tectothalamic tracts and are located medial to the axons of the pear-shaped neurons of superficial tectal layer 8. The majority of type-3 neurons project to the posterior lateral ventral nucleus and the anterior lateral nucleus, but terminals do not display a tectotopic organization. Another major projection to the thalamus originates from the pretectal gray and innervates the pretectal nucleus lentiformis mesencephali, the posterior lateral dorsal nucleus, the anterior lateral nucleus, dorsal and ventral divisions of the ventral lateral thalamus, and the nucleus of Bellonci. Other axons from the pretectal gray terminate in the contralateral medial portions of the posterior lateral dorsal thalamus, the ventral lateral thalamus, and the anterior lateral nucleus.

In *P. jordani*, ascending tectal projections were studied by tracer application and intracellular injection of biocytin into neurons (Figures 9 and 11c). Tracer application to the tectal hemisphere likewise labels retinal afferent fibers, and double labeling of the optic nerve and the tectum using different tracers reveals that the retinofugal axon bundles and ascending axons of tectal neurons take partially overlapping courses. The ascending axons of tectal neurons leave the tectum through fiber layers 3–5 and ascend superficially at the lateral edge of the tectum. During their course, axons give rise to many collaterals extending in the ipsilateral dorsal white matter. In the ipsilateral pretectum, two dense neuropils, a dorsolateral and a lateral one, are formed. In the ipsilateral thalamus, axons run laterally in the fiber layer, and collaterals are distributed in the entire white matter of the dorsal and ventral thalamus. They form a distinct neuropil at the border between the gray and white matter in the dorsal thalamus, where the neuropil and NB are situated. Many axons cross in the postoptic commissure to the contralateral thalamus, where they branch inside the ventral and dorsal white matter and again form a neuropil in the dorsal thalamus. Axon collaterals are labeled in the ipsi- and contralateral preoptic area, and only few extend to the ventral fiber layer of the ipsi- and contralateral caudal telencephalon.

In summary, the ascending pathways of amphibians are constituted by small-field neurons with only ascending projections and by two types of wide-field neurons with ascending and descending projections. The former neurons constitute the majority of ascending tectal projection neurons: they are regularly distributed throughout the tectum and give rise to a retinotopic tectal projection to the thalamus in the frog *Rana* and most likely in the salamander *Plethodon*. In contrast, the latter two types of neurons either are very low in number or are unevenly distributed in the tectum. They appear to give rise to a nonretinotopic tectal projection to the thalamus. Accordingly, in amphibians the ascending pathways may be divided into two functional systems, a retinotopically and a nonretinotopically organized system, which is comparable to the

situation found in reptiles and birds (see Evolution of the Nervous System in Reptiles).

In the tecta of reptiles and birds, efferent cells constitute ipsilaterally and contralaterally descending tracts as well as ipsi- and contralaterally ascending tracts (Reiner and Karten, 1982; Sereno, 1985; Sereno and Ulinski, 1985; Dacey and Ulinski, 1986a, 1986b; ten Donkelaar, 1990; Reiner, 1994). The morphology of neurons of origin of these tracts and their axonal projection patterns reveal similarities with the situation found in amphibians. One ascending pathway arises from neurons that possess wide dendritic fields in the retinorecipient layer; this pathway terminates in a nonretinotopic manner in the nucleus rotundus, the possible homologue to the pulvinar of mammals. The other pathway arises from radial neurons with long dendrites ascending to the stratum griseum superficiale (SGF); it ascends to the dorsal and ventral lateral geniculate nucleus (LGN) of the thalamus. In amphibians, we likewise find wide-field as well as small-field tectal neurons that give rise to pathways ascending to the thalamus. Axons of small-field neurons form neuropils in the dorsal thalamus, whereas wide-field neurons predominantly project to the ventral thalamus. In the thalamus, in turn, a large group of neurons project to the striatum, and a small group to the medial and dorsal pallium. Thus, a tectothalamopallial pathway exists in salamanders, but its thalamopallial part is formed by relatively few neurons. This will be discussed in greater detail below.

2.04.3.4.10 The distribution of transmitters and neuropeptides in the retinotectal system

2.04.3.4.10.(i) Retinal ganglion cells In amphibians, a large number of RGCs use glutamate as transmitter. Polysynaptic responses of tectal cells in *Rana* were found to be mediated by NMDA and non-NMDA receptors, and examination of monosynaptic currents revealed that retinotectal synapses express functional NMDA receptors that were voltage dependent and not responsible for the bulk of normal excitatory transmission (Hickmott and Constantine-Paton, 1993). GABA is likewise used as transmitter in retinotectal transmission; the number of GABAergic ganglion cells synapsing on tectal neurons differs across species. In *B. marinus*, roughly 3% of retrogradely labeled RGCs contained GABA; 88% of retinal axon terminals in the tectum revealed glutamate-ir, 6% GABA-ir, and 6% were negative for both GABA and glutamate (Gabriel *et al.*, 1992; Gabriel and Straznicky, 1995), while in *R. pipiens*, 15% of back-filled RGCs contained GABA (Li and Fite, 1998). Over 50% of cells in the retinal ganglion cell layer of *R. esculenta* contained calretinin, and many optic fibers were also labeled; a co-localization of calretinin and GABA was rarely observed in RGCs (Gabriel *et al.*, 1998). In *Ambystoma*, small populations of retrogradely labeled RGCs contained substance P (2%) or GABA (less than 1%); substance P and GABA were not co-localized in RGCs (Watt *et al.*, 1994). In the salamandrid salamanders *P. waltl* and *Triturus alpestris*, axons in the retinal radiation in the diencephalon are mainly GABA-negative (Naujoks-Manteuffel *et al.*, 1994).

2.04.3.4.10.(ii) Tectum mesencephali In *R. catesbeiana* and *X. laevis*, GABA-ir cell bodies are distributed throughout all tectal cellular layers, and form dense GABAergic populations in layers 2, 4, and 6, that in layer 6 probably has the densest population in the entire brain. In *Xenopus*, the laminar organization was less distinct and fewer labeled cells were present compared to *Rana* (Hollis and Boyd, 2005). In the tectum of *R. pipiens*, the synthesizing enzyme GAD is distributed with punctate structures in several laminae of the optic tectum, and the highest concentrations are found in layers 9 and 8 (Tyler *et al.*, 1995). GABA immunochemistry in this ranid species reveals that perikarya and fibers are labeled in superficial layers 8 and 9, but densely packed immunoreactive perikarya occur in deep tectal layers 2, 4, and 6 (Li and Fite, 1998). In the tectum of *R. esculenta*, nearly one-third of the total population of cells appears to be GABA-immunoreactive (Antal, 1991); the stained population consists of neurons with small perikarya, and the proportion is highest in layer 9 (61%), and lower in layers 7 (21%) and 6 (27%).

A substantial proportion of retinal axons terminate on GABA-containing tectal neurons. In *B. marinus*, 57% of retinal axons synapsed on GABA-ir and 5% on glutamate-ir tectal elements, while the remaining axons synapsed on dendrites revealing neither GABA- nor glutamate-ir (Gabriel and Straznicky, 1995). In *Xenopus*, an ultrastructural analysis of tectal layers 8 and 9 using labeling of retinotectal axon and GABA immunohistochemistry revealed that GABA-ir neurons participate in serial synaptic arrangements, in which retinotectal axons are the first element (Rybicka and Udin, 1994). Furthermore, retinotectal and isthmotectal axons do not synapse close to each other on the same dendrites. Surprisingly, axons of isthmotectal neurons relaying ipsilateral eye input to tectal cells mainly synapse onto GABA-ir interneurons (Rybicka and Udin, 2005).

In *R. esculenta*, a substantial portion of axons of RGCs that terminate in laminae B, C, and F of tectal layer 9 contain the calcium-binding protein calretinin. Also, approximately 10% of the tectal cells

were found to be immunoreactive for calretinin. Tectal neuron populations in layers 4, 6, 8, and 9 were labeled, and a few calretinin-positive cells were detected also in layer 2. Cells in layers 4, 6, and 8 belonged to projection neurons. Co-existence of GABA and calretinin was characteristic of cells in upper tectal layers, but was absent in neurons of deep layers of the tectum (Gabriel *et al.*, 1998). Several Met-enkephalin immunoreactive perikarya were found in tectal layer 6 of *R. esculenta*, and a third of these neurons showed GABA-ir in addition. Also, GABA and neuropeptide Y (NPY) were co-localized in half of NPY-immunopositive cells in layer 6, while only a few cells were double-stained in layers 9 and 4 (Kozicz and Lázár, 2001).

In salamanders, GABA-ir neurons are scattered in all cellular layers of the tectum in *Triturus cristatus* and *P. waltl*, and a rich GABergic innervation characterizes tectal fiber layers (Franzoni and Morino, 1989; Naujoks-Manteuffel *et al.*, 1994). In *P. jordani* and *Hydromantes italicus*, GABA-ir somata were found in one-third of tectal neurons, with the majority located in the deep cellular layer 8 and to a lesser degree in cellular layer 6. They were either immunoreactive for GABA only, for GABA and glutamate, or for GABA and glycine. About 80% of tectal somata revealed glutamate-ir, including those with GABA-ir in addition (one-fourth), and were situated in both cellular layers (Wallstein and Dicke, 1996). On the basis of immunochemical detection of co-localization of transmitters in tectal neurons with descending projections, the majority of the latter neurons appears to contain glutamate and a substantial part of them GABA in addition (S. Landwehr, unpublished data). It is unclear, however, to which degree glutamate appears as precursor of GABA.

In addition to the cholinergic and serotonergic innervation of the tectum already described above, catecholamines were investigated in the tectum of *Rana perezi* and *P. waltl* (Sanchez-Camacho *et al.*, 2002). Dopaminergic fibers were found primarily in deeper tectal layers of *Rana* (5–8) and in all tectal layers of *Pleurodeles*, whereas noradrenergic fibers predominated in superficial layers (7–9 in *Rana*; 1–5 in *Pleurodeles*); catecholaminergic somata were not found in the tectum. The catecholaminergic fiber input originates mainly from the pretectal area (*Pleurodeles*) and juxtacommissural nucleus (*Rana*), a smaller component from the suprachiasmatic nucleus, and in *Rana* also from the posterior tubercle as well as from the noradrenergic locus coeruleus. In plethodontid salamanders, the dopaminergic fiber input to the midbrain tectum appears to be less pronounced, since only few ir-fibers were found in the deep fiber layers 4 and 5 (Wallstein and Dicke, 1997). Furthermore, histochemistry of NADPH-diaphorase revealed labeled fibers and cell bodies in the tectum of *R. perezi* (Muñoz *et al.*, 1996).

The lamination of tectal cells and fibers is paralleled by another lamination established by peptides (cf. review of Lázár, 2001). A variety of peptides (23 of 28 peptides including those already mentioned above) is present in the frog tectum, and a substantial number of peptides was also localized in the lateral geniculate complex and pretectal area (13 and 15 of 28 peptides, respectively). Immunoreactivity of some peptides overlap tectal laminae or layers, while others partly overlap. Again other peptides share one lamina, but may be sharply separated within the lamina.

2.04.3.4.10.(iii) Pretectum and BON The BON contains a small number of lightly labeled GABA-ir perikarya, mostly located in its dorsal half (Li and Fite, 1998). GABAergic afferents extend from the retina to the contralateral tectum, from the BON to the ipsilateral pretectal nucleus lentiformis mesencephali, and a second-order pathway from the isthmic nucleus bilaterally to the optic tectum (Li and Fite, 2001). In *S. salamandra*, the pretectal and the accessory optic system display many GABAergic neurons (Naujoks-Manteuffel *et al.*, 1994). Labeled fibers and cell groups stained for the enzyme NADPH-diaphorase were observed in the pretectal area. NADPH-diaphorase and catecholamines were co-distributed in these areas; however, restricted co-localization in the same neurons was found (Muñoz *et al.*, 1996).

2.04.3.5 Neurophysiology of the Retino-Tecto-Pretectal System

2.04.3.5.1 Response properties of RGCs Based on recordings from the optic nerve and in the superficial layers of the tectum, five classes of RGCs have been identified in ranid frogs and three classes in toads and in salamanders (frogs: Maturana *et al.*, 1960; Grüsser and Grüsser-Cornehls, 1970, 1976; Ewert and Hock, 1972; Grüsser-Cornehls and Langeveld, 1985; salamanders: Cronly-Dillon and Galand, 1966; Norton *et al.*, 1970; Grüsser-Cornehls and Himstedt, 1973; 1976). The classes differ in the size of the excitatory and inhibitory receptive field (RF), the response to the on- and/or offset of illumination, the response to stationary or moving stimuli of different velocity, size, shape, or contrast, and the response to stimulation with light of different wavelengths. In brief, three universal classes of RGCs exist, which appear to constitute (1) a shape/color pathway, (2) a motion pathway, and (3) an ambient illumination pathway

(for an extended summary on the properties of RGCs, see Roth *et al.*, 1998).

Neurons of the first class of RGCs respond either to moving or nonmoving objects and require relatively high visual contrast. They can be classified as small-field edge-detector cells. They exhibit low conduction velocity due to unmyelinated fibers. Their axons terminate in the uppermost layer of the optic tectum. Class-1 and class-2 cells of frogs, R2 cells of toads, and layer-1 cells of salamanders belong to this class. They may include several subclasses differing in color sensitivity, responses to light ON or OFF, and erasability or nonerasability of stimulation by stationary edges. These cells are most probably involved in the detection of small, high-contrast objects such as prey. They are comparable to X-cells in cats and to P-cells in primates (Spillmann and Werner, 1990).

The second class of RGCs comprises neurons that respond to small changes in contrast and small dislocations of edges. They do not respond to nonmoving objects and are considered medium-field motion-detector or ON–OFF cells. They exhibit high-conduction velocity due to myelination of fibers. Axons run to the thalamus, pretectum, and tectum in parallel; in the tectum, they terminate in the intermediate layer of retinal afferents. They are represented by class-3 RGC in frogs, R3 cells in toads, and layer-2 cells in salamanders. The RGCs of this class are predominantly involved in motion and movement pattern detection. They correspond to Y-cells in cats and M-cells in primates.

RGCs of the third class respond well to large objects and to changes in illumination in larger parts of the visual field, but do not respond well to small- or medium-sized objects. They are classified as large-field dimming-detector or OFF cells. They show high-conduction velocity and have thick myelinated fibers, which project in parallel to the thalamus, pretectum, and tectum. Inside the tectum, they terminate in the deepest layer of retinal afferents. Class-4 and R4 cells of frogs and toads, respectively, and layer-3 cells of salamanders form this class. They may be involved in predator detection, optomotor behavior, or respond to changes in overall illumination.

2.04.3.5.2 Tectum

2.04.3.5.2.(i) Topic organization Retinal afferents from each retina form a contralateral and an ipsilateral two-dimensional representation or map in the tectum. In the plethodontid salamander *Hydromantes*, these maps were identified on the basis of data from single-cell recording and neuroanatomy (Wiggers and Roth, 1991; Wiggers *et al.*, 1995). Each visual hemifield is projected completely onto the contralateral tectal hemisphere. The ipsilateral retinotopic projection covers roughly the rostral two-thirds of the tectal surface. This representation is rotated 180° compared to that of the contralateral retinotopic projection such that the contralateral and ipsilateral retinotectal projection run in opposite directions. The ipsilateral tectal representation from one eye and the contralateral representation from the other eye are in register, whereas the left and right contralateral and the left and right ipsilateral representations are arranged opposite to each other. An object that moves from lateral to frontal in the visual hemifield shifts from rostral to caudal in the ipsilateral tectum, i.e., in a direction opposite to the contralateral projection from the same eye. When objects move along the *z*-axis, i.e., straight toward or away from the animal, the two contralateral tectal representations move in the same direction and opposite to the two ipsilateral representations. This topographic arrangement apparently is the basis for a precise localization of objects and is also important for depth perception based on retinal disparity (Wiggers and Roth, 1994; Eurich *et al.*, 1995; Wiggers *et al.*, 1995).

2.04.3.5.2.(ii) Neurons The visual field covers an area of 360°–400° in different frog species. Several classes of tectal neurons have been defined by the size and shape of their RFs as well as their location in the visual field, by their responses to stationary or moving objects of different velocity, size, shape, or contrast, and their responses to the direction of movement. The RFs of tectal neurons range from 1° to the size of the entire visual field, and seven different types of tectal neurons have been identified in various frog species (cf. Grüsser and Grüsser-Cornehls, 1976). Ewert and von Wietersheim (1974) and Roth and Jordan (1982) studied the response properties of tectal neurons in *Bufo bufo*, and Schürg-Pfeiffer and Ewert (1981) those of *Rana temporaria*. A detailed comparison of response properties of tectal neurons in frogs and salamanders is given in Roth (1987).

In salamanders, tectal neurons were classified in *S. salamandra* (Grüsser-Cornehls and Himstedt, 1973; Himstedt and Roth, 1980; Finkenstädt and Ewert, 1983a, 1983b; Himstedt *et al.*, 1987), in *H. italicus* (Roth, 1982), and in *Hydromantes* and *Bolitoglossa subpalmata* (Wiggers *et al.*, 1995). In plethodontid salamanders, the RFs of tectal neurons are not evenly distributed across the tectum, but concentrate in the frontal area of the visual field (Wiggers *et al.*, 1995). More than half of recorded neurons are situated in the rostral tectum, and their RFs are located in the binocular visual field. The size and shape of RFs does not differ between in the monocular contralateral visual field and in the

binocular field. In *H. italicus*, the size of the RFs ranges from 10° to 360°, with an average of about 40° (Wiggers *et al.*, 1995); in *Plethodon shermani* (formerly *P. jordani*) the RFs in the binocular visual field range from 6° to 200° with an average of 22° (Schuelert and Dicke, 2005).

A comparison between tectal response types in urodeles and anurans shows that similar types can be found in *Salamandra* and *Bufo*, on the one hand, and plethodontid salamanders and *Rana*, on the other. In the two former species, a worm-preference type was found, i.e., neurons responded best to the presentation of a horizontal rectangle moving in direction of its long axis inside the RF, with lower frequencies to the presentation of a square and with lowest frequencies to a rectangle moving perpendicular to its long axis. Such a preference for worm-like stimuli was absent in tectal neurons of *Rana* and plethodontid salamanders. This difference fits nicely with natural prey preferences of the species under consideration (cf. Roth, 1987).

In these studies on the response properties of tectal neurons, the relationship between neuronal responses elicited by a given object and the response of the behaving animal to such a stimulus remained unclear. In toads, a strong correspondence between the configural features of elongated visual objects and the response selectivity of one type of neuron was proposed (Ewert and von Wietersheim, 1974; Ewert *et al.*, 1978; Schürg-Pfeiffer and Ewert, 1981). Other studies demonstrated that a combination of stimulus features rather than a single feature determines the responses of tectal neurons (Himstedt and Roth, 1980; Roth, 1982; Roth and Jordan, 1982). From these latter studies it was concluded that visual features are encoded only ambiguously by the spike rate of a single neuron, and that object recognition is based rather on population coding (an der Heiden and Roth, 1987).

In a recent extracellular recording and labeling study of tectal neurons in *Plethodon* (Schuelert and Dicke, 2005), prey dummies differing in size, contrast, velocity, or movement pattern were presented either singly inside the excitatory RF or paired with one stimulus inside and another stimulus outside the excitatory RF (Figure 15). The authors found that

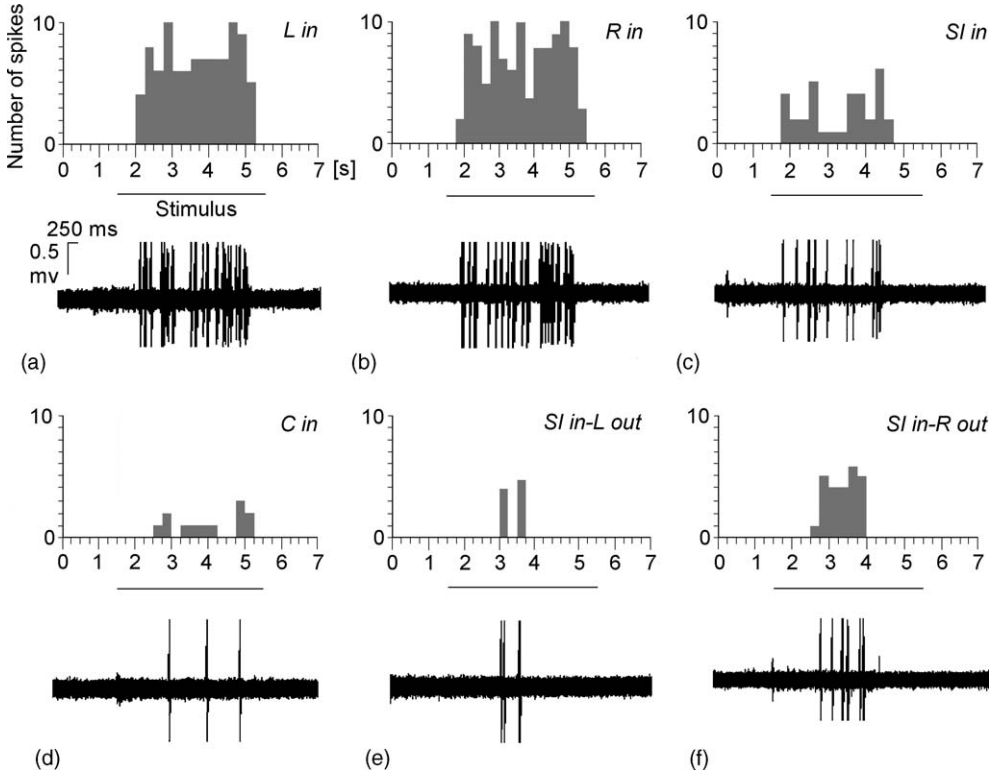

Figure 15 Responses of a tectal neuron in *Plethodon shermani* to the following stimuli: single presentation of a large-sized cricket (a; *L in*), a rectangle (b; *R in*), a still-image cricket (c; *SI in*) and a contrast-reduced cricket (d; *C in*) inside the excitatory receptive field (ERF). Although the number of spikes is comparable at single presentation of the L and the R, at paired presentation of the SI inside and the L (e; *SI in-L out*) outside the ERF, the spike number is much lower at presentation of *SI in-L out* compared to *SI in-R out*. Histograms of spike number at presentation of stimuli ($n=3$ for each stimulus type) are shown above the recording traces; the black line below the trace indicates the duration of stimulus presentation. From Schuelert, N. and Dicke, U. 2005. Dynamic response properties of visual neurons and context-dependent surround effects on receptive fields in the tectum of the salamander *Plethodon shermani*. *Neuroscience* 134, 617–632.

tectal neurons are not merely tuned to simple stimulus properties; rather, their responses are heavily influenced by the type of stimulus, i.e., the combination of single features, the familiarity of an object, and the context in which a visual stimulus occurs.

It became evident that in amphibians, visual object recognition involves much more complex spatial and temporal processing than previously assumed and concerns changes in spike number, temporal pattern, and dynamic changes in the size of the RF. Also, the response properties of tectal neurons indicate that these neurons integrate information across a much larger part of visual space than covered by the RF. For example, an inhibitory surround effect resulting in a decrease in the number of spikes and a reduction in RF size occurred at paired presentation, when a large-sized cricket or a rectangle was located outside the RF. However, this inhibition was significantly greater for the large-sized cricket stimulus than for the rectangle and indicates the biological relevance of the prey-like stimulus in object selection. This dynamic processing corresponds with the selection of stimuli in the visual orienting behavior of *Plethodon*, in which orientation toward a stimulus depended on the precise combination of different features (Schulert and Dicke, 2002). These findings suggest that prey recognition is guided by a number of visual features instead of a single feature and supports the idea of population coding as the basis for object recognition.

2.04.3.5.3 Nucleus isthmi Gruberg and co-workers found that unilateral lesions of the nucleus isthmi resulted in a scotoma to visually presented prey and threat stimuli in the contralateral monocular visual field (Gruberg *et al.*, 1991). A correlation exists between the size of the scotoma and the amount of nucleus isthmi ablated. Electrophysiological recording from positions within the area of the optic tectum including the scotoma reveal a roughly threefold increase in the size of the multi-unit RFs compared to mirror-image positions in the contralateral optic tectum. Across the entire extent of the isthmic nucleus, two superimposed maps exist, one representing the entire visual field of the contralateral eye, the other one representing the binocular visual field of the ipsilateral eye (Winkowski and Gruberg, 2002).

The role of the isthmic nucleus in enhancing intracellular calcium concentrations in retinotectal fibers was studied *in vitro*; results suggest that the input of the isthmic nucleus can facilitate retinotectal neurotransmission. This mechanism could be used to allow the frog to attend to a single prey stimulus in an environment of several prey stimuli (Dudkin and Gruberg, 2003). Recent recordings from the intermediate layer 7 of *Rana* revealed the existence of superimposed topographic maps of the monocular visual fields in the caudolateral tectum. The ipsilateral eye monocular visual field representation can be abolished by electrolytic ablation of the contralateral isthmic nucleus (Winkowski and Gruberg, 2005).

In the salamander *H. italicus*, the representation of the visual field and the properties of isthmic neurons were studied by Wiggers and Roth (1991). The RFs of isthmic neurons are centered in the frontal 100° field. The visual hemifield covered by neurons of each nucleus extends horizontally from 50° contralateral to 30° ipsilateral to the nucleus, and vertically from 36° below to 50° above the horizon. Thus, the projection fields of the isthmic nucleus overlap by 60°. About two-thirds of recorded neurons had their RFs within the upper part of the visual field, above eye level. The majority of neurons preferred stimulus sizes with edge lengths between 4.6° and 9.1°. The highest impulse rates, up to 25 impulses s^{-1}, were recorded at velocities between 20 and 36° s^{-1}. Half of isthmic neurons responded to stimuli from both eyes, whereas 35% responded only to contralateral stimulation. The remaining 14% responded weakly to ipsilateral stimulation and strongly to contralateral stimulation.

In summary, neurons of the isthmic nucleus reveal response properties that are similar to those found in tectal neurons; however, the representation of the visual space in the isthmic nucleus is not a simple copy of the tectal representation of visual space. The findings support the view of the isthmic nucleus as an essential structure involved in object localization and selection.

2.04.3.5.4 Pretectum In the pretectum of frogs and salamanders, a superficial nucleus (nucleus lentiformis in frogs) consisting of migrated, large-celled neurons and a deep subnucleus are found (Figure 16). Neurons in the pretectum in *R. pipiens* and *R. esculenta* are directionally selective and particularly sensitive to horizontal optokinetic patterns moving at velocities of 5–10° s^{-1} (Katte and Hoffmann, 1980). Neurons in the nucleus lentiformis mesencephali are involved in horizontal optokinetic nystagmus in *R. pipiens* (Fite *et al.*, 1989). At presentation of a large-field patterned stimulus at eight directions and three velocities of movement, all recorded units were spontaneously active and motion sensitive. Directional information appears to be encoded in the activity of a large population of motion-sensitive units, which includes both narrowly and broadly tuned individual response profiles. In contrast, neurons recorded in the nucleus/neuropil of the basal optic root respond more selectively to slowly

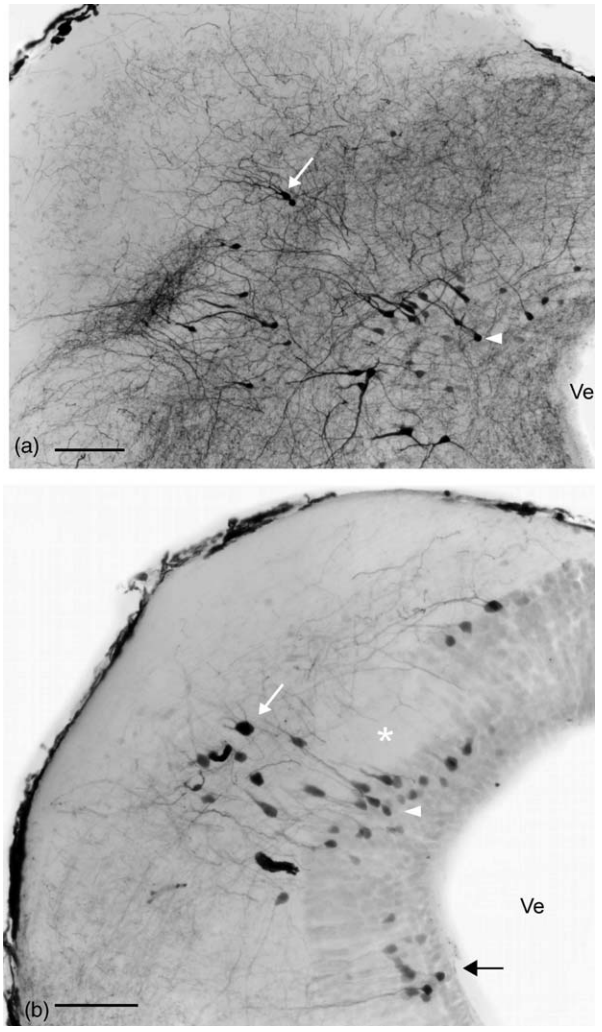

Figure 16 Microphotographs of transverse sections through the superficial and deep pretectal nucleus of *Discoglossus pictus* (a) and *Plethodon jordani* (b). Neurons were retrogradely labeled after application of biocytin to the ventral rostral medulla oblongata. Asterisk indicates the posterior commissure, white arrows and arrowheads point to neurons in the superficial and deep pretectal nuclei, respectively, and black arrow in B to ventral thalamic neurons. Ve, Ventricle. Scale bars: 100 μm. From Dicke, U., Roth, G., and Matsushima, T. 1998. Neural substrate for motor control of feeding in amphibians. *Acta Anat.* 163, 127–143.

moving vertical patterns, although horizontally sensitive neurons also have been reported (Katte and Hoffmann, 1980; Gruberg and Grasse, 1984).

Recordings of pretectal cells were also carried out in *S. salamandra* (Manteuffel, 1984a, 1984b, 1989; Sperl and Manteuffel, 1987). Two-thirds of recorded cells were sensitive to a temporonasal movement of stimuli; the majority preferred velocities between 1° and 5° s^{-1}. These neurons mostly possessed large RFs with a diameter of 82° and 34° in horizontal and vertical direction, respectively, and the RF center was situated always within the contralateral visual hemifield. Nearly half of pretectal cells were binocular and did not respond to ipsilateral stimulation. Cells in the BON of *Salamandra* and *T. cristatus* were also sensitive to temporonasal direction of stimulus movement, except one cell which was sensitive to the opposite direction (Manteuffel, 1982, 1984b). All neurons recorded from the BON or the nucleus of the oculomotor nerve were strictly monocular. Deeper and more caudal sites close to the BON cells that respond preferentially to vertical movement tend to be more numerous.

According to lesion experiments, the amphibian pretectum has proven to be essentially involved in control of gaze-stabilizing reflexes (Lázár, 1972; Montgomery *et al.*, 1982; Manteuffel *et al.*, 1983). In summary, the findings of recording and lesion experiments provide evidence that pretectal and accessory neurons are involved in oculomotor and optokinetic behaviors.

2.04.3.6 Diencephalon

The diencephalon of amphibians forms the walls surrounding the third ventricle and is, like that of all tetrapod vertebrates, traditionally divided into three parts, i.e., epithalamus, thalamus, and hypothalamus (Figures 17h–17j). The pretectum is considered to form either the posterior part of the thalamus or – together with the anterior portion of the tectum mesencephali – to represent a transition zone between diencephalon and mesencephalon surrounding the posterior commissure and called synencephalon (Kuhlenbeck, 1977).

2.04.3.6.1 Epithalamus and pineal complex The rostral part of the epithalamus contains the dorsal and ventral habenular nuclei and the habenular commissure. The ventral habenular nucleus is divided by the fasciculus retroflexus. Caudal to the habenular nuclei, the pineal gland or epiphysis, the posterior commissure, and below it the subcommissural organ (a gland) are found. The pineal gland is connected, via the pineal nerve, with the light-sensitive frontal organ located in the skin between the two eyes. Pineal gland and frontal organ project, among others, to the amygdala, pretectum, ventrolateral thalamic nucleus, and ventrolateral mesencephalic tegmentum.

2.04.3.6.2 Dorsal and ventral thalamus Dorsal and ventral thalamus are separated by the sulcus medialis, and the ventral thalamus is separated from the hypothalamus by the sulcus hypothalamicus (Figures 17h–17j, 5, and 6). In anurans, a number of thalamic nuclei can be distinguished morphologically. The dorsal thalamus is comprised of three

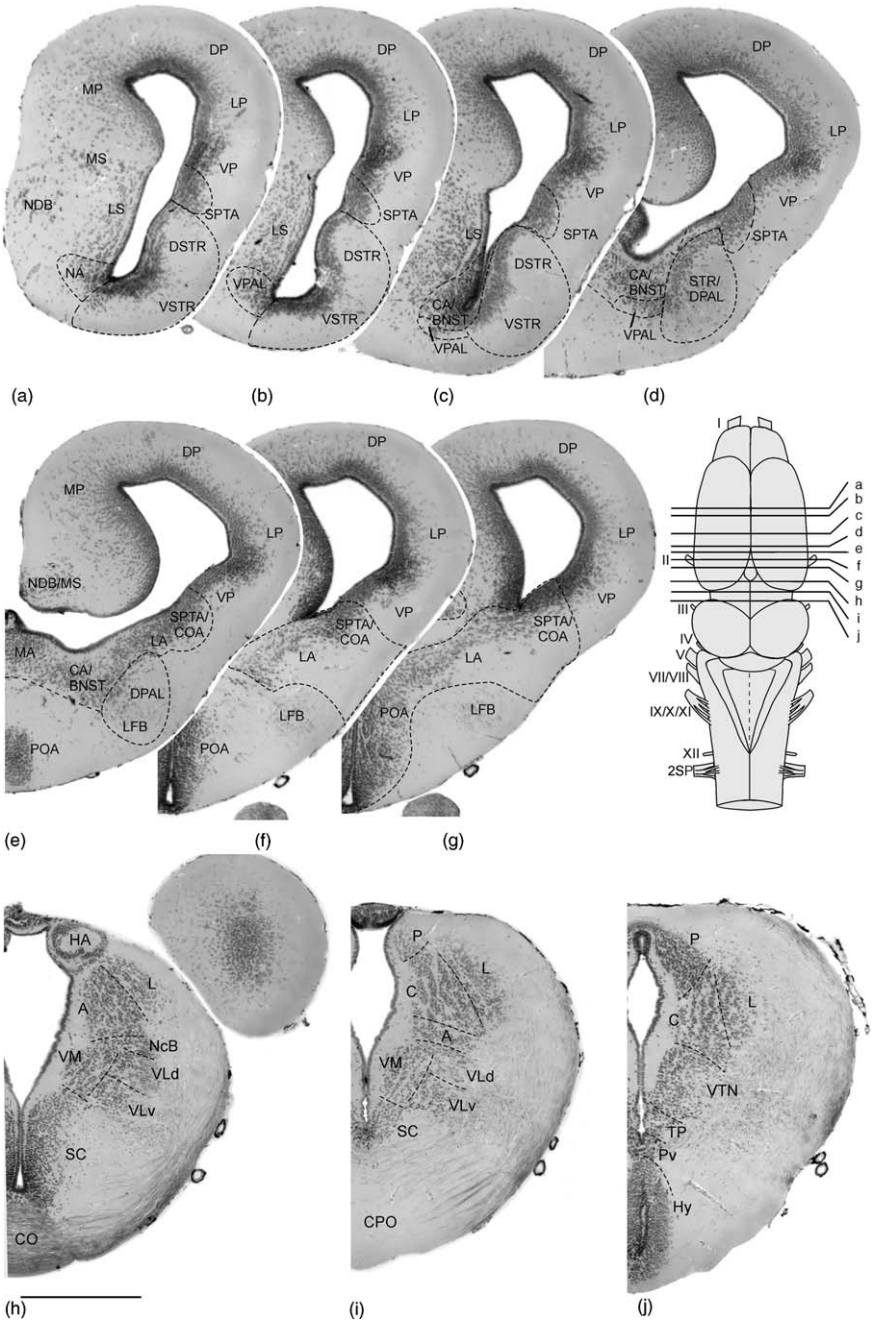

Figure 17 a–j, Transverse sections (Kluver–Barrera staining) through the telencephalon and diencephalon of *Bombina orientalis* at levels indicated in inset. Anterior mid-telencephalon (a), intermediate mid-telencephalon (b), posterior mid-telencephalon (c), anterior caudal telencephalon (d), mid-caudal telencephalon at the level of the foramen interventriculare (e), posterior caudal telencephalon at the level of the telencephalic commissures (f), posterior caudal telencephalon at the level of the magnocellular preoptic nucleus (g), anterior thalamus at the level of the optic chiasm and habenula (h), central thalamus at the level of the posterior commissure (i), and caudal thalamus at the level of the postoptic commissure (j). Scale bar: 500 μm. Modified from Roth *et al.* (2003, 2004).

periventricular nuclei, i.e., an anterior, a central, and a posterior (pretectal) nucleus, as well as of a migrated lateral nucleus with an anterior and posterior subdivision. The ventral thalamus consists of a periventricular ventromedial nucleus and a number of migrated nuclei, i.e., a ventrolateral nucleus subdivided into a dorsal and a ventral portion, a dorsally situated NB, and a superficial ventral nucleus (Neary and Northcutt, 1983; Roth *et al.*, 2003).

In salamanders, the dorsal and ventral thalamus consists – like the entire diencephalon – of a more or less compact cellular layer surrounding the third ventricle, with very few, if any, cells found in the white matter, and nuclei cannot be distinguished by morphological boundaries. However, on the basis of retrograde and anterograde tracing and intracellular labeling experiments, anterior, central, and posterior zones can be distinguished, with projection patterns that correspond to those found in anurans, but show great overlap. In the ventral thalamus, neurons with different projection patterns can be distinguished, which likewise correspond with the ventral thalamic divisions of anurans, but do not form distinct nuclei (Roth and Grunwald, 2000).

Sensory afferents to the thalamus include (1) primary visual afferents from the optic nerve and secondary visual afferents from the tectum, (2) secondary auditory afferents from the midbrain torus semicircularis, and (3) somatosensory and vestibular afferents from the spinal cord and the Vth and VIIth cranial nerves. As described above, the optic nerve/tract forms two neuropils in the thalamus, i.e., the NB and the CGT (Scalia *et al.*, 1968; Scalia and Gregory, 1970; Scalia, 1976; Levine, 1980; Roth *et al.*, 2003) (Figures 5 and 6). These two neuropils occupy most of the lateral white matter leaving a narrow zone between them and the gray matter of the thalamic nuclei. Here and in the entire lateral zone occupied by the retinofugal fibers, afferents from the optic tectum terminate (Dicke, 1999).

In the thalamus of *R. pipiens*, intensely labeled GABA-immunoreactive neurons and fibers were observed within the NB and CGT. In the pretectum, the posterior thalamic nucleus contained the most intensely labeled GABA-immunoreactive perikarya and fibers in the entire brain (Li and Fite, 1998). In *R. catesbeiana* and *X. laevis*, GABA-ir somata were distributed throughout the different areas of the thalamus. At mid-thalamic level, GABA-ir somata were arranged in columns that extended through the anterior, ventrolateral, and ventromedial thalamic nuclei (Hollis and Boyd, 2005). In the pretectum of *S. salamandra*, the transition zone of the dorsal to the ventral thalamus is almost completely devoid of GABA-ir cells (Naujoks-Manteuffel *et al.*, 1994), whereas the ventral thalamus contains a substantial number of GABAergic cells.

Numerous neurons stained for the enzyme NADPH-diaphorase were localized in the dorsal anterior, lateral anterior, central, and lateral posteroventral thalamic nuclei of *R. perezi*, and highly labeled terminal fields were found in the NB, the CGT, and the superficial ventral thalamic nucleus. The distribution of labeled cells did not correspond to any single known neurotransmitter or neuroactive molecule system. Abundant co-distribution of NADPH-diaphorase and catecholamines was found; double labeling techniques revealed restricted co-localization in the same neurons (Muñoz *et al.*, 1996).

Anterograde and retrograde tracing and intracellular labeling studies (Roth and Grunwald, 2000; Roth *et al.*, 2003; G. Roth *et al.*, unpublished data) reveal the projection pattern of dorsal thalamic neurons in anurans and urodeles (summary in Figure 18a–18c). These studies confirm earlier findings that the anterior nucleus or zone of the dorsal thalamus projects bilaterally or ipsilaterally via the medial forebrain bundle to the ventromedial, medial, dorsal, and dorsolateral part of the telencephalon (Kicliter, 1979; Neary, 1984) (Figures 19 and 20). Inside the anterior dorsal thalamic nucleus, the majority of neurons innervate the entire medial, dorsal and lateral pallium and most strongly the rostral portion of the medial and dorsal pallium. Many fibers form a dense terminal neuropil around the cellular prominence at the level of the sulcus rhinalis dividing the lateral and ventral pallium (Figure 15a, right). This thalamopallial tract as part of the medial forebrain bundle sends collaterals to the central and medial amygdala, nucleus accumbens, and septal nuclei (Figure 15a, right). A subpopulation of anterior dorsal thalamic neurons targets only the superficial neuropil in the ventral portion of the rostral medial pallium. These two pathways appear to supply sensory information to the pallium (with the exception of olfaction), because stimulation of the optic nerve (visual), spinal nerve (somatosensory), and torus semicircularis (auditory) elicits evoked potentials with shorter latency and higher amplitude in the rostral two-fifths of the medial pallium, from where responses flow into the caudal medial pallium and the dorsal and lateral pallium (F. Laberge, unpublished results).

An additional thalamotelencephalic pathway originating in the anterior dorsal thalamus and to a lesser extent from a region below runs, via the lateral forebrain bundle, to the caudal lateral pallium – a region that receives input from the main olfactory bulb (Moreno and Gonzalez, 2004).

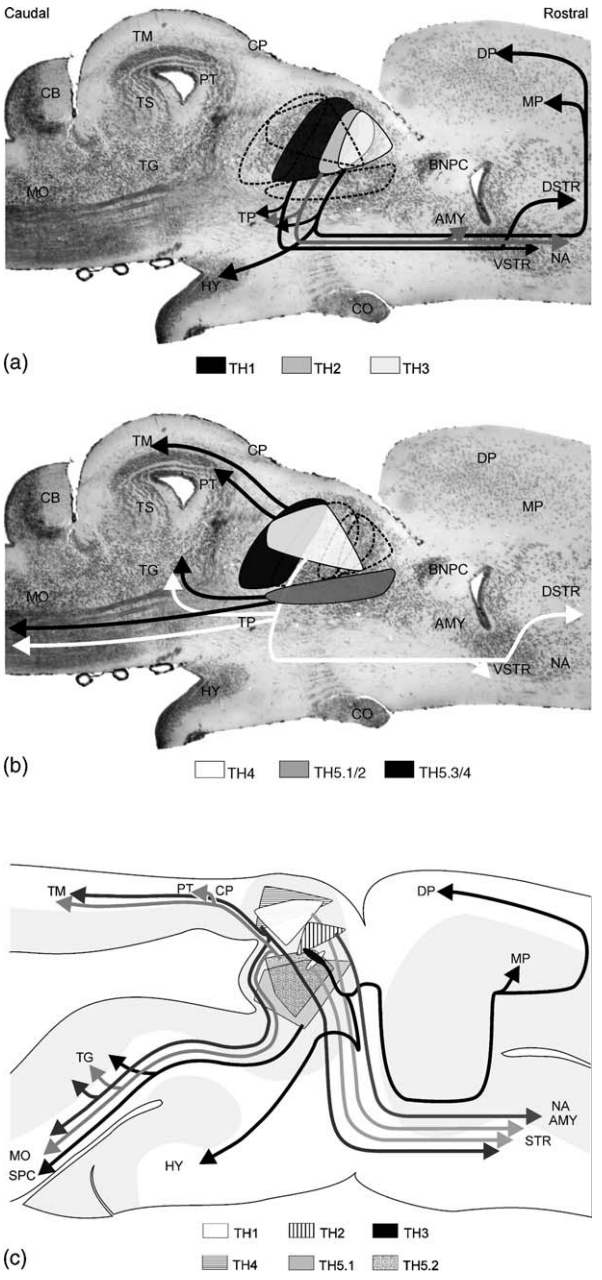

Figure 18 a, b, Diagrams of projection patterns of thalamic neurons combined with a lateral view of the caudal telencephalon, diencephalon, and mesencephalon in *Bombina orientalis*. c, Same in *Plethodon jordani*. CB, cerebellum; MO, medulla oblongata; TG, tegmentum; TM, mesencephalic tectum; TS, torus semicircularis; TP, posterior tubercle; CP, posterior commissure; DP, dorsal pallium; MP, medial pallium; BNPC, bed nucleus of the pallial commissure; DSTR, dorsal striatum; AMY, amygdala; NA, nucleus accumbens; VSTR, ventral striatum; PT, pretectum; CO, optic chiasm; Hy, hypothalamus; SPC, spinal cord. Modified from Roth and Grunwald (2000) and Roth *et al.* (2003).

The central dorsal nucleus/zone receives auditory input from the torus semicircularis (Hall and Feng, 1986; Mudry and Capranica, 1987; Feng *et al.*, 1990) and projects, via the lateral forebrain bundle, to the lateral amygdala and striatopallidum (Figure 21), where it contributes to the dense striatal neuropil (Figure 21B, right) (Wilczynski and Northcutt, 1983; Neary, 1988; Marín *et al.*, 1997a; Endepols *et al.*, 2004a). The ventromedial thalamic nucleus (probably homologous to the mammalian zona incerta), which receives auditory input from the torus semicircularis, likewise projects to the striatopallidum (frogs: Vesselkin *et al.*, 1980; Marín *et al.*, 1997a; Endepols *et al.*, 2004; salamanders: U. Dicke, unpublished data). The ventrolateral thalamic nucleus projects to the ventral pallium/SPTA. The lateral and posterior nuclei of the dorsal thalamus have no ascending but only descending projections to the pretectum, tectum, and tegmentum. (Roth and Grunwald, 2000; Roth *et al.*, 2003).

A long-standing question is whether the anterior and central nuclei/zones of the dorsal thalamus that project to the telencephalon receive direct or only indirect sensory afferents. Stimulation of the optic nerve in the salamander, *Plethodon*, and the frog, *Bombina*, elicited intracellular responses in the anterior dorsal thalamic nucleus, which showed either inhibition or excitation, but always at long latencies (about 35 ms on average). In contrast, short-latency, probably monosynaptic, responses could be recorded only from the ventral thalamus (Roth and Grunwald, 2000; Roth *et al.*, 2003) (Figure 22). Likewise, stimulation of the trigeminal and facial root (somatosensory and vestibular afferents) produced field potentials at long latencies in the anterior and central dorsal thalamus (Westhoff *et al.*, 2004), and the same holds for stimulation of the auditory pathway including the torus semicircularis (Mudry and Capranica, 1987; Hall and Feng, 1986; Feng *et al.*, 1990). Responses of neurons in the central dorsal thalamic nucleus at stimulation of auditory afferents show extreme habituation (Mudry and Capranica, 1987). This corroborates the view that the dorsal thalamus of frogs and salamanders does not receive substantial direct visual, auditory, somatosensory, and vestibular input. Rather, primary (only visual) or secondary (auditory, somatosensory) sensory afferents terminate in the ventral thalamus, which in turn projects to the dorsal thalamus (Dicke and Muhlenbrock-Lenter, 1998).

2.04.3.6.3 Response properties of thalamic neurons In anurans, thalamic and pretectal neurons were studied electrophysiologically in the toad, *Bufo americanus* and *B. bufo* (Ewert, 1971; Ewert and von Wietersheim, 1974). Ten classes of neurons were distinguished; eight of them responded to visual stimulation. One type of neuron responded best to large moving stimuli and had RF sizes between 30°

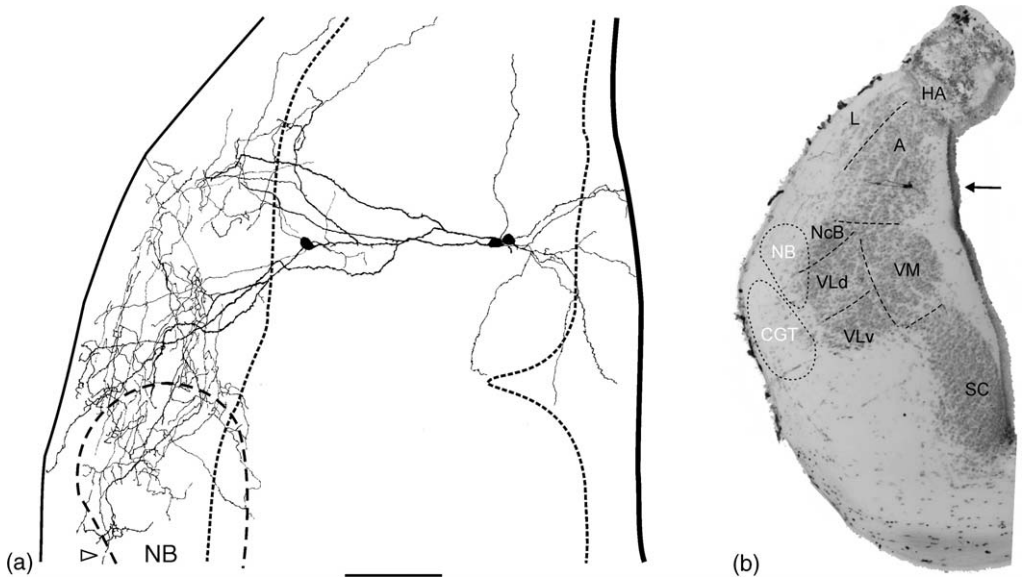

Figure 19 Camera lucida drawings of intracellularly labeled neurons in the dorsal thalamus of *Bombina orientalis*. a, Three neurons in the anterior dorsal thalamus, two of them in the periventricular anterior dorsal nucleus, with axons running to the medial and dorsal pallium, and one in the lateral anterior dorsal nucleus, without ascending projections. Only the dendrites of the latter enter the NB. The site of the neurons is indicated by a black arrow in (b). NB, neuropil of Bellonci; CGT, corpus geniculatum thalamicum; HA, habenula; A, anterior dorsal thalamic nucleus; L, lateral dorsal thalamic nucleus; NcB, nucleus of Bellonci; VLd, dorsal portion of the ventrolateral nucleus; VLv, ventral portion of the ventrolateral nucleus; VM, ventromedial thalamic nucleus; SC, suprachiasmatic nucleus. Scale bar: 100 μm. Modified from Roth, G., Grunwald, W., and Dicke, U. 2003. Morphology, axonal projection pattern and responses to optic nerve stimulation of thalamic neurons in the fire-bellied toad *Bombina orientalis*. *J. Comp. Neurol.* 461, 91–110.

and 46°. Another type responded selectively to motion; its RFs covered the contralateral or the entire visual field. Some of these neurons adapted quickly to stimuli, while others did not. Furthermore, one type of neuron responded best to stimuli approaching the toad along the *z*-axis, while another type represented luminance or darkness detectors.

Himstedt *et al.* (1987) studied the response characteristics of thalamic visual neurons in *S. salamandra* using a square, a horizontal, and a vertical rectangle as well as a random-dot pattern at different velocities. Neurons in the rostral thalamus, at the level of the NB and CGT, mostly had RF sizes between 36° and 50° and responded preferentially to the horizontal or vertical rectangle moved horizontally at low stimulus velocity. At intermediate velocity, most neurons responded best to the horizontal rectangle or square, and some responded best to the random-dot pattern. At high velocity, most neurons responded only to the horizontal rectangle or responded best to the square; one neuron responded best to the random-dot pattern. In the caudal dorsal thalamus, rostral to the pretectal neuropil and to the posterior commissure, RF sizes of neurons were comparable to those measured in the rostral thalamus. Likewise, in the majority of neurons the preferences of responses were similar to those of neurons in the rostral thalamus, but neurons did not respond to the random-dot pattern.

In summary, a topographically ordered representation of the visual space has not been reported in thalamic neurons. In general, the physiological properties of thalamic visual neurons differ from tectal neurons by their larger RFs and/or by profound adaptation to visual stimuli.

2.04.3.6.4 Hypothalamus The hypothalamus is divided into a preoptic and an infundibular region divided by the chiasmatic ridge (Neary and Northcutt, 1983). The preoptic region consists of the anterior preoptic area and the magnocellular preoptic nucleus. This nucleus is part of the cholinergic basal forebrain and also contains neurons belonging to the lateral, vomeronasal amygdala (see below). Therefore, it should be considered part of the telencephalon (secondary prosencephalon *sensu* Puelles, 1996). The suprachiasmatic nucleus is separated from the anterior preoptic area by a cell-free zone and is situated below the anterior thalamus and above the optic chiasm. Laterally, the posterior entopeduncular nucleus is found. The infundibular hypothalamus consists of a periventricular dorsal, ventral, and lateral nucleus composed of scattered neurons. Between the ventral hypothalamus and the ventromedial thalamic nucleus, the small posterior tuberculum and the equally small nucleus of the periventricular

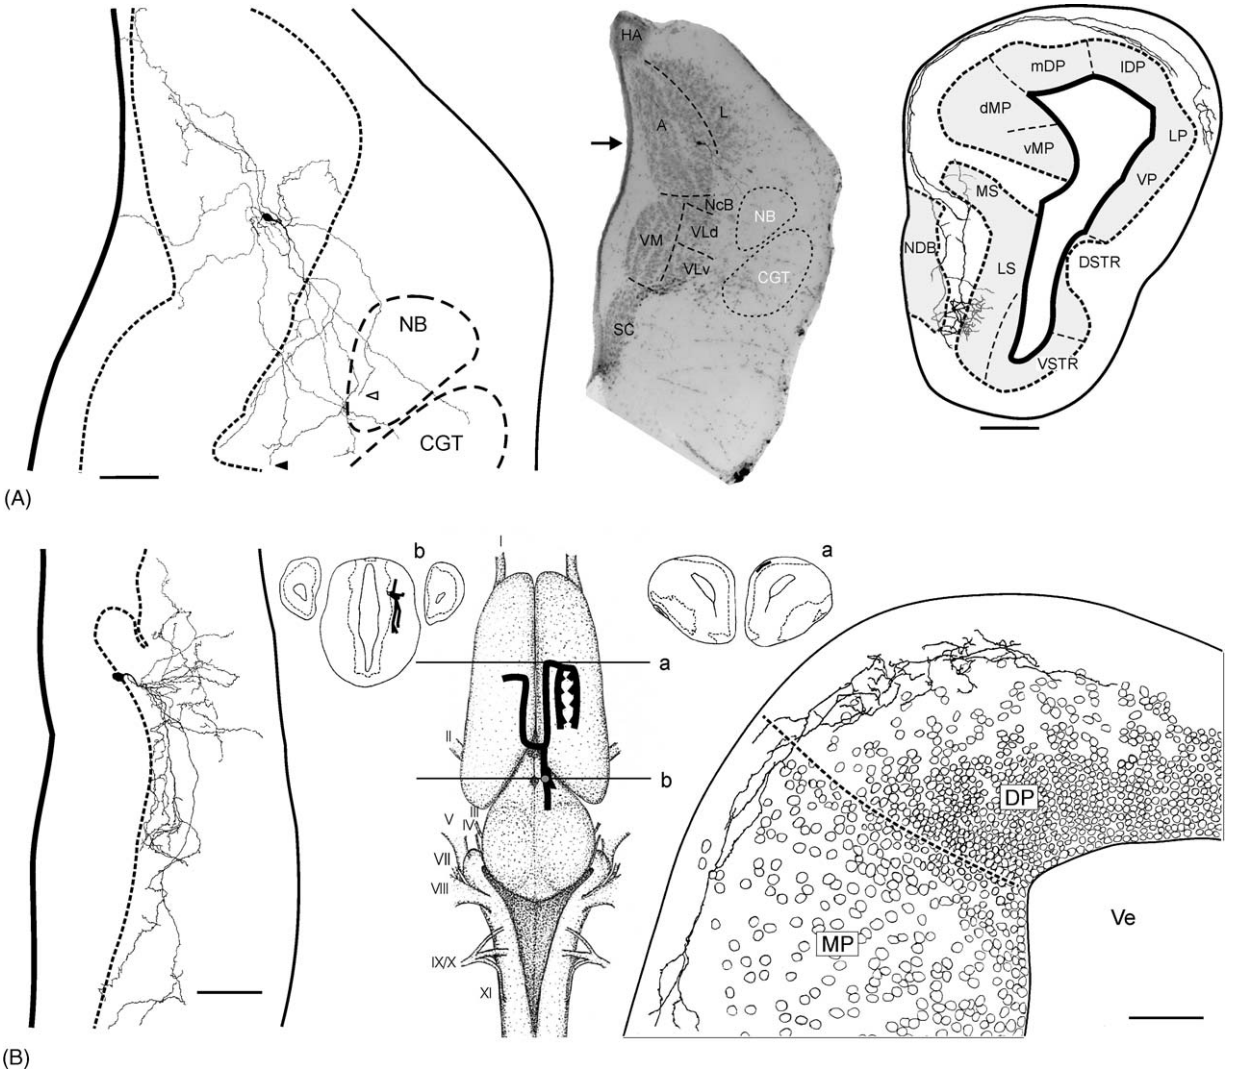

Figure 20 Camera lucida drawings of intracellularly labeled neurons in the anterior dorsal thalamus projecting to the medial and dorsal pallium of *Bombina orientalis* (A) and *Plethodon jordani* (B). In (A), middle, the site of the neuron is indicated by a black arrow; in (A), right, the course and terminal arborization of the axon in the septum, medial, dorsal, and lateral pallium is shown. In (B), middle, the site of the neuron (b) and the projection pattern of the neuron are indicated; in (B), right, the axon terminals in the medial and dorsal pallium at level (a) are shown. I–V, VII–XI, cranial nerves; NB, neuropil of Bellonci; CGT, corpus geniculatum thalamicum; A, anterior dorsal thalamic nucleus; HA, habenula; L, lateral dorsal thalamic nucleus; NcB, nucleus of Bellonci; VLd, dorsal portion of the ventrolateral nucleus; VLv, ventral portion of the ventrolateral nucleus; VM, ventromedial thalamic nucleus; SC, suprachiasmatic nucleus; NDB, nucleus of the diagonal band of Broca; LS, lateral septum; MS, medial septum; dMP, dorsal medial pallium; vMP, ventral medial pallium; mDP, medial dorsal pallium; lDP, lateral dorsal pallium; LP, lateral pallium; VP, ventral pallium; DSTR, dorsal striatum; VSTR, ventral striatum; Ve, ventricle; MP, medial pallium; DP, dorsal pallium. Scale bars in (A) left and (B) 100 μm, in (B) right 200 μm. Modified from Roth *et al.* (2003) and Roth and Grunwald (2000).

organ are found (Neary and Northcutt, 1983). The posterior tuberculum is considered to be homologous to the substantia nigra of mammals, because of the presence of dopaminergic neurons that show a distinct projection to the striatopallidal complex (Marín *et al.*, 1995).

The preoptic-hypothalamic region exhibits a pattern of wide connections, as revealed by biocytin tract tracing (Roth *et al.*, 2004) (Figure 23). The anterior preoptic area projects to the mediocentral amygdala, medial septum, nucleus of the diagonal band, suprachiasmatic nucleus, infundibular hypothalamus, ventral tegmentum, torus semicircularis, caudal tegmentum, and rostral medulla oblongata. Injection into the entire hypothalamus reveals projections to the periventricular zone of the central amygdala, ventral portion of the nucleus of the diagonal band,

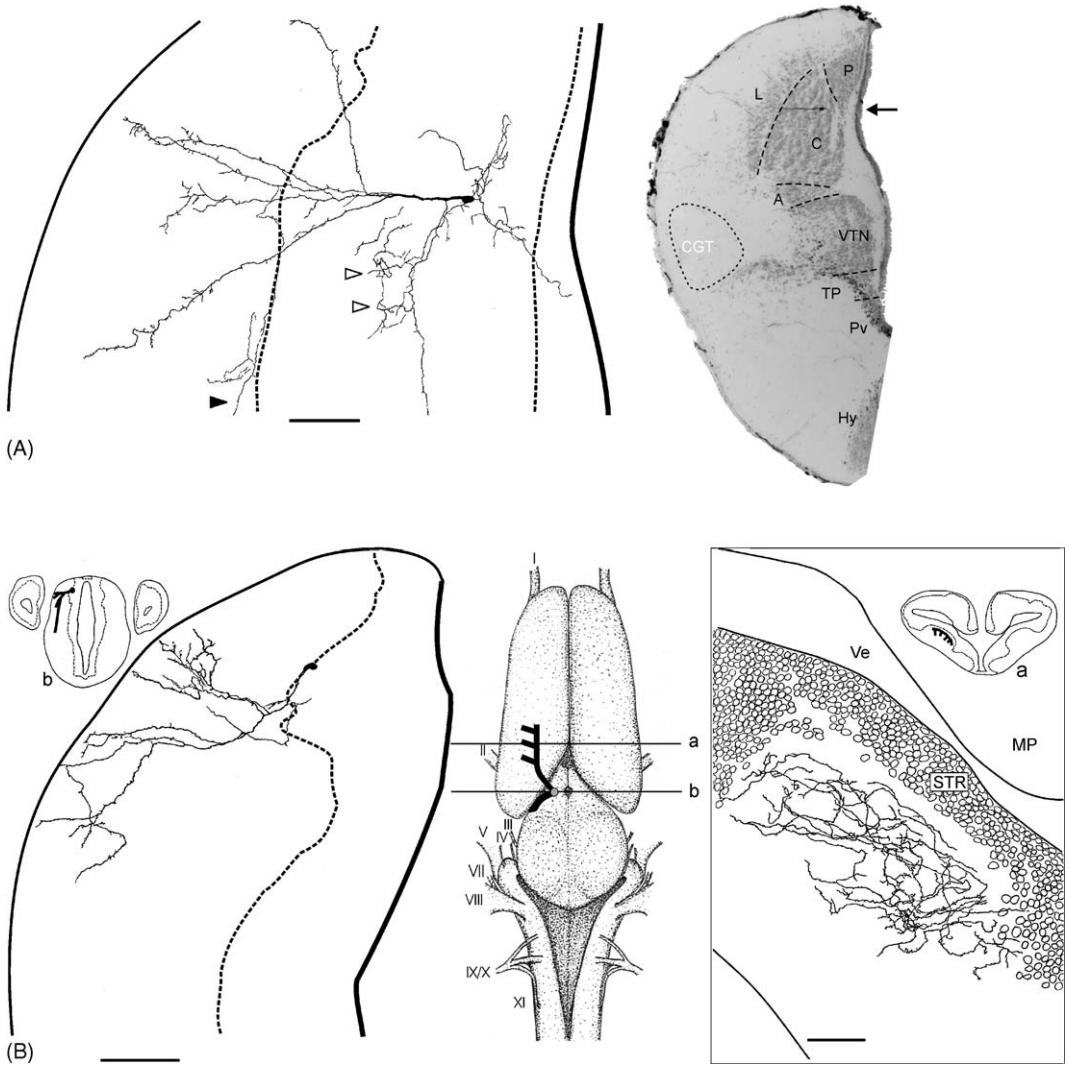

Figure 21 Camera lucida drawings of intracellularly labeled neurons in the central dorsal thalamus with ascending projections to the striatal neuropil in *Bombina orientalis* (A) and *Plethodon jordani* (B). Open arrowheads in (A) point to the ascending, black arrowhead to the descending axon. The site of the neuron is indicated by a black arrow in (A), right side. In (B), the site of the neuron is indicated by the left insert (b) and the projection pattern of the ascending axon in the middle with indications of the site of the striatal neuropil (a) and the neuron (a). Drawing in (B), right side, illustrates the terminal arborization of the axon inside the striatal neuropil at level a. I, II, III, IV, V, VII, VIII, IX, X, XI, cranial nerves; A, anterior dorsal thalamic nucleus; C, central dorsal thalamic nucleus; L, lateral dorsal thalamic nucleus; P, posterior dorsal thalamic nucleus; Pv, paraventricular organ; TP, posterior tubercle; CGT, corpus geniculatum thalamicum; Hy, hypothalamus; VTN, ventral thalamic nucleus; Ve, ventricle; STR, striatum; MP, medial pallium. Scale bars: 100 μm. Modified from Roth *et al.* (2003) and Roth and Grunwald (2000).

medial amygdala, the transition zone between medial pallium and dorsal septum, dorsal medial septum, nucleus accumbens, anterior preoptic area, and lateral (vomeronasal) amygdala; descending fibers run to the medulla oblongata and spinal cord. Injections of biocytin restricted to the dorsal hypothalamus reveals projections to the ventral pallidum, medial and central amygdala, ventral–lateral septum, caudal preoptic area, and suprachiatic nucleus.

Afferents to the anterior preoptic area originate in the nucleus of the solitary tract and the rostral medulla oblongata; the suprachiasmatic nucleus receives a sparse retinal input. The infundibular hypothalamus receives afferents from the ventral pallium, commissural medial pallium, medial and central amygdala, anterior preoptic area, suprachiasmatic nucleus, medial septum, nucleus of the diagonal band, lateral septum, lateral amygdala, magnocellular preoptic nucleus, dorsal and ventral thalamus, posterior tubercle, ventral tegmentum, torus semicircularis, locus coeruleus, and nucleus visceralis secundarius/parabrachial nucleus (Roth *et al.*, 2004).

Arrows indicate the onset of postsynaptic potentials. a, Inhibition in a dorsal thalamic neuron at long latency in *Bombina orientalis*. b, Same in *Plethodon jordani*. c, Short-latency response of a ventral thalamic neuron in *Bombina orientalis*. d, Same in *Plethodon jordani*. From Roth *et al.* (2003) and Roth and Grunwald (2000).

2.04.3.7 Telencephalon

The amphibian telencephalon, like that of all tetrapods, consists of pallial and subpallial regions (Figures 17a–17g). The pallium was traditionally divided into a medial, dorsal, and lateral pallium, but recent gene expression data led to a subdivision of the lateral pallium into a lateral and ventral pallium as different types of pallium (Puelles *et al.*, 2000; Puelles, 2001). Also, the rostral portion of the pallium appears to be a pallial region of its own. The subpallium includes a septal region below the medial pallium and a nucleus accumbens/ventral striatum situated in the rostral and central part of the ventromedial telencephalon, caudally tapering into a shell-like ventral pallidum situated below the septal region. The caudal ventral telencephalon of anurans is occupied medially and ventrally by the mediocentral amygdala and laterally by the lateral (vomeronasal) and cortical amygdala (Roth *et al.*, 2004). In salamanders, the mediocentral amygdala is situated more rostrally (Laberge and Roth, 2005). The striatopallidal complex is situated in the ventrolateral aspect of the telencephalon, bordered dorsally by the striatopallial transition area (SPTA).

2.04.3.7.1 Pallium

2.04.3.7.1.(i) Medial pallium The medial pallium of frogs and salamanders occupies the dorsomedial quadrant of the telencephalon and is characterized by extensive cell migration, which, however, does not

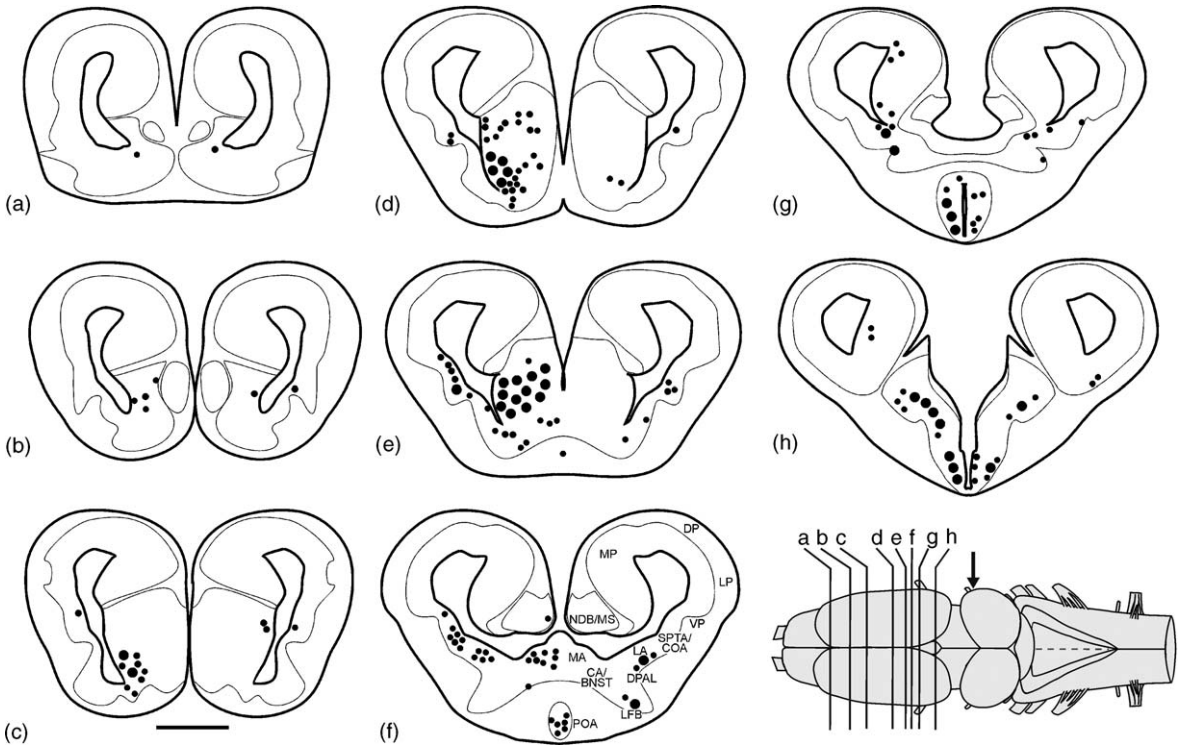

Figure 23 a–h, Schematic view of ipsilaterally labeled cell bodies after tracer application to the hypothalamus. Left, neurons retrogradely labeled after application of biocytin to the entire hypothalamus. Right, labeled neurons after application to the dorsal hypothalamus. Levels of sections and of tracer application (black arrow) are indicated in the inset. Large black dots represent 10 cell bodies, small black dots a single cell body. MP, medial pallium; LP, lateral pallium; VP, ventral pallium; DP, dorsal pallium; NDB, nucleus of the diagonal band of Broca; MS, medial septum; SPTA, striatopallial transition area; COA, cortical (olfactory) amygdala; LA, lateral (vomeronasal) amygdala; DPAL, dorsal pallidum; LFB, lateral forebrain bundle; BNST, bed nucleus of the stria terminalis; CA, central amygdala; MA, medial amygdala; POA, anterior preoptic area. Scale bar: 500 μm. Modified from Roth, G., Mühlenbrock-Lenter, S., Grunwald, W., and Laberge, F. 2004. Morphology and axonal projection pattern of neurons in the telencephalon of the fire-bellied toad *Bombina orientalis*. An anterograde, retrograde and intracellular biocytin labeling study. *J. Comp. Neurol.* 478, 35–61.

show any lamination. Ventrally, the medial pallium is confined by the zona limitans medialis – a cell-free zone separating the pallium from the septal region.

The dorsal border of the medial pallium of anurans is difficult to assess because of the gradual decline in cell migration toward the dorsal pallium. Consequently, some authors draw the border between medial and dorsal pallium more medially, i.e., at the level of the dorsomedial telencephalic sulcus (Hoffman, 1963; Northcutt, 1974; Scalia *et al.*, 1991) and others more laterally (Scalia, 1976; Northcutt and Kicliter, 1980; Neary, 1990; Northcutt and Ronan, 1992; Westhoff and Roth, 2002). After tracer application to the medial pallium, labeled neurons and fibers form a rather sharp border at the level of the dorsal sulcus (S. Mühlenbrock-Lenter, unpublished data). This would speak in favor of a more medial border between medial and dorsal pallium.

In the anuran medial pallium, authors distinguish either two subdivisions, i.e., a ventral small-celled part and a dorsal large-celled part (Röthig, 1912; Hoffman, 1963), or three subdivisions, i.e., a small-celled part, a large-celled part, and a transitional part (Neary, 1990). The medial pallium of salamanders has likewise been proposed to consist of two subdivisions, a ventral small-celled and a dorsal large-celled portion that might correspond to those observed in anurans (Herrick, 1933a; Northcutt and Kicliter, 1980; Neary, 1990).

Intratelencephalic afferents to the medial pallium originate in the dorsal and lateral pallium, mediocentral amygdala, nucleus accumbens, ventral pallidum and dorsal and central septal nuclei, the nucleus of the diagonal band, and the bed nucleus of the pallial commissure (Endepols *et al.*, 2005). Extra-telencephalic afferents come from the anterior dorsal thalamic nucleus, thalamic eminence, preoptic region, hypothalamus, periventricular organ, ventral tegmentum, locus coeruleus, raphe nucleus, and nucleus of the solitary tract (Roth *et al.*, 2004).

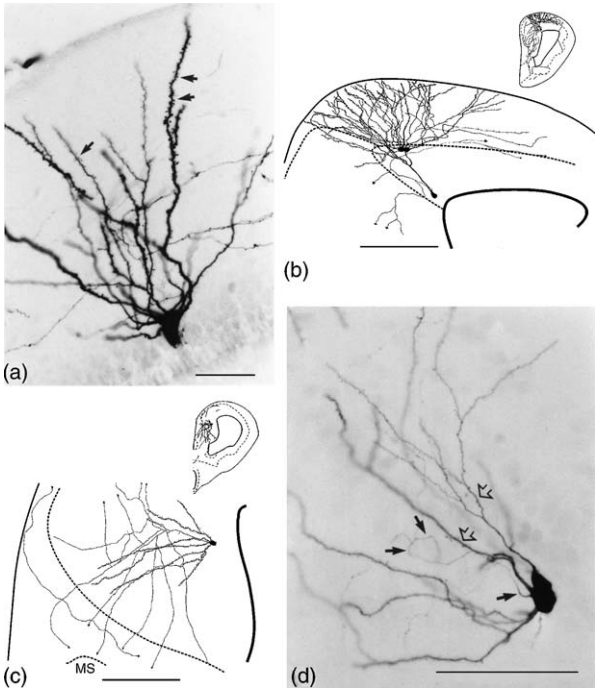

Figure 24 Microphotographs and reconstructions of intracellularly labeled neurons situated in the medial and dorsal pallium of *Discoglossus pictus* (a, c) and *Plethodon jordani* (b, d). a, Microphotograph of a cluster of two neurons situated in the dorsal pallium of *Discoglossus*; note that dendrites are heavily covered with spines (arrows). b, Camera lucida drawing of a cluster of neurons in the medial portion of the dorsal pallium (see inset) of *Plethodon*. c, Drawing of a type-1 neuron situated in the ventral half of the medial pallium of *Discoglossus* (see inset). d, Cluster of two neurons situated exactly at the border between medial and dorsal pallium, with one neuron in the medial and the other in the dorsal pallium. Dendrites of the dorsal pallial neuron are thinner than those of the medial pallial one (open arrows); filled arrows point to the primary axon of the medial pallial neuron. MS, medial septum. Scale bar: 50 μm in (a, d), 200 μm in (b, c). From Westhoff, G. and Roth, G. 2002. Morphology and projection pattern of medial and dorsal pallial neurons in the frog *Discoglossus pictus* and the salamander *Plethodon jordani*. *J. Comp. Neurol.* 445, 97–121.

Efferents of the medial pallium in the frogs *Discoglossus pictus* (Westhoff and Roth, 2002) and *Bombina orientalis* (G. Roth, unpublished data) have been studied by intracellular labeling (Figure 24). In *Discoglossus*, three types of medial pallial neurons were identified:

1. Neurons in the ventral medial pallium with bilateral projections to telencephalic areas including septum, amygdala, and striatum (weak), and diencephalic areas including the preoptic area, hypothalamus, anterior dorsal, and ventral thalamus (Figure 24c).
2. Neurons in the dorsal medial pallium with projections to the contralateral medial pallium and only ipsilateral projections to the dorsal and lateral pallium, septum, nucleus accumbens, amygdala, preoptic area, hypothalamus, anterior dorsal, and ventral thalamic nucleus.
3. Neurons at the border between medial and dorsal pallium with ipsilateral and contralateral projections to the medial and dorsal pallium, ipsilateral projections to the septum, and no extra-telencephalic projections.

In *Bombina*, of the neuron clusters labeled in the dorsal and intermediate medial pallium, all except one exhibited projections to the contralateral medial pallium and septum and ipsilateral projections to the dorsal pallium, septum, and nucleus accumbens. In addition, a substantial number of neurons projected to the dorsal portion of the ipsilateral lateral pallium. Two-thirds of them had extra-telencephalic to the suprachiasmatic nucleus, dorsal or ventral hypothalamus, and rostral tegmentum. Projections to the ventral pallium or to the dorsal portion of the striatopallidum originated only from neurons situated in rostral pallial regions. In contrast to the situation found in *Discoglossus*, neurons with and without extra-telencephalic projections showed no clear spatial separation. Of the 10 clusters labeled in the ventral-most part of the medial pallium, all projected to the dorsal septum and to the intermediate medial pallium, two to the dorsal medial and the medial part of the dorsal pallium, one to the nucleus accumbens, and four to the eminentia thalami. None projected to the contralateral side or to any extra-telencephalic target.

In the salamander, *Plethodon*, medial pallial neurons could be divided into a dorsal and a ventral group (Westhoff and Roth, 2002). Dorsal neurons project bilaterally to all telencephalic areas and to the preoptic area, ventral thalamus, and caudal hypothalamus. Ventral neurons project bilaterally to the medial pallium, medial septum, and nucleus accumbens, ipsilaterally to the dorsal pallium, and contralaterally to the anterior preoptic area and hypothalamus.

2.04.3.7.1.(ii) Dorsal pallium The delimitation of the amphibian dorsal pallium is likewise debated. While some authors denied the existence of a dorsal pallium in anurans (Kicliter and Ebbesson, 1976) or defined it as a narrow dorsal band between the medial and lateral pallium (Gaupp, 1899; Herrick, 1933b; Ariens Kappers *et al.*, 1936; Hoffman, 1963; Scalia *et al.*, 1991), other authors positioned the dorsal pallium (again as a relatively narrow band) more laterally, occupying the dorsal portion of the earlier lateral pallium (Northcutt, 1974; Northcutt and Kicliter, 1980; Northcutt and Ronan, 1992). Here, we adopt the above view that the border between medial and dorsal pallium is marked by the dorsomedial telencephalic sulcus and the border

between dorsal and lateral pallium by the rhinal sulcus.

The dorsal pallium consists of a periventricular cellular layer of densely packed somata and a number of migrated neurons which are substantial in number medially and decrease toward the lateral pallium. There is no sign of lamination.

Extra-telencephalic afferents to the dorsal pallium come from the anterior dorsal thalamic nucleus, hypothalamus, nucleus parabrachialis, and raphe nuclei (Roth *et al.*, 2003, 2004). Intra-telencephalic afferents originate mostly from the ipsi- and contralateral medial pallium and the ipsilateral lateral pallium, including the cellular prominence. Intracellular labeling experiments in the frogs, *Discoglossus* (Westhoff and Roth, 2002) and *Bombina* (G. Roth, unpublished data), reveal that dorsal pallial neurons in general lack extra-telencephalic and reveal only ipsilateral intra-telencephalic projections. They project ipsilaterally to the medial and lateral pallium and some of them also to the septal region, mostly to its dorsal part, as well as to the nucleus accumbens (Figure 3a).

In the salamander, *Plethodon* (Westhoff and Roth, 2002), neurons in the dorsal pallium are likewise defined by the absence of extra-telencephalic projections. Neurons in the medial part of the dorsal pallium project to the contralateral medial pallium and to the ipsilateral medial pallium, septum, nucleus accumbens, medial amygdala, and internal granular layer of the olfactory bulb (Figure 24b). Neurons in the lateral dorsal pallium have no contralateral projection; they project mainly to the ipsilateral medial pallium and about half of them to the ipsilateral septum. If we consider the medial portion of the dorsal pallium as representing the dorsal-most portion of the medial pallium, then the situation becomes similar in urodeles and anurans.

2.04.3.7.1.(iii) Lateral and ventral pallium
Traditionally, the lateral pallium has been divided into a dorsal and a lateral portion (cf. Kicliter and Ebbesson, 1976) divided by the rhinal sulcus and the lateral pallial cellular prominence. However, recent gene expression data demonstrate that these parts have to be considered different types of pallium called lateral and ventral pallium (cf. Puelles *et al.*, 2000; Puelles, 2001).

The lateral pallium receives essentially the same input as the dorsal pallium and some input from the ventral pallium as well. Intracellular labeling in *Bombina* (G. Roth, unpublished data) demonstrates that neurons in the precommissural lateral pallium are similar in morphology to those in the dorsal pallium and project to the dorsal and medial pallium and the dorsal septal region, often with extensive arborization, and a few axon collaterals extend to the ventral pallium. Neurons in the caudal, postcommissural portion of the lateral pallium likewise project to the dorsal and medial pallium, septum, and diagonal band of Broca. Neurons in the posterior part send axons rostrally at a subpial position inside the diagonal band of Broca, resembling the perforant path of mammals and terminating in the rostromedial pole of the telencephalon. In addition, neurons in the posterior part send dendrites and axons around the ventral caudal pole of the hemisphere accompanying the course of the lateral olfactory tract (olfactohabenular tract). This tract extends through the fiber layer of the lateral pallium close to the cellular prominence (and ventral to it); in the precommissural portion of the lateral pallium, it gives off only a few and in the postcommissural, caudal portion a substantial number of collaterals.

The ventral pallium is separated from the lateral pallium by the dorsolateral cellular prominence. The accessory (vomeronasal) olfactory tract runs through the periventricular cellular layer of the ventral pallium giving off numerous collaterals on its way to the vomeronasal amygdala. The ventral pallium terminates at the level of the pallial commissures where it merges with the vomeronasal amygdala. It receives intratelencephalic afferents from the dorsally adjacent lateral pallium, the caudal medial pallium, vomeronasal amygdala, nucleus accumbens, and striatopallidum. Extra-telencephalic afferents originate in the preoptic area, hypothalamus, anterior and central dorsal thalamus (weak), and the tegmental parabrachial nucleus (Moreno and González, 2004).

Intracellular labeling (Roth *et al.*, 2004, and unpublished data) reveals that neurons situated in the ventral pallium differ in morphology from those found in the lateral pallium in that they do not, or with only few dendrites, reach into the lateral pallium; rather, they extend their dendrites laterally or ventrolaterally (Figure 25). In most cases, ascending axons reach the accessory or main olfactory bulb; descending axons terminate in the neuropil of the vomeronasal and central amygdala, ventral pallidum, suprachiasmatic nucleus, and dorsal and ventral hypothalamus. Moreno and González (2004) consider the ventral portion of the ventral pallium (called SPTA by Marín *et al.*, 1998) a separate region, which they interpret as anterior amygdala (see below). However, there are no major differences in the morphology and projection pattern between the more dorsal portion of the ventral pallium and the SPTA (Roth *et al.*, 2004).

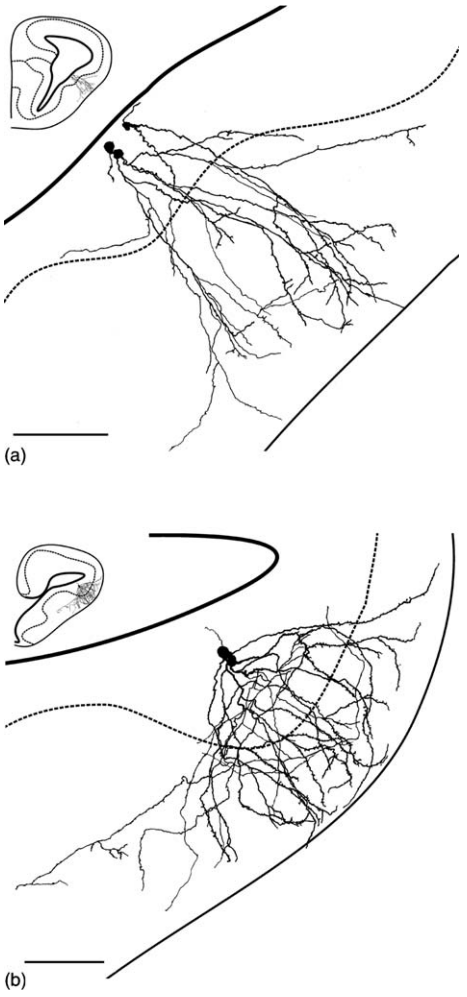

Figure 25 Reconstruction of an intracellularly labeled neuron situated in the ventral pallium/SPTA of *Bombina orientalis* (a) and *Plethodon shermani* (b). This type of neuron projects to the vomeronasal neuropil and the hypothalamus. Scale bar: 100 μm. From Roth *et al.* (2004) and Laberge and Roth (2005).

2.04.3.7.1.(iv) Rostral pallium Neurons situated in the rostral pole of the medial, dorsal, lateral, and ventral pallium receive the mass of dorsal thalamic afferents (see above) and differ in their projection pattern from neurons in more posterior regions in that all of them project to the main olfactory bulb and some of them to the SPTA and dorsal or dorsolateral edge of the dorsal striatal complex (G. Roth, unpublished data).

2.04.3.7.1.(v) Summary In summary, based on intracellular labeling, tract-tracing, and (immuno)-histochemical experiments, we can distinguish the following areas of the pallium of frogs and salamanders:

1. A medial pallium, which in many species is divided into a small-celled ventral and a large-celled dorsal portion. Neurons in this region, except those situated in the ventral part, generally have wide intra- and extra-telencephalic projections, the latter predominantly to the hypothalamus and ventral and dorsal thalamus. In frogs, ventral neurons, except those in the ventral-most part, exhibit mostly bilateral projections and dorsal neurons only ipsilateral extra-telencephalic projections. Most authors consider the dorsal portion of the medial pallium as homologous to the mammalian Ammon's horn and the ventral portion to the subiculum; a dentate gyrus seems to be missing.
2. A dorsal pallium separated from the medial pallium by the dorsal pallial sulcus. A dorsomedial portion (which could also be considered the dorsal portion of the medial pallium) contains neurons that have projections to the contralateral medial pallium via the anterior commissure and ipsilateral projections to the olfactory bulb to medial and ventral limbic centers and extra-telencephalic targets, mostly the preoptic region and hypothalamus; and a dorsolateral portion that contains neurons with projections confined to the ipsilateral dorsal septum, medial and lateral pallium, and are lacking extra-telencephalic projections.
3. A rostral-intermediate, or precommissural, lateral pallium, with neurons that project to the medial, dorsal, and ventral pallium and to the main olfactory bulb. The lateral olfactory tract runs through this region around the cellular prominence, but gives off only a few collaterals on its way to the caudal pallium.
4. A caudal, postcommissural, lateral pallium that receives massive input from the lateral olfactory tract and contains neurons that send their dendrites and axons along that tract (here the olfactohabenular tract) to the dorsal and medial pallium and to the entire septum.
5. A ventral pallium, including the SPTA containing neurons that project to the accessory olfactory bulb (AOB), the neuropil adjacent to the vomeronasal amygdala and preoptic region, striatopallidum, suprachiasmatic nucleus, and hypothalamus.
6. A rostral pallium occupying the rostral pole and projecting, unlike the medial, dorsal, and lateral pallium and like the ventral pallium, to the dorsal edge of the striatal complex.

The homologies and functions of the pallial regions mentioned are largely unclear. Most authors agree that the medial pallium is homologous to at least parts of the mammalian hippocampus,

i.e., Ammon's horn and subiculum, and that a dentate gyrus is lacking (for a more extended discussion see Westhoff and Roth, 2002). Extra- and intracellular recordings from neurons of the medial pallium in frogs including *B. orientalis* after stimulation of visual, somatosensory, and olfactory afferent pathways reveal only multimodal response properties (Supin and Guselnikov, 1965; Karamian *et al.*, 1966; F. Laberge and G. Roth, unpublished data). A few studies suggest that the medial pallium is involved in learning and memory formation (Finkenstädt and Ewert, 1988; Wenz and Himstedt, 1990; Papini *et al.*, 1995; Ewert *et al.*, 2001).

The function of the dorsal pallium is unclear. It receives essentially the same sensory and associative afferents as the medial pallium, but lacks extra-telencephalic and, with the exception of the dorsal septum, extra-pallial efferents. The response properties of neurons in the medial portion of the dorsal pallium are indistinguishable from those of the adjacent medial pallial neurons, which means that unimodal sensory areas are lacking. Thus, the dorsal pallium appears to have integrative-associative and limbic but no primary sensory functions.

The lateral pallium in the traditional sense (i.e., including the ventral pallium) is generally considered an olfactory pallium and homologous to the mammalian piriform cortex. However, although the zone around the cellular prominence dividing the lateral and ventral pallium receives collaterals from the lateral olfactory tract (originating in the main olfactory bulb), these collaterals are substantial only in the caudal, postcommissural portion. Thus, at least the caudal portion of the lateral pallium has to be considered olfactory pallium, while the function of the rostral and intermediate (precommissural) portion remains unclear.

The ventral pallium includes, together with the SPTA, the zone between the lateral pallium and the striatopallidal complex stretching from the olfactory bulb to the level of the telencephalic commissures, where it merges with the olfactory and lateral, vomeronasal amygdala. The ventral pallium is crossed by the accessory olfactory tract originating in the accessory olfactory or vomeronasal bulb; this tract gives off numerous collaterals on its way to the vomeronasal amygdala, where it forms a dense terminal neuropil. Thus, it is safe to consider the ventral pallium representing the vomeronasal pallium homologous to the mammalian posteromedial cortical amygdala (of pallial origin). Detailed functional studies are lacking.

2.04.3.8 Subpallium

2.04.3.8.1 Striatopallidal complex The dorsal striatum occupies the ventrolateral wall of the telencephalic hemisphere (cf. Figures 17a–17d). It is distinguishable from the ventral pallium/SPTA by neurons that extend their dendritic trees into the striatal neuropil (Roth *et al.*, 2003). The majority of the intracellularly labeled neurons are covered with spines and resemble the medium-spiny neurons of the mammalian caudate-putamen (cf., Heimer *et al.*, 1995) (Figure 26).

The dorsal striatopallidal complex receives afferents from a wide variety of brain regions including the medial pallium, ventral pallium-SPTA, vomeronasal amygdala, a number of mesencephalic and rhombencephalic nuclei, including the raphe nucleus, locus coeruleus, parabrachial nucleus, and the nucleus of the solitary tract, the hypothalamic-preoptic area, and the central dorsal and ventromedial thalamic nuclei (Marín *et al.*, 1997d). Efferents reach the medial and lateral amygdala, dorsal (sparse) and ventral thalamic nuclei, posterior tubercle, pretectum, tectum mesencephali, torus semicircularis, mesencephalic, and rhombencephalic reticular nuclei and the caudal brainstem (Marín *et al.*, 1997a). Endepols *et al.* (2004) as well as Roth *et al.* (2004) demonstrated that neurons with descending projections to the caudal tegmentum and rostral medulla oblongata are mostly found in the intermediate and caudal portion of the striatopallidal complex, and that more rostrally situated neurons project to the caudal portion of that complex (Figure 27). No projections to the medial or dorsal pallium are found.

The striatopallidum of amphibians and of tetrapod vertebrates in general (Reiner *et al.*, 1998) is characterized by the presence and co-localization of certain transmitters and neuropeptides such as glutamate, GABA, acetylcholine, dopamine, substance P, dynorphin, and enkephalin. GABAergic neurons are densely packed close to the ventricle, whereas cholinergic neurons typical of the amniote striatum are absent (Marín *et al.*, 1998; Mühlenbrock-Lenter *et al.*, 2005), but scattered ACh neurons are found in the dorsal pallidum (Marín *et al.*, 1998; Mühlenbrock-Lenter *et al.*, 2005). Thyroxin-hydroxylase-immunoreactive fibers indicating the presence of dopamine or noradrenaline are found in high concentrations in the cellular layer of the striatopallidum. Enkephalin-ir cell bodies are found in the rostral striatopallidum, i.e., the striatum proper. The striatal neuropil exhibits the highest density of Met+Leu-enkephalin-ir fibers, but many immunoreactive axons are found among cell bodies.

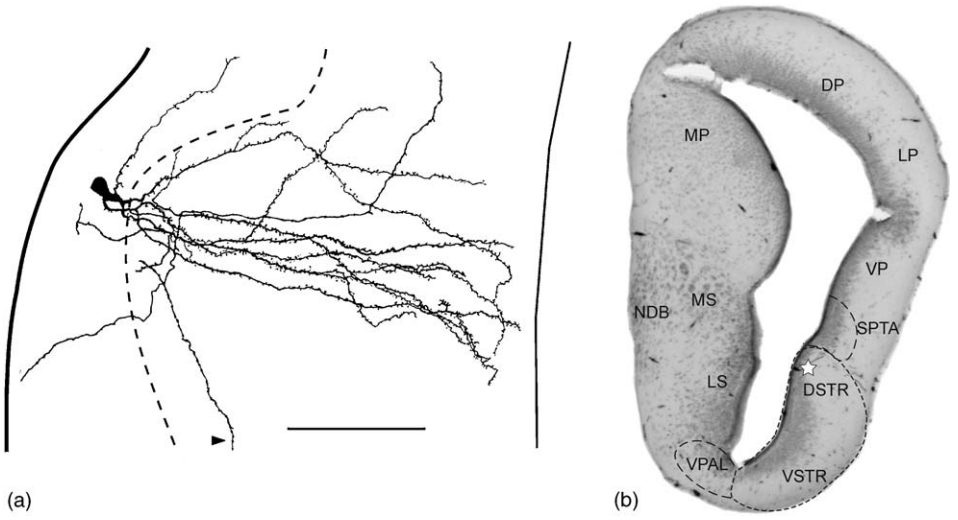

Figure 26 Reconstruction of an intracellularly labeled neuron situated in the striatopallidal complex of *Bombina orientalis*. Dendrites are heavily covered with spines. The site of the neuron is indicated by a white star in (b). This type of neuron has descending projection to the medulla oblongata. Dorsal striatopallidal system in anurans. *J. Comp. Neurol.* 468, 299–310.

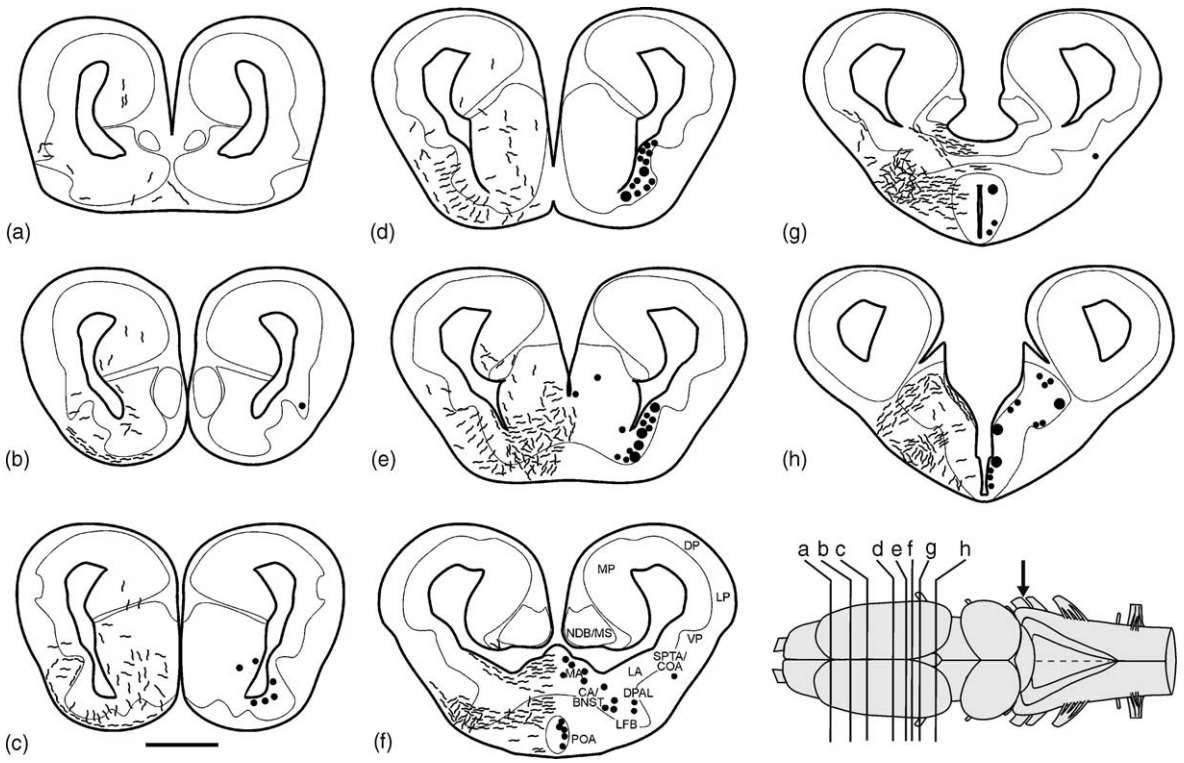

Figure 28 a–h, Schematic view of anterogradely labeled fibers (left hemisphere) and retrogradely labeled cell bodies (right hemisphere) in the telencephalon of *Bombina orientalis* after tracer application to the rostral medulla oblongata. Levels of sections and site of tracer application (black arrow) are indicated in the inset. Large black dots represent ten cell bodies, small black dots a single cell body. MP, medial pallium; LP, lateral pallium; VP, ventral pallium; DP, dorsal pallium; NDB, nucleus of the diagonal band of Broca; MS, medial septum; SPTA, striatopallial transition area; COA, cortical (olfactory) amygdala; LA, lateral (vomeronasal) amygdala; DPAL, dorsal pallidum; LFB, lateral forebrain bundle; BNST, bed nucleus of the stria terminalis; CA, central amygdala; MA, medial amygdala; POA, anterior preoptic area. Scale bar: 500 μm. Modified from Roth, G., Mühlenbrock-Lenter, S., Grunwald, W., and Laberge, F. 2004. Morphology and axonal projection pattern of neurons in the telencephalon of the fire-bellied toad *Bombina orientalis*. An anterograde, retrograde and intracellular biocytin labeling study. *J. Comp. Neurol.* 478, 35–61.

In contrast, Leu-enkephalin-ir fibers are sparse in the striatum proper. Its concentration increases along the rostrocaudal extent of the striatopallidum, with a maximum in the dorsal pallidum. Substance-P neurons are labeled in the rostral part of the striatal complex (Marín *et al.*, 1998; Endepols *et al.*, 2004; Mühlenbrock-Lenter *et al.*, 2005).

These immunohistochemical findings, together with the projection pattern of striatopallidal neurons mentioned, corroborates the view of Endepols *et al.* (2004) that the rostral portion of the dorsal striatopallidal complex can be regarded as dorsal striatum proper and the caudal portion as the dorsal pallidum, with a transition zone in between (Figure 28).In mammals, the striatum consists of functional compartments (striosomes and matrix) which differ in input and output as well as in immunohistological staining patterns (Graybiel and Ragsdale, 1978, 1983; Heimer *et al.*, 1995). Such compartments are absent in amphibians, but neurons and fibers of different immunoreactivity are arranged in layers (Mühlenbrock-Lenter *et al.*, 2005).

2.04.3.8.2 Ventral striatopallidal complex: nucleus accumbens/ventral striatum and ventral pallidum The ventral striatum *sensu* Northcutt and Kicliter (1980), i.e., the area ventrally adjacent to the dorsal striatopallidal complex (cf. Figures 17a–17d), most probably is not homologous to the ventral striatum of mammals. There is no difference in immunohistochemistry and the projection pattern between the dorsal and ventral parts of the dorsal striatopallidal complex (Mühlenbrock-Lenter *et al.*, 2005) and neurons in the two regions exhibit the same morphology and projection pattern (Roth *et al.*, 2004). Instead, the amphibian nucleus accumbens/ventral striatum is found in the medial rostral ventral telencephalon and extends caudally to what is now considered the ventral pallidum, which is confined to the superficial layer

surrounding the rostral central amygdala–BNST complex (BNST, bed nucleus of the stria terminalis) (Marín *et al.*, 1997a, 1997d, 1998; Roth *et al.*, 2004).

The nucleus accumbens receives afferents from the olfactory bulb, medial pallium, SPTA, medial amygdala, preoptic area and hypothalamus, dorsal and ventral thalamus, and posterior tubercle, i.e., from the same mesencephalic and rhombencephalic reticular nuclei that project to the striatopallidum, and from the anterior dorsal thalamic nucleus. Efferents run to the medial amygdala, preoptic area and hypothalamus, posterior tubercle, and to reticular brainstem nuclei (Marín *et al.*, 1997a, 1997d, 1998; Roth *et al.*, 2004).

In the ventral pallidum of anurans, as in other vertebrate species, a substantial number of numerous cholinergic neurons are found. Also, the nucleus accumbens/ventral striatum and the ventral pallidum are richly supplied by noradrenergic/dopaminergic fibers as well as by fibers containing substance P. In addition, somatostatin-ir fibers are found in the entire complex, and a strong enkephalinergic innervation exists in the rostral nucleus accumbens (Mühlenbrock-Lenter *et al.*, 2005). Nucleus accumbens/ventral striatum and ventral pallidum are closely interconnected (Marín *et al.*, 1997d; Roth *et al.*, 2004), but reveal only weak connections to the dorsal striatopallidum in the ventrolateral telencephalic wall – a situation similar to that found in mammals.

2.04.3.8.3 Septal region The amphibian septal region occupies the medial aspect of the telencephalon ventral to the medial pallium and dorsal to the nucleus accumbens/ventral striatum, ventral pallidum, and medial amygdala. Traditionally, the amphibian septal region is divided into a dorsally situated medial septum, a lateral septum bordering the ventricle and a nucleus of the diagonal band of Broca situated along the ventromedial surface of the telencephalic hemisphere (Ariens Kappers *et al.*, 1936; Kicliter and Ebbesson, 1976). Scalia (1976) distinguished a dorsal septum as a separate region. Additionally, the postolfactory eminence and the bed nucleus of the pallial commissure were thought to belong to the septum (Northcutt and Kicliter, 1980). More recent tracing studies distinguish (1) a medial complex consisting of a dorsally situated medial nucleus and a ventrally situated nucleus of the diagonal band of Broca, (2) a lateral complex consisting of a dorsolateral and a ventrolateral nucleus, and (3) a central complex consisting of a dorsal and a central nucleus. The postolfactory eminence, the bed nucleus of the pallial commissure, and the ventral portion of the septum are now excluded from the septal region (Endepols *et al.*, 2005; Roden *et al.*, 2005).

These two studies demonstrate that the central and medial septal nucleus receive direct input from the olfactory bulb, amygdala, and nucleus accumbens, whereas input from these regions to the lateral septal nucleus is less abundant or absent. The medial pallium projects to all septal nuclei, as does the anterior dorsal thalamic nucleus. The ventromedial thalamic nucleus/zona incerta of the ventral thalamus projects to the medial and lateral septal nucleus carrying visual, auditory, vestibular, and somatosensory information. The anterior preoptic, suprachiasmatic, and hypothalamic nuclei project to the central and lateral septal nucleus, and only the central septal nucleus receives input from the brainstem, particularly from the raphe nucleus (Roden *et al.*, 2005). All septal nuclei project to the medial pallium, the lateral and central nuclei, and to a lesser degree the medial nucleus projects to the olfactory nuclei, amygdala, nucleus accumbens, and hypothalamus, and the lateral septal nucleus also projects to sensory areas in the diencephalon and midbrain. Studies by Gonzalez and Lopez (2002) demonstrated that a cholinergic projection of the septum to the medial pallium is present in anurans, which the authors interpret as a forerunner of the mammalian cholinergic septohippocampal pathway. It appears that the amphibian septal region has essentially the same structural organization as the mammalian septum, but functional studies are lacking.

2.04.3.8.4 Amygdaloid complex The ventromedial, ventral, and ventrolateral part of the caudal telencephalon is occupied by the amygdaloid complex (cf. Figures 17c–17g, 22, and 27). Northcutt and Kicliter (1980), in their classical paper on the organization of the amphibian telencephalon, distinguished a medial amygdala caudal to the nucleus accumbens and ventral to the lateral septal nucleus, and a lateral amygdala starting rostrally as a lateral cellular prominence between lateral pallium and striatum, caudalward curving around the dorsal striatum in a C-shaped manner and eventually fusing with the anterior preoptic nucleus. The existence of a central amygdala, a BNST, and a dorsal and ventral pallidum was not discussed by the authors.

A new classification of the amygdaloid complex in anuran amphibians was presented recently by Marín and co-workers on the basis of histochemical and immunohistochemical data in the frog *Rana perezi* (Marín *et al.*, 1998). In their opinion, the lateral amygdala occupies the dorsal portion of the ventral pallium situated above an anterior amygdala that occupies the ventral portion of the ventral pallium, previously called SPTA (see above). More caudally, the ventral part of the ventral striatum *sensu*

Northcutt and Kicliter is considered by Marín *et al.* (1998) the dorsal and ventral pallidum and the lateral part of that complex the central amygdala. The medial amygdala now occupies part of the lateral amygdala *sensu* Northcutt and Kicliter, but rostralward curves around the striatum and joins the lateral and the anterior amygdala in the above sense. The medial amygdala *sensu* Northcutt and Kicliter, plus the ventral lateral septum, now becomes the BNST plus the ventral pallidum. Thus, compared to Northcutt and Kicliter, the entire amygdaloid complex is shifted laterally and dorsally in Marín *et al.* (1998).

In order to clarify this situation regarding the components of the amphibian amygdaloid complex and its possible homologies with that of mammals, it is useful to use a functional approach (Swanson and Petrovich, 1998) and look for four different functional parts:

1. A part receiving direct input from the main olfactory bulb (cortical amygdala of mammals).
2. A part receiving direct input from the accessory or vomeronasal olfactory bulb and projecting primarily to the hypothalamus (posteromedial cortical and medial amygdala of mammals).
3. A part with reciprocal connections with visceral-autonomic centers in the mesencephalic tegmentum, brainstem, and spinal cord (central amygdala-BNST of mammals).
4. A part with close connections to the pallium/cortex (basolateral amygdala of mammals).

The vomeronasal amygdala can be identified in the amphibian brain by its massive input from the AOB via the accessory olfactory tract that forms a distinct terminal neuropil in the caudolateral part of the telencephalon and by its projection to the preoptic area and hypothalamus via the ipsilateral stria terminalis (cf. Figure 23) and to the contralateral vomeronasal amygdala via the anterior commissure (commissural portion of the stria terminalis). Neurons in the telencephalon of both frogs and salamanders that exhibit these characteristics form a band of neurons continuous with the SPTA. This band covers the area called lateral amygdala by Northcutt and Kicliter (1980) and then stretches to the magnocellular nucleus of the periventricular preoptic area (Roth *et al.*, 2004; Laberge and Roth, 2005). Neurons in the vomeronasal amygdala extend most of their dendrites into the terminal neuropil of the accessory olfactory tract (Figure 29)

Based on its connections to olfactory structures and to the hypothalamus (Neary, 1990; Bruce and Neary, 1995; Roth *et al.*, 2004; Laberge and Roth, 2005), the region in the ventral part of the caudal pallium dorsolateral to the vomeronasal amygdala can be considered the main olfactory amygdala (Figure 30).

The extended central amygdala (i.e., central amygdala plus BNST) can be identified by reciprocal connections with visceral-autonomic brain centers, e.g., preoptic area, hypothalamus, posterior tubercle, periaqueductal gray, parabrachial nucleus, nucleus of the solitary tract, and DCN (Saper, 1995; Alheid *et al.*, 1995; Pitkänen, 2000). In *Bombina*, neurons fulfilling these criteria occupy the caudal ventral telencephalon around the ventricle medial to the caudal pole of the striatopallidum (Roth *et al.*, 2004) (Figure 23). In *Plethodon*, this visceral-autonomic amygdala is situated more rostrally, extending ventral to the striatopallidum (Laberge and Roth, 2005). Neurons in this zone distinctly differ in the morphology of their dendrites from those belonging to the striatopallidal complex (Roth *et al.*, 2004; Laberge and Roth, 2005). Many of them have a peculiar morphology in that one part of the dendritic tree is directed dorsally toward the ventricle and another one in the opposite, ventral direction (Figure 31).

It is disputed whether amphibians possess an amygdaloid complex homologous to the mammalian basolateral amygdala and it is assumed to be of pallial origin. As mentioned above, Moreno and González (2004, 2006), based on tracing experiments, recently proposed that the ventral pallium above the SPTA (which is believed by the authors to represent the anterior amygdala) is homologous to the mammalian basolateral amygdala.

2.04.4 Phylogenetic and Evolutionary Considerations

2.04.4.1 The Nervous System of Amphibians: Primitive or Simplified?

Traditionally, brains are viewed as having increased continuously in functional and morphological complexity during vertebrate evolution (Ariens-Kappers *et al.*, 1936; Romer, 1970; Kuhlenbeck, 1977; Bauchot, 1978; Ebbesson, 1980, 1984). This unilinear view of evolutionary progress has now been replaced by the concept that vertebrates have evolved independently in a radiative manner (cf. Northcutt, 1985; Nieuwenhuys *et al.*, 1998). Thus, it is no longer appropriate to speak of primitive and advanced organisms, arranged along a ladder of increasing complexity. One refers instead to primitive (plesiomorphic) and derived (apomorphic) traits of a taxon and to the shared derived states (synapomorphies) that can be used to infer patterns of genealogical relationship (Hennig, 1966). Nevertheless, it is still widely accepted that within vertebrate classes more recent taxa (teleosts vs.

chondrosteans, mammals and birds vs. reptiles and amphibians) possess relatively more complex brains.

In this context, the evolutionary status of the brains of amphibians has always created difficulties. The brains of frogs, and especially of caecilians (Kuhlenbeck, 1922) and salamanders (Herrick, 1948; Leghissa, 1962), appear to be simpler than those of chondrichthyans and osteichthyans, and even of cyclostomes in some respects. Despite an awareness that amphibians are tetrapods and thus not phylogenetically basal, their brains were viewed by leading comparative neuroanatomists as exemplifying the ancestral state of the vertebrate brain (Leghissa, 1962). However, Herrick (1948) suspected that the seemingly simple brains and sense organs of amphibians as well as many of their bodily characteristics had derived from a more complex ancestral state. This includes the reduction or loss

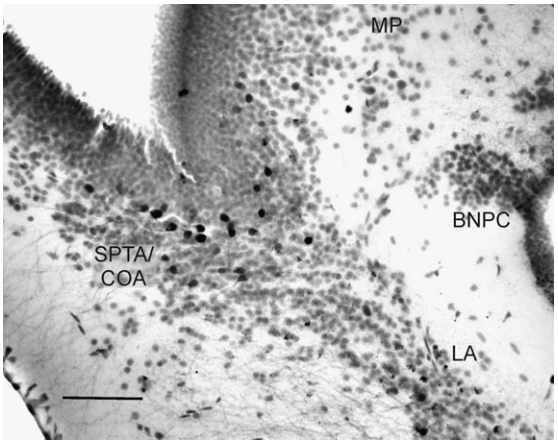

Figure 30 Microphotograph of a transverse section through the caudal telencephalon of *Bombina orientalis* showing retrogradely labeled neurons of the cortical (olfactory) amygdala after tracer application to the hypothalamus. For the level of section see Figure 28g. of ossification, limbs, a free-living larval stage, reduction of the inner ear, the electroreceptive, lateral line, and auditory system in a number of frogs, many salamanders, and caecilians. At the same time, among frogs, salamanders, and caecilians, derived traits can be found.

Today, it is widely accepted that lissamphibians have undergone secondary simplification and that secondary simplification arises from 'pedomorphosis', a form of heterochronic evolution in which traits that characterize larvae or juveniles of ancestral taxa are maintained in the adult stage of descendant taxa (cf. Gould, 1977). Pedomorphosis commonly involves different degrees of retardation, reduction, or absence of traits in otherwise fully developed organisms, as compared with phylogenetic outgroups. Thus, a mosaic of fully adult traits, weakly expressed traits, and missing characters appears in terminal ontogenetic stages. Accordingly, amphibian brains are expected to have fewer cells, a lower degree of morphological differentiation of cells, and reduced migration, but retain the plesiomorphic structural, functional, and developmental organization found among other vertebrates. However, this process has affected the three amphibian orders differently: anurans appear to be least and salamanders most pedomorphic, while caecilians exhibit an intermediate

Neurol.* 478, 35–61.

degree of pedomorphosis (Roth *et al.*, 1993). A similar situation is found in lungfishes, which as a group appear likewise to be pedomorphic; here, the Australian lungfish *Neoceratodus* is less pedomorphic and the lepidosirenid lungfishes profoundly pedomorphic (Northcutt, 1987; Roth *et al.*, 1993).

Among salamanders, the family Plethodontidae is the most specious one (comprising two-thirds of all salamanders in the world), and here the tribe Bolitoglossini (comprising half of salamander species in the world) exhibits many uniquely derived characteristics and has undergone a spectacular radiation in the Neotropics (Wake, 1966, 1987; Wake and Lynch, 1976). Bolitoglossines have developed a spectacular feeding mechanism, i.e., a projectile tongue, which is accompanied by the evolution of specialized characters of the visual system, e.g., in the context of depth perception (overview in Roth, 1987). At the same time, the brain, including the visual system, of plethodontid salamanders and bolitoglossines in particular has the simplest morphology. This includes a greatly reduced auditory system and nonexistent lateral-line system, a small number of large neurons in the sense organs and brain, a small proportion of myelinated fibers in the optic nerve, and a very low degree of cell migration throughout the brain and particularly in the tectum, consisting essentially of a periventricular cellular layer and a superficial fiber layer (Roth, 1987).

A phylogenetic analysis by Roth *et al.* (1993) based on 23 characteristics of the brain and sense organs of all groups of vertebrates came to the conclusion that 19 characters found in the salamander brains and sense organs, including the small number of types of RGCs, the low degree of myelinated fibers and the low degree of cell migration in the tectum, diencephalon, cerebellum, torus semicircularis, medulla oblongata, and spinal cord are most parsimoniously interpreted as secondarily simplified, while only one character appeared to be primitively simple (i.e., cell migration in the medial pallium) and in two cases (i.e., a low number of types of RGCs and a low degree of myelination of the nerve) the question of primitive versus simplified could not be decided. Of all salamander taxa, the Bolitoglossini, believed to be the most derived group, exhibit the most simplified brain and sense organs.

Reductions of brain and sense organs also appear to have occurred within gymnophionans and anurans. As a group, caecilians show reduction in 15 of 23 neuronal characters (Roth *et al.*, 1993). For example, whereas the so-called primitive caecilian *Epicrionops* possesses a multilaminated tectum, tectal lamination is greatly reduced in the derived taxon *Typhlonectes* (Himstedt and Manteuffel, 1985). Most frogs exhibit a multilaminated tectum, but in *B. orientalis* and the Australian frog, *Arenophryne rotunda*, both believed to be pedomorphic species, tectal lamination is substantially reduced (Roth *et al.*, 1994).

The hypothesis presented two decades ago by Roth and Wake (1985b) and now widely accepted is that secondary simplification in the salamander nervous system is related to enlarged genome and cell size (for a recent discussion, see Roth and Wake, 2000; Gregory, 2002a, 2002b). Genome size varies enormously among vertebrates. The smallest genome is found in teleost fishes, with less than 1 pg DNA per haploid nucleus. Some salamanders and all lungfishes have haploid genome sizes between 70 and 90 pg, which are the largest genomes found in any animals (Olmo, 1983). In salamanders, the smallest genome (13.7 pg) is found in the plethodontid *Desmognathus wrighti* (Hally *et al.*, 1986; Sessions and Larson, 1987) and the largest (83 pg) in the neotenic (perennibranchiate) *Necturus maculosus* (Olmo, 1983). The plethodontid salamander *H. italicus* (77 pg) has the largest genome of any terrestrial animal, although several tropical bolitoglossine plethodontids (e.g., *B. subpalmata*, 64 pg) approach this value (Sessions and Larson, 1987). Species of the Bolitoglossini, on average, have larger genome sizes than other plethodontids and than other salamander families, except for the perennibranchiate species (Olmo, 1983; Sessions and Larson, 1987). Caecilians also have relatively large genomes, but the largest known caecilian genome (13.9 pg per haploid nucleus) is equal to the smallest found in salamanders. Among anurans, the mean genome size reported by Olmo (1983) is 3.3 pg. The smallest (approximately 1 pg) is found in *Limnodynastes ornatus*, and the largest is found in *Arenophryne* (19 pg).

There is no universal agreement on the origin and significance of increased genome size in vertebrates (cf. Gregory, 2002a, 2002b). Apparently, genome size tends to increase until the tendency is halted by countervailing selection (Orgel and Crick, 1980). Among plethodontid salamanders, genome size appears to have increased many times independently, especially in the tribes Plethodontini and Bolitoglossini (Sessions and Larson, 1987). However, a phylogenetic analysis of the correlation between genome size and developmental rate concludes that several terrestrial plethodontid species have undergone a secondary reduction of genome size, which counteracts the general increase in genome size seen in terrestrial plethodontids. In the highly miniaturized *Thorius*, for example, the decrease is about 27% from the postulated ancestral bolitoglossine genome size of 34.5 pg (Sessions and Larson, 1987).

An increase in genome size has many important morphological consequences, including: (1) an

increase in cell size, (2) a decrease in cell metabolic rate, (3) a decrease in cell division rate, and (4) a decrease in cell differentiation rate (Sessions and Larson, 1987). Compared to other vertebrates, salamanders in general and bolitoglossines in particular have large to very large cells, very low metabolic rates (Feder, 1983), and slow to extremely slow developmental rates (Sessions and Larson, 1987). The ova of plethodontine and bolitoglossine salamanders are large to very large (up to 9 mm in diameter), and they develop very slowly; *Bolitoglossa* may take 10 or more months to hatch (Hanken, 1979; Houck, 1982; Collazo, 1988).

While in amphibians the correlation between genome and cell size on the one hand and metabolic rate on the other is significant only at certain temperatures (cf. Licht and Lowcock, 1991; Gregory, 2002a, 2002b), increased genome and cell size is significantly negatively correlated with anatomical complexity of the brain and sense organs. Species with small genomes have more and smaller nerve cells per volume of gray matter, their neurons are more differentiated morphologically, and the number of migrated nuclei and the degree of lamination (e.g., inside the tectum) is higher than in species with larger genomes (Roth *et al.*, 1988a, 1990, 1994). As a consequence, anurans – with genome and cell sizes much smaller than salamanders (see above) – generally have more differentiated brains than salamanders. Among anurans and salamanders, taxa with large genomes and cells such as *Bombina* and *Arenophryne* or bolitoglossine salamanders have simpler brains than those with smaller genomes, if we disregard miniaturized taxa (Roth *et al.*, 1994). (Miniaturization is a process that independently leads to secondary simplification; Roth *et al.*, 1990.) The same holds for lungfishes; here *Neoceratodus* has a much smaller genome size and a more complex brain anatomy than lepidosirenids (cf. Roth *et al.*, 1993).

An increase in genome and cell size leads to profound retardation of brain development, but not all developmental processes are retarded to the same degree. As a rule, processes appearing late in ontogeny are more affected than those appearing early. Accordingly, the cerebellum – a structure that develops very late – is deeply affected by retardation. In frogs, the cerebellum is small and simple, in nonbolitoglossine salamanders it is even simpler, and the simplest is found in bolitoglossines. The same holds true for the ontogenetically late cell migration processes in the spinal cord, brainstem, torus semicircularis, tectum, and thalamus as well as the formation of anatomically distinct nuclei all over the brain, which are increasingly retarded and even truncated in parallel to the increase in genome and cell size. However, the degree to which the morphology of the amphibian telencephalon is primitive or secondarily simplified remains undecided. This topic is discussed further below.

A phylogenetic comparison of the amphibian CNS with that of other vertebrates is hindered by several facts. It is generally assumed that modern amphibians are closest to the ancestors of all tetrapod vertebrates, but the sister group of tetrapods and that of amphibians is not precisely known. Most presumably, these are extinct members of sarcopterygians, and within this group forms that are most closely related to the extant dipnoans. However, the brains of the majority of lungfish species, i.e., the African *Protopterus* and the South American *Lepidosiren*, are most probably secondarily simplified (Northcutt, 1987).

One of the most interesting aspects is that secondary simplification of sense organs and brain regions at a morphological level has not, or at least not obviously, affected their functions. This is most apparent in the case of bolitoglossine salamanders, which, on the one hand, exhibit the simplest sense organs and brains at a gross morphological level, and on the other hand the most refined prey-catching apparatus and associated neuronal control system (Roth and Wake, 2000).

2.04.4.2 Comparative Aspects

Differences between amphibians and lungfishes on the one hand and amniotes on the other are minor with respect to the spinal cord, medulla oblongata, midbrain, and the preoptic-hypothalamic diencephalic region (see Evolution of the Nervous System in Fishes). Major differences between amphibians and amniotes are found with respect to (1) the thalamopallial system, (2) the visual system, (3) pallial regions, (4) striatopallidum, and (5) the amygdaloid complex.

2.04.4.2.1 The thalamopallial system In a series of seminal papers, Butler (1994a, 1994b, 1995) argued that the dorsal thalamus of all jawed vertebrates consists of two divisions, i.e., a collothalamic and a lemnothalamic one. The 'collothalamic' division is characterized by a pathway that originates predominantly from the midbrain (tectum mesencephali, colliculi superiores, and colliculi inferiores in mammals) and projects to dorsal thalamic nuclei such as the nucleus rotundus of reptiles and birds and the posterior dorsal thalamic and intralaminar nuclei of mammals, which in turn send projections to the striatum via the lateral forebrain bundle. The 'lemnothalamic' division is characterized by a pathway that includes predominantly sensory

(lemniscal) afferents and projects to dorsal thalamic nuclei such as the mammalian LGN and the lateral geniculate nucleus of reptiles, which in turn project to the medial and dorsal pallium/cortex via the medial forebrain bundle. One characteristic of the lemnothalamus is a direct sensory (mostly retinal) input to the dorsal thalamic nuclei. Butler (1995) argues that both divisions of the dorsal thalamus were elaborated to some degree during amniote evolution. While diapsid and anapsid amniotes mainly developed the collothalamus (with some further specialization of the lemnothalamus in birds), the evolution of the mammalian brain was characterized by an enormous evolution of the lemnothalamus.

Along this concept, Puelles and collaborators (Puelles *et al.*, 2000), based on a series of experiments in the developing chick, as well as Puelles (2001), developed the idea that the dorsal thalamus of tetrapods is organized in three tiers, i.e., a dorsal tier characterized by the lemnothalamic visual LGN (with direct retinal input), an intermediate tier characterized by collothalamic nuclei such as the nucleus rotundus of birds and reptiles and the intra- and paralaminar nuclei in mammals, and a ventral tier containing the auditory medial geniculate nucleus of mammals and the nucleus ovoidalis complex of birds. The dorsal tier receives direct retinal input and projects to the medial and dorsal pallium/cortex, the intermediate tier receives predominantly tectal/superior collicular input and projects to the striatum and ventral pallium (and its derivatives), and the ventral tier receives input from the torus semicircularis/inferior colliculus and projects to specific auditory regions inside the anterior dorsal ventricular ridge (aDVR) in reptiles and birds and to the auditory cortex in mammals.

The dorsal thalamus of amphibians contains a central nucleus, which in some respects resembles the collothalamus *sensu* Butler, the ventral tier and intermediate tier *sensu* Puelles, and an anterior nucleus resembling the lemnothalamus and the dorsal tier. However, there are major inconsistencies regarding its lemnothalamic nature. The anterior dorsal thalamic nucleus of amphibians projects in a lemnothalamic, or first tier, fashion to the medial and dorsal pallium, but it receives only indirect retinal input via ventral thalamus, tectum, and central dorsal thalamic nucleus. It also sends collaterals to the medial amygdala and lateral septum, which is atypical for a lemnothalamic pathway. It is, therefore, safe to conclude that in amphibians a lemnothalamus in a strict sense does not exist.

The central dorsal nucleus of amphibians projects to the caudal ventral pallium (sparsely) and striatum (massively); also, it receives a projection from the torus semicircularis. Therefore, this nucleus can be regarded as a combined collothalamic nucleus of the intermediate and ventral tier in the sense of Puelles and is probably homologous to the nucleus rotundus of reptiles and birds.

In turtles (Hall and Ebner, 1970; Hall *et al.*, 1977; Zhu *et al.*, 2005) and lizards (Desfilis *et al.*, 2002), three dorsal thalamic nuclei exist that project to pallial–cortical structures and constitute the thalamocortical system of these taxa:

1. the dorsomedial anterior nucleus, which projects to the small-celled medial cortex;
2. the dorsolateral anterior nucleus, which projects to the large-celled dorsal (ventral) medial cortex; and
3. the LGN, which is the main retinorecipient nucleus and projects to the dorsal cortex via the medial forebrain bundle and to the pallial thickening via the lateral forebrain bundle (Zhu *et al.*, 2005).

The dorsomedial and dorsolateral anterior nuclei are multimodal, including visual afferents, but apparently without direct retinal input (Pritz, 1995). The three nuclei mentioned surround the large nucleus rotundus, which does not receive direct retinal but rather visual afferents from the tectum and projects to the anterolateral portion of the dorsal ventricular ridge, but not to the cortex.

It is still controversial whether the cortical areas mentioned project back to the dorsal thalamic nuclei from which they receive afferents (for a discussion see Zhu *et al.*, 2005), as is the case in mammals. The small-celled medial and the large-celled dorsomedial cortices are considered to be homologous to the mammalian hippocampus (possibly Ammon's horn region and dentate gyrus or subiculum), whereas the dorsal cortex is considered homologous to the mammalian isocortex. Auditory information from the torus semicircularis is relayed to the nucleus reuniens, and this nucleus projects to the ventral aDVR, but not to the cortex.

While the projection of the LGN to the dorsal cortex most probably represents a lemnothalamic pathway and the projection of the nucleus rotundus to the anterior dorsal ventricular ridge certainly a collothalamic pathway *sensu* Butler (1994b), it is unclear what kind of pathway originates from the dorsomedial and dorsolateral nucleus (Zhu *et al.*, 2005). Given that in reptiles these two nuclei apparently do not receive direct retinal input, they can only be considered to carry multimodal and limbic information and are not lemnothalamic in a strict sense, but closely resemble the anterior dorsal thalamic nucleus of amphibians.

2.04.4.2.2 Pallium The pallium of amphibians is unlaminated, despite extensive cell migration in the medial and to a lesser degree in the dorsal and lateral pallium. In dipnoans, the pallium is relatively small and occupies the dorsolateral telencephalon. Laterally, it is divided from the striatum by the sulcus limitans pallii. In *Neoceratodus* and *Protopterus*, there is a thick periventricular layer and a thin layer of migrated cells. In *Neoceratodus*, a dorsal hippocampal pallium, an intermediate general pallium, and a piriform ventral pallium are distinguished, but there are no clear subdivisions (Nieuwenhuys, 1998). Unfortunately, no modern tracer studies exist on the afferents and efferents of pallial neurons in dipnoans. The reptilian pallium consists of two parts, the cerebral cortex and the dorsal ventricular ridge, unique to reptiles and birds. The cortex is divided into a medial, dorsomedial, dorsal, and lateral cortex plus a pallial thickening. The lateral cortex is the main olfactory cortex (ten Donkelaar, 1998). The medial and dorsomedial cortex receive olfactory information via the lateral cortex plus multisensory and limbic information via the dorsomedial and dorsolateral thalamic nuclei.

The situation found in reptiles and amphibians regarding pallial regions is similar: the small-celled medial and the large-celled mediodorsal cortices of reptiles are largely homologous to the small-celled ventral and the large-celled dorsal portion of the medial pallium of amphibians, and the dorsal cortex of reptiles is largely comparable to the dorsal pallium of amphibians. These regions receive multimodal sensory and limbic afferents from the anterior dorsal thalamus, which in reptiles comprise the dorsomedial and dorsolateral nuclei. The only major difference consists in the existence of a lemnothalamic sensory relay nucleus in the dorsal thalamus of reptiles, the LGN, which receives direct visual input and projects in parallel to the dorsal cortex and to the pallial thickening; such a lemnothalamic nucleus does not exist in amphibians. However, a strict homologization of the LGN of reptiles and the LGN of mammals is problematic, because in the medial, dorsomedial, and dorsal cortex of reptiles, as in the medial and dorsal pallium of amphibians, no precise topographic, unimodal sensory maps have been found to date (see overview in ten Donkelaar, 1998).

The dorsal ventricular ridge (DVR, Johnston, 1923) is a structure uniquely found in reptiles and birds. It is divided into an anterior and a posterior part (aDVR, pDVR) separated by the anterior commissure (ten Donkelaar, 1998). The aDVR is divided into three longitudinal zones as main targets of ascending sensory pathways. Visual information reaches the lateral part, somatosensory information terminates in the central part of the aDVR, and auditory information in the medial part of the aDVR. The pDVR receives nontopographically organized multisensory limbic afferents from the dorsal thalamus. The nucleus sphericus receives the main olfactory and vomeronasal afferents and projects to the ventromedial hypothalamus and to the AOB.

At present, it is debated to which structure of the mammalian telencephalon the aDVR should be considered homologous. Bruce and Neary (1995) regarded the aDVR as homologous to the mammalian basolateral amygdala, whereas Striedter (1997) homologized it with the mammalian endopiriform nucleus/claustrum, and Puelles *et al.* (2000) argued that the ventral pallium gives rise to the endopiriform nucleus and lateral amygdala nucleus in mammals and to the sensory-recipient part of the aDVR in reptiles and birds. More recently, Molnár and Butler (2002) argued that a strict homologization between these structures in the mammalian and sauropsid brain is impossible, but that a field homology can be postulated between the aDVR of sauropsids and the claustrum-endopiriform nucleus plus the basolateral amygdala of mammals, both developing from the collothalamic lateral–ventral pallium.

Amphibians, like mammals, lack a dorsal ventricular ridge. A strict homology of the anterior ventral pallium of amphibians with the aDVR is unlikely, because the ventral pallium receives no substantial visual, auditory, and somatosensory input from the dorsal thalamus, but its dominant input comes from the AOB. Also, it lacks connections with the dorsal pallium. However, one could envision an evolutionary process during the transition from amphibian to reptilian ancestors, in which sensory afferents from the dorsal thalamus extend further rostrally into the anterior ventral pallium replacing the olfactory and vomeronasal input.

In summary, the amphibian pallium is likely to represent a situation prior the divergent evolution of the mammalian cortex and the reptilian–avian cortex aDVR. However, the precise functions of the amphibian pallial regions are unclear. First, inside the medial, dorsal, and lateral pallium of frogs and salamanders, only multimodal responses can be recorded (F. Laberge, unpublished data). Second, the large dorsal and lateral pallium have no extra-telencephalic projections, and the only extra-pallial projection reaches the septum. The extra-telencephalic projections of the medial pallium, which is assumed to be homologous to the mammalian hippocampus, mostly reach the ventral thalamus and the dorsal and ventral hypothalamus, whereas projections to the dorsal thalamus and the brainstem are weak.

The major output regions of the amphibian telencephalon are the nucleus accumbens, septal region, the centromedial amygdala, and the caudal striatopallidum. Whereas nucleus accumbens, septum, and centromedial amygdala have reciprocal connections with pallial regions, the striatopallidum does not. It remains to be investigated how in amphibians the pallium influences the striatopallidal motor output. Only the rostral and ventral pallium exhibit some projections to the striatopallidal complex.

An unsolved question is whether the amphibian pallial regions are primitive or secondarily simplified (cf. Northcutt and Kicliter, 1980). This question can be answered only by a phylogenetic analysis. Such an analysis is hindered by the fact that the dipnoans have pallial regions that exhibit a simple morphology and closely resemble those of amphibians, but themselves are secondarily simplified. The pallium of *Latimeria*, representing the sister group of dipnoans, is assumed not to be secondarily simplified, but likewise gives a primitive appearance (cf. Nieuwenhuys, 1998). This would suggest that the pallium of amphibians is primitive and not secondarily simplified or pedomorphic. However, even in the medial and dorsal pallium of dipnoans, we find an incipient lamination, which is likewise found in turtles and lizards, but completely absent in amphibians. Therefore, it is safe to assume that some lamination in the medial and dorsal pallium is a plesiomorphic feature of sarcopterygians and all tetrapods and was lost in amphibians.

2.04.4.2.3 The visual system In amphibians, like in all anamniote vertebrates as well as in lizards and turtles and partly in birds, the tectum is the major brain center for visual perception and visuomotor functions. In the amphibian tectum, localization and recognition of objects and depth perception take place, and separate pathways descend to premotor and motor centers in the brainstem and cervical spinal cord involved in the guidance of visual behavior. Ascending pathways run bilaterally to the dorsal and ventral thalamus. Unlike other jawed vertebrates, the amphibian tectum has no saccadic system, because eye movements do not exist in adult amphibians, but this probably is due to a secondary loss, because eye movements are present during ontogeny of amphibians with an aquatic or semiaquatic lifestyle. Also, directionally selective neurons are absent in the amphibian tectum, but exist in all amniotes.

On the basis of recent tract tracing and intracellular and extracellular recording experiments in frogs and salamanders presented above, it appears that the amphibian visual system is organized in essentially the same way as that of amniotes in the sense that object recognition is based on population coding and occurs in a parallel-distributed fashion simultaneously and subsequently at several to many visual centers. Interaction and modulation between these centers occurs to a larger extent, because they are interconnected by several feedback loops, and top-down influences are most likely (Roth *et al.*, 1998; Schuelert and Dicke, 2005). This pattern of interaction is paralleled by a complex chemoarchitecture.

In amphibians as well as in all other vertebrates studied, three separate retinotectal subsystems for object recognition exist, which process information about (1) size and shape, (2) velocity and movement pattern, and (3) changes in ambient illumination (such as that caused by large moving objects). These kinds of information are processed at the level of different types of RGCs and tectal neurons, as described above, in close interaction with neurons in other visual centers such as the nucleus isthmi or the thalamus. Accordingly, different types of tectal neurons receiving different retinal input give rise to separate ascending pathways to thalamic and eventually telencephalic associative and limbic centers and to separate descending pathways to different premotor and motor centers in the medulla oblongata and rostral spinal cord, where they meet other descending pathways from diencephalic and telencephalic centers such as the central amygdala, septum, and striatopallidum.

At least three major streams of information meet at premotor and motor levels in order to elicit the various steps of visually guided behavior:

1. Information about certain properties of the object perceived concerning size, contrast, color, shape, velocity, movement pattern, etc.
2. Information about the precise location of that object. Pathways (1) and (2) need to interact in order to fully identify visual objects, including their absolute size.
3. Information about the level of motivation, most probably coming from limbic telencephalic regions (amygdala, nucleus accumbens/ventral striatopallidum) and the hypothalamus. How these latter influences are mediated to the main visual center is under investigation.

These tectal pathways found in the amphibian visual system strongly resemble those found in amniote vertebrates. However, there are remarkable differences between amphibians and mammals. One of them is the absence of a visual relay nucleus in the dorsal thalamus in amphibians that receives direct retinal input and projects monosynaptically to the cortex, and another is the presence or absence of

primary and topographically organized visual areas in the cortex (the striate cortex). Birds have evolved, apparently independently, a similar system, i.e., a pathway from the retina to the nucleus geniculatus lateralis pars dorsalis, which in turn projects to the visual Wulst. The situation in turtles and reptiles is somewhat intermediate, because there is the LGN, which receives direct retinal input and projects both to the dorsal cortex and the pallial thickening. However, in neither area are retinotopically arranged visual areas found (for details see ten Donkelaar, 1998; Dubbeldam, 1998; Voogd *et al.*, 1998; see Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, Visual Cortex of Turtles).

2.04.4.2.4 Amygdaloid complex According to a recent concept developed by Laberge and Roth (cf. Laberge *et al.*, 2006), the amphibian amygdaloid complex is composed of an autonomic-visceral component equivalent to the mammalian extended central amygdala including the BNST and to the striatoamygdaloid transition (SAT) area of reptiles (Russchen and Jonker, 1988; Bruce and Neary, 1995; ten Donkelaar, 1998). There is a vomeronasal amygdala of pallial origin in the ventral caudolateral telencephalon including the caudal SPTA and homologous to the mammalian posteromedial cortical amygdala and to the nucleus sphericus and medial amygdala of reptiles. Possibly, in amphibians there is a ventromedially situated subpallial vomeronasal amygdala comparable to the mammalian medial amygdala (F. Laberge, unpublished observation). Also, there is an olfactory amygdala in the caudal lateral pallium homologous to the anterior and posterolateral cortical amygdala of mammals and the external and ventral anterior amygdala in reptiles (Lanuza and Halpern, 1998).

An unsolved problem is which part of the amphibian telencephalon is homologous or at least equivalent to the mammalian basolateral amygdala. Bruce and Neary (1995) as well as Marín *et al.* (1998) and Moreno and González (2003, 2006) assume that this is the case for the ventral pallium. Based on studies of gene expression pattern and topological position, it has been suggested that in vertebrates the ventral pallium is homologous (at least in the sense of a field homology) to the ventral part of the anterior dorsal ventricular ridge in birds and part of the claustrum and lateral amygdala in mammals (Brox *et al.*, 2002; Molnár and Butler, 2002). However, there are problems with considering the ventral pallium of amphibians homologous with the mammalian basolateral amygdala. The latter is characterized by strong reciprocal connections with the hippocampal formation and sensory, associative, and limbic cortical areas as well as receiving collothalamic input from the posterior dorsal thalamus (Alheid *et al.*, 1995; Pitkänen, 2000). In amphibians, there are no primary visual, auditory, and somatosensory pallial regions; furthermore, the anterior ventral pallium receives no or only very weak sensory input from the anterior dorsal thalamic nucleus and only sparse input from the central dorsal thalamic nucleus. Also, this part does not project back to the medial pallium considered homologous to the hippocampal formation and has no connections with the dorsal pallium. Therefore, it cannot exert multisensory integration in close interaction with cortical/pallial and hippocampal regions. The fact that it receives strong olfactory and vomeronasal input and that its efferents join the stria terminalis on its way to the hypothalamus is atypical of the mammalian basolateral amygdala. However, this does not exclude the possibility that during the evolution of the amniote brain this area eventually developed into a mammalian basolateral amygdala.

A region that at least partially fulfills these connectional criteria is the ventromedial portion of the ventral caudal telencephalon of anurans including the ventral-most portion of the lateral septum, traditionally called medial amygdala. This region receives multimodal sensory and limbic input from the anterior dorsal thalamus and projects heavily to the septum; the septum in turn projects to the medial and dorsal pallium. This medial amygdala also contains neurons that project directly to the medial pallium, from where it receives substantial input. On the other hand, it is entirely of subpallial and not of pallial origin, as is the case for the basolateral amygdala of mammals. Therefore, it appears that the medial amygdala of amphibians is not homologous but homoplastic to the basolateral amygdala, i.e., it is of different origin, while serving similar functions (Laberge *et al.*, 2006).

Thus, the evolution of a portion of the amygdala of pallial origin with strong reciprocal connections to sensory, associative, and limbic pallial–cortical areas appears to be a major step in the evolution of the amniote telencephalon, enabling the formation of new and more complex types of emotional learning. The amygdaloid complex found in amphibians with a vomeronasal, olfactory, and a mixed autonomic-visceral and associative amygdala certainly represents the ancestral tetrapod and perhaps vertebrate condition. In this context, new findings demonstrate that in mammals not only the basolateral amygdala (as was assumed for a long time; cf. LeDoux, 2000), but also the central nucleus are the site of emotional

conditioning, albeit in a simpler fashion (Everitt *et al.*, 2003; Paré *et al.*, 2004). This would be consistent with the view that the presence of a mixed autonomic-visceral-associative amygdala enables amphibians to develop simple forms of affects and emotions, while the formation of more complex emotions would be based on the evolution of a basolateral amygdaloid complex (Everitt *et al.*, 2003).

2.04.4.2.5 Striatopallidum The amphibian dorsal striatopallidal complex is divided into a rostral portion corresponding to the dorsal striatum of mammals, a caudal portion corresponding to the dorsal pallidum of mammals, and an intermediate portion with properties shared by both structures. Enkephalin-ir and substance P-ir neurons are mainly found in the rostral and intermediate part of the dorsal striatopallidal complex, while Leu-enkephalin-ir and serotonin-ir fibers are most abundant in the intermediate and caudal parts. Furthermore, there is a distinct dopaminergic input from the posterior tubercle, which is believed to be homologous to the substantia nigra pars compacta of mammals (Marín *et al.*, 1995). All this characterizes the amniote including mammalian dorsal striatopallidum (Mori *et al.*, 1985; Graybiel, 1990; Reiner *et al.*, 1998).

Major differences between the amphibian and mammalian dorsal striatopallidum consist in the following:

1. A low number of GABAergic neurons in the amphibian striatum (H. Endepols, unpublished data), while in mammals nearly all striatal output cells are GABAergic.
2. A lack of segregation into histochemically different patches and matrix typical of the mammalian striatum; however, in amphibians histochemically different layers can be observed.
3. The complete or nearly complete absence of cholinergic neurons, which in mammals are concentrated in the so-called matrix.
4. Only weak input from the rostral and ventral pallium in amphibians, while there is a strong cortical input to the striatum in mammals.
5. No or only a weak projection of the caudal striatopallidal complex to the dorsal thalamus.

As a consequence, the main motor output of the amphibian striatopallidum is the projection of the pallidum to brainstem and spinal cord motor regions (which, of course, is also present in mammals), rather than the corticospinal tract in mammals. Furthermore, a modulation of sensory and executive functions does not take place in the pallium/cortex, because a projection of the pallidum back to the cortex via ventral thalamic nuclei is lacking. Such a modulation appears to occur either via a projection of the pallidum to the ventral thalamus and from there to the tectum or to the tegmentum (equivalent of the substantia nigra pars reticulata) and from there to the tectum. The tectum, then, projects to the premotor and motor regions in the brainstem and rostral spinal cord.

The striatopallidum of reptiles appears to represent an intermediate evolutionary stage between amphibians and mammals (cf. Reiner *et al.*, 1998; Marín *et al.*, 1998). First, the reptilian striatum contains both GABAergic output neurons and cholinergic interneurons, both of which are either small in number or absent in amphibians. However, the cholinergic neurons are not arranged in a distributed island typical of the mammalian striatum. Second, the striatum of reptiles, like that of amphibians and unlike that of mammals, receives very little input from the cortex. Third, it is presently unclear whether reptiles possess thalamic motor nuclei comparable to the ventral anterior and ventrolateral relay nuclei of mammals, which receive projections from the dorsal pallidum and project to cortical regions with connections with the striatum. Thus, it appears that neither amphibians nor reptiles posses a re-entrant circuitry (dorsal loop) between pallium/cortex, striatopallidum, and thalamus.

2.04.5 Summary and Conclusions

In zoology and evolutionary biology, amphibians have always played a problematic role. Although modern amphibians, the *Lissamphibia*, are highly derived vertebrates with very little resemblance to the paleozoic ancestors of tetrapods, they usually are considered primitive vertebrates. This misunderstanding results at least in part from many features of sense organs and brains of amphibians appearing to be much simpler than those of nearly all other vertebrates. As discussed above, many of these features have undergone secondary simplification, especially affecting processes of morphological differentiation, formation of laminae, and anatomically distinct nuclei in the brain. Other features, especially those concerning the thalamus and telencephalon, appear to be primitive. Thus, sense organs and brains of amphibians represent a mixture of primitive and secondarily simplified traits.

In recent years, a large amount of new data on the morphology of the brains of frogs and salamanders using modern neuroanatomical methods has accumulated. These studies demonstrated that the brains of frogs and salamanders possess nearly all the properties characteristic of the brains of amniotes. One main conclusion that can be drawn from these new

insights is that in many aspects the brains of turtles and lizards are closer to that of amphibians than to mammals and birds. Major differences between amphibians on the one hand and mammals and birds on the other are the following:

1. Visual object recognition and visual guidance of behavior is mostly exerted by the retinotectopretectal system; a unimodal visual thalamotelencephalic system characteristic of mammals and birds is absent in amphibians and poorly developed in reptiles. Thalamic and telencephalic centers appear to exert a modulatory role.
2. The amphibian medial pallium is partly homologous to the mammalian hippocampal formation, but a dentate gyrus appears to be missing; the precise homologization of the medial and dorsomedial cortex of reptiles to the mammalian hippocampus is likewise unclear.
3. The amphibian dorsal pallium possesses no unimodal, topographically organized areas as found in the mammalian isocortex and the avian hyper-, meso-, and nidopallium (cf. Reiner *et al.*, 2004), and is most probably homologous to the limbic-associative cortex of mammals. The situation found in turtles and lizards is unclear, but the presence of unimodal and topographically organized areas has not been demonstrated in the dorsal cortex.
4. The amphibian striatopallidum receives input from the rostral and ventral pallium and projects to ventral thalamic nuclei, which however do not project to pallial–cortical areas connected with the dorsal striatum (the ventrolateral and ventral anterior thalamic nuclei of mammals). Such a dorsal loop appears to be missing in reptiles as well.
5. Pallial premotor and motor areas are likewise missing in amphibians as well as in lizards and turtles. The main motor output of the telencephalon in amphibians, lizards, and turtles is the projection of the dorsal pallidum to the pretectum and to the mesencephalic tegmentum and from there to the tectum mesencephali.
6. In the anterior striatopallidum of amphibians corresponding to the mammalian dorsal striatum, GABAergic projection neurons and cholinergic interneurons, characteristic of the mammalian dorsal striatum, are largely or completely missing. The striatum of turtles and lizards, in contrast, appears to possess such types of neurons, although not in a quantity comparable to the mammalian situation.
7. The amphibian amygdaloid complex consists of a vomeronasal amygdala of subpallial and pallial origin homologous to the mammalian posteromedial cortical amygdala, a pallial olfactory amygdala homologous to the anterior and posterolateral cortical amygdala of mammals and the external and ventral anterior amygdala in reptile amygdala, and an extended central amygdala homologous to the mammalian BNST, medial amygdala, and central amygdala. An amygdala of pallial origin homologous to the mammalian basolateral amygdala appears to be missing in amphibians, but probably has – at least in part – a functional equivalent in the mediocentral amygdala.

In summary, the differences mentioned between amphibians on the one hand and mammals and birds on the other concern mostly the connection between thalamus and pallium/cortex, the intra-telencephalic connections of the pallium/cortex, predominantly to the striatopallidum, and the further differentiation, enlargement, and specialization of pallial/cortical structures. This further differentiation of the thalamocortical system apparently has occurred independently in mammals and birds originating from different reptilian ancestors.

2.05 Evolution of the Nervous System in Reptiles

L L Bruce, Creighton University, Omaha, NE, USA

Glossary

homologue	Traits that are derived from a common ancestral region and formed by similar developmental processes.
pallium	The dorsal part of the telencephalon that arises from the rostral, dorsal neural folds, including hippocampus, cortex, and part of the amygdala.
telencephalon	The rostral expansion of the brain including pallium and subpallium.
tetrapods	Vertebrates with four feet, generally including amphibians, reptiles, birds, and mammals.

2.05.1 Introduction

Living reptiles are traditionally classified as either anapsids or diapsids based largely on the morphology of a single key character, the temporal fenestrae (e.g., Williston, 1917). These fenestrae are presumed to provide better jaw muscle attachment in the diapsid rather than the anapsid condition. Anapsids lack temporal fenestrae. Diapsids have two fenestrae on each side and evolved from ancestors that had none. Snakes, lizards, crocodiles, and dinosaurs are diapsids. Testudamorpha (turtles and tortoises), as well as many Paleozoic reptiles, are anapsids. The absence of fenestrae is considered a primitive state and the presence of fenestrae is considered a derived state. In traditional interpretations of the phylogeny of extant reptiles, Testudamorpha are considered basal to other reptiles (lizards, snakes, tuatara, crocodiles, and birds) (Figure 1a). Testudamorpha are typically classified as living representatives of the more extinct anapsid reptiles, and placed with the early fossil reptiles. This has led many researchers, including comparative neurobiologists, to consider turtles as the reptile of choice for evolutionary studies.

A growing body of evidence from molecular and osteological analyses suggests that Testudamorpha should be reclassified as specialized diapsids. Cladistic analyses of 168 osteological characters in 14 living and fossil reptilian taxa led Rieppel and De Braga (1996) to conclude that Testudamorpha are nested within the clade Diapsida as the sister group to birds and crocodiles (Figure 1b).

The earliest molecular approach (Fitch and Margoliash, 1967), based on analyses of the cytochrome *c* gene amino acid sequences in vertebrates and invertebrates, resulted in a phylogenetic scheme that was largely similar to the traditional scheme with one notable exception – turtles were more closely associated with birds than with the other living reptiles. Fitch and Margoliash noted this departure from conventional interpretations, but at the time considered it to be an anomaly.

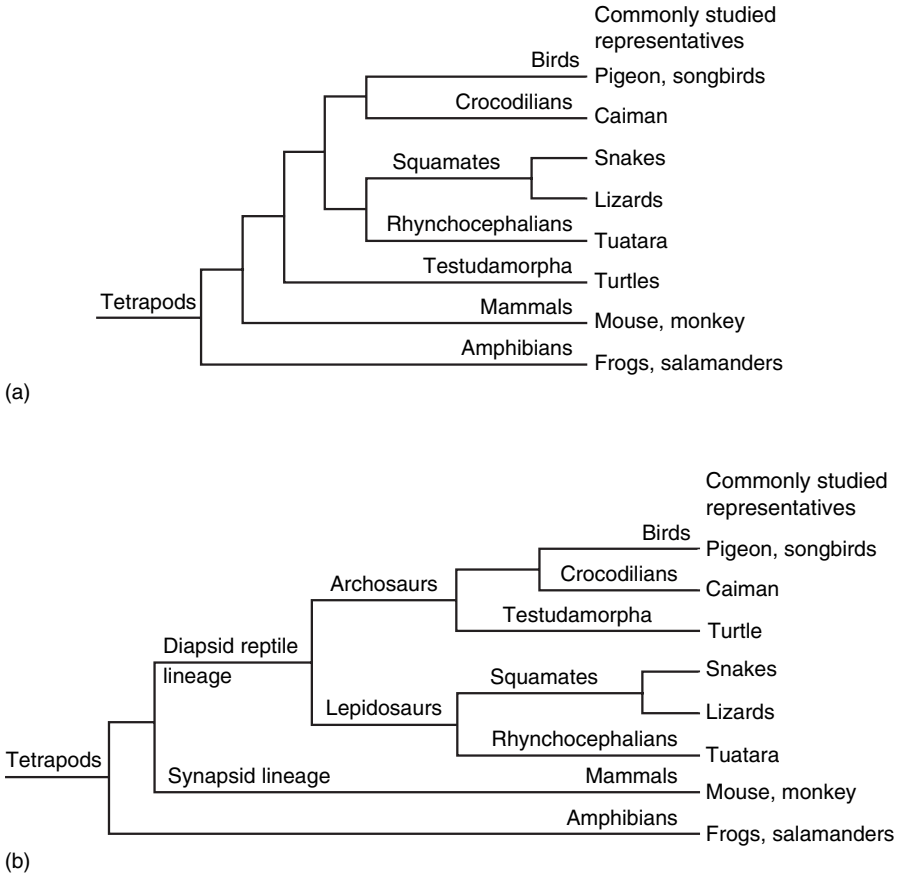

Figure 1 Relationships among the major groups of living tetrapods. a, The traditional phylogeny places Testudamorpha at a basal position relative to other reptiles. b, The consensus phylogenetic tree based on molecular and morphological analyses places Testudamorpha as a sister group to birds and crocodiles. Modified from Rieppel, O. 1999. Turtle origins. *Science* 283, 945–946 and Platz, J. E. and Conlon, J. M. 1997. . . . and turn back again. *Nature* 389, 246.

Platz and Conlon (1997) analyzed the molecular changes of pancreatic polypeptide, utilizing seven amphibians (representing all three orders) as the outgroup to examine living reptile phylogeny (snake, turtle, and alligator, and three birds). Their results were consistent with the earlier analyses of cytochrome *c*. Thus, turtles nest within the diapsids above snakes and are the sister group to birds and crocodiles. More recently, analyses of nuclear genes and mitochondrial genomes (Hedges and Poling, 1999; Janke *et al*., 2001) have provided further support for this tree.

In summary, five independent data sets, one morphological and four molecular, all support testudamorphs as diapsids. Because rhynchocephalians are presently endangered, lizards are the best alternative model to compare with other lepidosaurs, and to identify traits present in the common ancestors of birds and mammals. The evolutionary history of snakes remains controversial and requires further study, although the prevailing view is that they are derived from lizards. For studies of avian evolution, crocodilians (alligators, caiman, and crocodiles) are the most closely related living group. Testudamorpha represent a basal member of the living archosaurian diapsids, and therefore provide insights into crocodilian and avian evolution.

2.05.2 How Do Differences in Brain Organization Evolve?

The term 'homology' was coined by Owen (1848) to recognize organs of common tissue origin, regardless of form and function in different species. Applied to the brain, 'homology' typically refers to neural units that are formed by similar developmental processes.

The brains of extant animals are studied to identify presumed homologies. This involves examination and demarcation of neural regions that were derived from a common ancestral region (Campbell and Hodos, 1970; Northcutt, 1984). To do this we

must recognize and eliminate nonhomologous regions, in particular those that have arisen by parallel or convergent evolution; meaning those similarities that are not derived from common ancestry. If we can identify homologies, then mapping neuronal traits onto a well-established tree will allow one to differentiate between shared, derived, or primitive states, and those that arose by convergence.

Comparative neuroanatomists, like all scientists, are limited by the tools available to them as well as by assumptions made as to how evolution 'should work'. In the early part of the twentieth century, neuroanatomists made comparisons based on analyses of size, gross morphology, and cytoarchitecture, and followed the principle that brain regions evolved from 'simple' to 'complex' (e.g., Edinger, 1908; Ariëns Kappers *et al*., 1936). They relied on Nissl, myelin, and Golgi stains, and brain dissections, which provided information about neuronal morphology, topology, and some axonal pathways. Though some of their conclusions have been disproved, many are still valid today and others are still being debated. Continued searches for homologies are essential to resolving these issues.

There are well-accepted approaches for studying homology: topology, connections, neurochemical expression patterns, genetic expression patterns, cell morphology, and neurophysiological characteristics. Each approach has strengths and weaknesses. Therefore, evidence for or against a particular homology should be based on multiple approaches, and use multiple techniques. Again, if one has a good molecular-based phylogeny, one can 'map' neural states on to it.

2.05.2.1 Topology

Using topology as a criteria assumes that the relative position of a given brain region is determined by interactions with adjacent regions. This is useful because the topological fate of a neuronal group and its connections is determined by multiple genes that are expressed in specific spatial and temporal patterns. A weakness of this approach is that neuronal groups may migrate away from their ventricular site of origin. Therefore, topological analyses alone may be misleading. A classic example of a mistaken topology-based homology is Edinger's (1908) comparison of the avian nidopallium (previously named neostriatum; Reiner *et al*., 2004) and reptilian dorsal ventricular ridge (DVR) to part of the mammalian striatum, because they all form a large ridge in the lateral ventricle. Karten (1969) subsequently used histochemical analyses to show that these are pallial, and not striatal, structures.

2.05.2.2 Connections

The formation of neuronal pathways is regulated by multiple families of genes at both the sites of origin and termination. Identification of similar connections is thus another indication of homology. However, the weakness of this approach is that the same region (e.g., thalamus) may give rise to more than one projection to a target (e.g., telencephalon), or may invade new regions. Thus, a single connection may not be a reliable indicator of homology. The acquisition of novel connections reflects changes in genetic regulation, implying evolutionary change. If, for example, this change took place in a bird, but was not seen in crocodilians or turtles (basal group of the three; Figure 1b), one could tentatively assign the changed state in birds to a derived condition.

2.05.2.3 Neurochemical Expression Patterns

Comparisons of expression patterns have proven very useful for identifying homologies. Neuronal traits regulated solely by local genetic environment are best for identifying retained evolutionary features. Genes or peptides that are expressed during early developmental stages and maintained into maturity are especially useful for interspecies comparisons. For example, the expression of factors that regulate dopamine, noradrenaline, and serotonin are highly conserved in nuclei among different vertebrate classes (Smeets and Reiner, 1994), and are useful for identifying homologous nuclei and pathways. Care must be taken because some expression patterns can be sculpted by peripheral or environmental influences. For example, expression of calcium-sequestering peptides can be altered by the presence or absence of neuronal input (Britto *et al*., 1994; Diaz de Barboza *et al*., 2003); thus, their presence or absence may not correlate with neuronal ancestry. Finally, if the same antibody is used in two distant taxa, it is uncertain whether it is binding to the homologous peptide.

2.05.2.4 Gene Expression

Genetic analyses reveal expression patterns at earlier developmental stages than most neurochemical markers. The ontogenetic history of a neural group can be followed from ventricular origin, through proliferation, specification, and migration. A comparison of such embryological fate maps allows the identification of conserved neural domains. For example, analyses of gene-expression patterns

revealed the presence of a ventral pallial domain in tetrapods (Brox *et al*., 2004). However, limitations are that genes may be up- and/or downregulated during development. For example, heterochrony (expression of genes at different stages of development) may result in a positive expression in animal A but not in animal B at one stage, and the opposite expression a few days later. Thus, the stage at which two species are compared must be carefully selected.

2.05.2.5 Morphology

Neuronal size, shape, and packing density are variable, and are usually not regarded as strong indicators of homology. For example, the laminated optic tectum of reptiles and the nucleated superior colliculus of mammals are homologous although structurally different.

2.05.2.6 Physiological Characteristics

A neuron's function is determined by a complex interaction of local and nonlocal genetic factors within the brain, as well as influences from peripheral organs and the environment. Thus, comparative analyses of cellular response characteristics are more likely to reveal diverse evolutionary adaptations than retained homologous features. For example, comparisons of cellular responses at each level of the auditory pathway reveal that amphibians, reptiles, birds, and mammals have all evolved unique adaptations for processing auditory information (Grothe *et al*., 2004).

2.05.2.7 Summary

In summary, every neural region contains both evolutionarily conserved (primitive) and derived states. While recognizing the difficulty in identifying homologous features, using the total evidence from the approaches discussed above should allow us to reach a consensus with regard to homology. Mapping changed character states in the brain to a cladistically derived phylogenetic tree should reveal shared evolved patterns (synapomorphies) and at the same time identify instances of convergent evolution (a form of homoplasy), as well as derived traits.

2.05.3 How Can We Recognize Brain Areas That Have Evolved from a Common Ancestor?

Each brain region can be recognized by a unique set of traits, including gene-expression patterns, embryology, neurochemistry, and connections. Our null hypothesis is that a region does not change in the evolution from one species to another. Furthermore, we assume that homologous structures develop from topologically equivalent precursors (Braford, 1995). By searching for homologies, one should identify the neural regions that have retained most of their characteristics, and in the process recognize those that have changed.

The greater the number of traits two structures in divergent species have in common, the greater the likelihood that they are homologous. Thus, making a comparison based on a single pathway (e.g., the retino-tecto-thalamo-pallial projection), or a single gene is a weaker argument than a comparison based on multiple connections or characteristics. Controversies over homologues often occur because different investigators rely on or ignore different traits to reach their conclusions.

Evolution happens: brains clearly differ among the vertebrate classes, and the components have evolved to varying degrees. For example, evolutionary geneticists can identify a gene as 90% homologous with a similar gene from another species. Comparative neurology cannot achieve such quantification, yet we know that the homologues of some nuclei are easier to identify than others. As in gene evolution, we expect some neuronal traits to be more variable, while others are more constrained. Our current hypotheses about homologies will continue to be tested, and hopefully confirmed, as more and more traits are identified.

2.05.4 Sensory Pathways

The first mammalian studies of auditory, visual, and somatosensory pathways to the telencephalon recognized the main components of the sensory pathways, and found that sensory information was relayed through the midbrain and thalamus to the primary sensory areas of the cortex. The sensory pathways of amphibians, reptiles, and birds were compared to these pathways. With the introduction of new techniques, we have since learned that the components and connections of these sensory systems are more numerous and complicated, requiring re-evaluation of proposed homologues.

2.05.4.1 Auditory System

2.05.4.1.1 Reptiles In reptiles, peripheral sound is conveyed through a tympanic middle ear to the basilar papilla. The basilar papilla projects centrally to two subdivisions of the cochlear nucleus, nucleus magnocellularis and nucleus angularis (Carr and Code, 2000). A third brainstem target, nucleus laminaris, also receives direct peripheral auditory input in lizards and crocodiles (DeFina and Webster,

1974; Barbas-Henry and Lohman, 1988). Nucleus laminaris also has features comparable to the superior olive: it receives input from the cochlear nuclei and projects to the midbrain torus semicircularis. It is usually poorly developed in turtles and lizards, reflecting its role in all low-frequency processing (Miller, 1975; Miller and Kasahara, 1979; Barbas-Henry and Lohman, 1988b). In crocodiles and birds it is a larger, distinctly monolayer structure (Rubel and Parks, 1975). Further studies of the reptilian nucleus laminaris are needed to elucidate its evolutionary status. The next level of the vertebrate auditory system is the lateral lemniscus. Within the rostrolateral hindbrain of reptiles there is a region called the lateral lemniscus, but little is known of its connections or other characteristics.

The reptilian auditory midbrain is located in the medial torus semicircularis. It has similar structure, connections, and embryonic origin among tetrapods, and is thus considered a homologue (Wilczynski, 1988; McCormick, 1999). A tonotopic organization is present in crocodiles (Manley, 1971). In reptiles, as in other vertebrates, there is a core area that is the main target of ascending projections from the brainstem, and a belt or laminar area that appears to receive auditory input from the core or from nonbrainstem auditory areas. In lizards and crocodiles the auditory core of the torus projects to the thalamus (Pritz, 1974a; Foster and Hall, 1978). The laminar area projects to thalamus and spinal cord, and parts of it are correlated with vocalizations and social communication behaviors (Kennedy, 1975; Distel, 1978; Butler and Bruce, 1981; Hoogland, 1982).

The auditory midbrain projects to two thalamic areas in reptiles: nucleus medialis (known as nucleus reuniens in turtles and crocodiles), and the dorsolateralis anterior (Pritz, 1974a; Foster and Hall, 1978; Hoogland, 1982). In addition, auditory information from the superior olive projects to an area immediately lateral to nucleus rotundus (Hoogland, 1982). Thus, there may be as many as three distinct auditory thalamic areas, although nucleus medialis/reuniens is the main one. Further studies are needed are needed to resolve this issue.

Nucleus medialis/reuniens projects to the striatum and the medial part of the DVR, and the nucleus dorsolateralis anterior is reciprocally connected with the cortex (Pritz, 1974b; Foster and Hall, 1978; Lohman and van Woerden-Verkley, 1978; ten Donkelaar and de Boer-Van Huizen, 1981; Bruce and Butler, 1984a, 1984b).

2.05.4.1.2 Amphibian to reptile transition Amphibians have two sensory organs that detect airborne sound, the amphibian papilla and basilar papilla, but only the basilar papilla appears to be homologous to the acoustic-sensing organs of other tetrapods (Fritzsch and Neary, 1998; Fritzsch *et al.*, 2002). The amphibian cochlear nucleus, the dorsolateral nucleus, has features unique to amphibians, and its homology with the amniote cochlear nuclei remains unclear (McCormick, 1999). However, cells within the dorsolateral nucleus are morphologically and physiologically similar to those in the cochlear nuclei of other tetrapods. The brainstem auditory nuclei are extensively interconnected (see Fritzsch and Neary, 1998), so only the main connections will be described here (Figure 2a). The amphibian superior olive receives projections from the dorsolateral nucleus, and projects to the torus semicircularis in the midbrain.

The auditory part of the torus semicircularis has similar characteristics among tetrapods, although differences in local circuitry and sound processing are apparent. In amphibians it projects strongly to the central thalamic nucleus and more weakly to the lateral and anterior thalamic nuclei (Hall and Feng, 1987; Neary, 1990). Auditory information from the central and lateral thalamic nuclei is conveyed primarily to the striatum and sparsely to the ventral part of the lateral pallium; that from the anterior thalamic nucleus is conveyed primarily to the medial pallium (Mudry and Capranica, 1980; Wilczynski and Northcutt, 1983a; Hall and Feng, 1987; Neary, 1990; Allison and Wilczynski, 1991; Feng and Lin, 1991).

The basic pattern of connections can be recognized in amphibians and reptiles. Similar thalamic zones can be recognized, although there is increased size and specificity in the reptilian thalamus. The greatest change in the auditory pathway occurred in the telencephalon. Assuming that the common tetrapod ancestor had a forebrain similar to that of extant amphibians, then the ventral part of the lateral pallium in amphibians underwent extensive elaboration to give rise to the reptilian DVR with its distinct sensory regions. The amphibian medial pallium also underwent considerable change, including the development of separate hippocampal and cortical regions. See Sections 2.05.5.2 and 2.05.5.3 for further discussion of the evolution of the thalamus and pallium.

2.05.4.1.3 Reptile to bird transition During the transition from ancestral reptiles to crocodiles and birds, the cochlear nucleus laminaris appears to have enlarged and become distinctly laminated (Rubel and Parks, 1975). The auditory midbrain, torus semicircularis, appears to be generally homologous between reptiles and birds (Figure 2c). Its main projection in

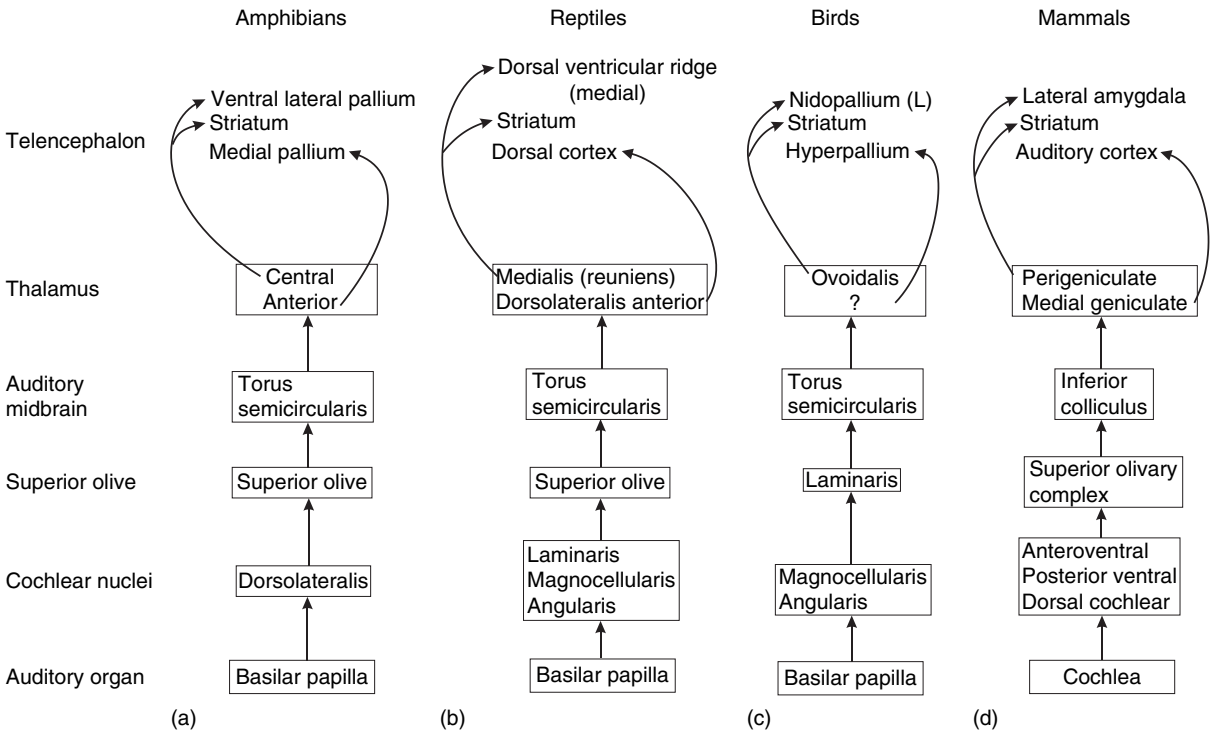

Figure 2 Comparison of the major ascending auditory pathways in tetrapods.

birds is to the auditory thalamic nucleus, ovoidalis (Arthur, 2005). Nucleus ovoidalis projects to the striatum and to Field L in the DVR (Wild *et al.*, 1993). A toral projection to a thalamic nucleus that projects to the hyperpallium has not been described, although Adamo and King (1967) recorded acoustic responses in the medial cortex. The auditory region of the DVR is more elaborate in birds than reptiles, and appears to be correlated with the evolution of vocal behaviors. Many of the connections from the auditory midbrain to circuits involving vocalization appear to be present among tetrapods, although the descending connections like those from the avian arcopallium (formerly archistriatum) to the midbrain have not been reported in reptiles.

2.05.4.1.4 Reptile to mammal transition The evolution of the mammalian auditory system is correlated with the appearance of more complex cell types and connections (Grothe *et al.*, 2004). The mammalian cochlear nucleus contains intrinsic connections and nonprimary inputs that have no known homologue in nonmammals, and which may be associated with the evolution of a high frequency hearing range, and of mobile pinnae that increased sound-localization cues (Grothe *et al.*, 2004). The correspondence of the three subdivisions of the mammalian cochlear nucleus with those of the reptilian nucleus remains uncertain. Nonetheless, the same basic pattern of connectivity seen in other tetrapods is also present in mammals (Figure 2d). The auditory midbrain, inferior colliculus, projects to two thalamic groups: the medial geniculate and a perigeniculate group. The medial geniculate projects to auditory areas in the temporal cortex, whereas the perigeniculate group, including the medial division of the medial geniculate nucleus, the posterior intralaminar nucleus, and the suprageniculate nucleus, projects to the lateral amygdalar nucleus (Doron and LeDoux, 1999, 2000). The mammalian thalamic nuclei and telencephalic regions devoted to audition and vocalization appear to have undergone considerable expansion and parcellation during the transition to mammals. They show considerable variation from the nonmammalian condition, and identification of their homologues is very controversial and will be dealt with separately (Sections 2.05.5.2 and 2.05.5.3).

2.05.4.1.5 Summary The general features and synaptic levels of the auditory pathways are present in all tetrapods, suggesting a conserved Bauplan. However, within each of these levels there is considerable anatomic and physiologic diversity among the vertebrate taxa. Another trend is the increase in size and complexity of the auditory thalamic and cortical regions, particularly in the reptile to mammal transition. Hypotheses about the homologues of thalamic

and pallial regions in amphibian reptiles, and birds are in general agreement, but comparisons with the mammalian auditory regions have proved more difficult and more controversial (see Shared Features of the Auditory System of Birds and Mammals).

2.05.4.2 Visual System

The targets of primary retinal projections will first be presented, followed by the visual pathways to the telencephalon.

2.05.4.2.1 Reptiles *Primary retinal projections.* The primary visual system has been studied in many reptiles, allowing the comparison of a general pattern of retinal projections. The retinal ganglion cells project bilaterally with a contralateral dominance in most lizards, but are predominantly contralateral in crocodiles, and entirely contralateral in *Chameleo* and *Uromastix* lizards (Bennis *et al*., 1994; Derobert *et al*., 1999). Retinal fibers terminate in six general targets within the diencephalon and midbrain of all tetrapods studied with modern experimental techniques (lizards: Northcutt and Butler, 1974; Cruce and Cruce, 1975, 1978; Bruce and Butler, 1984b; Reperant *et al*., 1978; de la Calle *et al*., 1986; Kenigfest, *et al*., 1997; Casini, *et al*., 1993; Bennis, *et al*., 1994; snakes: Repérant, and Rio, 1976; Schroeder, 1981; Dacey and Ulinski, 1986; turtles: Hall *et al*., 1977; Bass and Northcutt, 1981a, 1981b; Kunzle and Schnyder, 1983; Sjöström and Ulinski, 1985; Ulinski and Nautiyal, 1988; Hergueta *et al*., 1992, 1995; crocodiles: Derobert *et al*., 1999). These studies are summarized in the following paragraphs. A variety of nomenclatures have been used for these retinal-recipient nuclei, so we here follow that of Repérant *et al*., 1992 except as noted.

1. *Hypothalamus.* Retinal fibers terminate in the suprachiasmatic nucleus. The retinohypothalamic projection helps to synchronize endogenous rhythms with seasonal changes in the diurnal cycle (Underwood and Groos, 1982; Pickard, 1982). In chameleons and crocodiles there is an additional retinal projection to periventricular hypothalamic area, nucleus opticus periventricularis hypothalami posterior (Bennis *et al*., 1994; Derobert *et al*., 1999).
2. *Ventral thalamus.* The ventral thalamus is distinguished from the dorsal thalamus by its lack of projections to the telencephalon. Visual projections terminate in nucleus geniculatus lateralis pars ventralis, in a medially adjacent group, nucleus ventrolateralis, and in a dorsal group called either nucleus ovoidalis or geniculatus lateralis pars dorsalis (GLd). The dorsal surface of the retino-recipient ventral thalamic area is capped by a sheet of neuropeptide Y (NPY)-like immunoreactive cells, above which is dorsal thalamus (Medina *et al*., 1992).
3. *Dorsal thalamus.* Dorsomedial to the ventral thalamic area is a small cell group that receives retinal projections and projects to the telencephalon. In turtles, this nucleus is called the lateral geniculate nucleus (Hall and Ebner, 1970a, 1970b). In lizards, it is called intercalatus (Bruce and Butler, 1984a) or the lateral part of the dorsolateralis anterior (Bennis *et al*., 1994). It appears to be smaller in lizards than in turtles.
4. *Pretectal nuclei.* There are four visual pretectal nuclei. Nucleus lentiformis mesencephalicus is largest in snakes and some lizards, and poorly developed in most turtles (Reperant *et al*., 1992). Nucleus griseus tectalis is better developed in lizards than in snakes. Nucleus geniculatus pretectalis and nucleus posterodorsalis are similar features amongst reptiles.
5. *Optic tectum.* The retina terminates in the superficial optic tectum in a retinotopic organization.
6. *Mesencephalic tegmentum.* Nucleus opticus tegmenti is present in all reptiles, but is particularly large in chameleons.

Visual pathways to the telencephalon. Two visual pathways to the telencephalon are usually recognized in the reptilian visual system (see Repérant, *et al*., 1992, for a historical review). A primary pathway ascends from the retina to the thalamus to the telencephalic cortex. A secondary pathway ascends from the retina to the optic tectum (superior colliculus), to the thalamus, and then to a visual area within the DVR. The primary visual pathway is sometimes referred to as the lemnothalamic pathway, and the pathway through the tectum may be called the collothalamic pathway (Butler and Hodos, 1996). There is, however, a third distinct route through which visual information reaches the telencephalon, raising the question of which pathways are homologous among tetrapods (Figure 3b).

A retino-thalamo-telencephalic projection has been described in turtles (Hall and Ebner, 1970a, 1970b; Hall *et al*., 1977) and lizards (Bruce and Butler, 1984a; Kenigfest *et al*., 1997). In turtles it projects to the anterolateral parts of the dorsal cortex (Hall and Ebner, 1970a; Desan, 1988; Zhu *et al*., 2005). In lizards it projects to or near a rostral telencephalic nucleus, the pallial thickening (Bruce and Butler, 1984a). Further studies are needed to identify the specific telencephalic target in lizards and crocodiles.

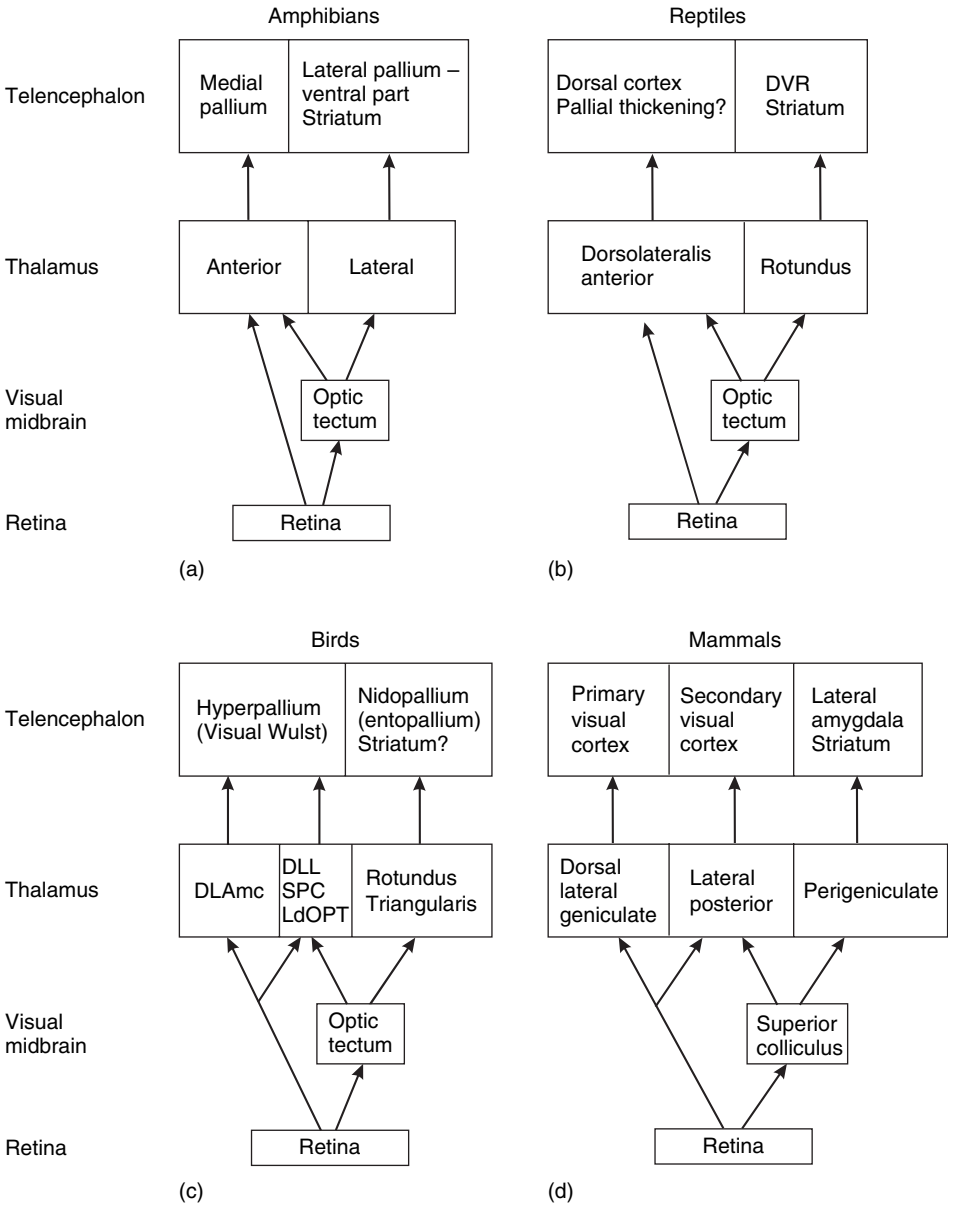

Figure 3 Comparison of the major ascending visual pathways to the telencephalon in tetrapods. Refer to text for abbreviations.

Retino-tecto-thalamo-telencephalic projections have been the focus of a number of studies (lizards: Butler and Northcutt, 1971; Bruce and Butler, 1984b; Guirado *et al.*, 2000; turtles: Hall and Ebner, 1970a, 1970b; Balaban and Ulinski, 1981; Rainey and Ulinski, 1982; Foster and Hall, 1975; Hoogland, 1982; Desfilis *et al.*, 2002; Belekhova *et al.*, 2003; crocodiles: Braford, 1972; Pritz, 1975). Neurons in the optic tectum that extend dendrites into the visual-recipient layers project to rotundus and, at least in lizards, to the dorsolateralis anterior. Nucleus rotundus then projects to the striatum and DVR, and the dorsolateralis anterior projects to the dorsal cortex. Thus, visual information reaching the optic tectum is conveyed to two different thalamic regions, and then each projects to a separate pallial region, either the dorsal cortex or the DVR. Visual responses have been recorded from the rostrolateral dorsal cortex, the lateral part of the medial cortex (Andry and Northcutt, 1976), and from the visual DVR (Peterson and Rowe, 1976; Manger *et al.*, 2002). These two regions develop from embryologically distinct pallial domains, dorsomedial and ventromedial, respectively (Fernandez *et al.*, 1998).

2.05.4.2.2 Amphibian to reptile transition The basic pattern of retinal projections seen in reptiles

is also present in amphibians, indicating that it was present in the common ancestor (Figure 3a). Visual projections terminate in the hypothalamus, ventral thalamus, dorsal thalamus, pretectum, mesencephalic tectum, and mesencephalic tegmentum (Scalia and Gregory, 1970; Scalia, 1976; Roth *et al*., 1998; Wye-Dvorak *et al*., 1992).

A retino-thalamo-telencephalic pathway is present in amphibians, as in reptiles. Retinal axons terminate on the dendrites of neurons in the anterior nucleus, within a cell-poor terminal region called the neuropil of Bellonci (Scalia and Gregory, 1970). The anterior thalamic nucleus then projects to the medial, dorsal, and lateral pallia (Neary, 1990; Northcutt and Ronan, 1992).

Two retino-tecto-thalamo-telencephalic pathways are present and comparable to those in reptiles. The optic tectum projects to the lateral and anterior thalamic nuclei. The anterior thalamic nucleus projects to the pallial cortices, especially the medial pallium, whereas the lateral thalamic nucleus projects heavily to the striatum and sparsely to the ventral part of the lateral pallium (Wilczynski and Northcutt, 1977, 1983a; Neary, 1990; Montgomery and Fite, 1991). These two pallial targets develop from embryologically distinct domains, dorsomedial and ventrolateral pallia, respectively (Brox *et al*., 2004).

2.05.4.2.3 Reptile to bird transition The avian visual system has been the subject of numerous studies, and a great deal more is known about it than the reptilian visual system, so here we focus on comparable studies (Figure 3c). As in other tetrapods the avian retina projects to targets in the hypothalamus, ventral thalamus, dorsal thalamus, pretectum, midbrain tectum, and midbrain tegmentum (Gamlin and Cohen, 1988; Norgren and Silver, 1989a, 1989b). Within the dorsal thalamus the retinorecipient nuclei that project to the hyperpallium are the dorsolateralis anterior thalami, pars lateralis (DLL), dorsolateralis anterior thalami, pars magnocellularis (DLAmc), lateralis dorsalis nuclei optici principalis thalami (LdOPT), and the suprarotundus (SpRt) (Güntürkün *et al*., 1993). This group is sometimes called the nucleus geniculatus lateralis, pars dorsalis. These nuclei project bilaterally to the hyperpallium (visual Wulst), except the SpRt, which projects ipsilaterally.

Thalamic nuclei that receive visual input via the optic tectum include rotundus, triangularis, superficialis parvocellularis (SPC), part of the DLL, and the LdOPT (Karten and Revzin, 1966; Sugita *et al*., 1996). One group of nuclei (SPC, DLL, and LdOPT) projects to the visual Wulst in the hyperpallium (Güntürkün *et al*., 1993). The SPC projects to additional telencephalic targets including the somatosensory Wulst and the area parahippocampalis. The other nuclei (rotundus and triangularis) project to the entopallium, a visual region within the nidopallium (Hellmann and Güntürkün, 2001). A projection from rotundus to the striatum apparently has not been documented, although rotundus axons clearly pass through the striatum enroute to the entopallium. Thus, visual information from the optic tectum projects through two separate thalamic regions and then to the hyperpallium and the nidopallium. The nidopallium, like the reptilian DVR is embryologically derived from the ventrolateral pallium; the hyperpallium, like the dorsal cortex is derived from the mediodorsal pallium (Fernandez *et al*., 1998; Puelles, 2000; Brox *et al*., 2004)

The avian visual system follows the same basic plan seen in reptiles, although the retino- and tectorecipient thalamic nuclei and the visual hyperpallium appear to have enlarged and segregated further during the reptile to bird transition. This enhanced ability to process visual cues may be correlated with the evolution of flight.

2.05.4.2.4 Reptile to mammal transition As in other tetrapods, ganglion cells in the mammalian retina project to targets within the hypothalamus, ventral thalamus, dorsal thalamus, pretectum, midbrain tectum, and midbrain tegmentum. These are, respectively, the suprachiasmatic nucleus, ventral lateral geniculate, dorsal lateral geniculate, several pretectal nuclei, superior colliculus, and medial terminal nucleus (Figure 3d; Sefton and Dreher, 1985).

The flow of information from the retina to the telencephalon is often regarded as a 'dual visual system', but in fact visual information reaches the telencephalon through at least three distinct pathways. One pathway is from retina to thalamus (dorsal lateral geniculate) to primary visual cortex. The second and third pathways are relayed through the superior colliculus to the thalamus. However, the superior colliculus projects to multiple thalamic groups, including perigeniculate, midline, and intralaminar nuclei, in addition to the well-known lateral posterior/pulvinar nuclei (Holstege and Collewijn, 1982; Linke, 1999; Linke *et al*., 1999). Thus, the second pathway is from the retina to the superior colliculus (midbrain tectum) to the lateral posterior (or pulvinar in primates) thalamic nuclei to secondary visual cortical areas (Diamond, 1976). The third pathway is from the retina to the superior colliculus to the visual perigeniculate thalamus (particularly the suprageniculate nucleus), which projects to the striatum and lateral amygdala (Linke *et al*., 1999, 2000; Doron and LeDoux, 1999). Embryological studies

show that the lateral amygdala is derived from the ventrolateral pallium, whereas the visual cortex arises from the dorsomedial pallium (Fernandez *et al*., 1998; Puelles *et al*., 2000; Brox *et al*., 2004). The midline and intralaminar nuclei have widespread, nonspecific projections to cortical and striatal regions. Which of these colliculo-thalamo-telencephalic targets are comparable among the vertebrate classes is currently under considerable debate. However, connectional and embryological data indicate that the visual areas of the reptilian DVR and mammalian lateral amygdala are comparable, and those of the reptilian dorsal cortex and mammalian visual cortices are comparable (see Section 2.05.5.3).

2.05.4.2.5 Summary In all tetrapods the retina projects to the hypothalamus, ventral thalamus, dorsal thalamus, pretectum, mesencephalic tectum, and mesencephalic tegmentum. Thus, this pattern was present in a common ancestor. Furthermore, in all tetrapods retinal information is conveyed to the telencephalon by at least three distinct pathways: (1) a thalamocortical pathway that runs from the retina directly to a cell group in the thalamus, and then to a dorsomedial pallial region; (2) a tecto-thalamo-cortical pathway that travels from the retina to the midbrain tectum to a cell group in thalamus and then to a dorsomedial pallial region. This dorsomedial pallial region corresponds to visual parts of the medial pallium in amphibians, dorsal cortex in reptiles, hyperpallium in birds, and isocortex in mammals; and (3) a tecto-thalamo-amygdalar pathway that runs from the retina to the optic tectum to a different cell group in the thalamus, and then to both the striatum and a nucleated region within the ventrolateral pallium. This ventrolateral pallium corresponds to a visual area of the ventral lateral pallium in amphibians, DVR in reptiles, nidopallium in birds, and lateral amygdala in mammals.

Another noteworthy trend is the increase in size and complexity of the visual thalamic and cortical regions, which occurred during each transition, but was especially remarkable in the reptile to mammal transition. Identification of homologues between amphibians, reptiles, and birds has been relatively straightforward, but comparisons with the mammalian visual system have proven more difficult to make and more controversial.

2.05.4.3 Somatosensory System

2.05.4.3.1 Reptiles Somatosensory information about the body reaches the thalamus from the spinal cord and dorsal column nuclei (Figure 4b). Information about the head reaches the thalamus from the trigeminal nuclei. In addition, the spinothalamic, dorsal column and trigeminal regions project to a somatosensory midbrain area, which then projects to the thalamus (snakes: Ebbesson, 1969; lizards: Ebbesson, 1967; Bruce and Butler, 1984b; Ebbesson, 1978; turtles: Ebbesson, 1969; Siemen and Kunzle, 1994; Kunzle and Schnyder, 1983; Kunzle and Woodson, 1982; crocodiles: Pritz and Northcutt, 1980; Ebbesson and Goodman, 1981; Pritz and Stritzel, 1994).

Spinal and dorsal column somatosensory information appears to terminate in three thalamic regions in reptiles: (1) a posterior thalamic group called medialis posterior and posterocentralis nuclei in lizards, called the medialis complex in crocodilians, and called the lateral part of nucleus reuniens in turtles; (2) the dorsolateralis anterior nucleus; and (3) the ventral thalamic nuclei (Pritz and Northcutt, 1980; Ebbesson and Goodman, 1981; Bruce and Butler, 1984b; Belekhova *et al*., 1985; Siemen and Kunzle, 1994). Trigeminal nuclei have a similar projection pattern, terminating in the dorsolateralis anterior nucleus, in a region near medialis posterior, and in the ventral thalamus (Hoogland, 1982; Desfilis *et al*., 2002).

These three somatosensory-recipient thalamic areas have different ascending projections. The posterior thalamic group projects to posterior regions of the striatum and to the caudal part of the anterior DVR; the caudal DVR may project back to the somatosensory thalamus. Nucleus dorsolateralis anterior has reciprocal projections to the dorsal, medial, and lateral cortices, although the main cortical somatosensory target is believed to be the dorsal cortex. The ventral thalamic nuclei lack telencephalic connections (Bruce and Butler, 1984a, 1984b; Pritz and Northcutt, 1980; Balaban and Ulinski, 1981; Gonzalez *et al*., 1990; Pritz and Stritzel, 1994; Lohman and van Woerden-Verkley, 1978; Voneida and Sligar, 1979).

2.05.4.3.2 Amphibian to reptile transition Two spinal somatosensory pathways to the telencephalon are present in amphibians, and thus are presumed to be present in the common tetrapod ancestor (Figure 4a). In amphibia the spinal cord projects directly to the thalamus, or indirectly via the torus semicircularis in the midbrain. There are three spinal and midbrain thalamic targets: a massive projection to the ventral nuclei, a moderate projection to the central nucleus, and a sparse projection to the anterior nucleus (Munoz *et al*., 1997). A homologue of the dorsal column nuclei appears to project only to the ventral thalamic nuclei (Munoz

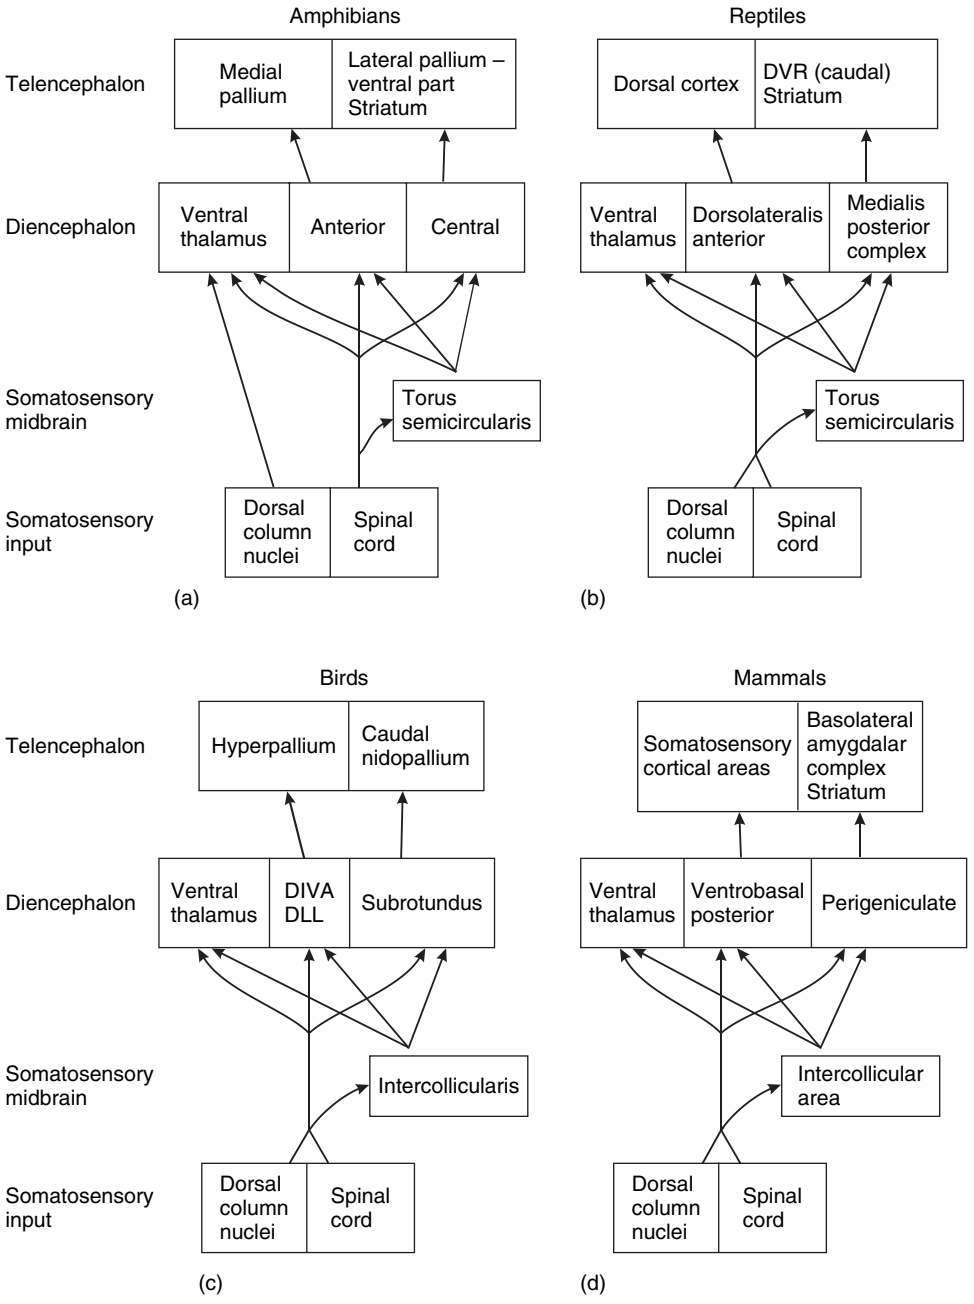

Figure 4 Comparison of the major ascending somatosensory pathways to the telencephalon in tetrapods. Refer to text for abbreviations.

et al., 1996) and thus more extensive brainstem-thalamic projections appear to have evolved in reptiles.

Three somatosensory-recipient thalamic groups in amphibians appear to correspond to those in reptiles: (1) the central thalamic nucleus, which projects heavily to the striatum and sparsely to the ventral part of the lateral pallium; (2) the anterior thalamic nucleus, which projects heavily to the medial pallium and sparsely to the dorsal and lateral pallia. Evoked potential studies suggest that the medial pallium is the target of polysensory ascending sensory information from the anterior thalamus (Karamian *et al*., 1966; Northcutt, 1970; Vesselkin *et al*., 1971; Mudry and Capranica, 1980); and (3) a ventral thalamic group lacks telencephalic projections (Neary, 1990). Thus, the central and anterior nuclei appear to be comparable to the reptilian posterior somatosensory group (medialis posterior and posterocentralis nuclei), and to the dorsolateralis anterior, respectively. Projections from the dorsal column nuclei to the dorsal thalamus appear to be

absent in amphibians, but present in reptiles, suggesting that the axons may have invaded new territory in a reptilian ancestor, or that the projection was present in the common tetrapod ancestor, but was lost in extant amphibians.

2.05.4.3.3 Reptile to bird transition The dorsal column nuclei, spinal cord, and trigeminal nuclei project to the midbrain (nucleus intercollicularis; Karten, 1963; Arends *et al*., 1984; Necker, 1989; Wild, 1997). They also have extensive thalamic projections, including: (1) three ventral thalamic nuclei, intercalatus, ventrolateral, and reticular nuclei; (2) nuclei that project to the hyperpallium, dorsointermedius ventralis anterior (DIVA), and DLL; and (3) a nucleus that projects to the caudal nidopallium, subrotundus. In addition, sensory information from the body and face reaches several intralaminar-like nuclei in birds (dorsolateralis posterior, and dorsolateralis anterior, pars medialis), but a comparable projection has not been reported in reptiles (Figure 4c; Karten, 1963; Schneider and Necker, 1989; Delius and Bennetto, 1972; Arends *et al*., 1984; Wild, 1989, 1997; Korzeniewska and Güntürkün, 1990; Veenman *et al*., 1997; Kroner and Güntürkün, 1999). There is a projection from the principle trigeminal nucleus directly to the nucleus basalis in the telencephalon, which is devoted to the bill and beak cavity sensation, and appears to be unique to birds (Cohen and Karten, 1974; Dubbeldam *et al*., 1981).

Thus, the basic pattern of most somatosensory connections was conserved during the evolution from reptiles to birds, although the thalamic targets were greatly elaborated in birds. A direct trigeminal projection to the telencephalon appears to be a unique avian feature. It may have evolved by the invasion of primary trigeminal fibers into the nearby parabrachial nucleus, which projects to the telencephalon in reptiles and mammals.

2.05.4.3.4 Reptile to mammal transition In mammals, spinothalamic, dorsal columnar, and trigeminal nucleus projections terminate in the mesencephalon (intercollicular area) and in four thalamic areas including: ventral thalamus (zona incerta); the ventrobasal and posterior thalamic nuclei; a perigeniculate area at the ventromedial edge of the medial geniculate; and the intralaminar nuclei, particularly the central lateral nucleus (Giesler *et al*., 1981; 1988; Cliffer *et al*., 1991; Willis and Coggeshall, 1991; LeDoux *et al*., 1987).

These four thalamic nuclei can be classified based on their additional connections: (1) a ventral thalamic nucleus that lacks projections to the telencephalon; (2) nuclei that project to the somatosensory cortex: the ventrobasal and posterior nuclei; (3) a limbic thalamic area that projects to the striatum and a ventrolateral pallial derivative, the basolateral amygdaloid complex, (LeDoux *et al*., 1987; Turner and Herkenham, 1991; Bordi and LeDoux, 1994; Price, 1995; Linke *et al*., 2000); and (4) intralaminar nuclei which project to the striatum and frontal motor cortex (Figure 4d).

2.05.4.3.5 Summary Somatosensory information from the spinal cord reaches the forebrain through similar pathways in all tetrapods, and thus appears to be a phylogenetically ancient feature. Somatosensory information from dorsal column nuclei appears to reach the telencephalon only in amniotes, suggesting that modifications of this pathway may have occurred in the common amniote ancestor. Three somatosensory recipient thalamic nuclei are common to all tetrapods including: (1) ventral thalamic nuclei; (2) nuclei that project to a cortical target; and (3) nuclei that project to a striatal and ventrolateral pallial target. An intralaminar-like somatosensory thalamic region has been identified in birds and mammals, and further studies are needed in amphibian and reptiles to determine its evolutionary origins (see The Evolution of the Dorsal Thalamus in Mammals, The Dual Elaboration Hypothesis of the Evolution of the Dorsal Thalamus).

This scheme suggests that the thalamic nuclei that project to the amphibian ventral lateral pallium, reptilian DVR, avian nidopallium, and mammalian pallial amygdala are homologous. This comparison is considered further in Section 2.05.5.3 (see Evolution of the Somatosensory System – Clues from Specialized Species, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?).

2.05.4.4 Olfactory System

In most tetrapods olfaction is detected in two peripheral organs, the main olfactory organ, which is sensitive to lighter, airborne molecules and the vomeronasal organ, which is sensitive to heavy odor molecules (Johnson and Leon, 2000). The vomeronasal system is unique to tetrapods and is involved in both foraging and reproductive behaviors, and in some pheromonally mediated behaviors (Eisthen, 1992; Halpern and Martinez-Marcos, 2003). The sensory neurons in the main olfactory organ and vomeronasal organ project to the main olfactory and accessory olfactory bulbs, respectively. This section compares the projections of the main and accessory olfactory bulbs.

2.05.4.4.1 Reptiles A vomeronasal organ is present in rhynchocephalians (tuatara), lizards, snakes, and turtles, but is absent in crocodilians and birds (Figure 5b). The central projections have been studied in four species of lizards, two snakes, a turtle, and caiman (Heimer, 1969; Scalia *et al.*, 1969; Halpern, 1976; Ulinski and Peterson, 1981; Reiner and Karten, 1985; Martinez-Garcia *et al.*, 1991; Lohman and Smeets, 1993; Lanuza and Halpern, 1998). The later studies that used more sensitive techniques provide greater details, and are the basis for the following summary.

The main olfactory bulb projections travel in a superficial sheet over the telencephalon to targets that include the olfactory tubercle, lateral cortex, rostral septum, nucleus of the diagonal band, and several cortical amygdalar nuclei. Olfactory fibers continue caudally in the stria medullaris, cross in the habenular commissure, and then innervate similar targets in the contralateral hemisphere.

The accessory olfactory bulb projects caudally, terminating in the medial amygdala and its medial extension (the bed nucleus of stria terminalis), in the nucleus sphericus in both lizards and snakes, and in

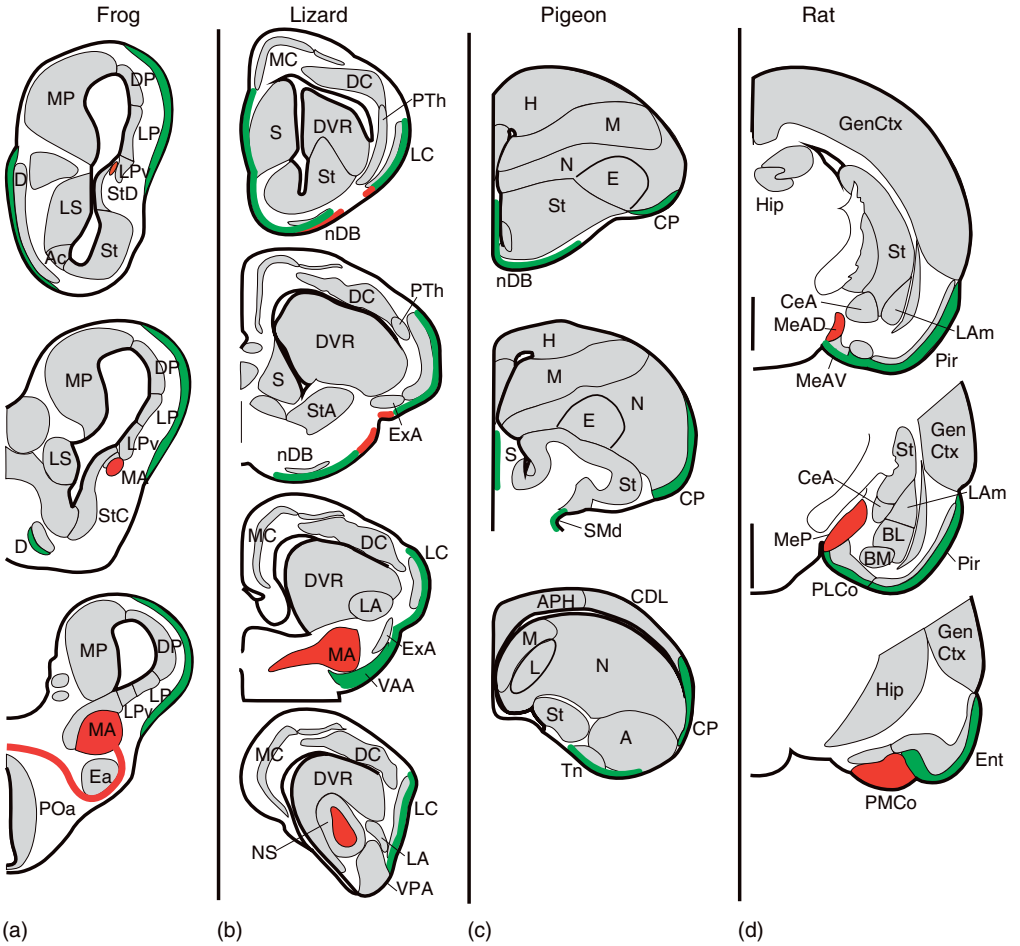

Figure 5 Comparison of the pathways from main olfactory bulb (green) and accessory olfactory bulb (red) in (a), amphibians; (b), reptiles; (c), birds; and (d), mammals. Sections are through the right hemisphere, with rostral sections at the top. Abbreviations: Frog – Ac, accumbens; D, nucleus of the diagonal band; DP, dorsal pallium; Ea, anterior entopeduncular nucleus; LP, lateral pallium; LPv, ventral part of the lateral pallium; LS, lateral septal nucleus; MA, medial amygdala; MP, medial pallium; POa, anterior preoptie area; St, striatum; StC, caudal striatum; StD, dorsal striatum. Lizard – DC, dorsal cortex; DVR, dorsal ventricular ridge; ExA, external amygdalar nucleus; LA, lateral amygdala; LC, lateral cortex; MA, medial amygdala; MC, medial cortex; nDB, nucleus of the diagonal band; NS, nucleus sphericus; PTh, pallial thickening; S, septal nuclei; St, striatum; StA, striatoamygdalar area; VAA, ventral anterior amygdala; VPA, ventral posterior amygdala. Pigeon – A, arcopallium; APH, area parahippocampalis; CDL, dorsal lateral cortex; CP, cortex piriformis; E, entopallium; H, hyperpallium; L, Field L; M, mesopallium; nDB, nucleus of the diagonal band; N, nidopallium; S, septal nuclei; St, striatum; SMd, stria medullaris tract, dorsal part; Tn, nucleus Taeniae. Rat – BL, basolateral amygdala; BM, basomedal amygdala; CeA, central amygdala; Ent, entorhinal cortex; GenCtx, general (nonolfactory, nonhippocampal) cortex; Hip, hippocampus; LAm, lateral amygdala; MeAD, anterodorsal division of medial amygdala; MeAV, anteroventral division of medial amygdala; MeP, medial pallium; Pir, piriform cortex; PLCo, posterior lateral cortical amygdala; PMCo, posterior medial cortical amygdala; St, striatum. Modified from Bruce, L. L. and Neary, T. J. 1995c. The limbic system of tetrapods: A comparative analysis of cortical and amygdalar populations. *Brain Behav. Evol.* 46, 224–234.

the ventral posterior amygdala in at least one lizard (Martinez-Garcia *et al*., 1991). Nucleus sphericus is present in most squamate reptiles, and is correlated with the importance of chemosensory function in their ecology (Halpern and Martinez-Marcos, 2003). Although a vomeronasal system is present in Testudamorpha, it is uncertain whether or not Reiner and Karten included it in their olfactory bulb injections (Reiner and Karten, 1985).

2.05.4.4.2 Amphibian to reptile transition Olfactory pathways have been studied in tiger salamanders and three species of ranid frogs (Northcutt and Royce, 1975; Kokoros and Northcutt, 1977; Kemali and Guglielmotti, 1987; Scalia *et al*., 1991; Moreno *et al*., 2005). The targets of the main olfactory bulb are very similar to those in reptiles, and include the postolfactory eminence, lateral and dorsal pallia, rostral septum, nucleus of the diagonal band, and ventral part of the lateral pallium (LPv; sometimes named the lateral amygdala); and a rostral part of the medial amygdala. The lateral and dorsal pallia are comparable to the reptilian lateral cortex, and the LPv and rostral medial amygdala may be comparable in part to the reptilian olfactory cortical amygdala (Bruce and Neary, 1995c; Moreno *et al*., 2005). A fascicle of fibers decussates in the habenular commissure, comparable to that in reptiles (Figure 5a).

A vomeronasal system is present in most aquatic and terrestrial amphibians, but is absent in some aquatic salamanders (Eisthen, 2000). The accessory olfactory bulb projects to the medial amygdaloid nucleus (formerly called the lateral amygdala) and to part of the caudal LPv. Accessory fibers cross in both the anterior commissure and the habenular commissure, unlike the ipsilateral reptilian condition. Thus, most accessory olfactory targets receive bilateral input. The amphibian medial amygdala thus appears comparable to the reptilian medial amygdala, and part of the caudal LPv appears comparable to the reptilian accessory recipient cortical nucleus. Furthermore, the reptilian nucleus sphericus appears to be a specialization of the accessory olfactory amygdala, reflecting the importance of vomeronasal information in the ecology of squamate reptiles.

2.05.4.4.3 Reptile to bird transition Birds, like crocodilians, have a main olfactory system but lack a vomeronasal system (Figure 5c). Olfactory bulb projections have been reported in pigeons and ducks (Reiner and Karten, 1985; Ebinger *et al*., 1992). The targets are remarkably similar to those seen in reptiles. Targets of the olfactory bulb include the olfactory tubercle, cortex pyriformis, rostral septum, nucleus of the diagonal band, and cortical amygdalar nuclei in the caudal telencephalon, including nucleus Taeniae. Axons cross in the habenular commissure. Unlike reptiles, the olfactory bulb does not project to most of the caudal telencephalic pole (the arcopallium).

2.05.4.4.4 Reptile to mammal transition In mammals, the main and accessory olfactory bulb projections are entirely ipsilateral (Figure 5d). Main olfactory bulb targets include the olfactory tubercle, olfactory cortex (pyriform and entorhinal), nucleus of the diagonal band, several cortical amygdalar areas (anterior amygdala, anterior cortical, and posterolateral cortical amygdalar nuclei), and the ventral anterior part of the medial amygdala (de Olmos *et al*., 1978; Switzer *et al*., 1985). Accessory olfactory bulb projections include most of the medial amygdala, the medial bed nucleus of the stria terminalis, and the posteromedial cortical amygdalar nucleus. Thus, the main and accessory olfactory targets of mammals are very similar to those of reptiles, except that mammals lack contralateral main olfactory projections.

2.05.4.4.5 Summary The main olfactory bulb targets are similar in all tetrapods, suggesting they were present in a common ancestor. A contralateral projection through the habenular commissure is present in amphibians, reptiles, and birds, but not mammals, suggesting it was lost in a mammalian ancestor.

Likewise, the accessory olfactory bulb targets are similar among most tetrapods, suggesting they were established in a common ancestor. However, contralateral projections are present only in amphibians, suggesting they were lost in ancestral reptiles. In squamate reptiles, the vomeronasal targets include nucleus sphericus, which is probably derived from the vomeronasal amygdala (Bruce and Neary, 1995c; Lanuza and Halpern, 1998). The absence of the vomeronasal system in crocodilians and birds, cetaceans, and in some primates suggests that it was lost independently in several taxa (see Evolution of Vertebrate Olfactory Subsystems, The Evolution of the Vomeronasal System).

2.05.5 Brain Regions

2.05.5.1 Hindbrain: Cranial Motor Nuclei

There are a number of extensive reports and reviews on the development and evolution of the tetrapod hindbrain (Barbas-Henry and Lohman, 1984, 1988a, 1988b; Roth *et al*., 1988; Szekely and Matesz, 1988; Bruce *et al*., 1997; Fritzsch, 1998; Gilland and Baker, 2005). These are summarized in the following description of cranial nerve motor nuclei (Figure 6).

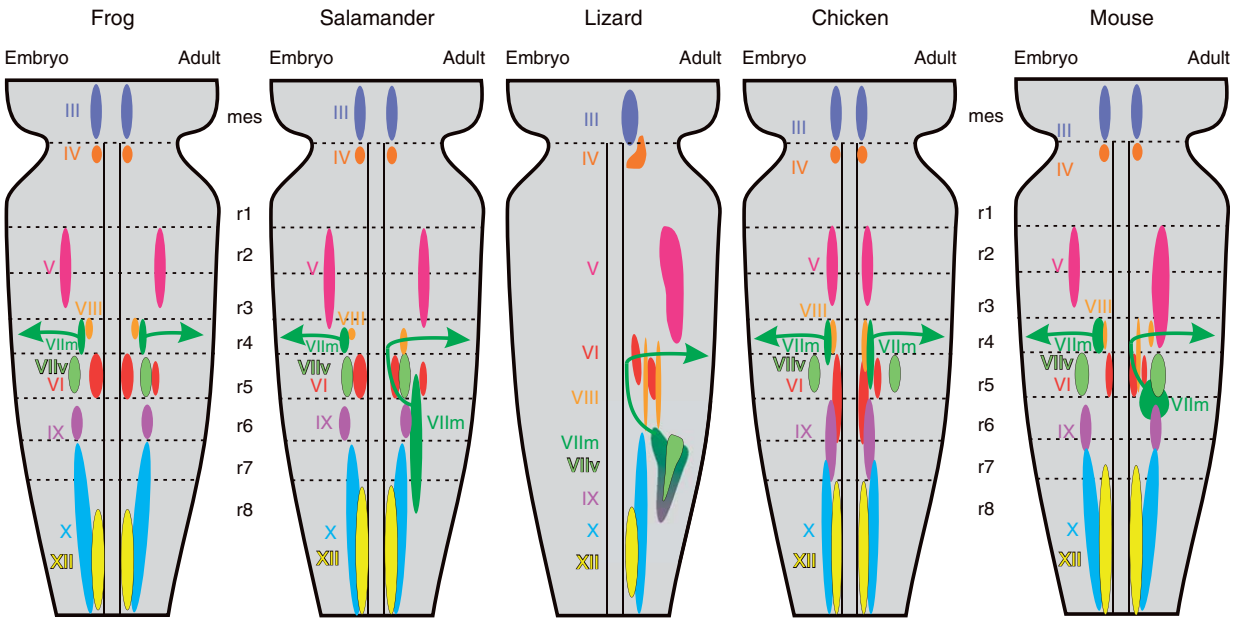

Figure 6 Comparison of the embryonic (left side) rhombomeric origin (r1–r8) and adult (right side) locations of cranial nerve motor nuclei in frog, salamander, lizard (adult only), chicken, and rat. Green arrows show the trajectory of VIIm axons. Note that the facial genu is formed by the caudal migration of VIIm neurons. Modified from Gilland, E. and Baker, R. 2005. Evolutionary patterns of cranial nerve efferent nuclei in vertebrates. *Brain Behav. Evol.* 66, 234–254 and Fritzsch, B. 1998b. Ontogenetic and evolutionary evidence for the motoneuron nature of vestibular and cochlear efferents. In: The Efferent Auditory System: Basic Science and Clinical Applications (*ed.* C. I. Berlin), pp. 31–60. Singular.

Hindbrain motor neurons can generally be divided into three major groups: somatic (cranial nerves III, IV, VI, and XII), branchiomotor (V, VII, IX, X, and XI), and visceral (VII, IX, and X). Somatic and branchiomotor neurons innervate striated muscle, and visceromotor neurons innervate parasympathetic ganglia. The octavolateral efferents innervate the auditory and vestibular periphery of tetrapods, as well as mechanosensory hair cells in the lateral line of amphibians, and are closely related to the branchiomotor neurons of VII.

The cranial nerve nuclei of all vertebrates are born near the midline floorplate and are derived from similar rostrocaudal segments, or rhombomeres, and from similar dorsoventral partitions within the hindbrain. A variety of genes regulate rhombomeric (e.g., Hox and Fgf gene families) and dorsoventral organization (e.g., Shh). Variations in gene expression are correlated with variations in the origin of the cranial nerve nuclei, and are beyond the scope of this review. The hindbrain is divided into eight rhombomeres (r1–8), although in mammals r8 is indistinct and usually included in r7. The development of hindbrain motor neurons has not been adequately studied in reptiles, but they are believed to follow the avian pattern.

2.05.5.1.1 Oculomotor nuclei (III) In all tetrapods the oculomotor motor neurons are born in the somatic column in the caudal mesencephalon, and remain near their origin. Their axons project mainly ipsilaterally, with contributions from a few cells in the contralateral caudal pole.

2.05.5.1.2 Trochlear nuclei (IV) Trochlear motor neurons of tetrapods derive from the contralateral somatic column in the rostral part of r1, and remain there. Their axons take a unique dorsal trajectory, decussating at the dorsal midline and then exiting the brain. A few ipsilateral trochlear neurons are present in mice.

2.05.5.1.3 Trigeminal nuclei (V) In all tetrapods the trigeminal motor nuclei are derived from r2 and the rostral two-thirds of r3. They remain close to their origin. Motor neurons derived from r2 appear to innervate muscles homologous to jaw adductors; those from r3 innervate the jaw openers (Song and Boord, 1993).

2.05.5.1.4 Abducens nuclei (VI) The origin of the abducens nucleus is variable, arising from r5 alone (frogs, salamanders, and mammals) or from both r5and r6 (chickens). In all tetrapods the abducens gives rise to the principal abducens, which remains adjacent to the medial longitudinal fascicle and innervates the lateral rectus muscle of the eye, and to the accessory abducens, which migrates laterally and innervates the ocular retractor muscles.

2.05.5.1.5 Facial motor nuclei (VIIm) In salamanders the facial motor nuclei are born in the caudal half of r4; in frogs, chickens, and mammals they originate from the full extent of r4. The facial motor nucleus migrates caudally but variably in salamanders, chickens, mice, but not in frogs. In salamanders it migrates to r5 and further caudally so that it overlaps the entire glossopharyngeal and parts of the vagus and hypoglossal nuclei. In chickens it extends from r4 to r5, and in mice from r5 to r6. In adult lizards the facial motor nucleus is located caudal to the abducens, suggesting that this is also a migrated population. Adult lizards have a flexure in their caudal brainstem, making relationships to other tetrapods imprecise. In animals with a migrated facial population, an internal facial genu is formed by the axons that remain in the migratory route. The facial motor nucleus innervates muscles derived from the second branchial arch.

2.05.5.1.6 Octavolateral nuclei (VIII) The octavolateral nucleus derives from the same ventricular area of r4 as the facial motor nucleus. In all tetrapods the octavolateral nuclei remain in r4, but in lizards and mice some of the neurons migrate laterally and away from the ventricle and form two clusters. In chickens a contralateral octavolateral population forms by neuronal migration across the midline; in mice it forms by the growth of axons to the contralateral side. Lizards also have a contralateral projection, although its origin is unknown. The octavolateral efferents innervate hair cells in the auditory and vestibular epithelia. In amphibians a group of octavolateral efferents arising from r4 (with the facial motor) and r6 (with the glossopharyngeal) innervate mechanoreceptors of the lateral line.

2.05.5.1.7 Facial visceral nuclei (VIIv) Also known as the superior salvitory nucleus, the facial visceral nucleus arises from r5 in all tetrapods, and remains there in adults. Although in reptiles the facial motor, facial visceral, glossopharyngeal, and vagal nuclei appear to overlap in dorsal view because of the flexure in this region, they are largely distinct nuclei (Figure 6). The facial visceral nucleus innervates postganglionic neurons to the Haderian gland.

2.05.5.1.8 Glossopharyngeal nuclei (IX) The glossopharyngeal nuclei include both a branchiomotor and a visceral group. In frogs and mammals the glossopharyngeal nuclei originate from r6, but in chickens they originate from both r6 and r7. The neurons remain in their rhombomere of origin. In adult salamanders and lizards the glossopharyngeal nuclei are intermingled with the facial motor neurons. The glossopharyngeal nucleus innervates muscles derived from the third branchial arch.

2.05.5.1.9 Vagal nuclei (X) The vagal nuclei of frogs and mice originate from r7 and r8, whereas those of chickens originate from r8. In adults the vagal nuclei may extend into the spinal cord, but it is not clear if this is due to neuronal migration.

2.05.5.1.10 Spinal accessory nuclei (XI) In tetrapods the spinal accessory nuclei originate in the rostral spinal cord. Its rostral extent often blends with the caudal extent of the vagal nuclei.

2.05.5.1.11 Hypoglossal nuclei (XII) Hypoglossal nuclei are present in all tetrapods with tongues. The rostral pole originates from progressively more rostral levels in frogs (caudal border of r8; called the first spinal nerve nucleus), chickens (caudal border of r7; called the supraspinal nucleus), and mice (middle of r7). The hypoglossal nucleus innervates the tongue musculature.

2.05.5.1.12 Summary The comparative development of the tetrapod hindbrain motor nuclei is fairly sparse, and requires analysis of more taxa, particularly from reptiles. The rostral poles of the motor nuclei have similar rhombomeric limits in all tetrapods, and thus appears to be a highly conserved feature. In contrast, the caudal pole may vary by as much as one rhombomere, particularly in chickens, and thus appears to be under fewer genetic constraints. Motor nuclei V, VIIm, and VIII migrate caudally from their ventricular origins in some taxa. In frogs there is no caudal migration, in salamanders only the facial motor nucleus migrates, in chickens the facial motor and octavolateralis nuclei migrate, and in mice the facial motor, octavolateralis, and trigeminal nuclei migrate caudally. Thus, caudal migration appears to be most prominent in mammals and least prominent in amphibians. The genu of the facial nerve forms as a result of the caudal neuronal migration, and is prominent in salamanders, lizards, and mammals. Thus, the facial genu may have been present in the common ancestor of amphibians, mammals, and reptiles, but lost in the anuran lineage.

2.05.5.2 Dorsal Thalamus

The reptilian diencephalon consists of the epithalamus, dorsal thalamus, ventral thalamus, and the hypothalamic regions. The organization of the dorsal thalamus is the best-studied region, yet some of its mammalian homologues are controversial. Thus,

the functional connections will be described and compared in this section.

2.05.5.2.1 Reptiles The reptilian dorsal thalamus consists of nuclei that project to and often receive projections from the telencephalon. It can be subdivided into at least four groups on the basis of connectional and functional characteristics (Table 1).

1. *Nuclei that receive specific sensory projections and project to the cortex*. In squamates this group includes the dorsolateralis anterior (DLA) and a retino-recipient nucleus, called either lateral geniculate, intercalatus, or the lateral part of the dorsolateralis anterior (Hall and Ebner, 1970a, 1970b; Cruce and Cruce, 1975; Hall *et al*., 1977; Hoogland, 1982; Bruce and Butler, 1984a, 1984b; Bennis *et al*,. 1994; Desfilis *et al*., 2002; Guirado and Davila, 2002). The DLA receives spinal, septal, and hypothalamic projections and a small projection from the auditory/vocal area of torus semicircularis in the midbrain. In some lizards the DLA is further subdivided into the pars magnocellularis (DLAm), which projects bilaterally to the lateral and medial cortices, and the pars parvocellularis (DLAp), which projects ipsilaterally to the dorsal cortex and pallial thickening. In Testudamorpha these subdivisions correspond to the dorsomedial anterior and the dorsolateral anterior, respectively (Desan, 1988; Zhu *et al*., 2005).
2. *Nuclei that receive specific sensory brainstem projections and project to specific regions of the striatum and DVR*. These include rotundus, medialis (reuniens in turtles and crocodilians), and medialis posterior (caudalis in turtles; medialis complex in crocodilians), which convey visual, auditory, and somatosensory information, respectively (see Section 2.05.4).
3. *A nonspecific midline area that receives widespread input and projects to cortex, DVR, central amygdala, accumbens and striatum* (Hoogland, 1982; Gonzalez *et al*., 1990; Desfilis *et al*., 2002; Heredia *et al*., 2002). In lizards the dorsomedial nucleus projects to the accumbens, striatum, and receives projections from the septum, preoptic area, ventromedial hypothalamus, ventral thalamus, and locus coeruleus.
4. *Calcitonin gene-related peptide (CGRP)-positive neurons that project to the pallium (cortex and DVR)*. In lizards these cells lie at the posterior ventral pole of the thalamus (Martinez-Garcia *et al*., 2002a).

Table 1 Comparisons of dorsal thalamic nuclei in tetrapods

	Reptile				*Mammal (rodent)*	
Amphibian	*Lizard*	*Crocodilian*	*Turtle*	*Birds*	*Revised*	*Traditional*
	DM		DM	DLM, DMA, DMP, SHL, DIP, DLP	Paraventricular, MD, CL, CM, PC, PF, IMD	Paraventricular, MD, CL, CM, PC, PF, IMD
Anterior	DLAm and DLAp		Dorsomedial anterior and Dorsolateral anterior	Superficialis parvocellularis, DLA	Anterior, reuniens, VPM, VPL, MGN, LP	Anterior, reuniens
Anterior	Intercalatus (lateral DLA)		Dorsal lateral geniculate	Dorsal optic complex	Dorsal lateral geniculate	Dorsal lateral geniculate
Lateral	Rotundus	Rotundus	Rotundus	Rotundus	Perigeniculate: Supragenículate	Lateral posterior (pulvinar)
Central	Medialis	Reuniens	Reuniens	Ovoidalis	Perigeniculate: MGm	Medial geniculate
Central	Medialis Posterior and posterocentral	Medialis complex	Caudalis	Subrotundus	Perigeniculate: Posterior intralaminar	VPM, VPL
				Ventral intermediate area	VA, VL	VA, VL

CM, central medial thalamic nucleus; CL, centrolateral thalamic nucleus; DIP, nucleus dorsointermedius posterior thalami; DM, nucleus dorsomedialis; DLA, dorsolateral anterior thalamic nucleus; DLAm, dorsolateral anterior thalamic nucleus, magnocellular part; DLAp, dorsolateral anterior thalamic nucleus, parvocellular part; DLM, nucleus dorsolateralis anterior thalami, pars medialis; DMA, nucleus dorsomedialis anterior thalami; DMP, nucleus dorsomedialis posterior thalami; DLP, nucleus dorsolateralis posterior thalami; IMD, intermediodorsal nucleus; LP, lateral posterior thalamic nucleus; MD, mediodorsal nucleus; MGN, medial geniculate nucleus; PC, paracentral thalamic nucleus; PF, parafascicular thalamic nucleus; SHL, lateral subhabenular nucleus; VA, ventral anterior thalamic nucleus; VL, ventral lateral thalamic nucleus; VPM, ventral posterior medial thalamic nucleus; VPL, ventral posterior lateral thalamic nucleus.

2.05.5.2.2 Amphibian to reptile transition The amphibian dorsal thalamus consists of the anterior, central, and lateral thalamic nuclei (Neary and Northcutt, 1983).

1. *Nuclei that receive specific sensory projections and project to the cortex* (Mudry and Capranica, 1980; Wilczynski and Northcutt, 1983a; Neary, 1984, 1988, 1990; Allison and Wilczynski, 1991; Montgomery and Fite, 1991; Northcutt and Ronan, 1992). The anterior thalamic nucleus receives visual inputs from the retina, somatosensory inputs from the obex region, spinal cord, and torus semicircularis, and auditory inputs from the lateral torus semicircularis and pretectal grey. It projects heavily to the medial and dorsal pallia and the septum, and more weakly to most parts of the telencephalon and the ventral hypothalamus.
2. *Nuclei that receive specific sensory brainstem projections and project to specific regions of the striatum and DVR*. Both the central and lateral thalamic nuclei receive widespread sensory brainstem projections and project to specific regions within the striatum and ventral part of the lateral pallium (Wilczynski and Northcutt, 1983a, 1983b; Hall and Feng, 1987; Neary, 1990, 1995; Allison and Wilczynski, 1991; Feng and Lin, 1991). The central nucleus receives input from the optic tectum and somatosensory part of the torus semicircularis. The lateral thalamic nucleus receives input from the auditory part of the torus semicircularis. Both the lateral and central nuclei project to the striatum and the ventral part of the lateral pallium.
3. *A nonspecific midline area that receives widespread input and projects to the telencephalon.* Neurons with these characteristics have not been described in amphibians.
4. *CGRP-positive neurons that project to the pallium.* These neurons are scattered within the ventromedial and posterior part of the central thalamic nuclei (Petko and Santa, 1992).
5. Thus, at least three of the four thalamic groups present in reptiles are also recognized in amphibians, suggesting that they were present in the common tetrapod ancestor. A nonspecific midline thalamic area has not been identified in amphibians, and further studies are needed to determine if it exists. Furthermore, the reptilian thalamus appears to have increased in size and become further segregated during the amphibian to reptile transition.

2.05.5.2.3 Reptile to bird transition The following thalamic groups are present in birds:

1. *Nuclei that receive specific sensory projections and project to the cortex*. Visual information from both the retina and optic tectum reaches the dorsolateralis pars lateralis (DLL), SPC, and LdOPT, whereas only the retina projects to the DLAmc. Somatosensory information from the torus semicircularis reaches the DIVA and DLL. All these thalamic nuclei project to visual and somatosensory Wulst areas in the hyperpallium (hyperstriatum).
2. *Nuclei that receive specific sensory brainstem projections and project to specific regions of the striatum and DVR (see Section 2.05.5.3)*. Auditory, visual, and somatosensory information reaches nucleus ovoidalis, nucleus rotundus, and nucleus subrotundus, respectively. Each of these thalamic nuclei then projects to a unique target in the nidopallium (previously called the neostriatum).
3. *A nonspecific midline area that receives widespread input and projects to cortex, nidopallium, accumbens, and striatum*. The dorsomedialis posterior, dorsomedialis anterior, subhabenular nucleus, dorsointermedius posterior nucleus, and dorsolateralis posterior meet these connectional criteria, and have also been compared to mammalian homologues based on neurochemical and mRNA expression patterns (Veenman *et al*., 1997; Bruce *et al*., 2002; Atoji and Wild, 2005).
4. *CGRP-positive neurons that project to the pallium*. A scattered population of CGRP-expressing neurons that projects to the hyperpallium and nidopallium is mainly located in the shell surrounding nucleus ovoidalis and in nucleus dorsolateralis posterior (Brauth and Reiner, 1991; Lanuza *et al*., 2000).
5. *Thalamic nuclei that receive motor input from cerebellar nuclei, substantia nigra, and globus pallidus, and project to the pallium*. In pigeons the ventral intermediate area has these characteristics (Medina *et al*., 1997).

Thus four of the five thalamic groups (1, 2, 3, and 4) described in birds can also be identified in reptiles (Table 2). However, a motor thalamic nucleus (5) has been identified in birds, but not reptiles. Further studies are needed to determine if it has a reptilian homologue. Also noteworthy is the increased size of many of the avian thalamic nuclei, compared to those in reptiles.

Table 2 Comparison of current models of the evolution of the avian hyperpallium, mesopallium, and sensory nidopallium

	Hyperpallium dorsal cortex	*Mesopallium pallial thickening*	*Sensory nidopallium anterior DVR*	*Caudal nidopallium posterior DVR*
Bruce and Neary (1995c), and Bruce (this article)	Isocortex	Claustrum and endopiriform	Lateral amygdala (sensory part)	Basolateral amygdala
Striedter (1997)	Isocortex	Claustrum	Endopiriform	Pallial amygdala
Puelles *et al.* (2000) and Martinez-Garcia *et al.* (2002b)	Isocortex – claustrum	Isocortex – claustrum	Endopiriform	Basal and lateral amygdalar nuclei
Butler and Molnar (2002)	Isocortex	Not mentioned	Isocortex, claustrum, endopiriform, basal and lateral amygdalar nuclei	Isocortex, claustrum, endopiriform, basal and lateral amygdalar nuclei
Karten (1997) and Reiner (2000)	Isocortex	Isocortex	Isocortex	Isocortex

These four avian territories (top row) are compared to their suggested mammalian homologue according to the proposals of various authors (left column).

2.05.5.2.4 Reptile to mammal transition The following thalamic groups are present in mammals:

1. *Nuclei that receive specific sensory projections and project to the cortex*. Auditory information from the inferior colliculus reaches the medial geniculate nucleus. Visual information from the retina reaches the dorsal lateral geniculate, and from the superior colliculus reaches the lateral posterior nucleus in rodents (LP; called pulvinar in primates). Somatosensory information from the spinal cord, dorsal column nuclei, trigeminal nuclei, and intercollicular area reaches the ventrobasal and posterior nuclei. All of these thalamic nuclei project to specific auditory, visual, and somatosensory areas in the isocortex.
2. *Nuclei that receive specific sensory brainstem projections and project to specific regions of the striatum and amygdala (see Section 2.05.5.3)*. Auditory, visual, and somatosensory information reaches the perigeniculate region, sometimes called the posterior intralaminar region. Each of these thalamic nuclei then projects to a different region of the lateral amygdala (Doron, and LeDoux, 1999; LeDoux *et al.*, 1987, 1990; Linke, 1999; Linke *et al.*, 1999, 2000; Linke and Schwegler, 2000).
3. *A nonspecific midline area that receives widespread input and projects to cortex, amygdala, accumbens, and striatum*. The centromedial thalamic nucleus, intermediodorsal, paraventricular, and parafascicular nuclei meet these connectional criteria and also have similar neurochemical expression patterns (Veenman *et al.*, 1997; Bruce *et al.*, 2002).
4. *CGRP-positive neurons that project to the pallium*. CGRP-expressing neurons project to diffuse targets in the cortex, amygdala, and striatum. They are scattered in the peripeduncular nucleus, posterior intralaminar nucleus, subparafascicular nucleus pars lateralis, and subparafascicular nucleus (Brauth and Rener, 1991; Yasui *et al.*, 1991).
5. *Thalamic nuclei that receive motor input from cerebellar nuclei, substantia nigra, and globus pallidus, and project to the pallium*. The ventral lateral and ventral anterior thalamic nuclei meet these criteria (Price, 1995).

The reptile to mammal transition is marked by a considerable increase in size and subdivisions of the thalamic nuclei that project to the cortex. At least three of these thalamic populations are comparable in reptiles and mammals (1, 3, and 4). A motor thalamic nucleus (5) has not yet been identified in reptiles, although one is present in birds. Whether the reptilian thalamic nuclei that project to the DVR should be compared with the mammalian thalamic nuclei that project to the cortex (traditional view) or with those that project to the lateral amygdala (revised view), is an ongoing controversy. These two thalamic populations appear to have few discriminating neurochemical expression patterns, which would resolve the issue. The group they are compared to is currently determined by the homology of their telencephalic target, a controversy addressed in Section 2.05.5.3. Most evidence suggests that the reptilian thalamo-DVR population is comparable to the mammalian thalamo-amygdalar population.

2.05.5.2.5 Summary The transition from amphibians to reptiles, and from reptiles to birds and mammals is marked by an increased hypertrophy and segregation of the thalamic groups with projections to the cortex. Homologues of the reptilian thalamic nuclei that project to the DVR have been identified in amphibians and birds, but the comparable group in mammals is controversial, with some

comparing these nuclei to the sensory nuclei that project to specific cortical areas (traditional view), and others to sensory nuclei that project to the lateral amygdala (revised view). Two additional thalamic groups, sensory nuclei that project to the cortex, and a CGRP-positive group, are present in amphibians, reptiles, birds, and mammals, suggesting that they were present in the common ancestor of tetrapods. A nonspecific midline group with widespread pallial projections is present in reptiles, birds, and mammals, but has not been identified in amphibians, and a motor thalamic group has been identified in birds and mammals, but not in reptiles or amphibians. Further study is needed to determine if these are present, before its evolutionary appearance can be considered.

2.05.5.3 Telencephalon

2.05.5.3.1 Reptiles The reptilian telencephalon contains two major divisions, the pallium and the subpallium. This section focuses on the pallium (telencephalic roof), including the pallial amygdalar nuclei. The pallium includes the medial, dorsal, and lateral cortices, the pallial thickening, DVR, and several amygdaloid nuclei (Figures 7b and 8b). The subpallium includes the striatum, central amygdaloid nucleus, and most septal nuclei. The medial amygdaloid nucleus contains both pallial and subpallial characteristics (Northcutt, 1978; Puelles *et al*., 2000; Brox, *et al*., 2004).

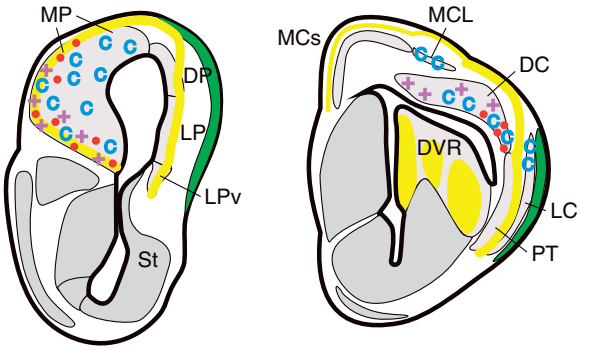

Figure 7 Comparison of pallial connections in frog (a), and lizard (b). Schematic shows the locations of neurons that project to the contralateral pallium (c), to the thalamus (+), and to the hypothalamus (red dots) in sections through the right hemisphere. Terminal areas from neurons in the olfactory bulb (green), and thalamic nuclei (yellow) (anterior nucleus in frogs; dorsolateral and dorsal lateral geniculate in reptiles) and caudal thalamic nuclei (lateral and central in frogs; medialis, medialis posterior, and rotundus in lizards: orange) are also shown. Rostral-most sections are at the top. Note that the connections of the ventral part of the frog medial pallium are most similar to those of the lizard DC. Abbreviations: frog – DP, dorsal pallium; LP, lateral pallium; LPv, ventral part of the lateral pallium; MP, medial pallium; St, striatum. Lizard – DC, dorsal cortex; DVR, dorsal ventricular ridge; LC, lateral cortex; MCL, large-celled part of medial cortex; MCs, small-celled part of medial cortex; PT, pallial thickening.

Cortical regions. The lateral cortex is the primary target of the main olfactory bulb, and reciprocates this connection (Lohman and Mentink, 1972; Martinez-Garcia *et al*., 1991; Lohman and Smeets, 1993; Lanuza and Halpern, 1998). The medial cortex is generally regarded to be a hippocampal region based on connectional and neurochemical staining patterns (e.g., Ariëns Kappers *et al*., 1936; Northcutt, 1969; Belekhova and Kenigfest, 1983; Bruce and Butler, 1984b; Olucha, 1988; Perez-Clausell, 1988; Smeets *et al*., 1989, Butler, 1994), and corresponds to the medial cortex of Testudamorpha (Desan, 1988; Zhu, 2005). The dorsal cortex appears to be a general cortical area (e.g., nonhippocampal, nonolfactory cortex). It is reciprocally connected with sensory thalamic nuclei and with the contralateral hemisphere (Northcutt, 1969, 1981; Hall and Ebner, 1970a; Bruce and Butler, 1984a; Desan, 1988; Hoogland and Vermeulen-Vanderzee, 1989; Reiner, 1991; Butler, 1994; Bruce and Neary, 1995c).

Pallial thickening. In turtles part of the pallial thickening lies deep to the olfactory-recipient lateral cortex, but the rest (the primary visual thalamic target) extends superficially and becomes continuous with the dorsal cortex (Desan, 1988; Zhu, 2005). The deep part of the pallial thickening lies over the sensory-recipient DVR, and has mainly intrinsic telencephalic connections. In lizards the pallial thickening receives a projection from the dorsolateral anterior nucleus and from the retinothalamic nucleus (intercalatus or dorsal lateral geniculate) (Bruce and Butler, 1984a; Kenigfest *et al*., 1997; Desfilis *et al*., 2002). Further studies are needed to determine if these projections are segregated into two regions of the pallial thickening, as in turtles. The pallial thickening appears to be mainly a lateral pallial derivative (Fernandez *et al*., 1998).

Dorsal ventricular ridge (DVR). The anterior DVR contains three sensory-recipient regions (auditory, visual, and somatosensory). The posterior DVR contains a caudomedial region that projects to the ventromedial hypothalamus, and a caudodorsal region that projects to the lateral hypothalamus (Bruce and Neary, 1995c). Based on Testudamorpha and avian data, the anterior DVR appears to be a ventral pallial derivative and the posterior DVR appears to include both ventral and lateral pallial territories (Fernandez *et al*., 1998; Puelles *et al*., 2000; Martinez-Garcia *et al*., 2002b).

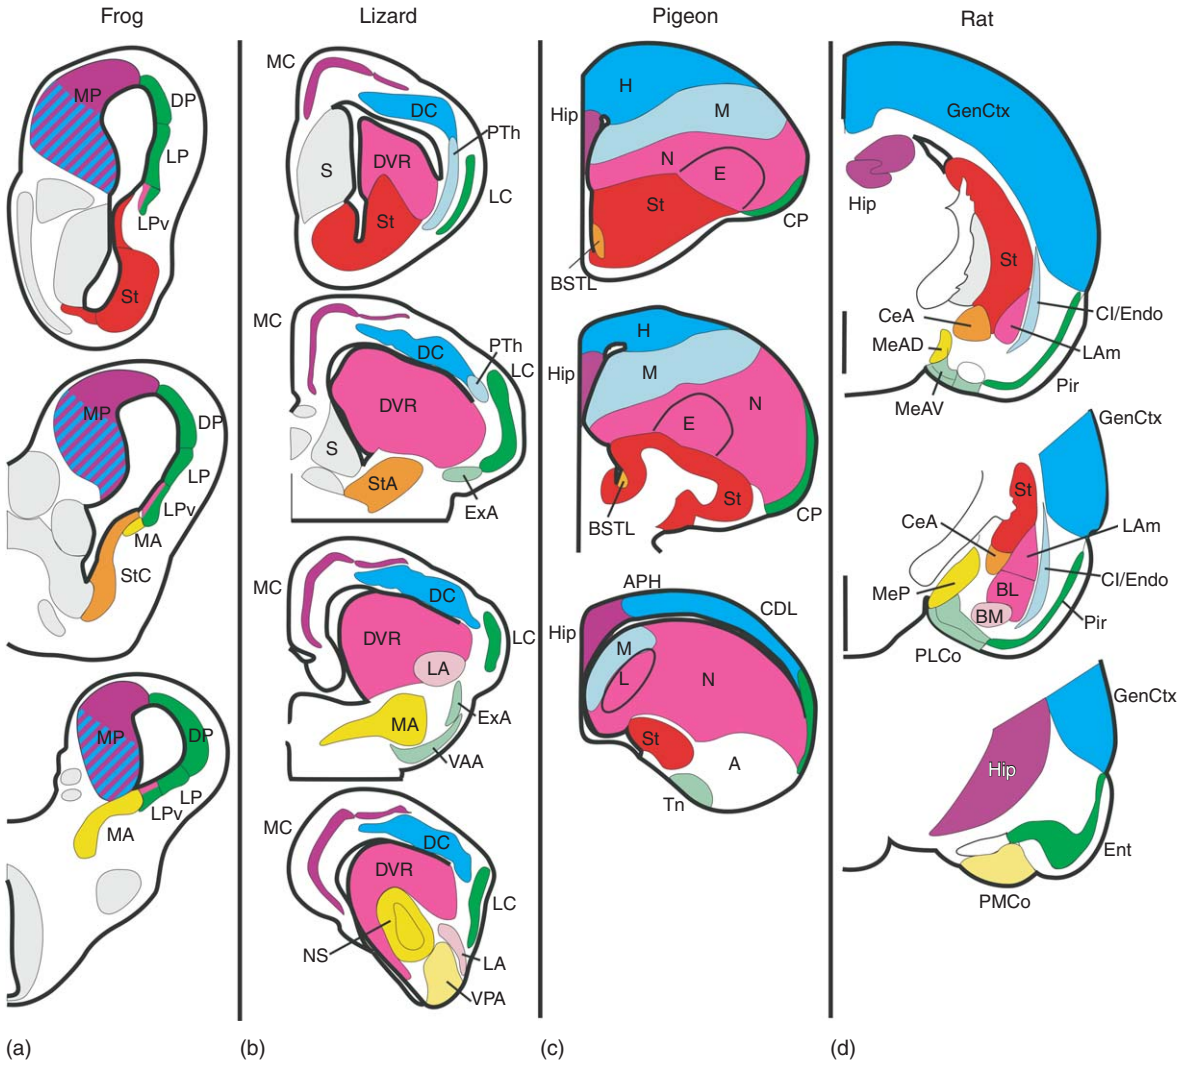

Figure 8 Summary of homologous telencephalic areas in a, amphibians; b, reptiles; c, birds; and d, mammals. Homologous areas are identified by the same color. Abbreviations: frog – DP, dorsal pallium; LP, lateral pallium; LPv, ventral part of the lateral pallium; MA, medial amygdala; MP, medial pallium; St, striatum; StC, caudal striatum. Lizard – DC, dorsal cortex; DVR, dorsal ventricular ridge; ExA, external amygdala; LA, lateral amygdalar nucleus; LC, lateral cortex; MA, medial amygdala; MC, medial cortex; NS, nucleus sphericus; PTh, pallial thickening; S, septal nuclei; St, striatum; StA, striatoamygdalar area; VAA, ventral anterior amygdala; VPA, ventral posterior amygdala. Pigeon – A, arcopallium; APH, area parahippocampalis; BSTL, lateral bed nucleus of stria terminalis; CDL, dorsolateral cortex; CP, cortex piriformis; E, entopallium; H, hyperpallium; Hip, hippocampus; L, Field L; M, mesopallium; N, nidopallium; St, striatum; Tn, nucleus Taeniae. Rat – BL, basolateral amygdala; BM, basomedal amygdala; CeA, central amygdala; cl/Endo, claustrum and endopiriform; Ent, entorhinal cortex; GenCtx, general (nonolfactory, nonhippocampal) cortex; Hip, hippocampus; LAm, lateral amygdala; MeAD, anterodorsal division of medial amygdala; MeAV, anteroventral division of medial amygdala; MeP, medial pallium; Pir, piriform cortex; PLCo, posterior lateral cortical amygdala; PMCo, posterior medial cortical amygdala; St, striatum. Adapted from Bruce, L. L. and Neary, T. J. 1995c. The limbic system of tetrapods: A comparative analysis of cortical and amygdalar populations. *Brain Behav. Evol.* 46, 224–234, with permission from Karger, Basel.

Amygdalar groups. The medial amygdaloid nucleus and nucleus sphericus receive input from the accessory olfactory bulb. The medial amygdaloid nucleus projects to the ventromedial and lateral hypothalamus (Bruce and Neary, 1995a, 1995b). The lateral amygdaloid nucleus receives sensory information from the anterior DVR and projects to the core of the ventromedial hypothalamus (Voneida and Sligar, 1979; Bruce and Neary, 1995a). The dorsolateral amygdaloid nucleus (DLA) receives sensory input from nucleus medialis posterior in the thalamus and from the anterior DVR. It receives dopaminergic input from the ventral tegmental area and cholinergic input from the basal forebrain. Its main output is to the striatum and accumbens (Lanuza *et al.*, 1998). The ventral anterior amygdaloid nucleus lies superficial to the medial amygdala. It receives olfactory input and projects to the

ventromedial hypothalamus. The ventral posterior amygdaloid nucleus lies superficial to nucleus sphericus, receives vomeronasal input, and projects to the lateral hypothalamic area. Further studies are needed to determine if these groups are derived from the ventral or lateral pallium.

The central amygdaloid nucleus has a subpallial origin, and is the only subpallial region with long descending projections to both the hypothalamus and brainstem (Russchen and Jonker, 1988; Bruce and Neary, 1995b).

2.05.5.3.2 Amphibian to reptile transition *Lateral, dorsal, and medial pallia*. The pallium of amphibians is divided into lateral, dorsal, and medial pallial fields (Northcutt, 1981), which were traditionally compared to the lateral, dorsal, and medial cortices of reptiles. However, a re-analysis of the amphibian pallial connections led Bruce and Neary (1995c) to conclude that both the dorsal and lateral pallia are comparable to those of the reptilian lateral cortex, whereas the medial pallium is comparable to both the reptilian medial and dorsal cortices (Figures 7a, 7b, and 8a). The connections of the reptilian lateral cortex and the amphibian lateral and dorsal pallia are similar: they receive a substantial projection from the main olfactory bulb, moderate input from the rostral thalamus, lack commissural connections, and do not project outside the hemisphere (Northcutt and Royce, 1975; Neary, 1990; Scalia *et al*., 1991). The amphibian medial pallium is topographically and connectionally similar to the reptilian medial cortex, but it also has connections in common with the reptilian dorsal cortex. These include projections to the olfactory bulb, hypothalamus, thalamus, and midbrain, contralateral projections, and the lack of direct olfactory input (Bruce and Butler, 1984a; Hoogland and Vermeulen-Vanderzee, 1989; Neary, 1990; Northcutt and Ronan, 1992).

Ventral part of the lateral pallium (LPv). The LPv is an embryologically and connectionally unique subdivision of the lateral pallium that is comparable to the DVR and overlying olfactory cortex in reptiles (Bruce and Neary, 1995c; Brox *et al*., 2004; Moreno and Gonzalez, 2004). Both the anterior LPv and the anterior DVR are ventral pallial derivatives, whereas the posterior LPv and part of the posterior DVR are lateral pallial derivatives (Fernandez *et al*., 1998; Martinez-Garcia *et al*., 2002b; Brox *et al*., 2004). The caudal LPv is the only pallial region that receives input from the main olfactory bulb and the hypothalamus, and projects to the medial hypothalamus.

Medial amygdala. Traditionally known as the pars lateralis of the amygdala (Northcutt and Kicliter, 1980), the medial amygdala receives input from the accessory olfactory bulb and projects to the hypothalamus (Northcutt and Royce, 1975; Wilczynski and Allison, 1989; Scalia *et al*., 1991; Neary, 1995), and thus appears to be homologous to the reptilian medial amygdaloid nucleus, nucleus sphericus, and the ventral posterior amygdalar nucleus (Bruce and Neary, 1995c).

2.05.5.3.3 Reptile to bird transition *Cortical areas*. There is general agreement about the homologues between the reptilian and avian cortical regions (Figures 7c and 8c). The squamate medial cortex is comparable to the avian hippocampus (dentate and Ammon's horn). The reptilian dorsal cortex is comparable to the avian parahippocampal area, dorsolateral cortex, and hyperpallium. The reptilian lateral cortex is comparable to the avian cortex piriformis (e.g., Ariëns Kappers *et al*., 1936; Bruce and Neary, 1995c; Striedter, 1997; Reiner, 2000).

Nidopallium and arcopallium. The reptilian dorsal ventricular ridge has been compared to the avian nidopallium, mesopallium, and arcopallium (Striedter, 1997), or to only the nidopallium (Bruce and Neary, 1995c). These homologues are evaluated in detail below. Several connections of the arcopallium have not been identified in reptiles (e.g., afferents to the optic tectum), and further studies are needed to identify its homologue with certainty.

Mesopallium. Although the mesopallium (formerly named hyperstriatum ventrale) and nidopallium together form a ventricular ridge like the reptilian DVR, the connections of the mesopallium compare best to those of the reptilian pallial thickening, rather than the DVR. The mesopallium is reciprocally connected with the nidopallium, hyperpallium and striatum, and receives input from the posterior amygdala, substantia nigra, and locus coeruleus (Bradley *et al*., 1985; Alpar and Tombol, 1998; Metzger *et al*., 1998; Csillag *et al*., 1994). Comparable connections are associated with the pallial thickening of lizards (Bruce and Butler, 1984a).

Amygdalar groups. In birds the posterior amygdala and olfactory recipient nucleus Taeniae are the only regions of the avian brain consistently agreed to be amygdalar. Thus, a great deal more work is needed to identify avian amygdalar groups. A homologue of the posterior amygdala has not been identified, but nucleus Taeniae is homologous in part with olfactory-recipient amygdalar groups of reptiles.

2.05.5.3.4 Reptile to mammal transition *Cortical areas*. The lateral, dorsal, and medial cortices are generally compared to the piriform, general (i.e., nonolfactory, nonhippocampal), and hippocampal

cortices of mammals (Figures 7d, 8b, and 8d). There is little controversy over these comparisons as they occupy similar positions in the hemisphere and have similar connections (Ariëns Kappers *et al*., 1936; Northcutt, 1969; Bruce and Neary, 1995c). In addition to the massive increase in the size of the mammalian cortex relative to the reptilian dorsal cortex, the major difference is that the mammalian general cortex develops with an 'inside-out' migration pattern (Goffinet *et al*, 1986).

Claustrum, endopiriform, and the basolateral amygdalar complex. The homologues of these regions are highly controversial and will be addressed in detail below.

Basomedial amygdala. The reptilian lateral amygdalar nucleus and basomedial amygdalar nucleus of mammals have similar connections, including a projection to the ventromedial hypothalamus, and appear to be homologues (Bruce and Neary, 1995c; Martinez-Garcia *et al*., 2002b).

Vomeronasal and olfactory amygdaloid nuclei. Amygdaloid nuclei receiving vomeronasal and olfactory input have been identified in reptiles and mammals, and appear to be homologuous, in part (see Section 2.05.4.4).

Central amygdala. Both the mammalian central amygdala and reptilian striatoamygdalar area have long descending projections to the brainstem and appear to be homologues (Russchen and Jonker, 1988; Bruce and Neary, 1995c; Martinez-Garcia *et al*., 2002b).

2.05.5.3.5 Homologues of the DVR and pallial thickening The identification of mammalian homologues of the reptilian DVR and pallial thickening, and the avian nidopallium and mesopallium has been a long-standing controversy (Table 2). The avian nidopallium (neostriatum) and reptilian DVR are often compared to parts of the mammalian neocortex (Karten, 1969, 1997; Reiner, 2000). However, a number of laboratories have recognized similarities between the avian nidopallium, the reptilian DVR, and the mammalian basolateral amygdalar group. Several of these have focused on the comparison between the sensory nidopallium and its mammalian homologue. Striedter (1997) compared the mesopallium and nidopallium to the claustrum and endopiriform areas, respectively. Puelles *et al*. (2000) and Martinez-Garcia *et al*. (2002b) suggested that the nidopallium/DVR may contain cells comparable to the endopiriform area and the basolateral amygdalar complex. Butler and Molnar (2002) compared the nidopallium/DVR to the mammalian basolateral amygdalar complex plus temporal isocortex and the claustrum-endopiriform area. Bruce and Neary (1995c) compared only the basolateral amygdalar group to the nidopallium, and specifically compared the rostral sensory nidopallium to the mammalian lateral amygdala (also a sensory thalamic target).

To determine which evolutionary model fits the current data best, the expression patterns of various early genetic markers, receptors, and ligands in reptiles, birds, and mammals will be summarized, as well as developmental and connectional data (Table 3).

Emx-1. In turtles Emx-1 expression appears in the cortices and pallial thickening, but little or none is expressed in the anterior (sensory) DVR; in mammals it is expressed in the claustrum and cortex, but not in the lateral amygdala (sensory amygdala) or the endopiriform nucleus; in birds Emx-1 is expressed in the hyperpallium (Wulst) and mesopallium, but not in the sensory nidopallium (Fernandez *et al*., 1998; Puelles *et al*., 2000). Thus, the mammalian cortex and claustrum are in the same Emx-1

Table 3 Comparison of various traits

	Mammalian structures				*Avian structures*		
	Iso	*Cl*	*E*	*LA*	*H*	*M*	*Ns*
Emx-1 gene	+++	+++			+++	+++	
a-adrenergic receptor	++	+++	+++	+	++	+++	+
Opiate delta receptor	+++	++++	++++	+++	+/++	++	+/++
Opiate kappa receptor	++	++++	++++	+++	+++	++++	++
VIP	+++	+++	+++	++	+/++	+++	+
NT receptor	+	+	+++	+/++	+	+/+++	+
Development	Dorsal	Lateral	Lateral	Ventral	Dorsal	Lateral	Ventral & lateral
Sensory thalamic afferents	Yes	No	No	Yes	Yes	No	Yes
Sensory thalamic efferents	Yes	No	No	No	Yes	No	No

Cl, claustrum; E, endopiriform nucleus; H, hyperpallium; Iso, isocortex; LA, lateral amygdala; M, mesopallium; Ns, sensory nidopallium; NT, neurotensin; VIP, vasoactive intestinal protein.
+ – density of expression from low (+) to very dense (++++).

positive pallial domain as the avian hyperpallium and mesopallium, and the reptilian cortex and pallial thickening. The mammalian endopiriform nucleus and lateral amygdalar nucleus, the avian sensory nidopallium, and most, if not all, of the reptilian anterior DVR belong to an Emx-1 negative region.

Alpha 2 adrenergic receptor. In quails the hyperpallium, cortex dorsolateralis, and mesopallium contain high levels of expression, in contrast to the adjacent nidopallium, which expresses low to moderate levels (Ball *et al*., 1989; Ball, 1994; Fernandez-Lopez *et al*., 1990). In rats the alpha 2A adrenoreceptor subtype is expressed only in cortical layers 1–4 and in the claustrum and endopiriform nuclei, but not within the amygdala, and the alpha 2C-adrenoreceptor is expressed in the striatum but not the pallium (Uhlen *et al*, 1997). These data indicate that the alpha 2 adrenoreceptor differentiates the mammalian cortico-claustro-endopiriform areas and the avian cortico-hyperpallial-mesopallial areas from the mammalian lateral amygdala and avian neostriatum.

Opiate receptors. In turtles the delta opiate receptor is expressed more densely in the pallial thickening than surrounding areas (figures 2 and 4 of Xia and Haddad, 2001). In pigeons the delta and kappa opiate receptors are more abundant in the hyperstriatum ventrale relative to the neostriatum, and this is especially true for the kappa opiate receptor (Reiner *et al*., 1989). In rats the endopiriform-claustrum exhibits very dense binding with delta and kappa opiate receptors (Mansour *et al*., 1987). The lateral and basolateral amygdalar nuclei exhibit moderate to dense delta and kappa labeling. The density of labeling in the lateral amygdala appears to be considerably less than in the endopiriform-claustrum. Thus, the delta and kappa opiate receptors are expressed throughout the pallium of mammals, birds, and turtles, but are expressed more strongly in the mammalian claustro-endopiriform, avian mesopallium, and turtle pallial thickening than in adjacent areas.

Vasoactive intestinal protein (VIP). In birds VIP-like immunoreactivity and mRNA expression is present in most, but not all, of the hyperpallium and mesopallium, whereas little or none is expressed throughout the nidopallium (Shimizu and Karten, 1990; Hof *et al*., 1991; Kuenzel *et al*., 1997). In rats VIP is expressed in neurons and terminals in the claustrum and endopiriform, but in the lateral amygdala cell bodies but not terminal fibers express VIP (Sims *et al*., 1980; Kowianski *et al*., 2001). Thus, VIP expression is higher in the mammalian claustro-endopiriform area and avian mesopallium than in adjacent cortical and amygdalar/neostriatal areas.

Neurotensin. In turtles neurotensin immunoreactive terminals are particularly dense in the molecular layer of the dorsal cortex and lateral to the pallial thickening (Reiner, 1992). In lizards it is expressed in the lateral (olfactory) cortex, including a region that appears to correspond to the pallial thickening (Bello *et al*., 1994). In mammals they are scattered in the piriform cortex and have a dense accumulation in the claustrum and a small part of the lateral amygdalar nucleus (Jennes *et al*., 1982).

Neurotensin receptors. In pigeons neurotensin receptors are distributed densely in the hyperpallium and mesopallium, although a small region within the lateral mesopallium is conspicuously lightly labeled (Brauth *et al*., 1986). The nidopallium is less intensely labeled except for a group of cells surrounding Field L that are densely labeled. In rats, very high densities of neurotensin receptors occur in the superior rhinal cortex and in the endopiriform cortex, whereas the core of the claustrum has a very low density. Labeling in the lateral amygdala has a lower density of expression than in the adjacent endopiriform area (Young and Kuhar, 1981; Quirion *et al*., 1982).

Development. Developmental studies have concluded that the nidopallium develops from a precursor region that in mammals gives rise to olfactory cortex, the endopiriform, claustrum, and the basolateral amygdaloid complex (Bayer and Altman, 1991; Fernandez *et al*., 1998; Striedter *et al*., 1998; Puelles *et al*., 2000; Reblet *et al*., 2002; Brox *et al*, 2004).

Connections. The connections of the avian hyperpallium and nidopallium are similar to those of the reptilian dorsal cortex and DVR, and of the mammalian isocortex and lateral amygdala, respectively (see Bruce and Neary, 1995c). In mammals the endopiriform projects principally to olfactory cortical areas including amygdalocortical nuclei, and sparsely to all the deep amygdalar nuclei except the accessory basal nucleus to which it projects densely (Behan and Haberly, 1999). The claustrum is extensively interconnected with cortical areas, receives projections from the nucleus centralis thalami, and probably from the locus coeruleus and the lateral hypothalamus (LeVay and Sherk, 1981). The avian mesopallium receives projections from the hyperpallium accessorium, caudal and intermediate parts of the nidopallium. Thalamic projections to mesopallium arise from the nucleus dorsolateralis posterior thalami (Funke, 1989; Gamlin and Cohen, 1986; Metzger *et al*., 1998; Leutgeb *et al*., 1996; Lanuza *et al*., 2000), which is comparable to a

group of mammalian thalamic nuclei that includes the central lateral nucleus (Veenman, 1997; Bruce *et al*., 2002). Efferents from the mesopallium include a projection to the nidopallium (Wild *et al*., 1993). Most studies indicate that the mesopallium projects principally within the telencephalon, including a projection to the dorsal arcopallium (Karten, 1969; Nauta and Karten, 1970; Metzger *et al*., 1998). The connections of the mammalian endopiriform and claustrum, avian mesopallium, and reptilian pallial thickening are similar and thus are consistent with a possible homology. However, none of the connections are unique to claustrum-endopiriform, mesopallium, or pallial thickening, and so cannot be used as strong indicators of a homology.

Together the data indicate that:

1. The best comparison of the mammalian general cortex (including isocortex) is with the avian hyperpallium and dorsolateral cortex and with reptilian dorsal cortex. This is consistent with all models.
2. The best comparison of the mammalian claustrum and endopiriform areas is with the avian mesopallium and reptilian pallial thickening. This is consistent with the models of Bruce and Neary (1995c), Bruce (this article), Striedter (1997), and Puelles *et al*. (2000).
3. The best comparison of the mammalian sensory lateral amygdala is with the avian sensory nidopallium and reptilian DVR. This is consistent with the models of Bruce and Neary (1995), Puelles *et al*. (2000), and Butler and Molnar (2002).
4. The hypotheses that the avian sensory nidopallium is comprised of overlapping territories corresponding to the mammalian claustrum, endopiriform nucleus, and lateral amygdala (Butler and Molnar, 2002), or the mammalian endopiriform nucleus and lateral amygdala (Striedter, 1997; Puelles *et al*., 2000) are weakly supported by this data.
5. The hypothesis that the avian sensory nidopallium is comparable to parts of the mammalian neocortex (Karten, 1997; Reiner, 2000) is also poorly supported by this data.

2.05.5.3.6 Summary If we assume that the forebrain of the common tetrapod ancestor was similar to that of extant amphibians, then the amphibian–reptile transition was marked by segregation of pallial fields (Figure 8). The medial pallium gave rise to the medial and dorsal cortices of reptiles, the dorsal and lateral pallia gave rise to the pallial thickening and most of the lateral cortex, and the ventral part of the lateral pallium gave rise to the DVR and overlying lateral and amygdalar cortices.

The changes during the transition from the reptilian to avian forebrain were not dramatic, since recognition of homologous regions is fairly straightforward. However, the identification of a homologue of the avian arcopallial region is uncertain. In reptiles the vomeronasal system projects to a topographically similar region as the arcopallium. Thus, the appearance of the arcopallium may result from an adaptation to the loss of the vomeronasal input.

Connectional as well as genetic and neurochemical expression patterns indicate that the reptilian DVR, avian nidopallium, and mammalian basolateral amygdalar complex are homologous. The reptile to mammal transition is marked by a massive hypertrophy of the dorsal (general) cortex, which may be associated with a more caudal location of the amygdaloid groups in mammals, compared to reptiles or birds (see The Origin of Neocortex: Lessons from Comparative Embryology, What Fossils Tell Us about the Evolution of the Neocortex, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?, Evolution of the Amygdala in Vertebrates).

2.06 The Evolution of Dome Pressure Receptors in Crocodiles

D Soares, University of Maryland, College Park, MD, USA

Glossary

crocodilian sensory skin	Skin with concentrations of sensory receptors, the dome pressure receptors.
tactile	Relating to the sense of touch.

2.06.1 Introduction

2.06.1.1 Crocodilian Phylogeny

Presently, three primary families are currently recognized within the Crocodilia: the Alligatoridae (which includes the genera *Alligator, Caiman, Melanosuchus*, and *Paleosuchus*), the Crocodylidae (*Crocodylus, Osteolaemus,* and *Tomistoma*), and the Gavialidae, which includes only one species, *Gavialis gangeticus* (Figure 1). The dominant terrestrial vertebrates during the Mesozoic (225–65 Mya) were reptilians of the subclass Archosauria. During the Triassic (250–205 Mya) the order Thecodontia, the basal group of Archosaurs, radiated to produce the orders Saurichia and Ornitischia (together commonly known as dinosaurs); the Pterosaurs, fliers with wings made of skin, and the Crocodilia. Crocodilia is a crown-group name based on the last common ancestor of *Gavialis, Alligator, Paleosuchus, Caiman, Melanosuchus, Tomistoma, Osteolaemus,* and *Crocodylus,* and all of its descendants (Benton and Clark, 1988; Clark, 1994; Brochu, 1997, 1999). Crocodilians are the only surviving archosaurian reptiles (Pough *et al*., 1998) and have been successful freshwater predators for the past 200 My. Extinct crocodilians outnumber their living relatives by a wide margin and three major forms have existed: (1) completely terrestrial, (2) completely aquatic, and (3) semi-aquatic animals. Extant crocodilians are all semi-aquatic and constitute 23 living species within this order. Fossils of extant species begin to appear in the Cretaceous era and the emergence of the eight genera present in the order Crocodilia begins in the Tertiary of Europe with Crocodylus (true crocodiles) (Densmore and Owen, 1989). Gavials emerged between the Oligocene and

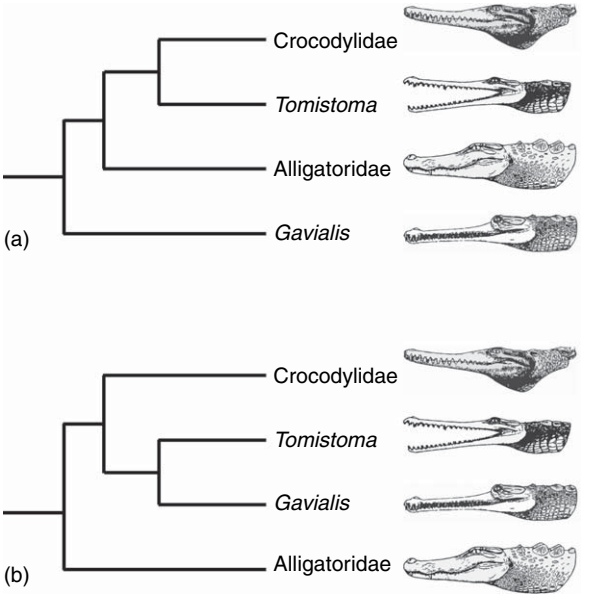

Figure 1 Schematic view of crocodilian relationships based on: a, morphological data and b, molecular data. Modified from Janke, A., Gullberg, A., Hughes, S., Aggarwal, R. K., and Arnason, U. 2005. Mitogenomic analyses place the gharial (*Gavialis gangeticus*) on the crocodile tree and provide pre-K/T divergence times for most crocodilians. *J. Mol. Evol.* 61, 620–626.

Miocene periods in South America and India, while the *Caiman* (true caimans) and Paleosuchus (smooth-fronted caimans) emerged in the Pliocene period. Alligators emerged in the Miocene period of North America. Alligators and Paleosuchus are both monophyletic phyla and are sister taxa. Within alligators, the American alligator and the Chinese alligator (*Alligator sinensis*) are sister taxa, possessing the same most recent ancestor. Although the intergeneric and interspecific relationships within the order Crocodilia has been largely determined utilizing nontraditional DNA analysis, advanced research in this respected analysis as well as new methods of research are required to finalize and complete the true phylogenetic tree (see Evolution of the Amphibian Nervous System).

2.06.1.2 Crocodilian Skin

Most species of crocodilians occur in freshwater, but some invade brackish or salt-water environments, tightly constraining the qualities in the skin (Davis *et al.*, 1980; Dunson and Mazzotti, 1988). Briefly, the crocodilian skin is hard, although its stiffness is different in different regions of the body. The skin is harder and thicker in dorsal parts where it often contains osteoderms (bony plates), and less in ventral and lateral parts (Brazaitis, 1987). The toughness results from both the strongly collagenous dermis (Alibardi and Thompson, 2000) and the presence in the epidermal layers of a hard form of keratin (Alibardi and Thompson, 2001). The epidermis of the Crocodilia closely resembles that of birds and mammals and has a stratified epithelium with a layer of cornified cells which varies in thickness and shape across the scale depending on function.

2.06.2 Dome Pressure Receptors

2.06.2.1 Anatomy

The skin of crocodilians is covered with small pigmented domes (Figure 2). Initially, before the function of these organs was known, these organs were named integumentary sensory organs (von During, 1973) but were renamed dome pressure receptors (DPRs) (Soares, 2002) once their sensory modality was discovered. The distribution of DPRs is different in the families of the Crocodilia: in the Alligatoridae DPRs are segregated to the face and mouth while in the Crocodylidae DPRs are seen all over the body, being present on the caudal portion of most scales (dorsal and ventral), including those on the belly, the legs, the tail, and even around the cloaca. In the gavial, DPRs are also present all over the body but in less density. The significance of this differential distribution is still elusive since all crocodilians have populated similar niches. One exception may be that the gavial, although sharing many of the characteristics of a crocodilian lifestyle, feeds almost solely on fish. Their physiognomy is adapted for this diet and their long thin snouts give little resistance to the water during swiping motions that snap up fish.

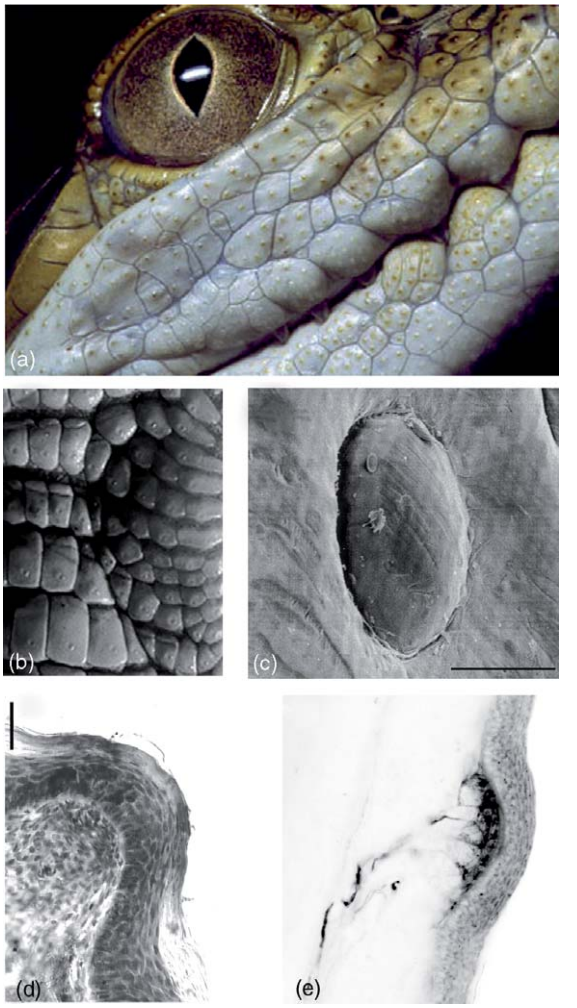

Figure 2 Anatomy of DPRs. a, DPRs are present on the faces of alligators but (b) all over the bodies of crocodiles and gavials. Photograph showing the distribution of DPRs on the ventral portion near the cloaca of a crocodile. Note a single DPR per scale. c, Scanning electron micrograph of a single DPR of an alligator. d, Cresyl violet-stained transverse section of single DPR. e, Cross section of DPR showing trigeminal innervation in the dermis region. Scale bar : 100 μm. a, Courtesy of Adam Britton.

DPRs are round dome-like structures that lack pores or protruding hairs. The epidermis is thinner immediately above the DPRs while the keratin layer is approximately 60% finer and compact. The dermal evagination where each organ is located contains highly branched nerve bundles where

secondary and tertiary branching occurs immediately under the epidermis. Electron microscopy studies show that at least in alligatorids unmyelinated branches rise from larger myelinated branches of axons. In the American alligator, these bundles are of trigeminal origin and somata of innervating neurons are located in the trigeminal ganglion lateral of the brainstem. The trigeminal nerve is the largest of all the cranial nerves in the alligator. Within the brainstem itself, fibers terminate in sensory nucleus V. This brainstem nucleus is hypethrophied and can be seen as large lateral lobes of the brainstem during gross observations of the brain. It is not surprising that the trigeminal system innervates DPRs, for this pathway innervates many specialized organs in vertebrates, such as the electrosensory organs in the platypus (Gregory *et al*., 1987), infrared detectors in snakes (Molenaar, 1974), gustatory organs in the catfish (Finger, 1976), and mechanosensory vibrissa in rats (Gibson and Welker, 1983). The source of innervation of DPRs located on the bodies of crocodiles and gavials is still unknown.

2.06.2.2 Behavior

2.06.2.2.1 Hunting Although crocodilians in general are known to have diverse diets, all species are believed to be opportunistic feeders and lay-and-wait hunters. Additionally, crocodilians will engage in necrophagy. Studies on stomach contents of crocodiles and alligators have yielded an understanding of food choices of animals during development. Subadult alligators for example, mostly eat invertebrates, such as giant water bugs (*Belostoma* spp.), apple snails (*Pomacea paludosa*), crayfish (*Procambarus penninsulatus*), round-tailed muskrats (*Neofiber alleni*), and marsh rabbits (*Sylvilagus palustris*). Adults primarily consume red-bellied turtles (*Pseudemys nelsoni*), peninsular cooters (*P. floridana*), stinkpots (*Sternotherus odoratus*), gizzard shad (*Dorosoma cepedianum*), and gars (*lepisosteus platyrhincus*) (Delany and Abercrombie, 1986).

Only one behavioral experiment has been done to date to elucidate the role of DPRs in feeding (Soares, 2002). During these behavioral trials, half-submerged subadult alligators (*Alligator mississippiensis*) responded to disturbances of the water interface by orienting themselves to the source of the stimulus. In this study the stimulus used was a droplet of water on to a flat body of water that contained a half-submerged alligator. This orienting behavior was robust and consisted of either head-turning or a full body lunge toward the source in a predatory manner and often included biting. Interestingly, this behavior only occurred when the alligators' faces were located on the air–water interface, and not when the animals were completely submerged or had their heads entirely out of the water. Errors when determining source location were very small. In one instance (unpublished), the same paradigm was used but a background surface wave noise was introduced. Alligators were still able to detect the source of the stimulus, albeit they were slower to reach the target and made a few more errors in precision. When all DPRs were covered by a plastic elastomer this behavior was extinguished. Animals did not orient to the source of the stimulus and many did not move at all. Removal of the plastic elastomer allowed for the behavior to be regained. Popular reports (personal communication) suggest that adult animals (American alligators) perhaps display the same type of orienting behavior and are attracted to animals that disturb the air–water interface either to drink or to submerge (such as turtles).

The importance of DPRs in hunting is likely to change according to the animal's size and may be correlated with prey choice. The distribution of DPRs changes during the life span of the animal, where hatchlings start with a very compacted array of DPRs and large adults have up to 2–3 cm of skin in between DPRs. This difference may be related to the prey choice, since, when juveniles, crocodilians tend to prefer smaller prey such as insects which will create smaller, higher-frequency surface waves and will avoid larger surface waves (such as those created by larger animals). So it is therefore possible that DPRs are tuned to different frequencies at different stages of life.

2.06.2.2.2 Mating Although no studies have been done on the importance of DPRs in other behaviors, it is likely that these sensory organs may play a role in the courtship of crocodilians. In the American alligator, initiation of breeding patterns begins with courtship activities. One notable courtship activity that may be especially suited for DPR detection is bellowing (Figure 3a). Bellowing occurs in shallow water, where the animal has its caudal part submerged and sometimes its rostrum on land. Bellowing serves as a sexual attractant (Vliet, 1989) between male and female alligators and this particular courtship activity requires various changes in body posturing of the male. Bellowing begins with inhalation, where the alligator raises its head above the water and performs gulping motions. Second, the alligator raises its head 30–40° above water and arches its tail. Then the

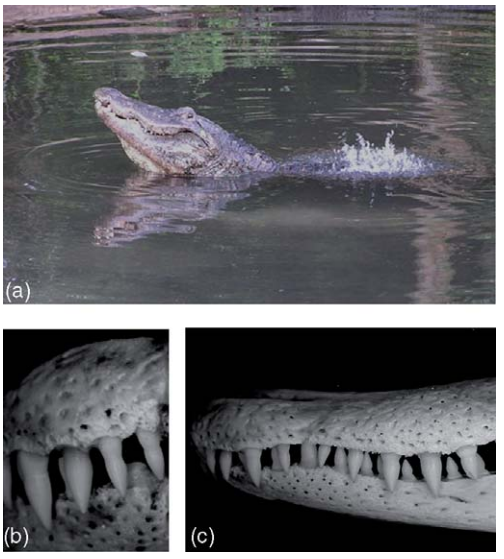

Figure 3 Behavior and osteology. a, Photograph of a bellowing alligator. b, and c, Foramina from which trigeminal innervation arises toward DPRs. Similar distribution of foramina can be seen in extinct forms of crocodilians that have a semi-aquatic lifestyle. Scale bar: 3 cm. a, Reproduced by permission of Glenn Baker.

alligator produces very low frequency vibrations with its throat and body, visibly tensing its muscles and inducing an upward motion of water on its torso. During this portion of the behavior many surface waves can be seen surrounding the animal's body, and the water has been described as on a 'frying pan' about the alligator's torso. Lastly, the alligator performs an audible bellow. Bellowing occurs in both the male and female and provides information about the size, sex, location, and social position of the active bellower.

In addition to bellowing, alligators display other forms of courtship behavior that may be sensed by DPRs, such as head-slapping and snout- and head-rubbing (Vliet, 1989). Male and female alligators (Davis *et al*., 2001) respond differently to these courtship activities. The male alligator portrays its size and strength and continues the courtship activities of bellowing and head-slapping in the presence of a bellowing female, while the female alligator migrates toward the strong bellowing and head-slapping activities of a male. Differential participation of DPR input can perhaps be involved in the differences in behavior of the two sexes.

2.06.2.3 Evolution

The phylogenetic history of DPRs can be traced because their innervation leaves markings in the mandibulary and maxillary bones in the form of foramina (Figure 3). These foramina allow for the passage of trigeminal nerve branches from the ganglia near the brain to the DPRs on the skin. The spatial distribution of these foramina is distinct in the skull bones of living crocolilians. It appears as a beehive pattern with many spatially distributed foramina. One study examined the distribution of foramina in extant and extinct crocodilians and found that all living specimens have both foramina and DPRs (Alligatoridae: *Alligator mississippiensis, A. sinensis, Caiman crocodilus, C. c. apaporiensis, C. c. fuscus, C. latirostris, C. yacare, Melanosuchus niger, Paleosuchus palpebrosus,* and *P. trigonatus*; Crocodylidae: *Crocodylus acutus, C. cataphractus, C. intermedius, C. johnstoni, C. mindorensis, C. moreletii, C. niloticus, C. novaeguineae, C. palustris, C. porosus, C. rhombifer, C. siamensis, Osteolaemus tetraspis*, and *Tomistoma schlegeli;* Gavialidae: *Gavialis gangeticus:* data not shown). Only extinct crocodilian forms that are believed to have had a semi-aquatic lifestyle also show this pattern of foramina (all specimens examined: Triassic: *Protosuchus richardsori, Eutretauranosuchus*; Jurassic: *Metriorhynchus, Mystriosaurus,* and *Goniopholis lucastii;* Creteceous: *Borrealosuchus [leidyoduchus]-stenobergii, Branchychampsa montana, Prodiplocynodon longi, Halops obsceris, Hypsaur rogersii, Deinosuchus rugosus, Teleorhinus robustus,* and *Lleidyosuchus gelmorei*; Paleocene: *Allognathosuchus mooki, Navajosuchus novemexicanus, Lleidyosuchus multidentatus,* and *Brachyuranochampsa zangeli;* Eocene: *Pristichampsa uorax, Asiatosuchus mongoliensis, Brachyuranochampsa zangeli,* and *Sebeceus caeorhinus*; Oligocene: *Diplocynodon ratelii;* Pliocene: *Porossaurus brasiliensis*; Plesitocene: *Crocodilus rhombifer*). Fully terrestrial crocodilians (such as *Sebecus*) do not show this pattern of foramina and the most ancient crocodilian specimen available (*Protosucus*) shows a pattern that is more lizard-like. All lizard groups display a linear pattern of foramina on top and bottom of the teeth line and none shows the crocodilian beehive pattern, including the marine iguana (*Amblyrhynchus cristatus*), which takes advantage of land and water environments. The emergence of DPRs is likely to have occurred during the early Jurassic and as a specialization of simpler reptilian cutaneous sensory organs. Since these organs are tuned to the air–water interface, ancestral, extinct crocodilians that were not semi-aquatic do not appear to have evolved or lost DPRs.

2.06.2.4 Physiology

To date, only one study has been done examining how DPRs encode sensory information (Soares, 2002). In this study, multicellular and unitary

extracellular recordings from the trigeminal ganglion of juvenile American alligators showed that DPRs are especially sensitive to surface waves (Figure 4). Surface waves evoked a single spike phase locked to the stimulus frequency and increasing the wave amplitude increased the probability of spike firing. Responses saturated at one spike per cycle of the surface wave stimulus. DPRs appeared to be tuned to frequencies up to tens of hertz (unpublished) and higher frequencies led to greater spike failure. With continuous stimulation, DPRs adapted and responses decreased with 5–10 min.

Similar coding strategies were seen when individually stimulating a single DPR with a small rod.

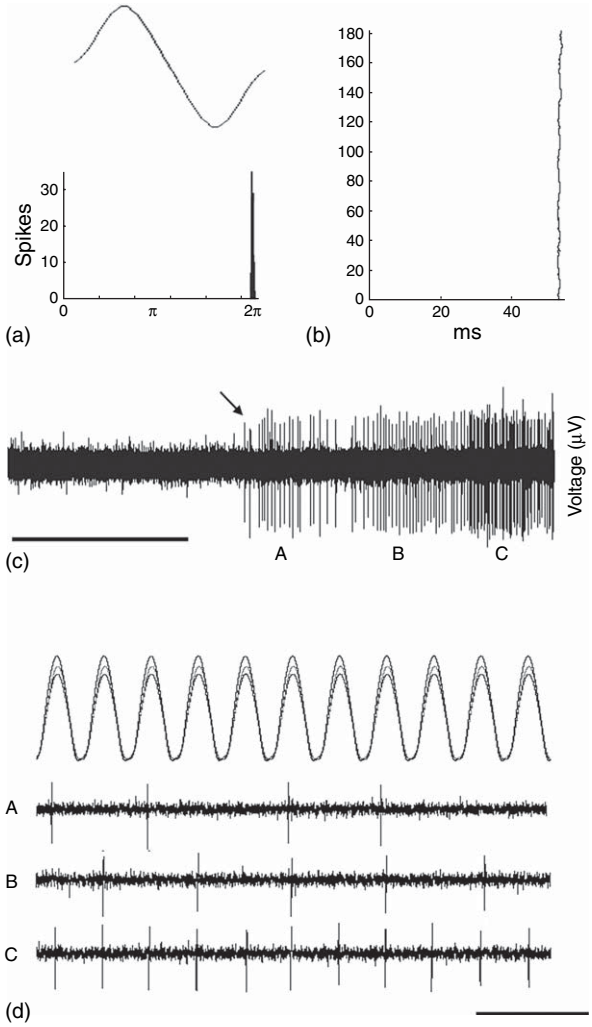

Figure 4 Physiological responses of DPRs. a, Representation of spike timing of trigeminal responses in relation to phase of stimulus. b, Raster plot showing the same date as in (a). c, Multiunit extracellular recording of trigeminal somata in the trigeminal ganglion; responses increase with increase of amplitude of surface wave stimulus (ABC). d, Close-up of ABC in c showing saturation of response. Scale bar: 200 ms.

No responses were noted when the skin between DPRs was pressed using the same pressure which evoked responses in the DPRs. This observation supports the notion that the DPRs themselves are sufficient and necessary for the trigeminal response that is associated with water interface disruptions. Although the transduction mechanism is yet to be discovered, it is likely that DPRs are sensitive to pressure differences, and not particle motion, although responses to shear cannot be ruled out.

2.06.2.5 Comparisons with Other Reptilians

There are four main groups within the reptilia: (1) turtles and tortoises, (2) lizards and snakes, (3) crocodiles and alligators, and (4) the tuatara (single species of the sphenodontia), making this a paraphyletic group. DPRs belong to a general class of sensory organs found in all reptilians. This class of tactile sensory organs (also called touch papilla) is well developed and occurs in all reptilian orders (von During and Miller, 1978). Touch papillae of lizards have bristles and forms and always indicate sensitive areas of the skin. Different receptor terminals such as discoid terminals, Merkel cells, and naked free nerve endings in dermal layers as well as laminated receptors are present in tactile sensory organs. Another common characteristic between all touch papillae are a modified keratin layer, where a more pliable region is located above the organ itself. DPRs appear to be the most complex arrangement of different receptor types while pythons and veranus show mainly discoid-like receptors and branched nerve receptors in the connective tissue papillae. These discoid receptors lie just deep of the modified keratinous layer and the connective tissue papillae contain columns of connective tissue cells that contact nerve ending fibers of other receptor types. Adaptation-driven selection appears to have worked on an ancestral form of a crocodilian touch papilla to give rise to DRPs. Modifications include hypertrophy of skin receptors in the periphery, in the central nervous system, and an increase in sensitivity. The most similar tactile sensory organ of a noncrocodilian to DRPs are the touch papillae of the iguana (personal observation), especially the marine iguana of the Galapagos, which takes advantage of an aquatic environment. No cutaneous comparative studies of turtles, tortoises, and the tuatara have been made at this date to determine any similarities to DPRs. Osteologically, foramina associated with tactile sensory organs of reptiles are spatially distributed differently than in the extant Crocodilia (personal observation). When present,

there are fewer foramina arranged in a line above and below the teeth line and not in the crocodilian beehive pattern.

2.06.3 Conclusions

In summary, crocodilians have evolved an armored body shield while maintaining tactile sensitivity to its environment. All living crocodilians that have taken advantage of a semi-aquatic niche either have DPRs or, in case of extinct species, bone markings suggesting the presence of DPRs. Ancient terrestrially bound crocodilians did not have ostealogical indications of DPRs. Crocodilians are able to detect surface waves based on the information from the DPRs and prey detection seems to be one of the roles for these receptors but other behavioral roles are possible since crocodilians use the water–air interface for communication and courtship. The transduction mechanism for DPRs is yet to be determined.

2.07 Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?

L Medina, University of Murcia, Murcia, Spain

Glossary

amniote Group of vertebrates that develop an amniotic membrane around the embryo; includes reptiles, birds, and mammals.

arcopallium A caudal (or posterior) subdivision of the dorsal ventricular ridge in birds.

cortex A laminar brain structure consisting of cells arranged in layers parallel to the ventricular/pial surfaces and generally orthogonal (perpendicular) to radial glial fibers.

developmental regulatory gene A gene encoding a transcription factor (or a cofactor) or a signaling protein that is expressed during development in specific patterns, and is able to control expression of other genes and regulate patterning and morphogenesis of specific body parts.

DVR Dorsal ventricular ridge: a large region of the ventrolateral pallium of the telencephalon of birds and reptiles.

hippocampal formation Derivative of the medial pallium in different vertebrates. In mammals it includes the dentate gyrus, the hippocampus proper (Ammon's fields), and the subiculum. In birds it includes the hippocampus and the area parahippocampalis, whereas in reptiles it includes the medial and dorsomedial cortices.

homologous Having the same relative position (topological position), embryonic origin, and common ancestor; exhibiting biological homology.

homologue The same organ in different animals under every variety of form and function (Owen's definition, in 1843; see A History of Ideas in Evolutionary Neuroscience and Field Homologies on this concept).

homology A similarity attributed to common evolutionary origin (see 'homologous').

hyperpallium A dorsal region of the avian telencephalon that develops from the dorsal pallium. It typically forms a bulge on the dorsal surface of the telencephalon. It was often called Wulst.

M1 Primary motor area of the mammalian neocortex.

mesopallium A dorsal subdivision of the DVR in birds.

neocortex Derivative of the dorsal pallium in mammals, that typically shows a six-layered organization. It is also known as isocortex.

nidopallium A ventral subdivision of the DVR in birds.

pallial thickening A lateral expansion of the dorsal cortex of reptiles, showing a non-cortical organization. It is generally considered a lateral part of the dorsal cortex. However, only part of it may be a dorsal pallial derivative, and more comparative and developmental studies of this structure are needed before reaching any conclusion.

pallium A major dorsocaudal division of the telencephalon in all vertebrates, which in mammals gives rise to the cortical regions, claustrum, and part of the amygdala (including the cortical areas plus the basolateral complex). It is subdivided into four parts, called medial, dorsal, lateral, and ventral pallia.

piriform cortex Olfactory cortex of different vertebrates. It derives from the ventrolateral pallium. In reptiles, it is also known as lateral cortex.

S1 Primary somatosensory area of the mammalian neocortex.

sauropsid Group of vertebrates that includes reptiles and birds.

subpallium A major ventrorostral (or basal) division of the telencephalon in all vertebrates, that in mammals gives rise to most of the septum, the basal ganglia, part of the amygdala (including the intercalated and centromedial nuclei), and other cell groups of the basal telencephalon, such as the cholinergic corticopetal groups. It is subdivided into striatal, pallidal, and anterior entopeduncular parts.

telencephalon Bilateral evaginations of the rostral forebrain. It shows two major divisions in all vertebrates: pallium and subpallium.

tetrapod Group of vertebrates having two pairs of limbs, that includes amphibians, reptiles, birds, and mammals.

thalamus Forebrain structure that derives from the alar plate of the diencephalon (in particular, from prosomeres 2 to 3). It is subdivided into a ventral thalamus (also called prethalamus, which derives from prosomere 3), and a dorsal thalamus (or simply thalamus, which derives from prosomere 2). The dorsal thalamus contains cell groups that typically relay sensory information to the subpallium and pallium in vertebrates. In amniotic vertebrates, the dorsal thalamus contains specific cell groups that relay unimodal sensory and/or motor information to specific areas of the dorsal pallium.

topology Geometric configuration of any given structure (such as the brain) according to internal coordinates, which remain unaltered independent of deformations or differential growth of subdivisions that occur during development. According to this, the topological position of any subdivision within the structure, and its relation to neighbors, remains the same throughout ontogeny. Further, in organisms sharing the same configuration and basic organization plan (for example, vertebrates), the topological position of homologous subdivisions should be the same across species.

V1 Primary visual area of the mammalian neocortex.

Wulst German term previously employed to name the hyperpallium. It literally means bulge, making reference to the swollen or protuberant appearance of this subdivision of the avian telencephalon.

2.07.1 Introduction

One of the most challenging questions in brain evolution is to ascertain the origin of neocortex and to know whether a comparable cortical (pallial) region is present in extant birds and reptiles, which would

mean that a primordium of this structure was already present in stem amniotes. This question has been addressed by researchers since the end of the nineteenth century and continues to be discussed nowadays (for example, see article by Aboitiz *et al.*, 2003, and commentaries on it). However, many issues related to this question still remain uncertain and controversial. Nevertheless, the combination of developmental, paleontological, and adult anatomical plus functional data, analyzed using a cladistic approach, has proven to be very useful for evolutionary studies; this combined approch has helped to clarify some aspects of cortical evolution and has offered some light on what direction to follow in this research (for example, Northcutt and Kaas, 1995; Striedter, 1997, 2005; Medina and Reiner, 2000; Puelles, 2001; Butler and Molnár, 2002; Aboitiz *et al.*, 2003). Here I will review evidence based on this approach that suggests that: (1) the pallium of birds and reptiles contains a sector that is homologous as a field to the mammalian neocortex (i.e., they evolved from the same primordium present in stem amniotes); (2) this pallial sector contains a primary visual and a primary somatosensory area that might be homologous to V1 and S1, respectively, of mammalian neocortex; and (3) the frontal part of this pallial sector contains a somatomotor control area in birds (apparently overlapped with the somatosensory field) and mammals (M1), but these areas likely evolved independently and are, therefore, nonhomologous (see Evolution of the Nervous System in Reptiles, Visual Cortex of Turtles, The Origin of Neocortex: Lessons from Comparative Embryology, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, The Evolution of Motor Cortex and Motor Systems).

2.07.2 Finding the Homologue of Neocortex in the Pallium of Nonmammals

The neocortex is a six-layered structure located in the dorsolateral part of the telencephalon in mammals, above the ventricle, and it covers the central and basal region that is occupied by the basal ganglia and other basal telencephalic cell groups (Figure 1a). The neocortex is also located above the rhinal fissure, which separates it from the piriform cortex and olfactory tract. In contrast to the neocortex, the basal ganglia and other basal telencephalic cell groups show a nuclear (nonlaminar) organization. The difference between laminar versus nuclear organization together with the relative position of the cell masses with respect to the ventricle was once considered a criterion to identify cortical (pallial) and basal (subpallial) regions in the telencephalon of nonmammals, and based on it the telencephalon of birds and reptiles was thought to be made of a very large basal ganglia and a very tiny cortical region (reviewed in Medina and Reiner, 1995; Striedter, 1997; Reiner *et al.*, 1998; Jarvis *et al.*, 2005). This is now known to be wrong, and there is a large amount of evidence showing that the telencephalon of birds and reptiles contains a large pallial region, a major part of which shows a nuclear organization and is located below the lateral ventricle (Figures 1b–1d) (Karten and Hodos, 1970; Reiner, 1991, 1993; Butler, 1994b; Striedter, 1997, 2005; Smith-Fernández *et al.*, 1998; Medina and Reiner, 2000; Puelles *et al.*, 2000; Jarvis *et al.*, 2005). The evidence showing this includes developmental and adult anatomical and functional data, and it has mainly been obtained after the development of modern techniques that allowed detection of gene products (such as enzymes, proteins and, more recently, mRNAs), tracing of axonal pathways, fate mapping, and functional studies of the brain.

The cortical region of mammals is subdivided into medial, dorsal, and lateroventral units during development and in the adult (Figures 1a and 2c), and the neocortex derives from the dorsal subdivision (Holmgren, 1925; Striedter, 1997). The cortical region (pallium) of birds and reptiles is also subdivided into medial, dorsal, and lateroventral units (Figure 1) (Reiner, 1991, 1993; Butler, 1994b; Striedter, 1997; Puelles *et al.*, 2000). The problem comes when trying to compare one-to-one these subdivisions of the avian/reptilian pallium with those of mammals. Some authors employing only adult anatomical and functional data (including connectivity patterns) believe that the dorsal subdivision of the avian/reptilian pallium is homologous to the dorsomedial part of the neocortex, whereas a large part of the lateroventral pallium of birds/reptiles (called dorsal ventricular ridge or DVR; in particular, its ventral part in birds) is homologous to the dorsolateral part of the neocortex or to specific cell groups of it (Karten, 1969, 1997; Reiner, 1993; Butler, 1994b). However, homologous structures must originate from the same embryonic primordium (Striedter, 1997; Puelles and Medina, 2002; see Field Homologies). In this sense, developmental studies indicate that only the dorsal subdivision of the avian/reptilian pallium can be compared to the neocortex, but not the DVR (in particular, its ventral part, which includes the nidopallium in birds) (Striedter, 1997; Puelles *et al.*, 2000). Rather, both developmental and some adult connectivity data suggest that the avian/reptilian DVR is homologous to the claustrum and pallial

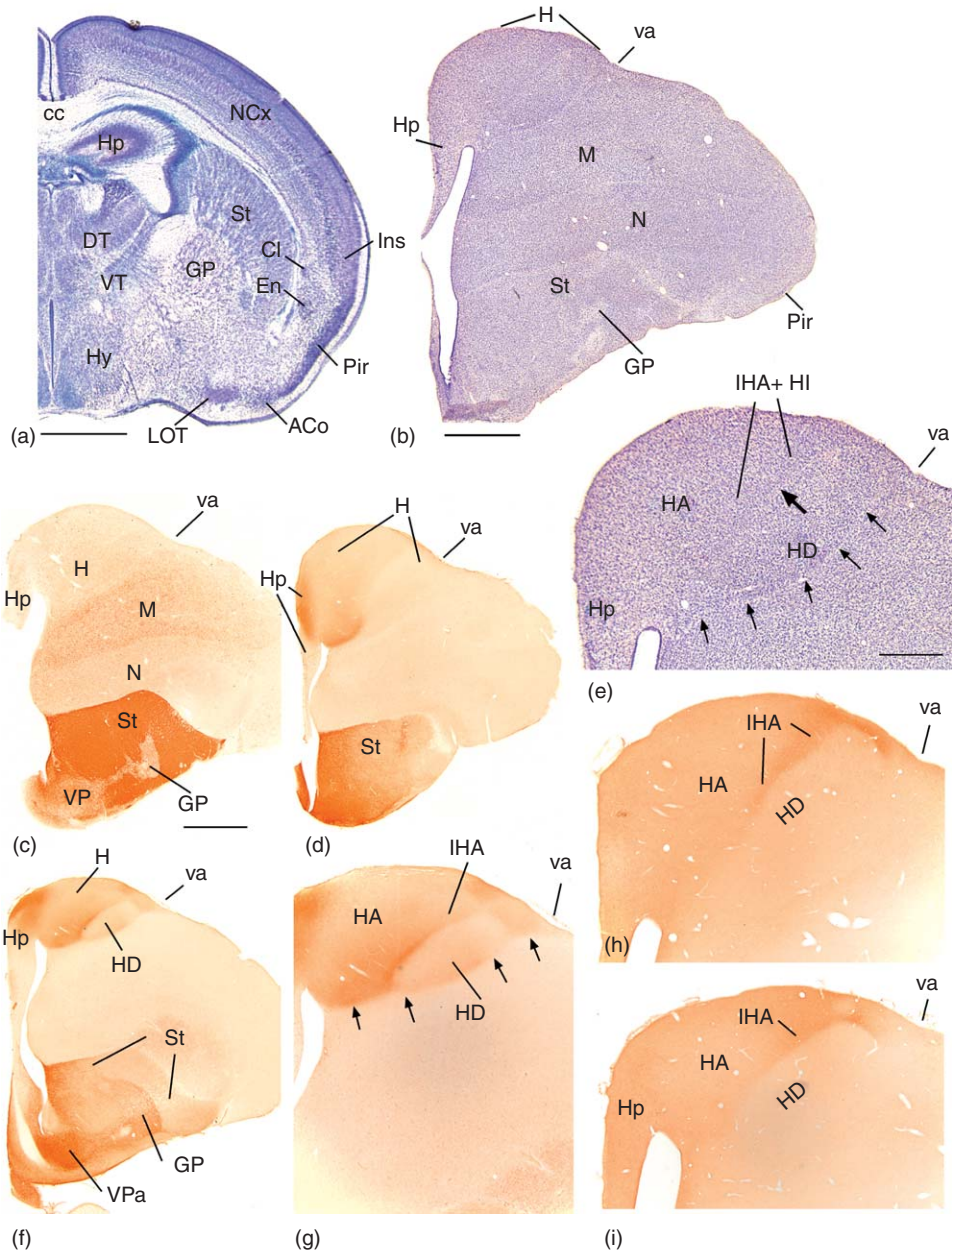

Figure 1 Photomicrographs of frontal sections through the telencephalon of a postnatal mouse (a) or adult pigeon (b–i), showing the general cytoarchitecture, as observed in Nissl staining (a), (b), (e), and some subdivisions based on immunostaining for tyrosine hydroxylase (c), substance P (d), (f), (g), of choline acetyltransferase (h), (i). Note the typical lamination in the cerebral cortex of mouse (a), that differs from the nuclear-like organization in the basal ganglia (striatum and pallium). In pigeon (b), as in other birds and reptiles, most of the telencephalon is not laminated. Nevertheless, neurochemical data help to locate the main intratelencephalic boundary in birds and reptiles, separating subpallium and pallium. The subpallium is relatively rich in tyrosine hydroxylase (c) and substance P (d), (f), and includes the basal ganglia (striatum and pallidum). The avian pallium includes four major subdivisions, including the hippocampal formation (medially), the hyperpallium (dorsally), the mesopallium (laterodorsally), and the nidopallium (lateroventrally). At caudal levels, the avian lateroventral pallium includes the arcopallium and part of the amygdala. The avian hyperpallium appears to be the only derivative of the dorsal pallium and is therefore comparable (homologous as a field) to the mammalian neocortex (see Figure 2). The avian hyperpallium (H) has four mediolateral subdivisions, called apical (HA), interstitial nucleus of apical (IHA), intercalated (HI), and densocellular (HD) hyperpallium (e–i). These subdivisions are not comparable to neocortical layers, although they show some functional features that resemble them. The lateral extension of the hyperpallium coincides with a cell-free lamina called superior frontal lamina (arrows in (e) and (g)), and generally relates to a superficial groove called vallecula (va), although this is not true at rostral levels. See text for more details. ACo, anterior cortical amygdalar area; cc, corpus callosum; Cl, claustrum; DT, dorsal thalamus; En, endopiriform nucleus; GP, globus pallidus; H, hyperpallium; HA, apical hyperpallium; HD, densocellular hyperpallium; HI, intercalated hyperpallium; Hp, hippocampal formation; Hy, hypothalamus; IHA, interstitial nucleus of the apical hyperpallium; Ins, insular cortex; LOT, nucleus of the lateral olfactory tract; M, mesopallium; N, nidopallium; NCx, neocortex; Pir, piriform cortex; St, striatum; va, vallecula; VPa, ventral pallidum; VT, ventral thalamus. Scale bars: 1 cm (a, b); 0.5 cm (c, d, f; scale in c); 1 cm (e, h, i; scale in e).

amygdala (Bruce and Neary, 1995a, 1995b, 1995c; Striedter, 1997; Guirado *et al.*, 2000; Puelles *et al.*, 2000; Puelles, 2001; Dávila *et al.*, 2002; Martínez-García *et al.*, 2002). Below I review the evidence that supports that the dorsal part of the avian/reptilian cortical region is homologous as a field to the mammalian neocortex, and that both evolved from a similar pallial subdivision present in the telencephalon of stem amniotes.

2.07.2.1 Developmental Evidence: Histogenetic Origin and Transcription Factors

During development, the telencephalon of vertebrates becomes parcellated into radial histogenetic divisions and subdivisions that are comparable across species (Striedter, 1997; Puelles and Medina, 2002). Each division/subdivision shows a unique molecular profile and produces specific cell groups, most of which stay within the radial domain, except for some selective cell populations that undergo tangential migration across boundaries (Striedter and Beydler, 1997; Striedter *et al.*, 1998; Puelles *et al.*, 2000; Cobos *et al.*, 2001; Marín and Rubenstein, 2001, 2002; Puelles and Medina, 2002). This conclusion is strongly supported by data on developmental regulatory genes (encoding transcription factors or signaling proteins that regulate the expression of other genes), which are expressed in specific and generally comparable spatiotemporal patterns in the telencephalon of different vertebrates during development (Smith-Fernández *et al.*, 1998; Puelles *et al.*, 2000; Brox *et al.*, 2003, 2004; Medina *et al.*, 2005), and play key roles in the regional specification and formation of telencephalic divisions and subdivisions (Marín and Rubenstein, 2002).

2.07.2.1.1 Pallial subdivisions in mammals and neocortical origin Classical and modern developmental studies, including data on developmental regulatory genes, indicate that the mammalian neocortex derives from the pallium, one of the major divisions of the telencephalon (Figure 2c) (Holmgren, 1925; Källén, 1951b; Puelles *et al.*, 2000). During development, the pallium shows specific expression of numerous transcription factor-expressing genes, including *Pax6*, *Emx1/2*, *Tbr1/2,* and several *LIM-homeobox* (*Lhx*) genes (Simeone *et al.*, 1992; Stoykova and Gruss, 1994; Bulfone *et al.*, 1995, 1999; Rétaux *et al.*, 1999; Puelles *et al.*, 2000; Bulchand *et al.*, 2001, 2003; Medina *et al.*, 2004), which play key roles in pallial specification and parcellation, cell proliferation, and/or cell differentiation (Stoykova *et al.*, 1996, 2000; Zhao *et al.*, 1999; Bulchand *et al.*, 2001; Hevner *et al.*, 2001, 2002; Yun *et al.*, 2001; Bishop *et al.*, 2002, 2003; Muzio *et al.*, 2002; Campbell, 2003). For example, *Pax6, Emx1,* and *Emx2* are involved in pallial specification and parcellation (Bishop *et al.*, 2002, 2003; Muzio *et al.*, 2002). *Emx1* and *Emx2* are also involved in pallial growth (cell proliferation) (Bishop *et al.*, 2003). On the other hand, *Tbr1* appears to be involved in the differentiation of glutamatergic neurons, which are typical in the pallium (Hevner *et al.*, 2001).

What part of the pallium gives rise to the neocortex? Classical developmental studies and studies on the expression and function of developmental regulatory genes indicate that the pallium of mammals contains three main radial subdivisions (Figure 2c): (1) a medial pallium, giving rise to the hippocampal formation; (2) a dorsal pallium, giving rise to the neocortex; and (3) a lateroventral pallium, giving rise to the piriform cortex, claustrum, and pallial amygdala (the lateroventral pallium is sometimes referred to as the piriform lobe, and has the olfactory tract at the surface) (Holmgren, 1925; Striedter, 1997; Puelles *et al.*, 2000; Puelles, 2001). The lateroventral pallium is also subdivided into dorsal and ventral parts (called lateral and ventral pallia, respectively, by Puelles *et al.*, 2000), which show distinct expression of the several developmental regulatory genes, including *Emx1* and *Dbx1*, and give rise to different parts of the claustrum and pallial amygdala (Figure 2c) (Puelles *et al.*, 2000; Yun *et al.*, 2001; Medina *et al.*, 2004). During early development, the lateral pallium expresses strongly *Emx1* but not *Dbx1*, whereas the ventral pallium expresses *Dbx1* in the ventricular zone but only shows *Emx1* expression in the subpial surface (Puelles *et al.*, 2000; Yun *et al.*, 2001; Medina *et al.*, 2004). However, a recent fate-mapping study indicates the existence of numerous *Emx1*-expressing cells in both lateral pallial and ventral pallial parts of the amygdala around and after birth (Gorski *et al.*, 2002), suggesting that there may be a high degree of cellular mixing between these subdivisions (Figure 2c).

The pallial subdivisions are apparently formed by the early action of: (1) signaling proteins (such as Wnt proteins) that diffuse from organizer centers such as the cortical hem (Figure 2c), which, by way of receptors, apparently control the expression of downstream genes (including genes encoding transcription factors) in adjacent pallial areas in a concentration-dependent way (Ragsdale and Grove, 2001); (2) transcription factors that are expressed in opposing gradients in the pallium during early development, involved in regional specification, parcellation, cell proliferation, and/or cell differentiation of the pallium (for example, *Pax6, Emx2, Lhx2*; Donoghue and Rakic, 1999;

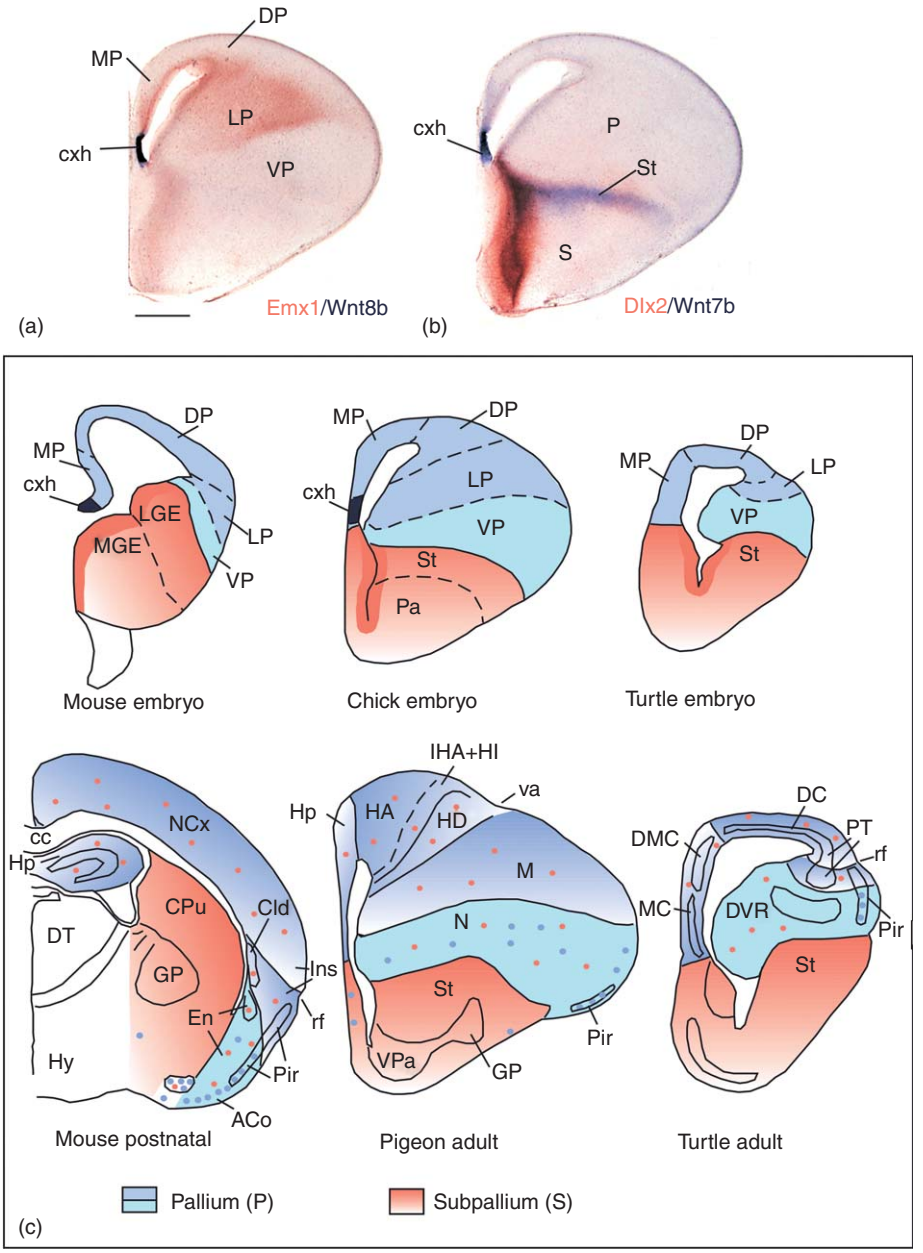

Figure 2 a and b, Photomicrographs of frontal sections through the telencephalon of chick embryos (10 days of incubation), showing expression of the chick genes *Emx1* (red in a), *Wnt8b* (blue in a), *Dlx2* (red in b), or *Wnt7b* (blue in b). The genes *Dlx2* and *Wnt7b* are expressed in the subpallium, either in the ventricular/subventricular zone of the whole subpallium (*Dlx2*) or the ventricular zone and mantle of the striatum (*Wnt7b*). Expression of *Emx1* helps to distinguish a ventral pallial (VP) subdivision, poor in *Emx1* expression and poor in subpallial marker genes. Note the expression of *Wnt* genes in the avian cortical hem, a putative secondary organizer comparable to the cortical hem of mammals. c, Schematics of the telencephalon of a mammal (mouse), a bird (chick or pigeon), and a reptile (turtle), as seen in frontal sections during development or in the adult. The pallial and the major subpallial subdivisions are represented in the different species, based on known expression patterns of developmental regulatory genes observed during development. Four major pallial subdivisions appear to exist in all groups, although the lateral and ventral subdivisions appear to have a large degree of cellular mixing in the adult (which occurs at the level of the ventral pallium). The dorsal pallium gives rise to the neocortex (NCx) in mammals, to the hyperpallium (H) in birds, and to the dorsal cortex (DC) in reptiles. The pallial thickening (PT) is often considered a lateral part of the dorsal cortex. However, available data suggest that only part of it may be a dorsal pallial derivative, and more studies are needed to know where the exact boundary between the dorsal and lateral pallium is, in reptiles. ACo, anterior cortical amygdalar area; cc, corpus callosum; Cld, dorsolateral claustrum; CPu, caudoputamen (dorsal striatum); cxh, cortical hem; DC, reptilian dorsal cortex; DMC, reptilian dorsomedial cortex; DP, dorsal pallium; DT, dorsal thalamus; DVR, dorsal ventricular ridge; En, endopiriform nucleus; GP, globus pallidus; H, hyperpallium; HA, apical hyperpallium; HD, densocellular hyperpallium; HI, intercalated hyperpallium; Hp, hippocampal formation; Hy, hypothalamus; IHA, interstitial nucleus of the apical hyperpallium; Ins, insular cortex; LGE, lateral ganglionic eminence; LP, lateral pallium; M, mesopallium; MC, reptilian medial cortex; MGE, medial ganglionic eminence; MP, medial pallium; N, nidopallium; NCx, neocortex; P, pallium; Pa, pallidum; Pir, piriform cortex; PT, pallial thickening; rf, rhinal fissure; S, subpallium; St, striatum; va, vallecula; VP, ventral pallium; VPa, ventral pallidum. Scale bar: 400μm.

Bulchand *et al.*, 2001; Bishop *et al.*, 2002); (3) cofactors (activators or repressors) and other regulatory proteins that regulate directly or indirectly the expression of specific transcription factors, that show sharp expression boundaries between subdivisions (for example, the LIM-only protein Lmo3, with a sharp expression boundary between dorsal and lateroventral pallial subdivisions; Bulchand *et al.*, 2003; Vyas *et al.*, 2003). The main pallial subdivisions are differentially affected by mutations targeting some of the above-mentioned developmental regulatory genes, supporting that they represent distinct histogenetic compartments. For example, a mutation in the LIM-homeobox gene *Lhx2* produces a severe malformation of the hippocampal formation and neocortex, but the piriform lobe appears unaffected (Bulchand *et al.*, 2001; Vyas *et al.*, 2003).

2.07.2.1.2 Pallial subdivisions in nonmammals: the dorsal pallium in birds and reptiles Since developmental regulatory genes generally show highly conserved sequences and expression patterns, they have become very useful tools for identifying comparable brain regions in different vertebrate species and for studies of brain evolution (Puelles *et al.*, 2000; Medina *et al.*, 2005). Classical and modern developmental studies, including radial glial analysis, fate-mapping studies, and expression of developmental regulatory genes, indicate that the telencephalic pallium in reptiles and birds contains three main radial divisions (Figure 2c): (1) a medial pallium, which gives rise to the medial/dorsomedial cortices in reptiles and to the hippocampal formation (hippocampus and parahippocampal area) in birds; (2) a dorsal pallium, which gives rise to the dorsal cortex in reptiles and the hyperpallium or Wulst in birds; and (3) a lateroventral pallium, which gives rise to the lateral or piriform cortex, to a large nuclear structure called the DVR and to some pallial amygdalar nuclei in reptiles and birds (Holmgren, 1925; Källén, 1951a, 1953, 1962; Striedter, 1997; Striedter and Beydler, 1997; Striedter *et al.*, 1998; Puelles *et al.*, 2000; Cobos *et al.*, 2001; Martínez-García *et al.*, 2002). As in mammals, the pallium of reptiles and birds shows specific expression of *Pax6*, *Tbr1/2,* and *Emx1* during development (Smith-Fernández *et al.*, 1998; Bulfone *et al.*, 1999; Puelles *et al.*, 2000; Garda *et al.*, 2002). Similarly to mammals, in birds there is an organizer center at the medial edge of the pallium expressing *Wnt*-family genes (the avian cortical hem; Figures 2a–2c), which may control the formation of the medial pallial subdivision (Garda *et al.*, 2002). This indicates that the specification and parcellation of the avian/reptilian pallium are controlled by many of the same regulatory genes and mechanisms that control pallial development in mammals.

Further, as in mammals, the lateroventral pallium of birds and reptiles is subdivided into a lateral pallium, showing broad and strong expression of *Emx1*, and a ventral pallium, which expresses *Emx1* only in a thin band of the subpial mantle (Figures 2a–2c) (Smith-Fernández *et al.*, 1998; Puelles *et al.*, 2000). These two pallial subdivisions of birds also differ by their distinct expression of *Dachsund* and several *Cadherin* genes during development (Redies *et al.*, 2001; Szele *et al.*, 2002). However, as in mammals, the derivatives of the lateral and ventral pallial subdivisions of birds apparently display a high degree of cellular mixing (Figure 2c), based on radial glial fiber disposition and fate-mapping analysis in chick embryos (Striedter and Beydler, 1997; Striedter *et al.*, 1998; Striedter and Keefer, 2000). The lateral pallium includes the so-called mesopallium and posterior amygdalar nucleus of birds, whereas in reptiles it appears to include a small dorsolateral part of the DVR plus the dorsolateral amygdalar nucleus (Smith-Fernández *et al.*, 1998; Guirado *et al.*, 2000; Puelles *et al.*, 2000; Martínez-García *et al.*, 2002). The ventral pallium includes the so-called nidopallium and arcopallium of birds, whereas in reptiles it appears to include most of the DVR plus the lateral and other amygdalar nuclei (Smith-Fernández *et al.*, 1998; Guirado *et al.*, 2000; Puelles *et al.*, 2000; Martínez-García *et al.*, 2002). The olfactory tract is located at the surface of the ventral pallium (or ventral DVR) in mammals, birds, and reptiles (Striedter, 1997; Guirado *et al.*, 2000; Puelles *et al.*, 2000; Puelles, 2001). Both the relative (topological) position and molecular profile of the pallial subdivisions (including expression of *Pax6, Tbr1,* and *Emx1*) suggest that the dorsal pallial subdivision of reptiles and birds, from which derive the reptilian dorsal cortex and avian hyperpallium, is comparable and possibly homologous as a field to the dorsal pallium of mammals, which gives rise to the neocortex (Striedter, 1997; Puelles *et al.*, 2000). As in mammals, in reptiles the rhinal fissure separates the dorsal cortex from the piriform cortex and olfactory tract (Figure 2c). These data also indicate that the ventral pallial part of the reptilian/avian DVR (which has the olfactory tract and piriform cortex at the surface, and is poor in *Emx1* expression) is not comparable and cannot be homologized to the neocortex, since they derive from different embryonic primordia (Striedter, 1997; Striedter and Beydler, 1997; Smith-Fernández *et al.*, 1998; Striedter *et al.*, 1998; Puelles *et al.*, 2000).

However, one important issue that developmental studies have not yet resolved is where to locate the exact boundary between the dorsal and lateral pallial subdivisions, since both subdivisions express many of the same developmental regulatory genes (for example, *Emx1*) and the morphological landmarks are not clear in birds and many reptiles. In other words, what is the exact lateral extension of the dorsal pallium in birds and reptiles? In mammals, some developmental regulatory genes are expressed differently in the lateral and dorsal pallium (for example, the LIM-only genes *Lmo2* and *Lmo3*), but, unfortunately, data on the orthologue genes are lacking in nonmammalian vertebrates (Medina *et al.*, 2005). I will return to this issue below.

2.07.2.2 Adult Anatomical Evidence: Morphological Landmarks, Molecular Markers, and Connections

2.07.2.2.1 Morphological landmarks and molecular markers: problematic delimitation of the dorsal pallium in birds and reptiles As noted above, the dorsal cortex of reptiles and the hyperpallium of birds appear to derive from the same pallial embryonic subdivision as the neocortex. In adult animals, these structures show cellular and molecular features typical of pallium. For example, they contain a majority of excitatory (glutamatergic) neurons (the principal or projection neurons) and only a relatively small subpopulation of inhibitory (GABAergic) interneurons (Ottersen and Storm-Mathisen, 1984; Reiner, 1993; Veenman and Reiner, 1994, 1996; Swanson and Petrovich, 1998; Fowler *et al.*, 1999; Medina and Reiner, 2000; Broman *et al.*, 2004). In mammals, birds, and reptiles, the principal pallial neurons have excitatory projections to the striatum and brainstem (Ottersen and Storm-Mathisen, 1984; Veenman and Reiner, 1996; Kenigfest *et al.*, 1998; Fowler *et al.*, 1999; Broman *et al.*, 2004). Some of the strongest evidence showing that the principal pallial neurons are glutamatergic has been provided recently by the localization of vesicular glutamate transporters VGLUT1 and VGLUT2, although data on these transporters exist only in mammals (Fujiyama *et al.*, 2001; Herzog *et al.*, 2001; Broman *et al.*, 2004; Fremeau *et al.*, 2004), but are lacking in birds and reptiles. The GABAergic interneurons of the mammalian neocortex and avian hyperpallium, as those of the rest of the mammalian and avian pallium, originate in the subpallium and migrate tangentially to the pallium during development (Figure 2c) (Anderson *et al.*, 1997, 2001; Pleasure *et al.*, 2000; Cobos *et al.*, 2001; Marín and Rubenstein, 2001; Nery *et al.*, 2002; Legaz *et al.*, 2005). This situation appears to be typical in all tetrapods, since it is also described in amphibians (Brox *et al.*, 2003).

In addition to these and other molecular and cellular features typical of the whole pallium, there are no comparative data on molecular markers that clearly distinguish the neocortex/dorsal pallium from other pallial subdivisions in adult animals. In mammals, the neocortex can be distinguished from the adjacent pallial subdivisions because of its typical six-layered structure and the presence of the rhinal fissure on its lateral egde. However, in birds and reptiles there are no clear morphological landmarks for distinguishing the lateral boundary of the dorsal pallium. The absence of dorsal pallial molecular markers has become an additional obstacule for delimiting the lateral extension of the dorsal pallium in adult birds and reptiles. As noted above, more comparative studies on the expression of developmental regulatory genes are also needed to resolve this issue. In reptiles, the dorsal cortex appears to include a rostrolateral extension called pallial thickening (reviewed in Reiner, 1993; Medina and Reiner, 2000). However, the identification of the pallial thickening varies between authors and reptilian species, and it appears that a ventral part of it is located deep to the piriform cortex and, thus, may be part of the lateral pallium (Figure 2c). Analysis of radial glial fiber disposition in that part of the reptilian pallium (Monzón-Mayor *et al.*, 1990) suggests that only the dorsal-most part of the pallial thickening may belong to the dorsal pallium (Figure 2c). This dorsal part of the pallial thickening appears located above the rhinal fissure (visible in only some reptiles), which is consistent with its dorsal pallial nature. As in reptiles, so also in birds, there is some confusion on where to locate the lateral boundary of the hyperpallium or Wulst. According to numerous studies, the hyperpallium includes the so-called apical, interstitial nucleus of apical, intercalated, and densocellular hyperpallium (HA, IHA, HI, and HD, respectively), and its lateral (or lateroventral) boundary coincides with both the superior frontal lamina and a superficial groove called vallecula (Figures 1b–1i and 2c) (Karten *et al.*, 1973; Shimizu and Karten, 1990; reviewed in Medina and Reiner, 2000). However, although this is generally true, the HD exceeds laterally the vallecula at rostral levels (Shimizu and Karten, 1990), and the superior frontal lamina appears to bend laterally when approaching the vallecula (Suárez *et al.*, 2006; see Figures 1e, 1g, and 2c). Further, the HD is sometimes misidentified and either confused

with the dorsal part of the mesopallium (a part of the DVR that belongs to the lateral pallium) or vice versa. This is partly due to the fact that the HD (or part of it) shares with the mesopallium expression of some molecular markers, such as some glutamate receptor subunits (Wada *et al.*, 2004). This has raised the question of whether the HD should or should not be considered part of the hyperpallium. However, the HD also differs from the mesopallium in many other molecular features, such as expression of calcium-binding proteins (Suárez *et al.*, 2006), expression of delta and mu opiate receptors (Reiner *et al.*, 1989), and expression of GluR1 glutamate receptor subunit, neurotensin receptors, or the neuropeptide substance P (Reiner *et al.*, 2004) (Figures 1f and 1g). Further, recent evidence indicates the existence of an additional pallial division (the laminar pallial nucleus) clearly located at the boundary between HD and mesopallium, showing distinct expression of calcium-binding proteins throughout development and in adult chicks (Suárez *et al.*, 2006). Thus, the questions raised on the identity and nature of HD may be partially due to the use of different species. Whereas all four subdivisions of the hyperpallium are clearly distinguished in birds with a large hyperpallium (such as the owl), it appears that the more lateral hyperpallial subdivisions, HI or HD, are difficult to distinguish in either pigeons/chicks or songbirds, respectively.

2.07.2.2.2 Connections One of the most typical features of the mammalian neocortex is that it contains unimodal sensory and motor areas that receive their input directly from specific nuclei of the dorsal thalamus (Northcutt and Kaas, 1995) (Figure 3). These primary functional areas of mammals show a detailed point-to-point representation of the body and/or world (Krubitzer, 1995). The presence of these primary, unimodal sensory and motor areas makes the neocortex unique and different from adjacent pallial divisions (such as the hippocampal formation, which typically receives multimodal thalamic input, and the piriform cortex, which typically receives olfactory input from the bulb), and this has been used for identifying the dorsal pallium or specific dorsal pallial functional areas in other vertebrates. Nevertheless, the use of connections (or any other single data) alone for identification of homologies is highly risky since they may have changed during the course of evolution (Striedter, 2005). For this reason, when searching for homologies and for evolutionary interpretations, data on connections need to be used in combination with other data, including embryological origin and/or topological position.

The neocortex contains: (1) a primary visual area (V1), receiving input from the retinorecipient dorsal lateral geniculate nucleus; (2) a primary somatosensory area (S1), receiving input from specific nuclei of the ventrobasal (or ventral posterior) thalamic complex (including the ventral posterolateral (VPL) and ventral posteromedial (VPM) nuclei in rodents), which in turn receive somatosensory information from the head and body via the trigeminal sensory and dorsal column nuclei; and (3) a primary motor area (M1), receiving input from specific nuclei of the ventrobasal thalamic complex (including the ventral anterior (VA) and ventral lateral (VL) nuclei in rodents) that receive motor information from the basal ganglia and deep cerebellar nuclei (Figure 3) (Krubitzer, 1995; Groenewegen and Witter, 2004; Sefton *et al.*, 2004; Tracey, 2004; Guy *et al.*, 2005). These primary functional areas are present in most groups of mammals and have a similar relative position within the neocortex, with M1 and S1 being always rostral to V1 (Krubitzer, 1995; Medina and Reiner, 2000; Kaas, 2004). This suggests that these areas (at least V1 and S1, as well as some other sensory areas) were likely present in the origin of the mammalian radiation (Krubitzer, 1995; Slutsky *et al.*, 2000). Further, it appears that the neocortex of early mammals had multiple somatosensory representations of the body, each one corresponding to a distinct area (Krubitzer *et al.*, 1995, 1997; Catania *et al.*, 2000a, 2000b; Kaas, 2004). However, current available data suggest that early mammals did not possess a separate motor cortical area (M1), and this possibly appeared with the origin of placental mammals (Kaas, 2004). In mammals with a small neocortex, the visual and somatomotor areas show a close spatial contiguity (for example, in monotremes or in the hedgehog). In mammals with a large neocortex, such as rodents, carnivores, and primates, V1 becomes secondarily displaced to the most caudal part of the neocortex (occipital lobe) by the development of novel cortical areas involved in higher-order or multimodal information processing. In these mammals, S1 is located in the parietal lobe (in the postcentral gyrus of the primate parietal lobe), whereas M1 is located in the frontal lobe (in the precentral gyrus of the primate frontal lobe). In rodents and primates, the initial parcellation of these functional areas during development is related (among other things) to their expression of specific ephrin ligands and receptors, some of which can be used as early markers of S1 (ephrinA5) or V1 (Ephrin receptor EphA6) (Donoghue and Rakic, 1999; Yun *et al.*, 2003).

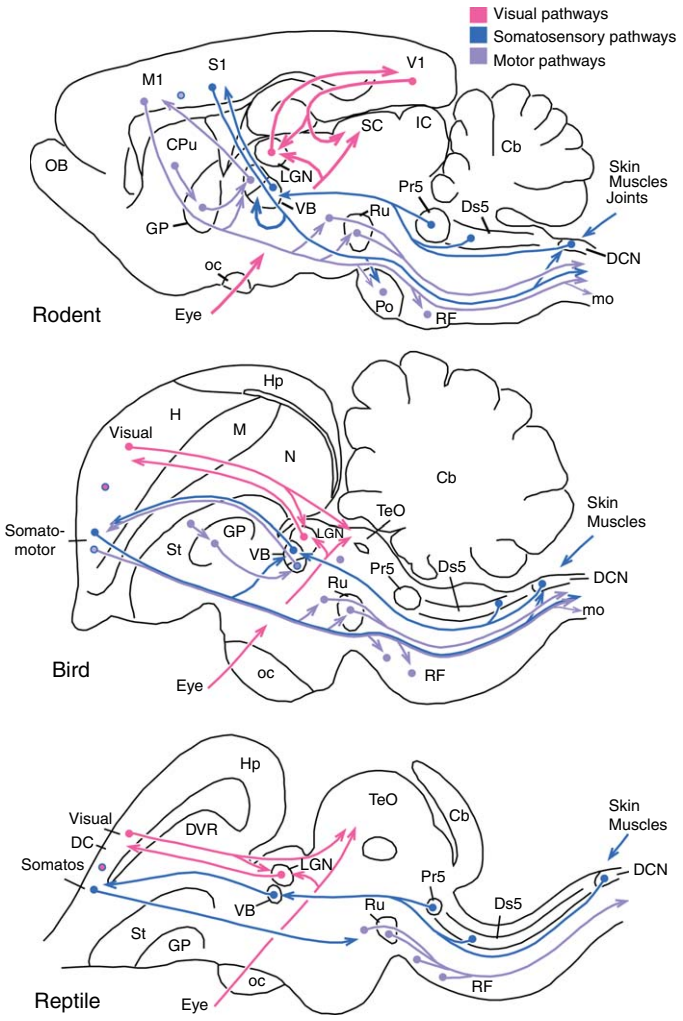

Figure 3 Schematics of lateral views of the brain of a rodent, a bird, and a reptile, showing the major connectivity patterns of the visual, somatosensory, and motor pathways. In mammals, birds, and reptiles, partially comparable visual and somatosensory pathways to the dorsal pallium are present. Visual information reaches a dorsal pallial primary visual area (V1 in mammals) by way of the lateral geniculate nucleus (LGN), located in the lemnothalamus. In turn, the visual cortical (dorsal pallial) area projects back to this thalamic nucleus and to the optic tectum. Somatosensory information reaches a dorsal pallial primary somatosensory area (S1 in mammals) by way of the ventrobasal complex of the lemnothalamus (VB). In birds, the body is mainly represented in the dorsal pallium, whereas in mammals and at least some reptiles, there is representation of both body and head. In birds and mammals, the ventrobasal complex has a motor subdivision that receives basal ganglia and cerebellar input, and projects to the dorsal pallium. In birds, this motor input ends in the somatosensory field (thus becoming a true somatomotor area). In placental mammals, such as rodents, the motor input ends mostly in a separate primary motor area (M1), although a small somatosensory–motor overlap occurs at the interface between M1 and S1. See text for details. In mammals, both S1 and M1 project back to the ventrobasal thalamic complex and to the brainstem and spinal cord by way of the pyramidal tract. S1 projections primarily end on precerebellar centers (such as the pontine nuclei) and somatosensory-relay centers (such as the dorsal column nuclei and the dorsal horn of the spinal cord). M1 projections primarily reach premotor precerebellar and reticulospinal centers (such as prerubral and rubral neurons), and also provide some input to motoneuron pools, such as those of the ventral horn of the spinal cord. In birds, the somatomotor dorsal pallial area shows descending projections resembling both S1 and M1 (especially in some avian species). In reptiles, the putative ventrobasal complex does not include any motor subdivision. The somatosensory area of the reptilian dorsal pallium only shows projections to diencephalic and midbrain tegmentum, reaching premotor precerebellar and reticulospinal cell groups, and suggesting that it may control or modulate motor behavior. However, this area lacks most of the connections typical of a true somatomotor area, suggesting that this likely evolved independently in birds and mammals. Cb, cerebellum; CPU, caudoputamen (dorsal striatum); DC, reptilian dorsal cortex; DCN, dorsal column nuclei; Ds5, descending sensory trigeminal nucleus; DVR, dorsal ventricular ridge; GLN, dorsal lateral geniculate nucleus; GP, globus pallidus; H, hyperpallium; Hp, hippocampal formation; IC, inferior colliculus; M, mesopallium; M1, primary motor area of neocortex; mo, motoneuron pools; N, nidopallium; OB, olfactory bulb; oc, optic chiasm; Po, pontine nuclei; Pr5, principal sensory trigeminal nucleus; RF, reticular formation; Ru, nucleus ruber; S1, primary somatosensory area of neocortex; SC, superior colliculus; St, striatum; TeO, optic tectum; V1, primary visual area of neocortex; VB, ventrobasal thalamic complex.

Are these areas present in the dorsal pallium of reptiles and/or birds? Data on ephrin ligands and receptors in the dorsal pallium of birds and reptiles are lacking but, in any case, the search for functional areas in the dorsal pallium of birds and reptiles requires the analysis of the thalamopallial projections in these vertebrate groups and/or electrophysiological recordings in the pallium.

Of interest, the adult hyperpallium of birds and dorsal cortex of reptiles show some patterns of connections with the dorsal thalamus similar to those of the neocortex (Figure 3). In particular, the patterns of connections suggest the existence of a primary visual area and a primary somatosensory area in the reptilian dorsal cortex and avian hyperpallium that are comparable and might be homologous to the primary visual (V1) and primary somatosensory (S1) areas of the mammalian neocortex (reviewed in Medina and Reiner, 2000; see also Wild and Williams, 2000). The somatosensory area found in the avian hyperpallium shows some connections, suggesting that it may represent a true somatomotor area, able to play a role in modulation of somatosensory input as well as in motor control, resembling aspects of mammalian S1+M1 (perhaps like the somatomotor area present in the origin of mammals). However, available data suggest that the motor control features of this avian hyperpallial area evolved independently from those found in M1.

The conclusion of homology of the visual and somatosensory cortical areas is partially based on assumption of homology of the thalamic nuclei of reptiles, birds, and mammals relaying the visual or somatosensory information to the dorsal pallium. But, for this to be true, these nuclei not only need to share similar connections, but also need to originate from the same embryonic primordium (or be located in the same histogenetic field). This will be analyzed in the following section.

2.07.3 Thalamopallial Projections and Sensory and Motor Areas in the Dorsal Pallium of Mammals, Birds, and Reptiles

2.07.3.1 Divisions of the Thalamus: Specific Relation of the Lemnothalamus with the Dorsal Pallium

To know whether the thalamic nuclei projecting to V1, S1, or M1 of mammalian neocortex are located in the same histogenetic unit as the avian and reptilian thalamic nuclei projecting to the hyperpallium/dorsal cortex, it is important to analyze the development and adult organization of the thalamus. In this sense, Butler (1994a) proposed the existence of two dorsal thalamic divisions, the lemnothalamus and the collothalamus, which receive sensory input through different systems and have different connections with the pallium (see The Dual Elaboration Hypothesis of the Evolution of the Dorsal Thalamus). The lemnothalamus includes nuclei receiving sensory input primarily from lemniscal systems and projecting to the medial and/or dorsal pallium (Butler, 1994a, 1994b). The collothalamus includes nuclei receiving a major collicular input and projecting to the lateroventral pallium (Butler, 1994a, 1994b). A similar but more complex subdivision of the thalamus was later proposed by other authors based on differential expression of cadherins or calcium-binding proteins by thalamic subdivisions during development or in the adult (Dávila *et al.*, 2000; Redies *et al.*, 2000). According to these authors, the dorsal thalamus is subdivided into three main histogenetic divisions, called dorsal, intermediate, and ventral tiers, each one showing a specific immunostaining profile and connections with a particular pallial subdivision (Dávila *et al.*, 2000; Redies *et al.*, 2000; Puelles, 2001). The dorsal tier corresponds roughly to the lemnothalamus, whereas the intermediate and ventral tiers roughly correspond to the collothalamus of Ann Butler (Butler, 1994a, 1994b; Dávila *et al.*, 2000; Redies *et al.*, 2000). Thus, the thalamic nuclei projecting to V1, S1, and M1 in mammals are all located in the dorsal tier or lemnothalamus (Puelles, 2001; Butler, 1994a). What about the visual and somatosensory/somatomotor thalamic nuclei projecting to the avian hyperpallium and reptilian dorsal cortex?

2.07.3.2 A Primary Visual Area in the Dorsal Pallium of Birds and Reptiles and Its Comparison to V1 of Mammals

In mammals, V1 (area 17) receives unimodal visual input from the dorsal lateral geniculate nucleus and projects back to this nucleus and to the superior colliculus (Figure 3) (Krubitzer, 1995; Sefton *et al.*, 2004). A comparable retinorecipient dorsal lateral geniculate nucleus is present in the lemnothalamus of birds and reptiles that projects to the avian hyperpallium and reptilian dorsal cortex (Figure 3) (Karten *et al.*, 1973; Hall *et al.*, 1977; Miceli and Repérant, 1982; Miceli *et al.*, 1990; Mulligan and Ulinski, 1990; Butler, 1994a, 1994b; Kenigfest *et al.*, 1997; Medina and Reiner, 2000; Zhu *et al.*, 2005). In lizards, this nucleus is sometimes called intercalatus (Bruce and Butler, 1984a) and apparently corresponds to the deeper part (cell plate) of the dorsal lateral geniculate nucleus of other authors (Kenigfest *et al.*, 1997; Dávila *et al.*, 2000). In lizards, the geniculate thalamic input only reaches a lateral extension of the dorsal cortex, called pallial

thickening (Bruce and Butler, 1984a; Kenigfest *et al.*, 1997). In birds, the geniculate thalamic input mainly reaches a hyperpallial subdivision called interstitial nucleus of the apical hyperpallium or IHA (Karten *et al.*, 1973; Watanabe *et al.*, 1983). As in mammals, the dorsal pallial area of birds and at least some reptiles (such as turtles) that receives visual input from the geniculate nucleus projects back to this thalamic nucleus and the optic tectum (Figure 3) (Karten *et al.*, 1973; Hall *et al.*, 1977; Miceli and Repérant, 1983, 1985; Reiner and Karten, 1983; Ulinski, 1986; Mulligan and Ulinski, 1990; Butler, 1994a, 1994b; Kenigfest *et al.*, 1998). Therefore, their similar position, histogenetic origin, and connections suggest that the visual lemnothalamic nuclei and related pallial areas of the neocortex, hyperpallium, and dorsal cortex of mammals, birds, and reptiles are homologous, and evolved from similar areas present in their common ancestor.

2.07.3.3 A Primary Somatosensory Area in the Dorsal Pallium of Birds and Reptiles and Its Comparison to S1 of Mammals

In the mammalian neocortex, S1 receives somatosensory input from the ventrobasal or ventral posterior thalamic complex (in particular, from VPL, receiving body information via the dorsal column nuclei, and from VPM, receiving head information via the principal sensory trigeminal nucleus; restricted parts of VPL/VPM also receive pain and temperature information directly from the spinal cord through the dorsal horn and spinal trigeminal nucleus) (Figure 3). In turn, S1 shows descending projections back to this thalamic complex and to the brainstem and spinal cord (reaching primarily precerebellar and/or somatosensory relay centers) (Weisberg and Rustioni, 1977; McAllister and Wells, 1981; Torigoe *et al.*, 1986; Krubitzer, 1995; Desbois *et al.*, 1999; Manger *et al.*, 2001; Martínez-Lorenzana *et al.*, 2001; Killackey and Sherman, 2003; Craig, 2004; Friedberg *et al.*, 2004; Gauriau and Bernard, 2004; Leergaard *et al.*, 2004; Oda *et al.*, 2004; Tracey, 2004; Waite, 2004; Guy *et al.*, 2005). Similarly to S1, the frontal part of the avian hyperpallium (Wulst) receives somatosensory input from the dorsointermediate ventral anterior thalamic nucleus (DIVA), which is a target of both the dorsal column nuclei (Wild, 1987, 1989, 1997; Funke, 1989a, 1989b; Korzeniewska and Güntürkün, 1990) and the spinal cord (Schneider and Necker, 1989) (Figure 3). The avian DIVA develops in the dorsal tier/lemnothalamus of the dorsal thalamus (Redies *et al.*, 2000) and, thus, appears comparable in position, histogenetic origin, and connections to the mammalian ventrobasal thalamic complex (mainly to VPL). In addition to receiving somatosensory input from DIVA, the frontal part of the Wulst (hyperpallium) projects back to this thalamic nucleus, to the brainstem, and, in some species of birds, to the cervical spinal cord (Figure 3) (Wild, 1992; Wild and Williams, 2000). As with S1, the frontal hyperpallial descending projections predominantly reach precerebellar areas and somatosensory relay areas, such as the thalamic DIVA, the dorsal column nuclei, and the vicinity of medial lamina V in the cervical spinal dorsal horn, which suggests that the frontal hyperpallium may be primarily concerned with the control/modulation of somatosensory input (Wild and Williams, 2000). This suggests that the avian frontal hyperpallium contains a primary somatosensory area that appears comparable to S1 of mammals (Wild, 1992; Medina and Reiner, 2000; Wild and Williams, 2000). However, unlike S1, a sensory trigeminal representation (with head information) has not been found in the hyperpallium (Wild *et al.*, 1985). To know whether these primary somatosensory areas of the avian hyperpallium and mammalian neocortex are homologous we need to analyze if a similar pallial area is present in the dorsal pallium of reptiles.

The frontal part of the reptilian dorsal cortex was previously thought to contain a somatosensory area based on input from a spinorecipient thalamic nucleus (Ebbesson, 1967, 1969, 1978; Hall and Ebner, 1970). Modern tract-tracing data in lizards indicate that the rostral dorsal cortex receives distinct ipsilateral input specifically from a ventral part of the dorsolateral thalamic nucleus (Guirado and Dávila, 2002), which receives somatosensory input from the dorsal column and trigeminal sensory nuclei as well as from the spinal cord (Figure 3) (Hoogland, 1982; Desfilis *et al.*, 1998, 2002). Of interest, the dorsolateral thalamic nucleus of lizards is located in the dorsal tier/lemnothalamus of the dorsal thalamus, and its ventral part DLV, which differs from the rest of the nucleus by its connections and calbindin immunostaining profile – shows a location that resembles that of avian DIVA and ventrobasal complex of mammals (Dávila *et al.*, 2000). The projection from the dorsal column and sensory trigeminal (both descending and principal) nuclei and from the spinal cord to the dorsolateral thalamic nucleus appears to reach specifically its ventrolateral part or DLV (plus the area adjacent to it, called intermediodorsal nucleus; Ebbesson, 1967, 1969, 1978; Hoogland, 1982). Thus, DLV of lizards appears to be a distinct subnucleus of the lemnothalamus that may be primarily involved in

somatosensory information processing. Using modern tract-tracing techniques, similar thalamocortical projections have also been described in crocodiles (Pritz and Stritzel, 1987; these authors also found a specific dorsolateral cell population projecting only ipsilaterally to the dorsal cortex) and in adult and developing turtles (Hall *et al.*, 1977; Cordery and Molnár, 1999). In turtles, the thalamocortical nucleus appears located in a perirotundal position, medially adjacent to the dorsal lateral geniculate nucleus and ventral to the dorsolateral thalamic nucleus (a position that resembles the DLV of lizards), and this perirotundal area is the site of termination of spinal and dorsal column nuclei (but not retinal) projections (Künzle and Schnyder, 1983; Siemen and Künzle, 1994). However, other authors studying turtles have not found any thalamic relay center projecting to the dorsal cortex other than the geniculate nucleus (Zhu *et al.*, 2005). This may be due to the more caudal location of the injections in the dorsal cortex (note that the somatosensory area is located at its rostral pole) or to the employment of *in vitro* tract-tracing techniques in the study done by Zhu *et al.* (2005). Based on the evidence presented above, two different thalamic relay centers conveying either visual or somatosensory information to the dorsal cortex are present in most reptilian groups, and were likely present in their common ancestor. Thus, the frontal part of the dorsal cortex of most reptiles contains a primary somatosensory area that is comparable and may be homologous to those present in the hyperpallium of birds and the neocortex of mammals. Consistent with this, the relative position of the primary somatosensory area in the dorsal pallium is similar in mammals, birds, and reptiles, being always located rostral (in a more frontal position) to the primary visual area.

2.07.3.4 Do Birds and/or Reptiles Possess a Somatomotor Dorsal Pallial Area Comparable to M1 of Mammals?

In the mammalian neocortex, M1 (area 4) receives motor input from a specific part of the lemnothalamic ventrobasal complex (VA/VL nuclei in rodents), and shows descending projections back to this thalamic complex, and to the brainstem and the spinal cord (Figure 3), where the projections reach precerebellar (including the red and pontine nuclei) and sensory-relay areas (including dorsal column nuclei and dorsal horn of the spinal cord), but also reach premotor reticulospinal cell groups (including the prerubral and rubral neurons) and, in some species (such as rodents and primates), motor neuron pools such as those of the ventral horn in the spinal cord (Weisberg and Rustioni, 1977; Humphrey *et al.*, 1984; Torigoe *et al.*, 1986; Liang *et al.*, 1991; Krubitzer, 1995; Song and Murakami, 1998; Kuchler *et al.*, 2002; Leergaard *et al.*, 2004). In general, the descending projections of M1 are similar to those of S1, and axons from both areas contribute to form the pyramidal tract. However, the descending projections of S1 and M1 are somewhat different. For example, in the brainstem, S1 projects significantly more heavily to the precerebellar pontine nuclei than M1 (Leergaard *et al.*, 2004), whereas M1 is the major source of corticorubral axons (Giuffrida *et al.*, 1991; Burman *et al.*, 2000) (Figure 3). Further, in the spinal cord, S1 axons primarily reach dorsal horn laminae, whereas M1 axons, but not S1 axons, also reach the motoneuron pools in the ventral horn (Figure 3) (Ralston and Ralston, 1985; Martín, 1996). Current available data suggest that early mammals lacked a separate motor cortical area (M1), and that a separate M1 likely evolved with the origin of placental mammals (Kaas, 2004). Thus, it appears that early mammals only had an S1 where somatosensory and motor attributes were overlapped, a situation which resembles that found in marsupials (Kaas, 2004).

Similarly to M1, the frontal part of the avian hyperpallium (Wulst) receives input from a putative motor thalamic nucleus, the ventrointermediate area (VIA), which receives input from the avian globus pallidus, substantia nigra pars reticulata, and deep cerebellar nuclei (Medina *et al.*, 1997) (Figure 3). The avian VIA resembles the motor part of the mammalian ventrobasal thalamic complex (VA/VL) in both its position (located in the lemnothalamus and adjacent to the somatosensory part of the avian ventrobasal complex or DIVA), and its connections (Medina *et al.*, 1997). Both DIVA and VIA project to the frontal part of the hyperpallium (Wild, 1987, 1989; Funke, 1989a, 1989b; Korzeniewska and Güntürkün, 1990; Medina *et al.*, 1997), where somatosensory and motor information may be completely overlapped (Medina and Reiner, 2000) (Figure 3). Of note, as S1 and M1 of mammals, the frontal hyperpallium of birds projects back to the thalamus (including DIVA), to the brainstem and, in some avian species, to the cervical spinal cord (Wild, 1989, 1992; Medina and Reiner, 2000; Wild and Williams, 2000) (Figure 3). In the brainstem and spinal cord, the frontal hyperpallial projections reach precerebellar (including pretectal and rubral nuclei), sensory-relay cell groups (including the dorsal column nuclei and the dorsal horn in the spinal cord), premotor reticulospinal neurons (such as rubrospinal neurons) and, in some birds, a few axons reach the ventral horn of the cervical spinal

cord, where motoneuron pools are located (Wild, 1992; Wild and Williams, 2000). Thus, the frontal hyperpallium contains a somatosensory/somatomotor area that appears at least partially comparable to the overlapped S1+M1 of marsupials, and possibly of early mammals. To know whether these areas are homologous we need to know if a similar sensorimotor field is present in the dorsal pallium of reptiles.

As noted above, in some reptiles (lizards), the frontal part of the dorsal cortex appears to receive somatosensory input from a specific subdivision of the dorsolateral thalamic nucleus, the DLV (Guirado and Dávila, 2002) (Figure 3). Further, this part of the reptilian dorsal cortex has descending projections to diencephalic and midbrain tegmetum (Hoogland and Vermeulen-vanderZee, 1989; Guirado and Dávila, 2002). In the prerubral tegmentum, these cortical projections reach at least the nucleus of the medial longitudinal fascicle, which is a well-known premotor precerebellar and reticulospinal cell group (Figure 3) (ten Donkelaar, 1976; Woodson and Künzle, 1982; Wolters *et al.*, 1986). This feature has been used to suggest that this part of the reptilian dorsal cortex may represent a rudimentary sensorimotor area, partially comparable to that in other amniotes (Medina and Reiner, 2000; Guirado and Dávila, 2002). However, this putative sensorimotor area of the reptilian dorsal cortex does not possess a distinct motor field comparable to M1 of mammals, since its thalamic input does not include a basal ganglia-recipient nor a cerebellar-recipient nucleus. No part of the dorsolateral thalamic nucleus and no part of the reptilian dorsal thalamus receives direct basal ganglia input (Reiner *et al.*, 1984, 1998; Medina and Smeets, 1991) nor input from the deep cerebellar nuclei (Künzle, 1985). Further, in some reptilian species (including the pond turtle) the descending projections of the dorsal cortex are rather modest and do not reach rubral and, perhaps, not even prerubral levels (Zhu *et al.*, 2005). Thus, at present it is unclear whether ancestral reptiles had a rudimentary somatomotor area in the dorsal cortex, and more data are needed in other reptilian species before any conclusion can be reached. If a rudimentary somatomotor area was present in the dorsal cortex of reptiles, this area lacked many of the connections that characterize the true somatomotor cortical area found in birds and mammals (including basal ganglia and cerebellar indirect input, or output to additional precerebellar and reticulospinal fields and to the spinal cord), meaning that these features likely evolved independently in the avian and mammalian radiations.

2.07.3.5 Other Functional Areas in the Pallium of Birds and Reptiles and Comparison to Mammals

In birds and reptiles, there are other sensory (visual, somatosensory, and auditory) areas in the pallium that are located in the DVR (Karten and Hodos, 1970; Dubbeldam *et al.*, 1981; Bruce and Butler, 1984b; Wild, 1987, 1994; Wild *et al.*, 1993, 1997; Guirado *et al.*, 2000; reviewed by Karten and Shimizu, 1989; Butler, 1994b; Reiner, 2000). These sensory areas are mainly located in the ventral pallial part of the DVR (called nidopallium in birds; Reiner *et al.*, 2004) and receive visual, somatosensory, or auditory input from specific nuclei of the collothalamus or directly from the brainstem (see above-cited references; this is described in detail in Evolution of the Nervous System in Reptiles, Visual Cortex of Turtles). In birds, some of these DVR areas appear to have a better (more detailed) sensory representation than those present in the hyperpallium, such as the nucleus basalis of the budgerigar, which shows a highly somatotopically organized representation of head and body (Wild and Farabaugh, 1996; Wild *et al.*, 1997). In addition, the caudal part of the DVR in birds (including the caudal nidopallium and the region called arcopallium) and reptiles contains associative and/or motor centers that project to the basal ganglia, hypothalamus, and/or, in birds, also to premotor brainstem centers (Zeier and Karten, 1971; Bruce and Neary, 1995a, 1995b, 1995c; Davies *et al.*, 1997; Dubbeldam *et al.*, 1997; Lanuza *et al.*, 1997, 1998; Kröner and Güntürkün, 1999; Bottjer *et al.*, 2000; Martínez-García *et al.*, 2002). Further, in songbirds and budgerigars, the caudal DVR (arcopallium) contains a specific motor area that projects directly to motor brainstem nuclei, the ambiguus, and/or hypoglossal motor nuclei, which control syringeal, respiratory, and tongue muscles (Nottebohm, 1991; Vicario, 1991a, 1991b; Wild, 1993; Brauth *et al.*, 1994; Striedter, 1994; Durand *et al.*, 1997; see details on this motor pallial area and its connections in The Evolution of Vocal Learning Systems in Birds). In songbirds and budgerigars, this motor area is well developed and plays a key role in vocalization (including vocal learning and vocal production), and apparently evolved independently in songbirds and budgerigars (Striedter, 1994). These sensory, associative, and motor areas of the DVR play very important roles in sensory processing, sensorimotor integration, and motor control, and in birds are also involved in cognitive tasks such as learning, memory, and spatial orientation, and they have been compared to specific areas or specific cell populations of the mammalian temporal,

frontal, and prefrontal neocortex (for example, Karten, 1969, 1997; Morgensen and Divac, 1993; Veenman *et al.*, 1995; Kröner and Güntürkün, 1999; see The Evolution of Vocal Learning Systems in Birds and Humans). Although this makes sense from a functional point of view, the different histogenetic origin of the DVR (lateroventral pallium) and neocortex (dorsal pallium) indicates that the similarities of such sauropsidian DVR and mammalian neocortical areas represent cases of analogy (homoplasy). Consistent with this, the thalamic nuclei that project to the DVR sensory areas are not comparable in location to those that project to the neocortex. Thus, the DVR receives sensory information via thalamic nuclei that are located in the intermediate and ventral tiers of the dorsal thalamus, whereas those that project to the neocortex are generally located in the dorsal tier or lemnothalamus (Dávila *et al.*, 2000, 2002; Puelles, 2001). Further, the avian motor area(s) of the caudal DVR projecting to the premotor and/or motor brainstem are not present in the caudal DVR of reptiles (some of them are not even present in all birds), which means that they evolved as novelties in some birds. Thus, it appears that, in contrast to mammals, the repertory of complex behaviors shown by birds and reptiles depends primarily (although not exclusively) on a large variety of cell groups that develop in the ventrolateral pallial histogenetic division, but the contribution of dorsal pallial areas to these behaviors is likely more modest (especially in reptiles).

2.07.4 Pallial Lamination in Birds and Mammals: Evidence for Independent Evolution

2.07.4.1 Different Development and Adult Organization of Neocortical Layers and Hyperpallial Subdivisions

In mammals, the neocortex shows a laminar structure of six layers, and each layer has a similar cytoarchitecture and general pattern of connections throughout all areas, including V1, S1, and M1 (Figure 4). Thus, the dorsal thalamic input mainly contacts cells in neocortical layer 4, a layer that is called granular layer because of its typical granule or stellate cells (Humphrey *et al.*, 1977; Kharazia and Weinberg, 1994). In this layer, thalamic axons contact granule cells as well as apical dendrites of pyramidal neurons located below, in layers 5/6 (Mountcastle, 1997). In addition, thalamocortical axons ending in layer 4 provide collaterals that terminate in layer 5 and/or 6, but other thalamocortical axons terminate in layer 1 (Figure 4) (Jones, 1975; Rausell *et al.*, 1992; Lu and Lin, 1993; Zhang and Deschenes, 1998; Groenewegen and Witter, 2004; Sefton *et al.*, 2004). Layers 2 and 3 are called supragranular layers, located superficially to layer 4, and typically contain small to medium-sized pyramidal neurons involved in corticocortical (associational) projections (Gilbert and Kelly, 1975; Jones and Wise, 1977; Swadlow and Weyand, 1981; Sefton *et al.*, 2004). Layers 5 and 6 are called infragranular layers, located deep to layer 4, and typically contain large pyramidal neurons that show descending projections to the striatum, thalamus, and brainstem (Figure 4). Layer 5 mainly projects to the striatum and brainstem (to the midbrain tectum in the case of V1 and to the brainstem tegmentum and spinal cord in the case of S1 and M1), whereas layer 6 typically projects to the thalamus (Gilbert and Kelly, 1975; Jones and Wise, 1977; Swadlow and Weyand, 1981; Sefton *et al.*, 2004; Tracey, 2004). The pyramidal neurons of the supra- and infragranular layers of the neocortex typically have a long apical dendrite that span the cortical layers above its cell body (Figure 4), which provides one of the anatomical bases for the columnar functional organization of the neocortex (Mountcastle, 1997; Lübke *et al.*, 2000).

In birds, the dorsal pallium (corresponding to the so-called hyperpallium) also shows cytoarchitectonic subdivisions, considered by some authors as the layers of the neocortex (for example, Karten *et al.*, 1973; Shimizu and Karten, 1990; reviewed by Medina and Reiner, 2000). From rostral (frontal) to caudal levels, each hyperpallial subdivision is characterized by a specific pattern of connections which partially resembles the connectivity organization of neocortical layers (Figure 4). For example, the thalamic input ends primarily in an intermediate hyperpallial subdivision called the IHA, in both the visual and somatomotor areas (Karten *et al.*, 1973; Watanabe *et al.*, 1983; Wild, 1987, 1997), resembling neocortical layer 4. Nevertheless, some thalamic axons appear to end in the hyperpallium outside IHA (Figure 4). Further, the descending projections to the striatum, thalamus, and brainstem mainly originate in the apical hyperpallium or HA (Reiner and Karten, 1983; Wild, 1992; Wild and Williams, 1999, 2000), resembling neocortical layers 5–6. Morever, the densocellular hyperpallium (HD) appears to be mainly involved in connections with other pallial and subpallial areas (Veenman *et al.*, 1995; Kröner and Güntürkün, 1999; Wild and Williams, 1999), thus partially resembling neocortical layers 2–3. In addition to the apparently similar laminar organization of both neocortex and hyperpallium, there is evidence suggesting that they also

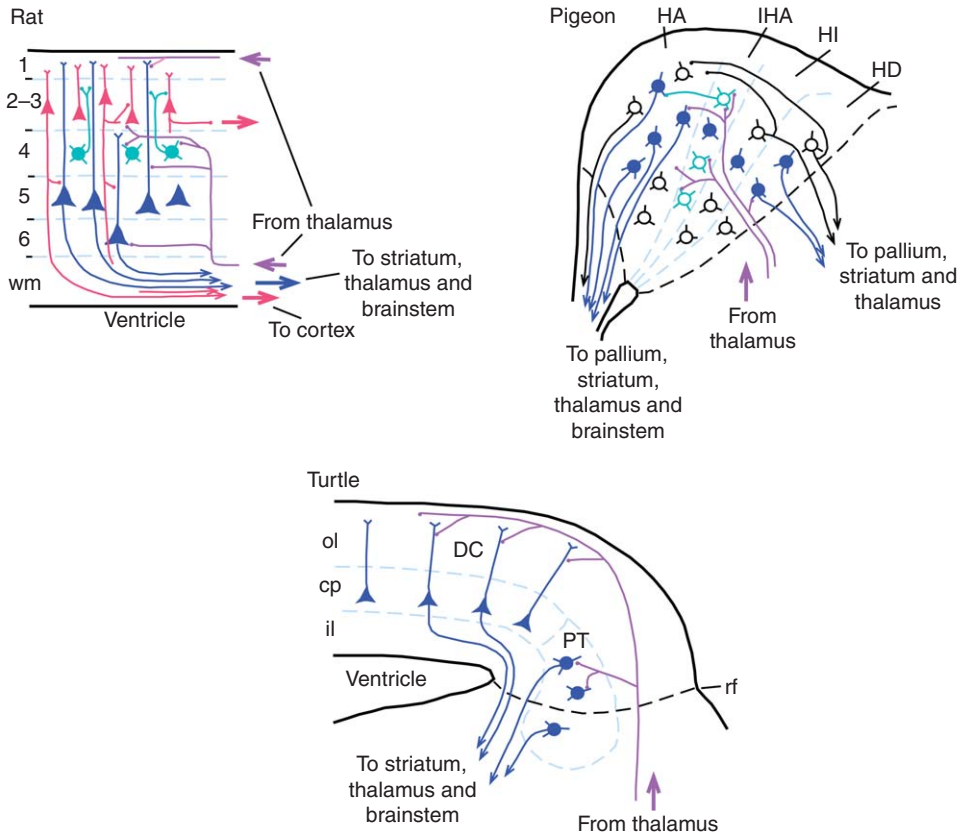

Figure 4 Schematics of the layers/subdivisions, cell types, and major connections of the mammalian neocortex, avian hyperpallium, and reptilian dorsal cortex. The mammalian neocortex shows a six-layered organization, and each layer shows specific cell types and connections. The thalamic input primarily reaches the intermediate layer 4 (also called granular layer, because of its typical granule or stellate cells). In this layer, thalamic axons contact stellate cells as well as apical dendrites of pyramidal neurons located in infragranular layers (layers 5 and 6). Some thalamic axons also reach layers 6 or 1. Infragranular layers contain large pyramidal neurons having apical dendrites that radially span the layers above, and give rise to descending projections to the striatum, thalamus, and brainstem. Supragranular layers contain small to medium pyramidal neurons involved in corticocortical (associational) connections. This anatomical and cellular organization, with radially oriented dendrites that span most layers, constitutes one of the basis of the functional columnar organization of neocortex. In contrast to this organization, the avian hyperpallium shows four mediolateral subdivisions that are formed and organized in a radically different way. These subdivisions contain multipolar or stellate-like neurons having star-like oriented dendrites that do not span adjacent subdivisions (i.e., they lack the translayer, radial dendritic organization typical of neocortex). In contrast to the neocortex, the connections between subdivisions occur by way of tangential projections, instead of the radial connections typical of neocortical columns. Nevertheless, the patterns of connections of hyperpallial subdivisions partially resemble those of neocortical layers. For example, thalamic input primarily ends in an intermediate subdivision (IHA), which is sandwiched between a subdivision (HA) giving rise to descending projections to the striatum, thalamus, and brainstem, and another subdivision (HD) giving rise to pallial projections. However, HA also projects to other pallial areas, whereas HD also projects to the striatum and thalamus, indicating that their similarity with specific neocortical layers in terms of connectivity is only partial. The reptilian dorsal cortex is very simple but resembles, in a very rudimentary way, both the laminar organization of neocortex and the mediolateral subdivisions of hyperpallium. Thus, the reptilian dorsal cortex contains a medial subdivision (dorsal cortex proper or DC) that resembles HA, and a lateral subdivision (pallial thickening or PT) that resembles HD. Further, the reptilian dorsal cortex shows a three-layered structure, with a main cell layer located between superficial and deep cell-sparse layers. The main cell layer contains pyramidal neurons having apical dendrites that span the superficial layer, where they are contacted by incoming thalamic axons. Further, these pyramidal neurons give rise to descending projections to the striatum, thalamus, and brainstem. This basic laminar and cellular organization partially resembles that of the neocortex, with pyramidal neurons located in deeper layers (5/6) giving rise to long descending projections, and thalamic axons contacting the apical dendrites of these cells. Cell types sharing these features and connections were likely present in the dorsal pallium of the common ancestor of mammals, birds, and reptiles (represented in dark blue in schematics). However, many of the cell types present in the mammalian neocortex and avian hyperpallium likely evolved independently in birds and mammals (such as the thalamorecipient stellate or stellate-like cells, or many of the neurons involved in corticocortical connections). cp, main cell layer; DC, reptilian dorsal cortex; HA, apical hyperpallium; HD, densocellular hyperpallium; HI, intercalated hyperpallium; IHA, interstitial nucleus of the apical hyperpallium; il, inner layer; ol, outer layer; PT, pallial thickening; wm, white matter.

share a similar functional columnar organization (Revzin, 1970). Both in the neocortex and the hyperpallium, the sensory input is topographically (retinotopically or somatotopically) organized (Pettigrew and Konishi, 1976; Wilson, 1980; Wild, 1987; Funke, 1989a; Manger *et al.*, 2002). In each single neocortical unit, the excitation reaches layer 4 by way of thalamocortical axons, and then spreads primarily in a columnar way first to supragranular and later to infragranular layers (Petersen and Sakmann, 2001), and this appears to be similar in the avian hyperpallium (Revzin, 1970).

However, the similarity of hyperpallial subdivisions and specific neocortical layers in terms of connectivity is only partial (Veenman *et al.*, 1995; Wild and Williams, 1999). More importantly, developmental and cellular analysis of the avian hyperpallium and mammalian neocortex indicates that the subdivisions of the avian hyperpallium are not true layers (as least, as defined from a developmental point of view, but see Striedter, 2005) and show important organizational differences with neocortical layers (reviewed in Medina and Reiner, 2000). For this reason, the subdivisions of avian hyperpallium have been called pseudolayers, meaning false layers (Medina and Reiner, 2000). This is based on the following facts. First, although the layers of the mammalian neocortex are aligned parallel to the ventricular surface and develop perpendicular to radial glial fibers, the hyperpallial subdivisions are generally organized parallel to radial glial fibers (Striedter and Beydler, 1997; Medina and Reiner, 2000). Since, during development, the majority of neurons migrate from ventricular to mantle positions following radial glial fibers (Rakic, 1972, 1995; Alvarez-Buylla *et al.*, 1988; Striedter and Beydler, 1997), the different disposition of neocortical layers and hyperpallial subdivisions with respect to the radial glial fibers likely reflects that they are formed in radically distinct ways (Medina and Reiner, 2000). Second, as a consequence of their apparently different development, whereas for any single neocortical area the majority of neurons of all layers are born in the same ventricular sector (except interneurons, which immigrate from the subpallium; Anderson *et al.*, 1997), in the avian hyperpallium the neurons of each subdivision (HA, IHA, and HD) are primarily born in different ventricular sectors (Medina and Reiner, 2000). Third, also as a consequence of their development, whereas many layers of the neocortex typically contain pyramidal neurons with an apical dendrite that span the layers above (where they can be contacted by axons of extrinsic origin ending in other layers, as well as by axon collaterals of local neurons of other layers; Mountcastle, 1997), the subdivisions of avian hyperpallium contain neurons showing multipolar or stellate-like morphology, with star-like oriented dendrites that generally do not cross subdivision boundaries (Figure 4) (Watanabe *et al.*, 1983; Tömbol, 1990; Medina and Reiner, 2000). This means that, whereas in the mammalian neocortex, the radial (translayer) disposition of dendrites allows functional integration of layers (and constitutes one of the anatomical basis of functional columns; Lübke *et al.*, 2000), the neuronal communication between subdivisions of the avian hyperpallium is apparently only possible by way of tangential, inter-area axonal connections (Figure 4) (Kröner and Güntürkün, 1999; Medina and Reiner, 2000; Wild and Williams, 2000).

2.07.4.2 Layers and Subdivisions of the Reptilian Dorsal Cortex. Possibilities and Uncertainties on Dorsal Pallial Evolution

How did the different pallial organizations found in neocortex and hyperpallium evolve and which was the primitive condition in stem amniotes? Extant reptiles have a very simple dorsal pallium, but this shows some features that partially resemble, in a very rudimentary way, both the medial–lateral subdivisions of avian hyperpallium and the lamination of mammalian neocortex (Figure 4). The reptilian dorsal pallium appears to have two parts that show different cytoarchitecture and connections: a medial part or dorsal cortex and a lateral part or pallial thickening (as noted above, only part of the pallial thickening may be part of the dorsal pallium) (Figure 4). In lizards, the thalamic input primarily reaches the pallial thickening, whereas the dorsal cortex gives rise to the descending projections to the striatum and brainstem (see references in previous section; reviewed in Medina and Reiner, 2000). In turtles, thalamic input reaches both the pallial thickening and the dorsal cortex (Mulligan and Ulinski, 1990), and extratelencephalic projections originate in the dorsal cortex (Hall *et al.*, 1977; Ulinski, 1986; Zhu *et al.*, 2005). In lizards and turtles, the pallial thickening shows important intratelencephalic connections (Medina and Reiner, 2000). Thus, the organization of the connections and the relative position of these two divisions in the reptilian dorsal pallium suggests a similarity of the reptilian dorsal cortex and avian HA and the reptilian pallial thickening and avian HD. As the dorsal cortex or pallial thickening, the avian HA and HD also appear to receive a minor direct input from the sensory thalamus (Karten *et al.*, 1973; Watanabe *et al.*, 1983; Wild, 1997; Wild and Williams, 2000). On the other hand, the reptilian dorsal cortex shows a simple three-layered structure, with a main, intermediate cell layer

containing pyramidal-like cells, flanked by a superficial and a deep cell sparse layer (Figure 4) (Reiner, 1993; Medina and Reiner, 2000; Colombe *et al.*, 2004). As neocortical layers, those of the reptilian dorsal cortex are disposed parallel to the ventricular surface and perpendicular to the radial glia. Further, the pyramidal cells of the main cell layer show apical dendrites that span the layer above, where they are contacted by thalamic afferent axons, and they give rise to long descending projections reaching the striatum and brainstem (Figure 4) (Mulligan and Ulinski, 1990; Colombe *et al.*, 2004). Thus, the reptilian dorsal cortex shares with the neocortex some aspects of its laminar and cellular organization. In both the neocortex and reptilian dorsal cortex, the thalamic axons contact the apical dendrites of deep pyramidal neurons, and in both these, deep pyramidal neurons are the source of long descending projections. Of interest, in the neocortex, some thalamic afferent axons travel tangentially in layer 1, where they contact apical dendrites of pyramidal neurons (Rausell *et al.*, 1992), resembling the trajectory of thalamic axons in the reptilian dorsal cortex. Further, analysis of chemically different neurons in the dorsal pallium of mammals, birds, and reptiles indicates that only the cell types present in neocortical layers 5–6 (which contain the deep pyramidal neurons giving rise to long descending projections) are found in birds and reptiles, suggesting that only layers 5–6 were present in the common ancestor (Reiner, 1991). Further, comparative developmental studies suggest that only the subpial layer 1 and the deepest neocortical layers may have been present in the common ancestor of extant reptiles, birds, and mammals (Marín-Padilla, 1998).

All these data together suggest that the pyramidal neurons found in the cell layer of the reptilian dorsal cortex may be homologous to the pyramidal cells of layers 5–6 of the mammalian neocortex, and possibly to some of the multipolar projection neurons of avian HA (at least including the neurons that, in addition to giving rise to long descending projections, receive thalamic input). In contrast, the thalamorecipient granule (or stellate) cells found in neocortical layer 4 have no counterpart in reptiles and are not homologous to the thalamorecipient stellate-like cells found in avian IHA (Figure 4). Stellate cells of neocortical layer 4 and stellate-like cells of IHA apparently evolved independently (and were produced as novelties) in the mammalian and avian radiations. On the other hand, the pyramidal neurons of neocortical layers 2–3 and part of the projection neurons of avian hyperpallium involved in corticocortical connections may also be newly evolved. Finally, it is unclear what part of the mammalian neocortex (if any) is comparable to avian HD and reptilian pallial thickening, both involved in intratelencephalic connections. As noted above, since the pallial thickening and apparently HD receive retinal input, they may be comparable to a lateral part of V1. In relation to this, V1 in rats contains medial and lateral subdivisions which differ in cyto-, myelo-, and chemoarchitecture (Palomero-Gallagher and Zilles, 2004). The medial subdivision represents a monocular subfield, whereas the lateral subdivision represents a binocular subfield. Nonplacental mammals, such as marsupials, also show similar medial–lateral V1 subdivisions in the neocortex, representing areas of either complex or simpler waveform processing (Sousa *et al.*, 1978). Thus, it is possible that such mediolateral subdivisions were present in the origin of mammals and, if so, the lateral V1 part may be comparable to HD/pallial thickening of birds and reptiles. Another possibility is that HD and/or the pallial thickening are not comparable to any part of V1, but rather to a more laterally located cortical or subcortical pallial area, such as the insular cortex (or part of it) or the claustrum (Striedter, 1997). The position of these structures at the lateral extreme of the neocortex, either abutting the lateral pallium or within it, resembles that of both HD and pallial thickening (Figure 2). In contrast to this possibility, the connectivity patterns of HD and pallial thickening are very different from those of the insular cortex or claustrum. For example, in contrast to HD and pallial thickening, neither the insular cortex nor the claustrum receive direct input from the dorsal lateral geniculate nucleus (Clascá *et al.*, 1997; Sefton *et al.*, 2004). More studies will be needed to resolve this issue. If the pallial thickening of reptiles were not homologous (as a field) to any part of V1, it would challenge the existence of a primary visual area in the dorsal pallium of the amniote common ancestor (since in lizards the geniculate projection only reaches the pallial thickening but not the dorsal cortex proper), opening new and important questions on neocortical evolution.

2.07.5 Functional Properties of the Visual and Somatosensory Areas of Neocortex and Sauropsidian Dorsal Pallium: Do Mammals, Birds, and Reptiles See and Feel the Same?

2.07.5.1 Visual Area: Retinotopy, Signal Types, Binocularity, and Perception

The mammalian V1 contains a detailed point-to-point retinal map, received through the retinogeniculocortical pathway, which subserves conscious

vision (Kahn *et al.*, 2000; Sefton *et al.*, 2004; Wässle, 2004). Neurons in V1 respond to orientation, direction, or color, and this information reaches the cortex through mostly segregated parallel pathways (Wässle, 2004). This information is then processed and combined (a process that involves higher-order areas), making possible animals' visual perception of the world. Visual signals are first detected by retinal photoreceptors, rods (involved in detection of low light levels), and cones (involved in detection of lights of different wavelengths; i.e., they are color-sensitive). The signals detected at the photoreceptor level are then processed and filtered through a complex retinal system involving several cell types (including horizontal, bipolar, amacrine, and ganglion cells), connected through specific circuitries (Lee, 2004; Wässle, 2004). At the end of this process, different types of retinal ganglion cells respond to orientation, direction, motion, or color, and this information is then transmitted to the brain through the retinofugal pathways (one of which is the retinogeniculate system). In primates, achromatic retinofugal signals mainly reach the visual cortex by way of the magnocellular layer of the geniculate nucleus, whereas chromatic retinofugal signals reach V1 mainly via either the koniocellular or the parvocellular geniculate cells, and each pathway mainly ends on a separate layer or sublayer in V1 (Chatterjee and Callaway, 2003; Lee, 2004).

In V1, orientation and direction signals represent a first step for analysis of form or movement, in which higher-order visual areas participate (Sincich and Horton, 2005; Saul *et al.*, 2005; Shmuel *et al.*, 2005; van Hooser *et al.*, 2005). Neurons responsive (or sensitive) to orientation or direction appear to be present in V1 of a large variety of mammals (including placental and marsupial species; Murphy and Berman, 1979; Parnavelas *et al.*, 1981; Crewther *et al.*, 1984; Orban *et al.*, 1986; Vidyasagar *et al.*, 1992; Ibbotson and Mark, 2003; Priebe and Ferster, 2005), and many mammals appear to have at least a second visual area (V2) involved in higher-order processing (Kaas, 2004; Sefton *et al.*, 2004), suggesting that some basic aspects of form and movement perception are common to all mammals. Nevertheless, in some mammals (such as marsupials) only a low percentage of V1 neurons respond to motion (Ibbotson and Mark, 2003), whereas other mammals possess multiple higher-order visual areas, one of which (V5/MT of primates) is specially involved in motion perception (Riecansky, 2004; Sincich *et al.*, 2005; Silvanto *et al.*, 2005). Thus, it appears that some mammals have a better visual perception of movement and form than others. Further, in mammals (such as primates, cats, and rats, as well as marsupials), some or many neurons of V1 are characterized by binocular convergence (depending on the degree of orbital convergence, which is maximal in primates), and are involved in perception of depth (stereoscopic vision) (Vidyasagar *et al.*, 1992; Barton, 2004; Grunewald and Skoumbourdis, 2004; Heesy, 2004; Menz and Freeman, 2004; Read, 2005). But again, some mammals show higher binocular convergence and have more visual cortical areas involved in its analysis, indicating that some species apparently have better depth perception than others. Nevertheless, in many mammals, several noncortical areas (including pretectum, superior colliculus, and other subcortical areas) are involved in motion processing (Ibbotson and Price, 2001; Price and Ibbotson, 2001; Sefton *et al.*, 2004). The superior colliculus appears to be involved in the spatial localization of biologically significant stimulus rather than its recognition (where it is rather than what it is) (Schneider, 1969), and can influence head/eye movements and guidance toward or away from a stimulus (reviewed by Sefton *et al.*, 2004). The visual cortex (with the participation of higher-order areas) appears to be involved in perception of both what the stimulus is (form and pattern discrimination) and where it is, among other aspects of visual perception.

Regarding color perception, the majority of mammals appear to have dichromatic vision, whereas – among placental mammals – only some primates have trichromatic vision. Among nonplacental mammals, it appears that some Australian marsupials may also have trichromatic vision. This depends on the pigment (opsin) variety found in retinal cone photoreceptors, and in the existence of color opponent systems. It appears that most mammals have two cone types: a majority of cones are sensitive to medium or long wavelengths (M/L-cones, sensitive to green or red), depending on the species; and a minority of cones are sensitive to short wavelengths (S-cones, sensitive to blue or ultraviolet (UV)), depending on the species (Peichl and Moutairou, 1998; Yokoyama and Radlwimmer, 1998, 2001; Shi and Yokoyama, 2003; Gouras and Ekesten, 2004). Among placental mammals, only some primates (including squirrel monkeys, New World monkeys, and humans) have a trichromatic color vision and their retina contains cones sensitive to green, red, or blue. Many marsupials also have M/L- and S-cones (Deeb *et al.*, 2003; Strachan *et al.*, 2004), and it seems that they were present in the retina of ancestral vertebrates well before the emergence of mammals (Shi and

Yokoyama, 2003). It has been suggested that the green-sensitive and red-sensitive cones present in mammals evolved from a single M/L cone present in the common ancestor well before the origin of mammals (Yokoyama and Radlwimmer, 1998). However, several species of Australian marsupials do have trichromatic retinas, with cones sensitive to short, medium, or long wavelengths (Arrese *et al.*, 2002, 2005), which appears to be due to retention from the ancestor (see below). It seems that the retina of ancestral placental mammals became dichromatic when these animals adopted nocturnality and some primates, subsequently, re-evolved trichromacy (Arrese *et al.*, 2002).

It seems that color perception involves a comparison of the relative activities of different cones by way of an opponent process, which starts in the retina and is conveyed to the visual cortex by parallel, anatomically segregated color-opponent systems (Dacey, 2000). In mammals having a dichromatic retina, only one opponent system exists, a blue–yellow system, in which signals from blue cones are opposed to signals from red or green cones. For trichromatic retinas (such as those of some primates), there are two color opponent systems, one for a red–green system, in which signals from red- and green-sensitive cones are opposed, and another one for a blue–yellow system, in which signals from blue cones are opposed to a combined signal from red and green cones (Dacey, 2000; Chatterjee and Callaway, 2003). Specific retinal ganglion cells exist for each color system. The blue–yellow information is conveyed to V1 through the koniocellular geniculate pathway, whereas the red–green information is conveyed by the parvocellular geniculate pathway (Lee, 2004). The information reaching V1 is later combined in higher-order visual areas. It is likely that ancestral placental mammals only had the blue–yellow system, and that the anatomical substrate for the red–green system evolved as a novelty in primates (Dacey, 2000; Lee, 2004).

In reptiles and birds, the retina contains cell types (including rod and cone photoreceptors, as well as horizontal, bipolar, amacrine, and ganglion cells) and circuitries in general similar to many of those present in mammals (Fernández *et al.*, 1994; Kittila and Granda, 1994; Ammermüller and Kolb, 1995; Haverkamp *et al.*, 1997, 1999; Luksch and Golz, 2003). Ganglion cells responsive to direction, motion, or color are found in the retina of both birds and reptiles, and cells responsive to orientation are also found in birds (Granda and Fulbrook, 1989; Guiloff and Kolb, 1994; Ammermüller *et al.*, 1995; Borg-Graham, 2001; Wilke *et al.*, 2001; Jones and Osorio, 2004). Retinal information is then conveyed to the dorsal pallium by way of a retinotopically organized retinogeniculodorsal pallial pathway (Bravo and Pettigrew, 1981; Miceli and Repérant, 1982; Ehrlich and Mark, 1984; Mulligan and Ulinski, 1990). This suggests that the dorsal pallium of birds and reptiles may be involved in some aspects of visual perception similar to those processed by V1 in mammals. Consistent with this, the visual hyperpallium of some birds (such as owls) contains neurons showing selectivity for orientation and movement direction (Pettigrew and Konishi, 1976), and has been shown to be involved in form discrimination, including some complex aspects such as subjective contour discrimination (Nieder and Wagner, 1999). In other birds (chicks or pigeons), the hyperpallium is involved in motion processing, far-field pattern discrimination, spatial discrimination acquisition, and in sun-compass associative learning (Gusel'nikov *et al.*, 1977; Leresche *et al.*, 1983; Britto *et al.*, 1990; Budzynski *et al.*, 2002; Watanabe, 2003; Budzynski and Bingman, 2004). Among birds, the complexity of visual processing by the hyperpallium appears to be higher in owls (which are frontal-eyed birds) than in other birds. In fact, the hyperpallium of owls shows a larger size, a more detailed retinotopic map, a much higher binocular convergence, and a more complex visual processing than that of lateral-eyed birds, such as pigeons (Pettigrew and Konishi, 1976; Nieder and Wagner, 1999, 2000, 2001; Liu and Pettigrew, 2003). Thus, the visual hyperpallium of owls is involved in depth perception and detection of visual illusions (subjective contours), exhibiting a functional complexity analogous to that of higher-order visual areas of highly visual mammals such as primates and cats (Nieder and Wagner, 1999, 2000, 2001; Liu and Pettigrew, 2003; van der Willigen *et al.*, 2003). In contrast, binocularity in pigeons is low (Martin and Young, 1983; McFadden and Wild, 1986; Holden and Low, 1989). Further, although the hyperpallium in pigeons is involved in motion perception and far-field discrimination, other brain areas, such as the optic tectum and the areas involved in the tectothalamo-DVR pathway, also play very important roles in motion processing or in other aspects of visual discrimination (Gusel'nikov *et al.*, 1977; Leresche *et al.*, 1983; Macko and Hodos, 1984; Britto *et al.*, 1990; Wang *et al.*, 1993; Laverghetta and Shimizu, 1999; Crowder *et al.*, 2004; Nguyen *et al.*, 2004). Among these areas, the thalamic nucleus rotundus and its DVR target play an important role in processing of ambient illumination, near-field discrimination, spatial-pattern vision, motion, and color (Wang *et al.*, 1993).

In reptiles, the visual dorsal cortex shows a coarse retinotopic map (Mulligan and Ulinski, 1990), and it appears involved in some aspects of visual processing, such as motion, discrimination acquisition, and spatial learning, but not in brightness discrimination (Reiner and Powers, 1983; Grisham and Powers, 1989, 1990; Prechtl, 1994; Prechtl *et al.*, 2000; Nenadic *et al.*, 2002). However, as in pigeons, other brain areas of reptiles, such as those involved in the tectothalamo-DVR pathway, play a more important role in brightness and pattern discrimination than the dorsal cortex (Morenkov and Pivovarov, 1975; Reiner and Powers, 1983).

Regarding color perception, the retina of birds and reptiles also supports color vision, but this appears to be more complex than in mammals. Thus, it appears that the retina of many diurnal birds and reptiles contains four types of cones, sentitive to red, green, blue, or UV or near-UV light (Ammermüller *et al.*, 1995; Bowmaker *et al.*, 1997; Kawamura *et al.*, 1999; Ventura *et al.*, 2001; Smith *et al.*, 2002). The cones of many diurnal birds and reptiles also contain colored oil droplets, which act as filters and apparently enhance color discrimination (Bowmaker *et al.*, 1997; Vorobyev, 2003). Parallel opponent retinal pathways have been shown in some species of reptiles, suggesting the existence of tetrachromatic color vision in these animals (Ammermüller *et al.*, 1995; Ventura *et al.*, 2001). In turtles, the opponent color systems described in the retina include a blue–yellow system, a red–green system, and a UV–blue system, among other possibilities (Ventura *et al.*, 2001). It is unclear whether all these systems are present in other reptiles or in birds. As noted above, the blue–yellow opponent system is apparently present in most mammals and may have been present in stem amniotes. However, the anatomical substrate of the red–green pathway of turtles is likely nonhomologous to that found in some primates. As noted above, birds and reptiles possess a retinotopically organized retinogeniculodorsal pallial pathway comparable (likely homologous) to the retinothalamo-V1 of mammals, suggesting that the avian and reptilian dorsal pallium may be involved in color vision processing. However, only a few aspects of color vision (if any) may be processed in the dorsal pallium of birds, and it appears that color vision in birds and possibly reptiles is mainly (if not only) processed by other brain areas and pathways, such as the tectothalamo (rotundal)-DVR pathway (Güntürkün, 1991; Chaves *et al.*, 1993; Wang *et al.*, 1993; Chaves and Hodos, 1997, 1998).

All of these data together indicate that, although the visual area of the reptilian dorsal cortex, avian hyperpallium, and mammalian V1 are involved in some similar basic aspects of visual perception, many complex functions shown by the visual hyperpallium of some birds and by V1 of highly visual mammals, such as depth perception (associated to binocularity) and subjective contour discrimination, among others, likely evolved independently. Consistent with this, the anatomical substrate for the binocularity is different in birds and mammals (Casini *et al.*, 1992; Medina and Reiner, 2000). Further, the role of V1 in color processing and the anatomical pathways related to it may have evolved only in mammals. Regarding motion, the dorsal pallial visual area of reptiles (at least turtles), birds, and mammals appears involved in its processing, and this may have characterized the dorsal pallial visual area of stem amniotes. All these data suggest that the retinogeniculodorsal pallial pathway found in birds and reptiles is mainly comparable to part of the magnocellular retinogeniculocortical pathway of mammals, but not to the parvocellular pathway (conveying mainly chromatic information of the red–green system) nor possibly the koniocellular pathway (conveying mainly chromatic information of the blue–yellow system).

In reptiles and many birds, the retinotectothalamo (rotundal)-DVR pathway is more developed than the retinogeniculodorsal pallial pathway, and appears to play an important role in some aspects of visual processing, such as motion, color, and pattern discrimination (perhaps important for knowing both what the stimulus is and where it is). This general pattern may have characterized stem amniotes. It appears that early mammals were nocturnal animals, which may explain why many extant mammals have dichromatic vision (instead of the tetrachromatic vision that characterizes many birds and reptiles). Perhaps this was accompanied by a regression in visual perception abilities and their anatomical substrate, and an improvement of other sensory systems, such as the somatosensory and the auditory systems. The evolution of new mammalian species living in diurnal niches was likely accompanied by the great development of the retinothalamodorsal pallial pathway, and by the development of more visual neocortical areas (Husband and Shimizu, 2001). An increase in size and complexity of the retinothalamodorsal pallial pathway also occurred in birds, but this was particularly important in some frontal-eyed birds (such as the owl). Did this involve the development of higher-order visual areas in the dorsal pallium of owls? As noted above, the visual hyperpallium of birds is involved in highly complex visual functions comparable to those carried out by higher-order

visual areas of the mammalian neocortex. However, physiological studies have not analyzed the existence of multiple visual areas in the hyperpallium of owls. A recent study has shown the existence of at least two somatosensory representations in the frontal hyperpallium of owls (Manger *et al.*, 2002), and it is likely that more than one visual representation exists in the large hyperpallium of owls.

Finally, regarding the question of whether mammals, birds, and reptiles see the same, it is clear that not all mammals have the same degree of depth, color, and/or form perception, and this is also true in birds. Regarding color vision, although many diurnal reptiles and birds appear to have tetrachromatic vision and most mammals have dichromatic vision, there are examples of color-blind or trichromatic animals within mammals. Further, a few mammals (such as mouse and rat) and many birds and reptiles detect UV light, whereas most mammals (including humans) do not. Thus, the question of whether mammals, birds, and reptiles see the same is nonsense since visual perception differs among mammals, among birds, and possibly among reptiles. Nevertheless, some basic aspects of visual perception appear to be similar between many amniotes. Of particular interest is the fact that some complex visual functions related to form and depth perception appear to be similar between frontal-eyed birds (such as owls) and some highly visual mammals such as cats and some primates. As noted above, the anatomical substrate for the complex visual processing by the dorsal pallium found in these animals likely evolved independently. Further, in birds and reptiles, many aspects of visual perception (including color perception) appear to be processed in the DVR (ventrolateral pallium), rather than the dorsal pallium.

2.07.5.2 Somatosensory Area: Somatotopy, Signal Types, Perception, and Multiple Maps

In mammals, S1 contains a somatotopically organized map of the whole body (contralateral side) (Tracey, 2004). The information received by S1 via the ventrobasal thalamic complex includes tactile (touch, pressure), vibration, and proprioceptive (postural) signals, as well as pain and temperature. The somatosensory information reaching the frontal hyperpallium in birds by way of DIVA is also somatotopically organized, and includes at least tactile (light touch and pressure signals) and vibration information, mostly from the contralateral body surface (Wild, 1987; Funke, 1989a). Based on the external cuneate (which receives proprioceptive information from extraocular and wing muscles; Wild, 1985; Hayman *et al.*, 1995) and spinal inputs to DIVA (Schneider and Necker, 1989; Wild, 1989), it is likely that the frontal hyperpallium also receives proprioceptive, pain, and temperature signals. However, in contrast to mammals, mainly the body (including the neck) appears to be represented in the frontal hyperpallium in several avian species (Wild, 1987, 1997), although some studies have also reported representation of the beak (Korzeniewska, 1987; discussed in Wild, 1989). In birds, it appears that the head somatosensory information is mostly represented in another pallial area, called nucleus basalis, located in the DVR (Berkhoudt *et al.*, 1981; Dubbeldam *et al.*, 1981; Wild *et al.*, 1997). The somatosensory information reaches this DVR nucleus by way of a direct, somatotopically organized projection from the principal sensory trigeminal nucleus (Dubbeldam *et al.*, 1981; Wild and Zeigler, 1996; Wild *et al.*, 2001). Further, in some birds, such as the budgerigar, the nucleus basalis of the DVR includes not only head but also body representation, and this appears to be more detailed than that in the hyperpallium (Wild *et al.*, 1997). Thus, it appears that birds possess two different systems for pallial somatosensory representation, which show different degrees of development depending on the species. As noted above, only the hyperpallial representation appears comparable to S1 of mammals. The frontal dorsal cortex of reptiles also appears to receive somatosensory information of the body (in lizards, turtles, and possibly crocodiles) and, at least in some lizards, also the head (Desfilis *et al.*, 1998). More studies are needed to know whether this pattern is common in other reptiles. It is unclear whether the somatosensory information reaching the frontal dorsal cortex in reptiles is or is not topographically organized. Although it seems likely that the primary somatosensory area observed in the dorsal pallium of extant birds, reptiles, and mammals evolved from a homologous area present in their common ancestor (stem amniotes), the scarcity of data in reptiles does not allow any suggestion on the specific features of this primitive area. In any case, this area was likely very small, and likely lacked many of the attributes (in terms of anatomical organization, connections, and functional complexity) found in S1 of mammals and in the frontal hyperpallium of birds. As noted above, the cytoarchitectural organization and intrinsic columnar circuitry shown by the neocortex and hyperpallium evolved independently. Since in birds there is a small overlap of the primary visual and somatosensory areas in the hyperpallium (Deng and Wang, 1992), it is possible that a partial

ovelap of sensory areas characterized the dorsal pallium of stem amniotes (Figure 3).

Of interest, the neocortex of extant mammals contains multiple somatosensory representations, many of which (including S1, a secondary somatosensory area or S2, and the parietal ventral area) appeared to be already present in the origin of mammals (Krubitzer, 1995; Kaas, 2004). This provides an idea of the importance and high quality of somatosensory perception in these animals, and this great development may be related to the fact that ancestral mammals were nocturnal animals, primarily relying on senses other than vision. Further, somatosensory representation is even more complex in some mammals, such as primates, in which S1 contains four subdivisions (areas 3a, 3b, 1, and 2), each one showing a complete body representation (Tracey, 2004). In other mammals, including rodents, S1 has a single body representation, possibly comparable to area 3b of primates (Northcutt and Kaas, 1995). In birds having a large hyperpallium (such as the owl), two separate somatosensory representations of the claw have been observed, each showing a detailed somatotopic organization (Manger *et al.*, 2002). Thus, it appears that at least some birds have a more complex somatosensory representation in the hyperpallium, which may mean that they have a more elaborated analysis of this information and a more sophisticated somatosensory perception. Since the somatosensory area of the dorsal cortex of reptiles is apparently very small, it seems unlikely that multiple somatosensory representations were present in the dorsal pallium of stem amniotes. This means that the additional somatosensory hyperpallial area found in owls likely evolved independently and cannot be compared to any of the multiple S1 areas found in primates, to S2, nor to other somatosensory areas of mammalian neocortex (Manger *et al.*, 2002). Another interesting aspect of somatosensory representation in the neocortex of mammals is its activity-dependent plasticity, which is important for behavior modification and adaptation as a result of sensory experience (Kaas, 1995; Tracey, 2004). It appears that plasticity also characterizes the somatosensory hyperpallial area of owls (Manger *et al.*, 2002).

Regarding the question of whether mammals, birds, and reptiles feel the same, based on the number of pallial representations and variety of somatosensory receptors found in mammals (Kaas, 2004; Tracey, 2004), it appears that in general mammals have a much better somatosensory perception than reptiles and most birds. But again, it appears that somatosensory perception differs among mammals, as well as among birds and maybe among reptiles. One of the reasons is that the number of somatosensory representations and higher-order areas varies between species (Kaas, 2004). Another reason may be the existence of differences in peripheral receptors (in terms of quality, quantity, and/or location). For example, the complex receptor type found in owl claws (Manger *et al.*, 2002) may not be present in the claws of other birds, or may be present at a low number/area ratio. Further, different parts of the body and head have a different representation (in terms of relative size) in the neocortex/dorsal pallium in different species, which depends on their specific behavior. For example, the S1 of humans has a very large (or relatively large) representation of digits (which is related to the great tactile discrimination and exploratory and manipulatory use of our fingers), whereas in S1 of mouse and rat, the digits are not so well represented but the area related to the whiskers (barrel field area) is relatively large (which relates to the great importance of vibrissae in exploratory behavior and texture discrimination in rodents; reviewed by Waite, 2004). This rule also appears to be true for somatosensory areas in pallial regions other than the dorsal pallium. An example of this is found in the nucleus basalis of the budgerigar, which shows a larger size and more extensive representation of areas such as the beak, highly used by these animals (Wild *et al.*, 1997). Similarly, the claw of barn owl, used for perching and grasping prey and containing an elaborated tactile sensory receptor, likely has a larger representation in the frontal hyperpallium of this animal (including two areas, as noted above; Manger *et al.*, 2002) than that of the pigeon or the canary.

2.07.6 Conclusions

The neocortex contains specific sensory, associative, and motor areas that allow mammals to obtain a detailed map of the world and to adapt their behavior to it. Available data suggest that at least two such areas, the primary visual area and the primary somatosensory area, are also present in the dorsal pallium of birds and reptiles, and likely evolved from similar areas found in stem amniotes. However, these dorsal pallial areas present in the common ancestor likely had a very simple cytoarchitecture (possibly including a rudimentary three-layered structure plus at least two mediolateral subdivisions), and possessed fewer cell types and connections than those found in the mammalian neocortex and avian hyperpallium. For example, the complex six-layered organization of neocortex and the four mediolateral subdivisions of hyperpallium evolved independently in mammals or

birds. Further, the columnar functional organization of neocortex and the columnar-like organization of hyperpallium also evolved independently. In addition, these primitive areas of stem amniotes were likely involved in few aspects of visual or somatosensory perception. The role of the visual area in complex aspects of form and pattern discrimination or in depth perception (associated to binocularity) likely evolved independently in mammals and some birds, and its role in color perception (and the anatomical substrate related to it) apparently evolved only in the mammalian radiation. Finally, available data suggest that the dorsal pallium of stem amniotes may have lacked a true somatomotor area, and this evolved independently in birds and mammals (see A History of Ideas in Evolutionary Neuroscience, Phylogenetic Character Reconstruction, Field Homologies, Evolution of the Nervous System in Reptiles, Visual Cortex of Turtles, The Evolution of Vertebrate Eyes, The Evolution of Ultraviolet Vision in Vertebrates, What Fossils Tell Us about the Evolution of the Neocortex, The Origin of Neocortex: Lessons from Comparative Embryology, Reconstructing the Organization of Neocortex of the First Mammals and Subsequent Modifications, The Evolution of Motor Cortex and Motor Systems, The Dual Elaboration Hypothesis of the Evolution of the Dorsal Thalamus).

2.08 Visual Cortex of Turtles

P Ulinski, University of Chicago, Chicago, IL, USA

Glossary

anterior dorsal ventricular ridge	A component of the telencephalon in reptiles and birds that is probably homologous to the neocortex of mammals.
archosaurian reptiles	A group of ancient reptiles that gave rise to modern crocodiles and birds.
clade	An evolutionary lineage of organisms.
dorsal lateral geniculate nucleus	A component of the thalamus that receives direct information from the retina.
fast spiking pattern	A pattern of neuronal firing in which a neuron produces relatively thin action potentials with little slowing of the firing rate of the cell.
isoazimuth lamellae	A band of neurons in the visual cortex of turtles that receives inputs from a band of neurons in the dorsal lateral geniculate nucleus.
lateral forebrain bundle	A group of axons that carry fibers from the thalamus and brainstem to the telencephalon and vice versa; equivalent to the internal capsule of mammals.
principal component analysis	A statistical method that identifies components in a complicated pattern, such as a cortical wave.
regular spiking pattern	A pattern of neuronal firing in which a neuron produces relatively thick action potentials and shows marked reduction in the firing rate of the cell with time.
spikelet	A small action potential, possibly of dendritic origin.
striatum	A ventral component of the telencephalon; equivalent to the basal ganglia.
Wulst	A bump on the telencephalon of some birds that appears to be a visual cortex.

2.08.1 Visual Telencephalon in Reptiles

Early comparative neuroanatomists were uncertain about the existence of visual projections to the telencephalon of reptiles (see Evolution of the Nervous System in Reptiles, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?). However, work in the 1970s with modern tract-tracing methods demonstrated that two visual pathways to the dorsal thalamus are present in representatives of each of the orders of reptiles (Northcutt, 1981). A tectofugal pathway consists of direct retinal projections to the optic tectum and a subsequent projection to nucleus rotundus in the dorsal thalamus. Nucleus rotundus projects to a large telencephalic structure, the anterior dorsal ventricular ridge, in all the orders of reptiles (Ulinski, 1983). A thalamofugal pathway consists of direct projections to the dorsal lateral geniculate nucleus (DLGN) in all the reptiles that have been studied (Repérant *et al.*, 1992). However, projections from the DLGN complex to the telencephalon vary substantially in members of the four orders of living reptiles and appear to be best developed in turtles. Turtles belong to the order Chelonia, which comprises two suborders of living turtles (Pritchard, 1967). The side-necked, or pleurodiran, turtles are restricted to Australia and fold their necks into their shells instead of retracting their necks. The cortex of the pleurodiran turtle, *Podocnemis*, contains a large nuclear mass in its lateral cortex that could be a telencephalic visual structure (Riss *et al.*, 1969), but there have been no experimental studies of visual cortex in pleurodiran turtles. This review will, consequently, be restricted to work on the visual cortex in cryptodiran turtles. Most experimental work has been done on freshwater

turtles of the genera *Pseudemys* (= *Trachtemys*), *Chrysemys*, and *Emys* in the family Emydidae.

2.08.2 Visual Cortex in Turtles

2.08.2.1 Cytoarchitecture

The cerebral cortex in turtles is a sheet of tissue that extends across the cerebral hemispheres. The anatomy and physiology of the cortex have been reviewed by Ulinski (1990, 1999). The cortex consists of three distinct layers. The outer layer (1) contains a relatively small number of loosely packed cells. The intermediate layer (2) contains many densely packed cells. The inner layer (3) contains a few loosely packed cells. The cortex can be divided into four cytoarchitectonic areas (Figure 1) based on variations in the histology of the three layers (Colombe and Ulinski, 1999). The medial cortex is situated at the medial edge of the cortex adjacent to the septum. The dorsomedial cortex is situated lateral to medial cortex. The medial and dorsomedial areas together appear to correspond to the hippocampal formation of mammals in terms of their connections with other parts of the brain. The lateral cortex is situated on the lateral surface of the hemisphere, receives direct projections from the main olfactory bulb, and clearly corresponds to the pyriform cortex of mammals. The dorsal cortex is situated between the dorsomedial and lateral areas of the cortex. Dorsal cortex is clearly divided into two subareas: the lateral part of dorsal cortex (D_L) and the medial part of dorsal cortex (D_M). Layers 1 and 3 are relatively thick in D_L and layer 2 forms a distinctive scroll-like configuration. D_L is called the pallial thickening in the classical literature. Layer 3 becomes narrow as it is traced from lateral to medial across the dorsal cortex so that layer 2 lies relatively close to the ependyma at the D_L/D_M border. Layer 3 becomes essentially nonexistent at the border of D_M with the dorsomedial area.

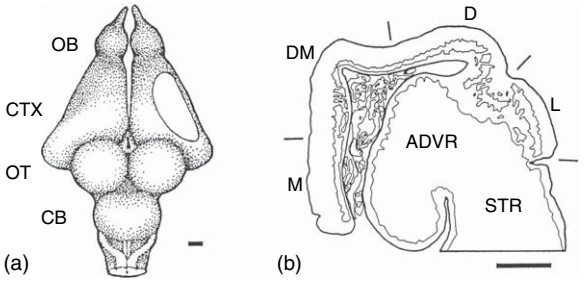

Figure 1 Visual cortex in a turtle. a, Dorsal view of the brain of a turtle, *Pseudemys scripta*. The white oval area is the visual cortex. b, Section through the telencephalon of *Pseudemys* at the level of the visual cortex. The visual cortex corresponds to the cytoarchitectonic area, D. ADVR, anterior dorsal ventricular ridge; CB, cerebellum; CTX, cortex; D, dorsal area; DM, dorsomedial area; L, lateral area; M, medial area; OB, olfactory bulb; OT, optic tectum; STR, striatum. Scale bars: 1 mm.

2.08.2.2 Geniculocortical Projections

The principal input to the visual cortex is from the DLGN, which lies internal to the optic tract and receives direct bilateral retinal projections (Ulinski and Nautiyal, 1987). DLGN contains two layers (Figure 2) situated concentric with the optic tract (Rainey and Ulinski, 1986). The neuropile layer is situated internal to the optic tract and contains a small number of cells whose dendrites extend parallel to the optic tract. The cell plate layer is the most noticeable and contains densely packed cells with dendrites that extend obliquely through the neuropile layer toward the optic tract. The dendrites end in finger-like processes that participate in a network of dendrodendritic synapses with flattened synaptic

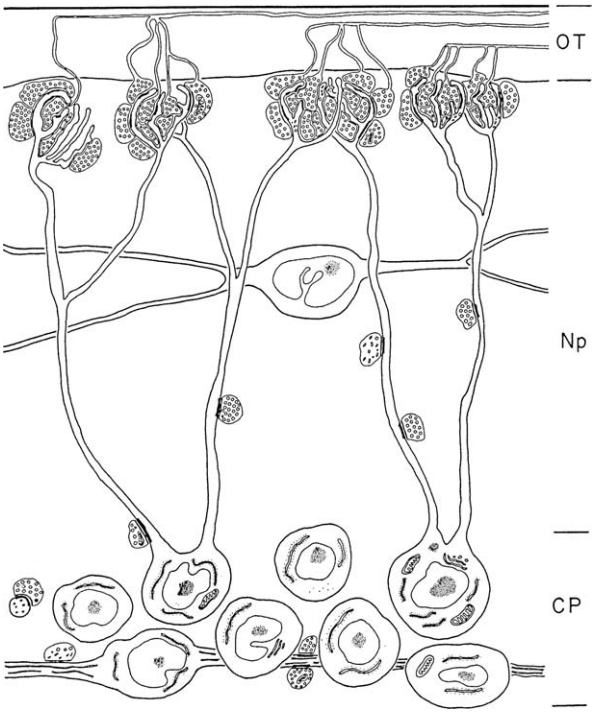

Figure 2 Organization of the OLGN. The basic organization of neurons in the dorsal lateral geniculate nucleus of turtles. The axons of retinal ganglion cells course over the outer surface of the geniculate complex in the optic tract (OT) and then turn into the neuropile (Np) layer of the geniculate complex. The majority of geniculate neurons have somata in the cell plate (CP) layer of the geniculate, and dendrites that extend into the neuropile layer. These dendrites end in finger-like processes that interact with each other through dendrodendritic synapses. The neuropile layer contains a few scattered cells with dendrites that extend parallel to the optic tract. Retinal ganglion cell terminals synapse on the dendrites of cell plate cell and on neuropile cells.

vesicles in their presynaptic elements (Ulinski, 1986a). It is reasonable to speculate that these synapses mediate inhibitory interactions between the cell plate cells.

Retinal ganglion cells show marked variations in their anatomy and physiology in turtles (e.g., Jensen and DeVoe, 1983; Granda and Sisson, 1992; Ammermuller and Kolb, 1995; Ammermuller *et al*., 1995; Dearworth and Granda, 2002). There is no agreement on the classification of turtle ganglion cells into groups in turtles. The simplest classification is that of Marchiafava and his colleagues, who recognize type A and type B cells, which differ in their soma sizes, the stratification of their dendritic trees in the inner plexiform layer of the retina, the diameters and conduction velocities of their axons, and their receptive field properties (Marchiafava and Weiler, 1980; Marchiafava *et al*., 1983). There is general agreement that a relatively large percentage of ganglion cells are directionally selective and prefer stimuli moving within specific ranges of speeds. Axons in the optic nerve can be placed in three conduction velocity groups and correspond to relatively thick-, medium-, and thin-diameter axons (Woodbury and Ulinski, 1986). The thick-diameter axons project to the basal optic nucleus, a component of the accessory optic system. Both the medium- and thin-caliber axons branch as they approach the brainstem and have collaterals that project to the optic tectum and the DLGN. The terminal arbors in the DLGN form two morphologically distinct groups (Sjöström and Ulinski, 1985). Relatively small arbors with many small boutons terminate in the outer half of the neuropile layer and are presynaptic to the dendrites of cell plate cells and to neuropile cells (Ulinski, 1986a). Large arbors with a few large boutons terminate in the inner half of the neuropile layer and are presynaptic to the dendritic shafts of the cell plate cells. The functional organization of the DLGN in turtles, thus, appears to be quite different from that of the DLGN complex in mammals. Projections from different groups of ganglion cells tend to be segregated into separate layers in the mammalian geniculate so that information from different physiological groups of ganglion cells is kept separate from the cortical level in mammals. By contrast, it appears that at least two types of ganglion cells (A and B) have convergent projections to the cell plate cells in turtles.

Retinal projections to the DLGN are bilateral, with the contralateral projection being the most extensive (Ulinski and Nautiyal, 1987). The nasotemporal axis of the retina is mapped along the rostrocaudal axis of DLGN and the dorsoventral axis of the retina is mapped along its ventrodorsal axis (Figure 3). A ventral rim of DLGN receives bilateral projections. The binocular region of turtle visual space includes a frontal field as well as a segment that extends above the turtle's head. Bilateral projections from the retinas to the DLGN extend from the caudal pole of the geniculate rostrally along its ventral rim.

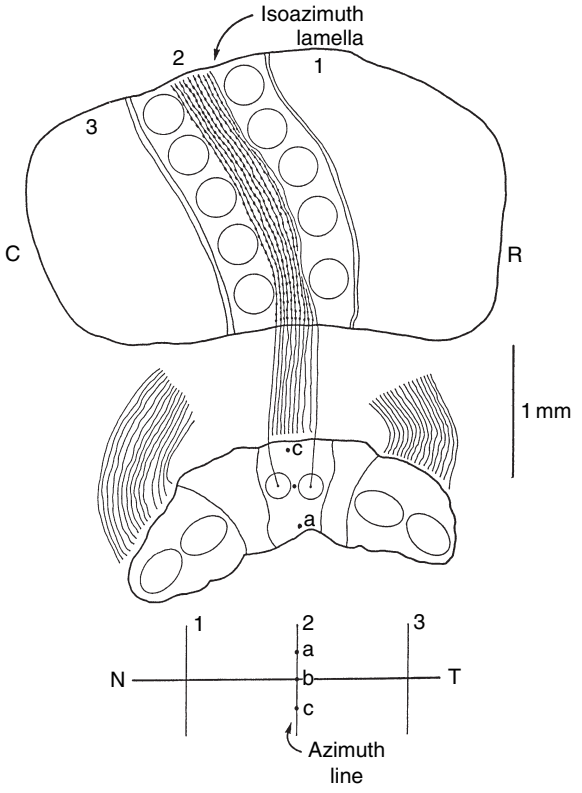

Figure 3 Organization of the geniculocortical projection. The nasal–temporal (N–T) axis of visual space and three azimuth lines (1, 2, and 3) are shown in the lower part of the figure. Three points of different elevation (a, b, and c) are shown on azimuth line 2. The dorsal lateral geniculate complex is shown in lateral view in the center of the figure. The N–T axis of visual space is mapped on to the rostral–caudal (R–C) axis of the geniculate. The superior–inferior axis of visual space is mapped on to the ventral–dorsal axis of the geniculate. Circles and ellipses on the geniculate represent the dendritic fields of individual geniculate cells. The visual cortex is shown in the upper part of the figure. Bundles of axons of geniculate neurons run across the visual cortex from lateral to medial, bearing synapses *en passant*. The circles in the visual cortex represent the dendritic fields of cortical neurons. The construction shows that a band of cortical neurons receives inputs from a band of geniculate neurons that contain information from the same azimuth of visual space. The cortical band is, thus, an isoazimuth lamella, and the diagram shows the approximate orientation of three isoazimuth lamellae that correspond to azimuth lines 1, 2, and 3.

Several studies have demonstrated that cell plate cells project to the dorsal cortex (Hall *et al*., 1977;

Belekhova *et al*., 1979; Desan, 1984, 1985; Zhu *et al*., 2005), but whether or not neuropile cells also project to visual cortex is controversial (Kenigfest *et al*., 1995). Geniculate axons leave the medial surface of DLGN and enter the telencephalon through the dorsal peduncle of the lateral forebrain bundle (Hall and Ebner, 1970; Heller and Ulinski, 1987). They turn dorsally as they approach the rostral recess of the lateral ventricle and enter the lateral edge of the dorsal cortex (Figure 3). Individual axons frequently course from lateral to medial across the dorsal cortex, bearing many varicosities *en passant* (Heller and Ulinski, 1987; Mulligan and Ulinski, 1990). The earliest studies of geniculocortical projections in turtles used anterograde degeneration techniques and interpreted degeneration in D_L as axons that passed through D_L without synapsing. However, more recent work has demonstrated that geniculate axons synapse on neurons in both D_L and D_M. Electron microscopic studies of degnerating synapses in D_M following large thalamic lesions show that thalamocortical synapses contain clear, round synaptic vesicles and synapse upon dendritic spines, dendritic shafts, and somata of cortical neurons (Ebner and Colonnier, 1975, 1978; Smith *et al*., 1980). The synapses are glutaminergic, access the α-amino-3-hydroxy-5-methyl-D-aspartate (AMPA) subtype of glutamate receptor and mediate fast excitatory postsynaptic potentials (EPSPs) in cortical neurons (Blanton and Kriegstein, 1991a, 1991b, 1992; Larson-Prior *et al*., 1991).

An interesting feature of the geniculocortical projection is that the laminar position of the bundle of geniculate axons shifts as it courses from lateral to medial across the dorsal cortex (Heller and Ulinski, 1987). It passes through the outer half of layer 3, layer 2, and the inner half of layer 1 as it courses through D_L, but then shifts its position to run in the outer third of layer 1 in D_M. Individual axons have slightly curved trajectories as they run across the dorsal cortex if the cortex is viewed from its dorsal surface (Mulligan and Ulinski, 1990). Axons cross over each other as the geniculate axons enter the lateral edge of cortex so that axons from the rostral pole of DLGN project to the caudal edge of the cortex and axons from the caudal pole of DLGN project to the rostral edge of the cortex. Since the nasotemporal axis of the retina is mapped along the rostrocaudal axis of the geniculate, a consequence of the geometry of the geniculocortical axons is that bands of cortical neurons receive synapses from a fascicle of geniculate axons that arise from a particular cluster of geniculate neurons. This band of cortical neurons receives inputs from points of all possible elevations along a given azimuth line of visual space and is called an isoazimuth lamella.

2.08.2.3 Cellular Structure of Turtle Visual Cortex

A rough estimate is that dorsal cortex contains approximately 100 000 neurons. Pyramidal cells account for approximately 80–90% of these neurons and are by far the most numerous neurons in layer 2 (Figure 4). They have vertically elongate somata that bear apical and basal dendrites. There are distinct differences between the pyramidal cells in D_L and D_M (Desan, 1984, 1985; Colombe and Ulinski, 1999). Those in D_L have roughly symmetric apical and basal dendritic trees that extend into layers 1 and 3, respectively (Figure 4a). The basal dendritic trees are reduced in pyramidal cells in D_M and become very short at the D_M/dorsomedial cortex border (Figure 4b). Because of the systematic shift in position of geniculate axons as they cross the dorsal cortex, pyramidal cells in D_L receive geniculate inputs on the somata and the proximal parts of both dendritic trees, while those in D_M receive geniculate inputs on the distal segments of their apical dendrites. Standard cable theoretic considerations predict that geniculate inputs should be far less effective in generating action potentials in D_M pyramidal cells than in D_L pyramidal cells. However, D_M pyramidal cells are electrotonically more compact than are D_L pyramidal cells and there is no systematic difference in the efficacy of geniculate synapses in the two groups of pyramidal cells (Ulinski, 1999). Intracellular current injections elicit two types of action potential in pyramidal cells (Connors and Kriegstein, 1986). The most common are large overshooting action potentials that appear to be somatic in origin. Smaller action potentials,

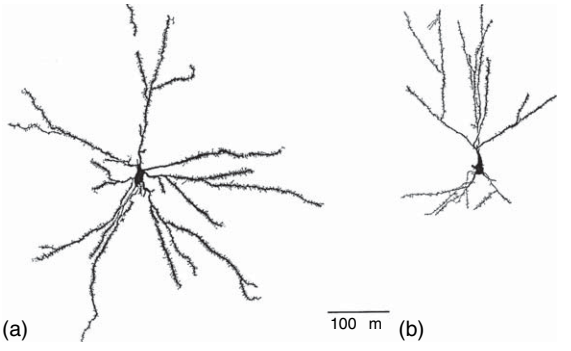

Figure 4 Morphology of pyramidal cells. a, Pyramidal cell from the lateral part of dorsal area, D_L. b, Pyramidal cell from the medial part of dorsal area, D_M. Both figures are drawings of pyramidal cells from Golgi preparations.

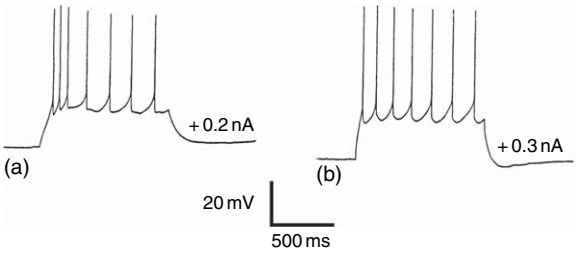

Figure 5 Firing patterns of cortical neurons. This figure shows the two most common firing patterns that are found in visual cortex neurons. a, A regular spiking cell, typical of pyramidal cells and subpial cells. b, A fast spiking cell, typical of stellate and horizontal cells. Each firing pattern was produced by injecting a square current pulse of + 0.2 or + 0.3 nA into a cell.

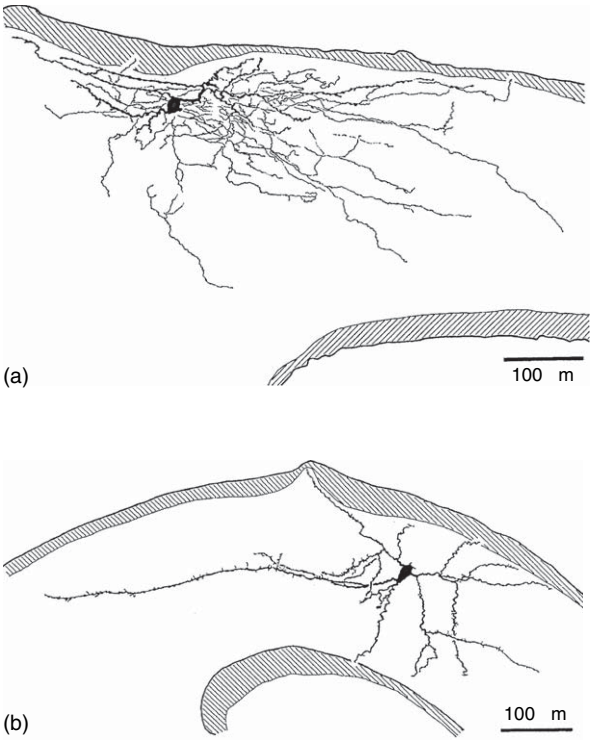

Figure 6 Inhibitory interneurons. a, A subpial cell from dorsal area. b, A stellate cell from dorsal area. Both drawings are of cells that were filled with Neurobiotin. Each is from a thick section. The pial and ventricular surfaces of the sections are shown with cross-hatching.

termed spikelets, are also seen frequently and may be dendritic spikes that propagate retrogradely into the somata of both D_L and D_M pyramidal cells (Millonas and Ulinski, 1997). Current injections can produce trains of action potentials that show a regular spiking pattern that is comparable to that seen in mammalian pyramidal cells (Figure 5a). The axons of pyramidal cells originate from their somata and extend into layer 3 where they bifurcate, one branch coursing medially into dorsomedial cortex and medial cortex and the other extending laterally into the lateral forebrain bundle (Connors and Kriegstein, 1986). These collaterals extend through the striatum and give secondary branches in the DLGN and optic tectum. In addition to these efferent projections, the primary branches of pyramidal cell axons give rise to a cone of collaterals that extends into layer 1. These collaterals form an ellipse-shaped field when viewed from the dorsal surface of the cortex, with the long axis of the ellipse extending along the isoazimuth lamellae (Cosans and Ulinski, 1990). The axonal field of individual pyramidal cells extends for approximately a third of the diameter of the dorsal cortex. Individual axons bear varicosities *en passant* and presumably synapse on other pyramidal cells as well as interneurons. Pyramidal cells are glutaminergic and their axons access both AMPA and *N*-methyl-D-aspartate (NMDA) receptors on other cortical neurons (Larson-Prior *et al.*, 1991). They mediate biphasic EPSPs that have both fast and slow components.

The remaining 20% of neurons in the dorsal cortex are nonpyramidal neurons that probably include both inhibitory and excitatory interneurons (Blanton *et al.*, 1987). Three groups of inhibitory interneurons are the best studied. The first of these are subpial cells (Figure 6a), which are completely embedded in the fascicle of geniculate afferents and consequently have somata positioned in the outer half of layer 1 (Colombe *et al.*, 2004). Their dendrites bear many distinct dendritic swellings or beads that appear to reduce the sensitivity of subpial cells to geniculate inputs. Like pyramidal cells, subpial cells show a regular spiking firing patterns following intrasomatic current injections. The axons of subpial cells arborize in the outer half of layer 1 and are presumably presynaptic to the apical dendrites of pyramidal cells and probably also synapse on other subpial cells. Subpial cells are GABAergic and appear to access both $GABA_A$ and $GABA_B$ receptors on their postsynaptic targets. The second major group of inhibitory neurons in D is stellate cells (Figure 6b), which have somata located in the inner half of layer 1 (Colombe *et al.*, 2004). They have dendrites that extend obliquely through layers 1 and 2 into layer 3. The dendritic arbors vary in size and individual dendrites are smooth or bear a small number of dendritic spines or appendages. They show relatively little adaptation in their firing rates following intrasomatic current injections and typically resemble the fast spiking firing patterns seen in many mammalian inhibitory interneurons (Figure 5b). Their axons ramify throughout all three layers of the dorsal cortex.

The third major group of inhibitory interneurons is horizontal cells, which have somata in layer 3 and dendrites that extend horizontally in layer 3 (Connors and Kriegstein, 1986). Like stellate cells, horizontal cells have a fast spiking firing pattern. Their axons appear to ramify in layers 3 and 2. Some horizontal cells are retrogradely labeled following injections of horseradish peroxidase into the thalamus, suggesting that they participate with pyramidal cells in forming the corticogeniculate projection system (Ulinski, 1986b). The anatomy and laminar positions of these three groups of neurons suggest that they have specific relationships to geniculate and intracortical projections. Subpial cells are literally embedded in geniculate afferents, suggesting that they play a dominant role in feedforward inhibition of pyramidal cells. Horizontal cells are embedded in the axons of pyramidal cells, suggesting they play a dominant role in intracortical feedback inhibition. Stellate cells are positioned to receive a mixture of geniculate and pyramidal cells inputs, raising the possibility that they are involved in both feedforward and feedback inhibition.

2.08.2.4 Responses of Visual Cortex Neurons to Visual Stimuli

The earliest physiological studies of turtle visual cortex used evoked potentials and flash stimuli to show that the cortical area now recognized as the dorsal cortex is responsive to visual stimuli (Orrego, 1961). Single-unit studies in alert turtles showed that neurons in this area have large, binocular receptive fields (Mazurskaya, 1974). The convergence of information from DLGN cells receiving inputs from all points along vertical meridians of visual space in the isoazimuth lamellae and the subsequent intracortical projections of pyramidal cells provide the anatomical substrate for the large receptive fields of neurons in the dorsal cortex. The cells respond robustly to small stimuli moving anywhere in binocular visual space or to two spots of light presented with temporal or spatial delays in an apparent motion paradigm (Mazurskaya, 1974). Since retinal ganglion cells in turtles frequently respond to stimuli moving with preferred directions or speeds in relatively small regions of visual space, they serve functionally as local motion detectors. Neurons in the dorsal cortex, thus, receive convergent inputs from many local motion detectors and serve as global motion detectors that can respond to large stimuli moving through visual space (Ulinski, 1999). Intracellular recordings from pyramidal and nonpyramidal neurons in the dorsal cortex can be efficiently carried out using an *in vitro* preparation of the turtle's eyes and brain (Kriegstsein, 1987). The cerebral hemisphere can be opened by a U-shaped incision that preserves the geniculate afferents that enter the cortex from its lateral end. The cortex is then unfolded, pinned flat in a recording chamber, and electrodes are inserted into the cortex from its ependymal surface. Intracellular recordings show that light flashes evoke combinations of EPSPs and inhibitory postsynaptic potentials (IPSPs) in neurons located in all three layers (Kriegstein, 1987; Mancilla *et al.*, 1998; Mancilla and Ulinski, 2001).

Recordings using multielectrode arrays in freely behaving turtles and in *in vitro* eye–brain preparations show that visual stimuli elicit waves of activity that propagate across the visual cortex. The spatiotemporal dynamics of the waves can be visualized using voltage-sensitive dyes (VSDs) and the eye–brain preparation (Prechtl, 1994, 1995; Senseman, 1996; Prechtl *et al.*, 1997, 2000; Senseman and Robbins, 1999). The waves appear to be triggered by the appearance of novel visual stimuli. VSD studies show that the waves always originate near the rostral pole of the dorsal cortex, regardless of the specific nature of the stimulus. Their propagation velocity depends on the nature of the stimulus, the light intensity, and the color of the light (Senseman, 1996). The waves are complex spatiotemporal events, but their properties can be analyzed quantitatively using a variation of a principal components method, the Karhunen–Loeve decomposition (Robbins and Senseman, 1998, 2004; Senseman and Robbins, 2002). This method can be used to represent individual waves in a low-dimensional phase space and to compare the dynamics of waves produced by different stimuli. Analysis of waves recorded in intact turtles, the eye–brain preparation, and a large-scale model of the dorsal cortex (Nenadic *et al.*, 2003) indicate that spots presented at different points in visual space or moving spots produce cortical waves with statistically different dynamics (Nenadic *et al.*, 2002; Du *et al.*, 2005). The dynamics of the wave can, consequently, be used to estimate the properties of visual stimuli, such as their positions in visual space or speed.

Analysis of waves using a large-scale model indicates that the waves are composed of three components (Wang *et al.*, 2005). The first is an initial depolarization that consists of a hill of depolarization that occurs near the rostral pole of the cortex and lasts approximately 200 ms after stimulus onset. In most cases, this depolarization triggers a primary propagating wave that moves from rostral to caudal across the cortex and reaches the caudal pole of the cortex after about 400 ms. In some cases,

a secondary propagating wave, or reflection, is generated at the caudal pole of the cortex as the primary wave begins declining. The secondary wave propagates from caudal to rostral across the cortex and typically subsides after about 800 ms. A long-lasting hyperpolarization can persist for more than 1.5 ms after stimulus presentation. Simulations of cortical waves in which the strengths of specific cortical synapses are systematically varied indicate that the initial depolarization is produced by the excitation of pyramidal cells in D_L by geniculate afferents and controlled by feedforward inhibition that is mediated by subpial cells (Wang *et al*., 2005). Consistent with this, intracellular recordings indicate that light flashes produce fast IPSPs in pyramidal cells that can regulate the amplitudes of geniculocortical EPSPs and the firing rate of pyramidal cells (Mancilla *et al*., 1998; Mancilla and Ulinski, 2001). Formation of the primary propagating wave is the result of recurrent excitation in the cortex that is mediated by pyramidal cell collaterals. Wave speed is regulated by the balance of excitation and by subpial cell-mediated inhibition. The duration of the primary and secondary waves is controlled by feedback inhibition mediated by horizontal cells.

2.08.3 Evolution of Visual Cortex

It is now well established that birds evolved from a group of archosaurian reptiles and that the four orders of living reptiles and birds are sister groups. Retinal projections to the optic tectum and to a dorsal thalamic nucleus are present in all of the species of reptiles and birds that have been studied, although the nomenclature of the dorsal thalamic retinorecipient nucleus varies from species to species (Ulinski and Margoliash, 1990). Tectal projections to nucleus rotundus and subsequent rotundal projections to the anterior dorsal ventricular ridge are also present in all reptiles and birds (Ulinski, 1983). This suggests that a retinorecipient structure in the dorsal thalamus and the tectofugal pathway are primitive, or symplesiomorphic, characters that were present in the stem reptiles and have been retained in all of the clades that evolved from these animals. The situation with regard to the thalamofugal pathway is less clear because telencephalic projections from the retinorecipient thalamic nucleus are quite variable and have not been carefully studied in many species. There are thalamic projections to a visual structure, the Wulst, that is situated on the anterior dorsal surface of the telencephalon in birds. The receptive field properties of neurons in the visual Wulst have been best studied in owls and shown to have many of the features associated with the receptive fields of neurons in the primary visual cortex of cats and monkeys such as a retinotopic map of visual space, orientation selectivity, and ocular dominance (Pettigrew and Konishi, 1976; Pettigrew, 1979). As reviewed above, the receptive field properties of neurons in turtle visual cortex are very different. There is no evidence for a retinotopic organization, all neurons have wide field receptive fields, and there is no indication of orientation selectivity. Thus, although the basic anatomy of a pathway from the retina, to a retinorecipient nucleus in the dorsal thalamus, and then to a dorsal telencephalic structure is a constant feature of reptiles, birds, and mammals, the functional organization of these telencephalic visual areas varies dramatically between species.

A reasonable working hypothesis is that visual cortex in turtles is involved in analyzing the movements of objects in visual space (Ulinski, 1999). Retinal ganglion cells in turtles tend to be directionally selective and can serve to analyze small objects or edges moving through restricted regions of visual space. However, naturally occurring visual stimuli usually have several edges with different orientations so that no individual retinal ganglion cell can adequately encode the motion of such a stimulus. Since neurons in DLGN and the dorsal cortex receive convergent inputs from many ganglion cells, they can integrate motion signals across both space and time and serve as global motion detectors. A similar set of transformations occurs in the motion pathways of primates, although it appears to take a longer sequence of transformations to reach essentially the same result. Retinal ganglion cells are typically not motion selective in the retinas of primates, but motion- and direction-selective neurons are found in the primary visual cortex and medial temporal areas of primates. A progressive increase in receptive field size occurs in successive structures in this pathway and neurons in extrastriate areas deep in the motion pathway have receptive fields that encompass all of visual space.

2.09 The Evolution of Vocal Learning Systems in Birds

M A Farries and D J Perkel, University of Washington, Seattle, WA, USA

Glossary

arcopallium Subdivision of the avian pallium located in the caudoventral telencephalon possessing descending projections to the brainstem.

mesopallium Large subdivision of the avian pallium dorsally adjacent to nidopallium.

nidopallium Large subdivision of the avian pallium dorsally adjacent to the striatum, receiving direct ascending sensory input of at least three modalities (auditory, visual, somatosensory).

pallium One of the two major subdivisions of the telencephalon, containing primarily glutamatergic projection neurons. In mammals, the vast majority of pallium consists of isocortex and hippocampus, but also includes the claustrum and parts of the amygdala. Evolutionary relationships between the pallial subdivisions of mammals and birds are still debated (see Evolution of the Amygdala in Vertebrates, Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?).

parcellation Mechanism for evolving new structures in the central nervous system advocated by C. J. Herrick and S. O. E. Ebbesson. New structures are said to emerge as newly distinguished subdivisions within established structures. Once these new subdivisions are defined, they can restrict their connections to only a subset of the subregions that emerged from the original structure and acquire other derived characteristics.

2.09.1 Song: A Learned Behavior Used for Communication

Like many other vertebrates, birds in most orders of Aves make unlearned vocalizations that are used to communicate a variety of signals, e.g., begging or alarm calls (Kroodsma *et al.*, 1982). But three avian orders contain species capable of producing far more complex vocalizations that are learned through copying from other individuals. Such vocal learning is a rare trait shared only with cetaceans and humans (see Zeigler and Marler, 2004; and The Evolution of Vocal Learning Systems in Birds and Humans). The best-studied avian vocal learners are oscines (songbirds), constituting the great majority of species in order Passeriformes. Songbirds use their learned vocalizations, or songs, in courtship and territory defense, and perhaps for other poorly understood purposes. The capacity for learning, producing, and recognizing songs is imparted by a specialized set of telencephalic, diencephalic, and brainstem structures known collectively as the song system. The evolution of the oscine song system has long been a matter of interest to specialists, but this topic has recently attracted broader attention. Vocal learning in songbirds and humans shares a number of behavioral similarities (Doupe and Kuhl, 1999), and the recent realization that structures required for vocal learning in songbirds bear a close anatomical and physiological resemblance to the basal ganglia of mammals has raised the possibility that the similarities run deeper than mere behavioral analogies. Exactly how profound are the parallels between birdsong and human speech remains a matter of debate and active research, but it seems that there might at least be mechanistic similarities between song learning and the general processes of basal ganglia-dependent motor learning in mammals. Another factor drawing fresh attention to the evolution of the song system is the appreciation that surprisingly similar vocal control systems have appeared in three separate avian lineages. Conservation within Aves and across other vertebrate classes raises important questions about

how the song system evolved and how it is related to comparable systems in other taxa.

Behavioral studies in a variety of oscine species, carried out in field and laboratory settings, have uncovered a diverse array of song repertoires and learning abilities (Beecher and Brenowitz, 2005; Brenowitz and Beecher, 2005). Nonetheless, a consistent schematic pattern of song learning can be inferred (for review, see Williams, 2004). Songbirds learn their songs in two phases. During an initial sensory phase, a young bird memorizes the song(s) of a tutor bird. Later, the bird begins vocalizing in a sensorimotor phase where initially highly variable vocalizations become more refined over the course of several weeks into a highly stereotyped copy of the tutor song. Once the song is stereotyped, it is said to have crystallized. Normal hearing is critical for all phases of song learning, and is also essential for song maintenance in adult birds singing crystallized song. Although all oscine species studied to date conform to this general pattern, major variations occur in the degree to which both males and females sing, the number of songs learned, the degree of copying, and the degree of song stereotypy. It appears that a broad spectrum of behavioral features has evolved, which gives experimentalists a rich source of study material. Understanding both the conserved rules and the variations will be important in addressing how the neural structures underlying this complex behavior accomplish their tasks.

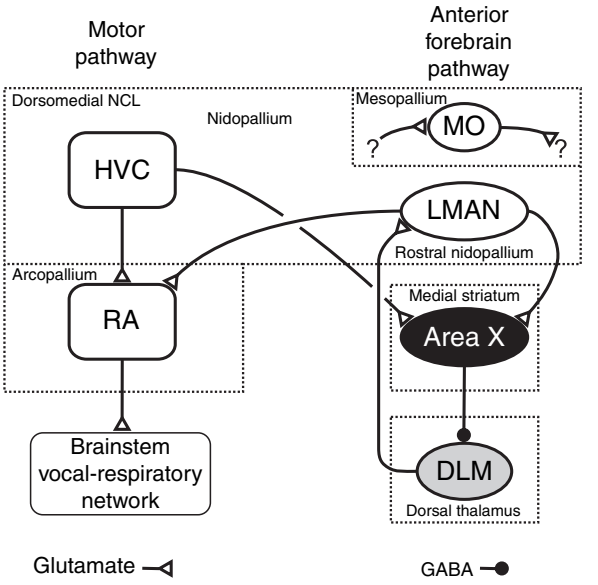

Figure 1 The oscine song system. This schematic shows the major components of the songbird vocal control system; abbreviations are defined in the text. For the sake of simplicity, some lesser known nuclei are omitted, including MMAN, DMP, NIf, and nucleus uvaeformis, a thalamic nucleus that projects to NIf and HVC. Within the forebrain, pallial (cortex-like) nuclei are white, subpallial (basal ganglia) nuclei are black, and thalamic nuclei are gray.

2.09.2 The Song System of Oscine Birds

The oscine song system consists of several discrete, interconnected brain nuclei that are devoted to song-related functions and are apparently absent in nonoscines (Farries, 2004). These nuclei and their connections were first reported in canaries (*Serinus canaria*), but have been most extensively studied in zebra finches (*Taeniopygia guttata*). The song system can be divided loosely into two major pathways (Figure 1). One pathway is a motor pathway that is essential for song production. This pathway is located in the arcopallium and caudal nidopallium, subdivisions of the avian telencephalon that appear functionally comparable to (but are not necessarily homologous to) mammalian isocortex. The motor pathway includes nucleus HVC (used as the proper name, not an abbreviation; see Reiner *et al.*, 2004b for nomenclature) of the caudal nidopallium, which receives strong auditory input from the interfacial nucleus of the nidopallium (NIf) and provides premotor output to the robust nucleus of the arcopallium (RA). RA, in turn, projects to several brainstem centers important for vocal control, including motor neurons in the tracheosyringeal portion of the hypoglossal nucleus (nXIIts) that control the syrinx, the avian vocal organ (Wild, 2004). RA also projects to a variety of respiratory premotor regions and to the dorsomedial nucleus of the intercollicular complex, which is involved in producing nonlearned vocalizations in all bird species studied to date.

HVC, in addition to sending projections to the motor pathway, also contains a separate population of neurons that project strongly to area X, a large nucleus located in the medial striatum. This connection initiates a circuit known as the anterior forebrain pathway (AFP). Area X projects to the medial part of the dorsolateral nucleus of the anterior thalamus (DLM), which then innervates the lateral magnocellular nucleus of the anterior nidopallium (LMAN). LMAN completes the AFP by projecting to RA, and collateral axons of the same neurons project back to area X. The AFP is not essential for song production *per se*, but is required for song learning and adult vocal plasticity. Lesions of LMAN or area X in juveniles dramatically disrupt learning, but lesions in adults do not alter normal song (Bottjer, 1984; Sohrabji *et al.*, 1990; Scharff and Nottebohm, 1991). In adults, however, the AFP does appear to play some role in active song maintenance, as lesions of LMAN prevent changes due to denervating the syrinx or deafening the

animal (Williams and Mehta, 1999; Brainard and Doupe, 2001). Since neurons in area X and LMAN exhibit auditory responses that are selective for the bird's own song (Doupe, 1997), one hypothesized role for the AFP is to compute some signal related to the degree of match between the bird's own song and his tutor's song and relay it to nucleus RA in the motor pathway, where it might influence behavioral plasticity. Three other nuclei in the oscine anterior forebrain should be considered a part of the song system, but whose functions are less well known. The medial magnocellular nucleus of the anterior nidopallium (MMAN) receives input from the posterior nucleus of the dorsomedial thalamus (DMP) and projects to HVC (Nottebohm *et al.*, 1982; Foster *et al.*, 1997). Finally, a nucleus just dorsal to LMAN, the oval nucleus of the mesopallium (MO), may also have song-related functions; it shows increased expression of the immediate early gene ZENK following bouts of singing (Jarvis *et al.*, 1998). However, the functions and anatomical connections of oscine MO are as yet unknown.

2.09.3 A Basal Ganglia Circuit Required for Song Learning

The AFP is of particular interest from an evolutionary point of view because it includes a specialized part of the oscine basal ganglia, area X. Since the basal ganglia have been implicated in some forms of learning in mammals (Graybiel, 1995), this raises the possibility that song learning in birds and motor learning in mammals employ related mechanisms. A brief glance at the AFP discloses some significant differences that undermine this idea. Although area X is part of the avian striatum, it projects directly to the thalamus (Bottjer *et al.*, 1989), while mammalian striatum communicates with the thalamus indirectly via the globus pallidus and substantia nigra, output stations of the basal ganglia (Parent and Hazrati, 1995). Furthermore, the projection neurons of area X are a sparsely distributed set of aspiny neurons (Bottjer *et al.*, 1989; Luo and Perkel, 1999), whereas the projection neurons of mammalian striatum are spiny neurons that comprise up to 95% of all striatal neurons (Gerfen, 1992). Nevertheless, a more thorough examination of area X uncovers a surprisingly long list of similarities. The vast majority of neurons in area X are spiny neurons that closely resemble their mammalian counterparts morphologically, histochemically, and physiologically (Farries and Perkel, 2002; Carrillo and Doupe, 2004; Reiner *et al.*, 2004a), even if they do not project out of the nucleus. All of the known interneuron types discovered in mammalian striatum are also present in area X (Farries and Perkel, 2002). As for the projection neurons, at least some (perhaps all) physiologically resemble neurons in the mammalian globus pallidus (Farries and Perkel, 2002; Farries *et al.*, 2005), suggesting that area X combines elements of the input (striatum) and output (globus pallidus) stations of the basal ganglia. Recent evidence suggests that area X may even contain functional equivalents of both major pathways through the mammalian basal ganglia (Farries *et al.*, 2005), the direct (having a net excitatory effect on the thalamus) and indirect (providing net inhibition to the thalamus). This curious pattern of conservation (or convergence?) and divergence raises new questions about the evolution of the basal ganglia, but also indicates that some highly specialized song-related circuitry has been built from common components that in their essentials remain unchanged after 300 million years of evolution.

Recently, parallels between birdsong and human speech received fresh interest when a possible molecular link between them surfaced. A familial speech and language disorder involving neuropathology of the cortex and basal ganglia results from mutations in the transcription factor FoxP2. A mutation in this gene also distinguishes humans, who are capable of vocal mimicry, from other primates, which are not. An intriguing hypothesis was that mutations in FoxP2 also distinguished bird taxa capable of vocal learning from those incapable, perhaps even enabling vocal learning in primates and birds. Two groups recently cloned FoxP2 from songbirds (Haesler *et al.*, 2004; Teramitsu *et al.*, 2004). Sequence analysis indicated that songbirds do not have the human-specific mutation. However, an intriguing fortuitous finding was that songbird FoxP1, a related member of the same gene family, is strongly expressed in several song nuclei. Since FoxP1 and FoxP2 can dimerize and influence transcription, it is possible that these proteins play some specific role in the development or function of the song system. On the other hand, given that these genes are relatively widely expressed, both within and outside the nervous system, it is also possible that they exert no specific function directly related to vocal learning, but rather a more general role in circuit development. Regionally and temporally specific manipulation of these genes will be needed to help determine any role these genes may play in vocal learning.

2.09.4 Vocal Control Circuits in Parrots and Hummingbirds

Oscines may be the most extensively studied vocal learners among birds, but they are not the only avian group that learns vocalizations. Parrots (order Psittaciformes) are famous for their vocal mimicry, with abilities ranging from the relatively modest (but still quite accomplished) budgerigar (Farabaugh and Dooling, 1996) to the African grey parrot capable of learning more than 70 English words (Pepperberg, 2002). Parrots also have an interconnected set of telencephalic vocal control centers bearing considerable resemblance to the oscine song system (Figure 2). Like songbirds, parrots have an arcopallial nucleus, the central nucleus of the anterior arcopallium (AAC), that directly innervates syringeal motor neurons and brainstem respiratory circuits (Paton *et al.*, 1981). This arcopallial nucleus receives input from a part of the nidopallium, the central nucleus of the lateral nidopallium (NLC), analogous to the oscine HVC (Paton *et al.*, 1981). Furthermore, parrots have a group of structures comparable to the songbird AFP, including a region of medial striatum containing sparsely distributed aspiny neurons that project directly to the dorsal thalamus (Striedter, 1994). The parrot AFP also incorporates an oval nucleus of the anterior MO which, unlike its oscine counterpart, has known connections to other vocal control nuclei (Striedter, 1994; Durand *et al.*, 1997). In addition to songbirds and parrots, at least some hummingbirds (family Trochilidae of order Apodiformes) appear capable of learning complex vocalizations (Baptista and Schuchmann, 1990). A study of the expression of the immediate early gene ZENK in hummingbirds after vocalization revealed a set of circumscribed telencephalic nuclei in locations similar to those of the vocal control nuclei of songbirds and parrots (Jarvis *et al.*, 2000). However, little is as yet known about the anatomical connections among these regions in hummingbirds.

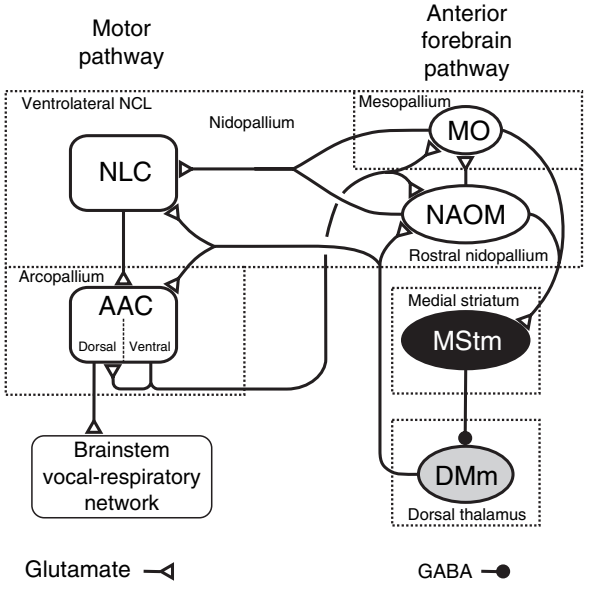

Figure 2 The psittacine vocal system. This schematic shows the known components of the parrot vocal control system. AAC is divided into distinct dorsal and ventral sectors; only the dorsal part has direct descending projections to the brainstem, while only the ventral part projects to NAOM and MO. Within the forebrain, pallial (cortex-like) nuclei are white, subpallial (basal ganglia) nuclei are black, and thalamic nuclei are gray. NAOM, medial part of the oval nucleus of the anterior nidopallium; MStm, magnocellular part of the medial striatum; DMm, magnocellular nucleus of the dorsomedial thalamus; other abbreviations are defined in the text.

2.09.5 Evolution of Avian Vocal Control Systems

The similarities between the vocal control systems of songbirds, parrots, and hummingbirds raise an obvious question: are these systems derived from an ancestral vocal control system that evolved just once somewhere in the lineage leading to these three taxa? At first glance, the similarities between these systems seem to demand an affirmative answer. Indeed, when components of the parrot vocal control system were first studied using modern tract-tracing techniques (Paton *et al.*, 1981), they were given names matching their oscine counterparts (i.e., NLC and AAC were originally known as HVC and RA, respectively), perhaps because the argument for homology seemed so compelling. However, songbirds, parrots, and hummingbirds are not closely related groups, and so the hypothesis of common ancestry for their vocal control systems implies that such systems were lost independently in the many other avian lineages descended from their last common ancestor – or that these other avian groups possess telencephalic vocal control systems in spite of the lack of evidence that they learn complex vocalizations. Furthermore, a closer look at the organization of the parrot vocal control system reveals several anatomical differences with the oscine song system (Striedter, 1994; Durand *et al.*, 1997), especially in the AFP (Figure 2). These two factors make the common ancestry hypothesis considerably less parsimonious than it first appears.

If we are to entertain the alternative hypothesis that the vocal control systems of songbirds, parrots, and hummingbirds evolved independently, we need to understand how these systems could nevertheless

be as similar as they are. To do that, we need to know something about the neural systems from which they might have evolved, found in birds that do not learn their vocalizations. Several anatomical studies conducted mainly in the pigeon (*Columba livia*) (Zeier and Karten, 1971; Kröner and Güntürkün, 1999) and domestic chick (*Gallus domesticus*) (Davies *et al.*, 1997; Metzger *et al.*, 1998), but also including the mallard (*Anas platyrhynchos*) (Dubbeldam *et al.*, 1997) and barn owl (*Tyto alba*) (Knudsen *et al.*, 1995), have elucidated a pathway in the caudal pallium that bears considerable resemblance to the motor pathway of the songbird (HVC and RA) and parrot (NLC and AAC) vocal control systems (hummingbirds appear to have comparable nuclei as well). This pathway (Figure 3) begins with a broad belt of caudolateral nidopallium (NCL) that projects topographically to a belt of intermediate arcopallium (AI). AI projects to many parts of the brainstem, including premotor neurons of the reticular formation, suggesting that at least parts of the NCL–AI system have motor functions (Wild *et al.*, 1985). However, AI does not directly innervate components of the brainstem vocal control circuitry in any avian species studied to date that does not learn complex vocalizations. NCL receives a variety of sensory inputs, including auditory input from field L1/3 confined mainly to the dorsomedial sector of NCL, and input from frontal trigeminal nidopallium (NFT) directed to the ventrolateral sector of NCL, potentially conveying both auditory and trigeminal somatosensory information (Metzger *et al.*, 1998; Kröner and Güntürkün, 1999). The NCL–AI system has received some attention in songbirds (Bottjer *et al.*, 2000), and the song system motor pathway appears embedded within, or at least lies immediately adjacent to, the dorsomedial segment of this system, i.e., the part receiving input from field L. The regions known in oscines as HVC shelf and RA cup are almost certainly homologous to this part of the NCL–AI system identified in pigeons and chicks (Vates *et al.*, 1996).

Given the location of HVC and RA relative to the oscine NCL–AI system, it is reasonable to suggest that this part of the song system emerged by parcellation of the pre-existing field L-recipient NCL–AI system (Farries, 2001). In this hypothesis, HVC and RA emerged as specialized subdomains of this system, acquiring some new connections (e.g., from RA to vocal–respiratory brainstem circuitry) and losing some old connections (e.g., from field L directly into HVC), but largely retaining the basic organization inherited from the NCL–AI system. It is less clear to what extent the AFP can also be regarded as a relatively simple alteration and specialization of a pre-existing system, but at least some of its connections have counterparts in the anterior telencephalon of pigeons and chicks (Kitt and Brauth, 1982; Wild, 1987; Veenman *et al.*, 1995; Montagnese *et al.*, 2003), including a projection from the dorsal thalamus to a region of anterior nidopallium (like the projection from DLM to LMAN) and a projection from that same nidopallial region to the medial striatum (like the projection from LMAN to area X). If the oscine song system inherited much of its organization from a larger system found in most or all birds, this could explain the similarities between the vocal control systems of songbirds, parrots, and hummingbirds – if all three

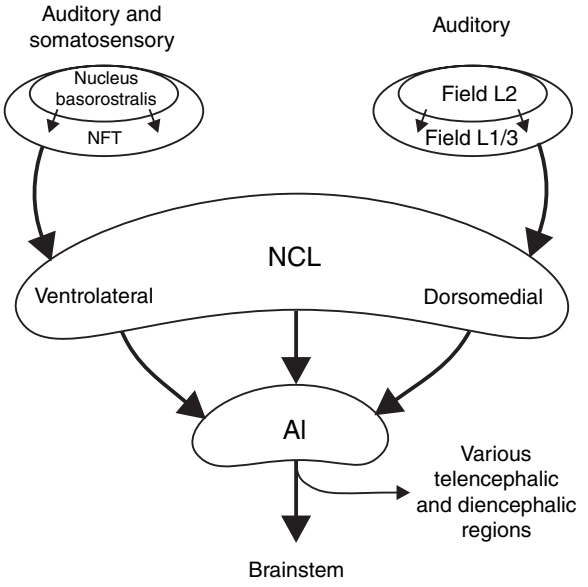

Figure 3 The NCL–AI pathway of avian caudal pallium. This schematic shows a pathway found in most or all birds that may be the evolutionary precursor to the vocal motor pathways of songbirds, parrots, and hummingbirds. NCL receives many sensory inputs, but only the ones involving auditory input are shown here. One major conduit for auditory information to the avian telencephalon passes through the thalamic nucleus ovoidalis, which projects to field L of the nidopallium, particularly to a subdivision called L2. Field L2 itself does not project widely in the telencephalon, but it does heavily innervate two other subdivisions of field L, L1, and L3, and they project to many areas, including the dorsomedial sector of NCL. A separate auditory pathway to the avian telencephalon arrives via an unusual direct projection from the intermediate nucleus of the lateral lemniscus in the brainstem to the nidopallial nucleus basorostralis, which also receives direct input from the principal trigeminal sensory nucleus. The nidopallium surrounding the nucleus basorostralis (NFT) relays this information to the ventrolateral sector of NCL. Songbird HVC is surrounded by dorsomedial NCL, whereas parrot NLC is surrounded by ventrolateral NCL. Auditory information also enters the NCL–AI pathway via direct projections from field L and NFT to AI. See Farries (2001) for a review of the primary literature describing this anatomy. Abbreviations are defined in the text.

systems are independent specializations of the same set of ancestral circuits (albeit without vocal functions), they would naturally share many characteristics inherited from those circuits.

This hypothesis predicts that the parrot and hummingbird vocal control systems are closely associated with or are embedded within the NCL–AI pathways of these taxa. At present, this is impossible to determine for hummingbirds due to a lack of anatomical data. In parrots, much less is known about the NCL–AI pathway than in songbirds, but regions of nidopallium have been identified that receive input from field L1/3 or NFT and that project to AI (Hall *et al*., 1993; Striedter, 1994). The parrot motor pathway nuclei are associated with this putative NCL–AI system, but not with the field L-recipient region as one might expect. Instead, the nidopallial tissue surrounding NLC receives input from NFT (and projects to arcopallial tissue adjacent to AAC) (Striedter, 1994). This part of the NCL–AI system probably also has access to auditory information, although via a different pathway, and thus may serve as an equally good base from which to evolve a system capable of vocal mimicry of an auditory model. The association of the parrot vocal control system with this putative NCL–AI system helps explain its similarities to the oscine song system, but at the same time its association with a different part of the NCL–AI system makes it extremely unlikely that these two vocal control systems could be homologous.

2.09.6 Conclusion

The vocal control systems of songbirds, parrots, and hummingbirds appear to be independently derived specializations of a common system found in most or all birds. This common system – the NCL–AI pathway and associated anterior forebrain circuitry – does not appear to play a significant role in vocal control outside of the three taxa that learn their vocalizations. Nevertheless, the avian vocal control systems appear to be relatively modest modifications of this basic plan. In spite of their striking specialization, avian vocal control systems are built from parts common to most birds, and to an extent from parts common to all amniotes. This is particularly true in the basal ganglia, where the oscine area X contains almost all of the basic components of the mammalian basal ganglia, with strikingly similar histochemistry, physiological properties, and functional organization. It is not unreasonable to hypothesize that the specialized basal ganglia domains of avian vocal learners share basic operating principles with the mammalian basal ganglia. In the specific case of human speech, one can imagine that convergent evolution makes the parallels even stronger because of the common requirements imposed by fundamentally similar tasks, although it is extremely unlikely that there is some deeper homology linking these instances of vocal learning. Study of the evolution of avian vocal control systems suggests that these specialized systems have much to tell us about general features of the amniote brain. Comparing vocal learning circuits in birds and humans also gives us at least two independent examples of evolution of a similar behavioral capacity from similar ancestral circuitry. Such comparisons could provide unique insights into whether these developments occurred through evolution by parcellation, and, if so, how this process yields new capabilities.

2.10 The Evolution of Vocal Learning Systems in Birds and Humans

E D Jarvis, Duke University Medical Center, Durham, NC, USA

Glossary

anterior vocal pathway Pathway in the anterior part of the forebrain that includes a pallial (cortical) region, striatal region, and thalamic region and that controls vocal learning and complex aspects of vocal production.

arcopallium Means arched pallium; a subdivision of the avian telencephalon with a border that is shaped like an arch along other pallial regions. It is a major output region of the telencephalon.

auditory learning The ability to make novel associations with sounds heard.

hyperpallium Means upper pallium; one of the dorsal-most subdivisions of the avian telencephalon. It has input, output, and intratelencephalic functions.

mesopallium Means middle pallium; a subdivision of the avian telencephalon that is located in between the nidopallium ventral to it and the hyperpallium dorsal to it. It is a major intratelencephalic region.

nidopallium Means nested pallium; a subdivision of the avian telencephalon that is shaped like a nest for the pallium regions dorsal to it and sits on top of the subpallium, or basal ganglia ventral to it. It has both input and intratelencephalic functions.

pallium Means mantle or covering. The pallium of vertebrates is the part of the embryonic brain that gives rise to all cortical regions in mammals and pallial named areas in birds.

posterior vocal pathway Pathway in the mid to posterior part of the forebrain, that includes pallial (cortical) regions, midbrain and medulla regions, and that controls production of learned vocalizations.

vocal learning The ability to modify acoustic and/or syntactic structure of sounds produced, including imitation and improvisation.

2.10.1 What is Vocal Learning

Vocal learning is the ability to modify acoustic and/or syntactic structure of sounds produced, including imitation and improvisation. It is distinct from auditory learning, which is the ability to make associations with sounds heard. Most, if not all, vertebrates are capable of auditory learning (see Organization and Correspondence of the Auditory Cortex of Humans and Nonhuman Primates, Shared Features of the Auditory System of Birds and Mammals), but few are capable of vocal learning. The latter has been found to date only in four distantly related groups of mammals (humans, bats, cetaceans, and recently elephants) and three distantly related groups of birds (parrots, hummingbirds, and songbirds) (Figure 1) (Nottebohm, 1972; Jarvis *et al.*, 2000; Poole *et al.*, 2005). Vocal learning is the behavioral substrate for spoken human language. An example helps in understanding the distinction between vocal learning and auditory learning. A dog can learn the meaning of the human words 'sit' (in English), 'sientese' (in Spanish), or 'osuwali' (in Japanese) or of a sentence ('come here boy'). Dogs are not born with this knowledge of human words or syntax. They acquire it through auditory learning. However, a dog cannot imitate the sounds 'sit', 'sientese', or 'osuwali'. A human, parrots, and some songbirds can. This is vocal learning, and though it depends upon auditory learning (Konishi, 1965), it is distinct from it.

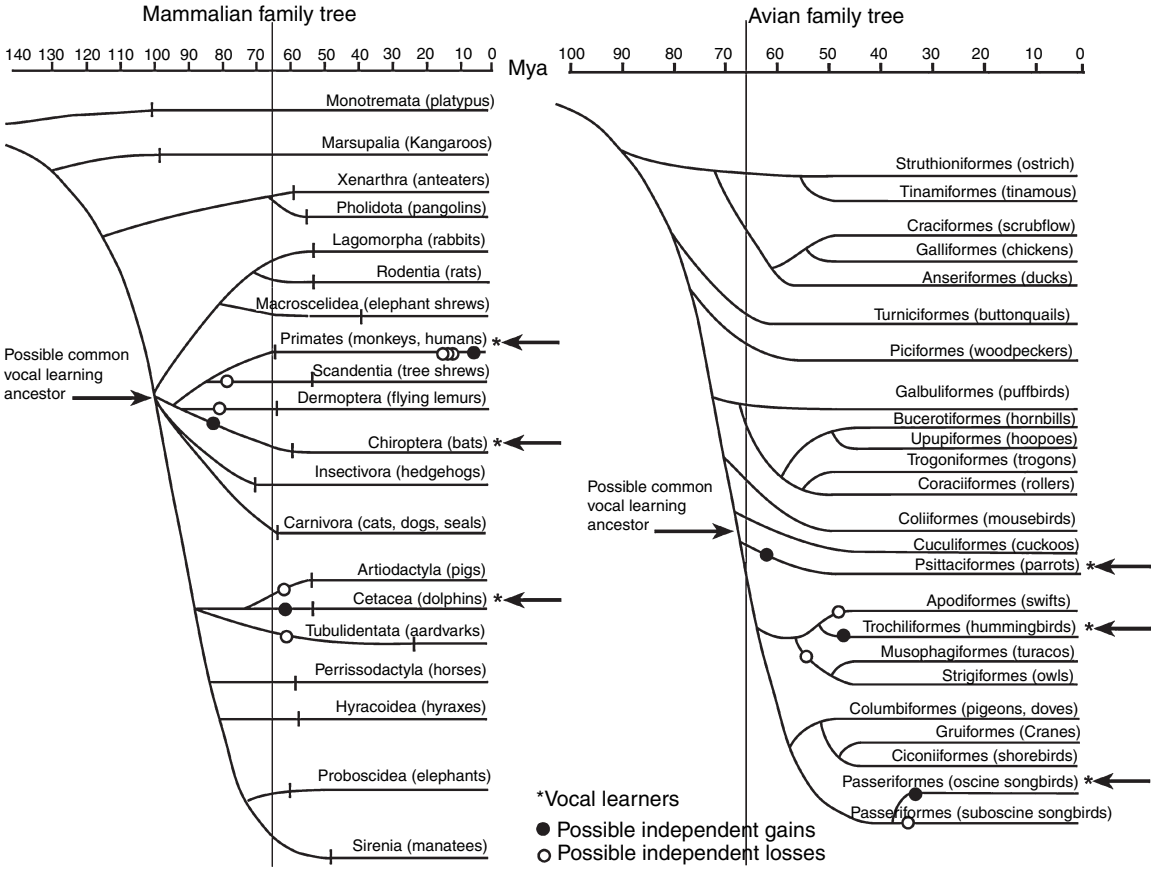

Figure 1 Family trees of living mammalian and avian orders. The mammalian tree is derived from the morphological analysis by Novacek (1992, 2001); horizontal lines indicate extant of geologic evidence from fossils. The avian tree was derived from DNA–DNA hybridization analysis by Sibley and Ahlquist (1990, p. 838). The Latin name of each order is given along with examples of common species. Passeriformes are divided into its two suborders, suboscine and oscine songbirds. The vertical line down the trees indicates the cretaceous–tertiary boundary; Mya = millions of years ago. Open and closed circles show the minimal ancestral nodes where vocal learning could have either evolved independently or been lost independently. Independent losses would have at least required one common vocal learning ancestor, located by the right facing arrows. Within primates, there would have to be least seven independent losses (tree shrews, prosimians, New and Old World monkeys, apes, and chimps) followed by the regain of vocal learning in humans (assuming that all nonhuman primates are vocal nonlearners). The trees are not meant to present the final dogma of mammalian and avian evolution, as there are many differences of opinion among scientists. Reproduced from Jarvis, E. D. 2004. Learned birdsong and the neurobiology of human language. *Ann. NY Acad. Sci.* 1016, 749–777, with permission.

Most vocal learners only imitate sounds of their own species, and not all vocal learning species have vocal abilities to the same degree. Humans are the most prolific vocal learners, as they learn to produce a seemingly infinite number of combinations of learned vocalizations. Not as prolific are some parrots, corvid songbirds, starlings, and mockingbirds, where they produce hundreds if not thousands of calls and/or learned warble/song combinations. Finally, less prolific are very stereotyped songbirds and hummingbirds, where they produce only one distinct song type with little variation (Catchpole and Slater, 1995; Farabaugh and Dooling, 1996; Ferreira *et al.*, 2006). Each of the vocal learning avian and mammalian groups has close vocal nonlearning relatives (Figure 1). Thus, it has been argued that vocal learning has evolved independently of a common ancestor in the three vocal learning bird groups (Nottebohm, 1972) and presumably in the four vocal learning mammalian groups (Jarvis, 2004). The question thus arises, is there something special about the brains of these animals that can imitate sounds.

2.10.2 Consensus Brain Systems of Vocal Learners

There is something special about the brain systems of vocal learners. Only vocal learners, songbirds, parrots, hummingbirds, and humans, have brain regions in their cerebrums (or telencephalon) that control vocal behavior (Jurgens, 2002; Jarvis *et al.*, 2000; see The Evolution of Vocal Learning Systems in Birds). Vocal control brain regions have not yet

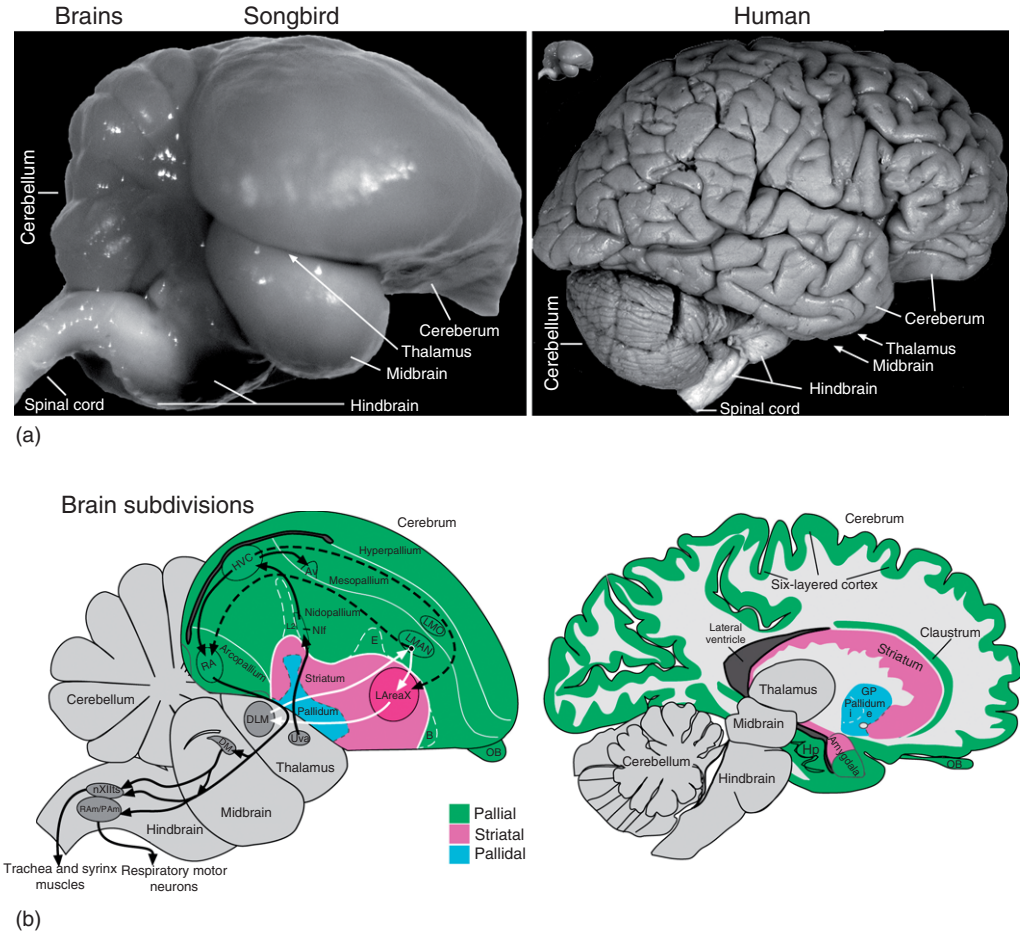

Figure 2 Avian and mammalian brain relationships. a, Side view of a songbird (zebra finch) and human brain to represent avian and mammalian species. In this view, the songbird cerebrum covers the thalamus and the human cerebrum covers the thalamus and midbrain. Inset (left) next to the human brain is the zebra finch brain to the same scale. b, Sagittal view of brain subdivisions according to the modern understanding of avian and mammalian brain relationships (Reiner *et al.*, 2004b; Jarvis *et al.*, 2005). Solid white lines are lamina (cell-sparse zones separating brain subdivisions). Large white areas in the human cerebrum are axon pathways called white matter. Dashed white lines separate primary sensory neuron populations from adjacent regions. Abbreviations in Table 1. Human brain image in (a), reproduced from, courtesy of John W. Sundsten, Digital Anatomist Project, Dept. of Biological Structure, University of Washington, with permission. b, Reprinted by permission from Macmillan Publishers Ltd: *Nat. Rev. Neurosci.* (Jarvis, E. D., Gunturkun, O., Bruce, L., *et al.* 2005. Avian brains and a new understanding of vertebrate brain evolution. *Nat. Rev. Neurosci.* 6, 151–159.), copyright (2005).

been investigated in cetaceans, bats, and elephants. Nonvocal learners, including nonhuman primates and chickens, only have midbrain and medulla regions that control innate vocalizations (Wild, 1997). Using this knowledge, it has been possible to generate a consensus vocal pathway, much like generating a consensus DNA sequence from comparing comparable genes of different species, by comparing vocal brain regions of different vocal learning and vocal nonlearning species. This comparison is facilitated by a recent revision to the nomenclature and understanding of avian brain organization relative to mammals and other vertebrates (Reiner *et al.*, 2004b; Jarvis *et al.*, 2005). Like mammals, birds have pallidal, striatal, and pallial subdivisions in their cerebrums. However, the pallial subdivision in mammals is layered in its cellular organization, whereas in birds it is nuclear (Figure 2). Even with this major difference, connectivity and other functional properties are similar. Below, the consensus brain regions, connectivity, and function studies of vocal learning species are described.

2.10.2.1 Brain Regions and Connectivity

Remarkably, all three vocal learning bird groups have seven comparable cerebral vocal brain nuclei: four posterior forebrain nuclei and three anterior forebrain nuclei (Figures 3a–3c; abbreviations in Table 1) (Jarvis *et al.*, 2000). These brain nuclei have been given different names in each bird group because of the possibility that each evolved their

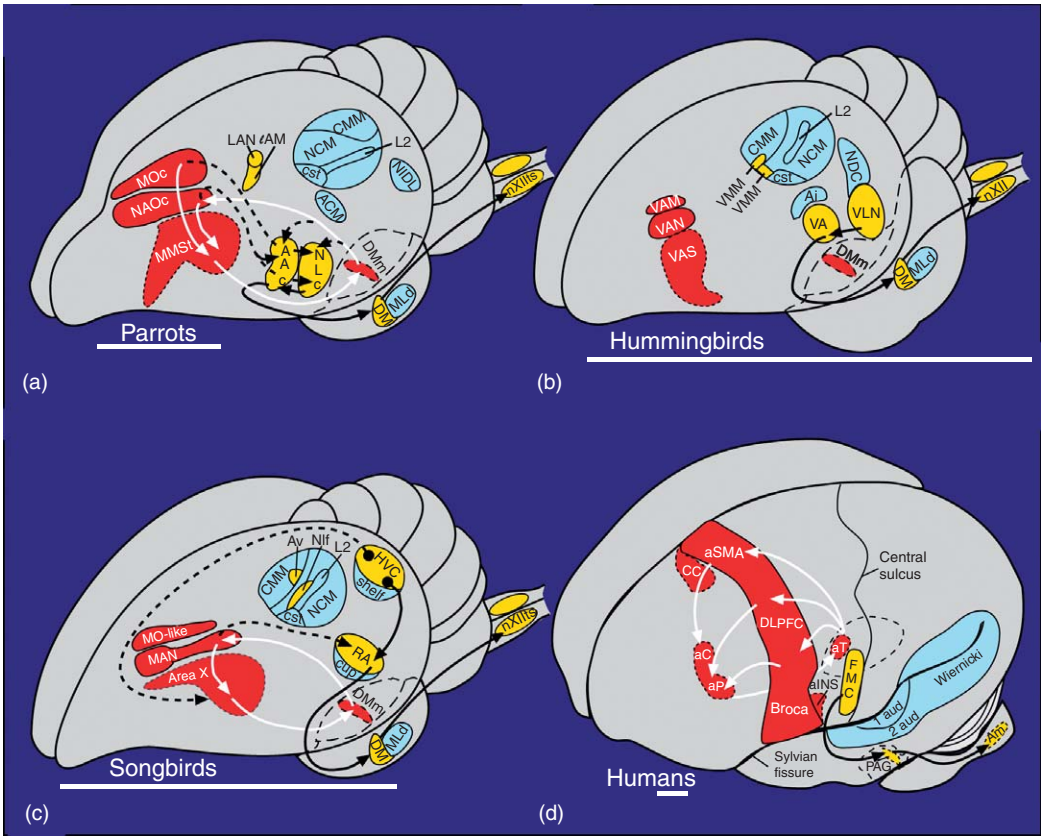

Figure 3 Proposed comparable vocal and auditory brain areas among vocal learning birds (a–c) and humans (d). Left hemispheres are shown, as this is the dominant side for language in humans and for song in some songbirds. Yellow regions and black arrows indicate proposed posterior vocal pathways; red regions and white arrows indicate proposed anterior vocal pathways; dashed lines indicate connections between the two vocal pathways; blue indicates auditory regions. For simplification, not all connections are shown. The globus pallidus in the human brain, also not shown, is presumably part of the anterior pathway as in nonvocal pathways of mammals. Basal ganglia, thalamic, and midbrain (for the human brain) regions are drawn with dashed-line boundaries to indicate that they are deeper in the brain relative to the anatomical structures above them. The anatomical boundaries drawn for the proposed human brain regions involved in vocal and auditory processing should be interpreted conservatively and for heuristic purposes only. Human brain lesions and brain imaging studies do not allow one to determine functional anatomical boundaries with high resolution. Scale bar: ~7 mm. Abbreviations are in Table 1. Modified from Jarvis, E. D. 2004. Learned birdsong and the neurobiology of human language. *Ann. NY Acad. Sci.* 1016, 749–777, with permission.

vocal nuclei independently of a common ancestor with such nuclei (Striedter, 1994; Jarvis *et al.*, 2000). In all three bird groups, the posterior nuclei form a posterior vocal pathway that projects from a nidopallial vocal nucleus (HVC, NLC, VLN) to the arcopallial vocal nucleus (RA, AAC dorsal part, VA), to the midbrain (DM) and medulla (nXIIts) vocal motor neurons (Figures 3a–3c, black arrows) (Striedter, 1994; Durand *et al.*, 1997; Vates *et al.*, 1997; Gahr, 2000); nXIIts projects to the muscles of the syrinx, the avian vocal organ. Vocal nonlearning birds have DM and nXIIts for production of innate vocalizations, but they appear not to have projections to these nuclei from the arcopallium (Wild *et al.*, 1997). The anterior nuclei (connectivity examined only in songbirds and parrots) are part of an anterior vocal pathway loop, where a pallial vocal nucleus (MAN, NAO) projects to the striatal vocal nucleus (area X, MMSt), the striatal vocal nucleus to a nucleus in DLM of the dorsal thalamus (DLM, DMM), and the dorsal thalamus back to the pallial vocal nucleus (MAN, NAO) (Figures 3a and 3c, white arrows) (Durand *et al.*, 1997; Vates *et al.*, 1997). The parrot pallial MO vocal nucleus also projects to the striatal vocal nucleus (MMSt) (Durand *et al.*, 1997). Connectivity of the songbird MO analogue has not yet been determined.

The major differences among vocal learning birds are in the connections between the posterior and anterior vocal pathways (Jarvis and Mello, 2000). In songbirds, the posterior pathway sends input to the anterior pathway via HVC to area X; the anterior pathway sends output to the posterior pathway via lateral MAN (LMAN) to RA and medial MAN (mMAN) to HVC (Figures 3c and 4a). In contrast,

Table 1 Some of the abbreviations used in this article

AAC	Central nucleus of the anterior arcopallium
AACd	Central nucleus of the anterior arcopallium, dorsal part
AACv	Central nucleus of the anterior arcopallium, ventral part
aCC	Anterior cingulate cortex
aCd	Anterior caudate
ACM	Caudal medial arcopallium
aDLPFC	Anterior dorsal lateral prefrontal cortex
Ai	Intermediate arcopallium
aINS	Anterior insula cortex
Am	Nucleus ambiguous
aP	Anterior putamen
area X	Area X of the striatum
aST	Anterior striatum
aT	Anterior thalamus
Av	Avalanch
CM	Caudal mesopallium
CSt	Caudal striatum
DLM	Medial nucleus of dorsolateral thalamus
DM	Dorsal medial nucleus of the midbrain
DMM	Magnocellular nucleus of the dorsomedial thalamus
FMC	Face motor cortex
HVC	A letter based name
L2	Field L2
MAN	Magnocellular nucleus of anterior nidopallium
MLd	Mesencephalic lateral dorsal nucleus
MMSt	Magnocellular nucleus of the anterior striatum
MOc	Oval nucleus of the mesopallium complex
NAOc	Oval nucleus of the anterior nidopallium complex
NCM	Caudal medial nidopallium
NDC	Caudal dorsal nidopallium
NIDL	Intermediate dorsal lateral nidopallium
NIf	Interfacial nucleus of the nidopallium
NLC	Central nucleus of the lateral nidopallium
nXIIts	Tracheosyringeal subdivision of the hypoglossal nucleus
Ov	Nucleus oviodalis
PAG	Periaqueductal grey
pre-SMA	Presupplementary motor area
RA	Robust nucleus of the arcopallium
St	Striatum
Uva	Nucleus uvaeformis
VA/VL	Ventral anterior/ventral lateral nuclei of the mammalian thalamus.
VAM	Vocal nucleus of the anterior mesopallium
VAN	Vocal nucleus of the anterior nidopallium
VAS	Vocal nucleus of the anterior striatum
VA	Vocal nucleus of the arcopallium
VLN	Vocal nucleus of the lateral nidopallium
VMM	Vocal nucleus of the medial mesopallium
VMN	Vocal nucleus of the medial nidopallium

in parrots, the posterior pathway sends input into the anterior pathway via ventral AAC (AACv, parallel of songbird RA) to NAO (parallel of songbird MAN) and MO; the anterior pathway sends output to the posterior pathway via NAO to NLC (parallel of songbird HVC) and AAC (Figures 3a and 4b) (Durand *et al.*, 1997).

In humans, imaging and lesion studies have revealed they have cortical and striatal regions that are active and necessary for learning and production of language (reviewed in Jarvis, 2004). These include what Jarvis has proposed is a lateral-to-medial strip of premotor cortex – from the anterior insula (aINS), the Brocas area, the anterior dorsal lateral prefrontal cortex (aDLPFC), the presupplementary motor area (pre-SMA), and the anterior cingulate (aCC) – below this level of cortex – an anterior region of the striatum and a posterior region of cortex – the face motor cortex (Figure 3d), as well as anterior parts of the thalamus. To date, these areas have not been found to be required for vocal behavior in vocal nonlearning mammals, including nonhuman primates. However, the anterior cingulate is required for voluntary control of when to vocalize, but not of the acoustic structure of vocalizations in vocal nonlearning mammals (Jurgens, 2002).

Ethical and practical issues prevent connectivity tract-tracing experiments in humans and thus the connectivity of vocal learning pathways is not known for any mammal. However, studies have been performed on the cerebrums of nonvocal learning mammals. Therefore, it is possible to make connectivity comparisons between vocal learning pathways in vocal learning birds with nonvocal pathways in vocal nonlearning mammals. In this regard, the avian posterior vocal pathways are similar in connectivity to mammalian motor corticospinal pathways (Figure 4). Specifically, the projecting neurons of songbird RA and parrot AACd are similar to pyramidal tract (PT) neurons of lower layer 5 of mammalian motor cortex (Matsumura and Kubota, 1979; Glickstein *et al.*, 1985; Karten and Shimizu, 1989; Keizer and Kuypers, 1989; Reiner *et al.*, 2003). The latter send long axonal projections out of the cerebrum through pyramidal tracts to synapse onto brainstem and spinal cord premotor or α-motor neurons that control muscle contraction and relaxation. The projection neurons of parrot NLC and the RA-projecting neurons of songbird HVC are similar to layer 2 and 3 neurons of mammalian cortex, which send intrapallial projections to layer 5 (Figure 4) (Aroniadou and Keller, 1993; Capaday *et al.*, 1998). Mammalian parallels to songbird NIf and Av are less clear.

The only connectivity determined among cerebral vocal brain areas of humans (Kuypers, 1958a) is the finding of face motor cortex projection to nucleus ambiguous (Am) of the medulla; Am projects to the muscles of the larynx, the main mammalian vocal organ (Zhang *et al.*, 1995; Jurgens, 1998) and is thus the mammalian parallel of avian nXIIts. This connectivity from face motor cortex in humans was

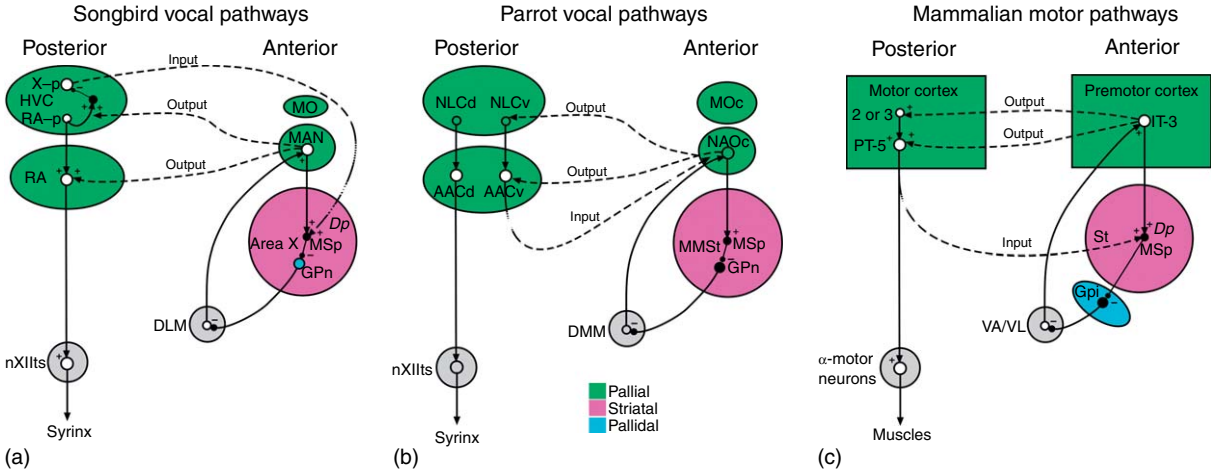

Figure 4 Comparative and simplified connectivity of posterior and anterior vocal motor pathways in (a) songbirds and (b) parrots and motor pathways in (c) mammals. Dashed lines: connections between anterior and posterior pathways; inputs and outputs are labeled relative to anterior pathways. Output from songbird MAN to HVC and RA are not from the same neurons; medial MAN (mMAN) neurons project to HVC, lateral MAN (LMAN) neurons project to RA. ○: excitatory neurons; •: inhibitory neurons; +: excitatory glutamate neurotransmitter release; −: inhibitory GABA release. MSp, medium spiny neuron; GPn, globus pallidus-like neuron in songbird area X and parrot MMSt. Only the direct pathway through the mammalian basal ganglia (St to GPi) is shown, as this is the one most similar to area X connectivity (MSp to GPn) (Reiner *et al.*, 2004a). X-p, X-projecting neuron of HVC; RA-p, RA-projecting neuron of HVC; PT-5, pyramidal tract neuron of motor cortex layer 5; IT-3, intratelencephalic projecting neuron of layer 3. Connections that need validation for this model to be correct are whether collaterals of the same neurons of mMAN project to mAreaX and to HVC, as opposed to different neurons, whether input from HVC into area X is onto the area X MSp neurons, whether the microcircuitry in parrot MMSt is the same as in songbirds, whether the collaterals of single IT-3 neurons of mammal cortex send branches to both layers 3 and 5 of motor cortex or just to one layer per IT-3 neuron. Abbreviations are in Table 1. Modified from Jarvis, E. D. 2004. Learned birdsong and the neurobiology of human language. *Ann. NY Acad. Sci.* 1016, 749–777, with permission.

determined using silver staining of degenerated axons in patients who had had vascular strokes to brain areas that included but were not limited to face motor cortex (Kuypers, 1958a). Kuypers (1958b) reproduced similar lesions in macaque monkeys and chimpanzees and found that their face motor cortex projects minimally, if at all, to Am, but it does project massively to the hypoglossal nucleus and to all other brainstem cranial motor nuclei as found in humans. The hypoglossal nucleus in mammals and the nontracheosyringeal part of nXII in birds controls muscles of the tongue (Wild, 1997). In this manner, the pallial nuclei of the songbird and parrot posterior vocal pathways combined are more similar to the human face motor cortex than to any other part of the human pallium.

The avian anterior vocal pathways are similar in connectivity to mammalian corticobasal ganglia-thalamic-cortical loops (Figure 4) (Bottjer and Johnson, 1997; Durand *et al.*, 1997; Jarvis *et al.*, 1998; Perkel and Farries, 2000). Specifically, the projection neurons of songbird MAN and parrot NAO (Vates and Nottebohm, 1995; Foster *et al.*, 1997; Durand *et al.*, 1997) are similar to intratelencephalic (IT) neurons of layer 3 and upper layer 5 of mammalian premotor cortex, which send two collateral projections, one to medium spiny neurons of the striatum ventral to it and the other to other cortical regions, including motor cortex (Figure 4) (Avendano *et al.*, 1992; Reiner *et al.*, 2003). Unlike mammals, the spiny neurons in both songbird area X, and presumably parrot MMSt, project to pallidal-like cells within area X and MMSt instead of to a separate structure consisting only of pallidal cells (Durand *et al.*, 1997; Perkel and Farries, 2000; Reiner *et al.*, 2004a). This striatal–pallidal cell intermingling may be a general trait of the anterior avian striatum (Farries *et al.*, 2005). The projection of the pallidal-like cells of songbird area X and parrot MMSt are similar to the motor pallidal projection neurons of the internal globus pallidus (GPi) of mammals, which project to the ventral lateral (VL) and ventral anterior (VA) nuclei of the dorsal thalamus (Figure 4) (Alexander *et al.*, 1986). Like songbird DLM and parrot DMM projections to LMAN and NAO, mammalian VL/VA projects back to layer 3 neurons of the same premotor areas, closing parallel loops (Jacobson and Trojanowski, 1975; Alexander *et al.*, 1986; Luo *et al.*, 2001).

Because connections between the posterior and anterior vocal pathways differ between songbirds and parrots, comparisons between them and mammals will also differ. In mammals, the PT-layer 5 neurons of motor cortex have axon collaterals, where one projects into the striatum and the other

projects to the medulla and spinal cord (Figure 4c) (Alexander and Crutcher, 1990; Reiner *et al.*, 2003). This is different from the songbird where a specific cell type of HVC, called X-projecting neuron, projects to the striatum separately from neurons of RA of the arcopallium that projects to the medulla. This is also different from the parrot, where AAC of the arcopallium has two anatomically separate neuron populations, AACd that projects to the medulla and AACv that projects to anterior pallial vocal nuclei NAO and MO (Durand *et al.*, 1997). Output of mammalian anterior pathways are proposed to be the collaterals of the IT–layer 3 and IT–upper layer 5 neurons that project to other cortical regions (Figure 4c) (Reiner *et al.*, 2003; Jarvis, 2004).

Taken together, the above analysis suggests that there are gross similarities between the connectivity of the consensus bird brain system for learned vocalizing and the nonvocal motor pathways (a posterior-like pathway) and cortical-basal-ganglia-thalamic-cortical loops (an anterior-like pathway) of mammals (Figures 4a–4c). Differences in connectivity between birds and mammals appear to be in the details, particularly with the pallidal cell types within the avian striatum and with connectivity between posterior and anterior pathways. Functions of these brain regions are now compared from lesion studies.

2.10.2.2 Brain Lesions

There are some gross similarities in behavioral deficits following lesions in specific brain areas of vocal learning birds (experimentally placed) and of humans (due to stroke or trauma). Lesions to songbird HVC and RA (Nottebohm *et al.*, 1976; Simpson and Vicario, 1990), on the left side in canaries, cause deficits similar to those found after damage to left human face motor cortex, this being muteness for learned vocalizations, i.e., for speech (Valenstein, 1975; Jurgens *et al.*, 1982; Jurgens, 2002). Innate sounds, such as crying and screaming, can still be produced. When the lesions are unilateral, both birds and patients often recover some vocal behavior, because the opposite hemisphere appears to take over some function; likewise, recovery is better when the canary is a juvenile or the patient a child (Nottebohm, 1977; Rey *et al.*, 1988; Hertz-Pannier *et al.*, 2002). Lesions to parrot NLC cause deficits in producing the correct acoustic structure of learned vocalizations, particularly for learned speech (Lavenex, 2000). The symptoms are similar to that of dysarthria in humans after recovery from damage to the face motor cortex. Lesions to the face motor cortex in chimpanzees and other nonhuman primates do not affect their ability to produce vocalizations (Kuypers, 1958b; Jurgens *et al.*, 1982; Kirzinger and Jurgens, 1982). Lesions to avian nXIIts and DM and mammalian Am and PAG result in muteness in both vocal learners and nonlearners (Brown, 1965; Seller, 1981; Nottebohm *et al.*, 1976; Jurgens, 1994, 1998; Esposito *et al.*, 1999). One difference is that lesions to songbird NIf or parrot LAN of the posterior pathway do not prevent production of learned vocalizations or cause dysarthric-like vocalizations, but lead to production of more varied syntax or impaired vocal imitation (Hosino and Okanoya, 2000; Plummer and Striedter, 2002).

Lesions to songbird MAN (Nottebohm *et al.*, 1990; Scharff and Nottebohm, 1991; Foster and Bottjer, 2001) cause deficits that are most similar to those found after damage to anterior parts of the human premotor cortex, this being disruption of imitation and/or inducing sequencing problems. In birds and humans, such lesions do not prevent the ability to produce learned song or speech. In humans, these deficits are called verbal aphasias and verbal amusias (Benson and Ardila, 1996). Damage to the left side often leads to verbal aphasias, whereas damage to the right can lead to verbal amusias (Berman, 1981). The deficits in humans, however, are more complex. Specifically, lesions to songbird LMAN (Bottjer *et al.*, 1984; Scharff and Nottebohm, 1991; Kao *et al.*, 2005) and lesions to the human insula and the Brocas area (Mohr, 1976; Dronkers, 1996; Benson and Ardila, 1996) lead to poor imitation with sparing or even inducing more stereotyped song or speech. However, in addition, lesions to the Brocas area and/or DLPFC (Benson and Ardila, 1996) lead to poor syntax production in construction of phonemes into words and words into sentences. Lesions to DLPFC also result in uncontrolled echolalia imitation, whereas lesions to pre-SMA and anterior cingulate result in spontaneous speech arrest, lack of spontaneous speech, and/or loss of emotional tone in speech, but with imitation preserved (Nielsen and Jacobs, 1951; Barris *et al.*, 1953; Rubens, 1975; Valenstein, 1975; Jonas, 1981). Lesions to songbird mMAN lead to a decreased ability in vocal learning and some disruption of syntax (Foster and Bottjer, 2001), as do lesions to the Brocas area.

Lesions to songbird area X and to the human anterior striatum does not prevent the ability to produce song or speech, but does result in disruption of vocal learning and disruption of some syntax in birds (Scharff and Nottebohm, 1991; Sohrabji *et al.*, 1990; Kobayashi *et al.*, 2001) or verbal aphasias and amusias in humans (Mohr, 1976; Bechtereva

et al., 1979; Leicester, 1980; Damasio *et al.*, 1982; Alexander *et al.*, 1987; Speedie *et al.*, 1993; Cummings, 1993; Lieberman, 2000). Specifically, songbirds do not crystallize onto correct syllable structure and syntax heard, and as adults they can stutter (Scharff and Nottebohm, 1991; Sohrabji *et al.*, 1990; Kobayashi *et al.*, 2001). Humans can have a combination of symptoms (Mohr, 1976) perhaps because, as in nonhuman mammals, large cortical areas send projections that converge onto relatively smaller striatal areas (Beiser *et al.*, 1997). Not many cases have been reported of lesions to the human globus pallidus leading to aphasias (Strub, 1989), but the fact that this can occur suggests some link with a striatal vocal area in humans.

Similar to a preliminary report on songbird DLM (Halsema and Bottjer, 1991), damage to anterior portions of the human thalamus (VA, VL, and A) leads to verbal aphasias (Graff-Radford *et al.*, 1985). In humans, thalamic lesions can lead to temporary muteness followed by aphasia deficits that are sometimes greater than after lesions to the anterior striatum or premotor cortical areas. This greater deficit may occur perhaps because there is further convergence of inputs from the striatum into the thalamus (Beiser *et al.*, 1997). However, the interpretation of thalamic lesions in humans is controversial (Benson and Ardila, 1996), perhaps because of small but important differences in lesion locations between patients among studies. The thalamus concentrates many functions into adjacent small nuclei, and thus, a relatively small variance in the location of a lesion may lead to a large difference in the brain function affected.

The lesions in birds and in humans can affect more than one modality. For example, lesions to LMAN or HVC in songbirds (Scharff *et al.*, 1998; Burt *et al.*, 2000) and to the Brocas area and anterior striatum in humans (Freedman *et al.*, 1984; Benson and Ardila, 1996) lead to decreased abilities in song/speech perception and discrimination. The perceptual deficits, however, are usually not as great as the motor deficits.

Taken together, the above evidence is consistent with the presence in humans of a posterior-like vocal motor pathway and an anterior-like vocal premotor pathway that are similar to the production and learning pathways of vocal learning birds. The relative locations of the brain regions in humans appear to be comparable to the relative location of the pathways in birds. The clearest difference between birds and humans appears to be the greater complexity of the deficits found after lesions in humans. Function of brain regions from activation studies is now compared.

2.10.2.3 Brain Activation

Brain activation includes changes in electrophysiological activity (recorded in both birds and in humans during surgery of patients), electrical stimulation (birds and humans), motor- and sensory-driven gene expression (birds and nonhuman mammals), and PET and magnetic resonance imaging of activated brain regions (in humans). In vocal learning birds, such studies have revealed that all seven comparable cerebral nuclei display vocalizing-driven expression of immediate early genes (Figure 5) (Jarvis and Nottebohm, 1997; Jarvis *et al.*, 1998, 2000 Jarvis and Mello, 2000); these are genes that are responsive to changes in neural activity. In deafened songbirds, these nuclei still display vocalizing-driven expression (Jarvis and Nottebohm, 1997), indicating that motor-driven gene activation is independent of hearing. Likewise, premotor neural firing has been found in HVC, RA, NIf, LAreaX, and LMAN when a bird sings (McCasland, 1987; Yu and Margoliash, 1996; Hessler and Doupe, 1999a; Hahnloser *et al.*, 2002). In deafened birds, similar singing-associated activity still occurs when a bird sings, at least for LMAN (Hessler and Doupe, 1999a). The firing in HVC and RA correlates with sequencing of syllables and syllable structure, respectively, whereas firing in LAreaX and LMAN is much more varied and in LMAN it correlates with song variability. In addition, neural firing and gene expression in LAreaX, LMAN, as well as RA differ depending upon the social context in which singing occurs (Jarvis *et al.*, 1998; Hessler and Doupe, 1999b); they are moderate when a bird sings directly facing another bird and high when a bird sings in an undirected manner. No difference has been observed between right (the dominant) and left HVC activity during singing in zebra finches, but in song sparrows activity in the left and right HVC is associated with production of specific sequences of song syllables (Nealen and Schmidt, 2002). Stimulation with electrical pulses to HVC during singing temporarily disrupts song output, i.e., song arrest (Vu *et al.*, 1998).

In humans, the brain area most comparable to songbird HVC and RA is one that is always activated (as measured with PET and fMRI) with all speech tasks: the face motor cortex (Figure 5) (Petersen *et al.*, 1988; Rosen *et al.*, 2000; Gracco *et al.*, 2005). Similar to other songbird vocal nuclei, other human vocal brain areas appear to be activated or not activated depending upon the context in which speech is produced. Production of verbs and complex sentences can be accompanied by activation in all or a subregion of the strip of cortex

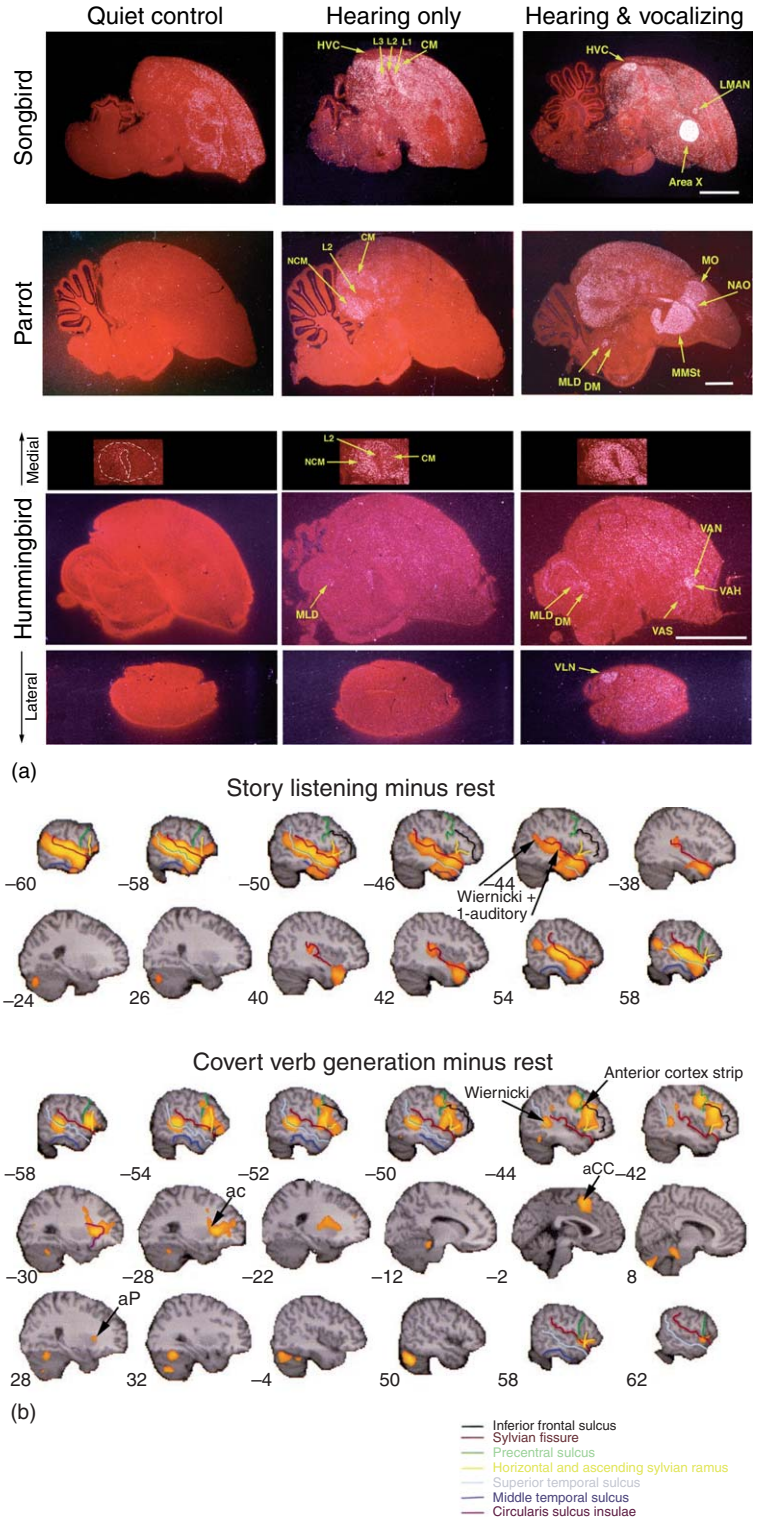

Figure 5 Hearing and vocalizing-driven brain activation patterns in vocal learning species. a, Example brain activation patterns in some brain regions of vocal learning birds (songbird-canary; parrot-budgerigar; hummingbird-sombre), as seen with hearing and vocalizing-driven *egr-1* gene expression (white). Shown are darkfield emulsion dipped sagittal sections reacted by *in situ* hybridizations to the *egr-1* gene; anterior is to the right, dorsal is toward the top. Red is cresyl violet staining. b, Example brain activation patterns in some brain regions of humans, as seen with hearing and vocalizing-driven PET signals minus rest. Shown are PET signals superimposed on sagittal slices, labeled with millimetric *x*-axis coordinates. The brighter the yellow signal the higher the activation. In all groups, different hearing and vocalizing tasks can differentially activate different brain areas. Not all activated brain areas are represented in these images. a, Figures based on Jarvis and Nottebohm (1997), Jarvis and Mello (2000), and Jarvis *et al.* (2000). b, Modified from Papathanassiou, D., Etard, O., Mellet, E., Zago, L., Mazoyer, B., and Tzourio-Mazoyer, N. 2000. A common language network for comprehension and production: A contribution to the definition of language epicenters with PET. *Neuroimage* 11, 347–357, Elsevier.

anterior to the face motor cortex: the anterior insula, Brocas area, DLPFC, pre-SMA, and anterior cingulate (Petersen *et al.*, 1988; Price *et al.*, 1996; Poeppel, 1996; Wise *et al.*, 1999; Crosson *et al.*, 1999; Papathanassiou *et al.*, 2000; Rosen *et al.*, 2000; Palmer *et al.*, 2001; Gracco *et al.*, 2005). Activation in the Brocas area, DLPFC, and pre-SMA is higher when speech tasks are more complex, including learning to vocalize new words or sentences, sequencing words into complex syntax, producing nonstereotyped sentences, and thinking about speaking (Hinke *et al.*, 1993; Poeppel, 1996; Bookheimer *et al.*, 2000; Buckner *et al.*, 1999). The left brain vocal areas show more activation than their right counterparts (Price *et al.*, 1996; Poeppel, 1996; Papathanassiou *et al.*, 2000; Rosen *et al.*, 2000). Like vocal nuclei in birds, premotor speech-related neural activity has been found in the Brocas area (Fried *et al.*, 1981). Further, low-threshold electrical stimulation to the face motor cortex, the Brocas area, or the anterior supplementary areas cause speech arrest or generation of phonemes or words (Jonas, 1981; Fried *et al.*, 1991; Ojemann, 1991, 2003).

In noncortical areas, speech production is accompanied by activation of the anterior striatum and the thalamus (Wallesch *et al.*, 1985; Klein *et al.*, 1994; Wildgruber *et al.*, 2001; Gracco *et al.*, 2005). Low-threshold electrical stimulation to ventral lateral and anterior thalamic nuclei, particularly in the left hemisphere, leads to a variety of speech responses, including word repetition, speech arrest, speech acceleration, spontaneous speech, anomia, and verbal aphasia (but also auditory aphasia) (Johnson and Ojemann, 2000). The globus pallidus can also show activation during speaking (Wise *et al.*, 1999). In nonhuman mammals and in birds, PAG and DM, Am, and nXII display premotor vocalizing neural firing (Larson, 1991; Larson *et al.*, 1994; Zhang *et al.*, 1995; Dusterhoft *et al.*, 2004) and/or vocalizing-driven gene expression (Jarvis *et al.*, 1998, 2000; Jarvis and Mello, 2000).

The cerebral vocal areas can also show neural firing during hearing, and this depends upon hearing task and species. In awake male zebra finches, firing is minimal in vocal nuclei (all the way down to nXIIts) when a bird hears playbacks of song, but greater when it is anesthetized or asleep and presented with playbacks of its own song (Williams and Nottebohm, 1985; Dave and Margoliash, 2000; Nealen and Schmidt, 2002; Cardin and Schmidt, 2003). In song sparrows, the reverse occurs: robust firing is observed in HVC when an awake bird hears playbacks of its own song, and this response is diminished when it is anesthetized (Nealen and Schmidt, 2002). In both species, the level or number of neurons firing in vocal nuclei during hearing is lower than that during singing. In humans, the face motor cortex, the Brocas area, and/or the DLPFC often show increased activation when a person hears speech or is asked to perform a task that requires thinking in silent speech (Hinke *et al.*, 1993; Price *et al.*, 1996; Poeppel, 1996; Wise *et al.*, 1999; Crosson *et al.*, 1999; Papathanassiou *et al.*, 2000; Rosen *et al.*, 2000; Palmer *et al.*, 2001). The magnitude of activation is usually lower during hearing than that seen during actual speaking. The anterior insula, the Brocas area, and DLPFC can also be activated by other factors, such as by engaging working memory (MacLeod *et al.*, 1998; Zhang *et al.*, 2003), which is a short-term memory that is formed before committing it to long-term storage. It is unclear, however, if this activation occurs in overlapping brain regions activated by speech or a speech perceptual task or whether the working memory tasks require language processing, or if there are separate but adjacent brain areas that are activated.

Taken together, the brain activation findings are consistent with the idea that songbird HVC and RA are more similar in their functional properties to face motor cortex than to any other human brain area and that songbird MAN, area X, and the anterior part of the dorsal thalamus are more similar in their properties to parts of the human premotor cortex, anterior striatum, and ventral lateral/anterior thalamus, respectively.

2.10.3 Consensus Auditory System

The above discussion focused solely on the motor component of vocal learning systems. This is because the motor component is what is specialized in vocal learners, whereas the auditory component is common among vocal learners and vocal nonlearners. Thus, the auditory component is only briefly discussed here; more detail is given in Jarvis (2004). Birds, reptiles, and mammals have relatively similar auditory pathways (Figure 6) (Webster *et al.*, 1992; Vates *et al.*, 1996; Carr and Code, 2000). The pathway begins with ear hair cells that synapse onto sensory neurons, which project to cochlea and lemniscal nuclei of the brainstem, which in turn project to midbrain (avian MLd, reptile torus, mammalian inferior colliculus) and thalamic (avian Ov, reptile reunions, mammalian medial geniculate) auditory nuclei. The thalamic nuclei in turn project to primary auditory cell populations in the pallium (avian L2, reptile caudal pallium, mammalian layer 4 of primary auditory cortex). Avian L2

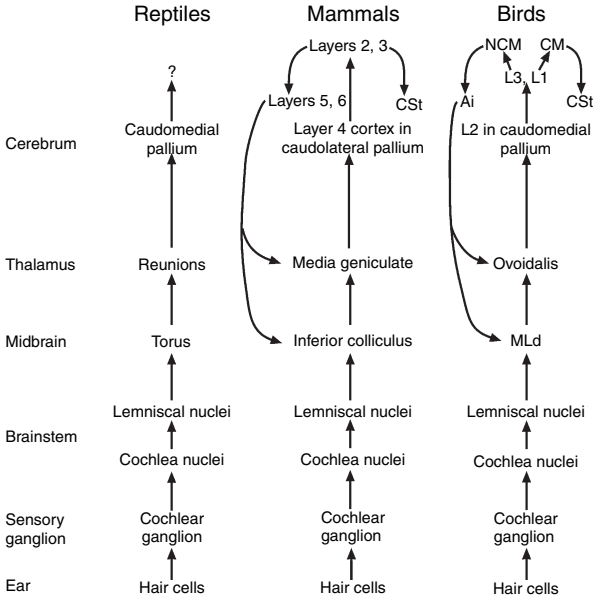

Figure 6 Comparative and simplified connectivity among auditory pathways in reptiles, mammals, and birds, placed in order from left to right of the most recently evolved. The connectivity from CM to CSt in birds needs verification by retrograde tracing. Abbreviations are in Table 1. Reproduced from Jarvis, E. D. 2004. Learned birdsong and the neurobiology of human language. *Ann. NY Acad. Sci.* 1016, 749–777, with permission.

then projects to other pallial cell (L1, L3, NCM, CM) and striatal (CSt) populations that form a complex network. Mammalian layer 4 cells then project to other layers of primary auditory cortex and to secondary auditory regions. Cerebral pathway connectivity is not known for reptiles. In terms of connectivity, avian L1 and L3 neurons are similar to mammalian layers 2 and 3 of primary auditory cortex, the latter of which receive input, like L2, from layer 4 (Karten, 1991; Wild *et al.*, 1993). Avian NCM and CM are also similar to layers 2 and 3 in that they form reciprocal intrapallial connections with each other and receive some input from L2.

The source of auditory input into the vocal pathways of vocal learning birds is unclear. Proposed routes include the HVC shelf into HVC, the RA cup into RA, Ov or CM into NIf, and from NIf dendrites in L2, in songbirds (Wild, 1994; Fortune and Margoliash, 1995; Vates *et al.*, 1996; Mello *et al.*, 1998). However, the location of the vocal nuclei relative to the auditory regions differs among vocal learning groups. In songbirds, the posterior vocal nuclei are embedded in the auditory regions; in hummingbirds, they are situated more laterally, but still adjacent to the auditory regions; in parrots, they are situated far laterally and physically separate from the auditory regions (Figures 3a–3c).

In humans, the primary auditory cortex information is passed to secondary auditory areas, which includes the Wernickes area (Figure 3d). When damaged, this area leads to auditory aphasias, sometimes call fluent aphasia. A patient can speak words relatively well, but produces nonsense highly verbal speech. One reason for this is that the vocal pathways may no longer receive feedback from the auditory system. Information from the Wernickes area has been proposed to be passed to the Brocas area through arcuate fibers that traverse a caudal–rostral direction (Geschwind, 1979), but this has not been demonstrated experimentally. Bilateral damage to primary auditory cortex and Wernickes area also leads to full auditory agnosia, the inability to consciously recognize any sounds (speech, musical instruments, natural noises, etc.) (Benson and Ardila, 1996).

No one has tested whether lesions to avian secondary auditory areas result in fluent song aphasias. Yet lesions to songbird NCM and CM result in a significant decline in the ability to form auditory memories of songs heard (MacDougall-Shackleton *et al.*, 1998). It is difficult to ascertain how nonhuman animals, including birds, perceive sensory stimuli, and therefore it is difficult to make comparisons with humans in regard to perceptual auditory deficits.

2.10.4 Evolution of Vocal Learning Systems from a Common Motor Pathway

Given that auditory pathways in avian, mammalian, and reptilian species are similar, whether or not a given species is a vocal learner, this suggests

that the auditory pathway in vocal learning birds and in humans was inherited from their common stem-amniote ancestor, thought to have lived approximately 320 Mya (Evans, 2000). Having a cerebral auditory area would explain why nonhuman mammals, including a dog, exhibit auditory learning, including learning to understand the meaning of human speech, although with less facility than a human. For vocal learning pathways, because the connections of the anterior and posterior vocal pathways in vocal learning birds bear some resemblance to those of nonvocal pathways in both birds and mammals, pre-existing connectivity was presumably a genetic constraint for the evolution of vocal learning (Durand *et al.*, 1997; Farries, 2001; Lieberman, 2002; Jarvis, 2004). In this manner, a mutational event that caused descending projections of avian arcopallium neurons to synapse onto nXIIts or mammalian layer 5 neurons of the face motor cortex to synapse onto Am may be the only major change that is needed to initiate a vocal learning pathway. Thereafter, other vocal brain regions could develop out of adjacent motor brain regions with pre-existing connectivity. Such a mutational event would be expected to occur in genes that regulate synaptic connectivity of upper pallial motor neurons to lower α-motor neurons. This hypothesis requires that avian nonvocal motor learning systems have up to seven areas distributed into two pathways in at least six brain subdivisions (the mesopallium, nidopallium, arcopallium, striatum, pallidal-like cells in the striatum, and dorsal thalamus). It would also require that mammalian nonvocal motor learning systems have brain regions distributed in two pathways involving at least four brain subdivisions (the six layers of the cortex, the striatum, the pallidum, and the dorsal thalamus). Not apparent in this view is the question of whether there is a genetic constraint for auditory information entering vocal learning pathways.

2.11 Forebrain Size and Social Intelligence in Birds

L Lefebvre, McGill University, Montreal, QC, Canada

Glossary

adaptive specialization — Adaptation to a particular selective context, e.g., food caching, brood parasitism.

cooperative breeding — Care of juveniles that is done by individuals other than the parents. Often occurs in the form of helping at the nest, where fledged offspring from a previous clutch provide food or protection for their younger siblings, instead of dispersing and producing their own offspring.

cultural transmission — The effect of social learning at the population level, leading to local traditions and diffusion of new behaviors.

general process skills — Cognitive differences between taxonomic groups that are thought to reflect broad, unspecialized abilities based on large and/or diffuse neural substrates.

innovation — A behavior seen for the first time in animal and that is not the result of a genetic change or a pathology. The novel behavior is an attempt to solve a problem (feeding, social) that the standard repertoire cannot resolve.

module — Information relevant to one specialized context or domain that is not available in other contexts.

motor imitation — The copying of a particular action.

phyletically independent contrasts — The most widely used procedure for removing the effects of common ancestry on taxonomic similarities or differences between traits. The technique measures differences between related taxonomic groups in the values of biological traits, rather than actual trait values on extant taxa. Relatedness between groups is usually measured through mitochondrial or nuclear DNA data.

social facilitation — Performance of a behavior by a demonstrator which stimulates the expression of that behavior in an observer.

social learning — A generic term describing the effects that information coming from other animals has on learned behavior. In experiments, originators of the information are called demonstrators or tutors, while recipients are called observers. The term 'social learning' includes more specific ones such as social facilitation, stimulus enhancement, motor imitation, or cultural transmission.

social or Machiavellian intelligence — Cognitive complexity selected in the context of social interactions. Usually contrasted with ecological intelligence, selected in the context of interactions with the nonsocial, physical environment.

specialized cognitive skills — Cognitive abilities that are specific to a restricted selective context (e.g., spatial memory, learned song) and whose neural substrate is often a restricted brain area (e.g., hippocampus, nucleus HVC in Oscines). The terms 'adaptive specialization' or 'module' embody similar ideas. The term can be opposed to general process skills.

stimulus enhancement — Interaction of a demonstrator with a feature in the environment that directs the attention of an observer to that feature, thereby facilitating its learning.

2.11.1 Introduction

Grouping patterns vary among animal species and populations. For example, weaverbirds in Africa move in flocks that can include several thousand individuals. In North America, chickadees form small, stable winter groups with a dominance

hierarchy based on individual recognition. In Barbados, Zenaida doves defend year-round territories and feed most often alone. Social life is clearly less complicated when you are alone than when you have to deal with many individuals. It thus makes intuitive sense to predict that variation in grouping patterns might be associated with variation in social cognition and the neural centers that control it. The idea that social information processing demands might be a driving force for the evolution of cognition was first proposed by primatologists such as Jolly (1966), Humphrey (1976), and Byrne and Whiten (1988). These authors contrast social pressures on the evolution of intelligence with those derived from the nonsocial environment such as foraging and predator avoidance. Social pressures on intelligence are sometimes called Machiavellian (Byrne and Whiten, 1988), based on cases where animals appear to deceive and manipulate others (Byrne and Corp, 2004); nonsocial pressures are sometimes referred to as ecological (e.g. Schultz and Dunbar, 2006).

Most of the experimental tests and taxonomic correlations on social intelligence have been done on primates (Dunbar, 1998; Reader and Laland, 2002; Byrne and Corp, 2004; see Role of Spindle Cells in the Social Cognition of Apes and Humans), but similar work has recently been extended to birds. The theoretical framework is the same as the one used for primates, but the definition of groups is sometimes broader, including large flocks that do not necessarily show the close individual interactions typical of a monkey troop. This article reviews some of the key studies on the taxonomic and experimental approaches, then discusses theoretical issues on the evolution of social intelligence.

2.11.2 Analyses of Taxonomic Distributions

A common way of testing evolutionary predictions on animal cognition is to correlate the taxonomic distribution of a cognitive measure, the size of its neural substrate, and lifestyle variables. The prediction is that animals with particular ecological demands on information processing should have relatively larger neural centers that allow more of a particular cognitive skill. For example, birds that successfully colonize new habitats are larger-brained and more innovative in their locus of origin than birds that are unsuccessful (Sol *et al.*, 2005). Using this logic, one can predict that birds that breed cooperatively or live in larger flocks or more complex groups might benefit from larger neural centers that allow more social information processing. One might also predict that the cognitive requirements of social learning or social play should benefit from larger neural centers, estimated either as relative size of the whole brain (Ricklefs, 2004), the telencephalon (Burish *et al.*, 2004), or association areas such as the mesopallium and nidopallium (Bouchard, 2002; see Do Birds and Reptiles Possess Homologues of Mammalian Visual, Somatosensory, and Motor Cortices?).

Taxonomic correlations on brains and social intelligence in birds have for the moment been done on social play (Diamond and Bond, 2003), complexity of the social system (Burish *et al.*, 2004; Ricklefs, 2004), social learning (Bouchard, 2002), cooperative breeding (Iwaniuk and Arnold, 2004; Ricklefs, 2004), and group size (Beauchamp and Fernandez-Juricic, 2004). Two of the analyses support the idea that social life is associated with large brain size in birds, while four do not. The study of Bouchard (2002) yields ambiguous results because of a statistical outlier. We will look at each of the analyses in more detail.

Bouchard (2002) examined avian social learning with the same method used by Reader and Laland (2002) for primates. She mapped the taxonomic distribution of all presumed cases of social learning in the field and correlated this distribution with relative size of the brain and of the mesopallium. Contrary to the data set collated by Reader and Laland (2002), field reports of avian social learning were relatively rare. Only 72 cases were found, compared to the 445 social learning observations collated for primates and the more than 2000 cases of innovation gathered by Lefebvre and colleagues on birds (Lefebvre and Bouchard, 2003). In birds, an innovation is operationally defined as the first report in the short notes section of an ornithology journal of a new or unusual food type or foraging technique, based on the presence in the paper of key words such as "never seen before," "not described in the handbook," "opportunistic," "we were surprised" (see table 1 in Lefebvre *et al.*, 1997, for examples). A gull that kills rabbits by dropping them from the air onto rocks (Young, 1987) is thus using an innovative form of its well-known shell- or crab-breaking technique.

Of the 72 reported cases of avian social learning, more than 70% belonged to the order Passeriformes, yielding an extreme outlier when the frequency is corrected for the usual biases of research effort or species number. The outlier cannot be discarded because it represents such a strong proportion of the data set and it makes the usual parametric multivariate statistics invalid. Rank

correlations of residual social learning rate against residual brain size or residual innovation rate yield nonsignificant values. This is consistent with the experimental data on the most complex form of social learning, motor imitation, which has been reported in large-brained species such as parrots (Dawson and Foss, 1965; Moore, 1992; Mottley and Heyes, 2003), small-brained species such as pigeons (Zentall *et al.*, 1996) and quail (Akins and Zentall, 1996, 1998), as well as species of intermediate brain size such as starlings (Fawcett *et al.*, 2002) and grackles (Lefebvre *et al.*, 1997).

The two studies on cooperative breeding (Ricklefs, 2004; Iwaniuk and Arnold, 2004) yield similar negative results. Ricklefs (2004) looked at all avian families and operationalized cooperative breeding as the proportion of species within each family for which helping behavior is reported in the literature. In birds, helping behavior is defined as a contribution to the care of nestlings by offspring from a previous clutch, at an age where they could theoretically be independent and move away from their parental area. Even though large-brained birds such as corvids and hornbills showed high proportions of helping, the overall relationship between the variables was nonsignificant. Iwaniuk and Arnold (2004) focused on 155 species of Corvida, using the extensive brain size database gathered by Iwaniuk (2003). They scored cooperative breeding on a four-point scale for percentage of nests including helpers; they also measured size of the cooperative breeding group. Most of their analyses yielded nonsignificant results, with the exception of one within-family comparison (honeyeaters) for presence versus absence of helpers and one phyletically uncorrected analysis of between family differences in percentage of nests with helpers.

Using extant species as well as phyletically independent contrasts, Beauchamp and Fernandez-Juricic (2004) looked at group size and forebrain size in three different data sets covering nearly 200 avian species. They operationalized group size as the mean and maximum size of avian flocks outside the breeding season, including individuals from more than one species when mixed species flocks occurred. They also used a dichotomous solitary versus gregarious measure to include cases where exact group numbers were not available. None of their analyses showed a relationship between flocking and relative brain size, although it is possible that an avian flock is more of a simple aggregation and less of a cohesive unit than is a mammalian group. A positive relationship has been reported between relative brain size and group size in several mammalian orders, including primates, ungulates, carnivores, and cetaceans (Worthy and Hickie, 1986; Sawaguchi and Kudo, 1990; Dunbar, 1992; Marino, 1996; Barton, 1999; Schultz and Dunbar, 2006; but see Connor *et al.*, 1998; van Schaik and Deaner, 2003).

Ricklefs (2004) defined sociality as presence or absence of a complex social structure. The large-brained parrots and corvids fall in the first category, while the smaller-brained ducks, cuckoos, doves, and quail fall in the second, but the overall trend among all birds is nonsignificant. Burish *et al.* (2004) classified 154 avian species as either solitary (one to three individuals), living in coveys (4–50 individuals with a dominance or lek structure), colonial (groups of hundreds and thousands), or transactional (presence of social cognition and individual communication). They found a significant relationship between social category and fraction of the whole brain represented by the telencephalon (see Role of Spindle Cells in the Social Cognition of Apes and Humans).

Finally, Diamond and Bond (2003) collated all reliable cases of social play in birds, which was found in 25 species from 5 families: parrots, corvids, hornbills, and babblers. Social play in birds is defined in much the same way as it would be in primates or dogs, where two individuals go through repeated, incomplete sequences of a behavior outside its context, using for example the biting, pushing, and grasping movements of fighting in a way that does not imply aggression (see examples in table 1 in Diamond and Bond, 2004). Diamond and Bond (2003) report a positive relationship between relative brain size and propensity to social play, as do the studies of Ortega and Bekoff (1987). Diamond and Bond (2004) show a further interesting difference between two closely related species of New Zealand parrots, the kea, *Nestor notabilis*, and the kaka, *N. meridionalis*. The kea is a highly exploratory generalist forager that goes through a prolonged social interaction period between juvenile groups and parents; the kaka has a much more specialized diet, is much less exploratory, and juveniles disperse early from their natal area. In accordance with these differences, social play is much more extensive in keas than it is in kakas.

In summary, the majority of taxonomic studies do not provide very strong support for the idea that social intelligence has co-evolved with brain size in birds.

2.11.3 Experimental Tests

An alternative to predictions on taxonomic distributions is to set up controlled experiments where a targeted species is given in captive conditions a test

that would imply intelligence if it were solved by a human. The advantage of this approach is that rigorous controls can be added to the study to eliminate simpler processes. Hypotheses about the cognitive rules animals follow can also be tested with the appropriate design. Solving an experimental problem does not prove humanlike cognition in an animal, but does provide empirical evidence consistent with operational predictions on a complex process. The best examples of this approach are the experiments of Templeton *et al.* (1999) on social learning, those of Bond *et al.* (2003) on the tracking of dyadic relationships, those of Bednekoff and Balda (1996) on memory for caches made by other birds, and those of Emery and Clayton (2001) on avoidance of cache pilfering. The common thread between these studies is that they are all conducted on corvids, one of the largest-brained avian taxa (Rehkämper *et al.*, 1991; Emery and Clayton, 2004).

Whether faced with a set of ordered color stimuli (Bond *et al.*, 2003) or actual conspecifics (Paz-y-Mino *et al.*, 2004), the highly social pinyon jay appears to track multiple dyadic relationships quickly and accurately, more so than the less-social western scrub jay (Bond *et al.*, 2003). A pinyon jay that observes pairs of unknown conspecifics aggressively interacting, then uses these observations of relative rank to attack or defer to these individuals when it meets them, is using a sophisticated form of social intelligence. Comparing the pinyon jay to the less-social Clark's nutcracker, Bednekoff and Balda (1996) have shown that the more social species is also better at remembering the location of food it sees a conspecific store. In contrast, a nutcracker is more efficient at remembering caches it has made itself. Templeton *et al.* (1999) also compared pinyon jays and nutcrackers on an individual learning and a social learning task. Pinyon jays learned faster from a tutor than they did on their own, while the two routes for learning did not differ in nutcrackers. Emery and Clayton (2001) studied recaching behavior of scrub jays and found that it was more frequent when the storer had been observed by a conspecific that could potentially steal the hidden food. Caching was also more often done in sites where the storer could not be seen by others, while recaching after observation was more frequent in individuals that were experienced pilferers themselves.

For the experimental studies on social intelligence to be complementary with the taxonomic correlations reviewed above, more tests need to be done on smaller-brained species to see if the abilities shown by corvids are unique to the larger-brained social birds. For the moment, there is no clear demonstration that relative brain size is a key determinant of the abilities demonstrated in social intelligence experiments with corvids.

2.11.4 Is Social Intelligence Different from Other Types of Intelligence?

The idea that intelligence in animals and humans is not a unitary ability, but a complex set of specialized operations supported by modular organization, has recently become popular in cognitive sciences. Proponents of this view argue that memory being limited, animals with different ecological requirements should trade off an increase in one type of cognition (including its neural substrate) by a decrease in others that are less important for that lifestyle (Sherry and Schacter, 1987; Shettleworth, 1998). The comparative experiments conducted by Kamil and co-workers on jays are based on this logic: differing demands in social lifestyle should have selected for differences in a restricted set of relevant cognitive abilities (Bond *et al.*, 2003). For example, Templeton *et al.* (1999) found that a social jay is better than a solitary jay at social learning, but not at individual learning. If all forms of learning were better in a species that differs only on the relevant ecological trait, in this case sociality, then the underlying cognitive process would have to be considered general, not modular (Lefebvre and Bolhuis, 2003).

Can social learning be considered a modular specialization? Apart from the results of Templeton *et al.* (1999), most of the evidence in birds (Lefebvre and Giraldeau, 1996) and primates (Reader and Lefebvre, 2001) suggests that social learning is the same thing as individual learning. Species that learn faster socially also tend to learn faster individually (Sasvari, 1985a, 1985b; reanalyzed by Lefebvre and Giraldeau, 1996). A consensus was reached on this point among social learning researchers at an international conference (Heyes and Galef, 1998) and workers in the area now speak of socially guided learning (Fragaszy and Perry, 2003) to express this similarity. The process that governs associations is currently seen as identical whether a stimulus that predicts an outcome comes from a conspecific or an inanimate feature of the environment.

Given this, are all other aspects of social intelligence also the same thing as nonsocial intelligence, even though the two presumed pressures on encephalization have traditionally been addressed separately? Researchers that have focused on the specific pressures that social life exerts on intelligence have long recognized that the ultimate

determinant of grouping patterns in animals is the spatial and temporal distribution of resources (see, for example, Kudo and Dunbar, 2001), but they have not explicitly thought of social and nonsocial cognition as correlated responses to similar ecological pressures. Resource defense theory can be useful here as a framework for making predictions. Brown (1964) was the first to propose that the distribution of resources in space and time determines whether animals should feed alone and defend access to food or whether they should live in relatively unaggressive groups. The more food is predictable in space and time and the more it occurs in low-density clumps, the more a single individual can profit by defending it. The more unpredictable food is and the more it occurs in densities that attract many individuals, the less profitable will be defense and, conversely, the more profitable will be group feeding. The actual size of the group should then be proportional to the average density of the food patches. There is a large body of theoretical and empirical work supporting these predictions (Warner, 1980; Davies and Houston, 1984; Grant, 1997; Goldberg *et al.*, 2001).

If food is unpredictable in space and time, this also implies that animals need to range over a wide area to find it and that using social information to find this food might be particularly critical. The wider the area and the more unpredictable the food, the higher the chance that animals will both encounter and need to take different food types. Similar patterns of resource distribution thus have parallel effects on both the solitary–group feeding continuum and the specialist–generalist continuum. All other things being equal, more predictable food should favor both more solitary feeding and specialization, while less predictable food should favor both more group feeding and more opportunistic generalism. There is experimental support for this idea. Rafacz and Templeton (2003) showed that starlings relied more on information provided by a conspecific tutor if they were foraging in an unpredictable environment than in a predictable one, while Gray (1981) showed that making food less predictable led rodents to select a more generalist diet. This implies that social and food-finding pressures on intelligence and brain size evolution might not be independent, but positively correlated.

2.11.5 Conclusions

Ecological theory suggests that social and nonsocial forms of intelligence might be correlated responses to similar patterns of resource distribution. In birds, there is consistent evidence that nonsocial forms of cognition (e.g., innovation, Timmermans *et al.*, 2000; tool use, Lefebvre *et al.*, 2002; bower building, Madden, 2001) are associated with the relative size of the whole brain and of the nidopallium–mesopallium complex. The evidence that brain evolution has been associated with the pressures of sociality in birds is not as clear. For the moment, the experimental evidence, gathered almost exclusively on corvids, suggests that complex forms of social cognition are present in large-brained birds. Experiments are needed on small-brained taxa, however, before an association can be made between avian encephalization and sociality. Taken together, the taxonomic distribution analyses that have tested this association directly provide poor evidence for it, with only two out of seven studies yielding a positive trend. More work is needed before social intelligence in birds is as well understood as it is in primates (Byrne and Whiten, 1988; Cheney and Seyfarth, 1990; Whiten and Byrne, 1997; Tomasello and Call, 1997), but recent reviews (Rehkämper and Zilles, 1991; Emery and Clayton, 2004; Lefebvre *et al.*, 2004) emphasizing the apparent convergence between the two taxa may help.

2.12 The Hippocampal Formation in Food-Storing Birds

A D Székely, Semmelweis University, Budapest, Hungary

Glossary

brain parcellation	Brain areas, or centers, may be delineated on the basis of cellular density, cellular morphology (e.g., cortical layers), neurochemical markers, or developmental origin.
cognitive map	An abstract representation of multiple factors (i.e., location, time or certain objects) contained in memory and dependent on the relationship between objects or stimuli.
food cache	A site where food storers keep pieces of collected food.
hippocampus	Part of the limbic system, a complex archicortical brain area consisting of several subdivisions. In mammals, it includes the Ammon's horn, dentate gyrus, and subiculum. The hippocampal formation is implicated in memory fomation.
hodological study	Connectivity studies of brain pathways, describing the afferent and efferent axonal projections of certain circumscribed areas.
medial pallium	The medial division of the cortical mantle (pallium) containing the hippocampal formation.
retrieval	Recovery of a once hidden food item from the food cache.
spatial navigation	An ability to explore and 'learn' space in search of food, nesting sites, or mates. Animals are then capable of identifying the exact location of an important site in relation to their environment.
storing (or hoarding)	Hiding selected food items in a cache.
synaptic plasticity	The neuromorphological/physiological basis for learning and memory; it includes the enlargement of synaptic surfaces, modification of synaptic proteins, or alterations in the firing pattern of the neurons.

2.12.1 Introduction

The avian hippocampal formation (HP) is considered to be homologous to the mammalian hippocampal complex on the basis of topography, connectivity, developmental origin, and its role in spatial memory. The HP of food-storing passerines and corvids exhibits an adaptive modification by showing certain enlargement relative to the rest of the telencephalon. The volumetric changes, also influenced by storing/retrieving experience, are paralleled by seasonal differences in neurogenesis and total cell number in storing passerines studied at different times of the year.

The underlying neuroanatomical organization is very different from that of mammals and equivalent morphological entities are not easily identified within the avian HP. Nevertheless, pathway tracing studies have revealed three distinct subdivisions (dorsolateral, dorsomedial, and ventral), which, on the basis of connectivity, may correspond to the subiculum, dentate gyrus, and cornu Ammonis of mammals, respectively. The transmitter and neuropeptide distribution of the avian HP differs, in terms of topography, substantially from that of the mammalian HP and offers an alternative subregional classification.

Certain neurochemical markers, detected by neurohistological methods or receptor autoradiography, including Calbindin, neuronal nitric oxide synthase, immediate early gene (IEG) products, or N-methyl-D-aspartate (NMDA)-receptor ligands show characteristic alterations in the storing HP when compared to that of related nonstoring passerines. Thus, the morphological framework, which is a neuronal basis of memory formation, has been modified to express an adaptive specialization to assist certain behavioral needs in parallel with the evolutionary changes. However, it has to be noted that other forebrain or brainstem nuclei connected to hippocampal subdivisions may express parallel structural changes in relation to storing behavior, as has been detected for the septal nuclei. Therefore, a hippocampopetal/fugal memory circuit has to be suggested in the processing of food-storing behavior.

2.12.1.1 Hippocampus – The Question of Homology

During the decade beginning in the mid-1990s, the avian HP has received considerable attention, due to certain birds' remarkable abilities in spatial navigation. Apart from their functional/behavioral parallels, the HP of avian and mammalian species share certain developmental, cytoarchitectonical, immunohistochemical, hodological, and electrophysiological characteristics, all suggesting homology (see Evolution of the Hippocampus, Sex and Species Differences in Hippocampal Volume).

The HP, or dorsomedial (DM) cortex, derives from the same medial pallial segment of the neural tube in mammals, birds, or reptiles as detected by genetical markers (Puelles *et al.*, 2000). Several authors (Montagnese *et al.*, 1996; Tömböl *et al.*, 2000) studying the cellular morphology of the HP employing Golgi impregnation describe two major neuronal classes, spiny projection neurons and nonspiny local interneurons. These two classes may further be classified according to their dendritic and axonal arbors, or locations within the HP of birds. The intrahippocampal distribution of different neuronal populations also offers a basis for identifying circumscribed hippocampal subregions (Montagnese *et al.*, 1996).

Immunohistochemical analyses (Krebs *et al.*, 1991; Erichsen *et al.*, 1991) and pathway tracing studies (reviews in Székely, 1999; Atoji and Wild, 2004) suggest certain equivalence between the avian and mammalian HP subdivisions, on the basis of their peptide and/or neurotransmitter content, as well as their extrinsic or intrinsic connectivity patterns. However, an accurate avian parallel for the trisynaptic loop of the mammalian HP has not yet been discovered.

Both long-term depression (LTD) and long-term potentiation (LTP) of synaptic efficacy, the electrophysiological correlates of synaptic plasticity (i.e., learning and memory), have been found to be prerequisites of memory formation in birds, as in mammals (Wieraszko and Ball, 1991, 1993). However, LTP in the avian HP is not correlated with a change in transmitter release and does not require activation of adenylyl cyclase (Margrie *et al.*, 2000) or NMDA receptors; therefore, an alternate form of synaptic plasticity might be characteristic for the avian HP.

2.12.1.2 Food-Storing Behavior

Middle-scale spatial navigation is an ability to explore an area in search of food, nesting sites, or mates. The majority of animals are capable of learning the exact location of an important site in relation to their environment. Many birds and rodents show the ability to remember the locations of hundreds of food caches and can store and retrieve food using these sites. Food hoarding, or storing, is a widespread behavior, practised by animals to provide a steady food supply during periods of low food abundance, such as in the winter. Food-storing birds, such as titmice, chickadees, jays, magpies, and nutcrackers have been used extensively in behavioral studies of spatial memory. These birds store pieces of food in their local environments and are capable of remembering the locations of over 100 different food caches (Vander Wall, 1990). In laboratory experiments (Clayton and Krebs, 1994; Cristol, 1996), birds are allowed to store and retrieve food items, mostly seeds, in an enclosure decorated with artificial trees. The laboratory contains a variety of spatial and visual cues to be manipulated in order to test whether they influence the ability to remember the locations of food items.

Notably, storing birds may not only rely on their remarkable spatial abilities, but they also have to employ specific sensory and motor skills to store and retrieve hidden food items successfully (Vander Wall, 1990). Most food-storing birds also use visual landmarks, or the sun compass, to locate their caches, and a few storers are able to recover their stores using olfactory cues (Sherry and Duff, 1996). Storing behavior is steadily built on experience as well as learning and practice in juveniles (Clayton and Krebs, 1994; Clayton, 1995).

Food-storers create a cognitive map of the explored environment, which is an abstract representation of the type of food, exact time of storing, and the location of sites contained in their memory ('hippocampal network'). The geometrical

relationships of objects within a cognitive map can be reconstructed from memory and do not have to rely on visual cues.

A cognitive map consists of a number of landmarks that are placed in a geocentric reference frame and then stored in memory. For each landmark to be stored in a cognitive map, it would require a form of vector addition. The location of the landmark with respect to the animal (egocentric vector) plus the location of the animal in the environment (geocentric vector) would generate a vector for each landmark. This would allow each landmark to be set in its correct location within a geocentric framework.

2.12.2 The Organization of the Hippocampal Formation

2.12.2.1 Subdivisions

Traditionally, the definition of hippocampal structures was based on standard histological techniques. In the early twentieth century, subfields of the avian hippocampus were determined on the basis of cytoarchitecture, enzyme reactivity (i.e., acetyl cholinestherase), and neuronal density (cresyl violet staining, review in Székely and Krebs, 1996). Table 1 summarizes all previous, recent, and present suggestions for hippocampal subdivisions (review in Atoji and Wild, 2004). More recently, several investigators have attempted to establish subregions within the HP using various anatomical and physiological techniques. Karten and Hodos (1967) have divided the dorsomedial cortex of pigeons into hippocampus proper and area parahippocampalis (APH), using the parahippocampal sulcus as a landmark between the two subregions. The regional distribution of neurotransmitters and neuropeptides (Krebs *et al.*, 1991; Erichsen *et al.*, 1991) enabled the characterization of seven subdivisions in the pigeon HP. Later, an alternative subregional system of five areas has emerged from the cytoarchitectonical observations in the zebra finch by employing zinc staining (Montagnese *et al.*, 1993) or Golgi impregnation (Montagnese *et al.*, 1996).

Hodological studies of the zebra finch HP (Székely and Krebs, 1996; Székely, 1999) have revealed three areas. Based on their specific projection patterns, the dorsolateral (DL) region was paralleled to the subiculum of mammals with its main projections to the basal ganglia, the limbic archistriatum, the lateral septum, and the paraxial mesodiencephalic centers. The ventral (V) subdivision was suggested to be equivalent to the Ammon's horn of mammals with its commissural projections to the contralateral HP. We thought that, based on its purely intrinsic connectivity, the dorsomedial (DM) region would be a good candidate for an avian dentate gyrus; however, its relative topographical position to the avian Ammon's horn seemed to be opposite to that described for the reptilian or mammalian hippocampi (review in Székely and Krebs, 1996).

Further studies on the connectivity or evoked field potentials of the homing pigeon HP (Hough *et al.*, 2002; Siegel *et al.*, 2002; Kahn *et al.*, 2003) have refined the above system and characterized five subregions including DM, DL and, respectively, the ventral core, VL, and VM of the V subdivision. Nevertheless, the borders between the subregions have been shifted, probably due to the obvious interspecies differences between songbirds and pigeons.

Table 1 Summary of all formerly and recently established subdivisional systems of the avian HP

	Subdivisional nomenclatures					
HP area	*K/H*	*E/B/K*	*B&Co*	*M/K/M*	*Sz/K*	*A/W*
Ventral (or medial)	Hp	Area 1	VL	HCl	V	Lateral blade
		Area 2	VM	HCm		Medial blade
		Area 3	Ventral core	APH, PHc		Tr
Dorsomedial	Hp-APH	Area 4	DM	CF	DM	Po
		Area 5				Ma
		Area 1				Pa
Dorsolateral	APH	Area 3	DL	APH	DL	DM
		Area 6		PHc		
Lateral	APH	Area 7	DL	Cl	SPf	DLd
						DLv

Note that certain topographically created terms (e.g., DL or DM) may refer to different subdivisions in the works of different authors. CF, crescent field; Cl, intermediate corticoid area; HCl, hippocampal complex pars lateralis; HCm, hippocampal complex pars medialis; PHc, central field of para hippocampus; SPf, substance P field. K/H refers to the work of Karten and Hodos (1967); E/B/K refers to Krebs *et al.* (1991) and Erichsen *et al.* (1991); M/K/M refers to Montagnese *et al.* (1993, 1996); Sz/K refers to Székely and Krebs (1996) and Székely (1999); B&Co refers to Hough *et al.* (2002), Siegel *et al.* (2002), and Kahn *et al.* (2003); A/W refers to Atoji and Wild (2004).

Table 2 Summary of the internal and external connectivity of the zebra finch HP following PHAL iontophoresis as described in Székely and Krebs (1996) and Székely (1999)

Target or source	*Intrinsic*		*Extrinsic*	
	Afferents	*Efferents*	*Ipsilateral efferents*	*Contralateral efferents*
DL	V	V	HA, HD/HV	A
	DM		DLC, AP	
			SL, FDB	
			MSt, PVT	
			Tn, AP	
			SCE, ME	
			DMP, SHb	
			GCt, AVT	
DM	V	V	Dorsorostral septum	
	DL	DL	Caudal HA	
V	DL	DL	SM	SM
	DM			V

DLC, dorsolateral cortex; DMP, nucleus dorsomedialis posterior thalami; FDB, fasciculus diagonalis Brocae; MSt, medial striatum; PVT, paleostriatum ventrale; SCE, stratum cellulare externum; SHb, nucleus subhabenularis.

The most recent parcellation of the avian HP has been based on connectivity studies and Nissl staining of the pigeon brain (Atoji and Wild, 2004). The V-shaped structure of the ventral subdivision has been separated into three elements, the lateral and medial blades (ll and ml, respectively) enclosing a triangular area (Tr). The DM subdivision of Székely and Krebs (1996) has been further classified, on the basis of neural density, to Po (cell poor), Ma (magnocellular), and Pa (parvocellular) subdivisions. The rest of HP has been named as DM, and the more lateral areas, demarcated by the parahippocampal sulcus have been termed as DLd and DLv.

2.12.2.2 Connectivity

As described in Székely and Krebs (1996), iontophoretic administration of Phaseolus vulgaris leucoagglutinin in the zebra finch HP have revealed specifically altering projection patterns ascribed to the three subdivisions of the DM cortex (summarized in Table 2), whereas previous tracing studies have discussed projections from the earlier defined two subdivisions in the pigeon brain. The efferent connectivity of the songbird HP shows certain resemblance to the wiring pattern of the mammalian hippocampal complex. Most importantly, there is a medial-to-lateral topographical organization of efferents in relation to the septal complex similar to that described in mammals. Axons arising from the ventral portion (i.e., medialmost aspect of the medial pallium, closest to the septohippocampal junction) will principally innervate the medial septum, whereas, fibers from the more dorsal and lateral aspects of the medial pallium (i.e., hyperpallial junction) will enmesh the lateral septum.

However, some recent investigations (Hough *et al.*, 2002; Siegel *et al.*, 2002; Kahn *et al.*, 2003; Atoji and Wild, 2004) have introduced a more intricate hippocampal circuitry using various tract tracing, lesion, and electrophysiological techniques.

2.12.2.2.1 Intrinsic projections Despite certain differences in terms of parcellation, most investigators agree on the direction of projections within the hippocampal connections (Hough *et al.*, 2002; Siegel *et al.*, 2002; Kahn *et al.*, 2003; Atoji and Wild, 2004). The intrinsic projections of HP are summarized in Table 2.

Generally, the DL aspect projects to the V-shaped layer and gives rise to axons terminating in the paraventricular fiber zones. The ventral strip of DL (DLv) innervates the more medial central field (DM) of HP which, in turn, projects back to the dorsal strip of DL (DLd). Furterhmore, DM is reciprocally connected with the neuronal layers of V together with the interposed triangular (Tr) field, as well as the magnocellular portion (Ma) of the dorsomedial corner of HP. The cellular elements of V form a presumably bisynaptic loop with the cells of Tr, which then give rise to efferents enmeshing DLd, but seem to avoid DLv.

According to a recent hypothesis (Atoji and Wild, 2004), the majority of neurons of the V-shaped layer should be intrinsic to the HP, whereas some cells in a small portion of the medial layer of V, together with the adjacent aspect of the Tr area, send comissural projections to the contralateral HP.

2.12.2.2.2 Extrinsic projections All studies describing 'hippocampal and parahippocampal'

efferents and afferents in detail have so far agreed on the majority of regions connected ipsi-, bilaterally, or even reciprocally to the entity named as HP. However, this consensus seems to fade when the accurate intrahippocampal origins or targets of the projections are discussed. Generally, the fibers leave and/or invade the HP via lateral, rostral, and ventromedial paths. The extrahippocampal connections are summarized in Table 3, on the basis of Atoji and Wild (2004).

The lateral-most aspect of HP, DL, receives intratelencephalic afferents from the ipsilateral hyperpallium, nidopallium, the DL cortex, and from the medial layer–Tr complex of the contralateral HP. Within the septum, afferent fibers arise both from the medial and lateral nuclei (SM and SL, respectively) and the diagonal band of Broca (NDB), as well as from the commissural nucleus adjacent to the pallial commissure and the ventral pallium (VP) further caudally. Diencephalic and brainstem sources of HP afferents include the bilateral nucleus dorsolateralis anterior (DLM) and the ipsilateral nucleus subrotundus of the thalamus and several hypothalamic areas, as well as the ventral tegmental area (AVT), midbrain central gray (GCt), locus ceruleus (LoC), and the contralateral 'raphe nucleus' (i.e., nucleus linearis caudalis). Most of the areas rostral to the level of the midbrain have established reciprocal connections with DL.

DM injections have resulted in a more extensive reciprocal pattern of afferent and efferent connections. Most of the afferents to DM appeared to be arising from ipsilateral sources except for the NDB, the medial layer of contralateral V, DLM, and the medial and lateral hypothalamic fields, as well as the AVT, LoC, and the 'raphe complex'. DM efferents invaded the contralateral HP and were widely distributed in the ipsilateral telencephalon, except for the nidopallium, mesopallium, and the dorsal basal ganglia. Further projections have enmeshed the septum (bilaterally), numerous diencephalic centers including the dorsal thalamic nuclei and the hypothalamus together with the AVT and GCt, but more caudal efferents have not been detected.

Table 3 Summary of the internal and external wiring of the pigeon HP following anterograde and retrograde tracing as described in Atoji and Wild (2004)

2.12.3 Neuronal Components of the Avian HP

2.12.3.1 Distribution of Neurochemical Markers

2.12.3.1.1 Neuropeptides and transmitters in the pigeon brain The neurotransmitter and neuropeptide content of the avian HP has been most extensively studied in the pigeon brain (Krebs *et al.*, 1990; Erichsen *et al.*, 1991). Choline acetyltransferase-, serotonin-, and tyrosine hydroxylase-like immunostaining has highlighted the subpial fiber tract passing through the septo-hippocampal junction and along the medial wall of HP. The most intensive fibrous labeling was found in the DM area. Glutamic acid decarboxylase-reactive neurons were sparsely scattered throughout the HP.

The distribution of substance P (SP), leucine (leu5-) enkephalin (LENK), vasoactive intestinal polypeptide (VIP), cholecystokinin (CCK), neuropeptide Y (NPY), and somatostatin (SS) was found in fiber tracts invading the septo-hippocampal junction and passing along the subpial wall. NPY-, SS-, and VIP-positive fibers were apparent in the pallial commissure. NPY and SS have seemed to co-localize within the hippocampal neurons, while VIP-positive cells were found dorsal to the SS/NPY cell region. CCK-like immunoreactive terminal baskets were seen around cells of the V-shaped structure. One of the most significant findings of the study was that a circumscribed area, containing SP- and LENK-positive neuropil, was found in a dorsal–lateral region, demarcating clearly the lateral border of HP. The suggested subdivisional pattern, emerging from the distribution of the aforementioned neuroactive substances, has been introduced in the previous section.

2.12.3.1.2 Calcium binding proteins and food-storing Calbindin-like (CB) immunocytochemistry (Figures 1a and 1b) has revealed a polymorphic neuronal population embedded in a dense neuropil. CB immunoreactive (CB+) cells have exhibited a specific topographical distribution throughout the hippocampal complex (review in Montagnese *et al.*, 1993), whereas no similar grouping was observed following parvalbumin or calretinin immuncytochemical stainings. CB+ neurons have delineated three subdivisions, DL, DM and V, largely identical to those described for HP as a result of tract tracing in the zebra finch. Large CB+ neurons (Figure 1a) have been found in the dorsal subdivisions of food-storers (marsh tits and magpies), but not in the HP of nonstorers (great tit and jackdaw, Figure 1b). Hence, it has been suggested that CB+ neurons are responsible for certain aspects of memory formation and/or the remarkable spatial abilities of food-storing songbirds.

Also forebrain ischemia seems to leave the CB+ neuronal elements of the HP largely unaffected (Székely, 1999), whilst the parvalbumin containing cells are severely damaged.

2.12.3.1.3 Neuronal nitric oxide synthase in the avian HP There is a rather small population of hippocampal cells (Székely, 1999), which contain neuronal nitric oxide synthase (NOS). The neuronal complex seems to spread from the edge of the lateral

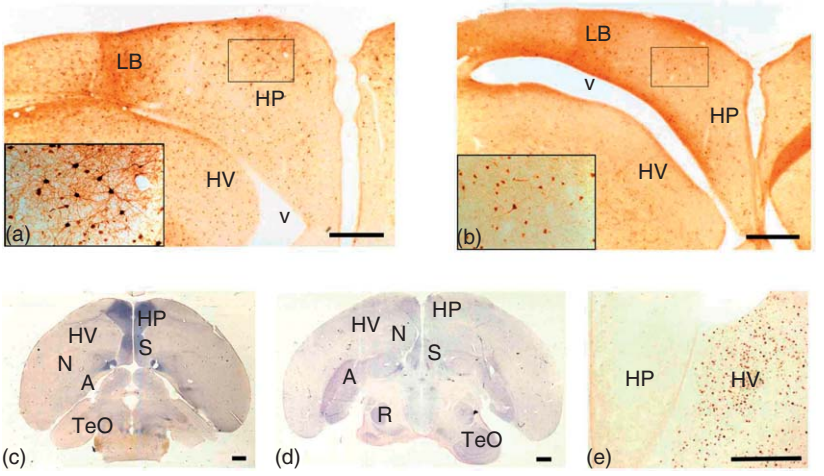

Figure 1 Neurochemical markers of memory formation in the forebrains of storing and nonstoring parids. Calbindin immunocytochemistry in the marsh tit (a) and the great tit (b) telencephalon. The inset in (a) shows a distinct population of immunoreactive neurons located in central HP absent from the nonstorer HP (inset in (b)). NADPH-diaphorase histochemistry gives a high diffuse reactivity within the neuropil of the marsh tit HP and dorsal septum (c), whereas the same staining method results in a significantly weaker neuropil reactivity in the great tit (d). Fos immunoreactive neuronal nuclei in the forebrain of a marsh tit (e); note the low level of labeling in HP, 30 min following cache retrieval. Scale bars: 1 mm.

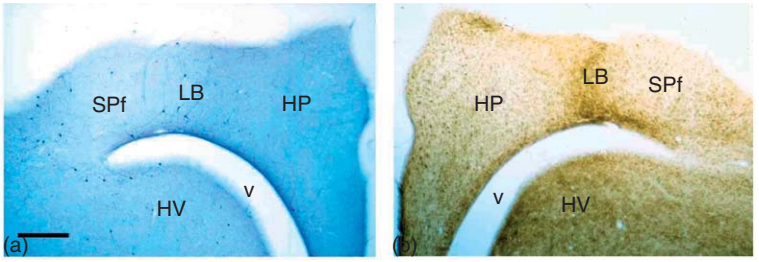

Figure 2 The songbird hippocampal complex demonstrated by: a, NADPH-diaphorase histochemical staining; and b, acetyl cholinestherase histochemistry. Note the prominent lateral boundary (LB). Scale bar: 1 mm.

ventricle to surround the substance P field, thus, clearly demarcating the lateral border of HP (Figure 2a). Within the lateral portion of HP, axonal baskets are found around unlabeled perikarya, with the fibers presumably belonging to the NOS reactive intrinsic cells.

In mammals and reptiles, there is an almost complete co-localization between NOS and GABA within HP, although GABA cells are far more numerous. In birds, the number of NOS reactive neurons is rather low, and only a minor contingent (~25%) contains both neuronal markers.

It is worth noting that in the HP of food-storers (marsh tit, coal tit) the diffuse NOS labeling of neuropil is stronger than in related nonstoring birds (great tit, blue tit, Figures 1c and 1d, respectively); however, no such correlations are apparent in neuronal cell counts (Székely, 1999).

2.12.3.2 Neuromorphological Correlates of Food-Storing Behavior

2.12.3.2.1 Expression of immediate early genes IEGs are thought to be associated with neural plasticity, including memory formation. In a recent account (Smulders and DeVoogd, 2000), the number of cells immunopositive for either of the three IEG products (Fra-1, c-Fos, and ZENK) were counted in order to map neuronal activity in the chickadee HP in relation to food-storing and retrieval. In storing and retrieving chickadees Fra-1-like immunoreactivity seemed to be downregulated in the dorsal HP when compared to controls. According to the present authors, the number of Fos-like immunopositive neurons very probably is associated with the number of items remembered by retrieving birds, while the number of ZENK-like immunoreactive neurons may be a marker of accuracy in cache retrieval. These results imply that neurons expressing different IEG proteins may establish a specific hierarchical order when processing the consecutive stages of food-storing memory. The hypothesis is supported by an earlier study by Székely *et al.* (1992), where hardly any Fos immunolabeled neurons were detected in the HP (Figure 1e) of marsh tits following a single storing session. It is therefore possible that storing experience alone does not trigger the expression of c-fos in HP neurons, but needs reinforcement, that is, retrieval of the cached item using spatial memory.

2.12.3.2.2 Glutamate receptor binding In an earlier study, quantitative receptor autoradiography was used to localize NMDA-sensitive [3H]glutamate, [3H]MK801, and [3H]alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) binding sites (Stewart *et al.*, 1999), in the forebrain of food-storing marsh tits and nonstoring blue tits. Although similarly high levels of labeling were apparent to both NMDA and AMPA receptors in both species, binding to NMDA ion channel sites appeared to be significantly lower (20%) in the HP in food-storers than in nonstorers. Other selected forebrain regions expressed remarkably similar levels of binding in the two species.

A recent investigation (Shiflett *et al.*, 2004) has assessed whether long-term memory for spatial locations requires NMDA receptor-dependent synaptic plasticity in food-storing birds. Black-capped chickadees were given bilateral infusions of the NMDA receptor antagonist AP5 into the HP, and their spatial memory was assessed. Inactivation of NMDA receptor during learning prevented the formation of long-term spatial memories but did not affect short-term memory or retrieval. Most notably, NMDA receptor inactivation immediately following learning did not interfere with the formation of long-term memory, thus suggesting that NMDA receptors may play a role both in the incorporation of new information into an already existing long-term memory, as well as in the formation of unitary long-term memories.

2.12.3.2.3 Adaptive modification of hippocampal size as a result of food-storing According to a widely accepted hypothesis, HP is larger in many birds and mammals that store food than in related

nonstorer species (Krebs *et al.*, 1989; Colombo and Broadbent, 2000; Shettleworth, 2003). The three-way association linking spatial memory, food-storing behavior, and the volumetric changes experienced in HP enable these birds to survive under harsh weather conditions because the duration of time over which they can remember spatial information is largely increased. Thus, the enlarged memory capacity is paralleled by an increase in relative hippocampal volume compared to the rest of the brain. There is, apparently, a certain difference in the HP/ telencephalon ratio between birds specified as large-scale or low-scale storers. Avian species, exhibiting a higher storing activity will have an HP relatively larger than those species which store less food (Healy and Krebs, 1992, 1996; Hampton *et al.*, 1995). Furthermore, the different latitudinal distribution of members of the same species (e.g., black-capped chickadees) seems to influence their storing activities accompanied by a consequent difference in hippocampal volume. Alaska chickadees cache more food and have a significantly larger HP, containing more neurons, when compared with Colorado chickadees (Pravosudov and Clayton, 2002).

The volume of HP shows seasonal alterations in relation to storing or nonstoring periods during the year (Krebs *et al.*, 1995). In the autumn, some food-storing birds spend more time caching, store more items, and leave their caches for longer periods than they do in the spring. Correspondingly, these birds have a larger HP in the autumn than in the spring and, together with the volumetric changes, there is an increase in hippocampal neuronal number. Thus, a higher rate of cell birth, or neurogenesis, has to occur in the autumn when caching activity is highest (Barnea and Nottebohm, 1994).

2.12.3.2.4 Neurogenesis In general, cells are continuously born within the ventricular zone of the avian brain and migrate into the deeper areas to differentiate into neurons. In a study by Patel *et al.* (1997), it has been shown that the rate of cell proliferation within HP and the hyperpallium ventrale (HV) is influenced by behavioral experience. Juvenile birds were allowed to store and retrieve food regularly between days 35 and 56, while controls were prevented from food-storing. Experienced birds have expressed a higher rate of cell proliferation (3.9–10%) and an increase in total cell number, presumably due to the higher rate of neurogenesis. Neuronal recruitment into HP may therefore occur in order to address the memory demands associated with storing and thus the subsequent behavior will be facilitated by hippocampal growth.

It has to be noted that neuronal recruitment seems to vary not only with experience (i.e., aging) but also expresses seasonal changes (Barnea and Nottebohm, 1994) with the different subregions exhibiting different rates of neurogenesis (the rostral-most portion contains most of the new cells).

It is, however, not yet clear whether in the experienced adult animals such changes of spatial memory should also be accompanied by morphological alterations and/or a higher cell proliferation. Cristol (1996) has found no detectable differences between experimental and control groups of adult storing willow tits, in terms of volume, neuron density, or total neuron number within their HP. Hoshooley and Sherry (2004) have reported similar findings for the hippocampal cellular recruitment of black-capped chickadees. Birds, caught from the wild during the winter, were injected with 5-bromo-2′-deoxyuridine and then neurogenesis, apoptosis, neuron number, and hippocampal volumes were determined. Chickadees collected in October, November, January, February, or March did not show alterations in any of the studied aspects of neuronal plasticity. Thus, the findings seem to suggest that increases in neuronal recruitment in the fall do not result from a higher neuron proliferation but, rather, the prolonged survival of previously born 'new' neurons.

Spatial memory performance was found to be inferior in socially subordinate food-storing birds (among mountain chickadees, Pravosudov and Omanska, 2005) whilst no significant differences in volume or the total number of neurons in the HP have been verified between dominant and subordinate chickadees. Nonetheless, subordinate birds had lower cell proliferation rates in the ventricular zone compared to dominants, thus suggesting that social status may affect cell proliferation rates and support the hypothesis that neurogenesis might be involved in memory function also in adult animals.

2.12.4 Evolutionary Considerations

Birds living in environments that produce food in abundance during one season of the year, and relatively little (or none) during others, may cope with the uneven supply in several different ways. One strategy is to leave the area for the periods of shortage, as many birds do in migrating from cold or polar regions to the relatively food-rich and warmer tropical areas for the winter. The perils of migration are accepted in return for the continuity of food supply. An alternate approach is to collect more

food than needed during periods of seasonal abundance for subsequent storage. This strategy, too, has its challenges, the cache may be pilfered while the birds must find enough fuel to maintain their relatively high daytime body temperature and to replenish the fat used during the nights. Food-storing is essential for the survival of winter for most parids, since they do not accumulate large fat reserves like finches. Nevertheless, being slim has a distinct advantage, plump redpolls or purple finches lack the mobility of titmice and are more likely to fall victims to predators.

A learning mechanism is able to detect and store information about casual relationships. Based on this definition, the environment should confer fitness in direct proportion to the assessment of causality by any network in which we would like to evolve the capacity to learn. Evolution should therefore act to set up the machinery which will subsequently allow an association to be formed, and these associations should be formed within the lifetime of a single individual.

Nonetheless, such changes in behavior will certainly need to be accompanied by an enlarged memory capacity to successfully localize the (sometimes) several hundred food caches. In food-storers, the neuronal basis of memory formation (i.e., HP) seems to express an adaptive specialization (increase in relative hippocampal volume) in parallel with the evolutionary changes of behavior. Comparative studies within the parids and corvids suggest two kinds of memory specialization associated with food-storing. Some storer species have a more accurate and enduring spatial memory, together with a strong preference to rely more upon spatial cues than some related nonstorers. Furthermore, some storing parids and corvids appear to be more resistant to memory interference by remembering additional information about the contents and status of cache sites. Still, the question remains as to how the HP is able to address such a complex task alone? Certainly, HP appears to be a key figure (or none at all, as suggested by Macphail and Bolhuis, 2001) of the underlying neuronal structure, a multiconnected neuronal network of several brain areas. It is possible that adaptation to a specialized behavior may lead to the coordinated evolution of several interconnected neural structures resulting in the evolution of the entire brain (Garamszegi and Eens, 2004), thus suggesting that the evolutionary shift from nonstoring toward food-storing might have been accompanied by robust evolutionary changes in brain volume during the long-term phylogenetic history of birds.

In fact, little is known about the role of telencephalic or subtelencephalic centers, apart from that of the HP in mediating food-storing behavior. Shiflett *et al.* (2002) have found septal specialization to parallel hippocampal changes in storing chickadees.

Finally, the question arises whether the concerted evolution of different brain structures leading to volumetric changes has been induced simultaneously but independently in storers or, instead, their behaviors are emerging from common ancestry. The apparently very close phylogenetic relationship between two food-storer families, Paridae and Sittidae (Sibley and Ahlquist, 1990), suggests that storing arose in their common ancestor (Brooks and McLennan, 1990). As food-storing is rather widespread in the animal kingdom, and espesially in Paridae and Sittidae (Vander Wall, 1990), the 'common origin' hypothesis is evolutionarily more feasible than the one of multiple origins (Brooks and McLennan, 1990).

2.13 Sex and Species Differences in Hippocampal Volume

S D Healy, University of Edinburgh, Edinburgh, Scotland, UK

Glossary

higher vocal center (HVC)	A region in the songbird brain that is involved directly in song production and indirectly in song learning.
lateral line	Sensory cells arranged either in groups or in rows found on the sides and head of fish, which enable them to detect changes in water pressure and very low frequency sounds (<100 Hz).
mental rotation	An experimental test procedure in which subjects are shown an object for a short period of time and then asked to choose from a number of similar alternatives, which is the same object rotated.
natural selection	The differential survival and reproduction of individuals that vary in a heritable trait. Via natural selection, traits that increase reproductive success will increase in frequency in the population through time.
ontogeny	The process of development from the fertilized egg, to the embryo, through to adulthood.
prepubescence	A juvenile stage, beyond infancy but not yet sexually mature.

The hippocampus in mammals (the dorsomedial forebrain in birds) is considered by many to be the brain region that is heavily involved with processing of spatial information. Much of the traditional support for this hypothesis came from lesion studies, mostly in rodents, which showed that damage to the hippocampus affected the animal's ability to solve cognitive tasks with a spatial component, while not affecting their ability to solve other cognitive tasks without a spatial component.

While there continues to be much debate over the degree to which the considerable lesion data from rodent studies, in particular, provide support for the involvement of the hippocampus in spatial information processing, an alternative avenue is proving useful for investigating hippocampal function. This is the use of another traditional approach, comparative neuroanatomy, framed within an evolutionary context. The underlying assumption of this work is that variation in hippocampal structure, between and, perhaps, within species, is due, to a significant degree, to variation in the selective pressure imposed on those species, via the physical and biological environment in which they live. In other words, natural selection has shaped cognitive regions of the brain just as it has moulded parts of the brain that are concerned solely with specific sensory information (e.g., visual and olfactory areas in primates/mammals: Barton *et al.* 1995; Barton and Harvey, 2000; olfactory bulbs in birds: Healy and Guilford, 1990).

2.13.1 Ecology and Sensory Brain Structures

In the late 1970s and early 1980s, there was a flurry of studies showing that variation in brain size in both birds (see Forebrain Size and Social Intelligence in Birds) and mammals was correlated with variation in the lifestyles of those animals. For example, frugivorous primates have larger brains than do folivorous or insectivorous primates (Harvey *et al.*, 1980). Whole brain size in birds, however, is not correlated with diet but rather with ontogenetic pattern – altricial birds (those that are born with their eyes shut and are totally dependent on parental care for at least the first few weeks of life, e.g., starlings, *Sturnus vulgaris*, sparrows, *Passer domesticus*) have larger brains as adults than do precocial birds (birds that, within a

few hours of hatching, are mobile and semi-independent of their parents, e.g., chickens, grouse, and quail). It soon became clear, however, that using whole brain size as a means of understanding the role of natural selection in shaping variation among species was only the beginning and, as neuroscientists had long known, greater understanding would be achieved only when component parts of the brain were the focus of attention (Mace *et al.*, 1980).

Within the brain it is relatively straightforward both to see and to understand that sensory structures are correlated with the lifestyle of an animal. Animals that live in the dark, for example, have to cope with the difficulty of seeing their surroundings, finding food, mates, home, and so on. This problem has been solved in a variety of ways: many bats detect prey via echolocation, owls use both enlarged eyes and highly sensitive hearing, kiwis (flightless, nocturnal birds from New Zealand) have a highly developed sense of smell, electric fish (as their name implies) use electric fields to find their way around, and, in the complete dark, as is the problem for Mexican cave fish, eyes have disappeared altogether to be replaced by a very sensitive lateral line system (for more details see de Perera and Braithwaite, 2005). In some cases, the system appears to have developed specifically in response to low lighting (e.g., echolocation); in others, there has been an increase in one sensory system at the cost of another (e.g., kiwis, cave fish). The change in brain structure as a result can be striking; for example, a third of a kiwi brain is occupied by the olfactory bulb, in contrast to a diurnal species such as a starling, in which the olfactory bulb is almost nonexistent. It should be noted, however, that even in starlings with such tiny olfactory neural structures, there is a functional sense of smell, enabling these birds, for example, to detect the volatiles given off by plants they use for their antiseptic qualities, to line their nests and thus reduce the parasite load for their nestlings (Gwinner, 1997; Gwinner *et al.*, 2000). The point here is that, although the size of structure can be taken as a measure of the amount of use to which the animal puts that structure, even very small structures are likely to play an important role in the animal's life. There is little evidence that there are brain regions that are vestigial in the way the appendix is thought to be.

2.13.2 Ecology and the Hippocampus

Like the relationship between ecology and the sensory apparatus in the brain, there is growing evidence that the volume occupied by cognitive brain regions can also be explained to a significant degree by an animal's lifestyle. The hippocampus is one of these areas for which there is considerable evidence that the demand for a specific cognitive ability is associated with an enlargement of the relevant brain region (see Evolution of the Hippocampus). In all of the cases to date, animals that have a more than usual need for spatial information processing have a larger hippocampus for their brain size than do closely related species that do not depend so heavily on spatial information. For example, migratory birds have a larger hippocampus than do birds that do not migrate (Healy *et al.*, 1991). The increase in hippocampus size is not related to the distance the birds fly but rather to the fact that they must remember details (e.g., relevant landmarks) of the stopping over places en route and both of the endpoints (the breeding grounds and the overwintering grounds). These differences are apparent within species: migrant dark-eyed juncos, *Junco hyemalis*, have both better spatial memory and more densely packed neurons in the hippocampus than do nonmigratory dark-eyed juncos (Cristol *et al.*, 2003). Older, experienced garden warblers, *Sylvia borin*, have larger hippocampal volumes than do young, inexperienced birds. While age itself contributes to some of this increase in volume, the experience of migration is a major component, as shown by changes in hippocampal volumes in birds kept in captivity for 12 months (Healy *et al.*, 1996).

Frequent, short-distance trips also seem to be spatially demanding. Homing pigeons have larger hippocampal volumes than do breeds of pigeons selected for attractive morphological features (Rehkamper *et al.*, 1988). Pigeons have provided much of the direct evidence for avian hippocampal function: an intact hippocampus is essential for learning the geometrical features of a landscape (Vargas *et al.*, 2004). Recording from cells in the hippocampus has shown that cells in the left hippocampus are responsive to nearby landmarks, whereas those in the right hippocampus respond to global cues around the experimental arena (Bingman *et al.*, 2003). The effects of lesions to each half of the hippocampus are consistent with the cell recording data: pigeons with left hippocampal lesions use global cues to solve a task, whereas right hippocampus-lesioned birds used local landmarks (Kahn and Bingman, 2004). As yet, however, there is no evidence for an equivalent cell type to the place cells found in rodent hippocampus (Bingman *et al.*, 2003).

Like homing pigeons, scatterhoarding birds, by dint of their response to excess food, constantly face a considerable spatial memory task. Species such as the black-capped chickadee, *Poecile*

atricapillus, for example, hide large numbers of food items, often singly, scattered throughout their territory. They may not retrieve this food for several hours, days, weeks, or months. Although considerable numbers of stores are made, these birds use memory to retrieve those stores (e.g., Sherry, 1984). Lesions to the hippocampus of black-capped chickadees result in the birds being unable to use spatial cues, in this case, to relocate food (Sherry and Vaccarino, 1989). As the birds can use color cues to find food, it appears that the hippocampus is involved specifically in the memory for locations.

A number of subsequent studies have shown a relationship between hippocampal volume and food storing. Food-storing species have a larger hippocampus than do nonstorers (Krebs *et al.*, 1989; Sherry *et al.*, 1989; Garamszegi and Eens, 2004; Lucas *et al.*, 2004; see The Hippocampal Formation in Food-Storing Birds). There is also a positive relationship between the degree of food storing and hippocampal volume, such that birds that store more and/or for longer have larger hippocampal volumes (Healy and Krebs, 1992; Hampton *et al.*, 1995; Basil *et al.*, 1996; Healy and Krebs, 1996). The difference in volume is due to an increase in the number of cells in the hippocampus, not to the size of the cells. As in the juncos that differed in migration propensity, black-capped chickadees that differ in dependence on food stores also differ in hippocampal volume: chickadees from Alaska have better spatial memory and larger hippocampus than do chickadees from Colorado, where the conditions the birds live under are significantly less harsh than they are in Alaska (Pravosudov and Clayton, 2002). All of the species tested differ both in the number of items stored and in the duration before they retrieve their food, so it is not clear from the hippocampal morphology whether or not an enlarged hippocampus confers specific spatial cognitive abilities. Some experimental data suggest that for some food storers, at least, an enlarged hippocampus specifically enables them to remember even small amounts of information for longer than can nonstorers (Biegler *et al.*, 2001).

Food storing is also common throughout mammals, although much of it is best described as larder hoarding in which the animals are storing all of their excess food in one or very few places. However, there are some mammalian scatterhoarding species and from the few data that currently exist, it appears that hippocampal volume in these animals is, like the birds, correlated with the presence/absence of food storing (e.g., Dipodomys kangaroo rats: Merriam's and bannertails; Jacobs and Spencer, 1994). It is not yet clear whether these hippocampal differences and ecological differences are also associated with variation in cognitive ability (as assessed experimentally).

2.13.3 Development

In food-storing birds, hippocampal volume increases once the birds have left the nest, which is when they begin to store and retrieve food (Healy and Krebs, 1993; Healy *et al.*, 1994). This has been shown experimentally to be due to the experience of storing and retrieval (Clayton and Krebs, 1994; Clayton, 2001). However, it is also the case that experience of a very similar kind to that of food storing, such as a food finding task that requires memory of those locations for successful return, may also affect hippocampal growth (Clayton, 1995). This effect has, so far, only been found in the food storing species. Nonstorers with the same experience do not achieve an enlarged hippocampus as a result. This may indicate some underlying propensity for response to certain kinds of cognitive experience that has been selected for in the food storers. This could be, for example, the ability to respond with increased neurogenesis or decreased apoptosis (Clayton and Krebs, 1994).

Far more is known about development and changes to hippocampal structure in mammals, particularly rodents. Unlike the interspecific differences in hippocampal morphology seen in birds, it is clear in mammals that actions of gonadal hormones (such as estrogen and testosterone) while the animal is *in utero* have significant and long-lasting effects on both hippocampus and spatial cognition (so-called organizational effects). Neonatal castration of male rats results in spatial cognition performance like that of females, while provision of estradiol (an androgen metabolite) to neonatal female rats enhances their spatial cognition as adults to levels indistinguishable from those of normal males (Williams *et al.*, 1990; Williams and Meck, 1991). Exposure to testosterone *in utero* via placental circulation also enhances the spatial cognitive abilities of female rats born into litters with more males than females, while those females born with more sisters than brothers have poorer spatial cognition (Williams and Meck, 1991). This effect of litter sex ratio has also been found in meadow voles (Galea *et al.*, 1994b) but not in gerbils (Sherry *et al.*, 1996). Experimental application of testosterone to young male and female rats enhances female spatial cognition but appears to impair that of males (Roof, 1993b).

Such ontogenetic effects of gonadal hormones are also apparent in humans: girls exposed to high levels of androgens tested on spatial tasks perform better

than do girls exposed to low levels (Hampson *et al.*, 1998).

The mechanism via which testosterone may act can be investigated by using an aromatase blocker to prevent the breakdown of testosterone into estradiol. Application of aromatase blockers to neonatal male rats results in significantly impaired spatial cognition. In rodents, at least, it appears that estradiol is the active agent controlling spatial cognition. There is little evidence from birds, one way or the other, that there is an organizational effect of gonadal hormones on adult spatial cognition. However, estradiol has been shown to have a small but significant positive effect on spatial cognition in zebra finches (Oberlander *et al.*, 2004).

Concomitantly with the organizational effects of gonadal hormones on spatial cognition are the effects on hippocampal structure. Prepubescent normal male and female rats differ in hippocampal morphology: the dentate gyrus cell layer of the hippocampus is thicker in males than it is in females (Roof, 1993a). There is also a difference between hemispheres: the layer in the right hippocampus is significantly thicker than that in the left, again only in males. The lateralization appears similar to that seen in the pigeons, although it is not clear whether there is a sex difference in the birds. The right hippocampus is larger than the left in human children but there are no differences between the sexes in total hippocampal volume (Giedd *et al.*, 1997). In spite of the rat data described above, this lack of a sex difference in prepubertal mammals is rather common (but see Kerns and Berenbaum, 1991), although still underexplored. Also, there are few data demonstrating sex differences in spatial cognition prior to sexual maturation in any mammal (e.g., Galea *et al.*, 1994a; see also Voyer *et al.*, 1995; Sherry and Hampson, 1997).

Testosterone administration to female rats in the first postnatal week results in male-like hippocampal structure, both in size and in lateralization (Roof and Havens, 1992). Testosterone administration to males does not increase the cell layer; if anything, it is decreased as a result. The increased thickness of the dentate gyrus cell layer is due to an increase in the number of cells and not to cell size. Neonatal castration of male rats results in a decrease in dendritic spine density in the hippocampus relative to those seen in females or intact males (Meyer *et al.*, 1978; Juraska *et al.*, 1988). Dendritic tree morphology is also affected by the environment in which young rats are raised: enriched environments lead to denser dendritic tree branching than do impoverished environments (Juraska *et al.*, 1985). There is also evidence that stressed pregnant rats shift the timing of testosterone delivery to a slightly earlier stage of gestation and that this effect has a significant, negative impact on maze performance in sons born to these females. This effect may be due to a decrease in hippocampal corticosteroid receptors (Szuran *et al.*, 2000). In rhesus monkeys, however, prenatal stress did not affect hippocampal volume of the resulting offspring (Lyons *et al.*, 2001).

2.13.4 Sex Differences

As will be clear from the developmental data described above, gonadal hormones affect hippocampal structure and spatial cognition during early ontogeny and into early postnatal stages in mammals. These effects result in differences between males and females as adults, at least in some species. In meadow voles, *Microtus pennsylvanicus*, and deer mice, *Peromyscus maniculatus*, for example, males have larger hippocampal volumes than do their conspecific females (Gaulin and FitzGerald, 1986, 1989; Galea *et al.*, 1996). Pine and prairie vole males, *M. ochrogaster* and *M. pinetorum*, on the other hand, do not show any sex differences in hippocampal volume. These hippocampal differences are also associated with differences in spatial cognition and in the ecology of the animals: deer mice and meadow voles are polygynous (mate with more than one female) and have home ranges that encompass the ranges of more than one female, whereas pine and prairie voles are monogamous with a home range that matches that of their mate. It is not clear whether the difference in mating system or in home range size has been the selection pressure resulting in these correlated differences, as both are completely confounded in all of the species examined thus far (see Jones *et al.*, 2003, for review of the status of the rival evolutionary theories).

One of the few instances of selection for enhanced female spatial cognition and hippocampal volume comes from birds: nest parasitic brown-headed cowbird females, *Molothrus ater*, which lay their eggs in the nests of other species (like cuckoos), scout out potential nests prior to hosts beginning to lay and return at a propitious moment (e.g., once the host female has laid at least one or two eggs of her own and at a time of day when the host female is away from the nest), to lay their own egg in among those of the host. As the female cowbird may visit more than 40 potential host nests prior to the hosts laying, it is thought that she may have to have quite a good memory in order to go back directly, but sneakily, so that the host remains unaware of the interloper in her nest. The male brown-headed cowbird, meanwhile, does nothing with regard to searching for

host nests and spends his time hanging out with other conspecific males. In this species, it is the female that has the larger hippocampus (Sherry *et al.*, 1993). Shiny cowbird females also scout alone for host nests and they, too, have larger relative hippocampal volumes than do their conspecific males (Reboreda *et al.*, 1996). Interestingly, there is a cowbird species in which both males and females search for nests (the screaming cowbird). There are no differences in hippocampal volume between the sexes but they have larger hippocampal volumes than do male shiny cowbirds and than either male or female baywinged cowbirds, which are not nest parasites. The degree to which the sex differences are specific to particular behaviors can be seen when comparing volumes of song nuclei: in all three species (shiny, screaming, and baywinged), males have larger higher vocal centers than do their conspecific females (Hauber *et al.*, 1999), consistent with the observation that males of all three species use song in sexually selected contexts (i.e., mate choice and territory defense).

2.13.5 Activational Effects of Gonadal Hormones

Although it seems likely that organizational hormone levels contribute to the sex differences seen in these species, there are multiple instances of adult sex differences in spatial cognition and hippocampal structure that are more obviously coupled with variation in circulating plasma gonadal hormones during adulthood (so-called activational effects). In deer mice, for example, the sex differences in spatial cognition and hippocampal structure are seen only in the breeding season (also when range size is sexually dimorphic). Outside the breeding season, the differences no longer exist. Sexual selection, mediated by circulating gonadal hormones (specifically testosterone, in these cases), seems to play a major role in this brain/cognition/behavior relationship (Gaulin and FitzGerald, 1986). It is not clear why this selection pressure should not have had so significant an impact on pine voles.

Seasonal differences in hippocampal volume are also apparent in the cowbirds described above: the sex differences seen in shiny cowbirds during the breeding season are not visible in the nonbreeding season (Clayton *et al.*, 1997). Seasonal variation in hippocampal volume that is not correlated with breeding has been seen in black-capped chickadees. Intensity of food-storing peaks in this species in the autumn, and there are correlated changes in hippocampal structure, both in volume and in the longevity of hippocampal neurons born during that season: the hippocampus is larger and autumn-born neurons live longer than do spring-born neurons (Barnea and Nottebohm, 1994; Smulders *et al.*, 1995). The volume of the septum, which shares reciprocal connections with the hippocampus, changes in a similar seasonal fashion in black-capped chickadees but not in two nonstoring species, blue tits, *Parus caeruleus*, and great tits, *P. major* (Shiflett *et al.*, 2002). These effects do not occur across the brain, as the nucleus of the diagonal band does not change seasonally.

In humans, there is less evidence for circulating testosterone affecting spatial cognition or hippocampal structure than there is that estrogen has an impact, especially on female spatial ability. Women's spatial ability is better (on tests, for example, such as mental rotation) during menstruation, when estradiol levels are lowest (e.g., Hampson, 1990; Hausmann *et al.*, 2000). However, data on changes in hippocampal structure in women are, unsurprisingly, scanty. The data from rats are inconsistent. Some studies have found improved spatial performance with high levels of estrogen (e.g. Healy *et al.*, 1999), others with low levels (Frye, 1995; Warren and Juraska, 1997) and yet others (e.g., Berry *et al.*, 1997) have found no effect. All of the morphological evidence points to a negative effect of estrogen on hippocampal morphology: pregnant rats tend to have smaller hippocampal volumes than do nonpregnant rats and dendritic spine density decreases by as much as 30% on estrous days (Gould *et al.*, 1990). In female meadow voles, hippocampal cell proliferation is lowered when estradiol is high (Galea and McEwen, 1999). It is not yet clear why there is such discrepancy in the rodent data as to the relationship between estradiol, hippocampal morphology, and spatial cognition, although it may be, in part, due to a nonlinear relationship between gonadal hormone level and spatial cognition. It may also be that the task used to assess cognition, or the level of stress the animals are under at test, may also contribute to the observed variation. That estrogens are involved via their receptors in the mammalian hippocampus is clear (e.g., Rissman *et al.*, 2002). It is less clear what role gonadal hormones play in the variation in hippocampal morphology in the bird examples.

2.13.6 Summary

There are a multitude of examples of variation in hippocampal volume, both within and between species. In mammals, the best studied of these is the sex difference, which appears to be primarily caused by

effects of gonadal hormones present when the fetus is *in utero*, although circulating levels during adulthood also have an impact. The particular selection pressure or pressures that have brought about this variation is still under debate. In birds, there is less evidence, as yet, for a role of gonadal hormones in changing hippocampal morphology, although there is considerable evidence for differences that are correlated with variation in demand for spatial cognition. Investigation of hippocampal structure in a wider range of mammalian species and of the effects of gonadal hormones on hippocampal structure and function in birds may help to resolve these issues.

Universitat de València, Burjassot, Spain

Glossary

agonistic behaviors Behaviors expressed during confrontation with conspecifics for resources, territory, or mates. This usually leads to aggressive/defensive behaviors different from prey–predator interactions. In territorial species, encounters with adult conspecifics can be either agonistic or reproductive.

conditioning, instrumental (or operant) This is a type of associative learning in which an unlikely motor response to a given clue (such as pressing a lever when the animal sees it) is associated with a reward (e.g., food) or to absence of punishment. The chances of showing the motor response augment due to its association with the reward. This can be interpreted as a stimulus–response association (detection of the lever – pressing it) due to reinforcement (food consumption).

conditioning, Pavlovian (or classical) As opposed to instrumental conditioning, in this kind of associative learning two stimuli called unconditioned (US) and conditioned stimulus (CS), are associated. The US renders an automatic response (usually not voluntary or not conscious), which is part of the repertoire of behaviors specific to that species (for instance, salivation, increased blood pressure). This is called unconditioned response. Repeated presentation of the CS together with the US leads to an

association of the former to the latter that results in a conditioned response, e.g., the CS alone provokes the response that was elicited by the US.

fear and anxiety Fear is an acute reaction to potentially harming stimuli that consists of behavioral (e.g., freezing, potentiated startle), vegetative (e.g., increased blood pressure, tachycardia) and endocrine responses (surge in epinephrine/norepinephrine, adrenocorticotropic hormone, and corticosteroid levels). Anxiety is a sustained reaction in advance to a potentially harming but ill-defined outcome.

hodology Study of pathways. In neurobiology, hodology is used to define the study of the interconnections of brain cells and areas.

homeotic genes A set of genes characterized by a sequence (homeobox) whose product constitutes a DNA-binding homeodomain. This binding to DNA mediates their ability to modulate or control transcription of other genes (in other words, homeotic genes code transcription factors). The expression of homeotic genes during early development determines the main positional coordinates of the different body parts, thus being fundamental for morphogenesis.

pheromone Substance secreted or excreted by an animal that has an intrinsic biological significance for conspecifics, thus inducing an unconditioned behavioral or neuroendocrine response. Although it is assumed that pheromones are mainly detected by the vomeronasal organ, it has not been demonstrated in every instance. Moreover, the vomeronasal organ also detects signals from common predators or preys, which obviously cannot be considered pheromones. Finally, some pheromones have been shown to be detected by the main olfactory system.

reinforcement, reward Etymologically, reinforcement means strengthening. In psychological terms, reinforcement designates the increase in the probability of expressing a given behavior induced by the positive outcome that this behavior renders, in the context of instrumental conditioning. Reinforcers (stimuli-reinforcing behaviors) are usually perceived as pleasant or rewarding, so that in many instances rewarding is used as synonymous with reinforcing.

stimulus–reward association Associative learning in which an initially neutral stimulus that precedes or is presented together with a reinforcer, becomes rewarding (secondary or conditioned reinforcer). After this association, the animal would work for the secondary reward.

topography Physical relationships of regions in the adult brain. For example, *A* is topographically dorsal to *B* if, in histological sections of the adult brain, *A* occupies a location nearer the dorsum than *B*.

topology In terms of anatomy, this refers to physical relationships of regions based upon their developmental history. Thus, when a structure *A* is said to be topologically deep to structure *B*, it is means that *A* and *B* derive from the same region of the embryonic neuroepithelium. Topology and topography may not coincide: a structure may be topologically lateral to another, but, due to a flexure of the medio-lateral axis, appears (topographically) medial to it in the adult brain.

Abbreviations: Mammals

AA Anterior amygdaloid area (AAD: dorsal; AAV: ventral).

AB Accessory basal (or basomedial) nucleus of the amygdala (ABa: anterior; ABp: posterior).

Acb Nucleus accumbens.

AHA Amygdalohippocampal area (or posterior nucleus of the amygdala).

APir Amygdalopiriform transition area.

AStr Amygdalostriatal transition area.

B	Basal (or basolateral) nucleus of the amygdala (Ba: anterior; Bp: posterior; Bv: ventral).
BAOT	Nucleus of the accessory olfactory tract.
BST	Bed nucleus of the stria terminalis.
Ce	Central amygdala.
CeC	Capsular or paracapsular division of the central amygdala.
CeL	Lateral central amygdala.
CeM	Medial central amygdala.
Cl	Claustrum.
COAa	Anterior cortical amygdala.
COApl	Posterior lateral cortical amygdala or periamygdaloid cortex.
COApm	Posterior medial cortical amygdala.
CPu	Caudate putamen (striatum).
CxA	Corticoamygdaloid transition.
DEn	Dorsal endopiriform nucleus.
DG	Dentate gyrus.
EA	Extended amygdala (CeEA: central; MeEA: medial).
I	Intercalated nuclei of amygdala.
IPAC	Interstitial nucleus of the posterior limb of the anterior commissure.
L	Lateral nucleus of the amygdala.
LGP	Lateral globus pallidus.
lot	Lateral olfactory tract.
LOT	Nucleus of the lateral olfactory tract.
Me	Medial amygdala.
MeA	Anterior medial amygdala.
MeP	Posterior medial amygdala (MePV: ventral; MePD: dorsal).
MGm	Medial division of the medial geniculate nucleus.
Pir	Piriform cortex.
PMv	Ventral premammillary nucleus.
SI	Substantia innominata.
SN	Substantia nigra.
st	Stria terminalis.
TR	Postpiriform transition area.
VEn	Ventral endopiriform nucleus.
VMH	Ventromedial nucleus of the hypothalamus.
VTA	Ventral tegmental area.

Abbreviations: Reptiles

ac	Anterior commissure.
Acb	Nucleus accumbens.
ADVR	Anterior dorsal ventricular ridge.
Amb	Nucleus ambiguus.
aot	Accessory olfactory tract.
BAOT	Nucleus of the accessory olfactory tract.
BST	Bed nucleus of the stria terminalis.
BSTl	Dorsolateral (supracommisural) division of the BST.
BSTm	Ventromedial (subcommissural) division of the BST.
DC	Dorsal cortex.
DLA	Dorsolateral amygdaloid nucleus.
dLC	Deep lateral cortex.
DMX	Dorsal motor nucleus of the vagus.
DSt	Dorsal striatum.
GP	Globus pallidus.
LA	Lateral amygdala.
LC	Lateral cortex.
LCc	Caudal lateral cortex.
lfb	Lateral forebrain bundle.
LHN	Lateral posterior hypothalamic nucleus.
lot	Lateral olfactory tract.
MA	Medial amygdala.
MC	Medial cortex.
NAOT	Nucleus of the accessory olfactory tract.
NLOT	Nucleus of the lateral olfactory tract.
NS	Nucleus sphericus.
PB	Parabrachial nucleus.
PDVR	Posterior dorsal ventricular ridge (PDVRv: ventral; PDVRdl: Dorsolateral; PDVRdm: dorsomedial).
PMv	Ventral premammillary nucleus.
S	Septum.
SAT	Striatoamygdaloid transition area (SATm: medial; SATl: lateral).
sm	Stria medullaris.
sol	Nucleus of the solitary tract.
st	Stria terminalis.
VAA	Ventral anterior amygdala.
Vds	Nucleus descendens nervi trigemini.
VMH	Ventromedial nucleus of the hypothalamus.
VP	Ventral pallidum.
VPA	Ventral posterior amygdala.
zl	Zona limitans.

Abbreviations: Birds

AA	Anterior arcopallium (anterior archistriatum).
Acb	Nucleus accumbens (medial aspect of the lobus paraolfactorius).
AD	Dorsal arcopallium (dorsal intermediate archistriatum).
AM	Medial arcopallium (medial archistriatum).

APH	Parahippocampal area.
AV	Ventral arcopallium (ventral intermediate archistriatum).
Bas	Nucleus basorostralis pallii.
BSTl	Lateral bed nucleus of the stria terminalis (called BST or nucleus accumbens depending on the authors).
BSTm	Medial bed nucleus of the stria terminalis.
CDL	Area corticoidea dorsolateralis.
CPi	Cortex piriformis.
E	Entopallium.
FA	Tractus frontoarcopallialis (frontoarchistriatalis).
GP	Globus pallidus (paleostriatum primitivum).
H	Hyperpallium.
Hp	Hippocampus.
INP	Intrapeduncular nucleus.
L	Field L of the NC.
LAD	Lamina arcopallialis dorsalis.
lfb	Lateral forebrain bundle.
LM	Lamina mesopallialis.
LPS	Lamina palliosubpallialis.
LSt	Lateral striatum (paleostriatum augmentatum).
M	Ventral mesopallium (hyperstriatum ventrale).
MSt	Medial striatum (lateral aspect of the lobus paraolfactorius, just medial to the paleostriatum).
N	Nidopallium (neostriatum).
NC	Caudal nidopallium, usually divided into lateral (NCL) and medial divisions (NCM).
OB	Olfactory bulb.
OM	Occipitomesencephalic tract.
OMH	Occipitomesencephalic tract, hypothalamic part.
PoA	Posterior nucleus of the pallial amygdala (posterior archistriatum).
Rt	Nucleus rotundus.
S	Septum.
SpA	Subpallial amygdala (ventral paleostriatum).
TnA	Nucleus teniae of the amygdala.
TPO	Area temporoparieto-occipitalis of the cerebral hemispheres.
tsm	Tractus septopalliomesencephalicus.
VP	Ventral pallidum.

Abbreviations: Amphibians

Aa	Anterior amygdala.
BST	Bed nucleus of the stria terminalis (BSTr: rostral; BSTc: caudal).
Ca	Central amygdala.
Dp	Dorsal pallium.
La	Lateral amygdala.
lfb	Lateral forebrain bundle.
Lp	Lateral pallium.
Ls	Lateral septum.
Ma	Medial amygdala.
Mp	Medial pallium.
PLa	Posterior lateral amygdala.
POA	Anterior preoptic area.
Str	Striatum.

Other Abbreviations

AChase	Acetylcholinesterase.
ChAT	Choline acetyltransferase.
CRF	Corticotropin-releasing factor.
NT	Neurotensin.
SP	Substance P.
SS	Somatostatin.

2.14.1 Introduction

The name amygdala (from the Latin–Greek *amygdala*, almond) was coined by Burdach (cited by Swanson and Petrovich, 1998) to designate an almond-shaped structure deep in the temporal lobe of the human brain. The amygdala is easy to identify macroscopically in the brain of many mammals as a smooth bump in the caudal ventral cerebral hemispheres (e.g., rat, lamb; Figure 1). In both lissencephalic and gyrencephalic mammals the amygdala is ventral to the rhinal fissure and apparently connected with the lateral olfactory tract (*lot*), which reflects the olfactory and vomeronasal function of some of its components.

A closer look at the mammalian amygdala reveals, however, that it is an extremely complex and anatomically heterogeneous structure. Thus, in the first comparative approach to the anatomy of the amygdala of vertebrates, Johnston (1923) proposed that the amygdala includes pallial (basolateral and cortical divisions) and subpallial derivatives (central and medial amygdala), a view demonstrated by Swanson and Petrovich (1998). Moreover, the amygdala is not just a component of the chemosensory (olfactory and vomeronasal) systems, but also includes nonchemosensory areas of diverse embryological origin displaying distinct anatomical and neurochemical features. This has led Swanson and Petrovich to conclude that "terms such as 'amygdala' ... combine cell groups arbitrarily rather than according to the structural and functional units to which they seem to belong. The amygdala is neither a structural nor a functional unit."

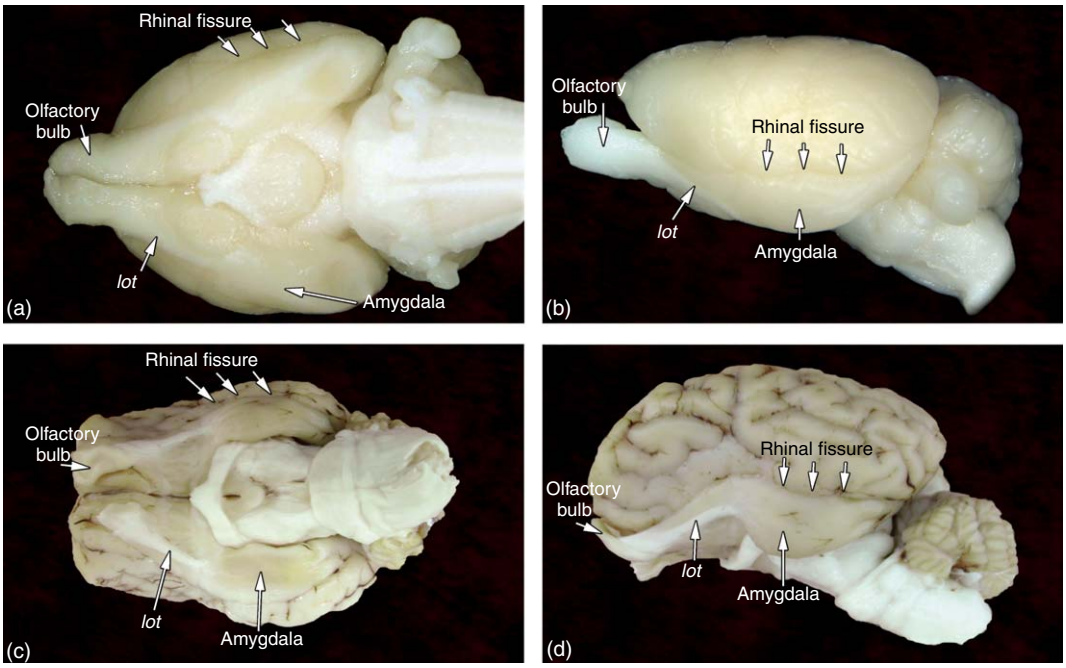

Figure 1 Gross anatomy of the mammalian amygdala. The amygdala can be easily identified in the brains of lissencephalic (e.g., the rat; ventral view (a); lateral view (b)) and gyrencephalic mammals (e.g., the lamb; ventral (c); lateral (d)). In both cases, the lateral olfactory tract (*lot*) can be followed from the olfactory bulbs up to a basal bump in the caudal cerebral hemispheres that corresponds to the amygdala.

The extreme morphological and functional complexity of the mammalian amygdala makes identifying its diverse components in nonmammals a very demanding task. This is further rendered difficult by the strong differences in the anatomical organization of the cerebral hemispheres of mammals and nonmammals, derived from the development of a huge isocortex in the mammalian forebrain. Therefore, a previous step to the comparative study of the amygdala of vertebrates is to characterize the divisions of the mammalian amygdala using developmental approaches (including expression of homeotic genes) as well as neurochemical and hodological data in the adult. Once the mammalian amygdala is fully characterized, we will identify the divisions of the amygdala of reptiles and birds using the same criteria. Then, we will discuss the evolutionary origins of the amniote amygdala and the possible influence that the amygdaloid function might have had on the evolution of the cerebral hemispheres.

2.14.2 Anatomical Heterogeneity of the Mammalian Amygdala

As a previous step to the study of the anatomy of the mammalian amygdala, and to understand its position within the cerebral hemispheres, we briefly discuss the identity and characteristic features of the main divisions of the vertebrate telencephalon: the pallium, striatum, and pallidum (Figure 2).

2.14.2.1 Organization of the Cerebral Hemispheres

In 1975, two groups independently observed that the nucleus accumbens (Acb) and olfactory tubercle showed a set of connections with the midbrain tegmentum that recalled those of the caudate putamen (CPu: Heimer and Wilson, 1975; Swanson and Cowan, 1975). Based on this evidence, Heimer and Wilson (1975) suggested that the Acb, olfactory tubercle, and fundus striatum were just the ventral portion of the striatum, the dorsal one being the CPu. Recent studies have revealed further similarities between the dorsal and ventral portions of the striatum, pertaining to their intrinsic organization, extrinsic connections, and neurochemistry. The common pattern of organization shared by all the striatal structures includes a massive glutamatergic input from areas of the cortex (archicortex – hippocampal formation – for the ventral striatum, isocortex for the dorsal striatum), as well as direct and indirect (through the ventral pallidum (VP) and globus pallidus (GP)) efferent projections to tegmental centers (ventral tegmental area (VTA) and substantia nigra

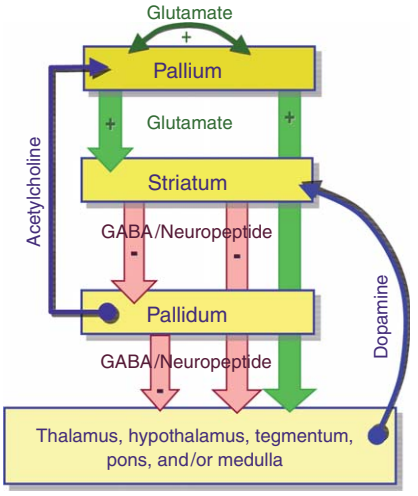

Figure 2 Organization of the vertebrate cerebral hemispheres. The telencephalon of vertebrates is composed of the pallium (cortex and other nuclear pallial centers) and subpallium (striatum and pallidum). The pallium gives rise to glutamatergic (excitatory) intrapallial and descending projections that reach the striatum and several extratelencephalic targets. The subpallium is engaged in a striatopallidotegmentostriatal loop in which the descending projections are GABAergic and peptidergic, whereas the tegmentostriatal pathway is dopaminergic. Both the pallium and subpallium project (directly or indirectly) to extratelencephalic executive centers. Whereas the pallium has an excitatory influence on them, the subpallium probably affects behavior by disinhibition. Based on Swanson and Risold (1999) and Lanuza *et al.* (2002).

(SN)), arising from spiny stellate, GABAergic (and peptidergic) cells. In turn, the tegmental targets of the striatum give rise to dopaminergic projections back to their striatal input areas (Figure 2).

Recent studies have revised and expanded this view. Thus, Swanson and Risold (1999) have reinterpreted the lateral septum as a portion of the striatum that they call the medial striatum (MSt), following a suggestion by Ramón y Cajal (1901). Like the striatum proper, the lateral septum receives a dense glutamatergic input from parts of the cortex (hippocampal formation *sensu lato*). Moreover, the spiny stellate cells of the lateral septum originate a GABAergic projection to pallidal (medial septum and diagonal band complex, which is thus considered the medial pallidum) and tegmental structures (VTA) from which they receive, in turn, a dopaminergic afferent. This scheme has been further extended to the cerebral hemispheres of all amniote vertebrates (Lanuza *et al.*, 2002). As indicated in Figure 2, the corticostriatopallidal pathway (including the striatotegmental loop) seems to be the basic circuit of the cerebral hemispheres. In addition to the hodological and neurochemical features mentioned above, this circuit is further characterized by the presence of dense (glutamatergic) corticocortical connections including, in some cases, commissural projections. Cortical connections also include descending projections to the thalamus, hypothalamus, pons, tegmentum, and/or brainstem that bypass the striatopallidum. Finally, a sparse population of cholinergic cells (and some GABAergic ones; Kohler *et al.*, 1984; Zaborszky *et al.*, 1999; Sarter and Bruno, 2002) located in the striatopallidum provides a feedback to the cortex.

The organization of the mammalian amygdala and its diverse anatomical components can be studied by using this simple model of the cerebral hemispheres that considers them to be composed of pallial structures, derived of the embryonic pallium, and subpallial ones, which are the adult derivatives of the ganglionic eminences. Although tangential migration during embryonic development (Marin and Rubenstein, 2003) might have partially blurred this scheme, it is still a useful framework to describe the anatomical heterogeneity of the amygdaloid complex.

2.14.2.2 The Pallial Amygdala

The definition of the pallial territories in the adult brain is a complex issue, as it is to delineate its different regions or compartments. This is so because not all the pallial territories use the same developmental program. Parts of the pallium develop in a very organized way, according to which those neurons produced in different times migrate following a neurogenetic gradient, either inside-out (isocortex) or outside-in (e.g., hippocampal fascia dentate; Jacobson, 1991). This leads to the formation of a cortex, a superficial structure showing a layered cytoarchitectonic organization that makes it easy to identify. Other pallial derivatives, however, the claustrum (Cl) and the endopiriform nucleus being good examples, show not a cortical but rather a nuclear organization, with no apparent stratification. We call them nuclear pallial structures. Since the amygdala occupies the lateroventral edge of the pallium, the nuclear pallial derivatives of the amygdala are adjacent to subpallial ones that are equally nonlayered, so that the palliosubpallial boundary becomes especially difficult to trace within the amygdaloid complex.

Two kinds of additional data can be helpful to delineate the palliosubpallial boundary. First, the pallium and subpallium express different sets of homeotic genes during intermediate embryonic development. Thus, the maps of expression of these genes in embryos are used to cartograph the pallial and subpallial territories of the amygdala (Puelles *et al.*, 2000; Medina *et al.*, 2004). However, during late embryonic stages, the

amygdala undergoes a topologically complex development that makes it difficult to interpret the fate of the embryonic labeled territories. This may be further complicated by tangential migration similar to that reported to occur from subpallial to pallial territories (Marin and Rubenstein, 2003).

Therefore, data on the neurochemistry and neuronal morphology of the adult brain are also helpful in this respect. As Swanson and Petrovich (1998) pointed out, pallial structures are characterized by originating excitatory (mostly glutamatergic) extrinsic projections to the subpallium and brainstem (as well as intrapallial projections), whereas subpallial structures give rise to descending GABAergic projections. Whereas labeling of GABAergic cells is relatively easy by using immunohistochemistry for GABA or glutamic acid decarboxylase (GAD), and/or *in situ* hybridization for the detection of GAD mRNA, the histochemical mapping of glutamatergic cells is not as easy. Nevertheless, it is well known that a subpopulation of the glutamatergic cells of the cerebral hemispheres are rich in zinc (Frederickson *et al.*, 2000) and can be visualized using a variety of histochemical techniques. The maps of the expression of GAD (Pare and Smith, 1993; Swanson and Petrovich, 1998) and of the distribution of zinc-rich (glutamatergic) cells in the amygdala of rats (Christensen and Geneser, 1995; Brown and Dyck, 2004) are nicely complementary and delineate quite a clear pallio-subpallial boundary. These data indicate that the subpallial amygdala includes the medial and central nuclei of the amygdala and the BST (at least its intra-amygdaloid portion). The remaining nuclei, including all the cortical amygdala and the AHA, as well as the whole basolateral division of the amygdala (lateral, basal, or basolateral and basal accessory or basomedial nuclei) are pallial derivatives (Figures 3 and 4). The presence of zinc-laden cells in the amygdalostriatal area (Brown and Dyck, 2004) suggests that some pallial cells may have migrated into putative striatal territories.

2.14.2.2.1 The cortical and basolateral divisions of the amygdala The pallial amygdala is composed of two kinds of structures. Some of them are superficial and show a layered organization, thus constituting the cortical amygdala. Topologically deep to these structures (and to the adjacent piriform cortex, see below) one finds a series of cell groups with nuclear configuration that conform the basolateral division of the amygdala. Some additional nuclei, not included in the basolateral amygdala, such as the AHA are also deep nuclear pallial structures.

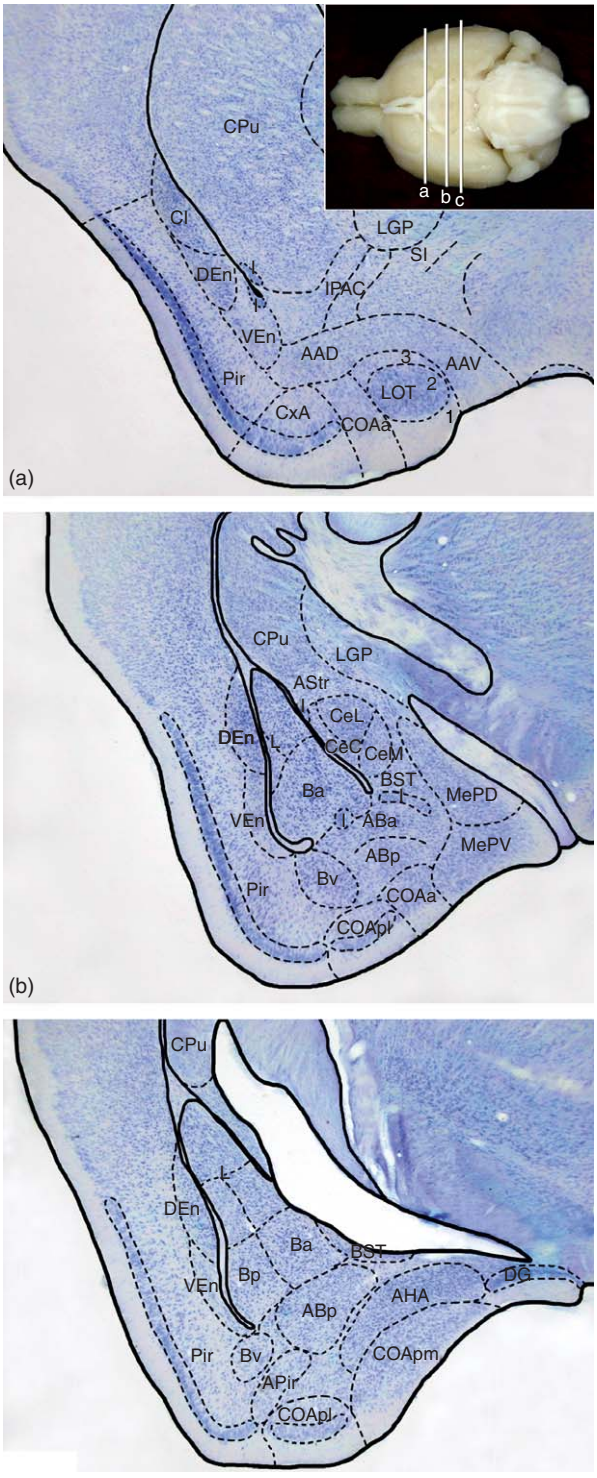

Figure 3 Cytoarchitecture of the amygdala of the mouse. Nissl-stained frontal sections through the left cerebral hemisphere of a mouse at about commissural (a); anterior postcommissural (b); and caudal levels of the telencephalon (c). The approximate levels of the sections are indicated on a ventral view of the brain in the inset. The cytoarchitectonic boundaries of the different amygdaloid nuclei and adjoining structures are delineated on the sections (for abbreviations, see 'Glossary').

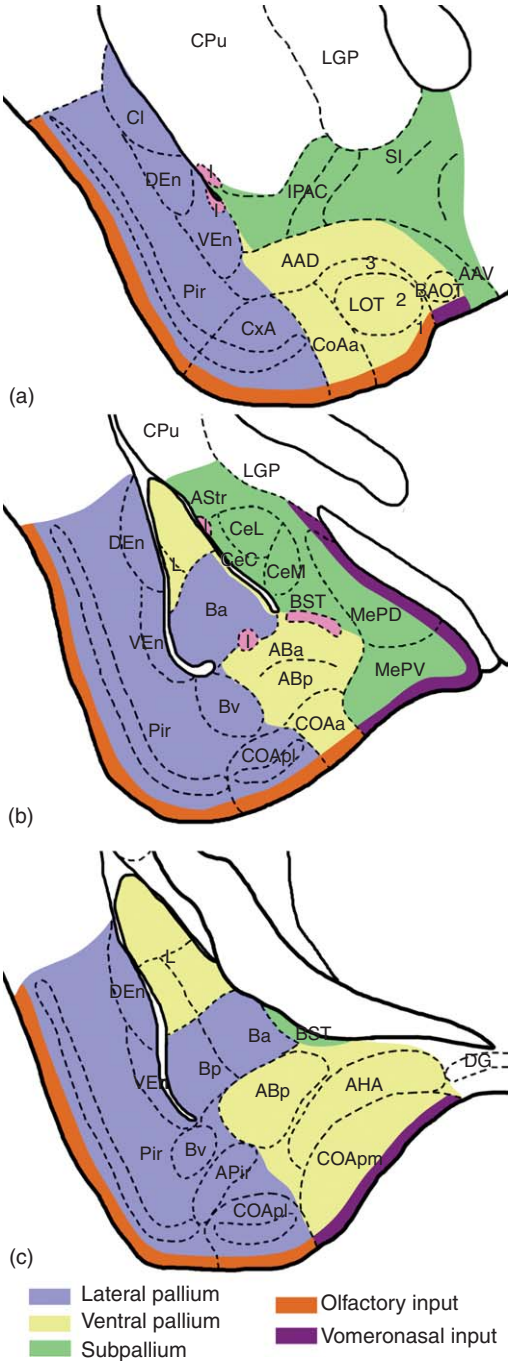

Figure 4 Pallial and subpallial territories of the mammalian amygdala. A schematic diagram of the mammalian amygdala, based on the Nissl-stained sections shown in Figure 3, shows the palliosubpallial boundary and the extent of the latero- and ventropallial territories within the pallial amygdala. The main olfactory bulb projects to entire superficial lateral pallium plus a small portion of the ventral pallium. In contrast, as indicated, the accessory olfactory bulbs project exclusively to ventropallial and subpallial structures. The intercalated cell masses (pink) and the amygdaloid capsule connect the deepest (L) with the more superficial (AB, COApm) parts of the ventropallial amygdala. This gives topological congruence to the proposed picture, since the deep lateral pallium (Ba) is separated from the subpallium (Ce and intra-amygdaloid BST) by a ventropallial bridge.

The cortical amygdala is composed of several areas on the ventral surface of the caudal cerebral hemispheres. These include the nuclei of the accessory (BAOT) and lateral olfactory tract (LOT), as well as the anterior cortical amygdala (COAa) rostrally, and the posterior cortical amygdala (the medial part, COApm, and the lateral part, COApl; also called periamygdaloid cortex by some authors) caudally. To these structures, some authors add rostral (corticoamygdaloid, CxA) and caudal (amygdalopiriform, APir; postpiriform, TR) transitional areas. All these structures show a similar (though not equally neat) layering with a (molecular) layer 1 that receives a superficial projection from the main (LOT, COAa, COApl) or accessory olfactory bulb (BAOT, COApm) and a deeper commissural-associative afferent (McDonald, 1998), thus resembling the piriform cortex.

The nuclear pallial amygdala includes at least the three nuclei that conform the basolateral division of the amygdala: the basal (B, or basolateral), accessory basal (AB, or basomedial) and lateral (L) nuclei. In addition, some of the structures rostral and caudal to these nuclei and deep to the cortical amygdala and/or the piriform cortex also belong to the pallial noncortical amygdala. Thus, the AHA (included in the posterior nucleus of the amygdala by Swanson and collaborators; Canteras *et al.*, 1992a) seems to be a caudomedial continuation of the AB. On the other hand, the dorsal portion of the anterior amygdaloid area (AA), which is immediately deep to the COAa and LOT, seems a rostral continuation of the AB.

2.14.2.2.2 Compartments of the pallium: Lateropallial and ventropallial portions of the mammalian amygdala Pallial derivatives occupy the dorsal surface of the cerebral hemispheres from the midline to the lateral ventricular sulcus. It is generally assumed (although this division is not based on solid experimental evidence) that the cortex is composed of three wide areas, derived from the medial, dorsal, and lateral pallia. In mammalian neuroanatomy, this roughly fits the traditional classification of the cortex into three cytoarchitectonically distinct regions: from medial to lateral, (1) the archicortex with a single cell layer sandwiched between two plexiform layers (hippocampal formation); (2) the isocortex (or neocortex) with 5–6 cell layers plus a molecular layer on top of the white matter; and (3) the paleocortex (olfactory cortex), characterized by a superficial molecular layer (I) and two cell layers (plus the endopiriform nucleus). Since the boundaries between these three areas are quite fuzzy, the existence of transitional cortical areas should be

taken into consideration. It is evident that the lateralmost regions of the pallium impinge on the amygdala.

The molecular and developmental bases for such a division of the pallium are not yet clear. Nevertheless, the expression of developmental genes in vertebrate embryos reveals an unexpected heterogeneity within the lateral aspect of the pallium (Puelles *et al.*, 2000; Medina *et al.*, 2004) that has led to the identification of a fourth pallial region, the ventral pallium (previously considered by Smith-Fernandez *et al.*, 1998, as an intermediate zone between the pallium and the subpallium). The ventral pallium was defined by a pattern of genetic expression that includes several pallial markers (Tbr-1 and a juxtaventricular rim of Pax-6) but excludes Emx-1 (Puelles *et al.*, 2000). *In situ* hybridization in 15-day-old mouse embryos indicates that the amygdala includes ventropallial derivatives together with portions of the lateral pallium (Puelles *et al.*, 2000; Puelles, 2001). Medina *et al.* (2004) further refined this analysis and demonstrated that during late embryonic development the lateral and ventral pallial territories display a differential pattern of genetic expression (lateral pallium: *Cadherin 8* and *Emx-1*; ventral pallium: *Dbx-1*, *Neurogenin*, and *Semaphorin 5A*).

From a comparative viewpoint, assigning each one of the areas and nuclei of the pallial amygdala to either the lateral or ventral pallium constitutes a key issue. Namely, derivatives of the embryonic ventral pallium of mammals can only be homologous to ventropallial structures of nonmammals, and the same is valid for the lateropallial derivatives. Data on the expression of homeotic genes during embryonic development, derived from the above-cited studies (Puelles, 2001; Medina *et al.*, 2004), indicate that the only lateropallial derivatives of the amygdala are the basal nucleus (B) and posterolateral cortical amygdala (COApl). In addition, it is likely that the transitional territories located between the cortical amygdala and the piriform/entorhinal cortex (CxA, APir, TR) also belong to the lateral pallium.

An analysis of the topology of the mammalian amygdala indicates that the remaining areas and nuclei of the pallial amygdala are ventropallial, since they are adjacent to striatal territories. Thus, the ventropallial division of the cortical amygdala consists of the LOT, COAa, BAOT, and COApm. In addition, the L and AB constitute the deep ventropallial amygdala. Thus, the L is adjacent to the striatal derivatives such as the CPu, the striatoamygdaloid transition, and the central amygdala. On the other hand, the AB and maybe its rostral (dorsal AA) and caudal neighbors (AHA) are adjacent to the Me (anterior or posterior divisions) and to the intra-amygdaloid portion of the BST. Topology demands that the B (lateropallial) and the Ce (striatal) be separated by a rim of ventropallial territory. This is likely constituted by the amygdaloid capsule and the adjoining posterior paracapsular intercalated cell masses of the amygdala (Medina *et al.*, 2004).

This renders a scheme of the mammalian pallial amygdala (Figure 4) in which every nucleus or area belongs to a compartment depending on its superficial or deep position as well as its ventropallial or lateropallial nature.

2.14.2.3 The Subpallial Amygdala

As discussed above, the subpallial telencephalon develops from two structures of the embryonic cerebral hemispheres, namely the lateral and medial ganglionic eminences. It is generally assumed that the pallidum of the adult telencephalon (including the GP, VP, and medial pallidum or medial septum, according to Swanson and Risold, 1999) derives from the embryonic medial ganglionic eminence. On the other hand, the Acb, olfactory tubercle, and CPu (striatal structures) are supposedly the adult derivatives of the lateral ganglionic eminence.

2.14.2.3.1 Striatal and pallidal compartments within the subpallial amygdala In the caudal cerebral hemispheres the striatal or pallidal identity of the subpallial structures becomes confused. These include the BST (both their intra- and extra-amygdaloid portions), the central amygdala (Ce), and the medial amygdala (Me) and several adjoining structures. The Ce is composed of three subnuclei, namely the medial (CeM) and lateral (CeL) divisions, plus the lateral-most cell group in touch with the amygdaloid capsule, the capsular or paracapsular central amygdala (CeC). Some authors consider that the CeC includes a ventral portion of the caudate, recognized by other authors as an independent structure called the amygdalostriatal transition (Cassell *et al.*, 1999). The Me is usually divided into anterior (MeA) and posterior parts, the latter divided in turn into a dorsal (MePD) and a ventral division (MePV). With regard to the extra-amygdaloid BST, it includes the supracapsular part plus a myriad of subnuclei within the BST proper, most of which receive topographical names. A detailed description of the BST is beyond the scope of this review. The interested reader is referred to Moga *et al.* (1989) and Dong *et al.* (2001). To sum up, an anterior and a posterior division of the BST are generally recognized. The anterior BST is

composed of several cell groups surrounding the anterior limb of the anterior commissure caudal to the Acb. The posterior division consists of several cell groups caudal to the anterior commissure, which apparently impinge on the preoptic hypothalamus.

Data on the neurochemistry, connections, neuronal morphology, and the pattern of expression of homeotic genes during embryonic development should be used to trace the pallidostriatal boundary at the level of the subpallial amygdala. Swanson and Petrovich (1998) delineated the palliosubpallial boundary by studying the expression of GAD mRNA. Topology requires that those subpallial structures that are in contact with pallial ones be striatal derivatives. Thus, these researchers proposed that the medial and central amygdaloid nuclei constitute the caudal tip of the (ventral) striatum. In addition, it is generally agreed that the BST constitutes a part of the pallidal complex related to the septal or amygdaloid formations (Swanson and Risold, 1999), since it derives from the medial ganglionic eminence. Taking these considerations into account, the projections from the basolateral division of the amygdala to the central and medial amygdala (Dong *et al.*, 2001) should be interpreted as corticostriatal projections (palliostriatal, glutamatergic), whereas the well-known projections from the central and medial amygdaloid nuclei to the anterior and posterior (roughly) portions of the BST (Dong *et al.*, 2001) would represent striatopallidal projections (GABAergic). However, as discussed in the next section, a closer analysis of the available evidence indicates a more complex panorama.

2.14.2.3.2 The extended amygdala: A striatopallidal structure or a third subpallial compartment? On the one hand, the basolateral amygdala projects not only to the Ce and/or Me (corticostriatal intra-amygdaloid pathways), but also portions of the BST (Adamec, 1989; Dong *et al.*, 2001). This projection is rich in zinc (Perez-Clausell *et al.*, 1989), thus glutamatergic, so that it represents a corticopallidal glutamatergic pathway that would contravene the scheme proposed for the organization of the cerebral hemispheres (but see Naito and Kita, 1994). On the other hand, the subpallial amygdala, including the BST, displays bidirectional intrinsic connections: as expected, the putative striatal compartments (Me and Ce) project to presumptive pallidal structures (anterior and posterior BST), but there are also important projections from the BST back to the Ce and Me (Ottersen, 1980; Coolen and Wood, 1998; McDonald *et al.*, 1999; Shammah-Lagnado and Santiago, 1999; Dong *et al.*, 2000; Shammah-Lagnado *et al.*, 2000; Dong and Swanson, 2003, 2004a, 2004b), which would represent pallidostriatal pathways. Therefore, the above-described general scheme on the organization of the cerebral hemispheres does not fit the hodological and histochemical features of the subpallial amygdala.

The exceptional properties of this region of the cerebral hemispheres have generated the idea that they belong to a third area of the subpallial telencephalon known as the extended amygdala (EA) (Alheid and Heimer, 1988; Olmos and Heimer, 1999; Shammah-Lagnado *et al.*, 1999), usually considered to be composed of two divisions, the central and medial EA (Alheid *et al.*, 1995). The medial EA is composed of the Me and the portions of the BST with which the Me is interconnected (roughly the posterior BST), plus a few intervening cell groups within the sublenticular substantia innominata and supracapsular BST (Shammah-Lagnado *et al.*, 2000). On the other hand, the Ce plus the anterior BST, together with a ring of additional cell groups linking these two structures both above (supracapsular BST) and below the internal capsule (fundus striatum or interstitial nucleus of the posterior limb of the anterior commissure (IPAC), within the sublenticular substantia innominata) make up the central EA. Data are more abundant and convincing for the existence of the central rather than the medial EA.

Although the internal capsule divides the EA into two apparently unconnected poles (Ce/Me amygdala and BST proper), the connective and histochemical properties of both poles of the EA are similar, thus suggesting a functional unity and a structural continuity (Roberts *et al.*, 1982). Thus, the Ce and those divisions of the anterior BST with which it is interconnected show a similar pattern of distribution of cells co-expressing different neuropeptides, such as corticotropin-releasing factor (CRF), neurotensin (NT), and enkephalin or substance P (SP)/somatostatin (SS) (Shimada *et al.*, 1989; Day *et al.*, 1999). In turn, the two main components of the medial EA, the Me and posteromedial BST, possess similar populations of vasopressinergic cells that are sexually dimorphic and display similar projections (Wang *et al.*, 1993).

Indeed, if they are interpreted as striatal or pallidal structures, the medial and central EA are also atypical in other respects besides the existence of intrinsic bidirectional connections and the presence of massive palliopallidal glutamatergic projections. Thus, the EA only receives a scarce tegmental innervation (compared with other

striatal compartments) that reaches presumed pallidal territories as well (BST; Hasue and Shammah-Lagnado, 2002). Moreover, the EA (at least its central division) displays long descending projections directed to the hypothalamus, periaqueductal gray, monoaminergic cell groups in the midbrain and brainstem, parabrachial region, and dorsal vagal complex (see below). This contrasts with the rest of the striatopallidal system, whose descending projections reach specifically the tegmental cell groups that originate their dopaminergic innervation.

The existence of the EA, or the usefulness of the concept of EA, is at the center of an intense debate (Canteras *et al.*, 1995; Swanson and Petrovich, 1998), from which two alternative views for the nature of the subpallial amygdala emerge: either it is viewed as a third subpallial compartment (neither striatal, nor pallidal), the EA, or it is envisaged as a patchwork of distinct striatal (Me and Ce) and pallidal territories (most of the BST). However, McDonald (2003) has recently put forward a third hypothesis that somewhat reconciles both views. According to his view, a certain mixing up of the striatal and pallidal cells has occurred in the caudal cerebral hemispheres. For instance, during embryonic development cells derived from the medial and lateral ganglionic eminences migrate tangentially (as has been shown to happen for the GABAergic cells in the pallium; Marin and Rubenstein, 2003), thus generating a series of structures where the striatopallidal boundaries are very fuzzy. This mixing up of striatal and pallidal cells may have generated special properties for the resulting cell groups, which constitute the above-mentioned distinctive features of the EA.

In line with this view, Cassell *et al.* (1999), using data on the cellular morphology, neurochemistry, and connections of the Ce, have proposed that it is composed of a striatal portion with a core-shell configuration (paracapsular and lateral divisions) and a pallidal one (the medial Ce). McDonald studied the morphology of Golgi-impregnated neurons in the Ce (McDonald, 1982b) and BST (McDonald, 1983). In both nuclei, he found a mixture of typical striatal medium-sized, spiny stellate cells (more abundant in the lateral aspect of both nuclei), with neurons displaying a pallidal morphology (long, thick, sparsely branched dendrites with few or no spines) more abundant in the medial Ce and posterior lateral BST. McDonald (2003) interprets these data as suggestive of a striatal nature of the lateral Ce and dorsolateral BST and of a pallidal or pallidostriatal nature of the rest of both nuclei. It is interesting to note that his drawings (McDonald, 1982a, 1983) show several cases of dendrites arising from cell bodies in the putative striatal compartment of the central EA that cross the boundaries to extend into the presumed pallidal (or striatopallidal) compartment (and vice versa). This dendritic exchange explains why the pallial and striatal projection fields overlap extensively within the central EA. A similar intermingling of striatal and pallidal cells has been suggested for nucleus X of the subpallium of songbirds (Perkel *et al.*, 2002).

This view is easy to test, since it predicts that inputs from pallial regions to the EA (e.g., zinc-positive fibers from the basolateral amygdala) should synapse onto (spiny) dendrites of striatal cells, whereas intrinsic connections within the EA should arise from striatal neurons (medium-sized spiny stellate cells) and terminate on pallidal ones.

2.14.3 Functional Neuroanatomy of the Mammalian Amygdala

Current ideas on the role of the mammalian amygdala in physiology and behavior are based on deep knowledge of its connections and on solid experimental evidence using techniques of functional neuroanatomy (lesion experiments, electrophysiology, and the study of the expression of immediate-early genes). In summary, it is generally accepted that the amygdala receives sensory information from many sources (brainstem, thalamus, olfactory bulbs, and different areas of the cortex) and gives rise to three main output pathways by which it modulates different aspects of behavior and physiology. First, the descending pathways of the central EA to hypothalamic and brainstem centers are involved in the generation of fear/anxiety responses (Davis, 2000; Ledoux, 2000), including motor, vegetative, and endocrine components (although the medial amygdala may also be involved in the endocrine responses to emotional stressors; Dayas *et al.*, 1999). Second, projections from the medial EA (and portions of the pallial amygdala) to hypothalamic centers probably constitute the pathway that mediates the neuroendocrine (and maybe some behavioral) responses to chemical cues (e.g., pheromones) in relation to reproduction (Newman, 2002; Halpern and Martinez-Marcos, 2003) but also to agonistic behaviors (Meredith and Westberry, 2004). Finally, the massive amygdalostriatal projections arising from the basolateral division of the amygdala and terminating in the ventral (but also in the dorsal) striatum seem involved in reward-related processes (Baxter and Murray, 2002). In this

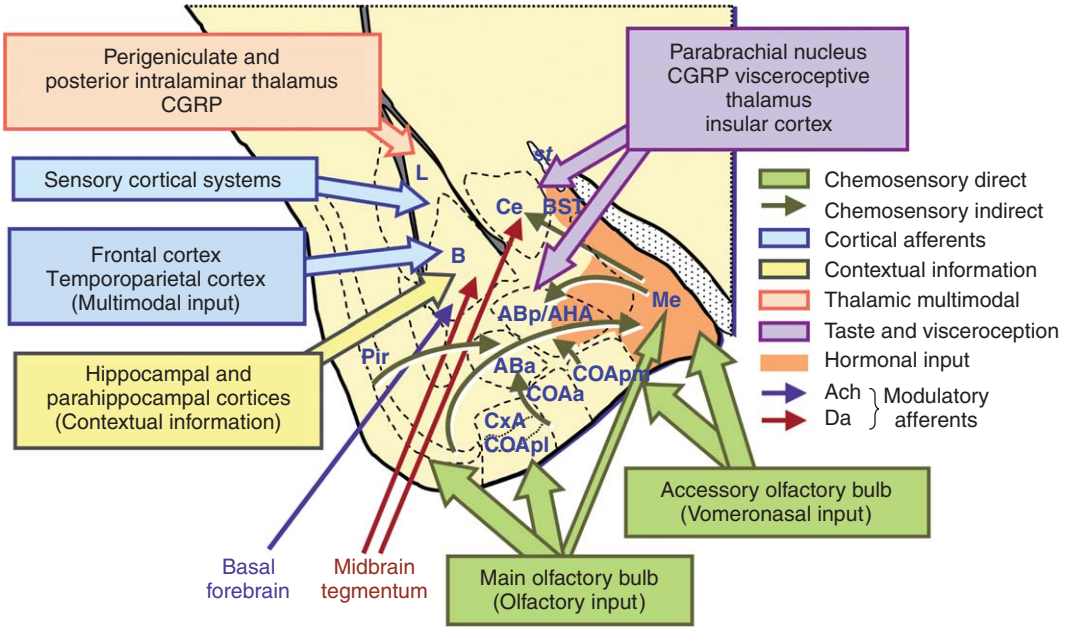

Figure 5 Inputs to the mammalian amygdala. Besides the olfactory and vomeronasal inputs to the corticomedial amygdala from the olfactory bulbs, the deep nuclei of the amygdala are targeted by brainstem, thalamic, and cortical afferents. The cortical inputs arise from different portions of the isocortex, including secondary and tertiary sensory areas, the frontal and temporal associative isocortex, the archicortex (hippocampal formation, *sensu lato*) and the paleocortex (see green arrows arising from the piriform cortex). The latter projection, together with the intra-amygdaloid projections from the corticomedial amygdala, makes the basolateral amygdala an olfactory–vomeronasal-associative center. As detailed in the text, most of the nonolfactory afferents reach both the basolateral and the central amygdala. Among them, it should be noticed that part of the thalamic and brainstem (parabrachial) sensory afferents contains the peptide CGRP. Several modulatory afferents reach the amygdala from many different sources, among which the cholinergic and dopaminergic ones (arising from the basal forebrain and the ventral tegmentum, respectively) converge on the B nucleus.

context, the intricate intrinsic circuitry of the amygdala apparently provides a basis for convergence of different stimuli onto amygdaloid neurons (especially in the basolateral amygdala, Pitkanen, 2000), which by means of synaptic plasticity (Blair *et al.*, 2001) would lead to the establishment of learned responses (e.g., conditioned fear or secondary reward).

In order to review the functional anatomy of the amygdala we will first describe the neural pathways that convey sensory information to the amygdala. Other afferents with a less clear sensory significance but having a modulatory role will be described. Moreover, different cell groups in the amygdala express receptors to steroid hormones, thus providing endocrine inputs to the amygdala, which will also be reviewed. Finally, the outputs of the amygdala will be analyzed on the context of their role in the expression of behavior and physiologically related processes.

2.14.3.1 Inputs to the Amygdala

In addition to its direct olfactory and vomeronasal inputs, sensory information reaches the amygdala from three different relay stations (Figure 5). First, some brainstem centers receiving relatively direct projections from the sensory organs project to the amygdala. Second, nuclei of the dorsal thalamus provide the amygdala with unimodal or multimodal sensory afferents. Finally, several parts of the cortex convey highly processed sensory information to the amygdala.

2.14.3.1.1 The amygdala as part of the olfactory and vomeronasal systems The amygdala is the recipient of several afferents from primary or secondary chemosensory centers. The most direct and massive ones arise from the main and accessory olfactory bulbs and terminate in the cortical and medial amygdala. Thus, olfactory information reaches directly the LOT, CxA, COAa, and COApl (although, according to Scalia and Winans (1975), the LOT shows only fiber but not terminal degeneration after lesions of the main olfactory bulbs). On the other hand, the accessory olfactory bulbs provide a direct vomeronasal input to the BAOT, COApm, Me, and portions of the BST (Broadwell, 1975; Scalia and Winans, 1975). Thus, whereas the

main olfactory system includes several cortical areas (parts of the cortical amygdala plus the piriform and entorhinal cortices), there is a single vomeronasal cortex, the COApm. In fact, not only does it receive a dense input from the accessory olfactory bulb but also it projects back to it (Canteras *et al.*, 1992a; Martinez-Marcos and Halpern, 1999). Other connections of the COApm include projections to olfactory centers (piriform cortex and endopiriform nucleus) and to its contralateral counterpart, via the anterior commissure (Canteras *et al.*, 1992a).

However, the amygdala is also a tertiary olfactory center. In fact, the piriform cortex projects to the cortical amygdala (a projection that recalls the associative connections within the olfactory cortex), to parts of the AB and to the Me (McDonald, 1998). Moreover, other cortical areas receiving olfactory projections, such as the CxA (Shammah-Lagnado and Santiago, 1999), and the COApl (or periamygdaloid cortex; Majak and Pitkanen, 2003) do project to the deep pallial amygdaloid structures, such as the anterior AB, posterior B and L nuclei. In addition, the LOT projects massively and bilaterally to the B and parts of the L (Santiago and Shammah-Lagnado, 2004). There is an additional projection, which has important functional implications, from the COApl to the COApm (Canteras *et al.*, 1992a; Majak and Pitkanen, 2003).

The data reveiwed above suggest that the Me is an associative olfactory–vomeronasal center. This associative role of the Me is in agreement with the existence of direct projections from the main olfactory bulb to the anterior Me reported in several mammals, including rabbits, rats, and several species of opossum (Scalia and Winans, 1975; Shammah-Lagnado and Negrao, 1981), as well as the Madagascan hedgehog tenrec (Kunzle and Radtke-Schuller, 2000). Therefore, there is anatomical evidence for an olfactory–vomeronasal convergence in both the Me and COApm. The latter has been confirmed electrophysiologically (Licht and Meredith, 1987).

In a similar way, the amygdaloid nuclei receiving projections from the accessory olfactory bulb also give rise to intrinsic amygdaloid projections. Thus, the Me projects to parts of the Ce and to the medial part of the BST, but also to parts of the basolateral amygdala, including the posterior AB, the AHA, and parts of the L (Gomez and Newman, 1992; Canteras *et al.*, 1995). In addition, the COApm displays a set of projections to the subpallial amygdala, including the Me and portions of the BST, but also to pallial regions such as the AB (Canteras *et al.*, 1992a) and the posterior part of the B (our unpublished results in mice). Finally, the AHA receives a strong input from the BAOT (in addition to the projections already described from parts of the Me).

In conclusion, although the amygdala is usually considered to contain distinct, nonoverlapping olfactory and vomeronasal territories, most of the vomeronasal amygdala (MeA and COApm) receives convergent inputs from the main and accessory olfactory bulbs and it projects, in turn, to several secondary olfactory centers. In addition, intra-amygdaloid connections (superficial to deep), including an intricate set of interconnections within the basolateral division of the amygdala (Pitkanen *et al.*, 1997), allow the association of both modalities of chemosensory information in discrete nuclei and subnuclei of the basolateral division of the amygdala.

2.14.3.1.2 Brainstem sensory afferents: The amygdala as part of the gustatory, viscerosensory, and nociceptive systems Other kinds of chemosensory information also reach the amygdala quite directly. Thus, brainstem gustatory/visceroceptive centers, namely the nucleus of the solitary tract and parabrachial pons (Ricardo and Koh, 1978; Saper and Loewy, 1980; Cechetto and Saper, 1987; Halsell, 1992), as well as the gustatory/visceroceptive thalamus (parvicellular division of the ventroposterior nucleus, central medial, interanteromedial, and paraventricular thalamic nuclei; Turner and Herkenham, 1991) project to different parts of the amygdala. These projections not only terminate in the pallial (nuclear) amygdala (mainly AB and COAa) but also in the subpallial amygdala (CeL and parts of the BST; Zardetto-Smith and Gray, 1987; Volz *et al.*, 1990; Turner and Herkenham, 1991).

It is interesting to note that part of the projection from the parabrachial nucleus to the amygdala contains calcitonin gene-related peptide (CGRP) in humans (de Lacalle and Saper, 2000) and rodents (Schwaber *et al.*, 1988), where this peptide has been shown to coexist with SP (Yamano *et al.*, 1988b) and NT (Yamano *et al.*, 1988a). This projection rich in CGRP/NT/SP, seems to convey specifically nociceptive stimuli (Bernard *et al.*, 1993). In this respect, the CGRPergic innervation of the amygdala consists of a dense fiber plexus in the CeL and CeC, which extends to the so-called amygdalostriatal transition (Figure 6e) and to most of the anterior BST (central EA), but not to the medial EA (Kawai *et al.*, 1985; Kruger *et al.*, 1988; Yasui *et al.*, 1991). As we will see, part of the thalamus also seems to contribute to the CGRP innervation of the central EA and neighboring areas (Yasui *et al.*, 1991).

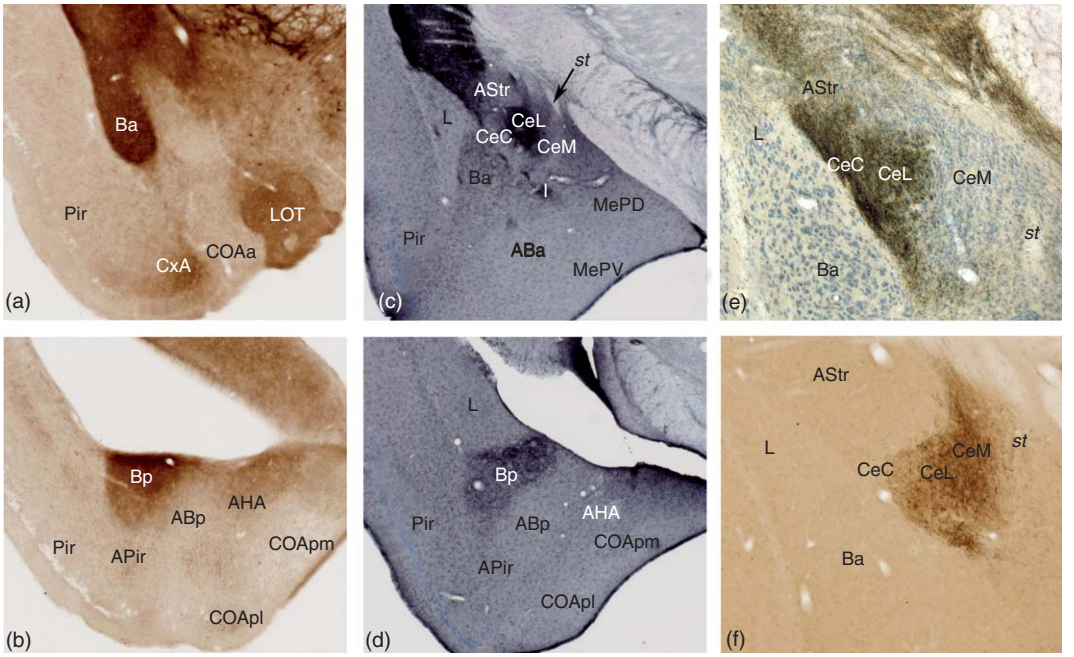

Figure 6 Histochemical features of the amygdala of mammals. a and b, Histochemical detection of AChase reveals a dense cholinergic innervation of the basal nucleus (both anterior, Ba; and posterior parts, Bp), as well as the LOT. c and d, The B (especially the Bp) also receives a distinctive dopaminergic innervation, as revealed by the immunohistochemical detection of dopamine transporter. e and f, The immunohistochemical detection of the peptides CGRP (e) and CRF (f) reveal the presence of two main compartments within the Ce. Thus, the capsular (CeC) and lateral (CeL) parts of the central amygdala display a dense innervation by CGRP-immunoreactive fibers (e). In contrast, most of the CRFergic cells are located in the medial aspect of the nucleus (CeM), although the CeL also displays a few CRFergic cells and fibers (f).

2.14.3.1.3 Thalamic inputs to the amygdala The amygdala is the target for several ascending pathways from the thalamus. As we have already described, the parvicellular division of the ventroposterior nucleus, central medial, interanteromedial, and paraventricular thalamic nuclei relay gustatory and viscероceptive information to the amygdala. In addition, there are reports of afferents to the amygdala from the magnocellular (medial and dorsal) portions of the medial geniculate nucleus, posterior intralaminar, suprageniculate, subparafascicular, and parataenial nuclei (Turner and Herkenham, 1991; Doron and Ledoux, 1999). The posterior intralaminar thalamus is the relay station for the main somatosensory pathways (dorsal column and spinothalamic pathways; Kunzle, 1994) and also receives visual and auditory information from the superior and inferior colliculi (LeDoux *et al.*, 1987; Linke, 1999; Linke *et al.*, 1999). Therefore, the posterior intralaminar thalamus conveys a mixture of somatosensory (mainly nociceptive and thermoceptive), visual, and auditory information to the central and basolateral amygdala (Bordi and Ledoux, 1994). This projection reaches both the pallial (L; Doron and Ledoux, 1999) and subpallial amygdala (Ce plus amygdalostriatal transition; Turner and Herkenham, 1991). Although most of the thalamic projections to the amygdala are glutamatergic (LeDoux and Farb, 1991), part of the projection from the posterior intralaminar thalamus also contains CGRP (Yasui *et al.*, 1991).

2.14.3.1.4 Highly processed sensory inputs: The cortical afferents to the pallial and subpallial amygdala All three main areas of the cortex project to the amygdala: (1) isocortex; (2) paleocortex (piriform cortex and adjacent areas); and (3) archicortex (hippocampus or Hp). For a thorough review of the corticoamygdaloid connections, the reader is referred to McDonald (1998). The pallial amygdala stands as the endpoint of a cascade of projections from the sensory areas of the isocortex. As a rule, projections to the amygdala from primary sensory cortical areas are scarce, if at all present, whereas secondary and associative sensory cortical areas display massive projections to the amygdala. This is true for the auditory temporoperirhinal cortex (Vaudano *et al.*, 1991; Mascagni *et al.*, 1993; Romanski and Ledoux, 1993; Shi and Cassell, 1999) and for the somatosensory parietal posterior insular cortex (Shi and Cassell, 1998a). The

gustatory visceroceptive anterior–posterior insular cortex (Shi and Cassell, 1998b) is exceptional, since both primary and secondary associative areas display important projections to the amygdala. Visual cortical areas also show a cascade-like projection to the amygdala, which is especially clear in cats and primates, where the bulk of the visual inputs to the amygdala arise from visual areas in the inferior temporal lobe, involved in complex higher-order visual processing (Shi and Davis, 2001). Cortical sensory inputs mainly reach the basolateral amygdala (L and B nuclei), though many of the cortical areas also show relatively minor projections to the lateral Ce (McDonald, 1998).

In addition, high-order associative areas of the cortex, such as the hippocampal and parahippocampal cortices (including the subiculum and entorhinal areas) project heavily to the amygdala (Brothers and Finch, 1985; Aggleton, 1986; Canteras and Swanson, 1992; McDonald and Mascagni, 1997). These connections are usually interpreted as providing the amygdala with information about the spatial and temporal context in which events take place (Ergorul and Eichenbaum, 2004). This is demonstrated by the fact that hippocampal lesions impair the capacity of acquiring fear to a context (test cage) where a foot shock is systematically given to the animals, but not to a pure tone with which the foot shock is paired (Phillips and Ledoux, 1992). Hippocampal/parahippocampal projections target the basolateral amygdala (mainly the L, B, and AHA). In addition, parts of the hippocampal and parahippocampal cortex (especially the entorhinal cortex; McDonald and Mascagni, 1997) also project massively to the CeL, Me, and intra-amygdaloid BST (Canteras and Swanson, 1992).

Finally, with minor differences, all the mammals studied (monkeys, cats, and rats; McDonald, 1998) display robust, topographically organized prefronto-amygdaloid projections. These include not only the aforementioned inputs from the anterior insular cortex, but also a set of projections from the medial (prelimbic, infralimbic, and anterior cingulate) and ventrolateral (orbitary) prefrontal areas (Carmichael and Price, 1995; McDonald *et al.*, 1996; Ghashghaei and Barbas, 2002). The prefrontal afferents terminate massively in the basolateral amygdala (B, AB, and L nuclei) but also in parts of the cortical (COAa and COApl) and the subcortical amygdala (CeL, MeA, and parts of the BST). Convergence of all the prefrontal afferents seems to occur, especially upon the B (and to a lesser extent the AB). Instead of providing information on the spatial, temporal, or spectral configuration of specific stimuli, or on the chemical nature of odorants (and pheromones), the prefrontal cortex seems to convey information on the outcomes of detecting incoming stimuli in terms of reward/aversion. In other words, the connections of the prefrontal cortex and amygdala are the substrate for emotional tagging of incoming stimuli by establishing, maintaining, or modifying associations of stimuli with reward (Gaffan *et al.*, 1993; Rolls, 2000) or aversion (Garcia *et al.*, 1999; Morrow *et al.*, 1999). In this context, it has been shown that lesions of the medial prefrontal cortex of rats interfere with the extinction of conditioned fear to a tone (Morgan *et al.*, 1993; Lebron *et al.*, 2004). This indicates that extinction of conditioned fear is an active process that involves modulation of the activity of neurons in the amygdala by prefrontal inputs (Milad and Quirk, 2002).

2.14.3.1.5 Redundant sensory pathways to the amygdala? All these anatomical data indicate that sensory information reaches the amygdala using two different gateways, namely thalamic (plus direct brainstem) afferents and cortical pathways. In this respect, conditioned fear to a simple tone is acquired by rats with either lesions of the medial division of the medial geniculate body (MGm) or of the auditory cortex (including temporal and perirhinal areas), but not by rats with combined cortical and thalamic lesions (Romanski and Ledoux, 1992). This suggests that the thalamic and cortical sensory pathways to the amygdala are redundant (for an alternative interpretation, see Shi and Davis, 2001). Nevertheless, it is likely that both pathways convey different kinds of information. Thus, the thalamic route provides the amygdala with crude sensory information that, nevertheless, can be biologically meaningful, such as loud noises, big moving objects or shadows (e.g., looming objects), pain, visceral sensations or sweet, salty, or bitter taste. In contrast, the cortical sensory pathway provides the amygdala with highly processed sensory information mediating recognition of stimuli with complex spatial (visual stimuli; Tanaka, 1996) or spectrotemporal configuration (e.g., species-specific vocalizations; Wang and Kadia, 2001), multimodal contextual information (hippocampal and parahippocampal (APH) areas), or information about the possible outcomes (reward/aversion) of the incoming stimuli (prefrontal cortex). Although both pathways can be used to elicit responses to simple stimuli (a pure tone), responding to complex stimuli surely requires the intervention of the cortical loop.

This is supported by physiological studies in different species indicating that neurons in the amygdala robustly respond to vocalizations of conspecifics and to biologically relevant sounds emitted by related species (Sawa and Delgado, 1963; Kling *et al.*, 1987), as well as to meaningful visual stimuli such as faces from conspecifics or closely related species (AB nucleus of monkeys; Leonard *et al.*, 1985) or sexually arousing images (humans; Hamann *et al.*, 2004). Interspecies differences are expected on the kind of sensory cortical processing performed (thus, in the cortical areas involved). Thus, primates are specialized in using visual and auditory stimuli for intra- and interspecies recognition, whereas most of the remaining mammals would use auditory or olfactory/vomeronasal cues instead.

2.14.3.1.6 Modulatory afferents: Cholinergic projections from the basal forebrain and tegmental monoaminergic afferents Afferents to the amygdala also include several neurochemically identified afferents. This has both functional and comparative implications. On the one hand, these afferents are surely playing a modulatory role of the amygdaloid function. On the other hand, using (immuno)histochemical tools, the terminal fields of these afferents are easily revealed and help to identify and delineate some of the amygdaloid nuclei (chemoarchitecture). Concerning this, the cholinergic and dopaminergic afferents are especially useful from a comparative viewpoint.

The innervation of pallial derivatives by basal forebrain cholinergic cell groups (Ch1–Ch4, according to the classification by Mesulam *et al.*, 1983) is part of the fundamental circuit of the cerebral hemispheres of, at least, tetrapod vertebrates (Medina and Reiner, 1994; Marin *et al.*, 1997c; Lanuza *et al.*, 2002) and seems to be present in some teleost species (Rodriguez-Moldes *et al.*, 2002; Mueller *et al.*, 2004). Therefore, cholinergic innervation is a neurochemical feature with an added value for comparative neuroanatomy. In this respect, the mammalian amygdala is richly innervated by cholinergic fibers (Amaral and Bassett, 1989), immunoreactive for choline acetyltransferase (ChAT), and positive for acetylcholinesterase (AChase histochemistry). The densest patches of cholinergic innervation are found in the B nucleus and the LOT (Figures 6a and 6b), which represent dense afferents from the Ch4 cholinergic cell group, namely the nucleus basalis–substantia innominata complex (Hecker and Mesulam, 1994).

Second, all the vertebrates studied show important ascending projections to the forebrain from dopaminergic tegmental cell groups (Smeets and Reiner, 1994). This consists of tegmentostriatal projections arising from groups A9 (SN) and A10 (VTA) that mainly terminate in the dorsal and ventral striatum respectively. Indeed, some of the putative striatal components of the mammalian amygdala, such as the Ce (Figure 6c) and the anterior and posterolateral BST (Freedman and Cassell, 1994; Freedman and Shi, 2001) display dopaminergic fibers. These fibers arise from the dorsocaudal A10 group, e.g., dopaminergic cells caudal to the VTA and medial to the SN, within the cytoarchitectonic boundaries of the dorsal raphe nucleus and periaqueductal gray (Hasue and Shammah-Lagnado, 2002). In addition, portions of the pallium are specifically innervated by dopaminergic tegmental cell groups, as is the case for the prefrontal cortex (mesocortical pathway) and the basolateral amygdala. Specifically, a dense plexus of dopaminergic fibers, mainly arising from A10, innervates the caudal aspect of the B nucleus (Fallon *et al.*, 1978; Brinley-Reed and McDonald, 1999; Figures 6c and 6d).

In addition, the amygdala displays distinct serotonergic and adrenergic innervations (Emson *et al.*, 1979; Sadikot and Parent, 1990; Canteras *et al.*, 1992a; Asan, 1998) arising from the raphe complex, and the locus coeruleus and A1/C1 A2/C2 medullary adrenergic cell groups respectively (Myers and Rinaman, 2002). Some of the adrenergic projections from the A1 group also contain neuropeptide Y (Zardetto-Smith and Gray, 1995).

Finally, the amygdala receives projections from diverse hypothalamic nuclei, such as the ventromedial (VMH; Canteras *et al.*, 1994) and anterior nuclei (Risold *et al.*, 1994), the lateral hypothalamic area (a projection that contains dynorphin; Zardetto-Smith *et al.*, 1988) and the ventral premammillary nucleus (PMv; Canteras *et al.*, 1992b). These nuclei receive strong inputs from parts of the amygdala (see below). The VMH displays diffuse projections to the medial, central, and basolateral amygdala whereas the PMv is interconnected with the principal nucleus of the BST, the MePD, as well as the AHA and adjacent portions of the COApm.

2.14.3.1.7 Hormonal inputs to the amygdala Besides receiving inputs from numerous sensory and modulatory centers of the brain, the amygdala is also the target for the action of steroid hormones. In fact, together with the hypothalamus, the medial EA (Me and posteromedial BST) is the area of the brain with the highest density of cells concentrating both estrogens and androgens (Pfaff and Keiner, 1973; Warembourg, 1977).

Immunohistochemical and *in situ* hybridization studies on the distribution of androgen and (α and β) estrogen receptors (Simerly *et al.*, 1990; Lu *et al.*, 1998; Mitra *et al.*, 2003; Perez *et al.*, 2003) reveal that sexual steroids influence not just the medial EA but also the remaining telencephalic centers projecting to the medial preoptic and ventrolateral aspect (shell) of the ventromedial hypothalamus. Thus, the ventral lateral septum and the AHA are among the nuclei displaying the highest concentration of steroid-sensitive cells in the forebrain. Since, at least in rodents, the VMH and medial preoptic nucleus are known to control feminine (Blaustein and Erskine, 2002) and masculine (Hull *et al.*, 2002) sexual behaviors, the receptors to gonadal steroids in the amygdala and septum are thought to be part of the mechanism for the endocrine control of copulatory behavior. However, other parts of the amygdala that do not project substantially to these hypothalamic centers also show a high (COAa) or moderate density (COApl, and, to a lesser degree, the COApm) of neurons expressing sexual steroid receptors. This suggests additional roles of sexual steroids in the modulation of amygdala-mediated behavioral and/or physiological processes.

Corticosteroids may also influence amygdaloid function. In fact, most of the peptidergic cells in the central EA display receptors to corticosteroids (Cintra *et al.*, 1991; Honkaniemi *et al.*, 1992). This is supposed to mediate stress-induced changes in the expression of peptides by the projection cells of the central EA, as part of the stress-adaptive changes (Palkovits, 2000). The medial EA is also rich in neurons expressing glucocorticoid receptors (Honkaniemi *et al.*, 1992) and may participate in stress responses (Dayas *et al.*, 1999). In addition, the basolateral amygdala displays low levels of receptors to glucocorticoids for which a role in modulating memory acquisition has been proposed (Roozendaal and McGaugh, 1997).

2.14.3.2 Outputs of the Amygdala

The influence of the amygdala on behavior is mediated by amygdaloid projections to diverse neural centers (Figure 7). Attaining their sites of

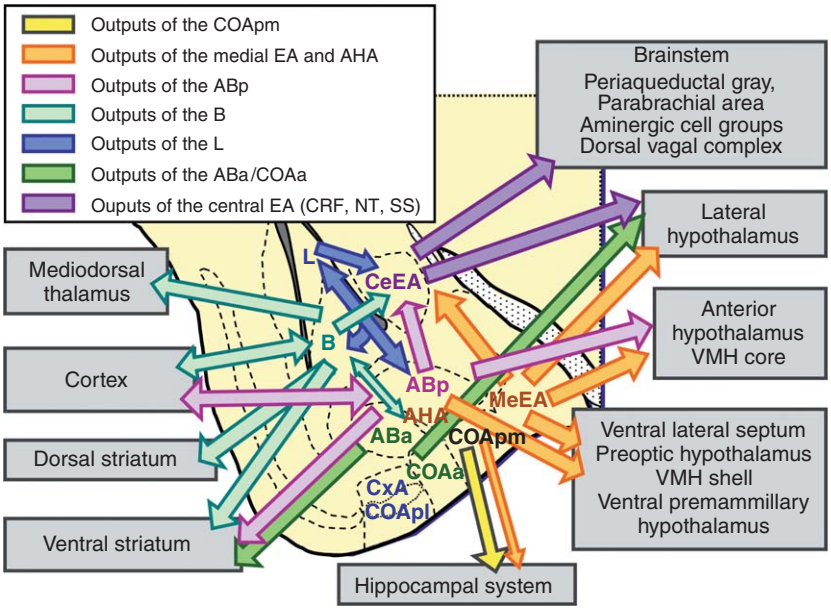

Figure 7 Schematic view of the main outputs of the mammalian amygdala. As a part of the pallium, the basolateral amygdala is engaged in connections with the rest of the pallium, the striatum, and the thalamus. In this respect the B nucleus constitutes the main (but not the only) source of outputs from the amygdaloid pallium. In contrast, the L is almost exclusively engaged in intra-amygdaloid connections. Since it is targeted by many sensory cortical and subcortical inputs, it is usually considered the sensory interface of the basolateral amygdala. The CeEA gives rise to long-distance descending projections to different centers of the hypothalamus, tegmentum, pons, and medulla. These projections seem to constitute the anatomical substrate of fear/anxiety reactions. Massive projections from the basolateral to the central (extended) amygdala allow fear reactions to different stimuli. The medial EA, together with the AHA, project to a sexually dimorphic forebrain system, including parts of the septum and the preoptic tuberal and premammillary hypothalamus. This seems to allow reproductive/agonistic behaviors elicited by vomeronasal-detected pheromones. In addition, the medial EA and AHA project to other parts of the hypothalamus (anterior nucleus and VMH core) involved in the expression of defensive behaviors. The basolateral amygdala, more specifically the posterior part of the AB, also projects to the circuit of defensive behavior.

origin and of termination, amygdaloid projections can be classified into five main pathways. Most of the pallial regions of the amygdala, and some subpallial centers, give rise to projections to striatal territories, including the dorsal and ventral striatum (*sensu stricto*) and parts of the lateral (striatal) septum. Second, parts of the pallial amygdala project to the ventromedial hypothalamus through the stria terminalis, and to the lateral hypothalamus through the ansa lenticularis. Third, the EA also projects to the several hypothalamic centers using both strial and nonstrial pathways. In addition, the central EA gives rise to long-distance projections directed to the pons and medulla (long descending projections of the amygdala). Finally, the cortical afferents to the pallial amygdala are reciprocated by a series of amygdalocortical pathways. This is complemented with projections from the pallial amygdala to the discrete regions of the dorsal thalamus.

2.14.3.2.1 Projections of the pallial amygdala to the basal telencephalon Virtually all the nuclei in the pallial amygdala project to striatal territories. The main amygdalostriatal pathway originates in the basolateral division of the amygdala and terminates in a continuum of structures within the ventral striatopallidum, which extends from the Ce caudally, to the shell of the Acb rostrally, and roughly defines the central EA. This projection mainly arises from the B and AB (Kelley *et al.*, 1982; Brog *et al.*, 1993; Petrovich *et al.*, 1996; Wright *et al.*, 1996; Dong *et al.*, 2001).

In addition, the basal nucleus (B), and, to a much lesser extent, the AB and L, are the origin of a massive projection to the dorsal striatum (CPu; Kelley *et al.*, 1982; Wright *et al.*, 1996). In contrast to the amygdaloid projection to ventral striatal territories, the projection from the B to the CPu is bilateral and is organized so that each portion of the amygdala projects to equivalent points of the striatum in both hemispheres.

Projections from the basolateral amygdala to the ventral striatum have been implicated in stimulus–reward associations (Everitt *et al.*, 1999) and, in fact, the basolateral amygdala is a focus for self-stimulation (through implanted electrodes) with a low-intensity threshold (Kane *et al.*, 1991a, 1991b).

The AHA displays a distinctive pattern of projections to the basal telencephalon (Canteras *et al.*, 1992a). Thus, in contrast to the B and AB, the AHA does not project to the central EA but rather to the medial EA (Me and posteromedial BST). This projection continues further rostrally to reach the ventral lateral septum and, to a lesser degree, the shell of the Acb, the olfactory tubercle, and the substantia innominata.

2.14.3.2.2 Projections of the extended amygdala to the striatopallidal telencephalon One of the features of the EA, in which it differs from the striatopallidum, is the presence of important reciprocal connections between the BST and the intra-amygdaloid EA (Me and Ce; see above). The Me gives rise to additional projections to the basal forebrain. First, the Me and the posteromedial BST also project to two striatal territories, the medial shell of the Acb and parts of the olfactory tubercle, as well as to the ventral aspect of the lateral septum (Canteras *et al.*, 1995). These projections mainly arise from the MeA. The projection of the Me to the lateral septum is known to contain vasopressin and shows a clear sexual dimorphism (Wang *et al.*, 1993).

As expected, the Me is interconnected with the posteromedial BST, a connection that defines the medial EA. However, the ventral aspect of the MeA also projects to the central EA (Canteras *et al.*, 1995; Shammah-Lagnado *et al.*, 1999; Dong *et al.*, 2001). This connection from the medial to the central EA is unidirectional. In fact, although the Ce shows minor intra-amygdaloid projections (Jolkkonen and Pitkanen, 1998), it projects neither to the Me nor to the posteromedial BST (Dong *et al.*, 2001). The functional significance of these connections is not properly understood. Nevertheless, since the Me is dominated by chemosensory inputs (mainly vomeronasal), its projections to the central EA and lateral septum are likely involved in orchestrating fear/anxiety (Ce) and other behavioral reactions (ventral lateral septum) to chemical cues derived from conspecifics (agonistic encounters and territorial behavior: Compaan *et al.*, 1993; Kollack-Walker *et al.*, 1997) or from predators (Meredith and Westberry, 2004). This is further discussed at the end of this article.

2.14.3.2.3 Projections from the pallial amygdala to the hypothalamus The second major output pathway for the amygdala is the stria terminalis. Although this is usually viewed as a single, homogeneous tract, it is indeed composed of fibers from different pallial and subpallial centers. The pallial component of the stria terminalis arises from cells within the boundaries of the posterior AB (ABp) and the AHA (Price *et al.*, 1991). The pallial stria terminalis in fact includes two different projections. The ABp projects to the core of the VMH (Petrovich *et al.*, 1996). On the other hand, the AHA (plus maybe the deepest parts of the COApl) projects the

anterior and preoptic hypothalamus (mainly to the medial preoptic nucleus), to the shell of the VMH and ventral lateral hypothalamic area in the tuberal hypothalamus, and to the PMv (Canteras *et al.*, 1992b). The pallial components of the stria terminalis are characteristically positive for zinc (Haug, 1973; Perez-Clausell *et al.*, 1989; Howell *et al.*, 1991), thus indicating their glutamatergic nature.

The pallial amygdala gives rise to additional projections to the hypothalamus. Thus, the anterior AB (ABa) and the COAa send a major projection to the lateral hypothalamic area (Price *et al.*, 1991; Canteras *et al.*, 1995; Petrovich *et al.*, 1996). This allows quite a direct influence of olfactory stimuli (received by the cortical amygdala) on physiology and behavior (probably reproductive and/or ingestive).

2.14.3.2.4 Projections from the extended amygdala to the hypothalamus The two main components of the subpallial amygdala are the sites of origin of projections directed to the BST that continue to the hypothalamus. Thus, the Me mainly projects to the posteromedial BST (a projection that delineates the so-called medial EA) and the whole medial EA projects to the preoptic hypothalamus, the anterior hypothalamic nucleus, the VMH, and the PMv (Kevetter and Winans, 1981; Price *et al.*, 1991; Canteras *et al.*, 1995; Dong and Swanson, 2004b). In contrast, the whole central EA projects to the posterior lateral hypothalamus (Price *et al.*, 1991; Bourgeais *et al.*, 2001) and the paraventricular nucleus (Gray *et al.*, 1989; Dong and Swanson, 2003, 2004a).

Projections from the amygdala to the hypothalamus may allow an influence of different stimuli (received directly and indirectly through the diverse pathways we have previously described), including pheromonal and olfactory ones (Me), in the expression of reproductive and agonistic behaviors (Canteras *et al.*, 1994, 1995). In addition, the direct and indirect projections from the amygdala (Ce) to the preoptic and paraventricular hypothalamus may be involved in the control of neuroendocrine responses associated with sexual and agonistic behaviors, as well as in responses associated with fear and stress (see below).

The central EA displays one of the densest populations of peptidergic cells of the cerebral hemispheres (Shimada *et al.*, 1989; Day *et al.*, 1999). Specifically, the Ce and the anterior and posterolateral BST contain cells immunoreactive for CRF (Figure 6f), NT, SP, and SS. Some of these peptides coexist in the same cells. Specifically, Shimada *et al.* (1989) described a population of cells co-expressing CRF and NT, and a second population in which SP and SS coexist. Peptidergic cells seem to be the projection neurons of the EA. For instance, the pathways from the Ce and Me to the BST, as well as the long-distance pathways directed to the lateral hypothalamus, are rich in SS/SP (Sakanaka *et al.*, 1981), NT (Allen and Cechetto, 1995), and CRF (Sakanaka *et al.*, 1986).

2.14.3.2.5 Amygdaloid projections to the brainstem Projections from the medial amygdala also reach portions of the periaqueductal gray, the VTA, and the midbrain raphe (Canteras *et al.*, 1995). In contrast the Ce displays much more abundant and long-distance projections that target centers in the midbrain and brainstem (Krettek and Price, 1978; Cassell *et al.*, 1986; Petrovich and Swanson, 1997; Bourgeais *et al.*, 2001). These include projections to most of the monoaminergic cell groups of the midbrain and brainstem, such as the dopaminergic cells in the VTA (A10), SN (A9), and retrorubral field (Gonzales and Chesselet, 1990; Vankova *et al.*, 1992; Dong and Swanson, 2003, 2004a), the adrenergic cells of the locus coeruleus (A6), as well as the noradrenergic and adrenergic cells in the nucleus of the solitary tract (C2/A2) (Wallace *et al.*, 1989). In addition, the Ce projects to the parabrachial nucleus and the NTS (Danielsen *et al.*, 1989; Petrovich and Swanson, 1997; Dong and Swanson, 2003, 2004a). Many of the neurons giving rise to these projections of the central EA are peptidergic (like the amygdalohypothalamic cells; see above). Thus amygdalonigral projections are rich in Met-enkephalin, dynorphin, and NT (Vankova *et al.*, 1992), whereas a low proportion of the Ce neurons projecting to the parabrachial region and nucleus of the solitary tract contain NT, SS, SP, or CRF (Veening *et al.*, 1984). In spite of the low proportion of projecting cells in the central EA containing this peptide, CRF-immunostaining depicts a nice amygdalofugal pathway, which is especially useful for comparative purposes. Thus, CRFergic fibers arising from the immunopositive cells in the CeL and CeM (Shimada *et al.*, 1989; Day *et al.*, 1999) and dorsolateral anterior BST course within the medial forebrain bundle and the periventricular system to innervate the substantia innominata, the medial and lateral preoptic areas, lateral hypothalamic area, central gray (Gray and Magnuson, 1992), laterodorsal tegmental nucleus, locus coeruleus (Van Bockstaele *et al.*, 2001), parabrachial nucleus, dorsal vagal complex, and regions containing the A1 and A5 catecholamine cell groups (Swanson *et al.*, 1983; Sakanaka *et al.*, 1987).

There is compelling evidence indicating that neuropeptide-rich descending projection systems arising from the central EA constitute the anatomical substrate for different fear reactions elicited by diverse stimuli under different experimental conditions (Ledoux *et al.*, 1988; Hitchcock and Davis, 1991; Rosen *et al.*, 1991; Walker and Davis, 1997; Kalin *et al.*, 2004; Sullivan *et al.*, 2004). In this context, CRF plays a double role in modulating fear, anxiety, and stress as both a neurohormone and a central neurotransmitter in the main descending projection of the central EA.

2.14.3.2.6 Amygdalocortical and amygdalothalamic projections Besides displaying projections to executive areas of the brain (striatum, hypothalamus, midbrain, and brainstem), the amygdala also originates ascending projections that target several areas of the cortex and projections to the thalamus that can influence cortical function.

As a rule, connections between the cortex and the pallial amygdala are reciprocal. Those areas of the pallial amygdala that receive the bulk of the cortical input, namely the L, B, and the anterior portion of the AB (Krettek and Price, 1978; Porrino *et al.*, 1981; Amaral and Price, 1984; Petrovich *et al.*, 1996), give rise to projections to the cortical fields that provide the most important inputs to the amygdala. Thus, amygdalocortical pathways mainly terminate in the prefrontal cortex (infralimbic, prelimbic, and anterior insular areas), the posterior insular and perirhinal cortices, as well as portions of the entorhinal cortex. Although there are several differences in the pattern of cortical projections of all three areas of the amygdala, probably the most striking one is the fact that the B (at least its anterior part) projects bilaterally to the cortex (Granato *et al.*, 1991). In addition to these projections, the AHA seems to be the interface area in the connections with the hippocampal formation (Canteras *et al.*, 1992a).

Amygdalocortical pathways constitute a likely substrate for modulation of memory storage within the cortex and of attention. Thus, stimuli related to emotional situations (such as fear, anxiety, or attraction and pleasure) are easily recalled. Beta-adrenergic transmission plays an important role in fear and anxiety enhancement of memory processes (Cahill and McGaugh, 1998). Therefore, it is likely that projections of the central EA (apparently mediating the emotional response of fear and anxiety; see above) to brainstem adrenergic cell groups (including locus coeruleus) are responsible for some of these effects. In addition, an action of corticosteroids on key brain structures such as the Hp also seems to account for fear and stress enhancement of memory acquisition (Blank *et al.*, 2003a, 2003b; Roozendaal *et al.*, 2003). Nevertheless, other emotional responses such as those elicited by rewarding stimuli, or by stimuli associated with reward, are probably mediated by amygdaloventral striatal pathways arising from the basolateral amygdala (Everitt and Robbins, 1992). Since the same areas that project to the ventral striatum are engaged in massive amygdalocortical projections (AB and B), it is tempting to suggest that corticosteroids may also play a role in memory enhancement by rewarding events. In addition, the amygdaloid input to the prefrontal (at least to the orbitofrontal) cortex has been shown to be necessary for maintaining in this structure an active representation of reward-predictive information (Schoenbaum *et al.*, 2003).

On the other hand, projections from the amygdala to the cortical areas providing sensory information can be regarded within the cortical circuitry as a feedback loop similar to the ones present within the cortex itself. Feedback pathways allow modulation of sensory processing in low-level sensory areas by higher-order ones, thus directing (for instance) attention to specific details of the sensory fields. This makes the amygdala a key structure within the circuitry of the isocortex.

Finally, the amygdala also projects to specific portions of the thalamus. Reardon and Mitrofanis (2000) have analyzed the amygdalothalamic pathways of the rat. Their results indicate that the amygdala displays reciprocal connections with the midline (e.g., paraventricular, parataenial) and intralaminar thalamus (including the medial division of the medial geniculate nucleus), to which all the divisions of the amygdala contribute (central, medial, olfactory, and basolateral). In addition, the basolateral amygdala (and, to a lesser extent, the medial and central amygdaloid divisions) projects to the mediodorsal nucleus and to the rostral zona incerta. Since the mediodorsal thalamus projects massively to portions of the prefrontal cortex (Porrino *et al.*, 1981), this constitutes an additional, indirect pathway for connections between the amygdala and prefrontal cortex. Nevertheless, both pathways to the prefrontal cortex may be functionally very different. McDonald (1987) demonstrated that the amygdaloid projection to the prefrontal cortex arises from class I cells, most of which are glutamatergic (McDonald *et al.*, 1989). In contrast, neurons within the basolateral amygdala projecting to the mediodorsal thalamus belong to class II cells (nonpyramidal), and the great majority of them did not exhibit glutamate or aspartate

immunoreactivity (McDonald, 1996). This is further supported by the lack of histochemically detectable zinc in the mediodorsal thalamus (Mengual *et al.*, 2001). The fact that the Ce and Me nuclei, which probably lack glutamatergic cells (Christensen and Geneser, 1995; Brown and Dyck, 2004) but are rich in GABAergic neurons (Swanson and Petrovich, 1998) also project to the mediodorsal thalamus supports the view that the amygdaloid projection to this thalamic nucleus is something more than a simple relay to the prefrontal cortex.

2.14.4 The Mammalian Amygdala: A Summary

The amygdala of mammals is composed of pallial and subpallial structures. The pallial amygdala (Table 1) is a mixture of lateropallial and ventropallial derivatives. The lateral pallium includes superficial (cortical) olfactory centers, including the COApl and maybe transitional areas such as the piriform (APir) and entorhinal cortices (TR). The only deep lateropallial structure of the amygdala is the B nucleus, which is also characterized by a dense cholinergic (AChase-positive) innervation and a less dense dopaminergic input from the midbrain tegmentum (mainly terminating in its caudal pole). Besides being involved in a complex intraamygdaloid circuitry, the B gives rise to a bilateral projection targeting both the dorsal and ventral striatum that constitutes the bulk of the amygdalostriatal pathway. Moreover, the B is bilaterally interconnected with the LOT and parts of the isocortex (mostly the prefrontal cortex), and projects to the mediodorsal thalamus.

The ventropallial amygdala also includes cortical superficial and deep nuclei. The cortical ventropallial amygdala is composed of olfactory areas, such as the COAa and LOT, and vomeronasal cortices, namely the BAOT and COApm. The COAa is especially rich in receptors to sexual steroids and, by means of its direct and indirect (through the anterior AB) projections to the lateral hypothalamus, constitutes a link for the transfer of olfactory information to the hypothalamus. The LOT is interconnected with the B, with which it shares a dense cholinergic and dopaminergic innervation as well as important contralateral connections through the anterior commissure. The COApm stands as a specialized vomeronasal cortex that projects to other secondary vomeronasal centers and back to the AOB, to olfactory centers (piriform and endopiriform), and to its contralateral counterpart.

The deep ventropallial amygdala is composed of the L, AB, and AHA nuclei. The former is usually considered as the sensory interface of the basolateral amygdala, since it is the target of most cortical and thalamic inputs, but shows projections virtually restricted to the remaining nuclei of this amygdaloid division. The AB projects to the ventral striatum and cortex. Moreover, it shows a double projection to the hypothalamus. Its anterior part (ABa), together with the overlying COAa (from which it receives a dense input), originates a projection to the lateral hypothalamus via the ansa lenticularis. The posterior AB, together with the AHA, gives rise to the pallial portion of the stria terminalis, and provides a glutamatergic and zinc-positive projection to the BST and medial hypothalamus (VMH). Finally, the AHA should be considered a deep pallial vomeronasal center since it is interconnected with the vomeronasal amygdala (mainly with the BAOT and medial EA), with which it shares a common pattern of afferents and efferents and the presence of receptors to sexual steroids.

The deep pallial amygdala gives rise to a massive projection to the central EA. This projection arises from all the nuclei of this amygdaloid division, with the exception of the anterior B and the AHA, the latter projecting to the medial EA instead.

The subpallial amygdala (Table 2) consists of two main divisions, namely the medial and the central EA. The medial EA is composed of the Me (with its different subdivisions that receive topographic names) and the posteromedial BST, which are deeply interconnected. It is dominated by cascade-like input from the AOB that includes direct and indirect projections through the COApm and AHA, and it is interconnected with the olfactory system. The whole vomeronasal amygdala (medial EA, AHA, COApm) is rich in receptors to steroid hormones. Its main outputs reach parts of the ventral striatum (mainly the olfactory tubercle), and different portions of the hypothalamus, including the preoptic, tuberal, and premammillary hypothalamus.

In addition, the medial EA shows projections to the basolateral amygdala, mainly targeting the ABp and L, as well as to the CeM. This interconnection allows the interplay between the medial and central EA, probably needed for the signaling of the attractive/aversive properties of conspecific chemical cues (such as pheromones) and associated stimuli.

The central EA (Table 2) is composed of the Ce (with medial, lateral, and capsular divisions) and the anterior and posterolateral BST, which are deeply interconnected. In contrast to the medial, the central EA does not express a high level of receptors to

Table 1 Summary of the characteristic features of the different nuclei of the mammalian pallial amygdala. In the columns describing the main inputs and outputs, the term 'intrinsic' has been used to refer to the existence of connections with other pallial amygdaloid nuclei. Most of these projections arise from the cortical amygdala and reach the basolateral (deep pallial) nuclei. In addition, there is an intricate set of interconnections among the nuclei in the basolateral amygdala

Pallial origin	*Topological position*	*Nucleus*	*Main afferents*	*Main efferents*	*Neurochemistry and other features*
Lateral pallium	Superficial	COApl	Main olfactory bulb	Intrinsic	Rich in receptors to sexual steroids
				Hippocampus (CA1, ventral subiculum)	Also called periamygdaloid cortex (see Majak and Pitkanen, 2003)
				Cortex	
	Deep	B	Intrinsic	Intrinsic	Cholinergic innervation
			NLOT (bilateral)	NLOT	Dopaminergic innervation
			Cortex	Cortex (bilateral)	Main output to the prefrontal cortex and striatum
				Ventral striatum (Acb, Tu; bilateral)	
				Dorsal striatum (CPu; bilateral)	
				Mediodorsal thalamus	
Ventral pallium	Superficial	NLOT	Main olfactory bulb	Main olfactory bulb	Dense cholinergic innervation
			B (bilateral)	B (bilateral)	
				Commissural	
				Ventral striatum	
		COAa	Main olfactory bulb	Lateral hypothalamus	Very rich in receptors to sexual steroids
					Olfactory link to the hypothalamus
		COApm	Accessory olfactory bulb	Accessory olfactory bulb	Vomeronasal cortex
			Commissural	Commissural	
			Intrinsic	Cortex	
			Piriform and endopiriform	Hippocampus (CA1)	
			Me	Intrinsic (especially to AB)	
				Medial EA	
	Deep	L	Intrinsic	Intrinsic (B, AB, and central EA)	Sensory interface of the basolateral division of the amygdala
			Thalamus		
			Cortex		
		AB	Intrinsic	Intrinsic (including central EA)	ABa: anterior part, deep and functionally related to COAa
			Cortex	Cortex	ABp: posterior part, functionally related to AHA
				Ipsilateral accumbens	
				Lateral hypothalamus (ABa)	
				Ventromedial hypothalamus (ABp)	
		AHA	Intrinsic (Me, COA)	Intrinsic (including medial EA and COApm)	Very rich in receptors to sexual steroids
			Hippocampus (CA1, ventral subiculum)	Hippocampus (CA1, ventral subiculum)	According to Canteras *et al.* (1992a), it is part of the posterior amygdala
			Ventral premammillary nucleus	Lateral septum (ventral)	Together with the ABp gives rise to the pallial portion of the stria terminalis
				Cortex	
				Ventral striatum	
				Ventromedial hypothalamus	
				Ventral premammillary nucleus	

Table 2 Summary of the characteristic features of the different nuclei of the mammalian subpallial amygdala (extended amygdala)

Division	*Nucleus*	*Main afferents*	*Main efferents*	*Neurochemistry and other features*
Medial EA	MeAD, MeAV, MePD, and MePV	Accessory olfactory bulb (AOB) Posteromedial BST COApm Secondary olfactory centers Subiculum Ventral premammillary hypothalamus AHA? Main olfactory bulb (only partially)	AOB COApm AB, L Lateral entorhinal cortex Posteromedial BST Ventral striatum (olfactory tubercle) CeM Lateral septum (ventral) Hypothalamus: medial preoptic, ventromedial, and ventral premammillary nuclei	• Vomeronasal subpallial amygdala • Very rich in receptors to sexual steroids • Sexually dimorphic population of vasopressinergic cells (projecting to septum and habenula)
	Posteromedial BST	Accessory olfactory bulb (only partially) Me COApm COApl Amygdalopiriform transition (APir) AHA Ventral premammillary hypothalamus	Me ABp and AHA CeM (only the Tr) Lateral septum (ventral) Hypothalamus: medial preoptic, ventromedial, and ventral premammillary Periaqueductal gray (PAG) Midbrain tegmentum (VTA, RR) Parabrachial/pericoerulear area (including Barrington nucleus)	• Very rich in receptors to sexual steroids • Sexually dimorphic population of vasopressinergic cells (projecting to septum and habenula)
Central EA	CeM, CeL, and CeC	Infralimbic and insular cortices CA1 Basolateral amygdala (L, ABa, ABp, Bp) Amygdalopiriform transition (APir) Postpiriform transition area (TR) Anterior and posterolateral BST MeAV Paraventricular, ventromedial, and subparafascicular thalamus Parabrachial pons	Anterior and posterolateral BST Substantia innominata Lateral hypothalamus Paraventricular and mediodorsal thalamus Midbrain tegmentum (VTA, SN, RR) PAG Parabrachial and pericoerulear pons NTS–dorsal vagal complex	• Receptors for corticosteroids • NT/CRF and SP/SS projecting cells in the CeL and CeM (not in the CeC) • CGRP innervation of CeC and CeL (parabrachial and thalamic origin)
	Anterior and posterolateral BST	Basolateral amygdala (ABa, ABp, Bp) Ce Amygdalopiriform transition (APir) Postpiriform transition area (TR) Parabrachial pons	Ce Substantia innominata Lateral hypothalamus Paraventricular and mediodorsal thalamus Midbrain tegmentum (VTA, SN, RR) PAG Parabrachial and pericoerulear pons NTS–dorsal vagal complex	• NT/CRF and SP/ SS projecting cells (lateral aspect). At least the NT/CRF population extends rostrally into the nucleus accumbens • CGRP innervation that extends rostrally into the nucleus accumbens

sexual steroids but it does to corticosteroids. It receives a cascade of sensory inputs (viscerceptive, nociceptive, gustatory, somatosensory, auditory, and maybe visual) directly and indirectly from the brainstem (mainly the parabrachial area and nucleus of the solitary tract), thalamus and cortex (perirhinal, insular, infralimbic), and basolateral amygdala (mainly L, AB, and posterior B), the latter constituting its main input. Many of the projection cells of the central EA are GABAergic and express neuropeptides (CRF, NT, SS, SP, enkephalin). The distribution of peptides may be of interest for comparative purposes. Most of the peptidergic cells are located in the CeL (plus CeM) division, whereas the CGRPergic input (visceroceptive nociceptive) from the parabrachial pons and thalamus terminates in the CeC and, to a lesser extent, in the CeL, and extends to the amygdalostriatal transition. Therefore, the Ce displays a medial aspect rich in peptidergic cells and a lateral one defined by CGRP innervation that partially overlaps with the former.

The projections of the central EA reach a huge variety of structures, including the paraventricular and lateral hypothalamus, periaqueductal gray, midbrain reticular formation, including dopaminergic cell groups (VTA, SN, retrorubral field), locus coeruleus and pericoerulear area, parabrachial area, nucleus of the solitary tract, and dorsal vagal complex. This allows a coordinated control of the somatomotor, vegetative, and endocrine components of fear/anxiety reactions.

This summary reveals the existence of two parallel systems in the amygdala of mammals. One is a multimodal system, composed of the basolateral amygdala (B, L, and AB) and the central EA and seems involved in the generation of two kinds of basic emotional reactions. The fear–anxiety reactions are produced through the long descending outputs of the central EA. Moreover, the basolateral nuclei (mainly the AB and B) massively project to the ventral striatum, and this may mediate the generation of reactions of attraction/reward elicited by incoming stimuli.

The second system of the mammalian amygdala is mainly composed of the secondary vomeronasal centers, since it includes the vomeronasal cortex (COApm) and the medial EA, plus a deep pallial nucleus, the AHA. Their pattern of connections with the preoptic, tuberal, and premammillary hypothalamus and septohippocampal system, as well as the presence of receptors to sexual steroids in most of the centers of this circuit, suggests that this system is involved in the control of reproductive and agonistic behaviors elicited by conspecific chemical signals (mostly pheromones). Both systems are interconnected. Most of these connections arise from the medial EA or COApm and terminate in the basolateral amygdala and central EA. These connections are seemingly providing a substrate for eliciting reactions to conspecific vomeronasal-detected chemicals (e.g., pheromones) such as fear/anxiety against a competitor (territorial behaviors) or attraction/reward, induced by probable mates.

2.14.5 The Amygdala of Reptiles

Identifying the amygdala of nonmammals constitutes a true challenge. One of the first attempts was due to Johnston (1923), who assumed that the amygdala was found in the caudal and basal cerebral hemispheres, in close association with the LOT. In fact, in a ventral view of the brain of most reptiles (Figure 8 shows the brain of the Old World lizard *Podarcis hispanica*), the *lot* is seen to arise from the olfactory bulbs, very developed when compared with mammals, and apparently terminating halfway within the cerebral hemispheres. The structures caudal to the *lot* are good candidates for the reptilian amygdala.

However, to identify the reptilian amygdala with certainty, we will apply to the reptilian brain the same criteria that define the different parts of the mammalian amygdala. Thus, we will explore the reptilian pallium and subpallium to try to delineate the reptilian pallial and subpallial (extended) amygdala.

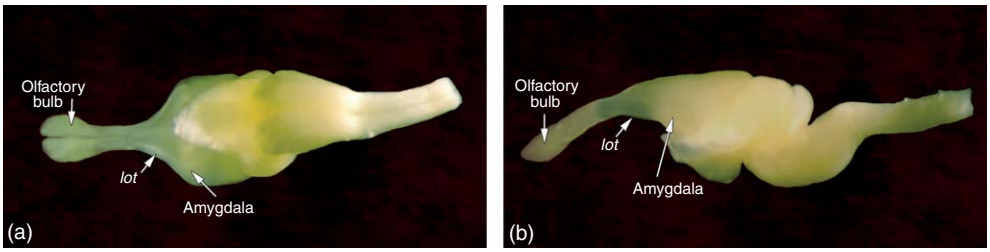

Figure 8 The amygdala in the brain of reptiles. In a ventral (a) and a lateral (b) view of the brain of the lizard *Podarcis hispanica*, the lateral olfactory tract (*lot*) is seen to leave the huge olfactory bulbs to terminate in the caudobasal cerebral hemispheres, where the presumed amygdala is located.

2.14.5.1 A Topological View of the Reptilian Pallial Amygdala

In order to delineate the pallial amygdala of reptiles we will use three main criteria. First, the afferents from the olfactory bulbs will be used to identify the different areas of the presumptive (superficial) cortical amygdala. Second, structures topologically deep to the cortical, olfacto-recipient amygdala would constitute the basolateral division of the amygdala. Finally, we will use topological data together with data on the expression of homeotic genes during development to delineate the lateral versus the ventral pallial derivatives. All of these data allow us to make a proposal of homologies between the reptilian and mammalian amygdalae, which will be further explored using connectional and histochemical data (Figure 9).

2.14.5.1.1 The olfacto-recipient pallial amygdala of reptiles There are several studies of the projections of the main and accessory olfactory bulbs in different reptiles, including squamate reptiles (lizards and snakes: Ulinski and Peterson, 1981; Martinez-Garcia *et al.*, 1991; Lohman and Smeets, 1993; Lanuza and Halpern, 1998) and turtles (Reiner and Karten, 1985). In all reptiles, the main olfactory bulbs project to the outer half of the molecular layer of what is usually called the LC, throughout its rostrocaudal axis. They also project to more ventral cell groups associated with the *lot*, named nucleus of the *lot* (NLOT) (Martinez-Garcia *et al.*, 1991; Figures 9a and 10a) or external amygdala (Lanuza and Halpern, 1998). At caudal levels,

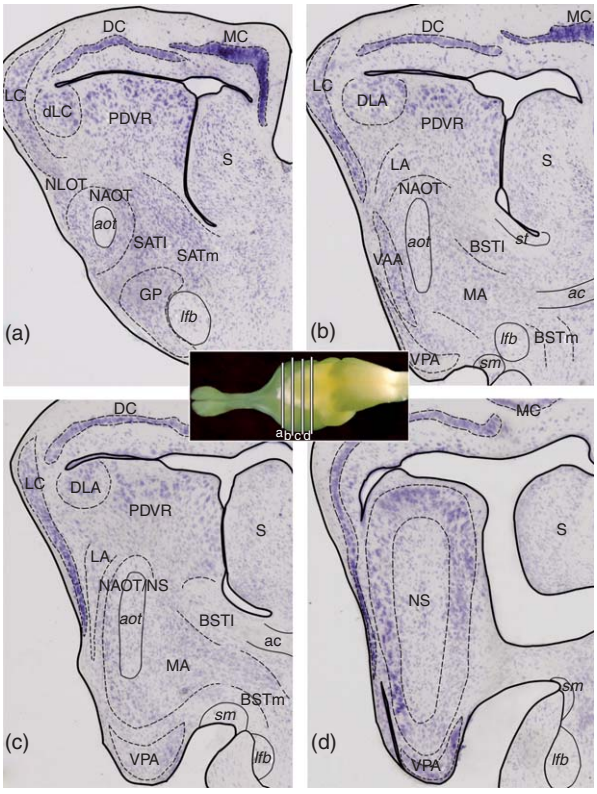

Figure 9 Cytoarchitecture of the amygdala of the lizard *Podarcis hispanica*. Nissl-stained frontal sections through the left cerebral hemisphere of a lizard at slightly precommissural (a); commissural (b); anterior postcommissural (c); and caudal levels of the telencephalon (d). The central inset shows the approximate location of the sections on a ventral view of the brain. The different nuclei and cortical areas of the amygdala and adjoining telencephalic structures are delineated using thin discontinuous lines, whereas thin solid lines indicate the main fiber tracts.

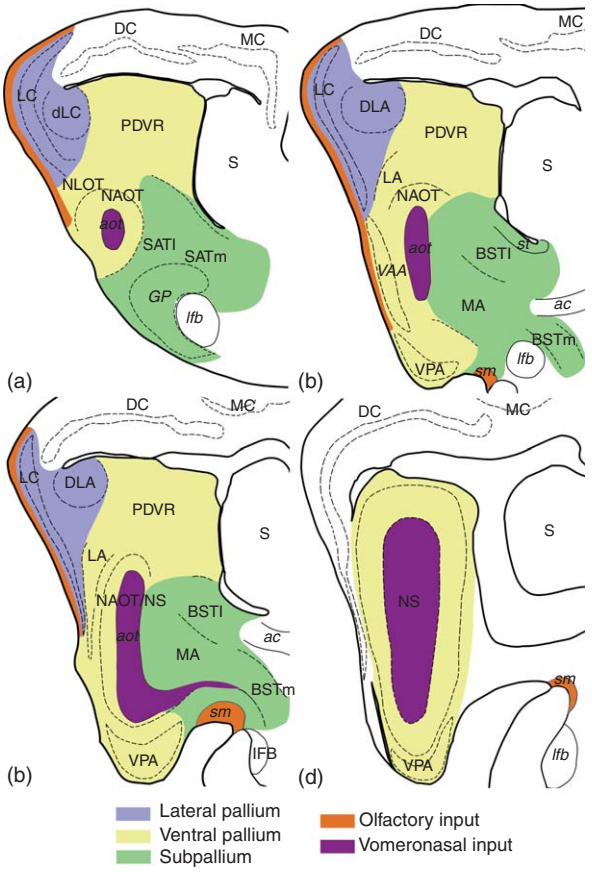

Figure 10 Pallial and subpallial territories within the reptilian amygdala. This diagram, which is based on the Nissl-stained sections of Figure 9, shows the palliosubpallial boundary as well as the lateral and ventral pallial territories in the amygdala of reptiles. The termination areas of the projections from the main (orange) and accessory olfactory bulbs (violet) are also indicated. This reveals that, as in mammals, the olfactory projection reaches mainly superficial lateral and ventropallial regions, whereas the vomeronasal one reaches ventropallial (NS) and subpallial regions (MA). In the brain of squamate reptiles the accessory olfactory tract is internalized (not superficial) and this results in an invagination of the vomeronasal cortex, the NS, which therefore shows an inverted lamination. On the other hand, the olfactory projection courses through the stria medullaris, just superficial to the MA, and reaches the contralateral hemisphere via the habenular commissure.

the LC extends further ventrally (LCc; Figures 9b and 10b). At these levels, MOB fibers extend beneath the surface of the ventrolateral cerebral hemispheres to enter the stria medullaris. In their way, they innervate a layered cell group, caudal to the NLOT, known as the VAA (Figures 9b and 10b; Martinez-Garcia *et al.*, 1991; Lanuza and Halpern, 1998).

In the rostral telencephalon, the fibers arising from the accessory olfactory bulb deepen into the cerebral hemispheres making up the accessory olfactory tract. The accessory olfactory tract is surrounded by a group of cells called bed nucleus of the accessory olfactory tract (NAOT), which is just deep to the boundary between the LCc and the VAA. The NAOT is rostral to and continuous with the main secondary vomeronasal center of squamate reptiles, the NS, which at caudal levels occupies the whole subventricular telencephalon (Figures 9c and 9d). In spite of its subventricular position, the NS displays a neat laminar organization (Ulinski and Kanarek, 1973), with most cells arranged in a single layer (mural layer) sandwiched between two molecular strata called marginal (juxtaependymal) layer and the hilus, where the accessory olfactory tract terminates (Figures 10c and 10d). This is suggestive of a cortical nature. In agreement with this interpretation, like other cortical structures the NS shows most of the GABAergic cells in the molecular layers and only a few of them in the mural layer (Martinez-Garcia *et al.*, 2002a). Perez-Clausell (1988) compared the distribution of zinc between the LC and NS and concluded that the NS is a cortical field whose lamination has become inverted. In fact, in a series of frontal sections through the caudal telencephalon of a squamate reptile, it becomes clear that, as the accessory olfactory tract deepens into the cerebral hemispheres, there is an invagination of the cortical amygdala to which it innervates. Consequently, the hilus constitutes the outer molecular layer, whereas the marginal layer is, in fact, the inner molecular layer. Therefore, in reptiles the vomeronasal cortical amygdala is typically invaginated in the form of an NS. The AOB also projects to a region of the striatopallidal forebrain, just medial to the rostral NS (Figures 10b and 10c) that is usually named as medial amygdala and/or BST (see below).

Considering together all these data, the olfactory cortical amygdala of reptiles seems to be composed of the NLOT, the VAA, and, presumably, parts of the LC. Although the LCc occupies a position compatible with its consideration as part of the caudalmost olfactory cortical amygdala, this is not clearly supported by hodological data (Hoogland and Vermeulen-Vanderzee, 1995; see below). In addition, reptiles possess two vomeronasal cortical structures, the BAOT and the NS.

2.14.5.1.2 The deep pallial amygdala: The reptilian basolateral amygdala Like its mammalian counterpart, the basolateral division of the reptilian amygdala should occupy a topological position deep to the cortical (olfacto-recipient) amygdala. This probably includes the PDVR plus two adjoining cell groups named lateral amygdala (LA) and DLA. Thus, dextranamine injections in the ependymal layer of the medial PDVR in *Podarcis* result in extensive labeling of the glial processes that could be followed up through the deep PDVR and rostral LA, to their contact with the pial surface at the level of the NLOT (Martinez-Garcia *et al.*, 2002a). On the other hand, the rostral LA looks deep to the VAA (Figure 9b). This allows us to consider the PDVR, LA, VAA, and NLOT as neurogenetically related structures. On the other hand, the distribution of radial glia in lizards (Monzon-Mayor *et al.*, 1990; Yanes *et al.*, 1990; Guirado *et al.*, 2000) indicates that the DLA, a cell group just below the lateral sulcus of the lateral ventricle at these caudal levels (Figures 9b and 9c), is topologically deep to the LCc.

In addition, there is a small cell group ventral to the rostral-to-intermediate NS, which, because of the inverted lamination of the NS, should be interpreted as deep to it. This is called VPA. The VPA is contiguous to the LA (Figure 9c) and caudal to the VAA. Some authors consider the VPA a caudal portion of the external amygdaloid nucleus, but this does not seem appropriate for a deep nucleus.

2.14.5.1.3 Lateropallial and ventropallial territories in the amygdala of reptiles From a comparative viewpoint, it is interesting to know the territory of the pallium to which each one of these structures belongs. Since the projections from the olfactory bulb terminate in the superficial layers of the lateral and ventral pallia, we will specifically analyze the ventropallial or lateropallial nature of the abovementioned structures (Figure 10). In this respect, it is sensible to consider the DLA and the LCc, apparently superficial to the former, as lateropallial structures. On the other hand, in their original definition of the ventral pallium, Puelles *et al.* (2000) indicated that it was composed of structures deep to the LOT. Therefore, it is reasonable to suggest that the LOT and its caudal continuation, namely the VAA and NS, are ventropallial derivatives. Finally, the structures deep to these cortical areas, the PDVR and LA and VPA, are also very likely ventropallial. This proposal is supported by data on the expression

of homeotic genes during the development of turtles. Indeed, Smith-Fernandez *et al.* (1998) used *Emx-1* and *Dlx-1* as markers of early telencephalic regionalization and concluded that the dorsal ventricular ridge (probably including its posterior part) is part of the intermediate territory (situated between the pallium and subpallium) renamed by Puelles *et al.* (2000) as ventral pallium.

2.14.5.1.4 A proposal of homologies for the reptilian and mammalian pallial amygdala This allows us to make a proposal of homologies between the reptilian and mammalian amygdala based mainly on topology (superficial-to-deep; ventral or lateral pallium) and on the projections from the olfactory bulb, which is presented in Table 3. According to this proposal, the LC would include the homologues of the COApl plus maybe the transitional areas with the piriform (APir) and entorhinal areas (TR). In turn, the deep lateropallial DLA is the best candidate for the homologue of the B. In the ventral pallium, the LOT and BAOT would be homologues to their mammalian homonyms; the olfactory cortical areas of mammals (COAa) and reptiles (VAA) would be homologous, as would be the vomeronasal cortices of mammals (COApm) and reptiles, the NS. In addition, the reptilian deep ventropallial nuclei, PDVR, and LA are the most likely candidates for the homologues of the mammalian L and AB.

Finally, being a caudal cell group deep to the vomeronasal cortex (NS), the VPA occupies a topological position comparable to that of the mammalian AHA (which indeed is just deep to the COApm). This is further supported by the continuity shown between the reptilian LA and VPA that recalls the relationship between the posterior AB and the AHA of mammals.

This proposal of homologies would be further explored and detailed by analyzing the available literature on the connections and histochemistry of the reptilian caudal cerebral hemispheres.

2.14.5.2 Connections and Histochemical Properties of the Reptilian Pallial Amygdala: Comparison with Mammals

2.14.5.2.1 Cortical amygdala Besides their afferents from the main or accessory olfactory bulb, the cortical amygdaloid areas of reptiles also share many connectional features with their mammalian counterparts, which we analyze in detail below.

2.14.5.2.1.(i) The olfactory cortical amygdala In their study of the connections of the LC of the gecko, Hoogland and Vermeulen-Vanderzee (1995) made restricted injections of lectins in different parts of the LC. According to their results, the dorsal rostral LC and the LCc display exclusively efferent projections to the hippocampal and parahippocampal cortices (medial and dorsal cortical areas). This had been previously reported in *Podarcis* by Martinez-Garcia *et al.* (1986) and confirmed in the snake *Thamnophis sirtalis* (Martinez-Marcos *et al.*, 1999). In contrast, the rostral ventral LC is closely related to the amygdaloid complex, since it projects to the external amygdala (presumably the VAA; from which it receives afferents; Martinez-Garcia *et al.*, 1986), PDVR, and LA (Lanuza *et al.*, 1998; Martinez-Marcos *et al.*, 1999). This was further supported by the results of deep injections in the ventral rostral LC (deep LC according to Novejarque *et al.*, 2004). This suggests that in reptiles and mammals the olfactory areas of the lateral pallium are differently compartmentalized. Whereas in mammals there is a number of cortical areas that project to the Hp and amygdala (COApl, APir, TR, entorhinal cortex), in reptiles the areas of the LC giving rise to these two projection systems are anatomically segregated.

The connections of the VAA (anterior part of the external amygdala, depending on the nomenclature) have been specifically studied in the context of amygdalohypothalamic pathways in lizards (Bruce and Neary, 1995a, 1995b; Lanuza *et al.*, 1997) and snakes (Martinez-Marcos *et al.*, 1999). The results of these studies indicate that the VAA projects mainly to the lateral hypothalamus and, apparently, to a cell population lateral and caudal to the ventromedial hypothalamus, called by Lanuza *et al.* (1997) lateral tuberomammillary nucleus (LTM), that might include ventral premamillary nuclei. A similar situation is observed in *T. sirtalis* (Martinez-Marcos *et al.*, 1999). Since the injections on which this projection was defined in lizards also included the VPA, it is difficult to ascertain whether the VAA and VPA display differential projections to the hypothalamus. New evidence suggests, however, that the projection to the lateral hypothalamus arises from the VAA, whereas the one directed to the LTM/ventral premammillary hypothalamus arises from the VPA (see below).

In conclusion, the available data on the connections of the olfactory cortical amygdala in reptiles suggest that the lateropallial olfactory cortices are differently compartmentalized in reptiles and mammals, so that specific homologues to the COApl and the transitional cortices of mammals are not found in reptiles. In contrast, within the ventral pallium the VAA seems the most likely reptilian homologue for the mammalian COAa (Table 3).

Table 3 Proposal of homologies between the mammalian, reptilian, and avian amygdaloid nuclei and areas

Embryological origin	*Topological position*	*Mammalian nucleus/area*	*Reptilian nucleus/area*	*Avian nucleus/area*	*Properties*
Lateral pallium	Superficial	COApl (APir, TR)	Parts of the LC?	Parts of the CPi?	Mainly intra-amygdaloid and to hippocampal formation
	Deep	B	DLA	Lateral NC TPO AD Lateral PoA	• Bilateral projections to striatum and NLOT • Dopaminergic + cholinergic innervation
Ventral pallium	Superficial	LOT	NLOT	AA	• Connected to the deep lateropallial amygdala • Cholinergic innervation
		COAa	VAA	Rostral olfacto-recipient area of the arcopallium, ventral to CPi	• Projections to striatum • Projections to lateral hypothalamus
		COApm	NS		Vomeronasal cortex
	Deep	L	PDVRdm (ADVR?)	Medial NC (field L, intermediate and frontal N, E, Bas?)	• Sensory interface • Intra-amygdaloid projections • Few extra-amygdaloid projections (to the striatum)
		ABa	Deep VAA	Rostrolateral AV deep to the olfacto-recipient arcopallium	• Projections to striatum • Projections to lateral hypothalamus
		ABp	PDVRv + LA	Posterior AV, nonolfacto-recipient	• Projections to VMH • Minor projections to striatum
		AHA	VPA	Ventromedial PoA / Caudal edge of the AV	• Projection to ventrolateral septum • Projections to preoptic hypothalamus • Interconnected with the ventral premammillary hypothalamus • Receptors to steroid hormones[a]
Subpallium		Central EA	SAT, BSTl	SpA, BSTL (subpallial AM?)	• Long-distance descending projections (e.g., lateral hypothalamus, parabrachial area, dorsal vagal complex) • CRF, NT cells (medial aspect)[b] • CGRP innervation (lateral aspect)
		Medial EA	MA, BSTm	TnA, BSTM (subpallial AM?)	• Massive projections to preoptic, lateral tuberal (ventromedial), and premammillary hypothalamus • High levels of receptors to sexual steroids • Vasopressin/vasotocin-containing projecting cells

[a] A cell group expressing receptors to sexual steroid is lacking in birds.
[b] The distribution of CRF and NT has not been properly studied in reptiles.

2.14.5.2.1.(ii) The vomeronasal cortical amygdala The connections of the NS have been studied in detail in the snake *T. sirtalis* (Lanuza and Halpern, 1997) and the lizard *P. hispanica* (Lanuza *et al.*, 1997; Novejarque *et al.*, 2004). The NS of squamate reptiles shows projections back to the AOB and to the remaining vomeronasal centers (putative medial amygdala and BST), as well as its contralateral counterpart through the anterior commissure. It also projects to olfactory structures such as the LC and displays intrinsic amygdaloid projections (mainly to deep nuclei; PDVR, DLA). Additionally, it displays important projections to the ventral striatum (olfactostriatum; Martinez-Marcos *et al.*, 2005) and projects to parts of the dorsal (hippocampal) cortex. This perfectly fits the pattern of projections from the mammalian COApm (Table 1), thus strongly supporting the homology between both structures.

2.14.5.2.2 The reptilian basolateral amygdala The basolateral amygdala of mammals receives sensory inputs from different sources (brainstem, thalamus, and cortex) and neurochemically identified modulatory afferents. In turn, its components show differential projections to the hypothalamus, to the dorsal and ventral striatum, and to portions of the cortex. As we discuss in detail, most of these same features are met by the proposed homologues in the reptilian brain.

2.14.5.2.2.(i) The deep lateropallial amygdala: The DLA as the reptilian homologue to the B nucleus of mammals The projections from the caudal cerebral hemispheres to the striatal territories in reptiles were neglected until recently (Gonzalez *et al.*, 1990), although there was some evidence suggesting that they existed in lizards (Voneida and Sligar, 1979; Martinez-Garcia *et al.*, 1993), turtles (Siemen and Kunzle, 1994), and snakes (Perez-Santana *et al.*, 1997). We reinvestigated this issue in the lizard *P. hispanica* (Novejarque *et al.*, 2004) using a combination of retrograde and anterograde tracing. Our results demonstrate that the DLA provides a massive and bilateral projection to the dorsal striatum (Figure 11). Moreover, the pallial amygdala gives rise to a massive projection to a continuum of

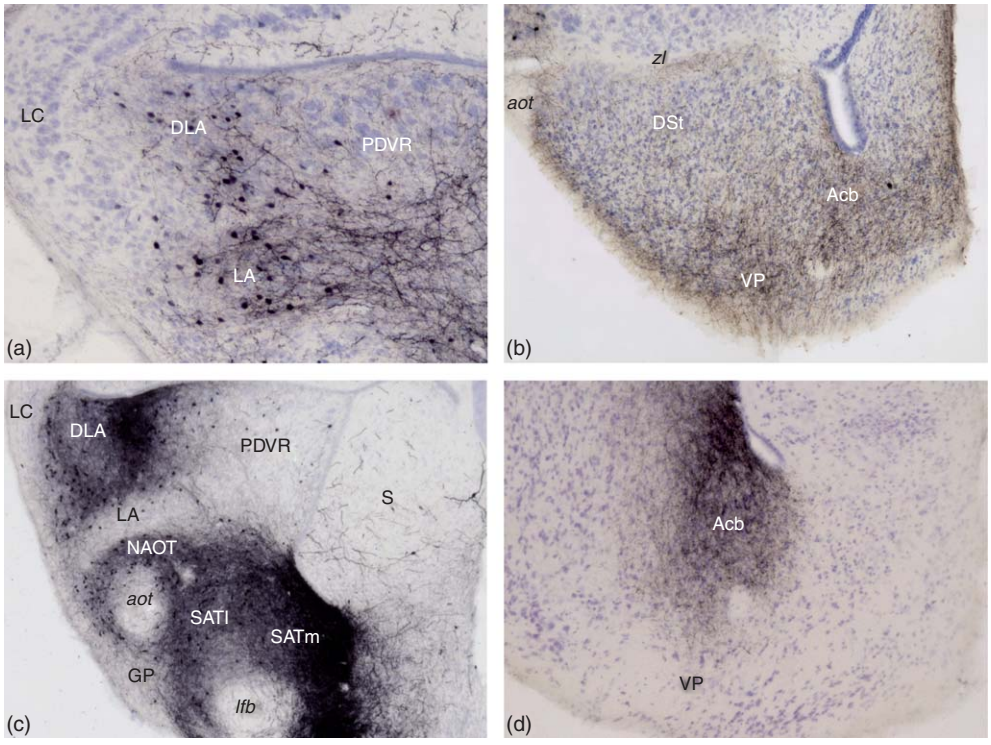

Figure 11 Amygdalostriatal connections in lizards. a and b, The DLA of lizards projects bilaterally to both the dorsal and ventral striata. Thus, retrograde transport is observed in the DLA (and part of the LA) in a lizard that received a tracer (dextranamine) injection encompassing the ipsilateral dorsal striatum (a). In addition, tracer injections into the DLA anterogradely label the dorsal and ventral striatum in the ipsilateral (b) and contralateral (not shown) telencephalon. This amygdaloid projection also reaches parts of the pallidum (VP). c and d, The PDVRdl of lizards projects exclusively to the ipsilateral Acb. Retrograde transport after injections in the Acb (c) indicates that the bulk of this projection arises from the DLA and the PDVRdl, whereas the PDVRvm and LA do not contribute substantially to it. Tracer injections restricted to the PDVR (d) result in anterograde labeling of the Acb but not in the dorsal striatum.

structures in the ventral striatum connecting the striatoamygdaloid transition area (SAT) and the Acb (rostrally). This projection arises mainly from the DLA, the dorsolateral aspect of the PDVR (PDVRdl), the VAA, VPA, and NS, and the deep LC (dLC). Among all these nuclei, only the DLA projects substantially to the contralatateral Acb.

Therefore, the DLA stands as the main source of amygdalostriatal pathways since it projects massively and bilaterally to the dorsal and ventral striatum. This strongly supports our proposal that the DLA is the reptilian homologue of the basal nucleus of the mammalian amygdala. In addition, like the mammalian B, the DLA projects bilaterally to the region of the NLOT (Novejarque *et al.*, 2004).

In the mammalian brain, the pallial amygdala is the target for two well-characterized ascending projections, namely the cholinergic input from the basal forebrain and the dopaminergic input from the dorsocaudal group A10. Both projections converge at the level of the B nucleus. Using appropriate (immuno)-histochemical techniques these projections can also be delineated in reptiles, and the results fully agree with the proposed homologies. Thus, the distribution of both ChAT (Medina *et al.*, 1993) and acetylcholinesterase (Lanuza *et al.*, 1997) reveals a dense cholinergic innervation of portions of the NLOT (Figure 12a) and of the DLA (Figure 12b). In addition, immunohistochemical detection of markers of dopaminergic fibers reveals a dense innervation of the DLA in the lizards *Psammodromus* (Andreu *et al.*, 1994) and *Podarcis* (Figure 12c).

2.14.5.2.2.(ii) Deep ventropallial nuclei: The PDVR and LA In squamate reptiles, the PDVR is composed of a juxtaventricular zone rich in cell groupings called glomeruli, plus a central core that shows no clear boundaries with the LA. In *Podarcis* the PDVR does not seem homogeneous, but is composed of cytoarchitectonically different zones: the ventromedial PDVR (PDVRvm) shows small glomeruli, the dorsomedial PDVR (PDVRdm) shows larger glomeruli, and the dorsolateral PDVR (PDVRdl), next to the DLA, display giant glomeruli. As we will see, the three areas display different connections that allow us to refine our proposal of homologies.

2.14.5.2.2.(ii).(a) The PDVRvm and LA constitute the reptilian homologue to the ABp of mammals The ABp of the mammalian amygdala gives rise to a part of the pallial component of the stria terminalis that terminates in the core of the VMH (Petrovich *et al.*, 1996). The amygdalohypothalamic projections have been fully characterized in different reptiles using retrograde and anterograde tracing techniques (Bruce and Neary, 1995a, 1995b; Lanuza *et al.*, 1997; Martinez-Marcos *et al.*, 1999). In all the species studied, the PDVRvm and LA (Figures 13a and 13b) project to the ventral and medial anterior tuberal hypothalamus (including the retrochiasmatic area and VMH core; Figure 13c). This pathway courses through a compact bundle that leaves the amygdala dorsal and caudal to the anterior commissure, and is called stria terminalis. From a comparative viewpoint, this seems quite a correct name in terms of both its origin (deep pallial amygdala) and its termination site (ventromedial hypothalamus). This tract contains zinc-rich fibers (Perez-Clausell, 1988; Smeets *et al.*, 1989), thus

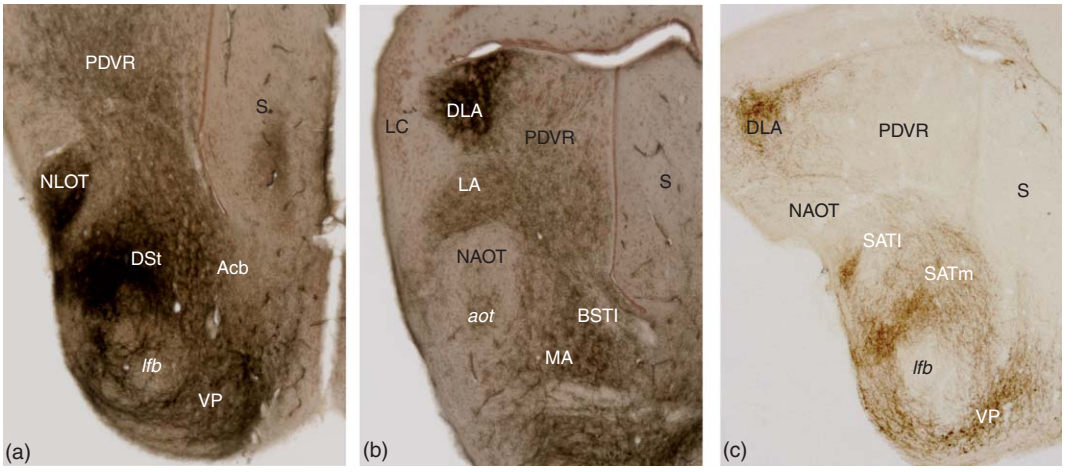

Figure 12 Chemoarchitecture of the amygdala of *Podarcis*. The (immuno)histochemistry for AChase (a and b) and tyrosine hydroxylase (TH, c) reveals a convergent cholinergic/dopaminergic innervation of the DLA. The NLOT also shows a dense AChase reactivity. Compared to the dorsal striatum proper (DSt), the subpallial amygdala shows a scarce AChase reactivity and a low density of TH-immunoreactive fibers.

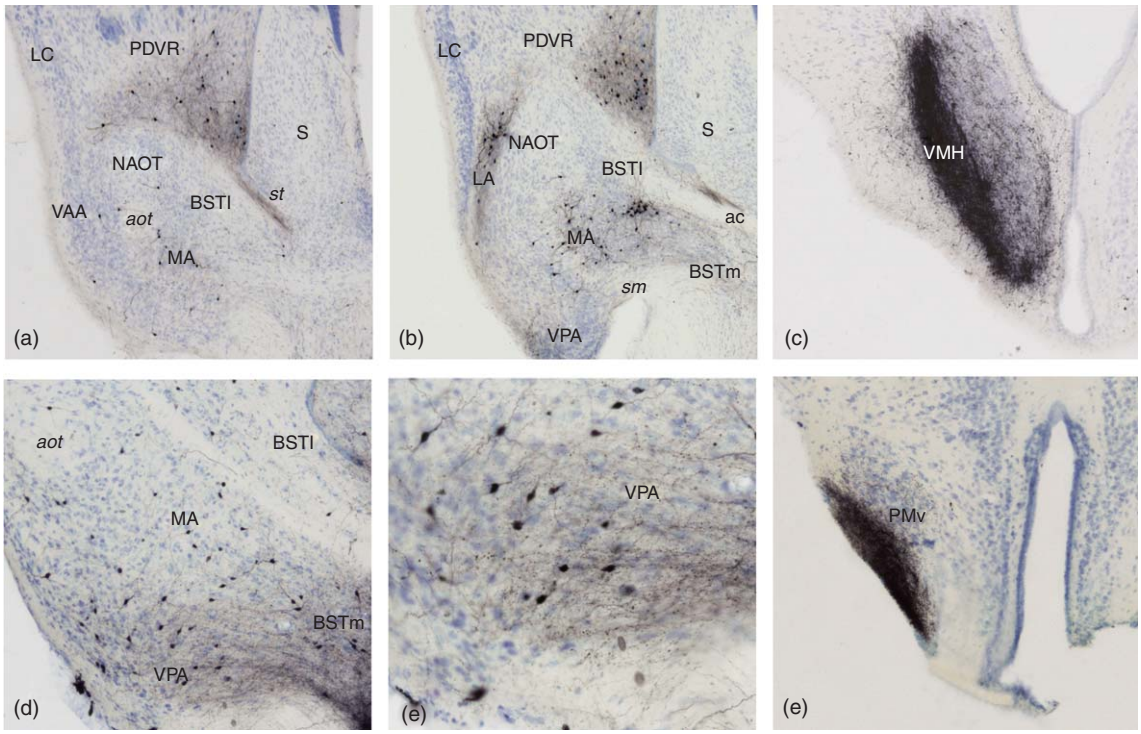

Figure 13 Amygdaloid projections to the hypothalamus in lizards. a and b, Rostral (a) and caudal (b) sections through the amygdala of a lizard that received an injection of dextranamine in the core of the ventromedial hypothalamic nucleus. Cells projecting to the VMH core are seen in the PDVRvm and LA as well as in most of the MA and portions of the BSTm. The pallial and subpallial bundles of the stria terminalis join at preoptic levels. c, The same projection is revealed by anterograde labeling after a tracer injection restricted to the PDVR. Labeling is seen in the VMH core. d and e, Labeling found in the amygdala of a lizard that received an injection of dextranamine in the premammillary hypothalamus, which did not involve the VMH core. Although the labeling in the subpallial amygdala is also located in the MA and BSTm, in the pallial amygdala, labeling is mainly observed in the VPA. At higher magnification (e), both retrograde and anterograde labeling is visible in the VPA, thus indicating that this nucleus is reciprocally connected with the premammillary hypothalamus. f, In a lizard that received an injection involving the VAA and VP, the presumed ventral premammillary hypothalamus shows a dense anterogradely labeled terminal field. More rostrally, labeled fibers avoid the VMH core but innervate the lateral shell (see Lanuza *et al.*, 1997).

confirming the glutamatergic nature (pallial origin) of some of its fibers. This strongly suggests that the ABp finds its homologue in the PDVRvm/LA of the reptilian ventral pallium (Table 3).

2.14.5.2.2.(ii).(b) The dorsomedial PDVR as the sensory interface of the reptilian amygdala As we have already seen, the PDVRdl projects to the ventral striatum (Figure 11c) and the PDVRvm contains the cells of origin of the pathway to the ventromedial hypothalamus (Figures 13a and 13b). In contrast, the PDVRdm seems only involved in intra-amygdaloid connections. Thus, tracer injections in the PDVR result in massive anterograde and retrograde labeling in the LA and DLA (Figure 14a). Moreover, in our material the PDVRdm only shows retrogradely labeled neurons after tracer injections involving most of the SAT, which, as we will discuss below, is the most likely candidate for the reptilian central amygdala.

The afferents to the PDVR were traced for the first time by Lanuza *et al.* (1998) in the lizard *P. hispanica*. Their findings suggest that the dorsal ventricular ridge of reptiles is anatomically and functionally heterogeneous. Its anterior aspect (anterior dorsal ventricular ridge: ADVR) receives discrete nonoverlapping auditory, somatosensory, and visual thalamic inputs. In contrast, the PDVR is the target of the medial posterior and posterocentral thalamus, which receives a convergent set of afferents from auditory, visual, and somatosensory midbrain and brainstem structures. The PDVR also receives direct afferents from the parabrachial region, probably conveying nociceptive, viscerosensitive, and/or gustatory information, and from the nucleus of the lateral lemniscus (auditory). In addition, highly processed sensory inputs arising from the dorsal (hippocampal) cortex (multimodal contextual), the ventral rostral LC (olfactory), and the three sensory areas of the ADVR (auditory, somatosensory, and visual) also reach the PDVR. Finally,

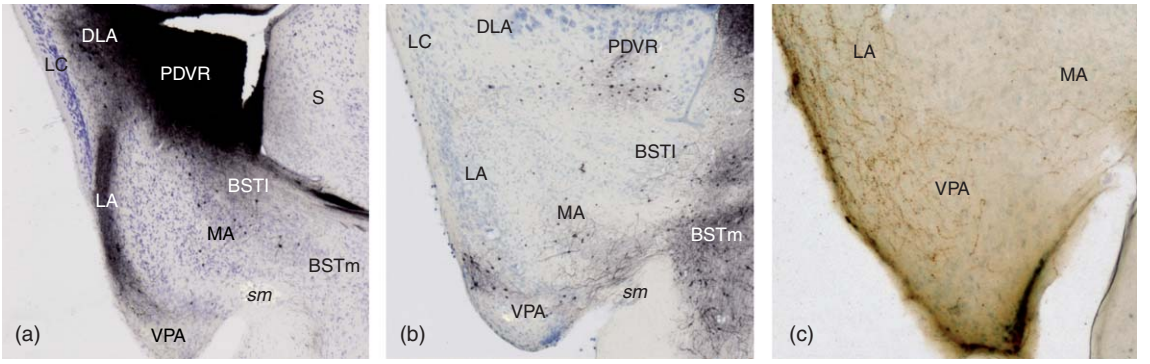

Figure 14 Intrinsic, preoptic, and hippocampal connections of the reptilian amygdala. a, Injections of dextranamine in the PDVR reveal an intricate set of interconnections within the basolateral amygdala of lizards. Thus, both the DLA and the LA show retrograde and anterograde labeling. In addition, the BSTI and SAT (Figure 15c), which constitute the central extended amygdala of lizards (Table 3), show anterograde labeling indicative of abundant basolateral-to-central intra-amygdaloid projections. The MA also seems to project to the basolateral amygdala (see retrogradely labeled cells). b, Retrograde labeling in the amygdala after a tracer injection involving the BSTm and the medial preoptic area. The presence of labeled cells in the PDVRvm should be attributed to the involvement of a part of the pallial stria terminalis in the injection site. In addition, strong retrograde labeling in the MA and VPA indicates a projection of both nuclei to the BSTm/preoptic area. c, Tracer injections (*Phaseolus vulgaris* leucoagglutinin) in the caudal dorsal (hippocampal) cortex of lizards reveal a projection to the basolateral amygdala, including the DLA (not shown), and LA as well as to the VPA and MA.

the PDVR is engaged in intra-amygdaloid afferents (with the DLA, LA, and MA; Figure 14a). Additional afferents to the PDVR arising from the caudal VTA, several hypothalamic nuclei (including the VMH), and the basal forebrain depict a complex pattern of sensory and modulatory afferents that fits with its homology with the basolateral amygdala of mammals.

In summary, the PDVRdm is the ventropallial amygdaloid center that receives massive sensory inputs and is only involved in projections to regions of the basolateral amygdala and to the central EA. In other words, it is the sensory interface of the basolateral amygdala of reptiles, thus being connectionally comparable to the mammalian L. However, when comparing reptiles and mammals, it becomes evident that the mammalian amygdala displays a more elaborated amygdaloid circuitry in which sensory interface and output centers are clearly separated (and interconnected), whereas in the reptilian amygdala both centers are somewhat mixed up.

After their studies of the projections to the hypothalamus in the gecko, Bruce and Neary (1995a, 1995b, 1995c) proposed that the anterior DVR, which receives direct sensory afferents from the thalamus (Ulinski, 1983) and projects to the PDVR (Lanuza *et al.*, 1998) but not to the hypothalamus, is the reptilian homologue of the mammalian L. This hypothesis is also supported by the ventropallial nature of the ADVR (Smith-Fernandez *et al.*, 1998). The amygdaloid nature of the ADVR was questioned by Lanuza *et al.* (1998) on the basis of its unimodal thalamic afferents, which contrasts with the polimodal and limbic thalamic afferents attributed to amygdaloid centers. However, this view needs to be revised in the light of new evidence suggesting that the principal sensory nuclei of the dorsal thalamus of reptiles (medial, posteromedial, posterocentral), including the nucleus rotundus (Guirado *et al.*, 2000), might indeed be homologues to the posterior/intralaminar thalamus of mammals (Davila *et al.*, 2000).

Another important difference between the mammalian L and the ADVR of reptiles that is very significant from a comparative viewpoint is the pattern of projections to the striatum. Whereas the ADVR projects massively and topographically to the dorsal (but not to the ventral) striatum, the mammalian L shows projections to the ventral (and scarce projections to the dorsal) striatum (our unpublished results; Pitkanen, 2000). Nevertheless, the comparative significance of the reptilian dorsal striatum (e.g., its homology with the mammalian CPu) is also a debatable issue (Lanuza *et al.*, 2002). Therefore, the possible homology of the ADVR of reptiles (and birds; see below) with part of the mammalian LA cannot be ruled out, although alternative views should be carefully considered (Striedter, 1997; Puelles, 2001).

2.14.5.2.2.(ii).(c) Amygdalocortical projections
Our proposal of homologies between the reptilian and mammalian amygdala predicts that the DLA, PDVR, and LA should project to the dorsal pallium, thus reciprocating the projection from the dorsal pallium to the amygdala (Hoogland and

Vermeulen-Vanderzee, 1989; Lanuza *et al.*, 1998). This would be the reptilian counterpart of the corticoamygdalocortical loops that in the mammalian brain involve the B and AB on the one hand, and the frontotemporal cortex on the other. However, in contrast to mammals, the amygdala of reptiles apparently display few projections directed to the dorsal pallium. This fact probably indicates that the presence of projections to the dorsal pallium is an acquired trait of the mammalian amygdala, related to the important changes that the dorsal pallium underwent during the early evolutionary history of mammals.

In contrast, all the studied reptiles display important interconnections with the ventropallial areas that provide nonchemosensory information to the amygdala. Thus, the LA projects back to the ADVR, thus reciprocating the strong input from the ADVR to the PDVR/LA (Bruce and Butler, 1984). The comparative significance of this pathway awaits further data on the nature of the ADVR.

2.14.5.2.2.(iii) The VPA shows many similarities with its putative mammalian homologue, the AHA The study of the amygdalohypothalamic pathways of reptiles has revealed the presence of a second projection within the pallial component of the stria terminalis, besides the one arising in the PDVRvm/LA. This projection arises in the ventral amygdala (VPA and VAA), leaves the cerebral hemispheres through the so-called lateral amygdalofugal tract (Lanuza *et al.*, 1997; Figure 13d), and terminates in the VMH shell, the LTM, and premammillary hypothalamus (Figure 13f). Injections of tracers in the premammillary and mammillary hypothalamus, which did not involve the VMH at all (and, as a consequence, show no labeled cells in the PDVR and LA), resulted in the presence of abundant, intensely labeled neurons in the VPA (Figures 13d and 13e). This strongly suggests that the VPA is the origin of the projection to the LTM and premammillary hypothalamus whereas the VAA originates a projection directed at the dorsal lateral hypothalamus.

In mammals, the amygdala also projects to the region of the posteromedial BST and the medial preoptic hypothalamus. This projection arises from both the EA (namely, the medial amygdala; Canteras *et al.*, 1995) and the AHA in the pallial amygdala (Canteras *et al.*, 1992a). The forebrain of reptiles displays a similar projection that arises from the VPA (Figures 14b and 14c). As in mammals, in lizards this connection with the preoptic hypothalamus is reciprocal.

Therefore, the VPA is connected with medial preoptic hypothalamus, the shell of the VMH, and the premammillary hypothalamus. These hodological properties strongly support its homology with the mammalian AHA, based on a similar topological position within the posterior ventral pallium and deep to the cortical vomeronasal amygdala.

Other hodological and histochemical properties of the VPA further support this homology. Thus, like the AHA of mammals (Canteras *et al.*, 1992a), the VPA projects to the ventral lateral septum (Font *et al.*, 1998) and receives afferents from the portion of the Hp (CA1 in mammals) that projects to the ventral lateral septum (Figure 14c). In addition, like the AHA of mammals (Simerly *et al.*, 1990), the VPA is the most prominent pallial cell group of the reptilian telencephalon, expressing high levels of receptors to sexual steroids. The distribution of receptors to sexual steroids has been studied with different techniques in different reptiles, such as the whiptail lizard (Young *et al.*, 1994), the geckonids *Gecko* (Tang *et al.*, 2001) and *Eublepharis* (Rhen and Crews, 2001), in *Sceloporus* (Moga *et al.*, 2000), in the green anole (Rosen *et al.*, 2002), and in the garter snake (Halpern *et al.*, 1982). In lizards steroid-sensitive cells are observed in a cell group called external amygdala that seems to correspond to the VPA, as defined here. In snakes, Halpern *et al.* (1982) described a group of steroid-concentrating neurons located in the ventral telencephalon just rostral to the ventral NS, named ventral amygdaloid nucleus, that seems also to correspond to the VPA (Lanuza and Halpern, 1998).

All these data indicate that the VPA, like its mammalian homologue (AHA), is engaged in a circuit composed of vomeronasal centers (medial EA) and steroid-sensitive structures in the forebrain (ventrolateral septum, medial EA, premammillary hypothalamus), and expresses itself as receptors to sexual steroids. This strongly suggests that the VPA is a nucleus of the pallial amygdala specialized in the control of agonistic and reproductive behavior, as has been suggested for its mammalian counterpart.

2.14.5.3 The Reptilian Subpallial Amygdala

The caudal pole of the striatopallidal telencephalon of reptiles, adjacent to the above-defined pallial amygdaloid centers, includes a number of nuclei that are generally considered as the reptilian subpallial amygdala. There, nuclei have been named using a mixture of topographical and comparative

terminology, such as the medial amygdala, the BST, central amygdala, or striatoamygdaloid transition area. Nevertheless, the delineation and identification of these nuclei are not clear in the literature due to both the use of inappropriate criteria to define them and to the presence of interspecies differences. In addition, the use of topographical terminology might cause confusion since it is suggestive of homologies with the mammalian amygdala that might be erroneous (Box 1).

Box 1 The vomeronasal system and the variability in the organization of the reptilian pallial amygdala

Our proposal of homologies for the reptilian pallial amygdala is mainly based on data from Lacertidae lizards and fit some of the published literature in teiidae (*Varanus* and *Tupinambis*; Hoogland, 1977; Voneida and Sligar, 1979). However, some of the published data in other squamate reptiles apparently do not fit well with the view proposed here. Thus, for instance, in geckonid lizards the massive projections from the amygdala to the striatum have not been described. This is probably due to slight differences in the organization of the pallial amygdala rather than to the absence of these projections in geckonids. For instance, the main source of amygdalostriatal projections in *Podarcis*, the DLA, can be identified in other reptiles by means of the histochemical markers referred to above. Thus, the caudal cerebral hemispheres of geckonids displays an area innervated by cholinergic/AChase fibers (*Gecko gekko*: Hoogland and Vermeulen-Vanderzee, 1990; *Tarentola mauritanica*: unpublished observations) that also shows a rich dopaminergic innervation (Smeets *et al.*, 1986b). Therefore, the DLA of geckonid lizards seems to show a relatively ventral location within the cerebral hemispheres compared with the lizards of the family Lacertidae (such as *Podarcis* and *Gallotia*).

These differences in the organization of the caudal cerebral hemispheres are probably related to the different development of the vomeronasal system that is revealed by the size of the NS, which is much smaller in Geckonidae than in Lacertidae. This is supported by the finding of a more ventral situation of the AChase/tyrosine hydroxylase-innervated amygdaloid area (probably the DLA) in anoles, where the vomeronasal system is nearly absent (Figures B1a and B1b).

On the other hand, comparison of the data in Lacertidae with those of snakes, where the vomeronasal system probably reaches its highest degree of development, also reveals some apparent differences. These pertain to the presence of the projections from the DLA to the hypothalamus in snakes (Martinez-Marcos *et al.*, 1999). Although this may reflect real differences between lizards and snakes, it may also be due to a misdefinition of the DLA of snakes. In fact, the structure named as DLA by Martinez-Marcos *et al.* (1999, see figure 1 in this article) does not seem deep to the lateral cortex (thus lateropallial) but a cell group interposed between the PDVR and the LA, located next to the NS (thus very likely ventropallial). In this respect, it is interesting to note that the DLA cells identified as projecting to striatal territories (olfactostriatum) in *Thamnophis* (see figures 7c and 8c in Martinez-Marcos *et al.*, 2005) occupy a position that is clearly more rostral than those projecting to the hypothalamus. Dealing with this, the study of the distribution of AChase and tyrosine hydroxylase (TH) reveals convergent catecholaminergic and cholinergic innervations (Figures B1c and B1d) of a cell group apparently displaying the same location as the cells projecting to the olfactostriatum (Martinez-Marcos *et al.*, 2005) but clearly rostral to the ones projecting to the hypothalamus (Martinez-Marcos *et al.*, 1999). Therefore, it seems that, when properly defined using reliable histochemical markers, the DLA of snakes turns out to be a cell group projecting bilaterally to the striatum, but not to the hypothalamus.

Although data in crocodiles and turtles are scarcer, in general they agree with the view we propose. For instance, in turtles the region of the posterior DVR shows a similar pattern of multimodal thalamic inputs (Belekhova and Chkheidze, 1992) and intratelencephalic (ADVR-PDVR) sensory afferents (Belekhova and Chkheidze, 1991; Chkheidze and Belekhova, 1992). In addition, the posterior DVR region of turtles also displays abundant projections to the striatum (Siemen and Kunzle, 1994) comparable to the ones described in lizards by our group (Novejarque *et al.*, 2004). Moreover, there is evidence of the existence of massive projections to the hypothalamus arising from the caudal cerebral hemispheres (PDVR and the so-called basal DVR) in turtles (see figure 9 in Cordery and Molnar, 1999).

In a similar way, Pritz and Stritzel (1992) described a projection to the posterior DVR of crocodiles from a thalamic cell group in the neighborhood of the auditory relay, the nucleus reuniens pars diffusa. As discussed in detail by Lanuza *et al.* (1998), this cell group seems part of the multimodal posterior

thalamus, thus suggesting an amygdaloid nature of the PDVR and adjacent areas also in crocodiles. Moreover, in the caudal cerebral hemispheres of the caiman (Brauth and Kitt, 1980), there are two patches intensely reactive for AChase in the NLOT and the lateral edge of the caudal DVR, which projects to the striatum, a situation that recalls the DLA. Data on the anatomy of the cerebral hemispheres of crocodilians are urgently needed, especially since they represent the closest living relatives of the stem reptiles that gave rise to birds (Whetstone and Martin, 1979). In fact, the study of the distribution of glial fibrillary acidic protein reveals a similar organization of the cerebral hemispheres of crocodiles (Kalman and Pritz, 2001) and chicken (Kalman *et al.*, 1998) that may be very useful to understanding the evolution of the amygdala.

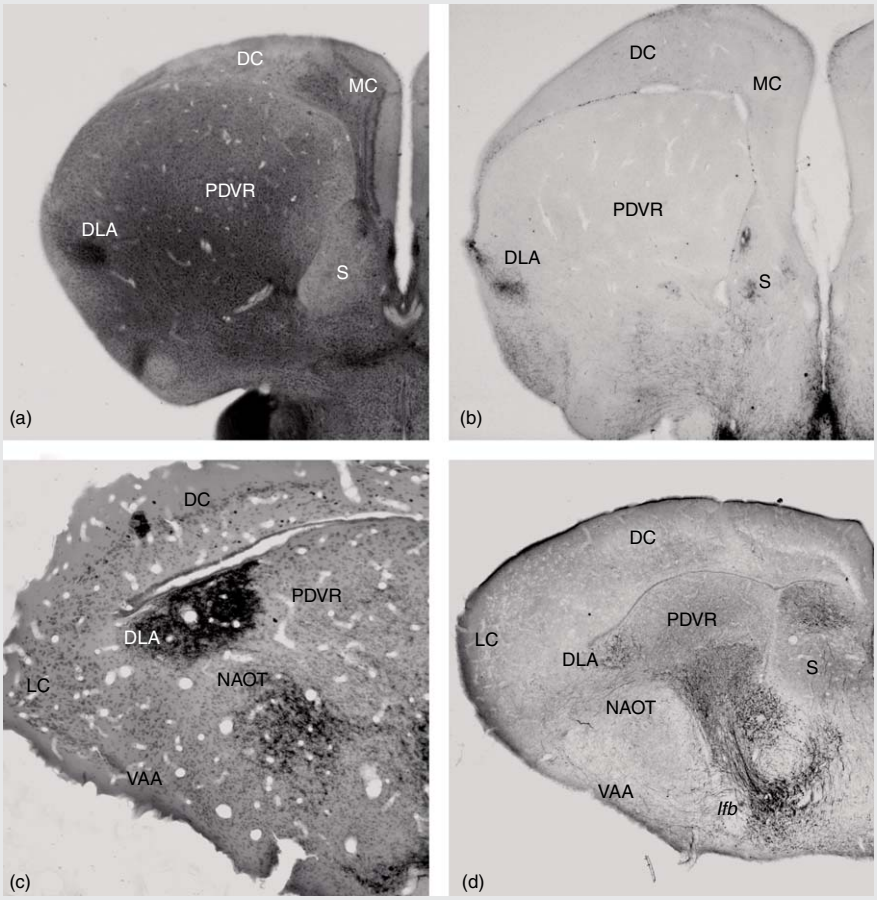

Figure B1 The amygdala of microsmatic and macrosmatic squamate reptiles. a and b, The strong reduction of the olfactory and vomeronasal system in the lizard *Anolis carolinensis* has introduced important changes in the organization of its brain. Nevertheless, the DLA can be identified by the convergent innervation of AChase (a) and TH (immuno)reactivity (b). The so-defined DLA seems displaced ventrally relative to the position it occupies in *Podarcis* (Figure 12), probably due to the lack of a nucleus sphericus in *Anolis*. The DLA of *Anolis* recalls the dorsal arcopallium of birds (Figure 19). c and d, This contrasts with the situation in the snake *Thamnopis sirtalis,* where the presence of a huge nucleus sphericus occupying the whole caudal half of the cerebral hemispheres has displaced the DLA rostralwards, as indicated by the AChase (c) and TH (immuno)reactivity (d). The pictures of *Thamnophis* have been kindly donated by Drs. Alino Martinez-Marcos and Mimi Halpern.

In this section, we try to clarify the architecture of the subpallial amygdala of reptiles, mainly using data of squamate reptiles. In this respect, we will identify the medial and central EA of reptiles by studying the features that define them in mammals.

2.14.5.3.1 The reptilian extended amygdala: The identity and divisions of the bed nucleus of the stria terminalis As we have seen above, in mammals the internal capsule separates the amygdala proper from the extra-amygdaloid BST (with the supracapsular BST and the sublenticular EA

connecting both structures). In reptiles, and in general in nonmammals, an internal capsule is absent (the lateral forebrain bundle is reduced to a compact tract that runs through the basal telencephalon; Figure 9). Therefore, in the subpallial amygdala of reptiles (and this is also valid for birds), the centromedial amygdala and the BST are not separated, but conform a single cell mass in the basal caudal cerebral hemispheres. This has generated a confusing and contradictory nomenclature of this area of the caudobasal cerebral hemispheres, which we are trying to clarify here.

The name 'bed nucleus of the stria terminalis' designates cells that are intermingled among the fibers of the stria terminalis and are targets for them. Our material reveals that, in lizards, the stria terminalis is composed of two main tracts (Figures 13a and 13b) that join at preoptic levels. The dorsal stria terminalis is a compact tract that leaves the PDVR medially, just ventral to the ventral sulcus of the lateral ventricle, and enters the hypothalamus caudal to the anterior commissure. The ventral stria terminalis (which arises from the VPA and MA; see below) is a less compact fiber tract that enters the preoptic area ventral to the anterior commissure. Both components of the stria terminalis have very short intratelencephalic trajectories, and the cell groups with which they are associated should be considered the two main parts of the reptilian BST, namely the lateral (accompanying the dorsal stria terminalis, BSTl) and the medial BST (BSTm).

Comparing this view with previous literature on the architecture of the reptilian forebrain, we conclude that the BSTl as defined here is equivalent to the structures of the brain of the gecko, named as nucleus of the anterior commissure by Smeets *et al.* (1986a), and to the caudomedial SAT according to Bruce and Neary (1995b). In turn, the BSTm is comparable to the BST of the gecko according to the terminology of Smeets *et al.* (1986a), the interstitial amygdala of the gecko according to Bruce and Neary (1995b), and the nucleus interstitialis of the whiptail lizard (Young *et al.*, 1994). The latter terminology was also adopted by our group in some papers on the anatomy of the brain of *Podarcis* (Font *et al.*, 1997; Lanuza *et al.*, 1997).

2.14.5.3.2 The medial extended amygdala of reptiles In most studies of the projections from the AOB, a more or less prominent terminal field has been observed just medial and ventral to the transition between the rostral NS and the BAOT. This structure was named ventromedial amygdala (Martinez-Garcia *et al.*, 1991), medial amygdala (MA; Lanuza and Halpern, 1998; this name was used in the gecko by Bruce and Neary (1995a), and has finally been adopted by us) or central amygdaloid nucleus (Lohman and Smeets, 1993) depending on the authors and/or species under study. In all of these studies, the projection from the AOB is seen to extend further medially into the ventrolateral aspect of the BSTm (Figure 10c). At these levels, the fibers from the main olfactory bulb running within the stria medullaris are just superficial to the MA. This situation recalls the TnA of birds (see below).

There are no studies devoted specifically to the study of the connections of the MA and BSTm. (In a series of experiments designed to unravel the neural basis of tongue-flick (a behavior that delivers chemicals into the vomeronasal organ), Martinez-Marcos *et al.* (2001) analyzed in detail the amygdaloid projections to the hypoglossal nucleus of the snake *T. sirtalis*. Their results indicate that the medial amygdala projects indirectly to the hypoglossal nucleus using a relay in the LHN, but directly to other centers of the dorsal medulla. However, if one compares the retrograde labeling they find after injections into the LHN (see figure 4g in Martinez-Marcos *et al.*, 2002) or their injections into the medial amygdala (see their figure 4a), with the projections from the AOB (see figures 1e and 1f in Lanuza and Halpern, 1998), it becomes evident that most of the cells projecting to the LHN are out of the chemosensory subpallial amygdala (MA), but in a location dorsal to the anterior commissure that probably corresponds to the SAT of snakes.) However, data derived from tracer injections in other areas of the brain of lizards and snakes indicate that, from a comparative point of view, the names MA and BSTm seem appropriate for these structures. As we have described above, the BSTm is crossed by axons from MA cells on their way to the hypothalamus and therefore, very likely, receives projections from the MA. In addition, tracer injections in the preoptic hypothalamus (Lanuza *et al.*, 1997; Martinez-Marcos *et al.*, 1999) suggest that the MA and the BSTm are reciprocally connected with the medial preoptic hypothalamus (Figure 14b). Moreover, both the MA and the BSTm project to the VMH (Figures 13a and 13b) and premammillary hypothalamus (Figures 13d and 13e; Bruce and Neary, 1995b; Lanuza *et al.*, 1997; Martinez-Marcos *et al.*, 1999). This clearly recalls the situation in mammals and suggests that the MA and BSTm conform to the reptilian medial EA. In fact, as

we will see, they share most of their connections and histochemical properties.

Like the mammalian medial EA, the reptilian MA and BSTm provide a feedback projection to the AOB (Martinez-Garcia *et al.*, 1991; Lanuza and Halpern, 1998) and receive a direct projection from the vomeronasal cortex (NS; Lanuza and Halpern, 1997; Lanuza *et al.*, 1997; Novejarque *et al.*, 2004). Moreover, like the medial EA of mammals, the BSTm of lizards projects to the ventral aspect of the lateral septum (Font *et al.*, 1997). Although there is no direct evidence using double-labeling experiments, immunohistochemical data in several reptiles suggest that this projection is rich in one of the forms of the reptilian vasopressin (vasotocin), like its mammalian counterpart (Wang *et al.*, 1993). Thus, the BST (very likely the BSTm plus portions of the MA) displays cells immunoreactive for vasotocin in lizards (Stoll and Voorn, 1985; Thepen *et al.*, 1987), snakes, and turtles (Smeets *et al.*, 1990), and in all the reptiles studied the ventral lateral septum is innervated by vasotocin-immunoreactive fibers. In agreement with the situation in mammals (Wang *et al.*, 1993), this projection system displays sexual dimorphism in reptiles (Stoll and Voorn, 1985; Smeets *et al.*, 1990).

This proposal of homology is strongly supported by the fact that the MA and BSTm of lizards (together with the ventral lateral septum, with which they are connected), display the most remarkable population of sexual steroid-sensitive cells in the whole subpallial telencephalon (Young *et al.*, 1994; Moga *et al.*, 2000; Rhen and Crews, 2001; Rosen *et al.*, 2002). A similar situation is present in snakes (Halpern *et al.*, 1982). This constitutes another of the defining features of the medial EA of mammals (Tables 2 and 3).

2.14.5.3.3 Central extended amygdala of reptiles

The name 'central' amygdala was first applied to designate a cell group in the brain of the gecko (Smeets *et al.*, 1986a) that occupies a central location within the putative amygdaloid region. However, since this nucleus is the target for a projection from the AOB (Lohman and Smeets, 1993), it is not comparable to the central but to the medial amygdala of mammals (see above). The reptilian homologue of the mammalian Ce was identified a few years later. In research primarily devoted to the study of the efferent connections of the dorsal and ventral striatum, Russchen and Jonker (1988) realized that injection of tracers in the caudal basal ganglia, what they called striato-amygdaloid transition area (SAT), resulted in a distinct pattern of anterograde labeling. The SAT seemed to project to the lateral hypothalamus (lateral posterior hypothalamic nucleus, LHN; Lanuza *et al.*, 1997), to the midbrain tegmentum (like the rest of the striatopallidal system) and to more distant targets in the central gray, parabrachial area (Figure 15a) and medulla (nucleus of the solitary tract and dorsal motor vagal complex; Figure 15b). This is a pattern of connections identical to the one displayed by the mammalian central EA. It is important to note that the caudal SAT fuses with the BSTl, so that it is tempting to suggest that, together, both structures conform the central EA of reptiles.

Several lines of evidence are in agreement with this proposal of homology. Like the mammalian Ce and the dorsal and posterolateral BST, the SAT of lizards receives afferents from the parabrachial nucleus (Figure 15a), as well as from several nuclei in the posterior thalamus, including the nucleus rotundus (Guirado *et al.*, 2000) and the posteromedial and posterocentral nuclei (Lanuza *et al.*, 1998). In addition, it receives projections from the basolateral amygdala (PDVR and DLA; Novejarque *et al.*, 2004; Figure 15c) and from the rostral deep lateral pallium (dLC). Moreover, the SAT displays at least some of the remaining defining features of the mammalian central EA. Thus, in *Podarcis* the lateral aspect of the SAT and the region of the striatum adjacent to it, just medial to the NAOT, display a dense CGRPergic innervation (Martinez-Garcia *et al.*, 2002b; Figure 15d), which recalls the projection to the CeC and amygdalostriatal transition of the mammalian brain. The origin of these CGRPergic fibers is not clear but the most likely candidates are the two cell groups projecting to the amygdala that display CGRP-immunoreactive cells, namely the parabrachial nucleus and the ventral aspect of the posterior thalamic nuclei (Lanuza *et al.*, 1998). This is also a feature shared with the mammalian central EA (Schwaber *et al.*, 1988; Yasui *et al.*, 1991). Unfortunately, there are no detailed descriptions of the distribution of CRF and NT in the brain of reptiles. These data are needed to prove the hypothesis of homology between the mammalian central EA and the SAT of reptiles.

2.14.5.4 The Reptilian Amygdala: A Summary

All the data reviewed above convincingly demonstrate that the reptilian amygdala contains pallial and subpallial components comparable to those of the amygdala of mammals. The pallial amygdala of

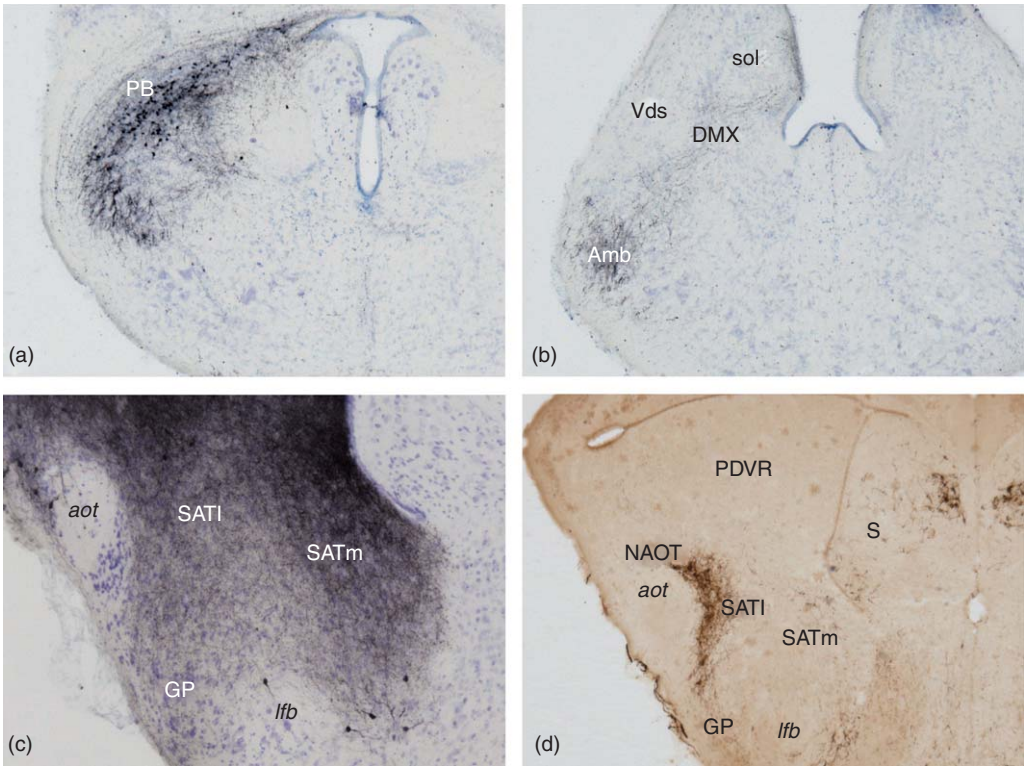

Figure 15 Connections and histochemical properties of the SAT. a and b, Tracer injections encompassing the SAT of *Podarcis* give rise to anterograde labeling in the lateral hypothalamus (Lanuza *et al.*, 1997), but also in the parabrachial area (a), where retrograde labeling is also visible, and in the medulla (b), including the nucleus of the solitary tract (sol), the dorsal motor vagal nucleus (DMX), and the ambiguus (Amb). c, Anterograde labeling in the SAT following a tracer injection in the PDVR and LA in *P. hispanica*. d, The lateral SAT (SATl) of the lizard *P. hispanica* shows a dense innervation by CGRP-immunoreactive fibers. The medial SAT (SATm) shows a much weaker innervation that is mainly composed of nests around the cell bodies.

reptiles is composed of cortical olfactory (VAA, portions of the LC) and vomeronasal centers (NS) plus deep, unlaminated regions (PDVR, LA, and DLA) that receive multimodal and unimodal afferents from different levels of the neuroaxis. An additional nuclear pallial nucleus that (in spite of its superficial location) is topologically deep to the vomeronasal cortex, the VPA, is part of a forebrain circuit closely related to the vomeronasal system which is rich in cells expressing receptors for sexual steroids.

The vomeronasal amygdala includes not only the NS (and VPA) but also a portion of the subpallium, the MA, and BSTm (medial EA), which is also very rich in receptors to sexual steroids. The pallial and subpallial centers of the vomeronasal amygdala are interconnected and project massively to centers in the limbic forebrain (septum, preoptic, and tuberal and premmamillary hypothalamus), probably involved in the control of reproductive and agonistic behaviors.

In contrast, the multimodal centers of the pallial amygdala (PDVR, LA, and DLA) project massively to the ventral striatum, including the Acb and the SAT. The latter is a part of the subpallial amygdala that shows long-distance projections reaching hypothalamic, tegmental, periaqueductal, pontine, and medullary targets. This pathway seems involved in the control of somatomotor, endocrine, and vegetative reactions. In addition, the deep lateropallial nucleus, the DLA, projects bilaterally to the dorsal striatum.

This picture is virtually identical to the one observed in mammals, thus suggesting that the amygdala as a whole has undergone quite a conservative evolution in the phylogeny of amniote vertebrates. As we will see, data from birds further support this view.

2.14.6 The Amygdala of Birds

Identifying the avian amygdala becomes a fundamental issue after the recent joint effort of an international forum of comparative neuroscientists to rename and reinterpret the telencephalon of

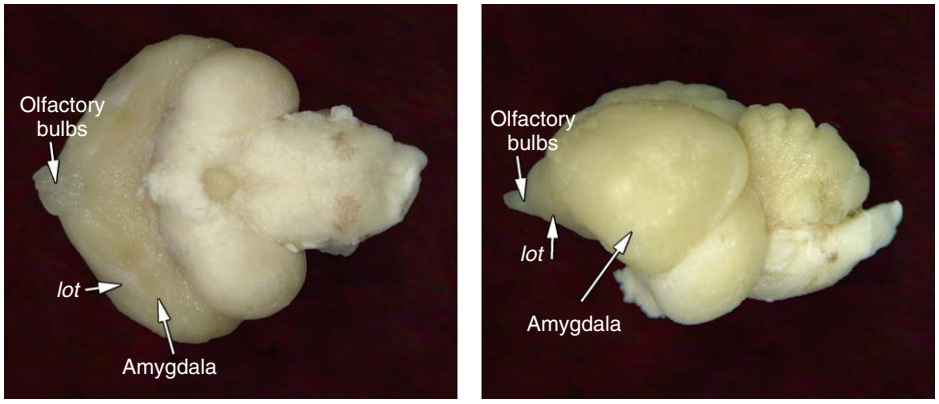

Figure 16 Ventral and lateral views of the brain of the quail (*Coturnix coturnix*). The regression of the olfactory system is evidenced by the small size of the olfactory bulbs (where accessory olfactory bulbs are absent) and the inconspicuous lateral olfactory tract (*lot*). An arrow points to the putative amygdala.

birds (Reiner *et al.*, 2004; Jarvis *et al.*, 2005). However, two features of the avian brain make this task especially difficult. First, as compared to mammals, birds possess very peculiar cerebral hemispheres, since they have a huge dorsal ventricular ridge (occupying an apparent subventricular position), but lack anything recalling the mammalian isocortex. This has resulted in important changes in the topographical relationships between the different areas of the pallium and subpallium of avian cerebral hemispheres, as compared to mammals. In addition, birds have undergone a regression of the olfactory and a virtual atrophy of the vomeronasal system, which, as we have seen, provide important inputs to the mammalian and reptilian amygdalae, where they constitute the defining features of their cortical and medial portions. This is clearly observed in a macroscopic view of the brain of birds (Figure 16), in which the olfactory bulbs are very small, the lateral olfactory tract is hardly visible, and no rhinal fissure is observed.

Nevertheless, once the reptilian amygdala and its components have been identified with a high degree of certainty, the similarities between the avian and reptilian brains (Ulinski, 1983) may be very helpful for our goal. In this section, we are using this strategy to identify the amygdala in the caudolateral telencephalon of birds and to delineate its main pallial and subpallial components by using the features that define them in both mammals and reptiles.

2.14.6.1 On the Nomenclature and Architecture of the Telencephalon of Birds

In this article, we will follow the revised nomenclature of the avian forebrain (Reiner *et al.*, 2004; Jarvis *et al.*, 2005). However some issues concerning this nomenclature need to be discussed prior to analyzing the identity of the amygdala of birds.

The caudal cerebral hemispheres of birds (Figure 17) includes several structures that conform a regular (superficial and layered) cortex, composed of several areas, from medial to lateral, the Hp, the APH, the area corticoidea dorsolateralis (CDL), and the CPi, that needed no renaming since their cortical nature was always recognized. Inner structures of the dorsal telencephalon include those pallial structures whose name contained the suffix striatum, which have been renamed to recognize their pallial nature. Thus, the deep pallium of the posterior telencephalon of birds is composed of the caudal edge of the mesopallium (M, formerly ventral hyperstriatum) and the caudal nidopallium (formerly caudal neostriatum), in which lateral and medial divisions are usually recognized (NCL and NCM respectively). The NCM includes the auditory field L. In addition, there is a region just deep to the CPi that extends dorsally up to the CDL, which is called the area temporoparieto-occipitalis (TPO).

More ventrally, the caudal poles of the lateral striatum (LSt; formerly paleostriatum augmentatum) and GP (formerly paleostriatum primitivum) occupy the medial aspect of the hemispheres. Just ventral to them (thus justifying the old name of ventral paleostriatum) there is a region now renamed as SpA, topologically superficial to the so-called lateral BST (occupying a juxtaventricular position).

Finally, ventral and lateral to the caudal subpallium there is a region traditionally called archistriatum and the nucleus teniae of the amygdala (TnA). The archistriatum was considered to be composed of several divisions that were named

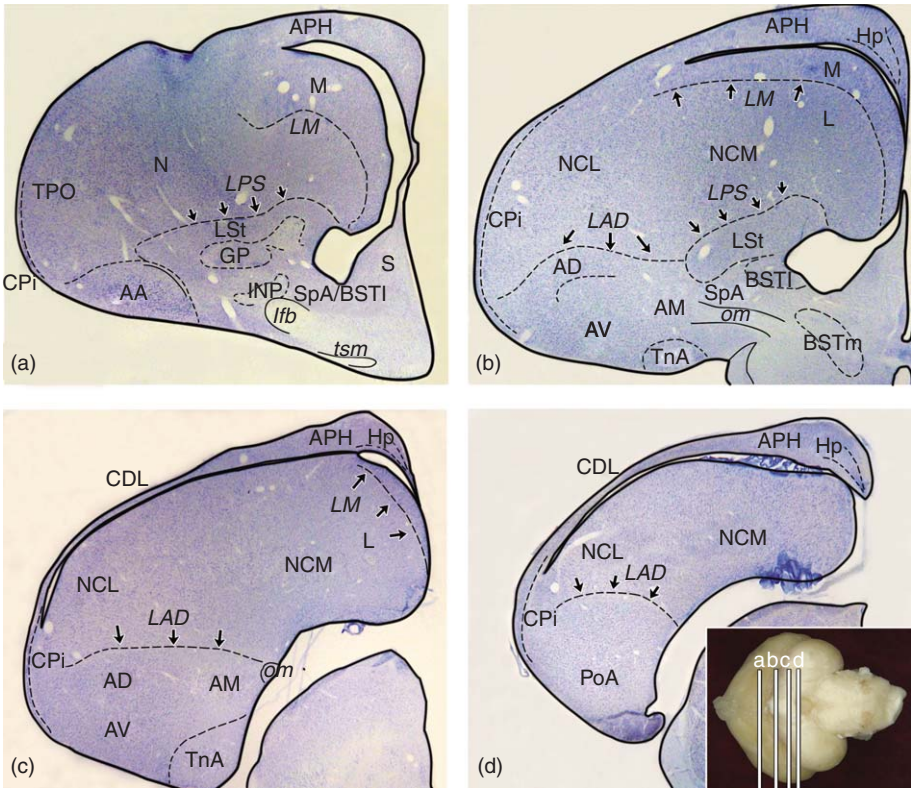

Figure 17 Cytoarchitecture of the caudal cerebral hemispheres of the chicken. Nissl-stained frontal sections through the left cerebral hemisphere of a newborn chicken at slightly precommissural (a); commissural (b); postcommissural (c); and caudal (d) levels of the telencephalon. The inset shows the approximate location of the sections on a ventral view of the avian brain. The different nuclei and cortical areas of the telencephalic structures are delineated using thin discontinuous lines, whereas thin solid lines indicate the main fiber tracts. Small arrows point to the laminae that separate the main divisions of the avian forebrain (also delineated in discontinuous lines), whose abbreviations are written in italics.

topographically as anterior, medial, intermediate (with dorsal and ventral subdivisions), and posterior. The new nomenclature reflects the putative pallial nature of the whole archistriatum by naming its parts as anterior arcopallium (AA), medial arcopallium (AM), dorsal arcopallium (AD; corresponding to the dorsal intermediate archistriatum), ventral arcopallium (AV; corresponding to the ventral intermediate archistriatum), and the posterior nucleus of the pallial amygdala (PoA, corresponding to the former posterior archistriatum).

Two problematic issues directly related to our purposes need to be discussed. First, the boundaries between the AA and the AD/AV (formerly intermediate archistriatum) have never been properly defined and the same happens with the border separating the AD/AV from the PoA. In this respect, the identity of the PoA is not clear and, consequently, different authors have labeled different structures as PoA (or posterior archistriatum), thus generating a confusing panorama (see, for instance, the extent of the PoA in Reiner and Karten, 1985, as compared to Kroner and Gunturkun, 1999). Most authors simply label as PoA (or posterior archistriatum) the caudal edge of the former archistriatum, thus including the caudal tip of the AD (like the latter, deep to the caudal-most CPi), plus the posterior aspect of the AV. Dealing with this, it is important to recall that the nowadays-accepted classification of the arcopallial-amygdaloid centers of birds is based on a topographical compartmentalization of this area introduced by Zeier and Karten (1971), who reported to have identified some four to eight cytoarchitecturally discrete nuclei in each of the major subdivisions of the former archistriatum. The poor understanding of the actual organization of the arcopallium/PoA is probably hindering our knowledge of its comparative and functional significance.

Second, the use of the term 'arcopallium' instead of the old name 'archistriatum' (Reiner *et al.*, 2004) is somewhat problematic since it excludes the possibility that a part of the former archistriatum may be subpallial. This is suggested by the distribution of

radial glia in developing chicken (Striedter and Beydler, 1997), indicating that the AM (formerly medial archistriatum) may be partially subpallial in nature and, therefore, part of the SpA. This issue requires a thorough analysis using modern techniques to identify the palliosubpallial boundaries in the avian brain.

2.14.6.2 Topological Identification of the Avian Pallial Amygdala

The mammalian and reptilian amygdalae contain lateropallial and ventropallial territories that, in turn, are composed of superficial laminar structures receiving subpial projections from the olfactory bulbs (the cortical amygdala) and deep nonlaminated centers (mainly multimodal), which constitute their basolateral amygdala. In this section, we are reviewing the literature available to identify and delineate these two pallial components of the avian amygdala (Figures 17 and 18). In addition, we will review the data on connections and histochemistry that may help to refine the comparison of the pallial amygdala of birds with that of reptiles and mammals.

2.14.6.2.1 Olfactory areas in the avian pallium: The avian cortical amygdala The small size of the olfactory bulbs of birds is probably the reason why their projections have been poorly investigated. Fortunately, Reiner and Karten (1985) traced the olfactory projections in pigeons by means of injections of tritiated amino acids. Their results demonstrate olfactory projections to the olfactory tubercle and the presence of abundant labeled fibers in the frontoarcopallialis (FA; frontoarchistriatal tract in the old nomenclature) through which they reach several parts of the pallium, including the whole CPi and more ventral regions in the caudal cerebral hemispheres. There, the olfactory projection reaches cortical areas

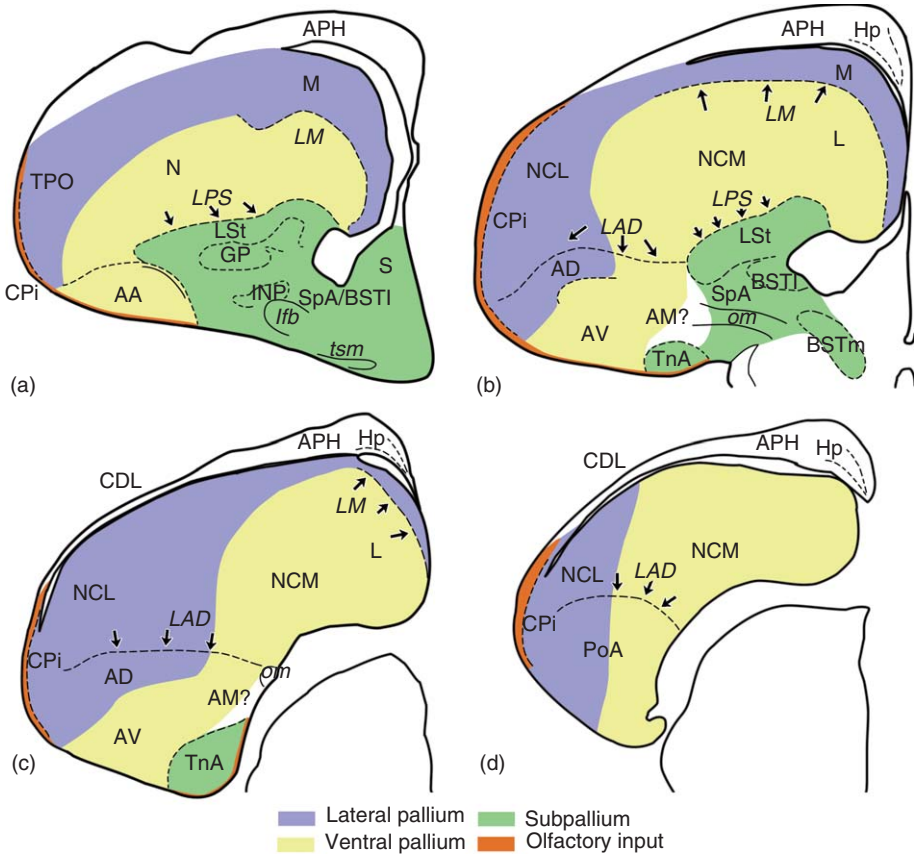

Figure 18 Pallial and subpallial territories of the avian amygdala. A schematic diagram of the amygdala of birds, based on the Nissl-stained sections of Figure 17, which shows the palliosubpallial boundary and the extent of the latero- and ventropallial territories within the pallial amygdala (based on Puelles *et al.*, 2000). The projection fields of the olfactory bulbs (based on the description by Reiner and Karten, 1985) are also indicated. The actual boundary of the ventral pallium with the subpallium is difficult to trace at the level of the AM (white region in the AM).

superficial to the AA, AD, and anterior part of the AV, up to the level of TnA. From there, olfactory fibers seem to enter the stria medullaris to reach the contralateral cerebral hemisphere through the habenular commissure. More caudally, a gap appears between the olfactory projection to the CPi and that to the TnA, so that apparently the structures superficial to the caudal portion of the AV are not olfacto-recipient. These results have been replicated in chick embryos using lipophilic tracers (Striedter *et al.*, 1998).

Reiner and Karten (1985) interpreted their results as demonstrative of the absence of olfactory projections to the amygdala in birds, with the exception of the olfactory pathway to the TnA. However, in the light of the results in reptiles and mammals, and of the interpretation of the nature and organization of the amygdala derived from them, the structures superficial to the AA and to the rostral AV, plus the caudal CPi, are to be interpreted as the cortical amygdala of birds. Reiner and Karten (1985) also discuss the lack of vomeronasal organ and of accessory olfactory bulbs and its possible consequences on the organization of the projections from the olfactory bulbs. In our view, this may have resulted in the disappearance of the projections to the superficial caudal aspect of the caudal AV that would have been the natural target for the projections from the AOB. This will be further discussed in relation to the existence or absence of a subpallial chemosensory amygdala (equivalent to mammalian Me).

2.14.6.2.2 The deep pallial amygdala in birds According to the general scheme of the amygdala of mammals and reptiles, those pallial structures deep to the olfacto-recipient cortical areas described above would constitute the pallial nuclear amygdala, e.g., the basolateral amygdala plus the AHA of birds. The distribution of radial glia in the cerebral hemispheres of chicken embryos (Kalman *et al.*, 1993; Striedter and Beydler, 1997) strongly suggests that the dorsolateral aspect of the arcopallium (pallial archistriatum, in the words of Striedter and Beydler, 1997) plus the caudal M, the NC, and TPO, are topologically deep to the olfacto-recipient cortical structures mentioned above (Figure 18). This was subsequently confirmed by combining an innovative method of tracing the fate of cells generated in specific zones of the telencephalic ventricles with labeling of the projections from the olfactory bulb in chicken embryos (Striedter *et al.*, 1998). In addition, as discussed above, the PoA contains the structures deep to the posterior edge of the CPi and fuses without clear boundaries with the caudal edge of the AD/AV. Consequently, its new name seems especially appropriate to designate a pallial amygdaloid structure.

These data indicate that the deep pallial amygdala of birds is conformed by, at least, the NC and the TPO plus the pallial arcopallium and the PoA.

2.14.6.2.3 Lateral and ventral pallial derivatives in the caudal avian cerebral hemispheres Although the olfactory projection is often taken as a marker of the lateral pallium (see, for instance, the title of the paper by Striedter *et al.*, 1998), data from the mammalian neuroanatomy reviewed above indicate that the olfacto-recipient cortical areas include lateropallial and ventropallial derivatives. This is fully supported by the pattern of expression of homeotic genes in the cerebral hemispheres of birds (Smith-Fernandez *et al.*, 1998), which indicates the lateropallial origin of the M and the ventropallial origin of the N. Using a similar approach and a detailed anatomical analysis, Puelles *et al.* (2000) mapped the ventropallial and lateropallial territories in the caudal cerebral hemispheres of chicken embryos. According to their results and their interpretation of the cytoarchitecture of the cerebral hemispheres of birds, the embryonic ventral pallial territories are composed of the rostral N, including the entopallium (E, formerly ectostriatum) and the basorostral pallial nucleus (Bas; formerly basal nucleus). In addition, the AV (classically called ventral intermediate archistriatum) displays a profile of gene expression typical of the ventral pallium that extends caudally into what most authors consider the PoA.

In turn, the lateral pallium includes the CPi, and the structures topologically deep to it, namely the whole M and the AD. Moreover, the lateral pallium seems to impinge into the PoA. As noted previously (Martinez-Garcia *et al.*, 2002a), topology and cytoarchitecture strongly suggest the existence of a lateropallial bridge connecting the rostral (M) with the caudal (AD) territories of the lateral pallium. This bridge is probably composed of the lateral aspect of the NC, including the TPO, part of which is indeed immediately deep to the CPi. This was fully confirmed by the pattern of expression of cadherins in the cerebral hemispheres of embryonic chicken (Redies *et al.*, 2001).

The position of the AA within this map requires further discussion. According to Puelles *et al.* (2000) and Redies *et al.* (2001), the AA (anterior archistriatum in the classical terminology) is part of the

subpallium. We consider, however, that the structure that they label as AA is a cytoarchitectonically distinct portion of the LSt of the embryonic chicken brain. In contrast, most of the avian neuroanatomists call AA to the anterior pole of what Puelles *et al.* (2000) and Redies *et al.* (2001) label as intermediate archistriatum, plus their nucleus of the LOT (see figures 3 and 4 in Redies *et al.*, 2001). If this interpretation is correct, the AA turns out to be a rostral ventropallial region (Figure 18) closely associated with the LOT (which in birds is named as frontal arcopallial tract, FA; Striedter *et al.*, 1998). As we will see, connectional data clearly support this view.

The palliosubpallial boundary is delineated by the lamina palliosubpallialis. However, at commissural and postcommissural levels, the AM is interposed between the SpA and the TnA, and crossed by the fibers of the occipitomesencephalic tract (OM) as they leave the cerebral hemispheres. Since the SpA and AM are subpallial, a transition between ventropallial and subpallial territories is expected at this level. Tracing this boundary becomes an unresolved and potentially important issue.

2.14.6.2.4 The avian pallial amygdala: A proposal of homologies with mammals The map of the pallial amygdala of birds depicted in Figure 18 leads to a proposal of homologies of the caudolateral cerebral hemispheres of birds with the mammalian pallial amygdala that is topologically consistent and shows congruence with the proposed map of the reptilian amygdala, with which the comparison is quite straightforward (Table 3). According to this proposal, within the lateral pallium, the CPi would contain the homologues of the mammalian lateropallial olfactory cortices, including the COApl and the transition areas with the piriform and entorhinal cortices (APi and TR, respectively). The structures of the avian brain deep to the CPi, including the lateral NC, TPO, AD, and the lateropallial PoA, would be the putative homologues for the mammalian deep lateropallial amygdala, the B nucleus.

The superficial ventropallial regions of the telencephalon of birds should be homologous to the olfactory and vomeronasal cortical areas of the mammalian amygdala. The AA is a rostral ventropallial region associated with the *lot* (FA), and consequently constitutes the most likely candidate for the avian homologue to the LOT of mammals. On the other hand, the superficial anterior part of the AV, which receives direct projections from the olfactory bulbs, occupies a position in the avian brain comparable that of the COAa in the mammalian amygdala. The deep anterior AV/AM seems topologically equivalent to the ABa of mammals, and therefore we conceive both structures as homologous.

In contrast, at the level of the caudal AV, a superficial olfacto-recipient cortex is lacking (this region is labeled as posterior archistriatum by Reiner and Karten, 1985). This occupies the topological position where the projections from the accessory olfactory bulbs should terminate (if they existed). Therefore, according to our view, birds have an only-deep caudal ventropallial region, where a vomeronasal cortex equivalent to the mammalian COApm is lacking, but the structures equivalent to the nuclei deep to it (ABp and AHA) are presumably located. In this respect, the location of the PoA in the caudal edge of the arcopallium (thus its name) suggests that its ventropallial portions are equivalent to the mammalian AHA (named posterior nucleus of the amygdala by Canteras *et al.*, 1992a) and the reptilian VPA. Finally, the NCM, a deeper ventropallial structure located in the dorsomedial PDVR of birds, is a good candidate for the mammalian L, thus equivalent to the reptilian PDVRdm (Table 3).

2.14.6.3 Connections and Histochemistry of the Avian Pallial Amygdala: Comparative Implications

There are few studies of the connections of the centers here proposed as the avian homologues of the pallial amygdala, and this is especially true for the putative cortical amygdala. Nevertheless, since the pioneer work by Zeier and Karten (1971) on the archistriatum of pigeons, all the published reports of projections of the arcopallium, PoA, and adjoining areas (Bingman *et al.*, 1994; Davies *et al.*, 1997; Dubbeldam *et al.*, 1997; Kroner and Gunturkun, 1999) coincide in indicating that the caudolateral pallial telencephalon originates a long descending projection known as occipitomesencephalic pathway (OM). This projection reaches not only parts of the hypothalamus (OM pars hypothalamii, OMH), as expected from a pallial amygdaloid structure, but also the posterior thalamus and deep midbrain (thus its name). This projection has been reported to reach also pontine regions, the reticular formation, and dorsal medulla (Zeier and Karten, 1971). No region of the caudal pallium of mammals or reptiles gives rise to such a projection. Thus, the OM seems exclusive of the avian brain. Consequently, we will not use this trait to discuss the identity of the avian pallial amygdala, but we devote a section to analyzing its possible origin, as well as its comparative and functional significance.

2.14.6.3.1 The connections of the cortical amygdala of birds The connections of the CPi have been studied in pigeons using large injections of anterograde and retrograde tracers (Bingman *et al.*, 1994). The results indicate that the CPi displays the characteristic projections of the piriform cortex, including associative and commissural projections and connections with other secondary olfactory centers, plus other connections that are difficult to interpret from a comparative viewpoint (e.g., connections with the dorsal mesopallium). In addition, the CPi is connected with the parahippocampal cortex and presumed deep pallial amygdaloid centers such as the AD, PoA, and TPO/N. It is also reciprocally connected with the bulbo-recipient subpallial amygdala (TnA). Moreover, it displays some descending projections to striatal territories, including the Acb and MSt (formerly lobus paraolfactorius), parts of the lateral septum, the BSTl, and the SpA. Finally, tracer injections in the CPi give rise to fiber labeling in the OM.

This pattern of intratelencephalic connections of the avian CPi is much more extensive than expected for a mere piriform cortex. Although the authors (Bingman *et al.*, 1994) accept that some of this labeling is seemingly due to the involvement of deep tissue in the injection site, these data can also be interpreted as suggestive of a field homology among the CPi of birds with the whole lateropallial olfactory cortex of reptiles and mammals. As discussed above, the olfacto-recipient lateral pallium seems to have undergone a differential compartmentalization in each group of amniotes.

Data on the ventropallial olfactory-related areas derive from the report by Davies *et al.* (1997) on the connections of the chicken archistriatum. Their results confirm the view put forward by Zeier and Karten (1971) that the AA is the region of the arcopallium giving rise to most projections through the anterior commissure. These contralateral projections mirror the intratelencephalic ipsilateral efferents of the AA, thus resulting in a pattern of bilateral intratelencephalic projections to extensive areas of the pallium (Hp, Wulst, M, and N). Bilateral efferents from the AA also target the olfactory bulbs and retrobulbar formation, the CPi, and portions of the AD and AV. Morever, the AA also shows bilateral projections to the subpallium, which specifically innervate the MSt (just lateral to the Acb) and olfactory tubercle. Finally, the AA projects massively to its contralateral counterpart.

This is demonstrative of the pallial nature of the AA (thus contradicting the view proposed by Puelles *et al.*, 2000), since only cortical areas are involved in commissural and ipsilateral projections to cortical areas (corticocortical pathways; see above). Moreover, this recalls the massive homotopic commissural projections of the mammalian LOT (Johnston, 1923) and its bilateral pathways to the olfactory system (olfactory bulbs, anterior olfactory nucleus, piriform and endopiriform cortex, olfactory tubercle), to atypical striatal structures (fundus striatum, IPAC), to parts of the pallial amygdala and to limbic and transitional cortical areas (Santiago and Shammah-Lagnado, 2004). Therefore, connectional data fully confirm our proposal of a homology of the avian AA with the LOT of mammals and reptiles (Table 3).

2.14.6.3.2 Connections of the avian basolateral amygdala The basolateral amygdala of mammals (B, L, and AB) receives sensory inputs from many different sources. In addition, its nuclei show differential projections to the dorsal and ventral striatum, to the hypothalamus, and to the cortical fields from which they receive their main inputs. As we describe below, most of these features are met by the proposed homologues to the basolateral amygdala in the brain of birds.

2.14.6.3.2.(i) Identity of the basal nucleus of the avian amygdala in the deep lateral pallium The B of the mammalian amygdala is the main source of projections to the dorsal and ventral striatum. The projections to both striatal compartments within the cerebral hemispheres have been thoroughly studied in pigeons twice by means of anterograde and retrograde tracing techniques (Veenman *et al.*, 1995; Kroner and Gunturkun, 1999). These studies reveal projections to dorsal striatal territories arising from some of the proposed pallial amygdaloid centers. Specifically, the deep lateropallial derivatives (deep CPi/TPO, NCL, and AD, plus maybe part of the PoA) project massively to the LSt. At least part of this projection, arising from rostral levels of the arcopallium, is bilateral. The deep lateropallial amygdala also projects to the ventral striatum, namely the Acb (formerly, the medial aspect of the lobus paraolfactorius). In many cases, this projection extends caudally to reach also the lateral BST and the SpA. Thus, tracer injections involving the posterior NCL and/or PoA (Veenman *et al.*, 1995; Kroner and Gunturkun, 1999) reveal a projection to the continuum Acb/BSTl-SpA. A similar pattern of anterograde labeling is found after large tracer injections into the CPi that also encompass deep structures (Bingman *et al.*, 1994; Veenman *et al.*, 1995).

This supports our hypothesis that the TPO/NCL, the AD, and its caudal continuation within the PoA

constitute the B nucleus of the amygdala of birds (Table 3). If so, these structures should display a convergent dopaminergic and cholinergic innervation, which constitutes the most remarkable defining histochemical feature of the mammalian B. In fact, birds show a dense dopaminergic innervation of the striatum plus a field of dopaminergic fibers in the caudolateral cerebral hemispheres that comprises the NCL, AD, and extends into the PoA (Figures 19a and 19b; Durstewitz *et al.*, 1999). These same pallial areas show a dense innervation by cholinergic fibers, as revealed by either ChAT immunostaining (Medina and Reiner, 1994) or AChase histochemistry (Figures 19c and 19d).

Therefore, the AD plus its neighboring areas within the deep caudal lateral pallium make up the most likely homologue of the mammalian B and the reptilian DLA. In fact, if one compares the images of the caudolateral cerebral hemispheres of birds (Figure 19) with similar images from the brains of

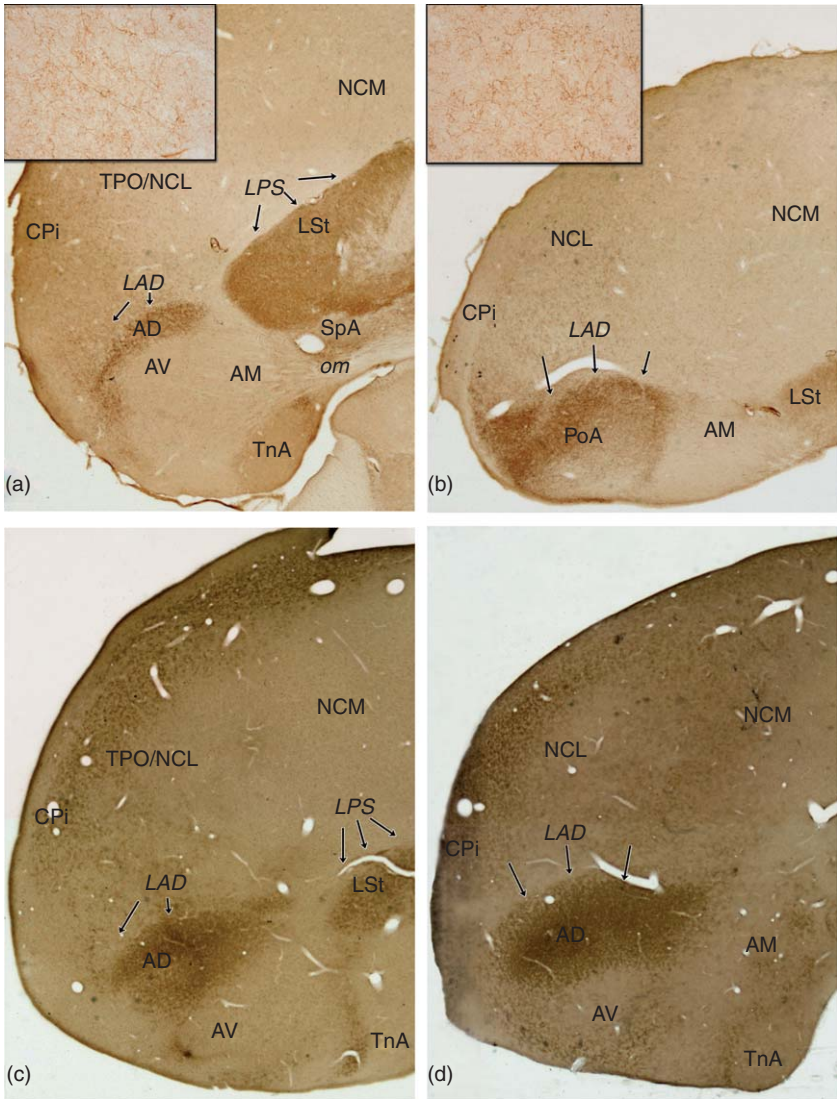

Figure 19 Histochemistry of the pallial amygdala of birds. a and b, The distribution of fibers immunoreactive for tyrosine hydroxylase (TH) in the caudal telencephalon of the quail (*Coturnix coturnix*) is shown in two frontal sections of the left hemisphere (slightly postcommissural (a) and caudal section (b)). Dopaminergic fibers innervate the striatum and parts of the amygdaloid complex. This includes a dense innervation of the AD and parts of the PoA and a scarcer innervation of the TPO and NCL (insets). In addition, the SpA also shows a remarkable TH-immunopositive innervation (a). c and d, Distribution of AChase histochemistry in two frontal sections of the left cerebral hemisphere of the chicken (*Gallus domesticus*) at slightly postcommissural (c) and caudal levels (d). The AD shows a remarkable AChase-positive innervation that extends into the TPO and NCL. Therefore, all three structures are targeted by convergent dopaminergic and cholinergic innervations, which supports their homology with the basal nucleus of the mammalian amygdala.

microsmatic lizards (such as *Anolis*; Box 1), the resemblance is astonishing. The lack or strong reduction in the vomeronasal system in birds and anole lizards has resulted in a similar displacement of the deep lateropallial amygdala. Their histochemical features, however, remain the same and clearly indicate that they are the sauropsidian homologues of the basal nucleus of the amygdala of mammals.

2.14.6.3.2.(ii) Deep ventropallial nuclei: The AV/AM and NCM The ventropallial basolateral amygdala of mammals contains a deep sensory interface, the L nucleus, and another more superficial nucleus projecting to the ventral striatum and hypothalamus, the AB. According to our hypothesis (Table 3), the avian AV/AM should display projections to the ventral striatum and hypothalamus (like the mammalian AB), whereas the deepest ventropallial amygdala, the NCM, would constitute the sensory interface of the pallial amygdala, like the mammalian L.

2.14.6.3.2.(ii).(a) The homology between the AV/AM and the mammalian AB The projections from the AV/AM to the ventral striatum have indeed been described. Tracer injections into the Acb of the pigeon (formerly medial lobus paraolfactorius; Veenman *et al.*, 1995; Kroner and Gunturkun, 1999) retrogradely label neurons in the lateropallial structures referred to above (NCL/TPO, AD, and, to a lesser degree, PoA) but also in the caudal AV (named archistriatum centrale by Veenman *et al.*, 1995). Anterograde tracing of this projection (Veenman *et al.*, 1995; Kroner and Gunturkun, 1999) indicates that it extends into the BSTl/SpA. The arcopallial projection to the Acb/BSTl/SpA also arises in part from the AM, as indicated by both retrograde (Veenman *et al.*, 1995; Kroner and Gunturkun, 1999) and anterograde tracing experiments (Davies *et al.*, 1997). This suggests that the AV/pallial AM are the avian counterpart of the mammalian AB, in terms of both topology and hodology.

Concerning the projections to the hypothalamus, our hypothesis predicts two projections arising from different areas of the AV/AM. Like the ABa, the rostral portions of the AV/AM should project to the lateral hypothalamus, whereas the caudal AV/AM, likely homologous to the mammalian ABp (and the reptilian PDVR and LA), would therefore project to the ventromedial tuberal hypothalamus. The existence of such a pathway in the brain of birds is evidenced by the presence of a zinc-rich terminal field in a nucleus of the caudal ventromedial hypothalamus of the chick (Faber *et al.*, 1989), clearly misidentified by the authors as the nucleus papillioformis, which seems to correspond to medial nucleus of the posterior hypothalamus (PMH). In addition, Montagnese *et al.* (1993) described a dense, zinc-containing terminal field in the PMH and an additional one in the nucleus tuberis of the premammillary/mammillary hypothalamus.

In this respect, the seminal paper by Zeier and Karten (1971) already described a tractus occipitomesencephalicus pars hypothalami (OMH) terminating mainly in the medial PMH (posterolateral and posteromedial nuclei) but also in the lateral hypothalamus and the so-called stratum cellulare internum and stratum cellulare externum. According to their description, this termination field extends into the infundibular hypothalamus at premammillary–mammillary levels. The site of origin of this zinc-rich arcopallial/amygdaloid projection (or projections) to the hypothamus is unclear. Zeier and Karten (1971) observed degeneration of the OMH after lesions of the posterior archistriatum and/or superficial parts of the caudal AV, plus the subpallial TnA (the latter projection is discussed below). However, they described the OMH as a single pathway, and did not contemplate the possibility of it being composed of several projections with different sites of origin in the archistriatum and termination fields in the hypothalamus, as apparently happens in mammals and reptiles.

Nevertheless, modern neuroanatomical techniques based on intra-axonic transport of tracers suggest that this is indeed the case. Thus, Davies *et al.* (1997) report anterograde labeling in the lateral hypothalamus after tracer injections centered in the anterior AM of the chicken. In contrast, injections in the caudal AM, just dorsal to the TnA in ring doves (Cheng *et al.*, 1999), specifically label fibers of the OMH directed to the preoptic anterior hypothalamus and to the PMH, which do not reach the mammillary–premammillary levels. This suggests that the AM includes a rostral portion displaying projections similar to those of the ABa and a caudal one, the hypothalamic projections of which recall those of the ABp. It is tempting to suggest that the anterior AM (projecting to the lateral hypothalamus) is topologically deep to the anterior olfacto-recipient archistriatum illustrated by Reiner and Karten (1985) in the pigeon, whereas the caudal AM, which projects to more medial areas of the preoptic to tuberal hypothalamus, is deep to the caudal, nonolfactory-recipient AV. However, studies on the histogenetic gradients and topological relationships of the arcopallium are lacking.

As a conclusion, like its putative mammalian homologue (the AB), the AV/AM of birds projects to the ventral but not the dorsal striatum. Apparently, part of this arcopallial region gives rise to a projection to the lateral hypothalamus. In addition, birds, like mammals and reptiles, display a zinc-rich projection directed to a cell group in the ventromedial posterior (tuberal) hypothalamus. This projection seems to arise, at least in part, from the caudal aspect of the AM, just dorsal to the TnA, which is therefore the most likely homologue of the mammalian ABp, in terms of both topology and connections. A systematic study of the projections to the hypothalamus from the caudal cerebral hemispheres using both retrograde and anterograde tracing techniques, and a deep analysis of the architecture of the arcopallium, PoA, and hypothalamus of birds, are urgently needed to clarify this issue further.

2.14.6.3.2.(ii).(b) Sensory afferents: The caudomedial nidopallium as the sensory interface of the avian amygdala In view of the organization of the reptilian amygdala we have described above, we expect to find a sensory interface of the pallial amygdala within the dorsomedial PDVR, which in birds is represented by the caudomedial nidopallium. In this respect, the NC is the target for important afferents from the different sensory centers of the cerebral hemispheres. This was reviewed in detail by Metzger *et al.* (1998) and Kroner and Gunturkun (1999), who realized that the NC is the target for thalamic and intratelencephalic sensory afferents. Thus, it receives projections from the secondary sensory areas of the neostriatum (fields L1 and L3, entopallial belt, frontal nidopallium, nucleus basalis, and intermediate nidopallium). The thalamic input to the NC arises mainly from the shell of nucleus ovoidalis and the dorsolateral posterior thalamic nucleus (DLP), which, according to Korzeniewska and Gunturkun (1990), constitute multimodal thalamic relays. Moreover, studies in chicken and quails strongly suggest that this thalamonidopallial pathway contains CGRP, as is the case for the projections to the L in mammals (see Lanuza *et al.*, 2000). In contrast to the NCL, the NCM seems mainly involved in intra-amygdaloid projections, since it does not display substantial projections to either the dorsal or the ventral striatum. Thus, NC projects to the AV and AD (Metzger *et al.*, 1998) in a topographic manner. These projections are reciprocated by arcopallial–nidopallial pathways (Kroner and Gunturkun, 1999).

These results indicate that the deep caudal cerebral hemispheres are organized very alike in birds and reptiles. In both groups, the caudal DVR receives afferents from different telencephalic and thalamic centers, and it is divided in two main areas with different embryological origin and connectional properties. The medial area (avian NCM and reptilian PDVRdm) is a ventropallial derivative mainly engaged in intra-amygdaloid projections within the ventral pallium (intra-amygdaloid) directed to the projecting areas of the pallial amygdala (AV and AD in birds, PDVRvm, LA, and DLA in reptiles). The lateral area is a lateropallial derivative (the avian NCL/TPO plus the AD; the reptilian DLA) that projects to the dorsal and ventral striatum. In this scheme, the NCM should be considered the sensory interface of the avian pallial amygdala, thus becoming functionally equivalent to its most likely homologue in the mammalian brain, the lateral nucleus of the amygdala. As in reptiles, in birds the possibility that the anterior sensory DVR (e.g., the sensory centers of the nidopallium, including the entopallial nucleus) constitutes an enlarged and highly specialized LA cannot be ruled out (Table 3). The presence of a primary auditory pallium immersed in the avian lateral amygdala, the field L, is a specific feature of the avian brain that probably had a strong influence in the organization of other parts of the amygdala of birds.

2.14.6.3.2.(ii).(c) Amygdalocortical projections Another attribute of the basolateral amygdala is the presence of projections to the cortical areas from which it receives projections. In mammals, this is represented by the projections arising in the basolateral amygdala (B and AB) directed to the prefrontal, insular, and perirhinal cortices. In reptiles, equivalent projections arise from the LA and terminate in the ADVR (Bruce and Butler, 1984; Martinez-Garcia *et al.*, 1993), thus constituting a corticocortical projection within the ventral pallium that reciprocates the ADVR–PDVR/LA projection. In contrast to mammals, in reptiles the amygdala does not project back to the dorsal pallial region (dorsal cortex; Hoogland and Vermeulen-Vanderzee, 1989; Lanuza *et al.*, 1998).

Birds apparently display a reptile-like organization of the amygdalocortical interconnections. Thus, the AV is interconnected with those portions of the anterior nidopallium that project to the pallial amygdala, namely the medial intermediate N, and the frontal N (Kroner and Gunturkun, 1999). This supports the proposed homology between the AV and the reptilian LA. However, pigeons also display projections from portions of the AV to dorsal pallial sensory areas such as the visual Wulst (part of the hyperpallium apicale), which provides a scarce

projection back to the AV (Shimizu *et al.*, 1995). This seemingly constitutes an apomorphic feature of the avian brain.

2.14.6.3.2.(iii) The posterior amygdala of birds and its homology with the mammalian AHA Several lines of evidence strongly suggest that the PoA constitutes the avian homologue for the AHA of the mammalian amygdala. From a topological point of view, the PoA and AHA occupy the caudal edge of the area bounding the ventral and lateral pallial territories. This is also consistent with the proposed scheme of the reptilian amygdala, since the position of the VPA (the reptilian homologue of the AHA; Table 3) in the reptilian cerebral hemispheres is clearly reminiscent of the avian PoA.

Moreover, most of the defining features of the mammalian AHA are accomplished by the PoA of birds. Thus, the PoA not only projects to the posterior medial hypothalamus, including the infundibular mammillary/premammillary levels (Zeier and Karten, 1971; Davies *et al.*, 1997; Kroner and Gunturkun, 1999), but also receives a projection from supramammillary–premammillary hypothalamus (Berk and Hawkin, 1985). Although there are no studies on the comparative significance of the mammillary region of the hypothalamus of birds, its interconnection of the PoA is reminiscent of the reciprocal connections displayed between the AHA and the PMv of mammals. This is supported by the fact that PoA, like the AHA, is the only structure of the pallial caudolateral cerebral hemispheres also projecting to the medial preoptic hypothalamus (Absil *et al.*, 2002).

The PoA is also connected to the septohippocampal system. Thus, reciprocal connections of the APH with the caudal PoA were reported in the pigeon by Casini *et al.* (1986), and recently confirmed by Atoji and collaborators (Atoji *et al.*, 2002; Atoji and Wild, 2004). In addition, the PoA projects unidirectionally to the portion of the ventral lateral septum that receives projection from the APH (Atoji and Wild, 2004). Therefore, the ventral lateral septum receives a projection from two pallial centers, one in the hippocampal formation (APH) and the other in the amygdala (the PoA), which are interconnected. This circuit recalls the one established by the mammalian AHA with the CA1-subiculum and the ventral lateral septum, thus giving strong support to our hypothesis of homologies (Table 3).

It is important to stress the similarity in the pattern of connections between the caudal AV/PoA and the whole medial EA, including the TnA (see below), concerning its connections with the hypothalamus and septohippocampal system. Thus, like the mammalian AHA, the caudal PoA is functionally related to the medial EA.

In this respect, the only feature expected for the homologue of the mammalian AHA (Tables 1 and 3) that seems not accomplished by the PoA, is the expression of receptors to sexual steroids (Simerly *et al.*, 1990). Data on this issue are, however, somewhat contradictory. Thus, whereas Watson and Adkins-Regan (1989) reported the presence in the quail of a few cells accumulating steroids (mainly estrogens) "in the basal archistriatum dorsal and lateral to the borders of the large-celled nucleus teniae," these results were not replicated using immunohistochemical detection of receptors (Balthazart *et al.*, 1989, 1992). On the other hand Metzdorf *et al.* (1999) described the presence of scattered cells expressing aromatase throughout the archistriatum (arcopallium plus PoA), not only in songbirds but also in nonsongbird species. It is interesting to note that songbirds display cells expressing receptors for sexual steroids in all the vocal centers of the forebrain, including the high vocal center in the mesopallium–NC interface and the nucleus robustus arcopallialis (Gahr *et al.*, 1993; Metzdorf *et al.*, 1999; Gahr, 2000). In addition, areas of the posterior AD, AV, and PoA next to the robustus also express androgen receptors in canaries (Balthazart *et al.*, 1992; Gahr and Wild, 1997) and zebra finches (Gahr and Wild, 1997; not detected by Balthazart *et al.*, 1992). The presence of cells expressing aromatase in the arcopallium/PoA of some nonsongbirds and of cells expressing receptors to steroids in arcopallial/PoA nonvocal centers in songbirds is suggestive of a minor expression of steroid receptors of this particular region.

As a conclusion, on topological and hodological grounds the PoA seems to be the avian homologue of the AHA of the mammalian amygdala. The lack or very low expression of steroid receptors by its cells seems, however, an apomorphic feature of birds, the significance of which is not yet understood.

2.14.6.3.2.(iv) The occipitomesencephalic tract, the somatomotor arcopallium, and the significance of birdsong According to our proposal, the amygdala of birds includes the whole arcopallium, the TnA, and the PoA (plus the posterior DVR: NCM, NCL, and TPO). This contrasts with the view, put forward by Zeier and Karten (1971), that the former archistriatum is composed of a limbic (amygdaloid) part that projects to the hypothalamus (TnA, AM, and PoA), and a

somatomotor one (AA, AD, and the dorsal part of the AV, sometimes called jointly central archistriatum) that is the origin of the OM. The rationale for this view comes from the fact that the OM, as traced in pigeon by Zeier and Karten (1971), innervates parts of the thalamus (mainly the dorsal posterior thalamus), tectal and tegmental structures in the midbrain (thus its name), the lateral reticular formation, lateral pontine nuclei, sensory nuclei in the dorsal medulla, and even the cervical spinal cord. The resemblance of the course of the OM, as defined by Zeier and Karten (1971) in pigeons, with a fascicle of the pyramidal tract of goats (Bagley's bundle), led the authors to propose that the central archistriatal regions originating in the OM should be considered equivalent to the sensorimotor cortex of mammals. Since then, this view has been further refined. In brief, the projections of parts of the arcopallium to the dorsal striatum have also been argued in favor of the comparative meaning of the arcopallium (or part of it) as a cortical sensorimotor area comparable to the infragranular layers of the mammalian isocortex (Veenman *et al.*, 1995). In line with this view, Veenman *et al.* (1995) propose that the thalamo-recipient parts of the nidopallium would be equivalent to isocortical layer 4 and the rest of the nidopallium would represent the supragranular layers of the avian isocortex. In this framework, the arcopallium is interpreted as the main motor output region of the cerebral hemispheres (Figure 20a).

However, several anatomical and functional observations seriously challenge this view. First, as discussed above, the OM has no counterpart in the reptilian brain, so that it probably represents an apomorphic character of the avian forebrain. In addition, the Wulst is a much more likely candidate for the avian homologue of the sensorimotor cortex (Medina and Reiner, 2000), a view that is topologically consistent since, like the mammalian isocortex, the Wulst is a dorsopallial derivative (but see Martinez-Garcia, 2003). Second, lesions of the AM encompassing the OM make animals apparently tame (thus recalling the effects of amygdaloid lesions; see Weiskrantz, 1956) but do not impair their movement (Phillips, 1964). In contrast, temporary inactivation of the LSt of pigeons results in a complete halt of movements so that animals appear paralyzed and unresponsive when handled or moved (Kalenscher *et al.*, 2003). These data suggest that telencephalic motor control in birds is executed by efferent projections from the LSt and, maybe, the somatomotor Wulst, instead of the OM.

Therefore, it is time to analyze which is the function of the OM on the control of behavior. The results of intra-axonic transport of tracers in pigeons (Wild *et al.*, 1993; Kroner and Gunturkun, 1999) and chicken (Davies *et al.*, 1997) have not revealed any target of the OM caudal to the nucleus of the lateral lemniscus. The caudal terminal fields reported by Zeier and Karten (1971) to show degeneration after transections of the OM are likely due to involvement of the BSTl/SpA in the lesion (Berk, 1987). In their study of the auditory forebrain of the pigeon, Wild *et al.* (1993) realized that the OM is a link within the auditory circuitry of the avian forebrain. Thus, the OM originates in the portion of the arcopallium that receives projections from the auditory N and terminates mainly in auditory thalamic (ovoidalis shell, nucleus semilunaris paraovoidalis, nucleus paramedianus internus) and midbrain/pontine centers such as the dorsomedial part of nucleus intercollicularis (ICo/DM) and the nucleus of the lateral lemniscus. On the other hand, songbirds display a very developed OM (see The Evolution of Vocal Learning Systems in Birds), which arises from a distinct arcopallial cell group called nucleus robustus arcopallialis (RA; Wild, 1993; Wild *et al.*, 1993). The RA directly innervates the tracheosyringeal hypoglossal motoneurons that control the syringe and premotor neurons for the respiratory system in the nucleus retroambigualis (Wild, 1997), thus having quite a direct control of the motor patterns leading to song generation.

Although this has led to the suggestion that the RA constitutes a portion of the motor cortex (Bottjer *et al.*, 2000) devoted to song control, in this kind of analysis the behavioral/physiological meaning of birdsong has largely been ignored (Cheng and Durand, 2004). Darwin already recognized vocalization as a form of emotional expression. Nonsongbirds, including pigeons, doves, chicken, and quails (which have often been used in anatomical studies), emit a repertoire of vocalizations for all kind of social interactions, including agonistic–territorial, parental, and reproductive ones. It is generally recognized that alarm calls or peeps emitted by newborn chicken when separated from the hen (distress peeps) are emotional behaviors. This has led Cheng (2003) to propose that song and vocalizations are amygdala-dependent behaviors. The pathway she suggests to mediate vocalization includes projections from the TnA to the PMH and then to midbrain song centers, namely the ICo/DM, whose electrical stimulation elicits singing. However, kainic acid lesions of the archistriatum of young chicken result in a decrease of distress calls (loud peeps; Phillips and Youngren,

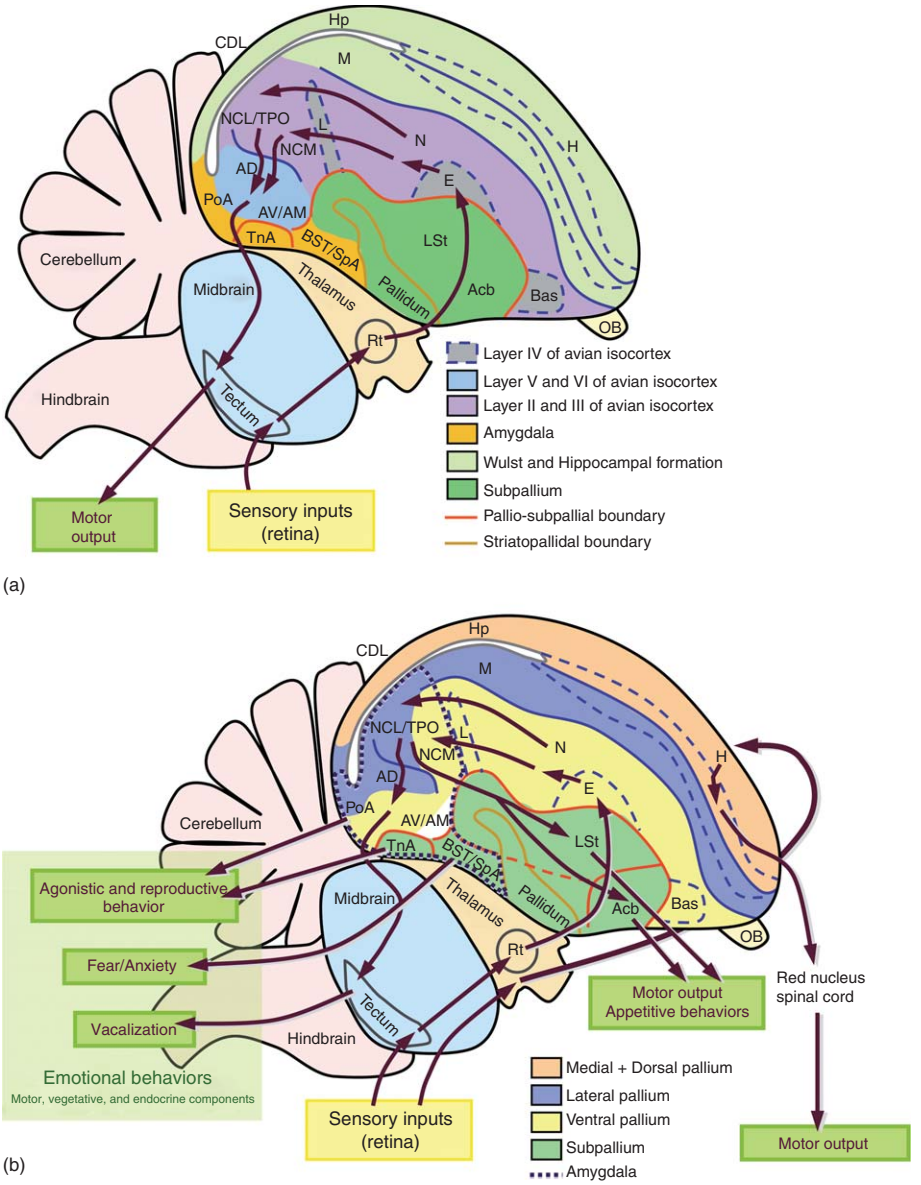

Figure 20 Alternative views on the comparative and functional neuroanatomy of the avian cerebral hemispheres. a, Diagram summarizing the classical view of the comparative neuroanatomy of the subventricular cerebral hemispheres of birds. According to this view, they include pallial regions equivalent to the granular (sensory nidopallium, including field L, basorostral and entopallial nuclei), supragranular (rest of the nidopallium, including the NCL and NCM), and infragranular layers of the mammalian isocortex (arcopallium). The arcopallium thus constitutes the main motor output region of the whole system, whereas the OM appears comparable to the mammalian pyramidal tract. In this view, the pallial amygdala of birds is restricted to the PoA. Arrows indicate the flow of sensory information (exemplified in the visual system) and the main intratelencephalic pathways for sensorimotor integration. b, Schematic diagram of the view proposed in this article. The pallial territories are labeled and the boundaries of the avian amygdala are delineated by a discontinuous line. Three main motor outputs, used for coordinating different kinds of response, arise from different output regions of the cerebral hemispheres. A motor cortex, engaged in coordinating pure motor actions through direct projections to the spinal cord and red nucleus, is present in the Wulst (hyperpallium). In addition, the lateral and ventral pallia are involved in processing sensory information (again, the visual system is drawn as an example) to elaborate different kinds of emotional response. Appetitive ones (involving delayed reward acquisition) are executed through palliostriatal pathways, whereas direct amygdaloid projections to the hypothalamus, midbrain, and brainstem are used to coordinate the motor, vegetative, and endocrine components of innate and learned emotional responses such as agonistic and reproductive behaviors, fear and anxiety, or vocalizations (song emission) used in both contexts. a, Modified from Jarvis, E. D., Gunturkun, O., Bruce, L., *et al.* 2005. Avian brains and a new understanding of vertebrate brain evolution. *Nat. Rev. Neurosci.* 6, 151–159.

1986), but no other visible motor impairments. Involvement of the OM in the control or generation of vocalizations is also suggested by the fact that in both songbirds (Wild, 1993) and nonsongbirds (Wild *et al.*, 1993) the OM reaches directly the midbrain song centers (ICo/DM). In this context, the OM can be envisaged as a projection of the avian amygdala accomplishing a specialized emotional behavior that includes generating or modulating the motor patterns leading to vocalization but also, very likely, the accompanying endocrine and vegetative responses (Figure 20b). The courtship and/or territorial singing of songbirds constitutes a sophisticated behavior with a strong emotional component that, in many species, includes a process of motor learning, for which intra-amygdaloid circuits are especially appropriate (Cheng and Durand, 2004).

2.14.6.4 The Subpallial Amygdala of Birds

The subcortical components of the avian cerebral hemispheres extend caudally into the amygdaloid complex. There, a subpallial striatopallidal amygdala is expected, which probably contains homologues of both the medial and central EA. As we discuss in detail below, the lack of a vomeronasal system in birds has not been accompanied by a disappearance of the medial EA.

2.14.6.4.1 The medial extended amygdala of birds The TnA has traditionally been considered the avian counterpart of the medial amygdala of mammals, based on three lines of evidence. First, it is one of the targets for the projections from the olfactory bulbs (Reiner and Karten, 1985). In birds, where the accessory olfactory bulb does not exist, the counterpart of the mammalian Me may still receive a projection from the main olfactory bulb, as occurs at least in the MeA of mammals and the region superficial to the MA associated with the stria medullaris in reptiles (Figures 10b and 10c). Second, the TnA also accomplishes another of the defining features of the medial EA of mammals (Table 2), since its cells express receptors to sexual steroids, especially to estradiol, in both nonsongbirds (Balthazart *et al.*, 1989, 1992; Watson and Adkins-Regan, 1989; Aste *et al.*, 1998; Foidart *et al.*, 1999) and songbirds (Metzdorf *et al.*, 1999). Third, the TnA contributes to the OMH (Zeier and Karten, 1971; Cheng *et al.*, 1999), through which it projects specifically to the medial preoptic region, the lateral hypothalamus, and medial nucleus of the posterior hypothalamus (which, as discussed above, seems to be the avian counterpart of the VMH). This projection continues further caudally to reach regions of the premammillary hypothalamus (Cheng *et al.*, 1999).

The remaining connections of the TnA, as described by Cheng *et al.* (1999) in doves and starlings, are remarkably similar to those described for the different portions of the Me of mammals (Canteras *et al.*, 1995). Thus, the TnA projects to a ventral striatal territory comprising the caudal Acb and the BSTl/SpA, which mimics the projections from the MeA to the Acb and central EA of mammals (the identity of the avian central amygdala is discussed below). In addition, the TnA projects to parts of the intermediate to caudal arcopallium, which would represent projections from the medial to the basolateral amygdala similar to those described in mammals. In addition the TnA is connected to the septohippocampal system consisting of projections to the ventral lateral septum and reciprocal connections with the parahippocampal cortex (AHP; Cheng *et al.*, 1999), for which comparable projections are found in the connections of the Me of mammals with fields CA1 and subiculum of the hippocampal formation.

The OMH, which at least partially arises from the TnA (Cheng *et al.*, 1999), courses through a region located just caudal and mostly ventral to the anterior commissure that links the cerebral hemispheres with the preoptic region. Along its course through this area, the OMH fibers show varicosities. This is suggestive of this area being the avian counterpart of the posteromedial BST of mammals. Aste *et al.* (1998) studied in detail the cytoarchitecture and the distribution of vasotocinergic and aromatase-expressing cells in this area and reported a sexual dimorphism in the vasotocinergic cell population (Panzica *et al.*, 2001). Therefore, they concluded that this area constitutes the medial BST of birds (BSTm) and named it accordingly. In fact, like the mammalian posteromedial BST, the avian BSTm is also rich in receptors to sexual steroids (see references cited above) and displays a similar set of connections with the preoptic hypothalamus (Absil *et al.*, 2002), the premammillary hypothalamus (Berk and Hawkin, 1985), and the PoA (Zeier and Karten, 1971; Kroner and Gunturkun, 1999).

Therefore, birds seem to possess a medial EA composed of, at least, the TnA (plus maybe parts of the AM just dorsal to it; Cheng *et al.*, 1999) and the BSTm. Unlike its mammalian and reptilian counterparts, the medial EA of birds does not receive vomeronasal inputs but instead does receive a scarce olfactory one. However, it shares

with the medial EA of the remaining amniotes the main defining features of this part of the subpallial amygdala. It is rich in receptors to sexual steroids and shows sexual dimorphism, including sexually dimorphic projections containing vasotocin. It is connected to the preoptic, lateral, ventromedial (medial posterior), and premammillary divisions of the hypothalamus, and receives ascending projections at least from the latter. This strong resemblance suggests a similar role of the medial EA in the control of behavior in all amniotes.

2.14.6.4.2 The central extended amygdala The identity of the central amygdala of birds is an unresolved issue. However, our understanding of the organization of the central EA of mammals and reptiles helps us to delineate its counterpart in the avian forebrain using appropriate histochemical and connectional data.

As in reptiles, in birds the first clues to the identity of the central EA came from studies on descending projections of the cerebral hemispheres. Thus, Berk (1987) demonstrated a projection from the basal telencephalon to the lateral hypothalamus, SN, parabrachial, pericoerulear, and subcoerulear areas and to the dorsal vagal complex and nucleus of the solitary tract in the medulla. When traced retrogradely, this projection was seen to arise from the former BST, now renamed BSTl, and the former ventral paleostriatum, now called SpA. In mammals, the only area of the cerebral hemispheres giving rise to a similar set of projection is the central EA.

This proposal of homology fits the remaining available data on the connections and neurochemistry of the avian brain. Thus, the projection of the BSTl/SpA to the parabrachial region was further analyzed by Wild *et al.* (1990), who also reported an ascending projection of the parabrachial region back to the BSTl/SpA. Therefore, like the central EA of mammals, the BSTl/SpA of birds is reciprocally connected to the parabrachial region. As in mammals, the ascending projection of the parabrachial area reaches not only the subpallial amygdala (BSTl/SpA) but continues to the pallial one to reach at least parts of the arcopallium, PoA, and TPO/NCL, thus giving additional support to our proposal of homologies for the pallial amygdala (see Box 2).

The intratelencephalic connections of the BSTl/SpA also agree with their homology with the mammalian EA. Thus, as reviewed above, the NCL/TPO and AD as well as most of the AV (Veenman *et al.*, 1997; Kroner and Gunturkun, 1999), display substantial projections to the BSTl and/or SpA. This recalls the important projections from the basolateral amygdala to the central EA in the mammalian brain. Additional data on the connections of the BSTl/SpA, which also fit our proposal of homologies, are described in the literature. Thus, the BSTl and SpA receive an important projection from the thalamus, including the periovoidal region (Durand *et al.*, 1992) and the adjoining dorsolateral and dorsointermediate cell groups of the posterior thalamus (Wild, 1987a, 1987b). These cell groups apparently constitute the posterior intralaminar thalamus of birds on the basis of its location, afferents, multimodal physiological response (Gamlin and Cohen, 1986; Wild, 1987a; Korzeniewska and Gunturkun, 1990; Durand *et al.*, 1992), and the presence of abundant CGRP immunoreactive neurons (Lanuza *et al.*, 2000; Durand *et al.*, 2001). Therefore, the BSTl/SpA, like the mammalian central EA, receives a dense afferent projection from the posterior intralaminar thalamus. These thalamic cell groups are the same ones that project sparsely to the NC (Metzger *et al.*, 1998; Kroner and Gunturkun, 1999), to the TnA, and to parts of the arcopallium (Durand *et al.*, 1992; Cheng *et al.*, 1999). This can be interpreted as the presence in birds of a massive projection of the posterior intralaminar thalamus to the central EA (and medial EA) and a sparse one to the basolateral amygdala. This mimics the situation in mammals and, therefore, supports our proposal on the identity of the avian amygdala. Therefore, the available data on the anatomical relationships of the BSTl/SpA support its homology with the central EA of mammals, but a detailed analysis of the connections of the central EA is still needed to improve our understanding of the organization of the avian forebrain.

Finally, neurochemical data fully support the view of the BSTl/SpA as the avian central EA. Thus, like the central EA of mammals, the BSTl/SpA displays populations of CRFergic (Richard *et al.*, 2004) and NTergic cells (Atoji *et al.*, 1996; see figure 5f in Reiner *et al.*, 2004) and a dense innervation by CGRP-immunoreactive fibers (Lanuza *et al.*, 2000). Comparison of the location of CGRP fibers and CRF-immunoreactive cells in the BSTl/SpA reveals a differential distribution. Cells expressing CRF (Figure 21a), like those expressing NT, are mainly located in the BSTl and extend into the SpA, whereas the CGRPergic innervation is very dense in the anterior SpA (Figure 21b) and much scarcer in the BSTl. This also recalls the situation in mammals (Figures 6e and 6f), where CRFergic cells are mainly distributed in the CeM

Box 2 On the identity of the prefrontal cortex of birds

The efforts of comparative neuroanatomists to understand the evolution of the brain have led to a continuous search for counterparts of areas of the mammalian brain with important and/or well-defined functions, in the brain of nonmammals. Although the prefrontal cortex (PFC) may not be present in all mammals (see Do All Mammals Have a Prefrontal Cortex?), it is nevertheless a paradigmatic example of these attempts. Thus, Mogensen and Divac found that the TPO/NCL of the avian cerebral hemispheres displays two of the defining features of the PFC. First, the TPO/NCL shows a high content of dopamine (Divac and Mogensen, 1985; Divac *et al.*, 1985), due to a dense meshwork of dopaminergic fibers (see, for instance, Waldmann and Gunturkun, 1993; Wynne and Gunturkun, 1995), arising from the ventral tegmental cell groups (mainly A10) (Metzger *et al.*, 1996), which recalls the dopaminergic innervation of the PFC of mammals. The presence of a dense dopaminergic innervation arising from the A9–A10 tegmental cell groups, however, does not constitute by itself a defining feature of the prefrontal cortex since in the mammalian brain the B nucleus of the amygdala is also targeted by a similar dopaminergic pathway (see main text).

In addition, Mogensen and Divac (1982, 1993) reported that lesions of the avian TPO/NCL resulted in deficits in behavioral tasks of delayed alternation. This seems indicative that the NCL/TPO is involved in working memory, a kind of memory that in mammals is dependent on prefrontal cortex function (Goldman-Rakic, 1996). Since then, the homology of the TPO/NCL with the mammalian PFC has gained a wide acceptance (Reiner, 1986). This view and the idea that the N and M are part of the isocortex of birds were mutually reinforcing.

Functional experiments demonstrate that the amygdala and the orbitofrontal cortex are part of the neural machinery for the control of those forms of associative learning (both Pavlovian and instrumental) that involve delayed reinforcement and reward expectancy (Cardinal *et al.*, 2002; Holland and Gallagher, 2004). In other words, in the face of a given stimulus (cue) the animal learns to behave (action) so that it gets a rewarding item (usually food, sucrose, or water). During learning the stimulus becomes a reward-predicting cue. Execution of those behaviors demands that reward expectancy during the delay phase (between the detection of the reward-predicting cue and reward consumption) is encoded by the activity of cells responding to the cue during the delay phase, usually just prior to the action leading to reward acquisition. In a go/no-go task that uses an odor as the reward-predicting cue and sucrose (vs. quinine) consumption as the reward, these working memory cells have been observed in mammals in both the basolateral amygdala and orbitofrontal PFC (Schoenbaum *et al.*, 1999).

Similar working memory cells, including reward expectancy-encoding cells, are found in the NCL of pigeons (Kalt *et al.*, 1999; Diekamp *et al.*, 2002), executing comparable (but more instrumental) go/no-go tasks, in which the cue was auditory or visual. These results led the authors to conclude that the NCL contains the analogue of the mammalian PFC. As they further discuss, differences in the topological position of both structures (revealed by the different patterns of expression of homeotic genes during development) make their homology very unlikely.

As reviewed above, the mammalian B and parts of the orbitary and medial and insular PFC are extensively and massively interconnected (McDonald, 1998). Consequently, in their functional classification of the mammalian amgydaloid nuclei, Swanson and Petrovich (1998) considered the B nucleus as part of the frontotemporal cortical system. Therefore, it is not surprising that lesions of the avian counterpart of the B nucleus lead to behavioral impairments reminiscent of those resulting from lesions of the PFC in mammals. On the other hand, in a forebrain lacking a true isocortex, like the avian one, it is likely that the amygdaloid portion of the frontotemporal system has assumed the functions of the whole system. In other words, it is sensible that the TPO/NCL and other deep lateropallial derivatives of the avian cerebral hemispheres (such as the AD and lateropallial PoA) are not just the homologues of the B nucleus of the mammalian amygdala but also the analogues of the PFC, including its dorsolateral portion.

and CeL, whereas the CGRPergic innervation is concentrated in the lateral-most capsular division of the central amygdala (CeC).

The name BSTl is suggestive of a homology of this juxtaventricular cell group with parts of the BST of mammals and, as a consequence, of the SpA with the mammalian Ce. The histochemical data discussed above clearly indicate that this is not the case. In mammals, the central EA is composed of two centers separated by the internal capsule, namely the Ce and anterior posterolateral BST. However, in the forebrain of birds (as in

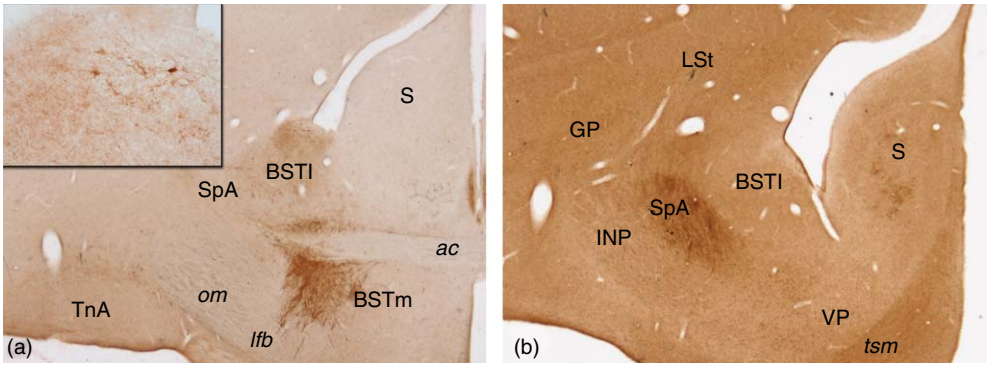

Figure 21 Histochemical characterization of the avian central extended amygdala. a, CRF-immunoreactivity in the BSTl of the left cerebral hemisphere of a quail (the inset shows a detail of the labeling). This is the main CRFergic cell group in the telencephalon of birds that supports the homology of the BSTl with parts of the central EA of mammals. CRF-immunoreactive fibers (probably arising from the reactive cells in the BSTl; Richard *et al.*, 2004) are observed in the lateral aspect of the BSTm. b, Frontal section of the left telencephalic hemisphere of a chicken through the anterior aspect of the BSTl, which has been processed for the immunohistochemical detection of CGRP. A dense CGRPergic innervation is observed in the former ventral paleostriatum, now renamed SpA. Taken together, these data (and additional data reported in other species) suggest that the central EA of birds is composed of the BSTl and SpA.

reptiles), an internal capsule is lacking and both groups are fused together: the SpA is adjacent and topologically superficial to the BSTl. We envisage both structures as the avian counterpart of the entire central EA of mammals in a case of field homology.

2.14.6.5 The Extent of the Avian Amygdala

The renewed avian neuroanatomical terminology (Reiner *et al.*, 2004) recognizes the homology of parts of the avian cerebral hemispheres with the mammalian amygdala. These include the TnA and PoA, as well as the so-called SpA. Our analysis confirms that these cell groups display histochemical, hodological, and topological features comparable to parts of the mammalian amygdala. As indicated in Table 3, the PoA seems comparable to the AHA of mammals, the TnA to part of the medial EA, and the SpA to part of the central EA.

Thus, the new nomenclature of the avian forebrain leaves it without a recognized homologue for the basolateral amygdala of mammals (L, B, and AB; Figure 20a). The search for this homologue has been hindered by the lack, in turn, of a clear idea of the identity of the central EA of birds. Now, when a wide consensus has been reached (in the Nomenclature Forum) to name SpA and BSTl to the structures composing the central EA of birds, it is time to look seriously for the avian basolateral amygdala. Any candidate for this should be ventro- and lateropallial, and provide a strong input to a continuum in the ventral striatopallidal telencephalon linking the central EA (SpA and BSTl) with the Acb. In addition, it should be adjacent to the known components of the avian amygdala (TnA, SpA, and PoA).

This simple reasoning, the quite straightforward comparison of the avian telencephalon with the cerebral hemispheres of reptiles, together with a cladistic analysis, leads us to reinterpret the comparative meaning of the arcopallium and the NC (Table 3; Figure 20b). They are the pallial derivatives of the avian brain that are best positioned using topological, embryological, and hodological data, to constitute the avian basolateral amygdala. In addition, their histochemical properties are comparable to those of the mammalian and reptilian components of the basolateral amygdala.

This solid hypothesis requires serious consideration. This would not only contribute to our better understanding of the organization and evolution of the brain of amniotes, but would give an extraordinary impulse to avian neurobiology. If we are right, birds are the amniote vertebrates that display a bigger and more accessible basolateral amygdala. Moreover, birds display a complex behavior that includes remarkable learning capacities such as auditory and visual imprinting, passive avoidance learning, song and instrumental conditioning (Jarvis *et al.*, 2005). Therefore, birds might constitute the ideal animal model for the study of the amygdaloid function (Box 2).

2.14.7 The Evolutionary Origins of the Amniote Amygdala

The common pattern of organization of the amygdala in reptiles, birds, and mammals described

above suggests that the amygdaloid complex of the ancestral amniote already possessed a pallial amygdala with lateropallial and ventropallial components and a subpallial EA with medial and central components. In this section, we discuss whether this pattern of organization of the amygdala was already present in anamniotes. To do so we review the available data on the structure and function of the telencephalon of amphibians, and some functional data available in fishes.

2.14.7.1 Functional Data in Teleostean Fishes

The telencephalon of ray-finned (actinopterygian) fishes is everted (Nieuwenhuys, 1963; see Evolution of the Nervous System in Fishes), instead of evaginated like the telencephalon of tetrapod vertebrates. Therefore, the structures located medially in the pallium of ray-finned fishes correspond to those with a lateral location in the telencephalon of tetrapods, and vice versa. This has led to the hypothesis that the amygdala should be located medially in the telencephalon of fishes, whereas the Hp should be positioned laterally. Anatomical and functional data strongly support this view as it concerns the hippocampal pallium (Northcutt and Braford, 1980; Nieuwenhuys and Meek, 1990; Braford, 1995; Northcutt, 1995; Butler, 2000; Rodriguez *et al.*, 2002; Salas *et al.*, 2003). In contrast, very few anatomical data are available either to support or discard the putative homology between the medial pallium of fishes and the amygdaloid complex of tetrapod vertebrates (but see Braford, 1995; Butler, 2000). There are, however, some functional studies (Portavella *et al.*, 2002, 2004) showing that the medial pallium of teleost fishes is involved in avoidance conditioning (a case of emotional learning). Therefore, topological and functional data suggest that ray-finned fishes and land vertebrates probably share an ancestor that already possessed an amygdala (medially located in everted brains, laterally located in evaginated brains) involved in fear/aversion acquisition and expression. Whether this structure includes pallial and/or subpallial derivatives is, at present, unclear.

2.14.7.2 Anatomical Data in Amphibians

The existence of an amygdala in the telencephalon of amphibians was already suggested in early anatomical studies by Herrick (1921). After that, the amphibian amygdala was defined as an area receiving direct projections from the accessory olfactory bulb (Scalia, 1972; Northcutt and Royce, 1975). The classical understanding on the organization of the amphibian amygdala divides it, on topographical grounds, into a lateral and a medial part (pars lateralis and pars medialis; Northcutt and Kicliter, 1980; Neary, 1990). However, recent data on neurochemistry (Marin *et al.*, 1998), hodology (Bruce and Neary, 1995c; Marin *et al.*, 1997a; Moreno and Gonzalez, 2003, 2004; Roth *et al.*, 2004; Laberge and Roth, 2005), and developmental gene expression (Brox *et al.*, 2003, 2004; Moreno *et al.*, 2004) have led to a complete redefinition of the amphibian amygdaloid complex (Figure 22). Although, at present, there are some discrepancies on the nomenclature of the amphibian amygdaloid complex, the terminology by Marin *et al.* (1998) and Moreno and Gonzalez (2003, 2004) will be used in the present section, since it is the most useful one for comparative purposes.

2.14.7.2.1 Vomeronasal and olfactory projections to the amygdala in amphibians The telencephalic target of the accessory olfactory bulb projections corresponds to the classical amygdala pars lateralis (Northcutt and Kicliter, 1980; Neary, 1990) but, given its comparative meaning, it was recently renamed as medial amygdala by Marin *et al.* (1998) (see also Moreno and Gonzalez, 2003). However, other authors keep using a purely topographical nomenclature, and name the structure receiving the bulk of the projection from the accessory olfactory bulb as lateral amygdala in anurans (Roth *et al.*, 2004) and caudal amygdala in urodeles (Laberge and Roth, 2005). Therefore, the same structure is named medial or lateral amygdala by different authors studying different species. However, from a comparative point of view, there is a certain consensus in considering the vomeronasal target within the caudal ventrolateral telencephalon homologous to the medial amygdala of mammals (the possible existence of a vomeronasal pallial amygdala in amphibians is discussed below).

Regarding the olfactory projections, the main structure receiving direct input from the main olfactory bulb is the lateral pallium (Northcutt and Kicliter, 1980; Neary, 1990). Within the lateral pallium, a dorsal and a ventral division have classically been recognized (Neary, 1990). Using neurochemical data, Marin *et al.* (1998) suggested that the ventral division of the lateral pallium was an amygdaloid structure, which in turn has been divided into an anterior amygdala (Aa, previously called striatopallial transition area by the same authors; Marin *et al.*, 1997a, 1997b) and a lateral amygdala (La, Figure 22) (Marin *et al.*, 1998; Moreno and Gonzalez, 2004).

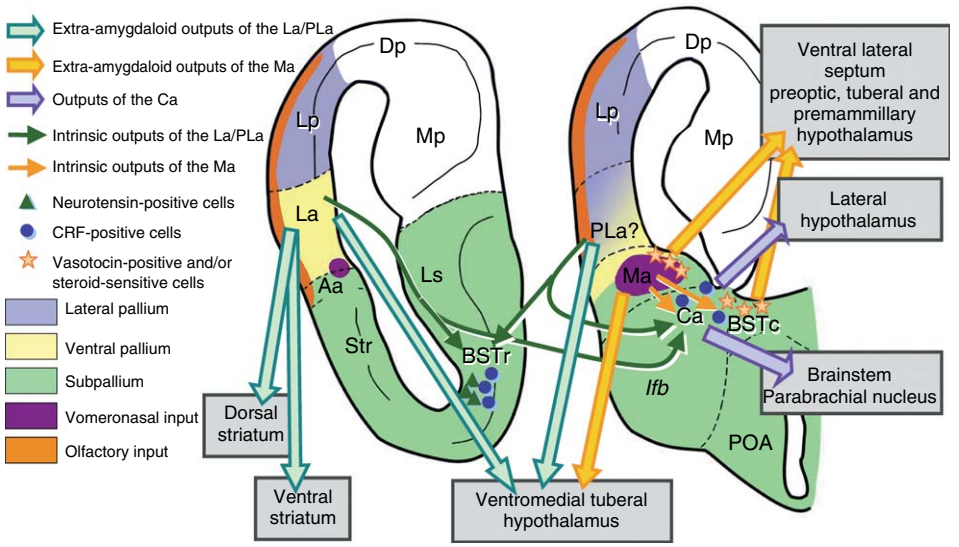

Figure 22 The amphibian amygdala. Schematic view of the amygdala of amphibians, based on two frontal sections (rostral (a); caudal (b)) of the left cerebral hemisphere of an anuran. The map of pallial territories (based on Brox *et al.*, 2003, 2004 and Moreno *et al.*, 2004), the bulbar afferents, the connections with the hypothalamus and striatum, and the intrinsic connections are represented. The PLa is depicted in a color mixture to represent that its ventropallial or lateropallial nature is uncertain. The Ma is depicted as composed of ventropallial (dorsal) and subpallial (ventral) regions. In addition, the location of cells expressing receptors for sexual steroids and/or immunoreactive for vasotocin, as well as the distribution of cells immunopositive for corticotropin-releasing factor and neurotensin (see section 2.14.7.2.5 of the text for the appropriate references), are depicted. These data suggest the existence of a medial and central EA, as well as a pallial amygdala in which cortical and deep nuclei are not separated (due to the low degree of cell migration).

2.14.7.2.2 New data on the divisions of the amphibian pallium: The pallial amygdala As discussed above, the pattern of expression of developmental genes in vertebrate embryos has revealed the existence of a pallial region interposed between the lateral pallium and the striatum, the ventral pallium. Similar studies in amphibians (Smith-Fernandez *et al.*, 1998; Bachy *et al.*, 2001, 2002; Brox *et al.*, 2003, 2004; Moreno *et al.*, 2004) indicate that a ventral pallium is also present in ampibians. In anurans, this is mainly represented by the La (formerly ventral division of the lateral pallium), which should therefore be homologous to the ventropallial derivatives of the amygdala of amniotes.

In addition, these studies indicate that, although the medial amygdala (as defined by Moreno and Gonzalez, 2004) (Ma, see Figure 22) is mainly subpallial (Brox *et al.*, 2003; Moreno and Gonzalez, 2004), a part of it (very likely its dorsal aspect adjacent to the La) might be ventropallial (Brox *et al.*, 2004). This suggests that the amphibian brain displays homologues for both the medial amygdala of amniotes (subpallial Ma; see below) and the ventropallial vomeronasal cortex (COApm of mammals, NS of reptiles), as previously suggested (Northcutt and Kicliter, 1980; Scalia *et al.*, 1991). The homology and boundaries of this putative ventropallial portion of the Ma with the vomeronasal cortex of amniotes should be further explored by analyzing in detail the connections and neurochemistry of the amphibian Ma.

The anterior amygdala is a relatively small structure located in a rostral position close to the accessory olfactory tract (Marin *et al.*, 1998). Available data on developmental gene expression and the presence of GABAergic cells suggest that it is a subpallial structure (Gonzalez *et al.*, 2002b; Brox *et al.*, 2003; Moreno and Gonzalez, 2004), but its amniote homologue is unknown.

One of the main conclusions of the study of the developmental gene expression patterns in the amphibian telencephalon is that there appears to be no amygdaloid division originated in the embryonic lateral pallium, in contrast to the situation in mammals (B and COApl), reptiles (DLA and LCc), and birds (NCL/TPO, AD, and lateropallial PoA). Therefore, the lateropallial amygdala would be an evolutionary acquisition of the amniote lineage. The opposite interpretation derives from recent data on the expression of the homeobox gene *xEmx1* (Brox *et al.*, 2004), which suggest that the posterior La (PLa) of anurans is a lateropallial derivative. However, in contrast to the lateropallial derivatives of the amniote amygdala (see above), the PLa of amphibians projects to the ventromedial hypothalamus (Bruce and Neary, 1995b; Moreno and

Gonzalez, 2004; see below). Thus, the possibility that the La of amphibians contains a lateropallial portion equivalent to the B and COApl of mammals requires further analysis (Figure 22).

2.14.7.2.3 Projections to the hypothalamus: The pallial stria terminalis of amphibians Besides its afferents from the olfactory bulbs, the other widely accepted defining feature of the amygdala of amniotes is the presence of important projections to the hypothalamus, mainly to its medial tuberal division. The telencephalic projections to the hypothalamus have been studied in anurans (Neary, 1995; Moreno and Gonzalez, 2004, 2005) and the results indicate that the amphibian La gives rise to important projections to the core of the ventromedial hypothalamus. Therefore, the La of amphibians is the ventropallial, olfacto-recipient structure that originates a major projection to the ventromedial hypothalamus through the stria terminalis. These features suggest that the LA includes the amphibian homologues for the mammalian AB and of the overlying COAa, as well as the PDVR and ventropallial olfactory amygdala of sauropsids.

The pallial component of the stria terminalis of mammals also includes fibers arising from the AHA that reach mainly the preoptic and tubero-premammillary hypothalamus (VMH shell and PMv). A homologue for the AHA of mammals, equivalent to the VPA of reptiles and the avian ventropallial PoA, is still to be found in amphibians. A useful clue to explore this possibility would be the study of the expression of receptors for sexual steroids in the La of amphibians, since they are present in the AHA of mammals and its reptilian homologue (VPA), although this trait has apparently been lost in birds (Table 3). Dealing with this, the few available data (Davis and Moore, 1996; Perez *et al.*, 1996) suggest that steroid-sensitive cells are lacking in the La of amphibians, but detailed studies are needed to clarify this issue.

2.14.7.2.4 The amygdalostriatal pathways and the lateropallial amygdala of amphibians The telencephalon of amniotes displays a set of amygdalostriatal projections arising from the pallial amygdala. First, the deep lateropallial amygdala (B in mammals, DLA in reptiles, AD and TPO/NCL) projects massively to the ipsilateral (and also to the contralateral) dorsal and ventral striatum, including its caudal extension, the central EA. In addition, parts of the ventropallial basolateral amygdala (mammals, AB; reptiles, PDVR and LA; birds, AV and AM) project to the ipsilateral Acb and to the central EA.

Anatomical studies in anurans and urodeles indicate the existence of similar projections in amphibians. Thus, the rostral La projects to the ipsilateral Acb (Marin *et al.*, 1997a, 1998; Moreno and Gonzalez, 2004), as well as to more caudal striatopallidal territories, including the central amygdala, the bed nucleus of the stria terminalis, the VP, and the nucleus of the diagonal band. This projection system recalls the connections of the pallial amygdala to the central EA (see next section), and further supports the homology of the La of amphibians with the basolateral division of the amygdala of amniotes.

Both anurans and urodeles display a bilateral projection to the dorsal striatum that arises from the La (Marin *et al.*, 1997a). However, since the amphibian La seems a ventropallial derivative, it is not clear whether this projection is equivalent to the amygdaloid pathway to the dorsal striatum of amniotes, which arises from the deep lateropallial nuclei (mammals, B; reptiles, DLA; birds, TPO/NCL, AD, and lateropallial PoA). In fact, the portion of the La for which a lateropallial nature has been suggested, the PLa (Brox *et al.*, 2004), apparently does not project to the dorsal striatum (Moreno and Gonzalez, 2004). In addition, no portion of the amphibian La shows remarkable immunoreactivity for either choline acetyltransferase (Marin *et al.*, 1997c) or for tyrosine hydroxylase (Marin *et al.*, 1998), which constitute the most outstanding histochemical features of the deep lateropallial amygdala of amniotes. The absence of a cholinergic innervation of the pallial amygdala of amphibians could be explained in view of the scarce population of ChAT-positive cells in the basal telencephalon of anurans and urodeles (Marin *et al.*, 1997c; Gonzalez *et al.*, 2002a). In contrast, the lack of dopaminergic input to the lateropallial amygdala is surprising, given that other dopaminergic inputs to the telencephalon are notably conserved (Marin *et al.*, 1998).

As a conclusion, at present it is unclear whether a homologue for the lateropallial amygdala of amniotes is present in amphibians. The lateropallial nature of the PLa (Brox *et al.*, 2004) is not consistent with its massive projections to the hypothalamus and the lack of projections to the dorsal striatum. Detailed analysis of the chemoarchitecture, development, and connections of the LA of amphibians is needed to clarify this issue.

2.14.7.2.5 The subpallial amygdala of amphibians The available data on the connections and neurochemistry of the telencephalon of amphibians strongly suggest that the caudal subpallium

includes structures comparable to the EA of amniotes. Moreover, there is evidence supporting the view that amphibians possess a central and a medial EA comparable to their amniote homonyms.

2.14.7.2.5.(i) The medial extended amygdala of amphibians As we have already discussed, the caudal cerebral hemispheres of amphibians include a subpallial structure that is targeted by the projections from the accessory olfactory bulb (Northcutt and Kicliter, 1980; Neary, 1990), which is now named medial amygdala (Ma) to suggest its homology with its mammalian homonym (Moreno and Gonzalez, 2003). In fact, like the medial amygdala of amniotes, the amphibian Ma gives rise to important projections to the hypothalamus (Neary, 1995; Moreno and Gonzalez, 2003, 2005; Roth *et al.*, 2004), including preoptic and tuberoinfundibular levels (ventromedial hypothalamus). In addition, the amphibian Ma projects to the central amygdala (see below), the BST, the Acb, and ventral lateral septum and nucleus of the diagonal band (Moreno and Gonzalez, 2003). In turn, the hypothalamic targets of the Ma (preoptic, and tuberoinfundibular hypothalamus) project back to it. This set of connections clearly recalls those of the medial amygdala of amniotes.

As we have discussed for reptiles and birds, in amphibians a portion of the BST (mainly its caudal aspect, BSTc; Moreno and Gonzalez, 2003) is interconnected with the Ma. This suggests that amphibians, like amniotes, also possess a medial EA composed of the Ma and the BSTc. Histochemical studies reveal further similarities between the medial EA of amphibians and amniotes. Thus, the medial EA of anurans and urodeles (and even of Gymnophiona; Gonzalez and Smeets, 1997; Hilscher-Conklin *et al.*, 1998) displays a population of cells immunoreactive for arginine vasotocin (Smeets and Gonzalez, 2001) that extends into the preoptic hypothalamus, thus recalling the medial EA of amniotes. This vasotocinergic neuronal population is sensitive to steroid hormones (Boyd, 1994), so that this cell group is sexually dimorphic at least in certain seasons (Boyd *et al.*, 1992). Accordingly, the medial EA of anurans (Morrell *et al.*, 1975) and urodeles (Davis and Moore, 1996), like its counterpart in amniotes, is rich in receptors to sexual steroids, especially estrogens. In addition, vasotocin-immunoreactive fibers innervate some forebrain centers (ventral lateral septum, ventromedial infundibular hypothalamus; Smeets and Gonzalez, 2001) that are reached by projections of the Ma (Moreno and Gonzalez, 2003) and are also sensitive to sexual steroids (Kelley *et al.*, 1975; Morrell *et al.*, 1975; Davis and Moore, 1996). Therefore, like amniotes, amphibians display a sexually dimorphic forebrain circuit in which the medial EA apparently gives rise to vasotocinergic projections. This strongly supports the homology of the medial EA of amphibians and amniotes. In this respect, the absence of a vasotocinergic innervation of a pallial amygdaloid center (specifically in the La), which would be part of this circuit in the amphibian forebrain, again suggests that amphibians lack a cell group equivalent to the AHA of mammals, the VPA of reptiles, and the ventropallial PoA of birds. However, detailed studies of the neurochemistry and connections of the amphibian pallium are needed to determine whether a pallial, vomeronasal-related, and steroid-sensitive pallial amygdaloid center is already present in the brain of amphibians.

2.14.7.2.5.(ii) The central extended amygdala of amphibians The caudal part of the striatum was renamed central amygdala (Ca) by Marin *et al.* (1998) on the basis of its chemoarchitecture and connections (Marin *et al.*, 1997a, 1997b). The amphibian Ca is interconnected with the parabrachial region, the lateral reticular zone, and the nucleus of the solitary tract (Marin *et al.*, 1997a, 1997b). Moreover, at least some of the projections to the tuberal hypothalamus originally attributed to the striatum are likely to originate in the Ca (Neary, 1995; Marin *et al.*, 1997b). In addition, the Ca receives important afferents from the other two amygdaloid divisions, the Ma (Moreno and Gonzalez, 2003) and La (Moreno and Gonzalez, 2004). Therefore, the afferent and efferent connections of the amphibian Ca resemble those of the mammalian central nucleus of the amygdala.

In amphibians, the projections of the La to the Ca continue rostrally to innervate a continuum of structures that include the rostral BST (BSTr) and the Acb. This recalls the projection from the basolateral to the central EA in amniotes, thus suggesting that the amphibian brain possesses a central EA composed of the Ca plus the BSTr. Available neurochemical data are consistent with this hypothesis. Thus, in *Xenopus* the Acb shows large neurons expressing CRF (Yao *et al.*, 2004), whereas the Ca, Ma, and BSTc display smaller and scattered CRF-immunopositive cells. In addition, the only study of the distribution of NT in the amphibian brain (Bello *et al.*, 1994) reports a few NT-immunoreactive cells in the BSTr.

2.14.7.3 What's New in the Amniote Amygdala?

The data reviewed above show that amphibians possess an amygdaloid formation with pallial and subpallial components. Within the pallium, the La and maybe the dorsal aspect of the Ma are ventropallial derivatives (Brox *et al.*, 2004; Moreno and Gonzalez, 2004), although the posterior La may be lateropallial (Brox *et al.*, 2004). Both the La and Ma project to the hypothalamus (Moreno and Gonzalez, 2003, 2004). In addition, the La also projects to the dorsal and ventral striatum (Marin *et al.*, 1997a). The subpallial amygdala of amphibians consists of most of the Ma, the Ca, and the BST (Marin *et al.*, 1998; Brox *et al.*, 2003, 2004; Moreno and Gonzalez, 2003, 2004). The latter two structures apparently display long descending projections directed to parts of the hypothalamus (Neary, 1995; Moreno and Gonzalez, 2003), tegmentum, and brainstem, including the parabrachial region (from which they receive in turn an important input) and the dorsal medulla (Marin *et al.*, 1997a, 1997b). In addition, the Ca and BSTr are reached by projections from the presumed amphibian homologue for the basolateral amygdala (Moreno and Gonzalez, 2004).

Therefore, the amygdala of amphibians already shows the pattern of organization present in amniotes. In spite of the relative lack of studies on the amphibian brain, the available data suggest that the subpallial amygdaloid centers (medial and central EA) were already present in the anamniote forebrain and underwent a conservative evolution during the anamniote–amniote transition.

However, the pallial amygdalae of amniotes and anamniotes display relevant differences that deserve being considered. First, it is still unclear whether the existence of a lateropallial amygdala is an acquisition of amniotes or whether anamniotes already possess it (see above). Moreover, the pallium of amphibians shows a low degree of radial migration (as compared with amniote pallium) and this applies for the presumed pallial amygdala. Consequently, in the amphibian pallial amygdala there is no differentiation between cortical (superficial, olfactorecipient) and deep pallial nuclei, but the cells of the pallial amygdala projecting to the EA, striatum, and hypothalamus (which in amniotes are mainly deep) are directly reached by olfactory inputs (Moreno and Gonzalez, 2004, 2005). Although the La of anurans also receives afferents from multimodal dorsal thalamic nuclei (anterior and central nuclei; Moreno and Gonzalez, 2004), this suggests that amygdala of anamniotes is mostly influenced by olfactory and vomeronasal information. In this respect, it is important to note that the cerebral hemispheres of amphibians lack true pallial visual, auditory, and somatosensory centers (thalamic sensory inputs reach only the striatum; see Evolution of the Amphibian Nervous System). In contrast, amniotes display pallial regions (reptiles, ADVR; birds, nidopallial sensory regions; mammals, isocortical sensory areas) that receive sensory thalamic inputs, and project directly and/or indirectly to the deep pallial amygdala (Figures 23 and 24).

2.14.8 The Amygdala and the Evolution of the Vertebrate Forebrain

2.14.8.1 The Amygdala: Physiology and Behavior

Considering together all the data reviewed above, it is clear that the amygdala has a long history and that it has undergone a conservative evolution during the phylogeny of tetrapods. This comparative perspective allows us to pose again one of the central questions of the research on the amygdala: whether the amygdala is a functional system (Swanson and Petrovich, 1998; Figure 23a). As we have seen, reptiles, birds, and mammals display a similar set of pallial and subpallial centers in the caudal cerebral hemispheres that can be grouped into two main circuits, structured around the central and medial EA respectively (Figure 23b). The roles of these two circuits in physiology and behavior are discussed below.

2.14.8.1.1 The roles of the central/basolateral amygdala The central EA is one of the output centers for the basolateral amygdala. Thus, the L, B, and AB of mammals, and their homologues in the remaining amniotes, project massively to the central EA. This projection, however, also extends to other striatal territories, including the whole Acb and the dorsal striatum (the latter projection arising exclusively from the B and its avian and reptilian homologues). This system is clearly multimodal as it receives inputs from cortical, thalamic, and brainstem centers, as well as diverse modulatory (mostly aminergic and cholinergic) afferents. In addition, it receives chemosensory inputs thanks to the presence of important superficial-to-deep projections within the amygdala, which convey the olfactory and vomeronasal stimuli received by the cortical (superficial) amygdala to the basolateral and central amygdala.

The role of this circuit has been extensively studied in mammals using different experimental approaches. The results of these studies indicate that the outputs through the central EA mediate fear/anxiety reactions to incoming stimuli, whereas

the amygdalostriatal pathways are part of the reward system of the brain.

2.14.8.1.1.(i) Expression and acquisition of fear/aversion In primates and nonprimate mammalian species (Roozendaal *et al.*, 1990; Davis and Shi, 1999; Choi and Brown, 2003; Kalin *et al.*, 2004; Rosen, 2004), lesioning or inactivating the central amygdala and/or anterior and posterolateral BST diminishes the expression of fear and anxiety

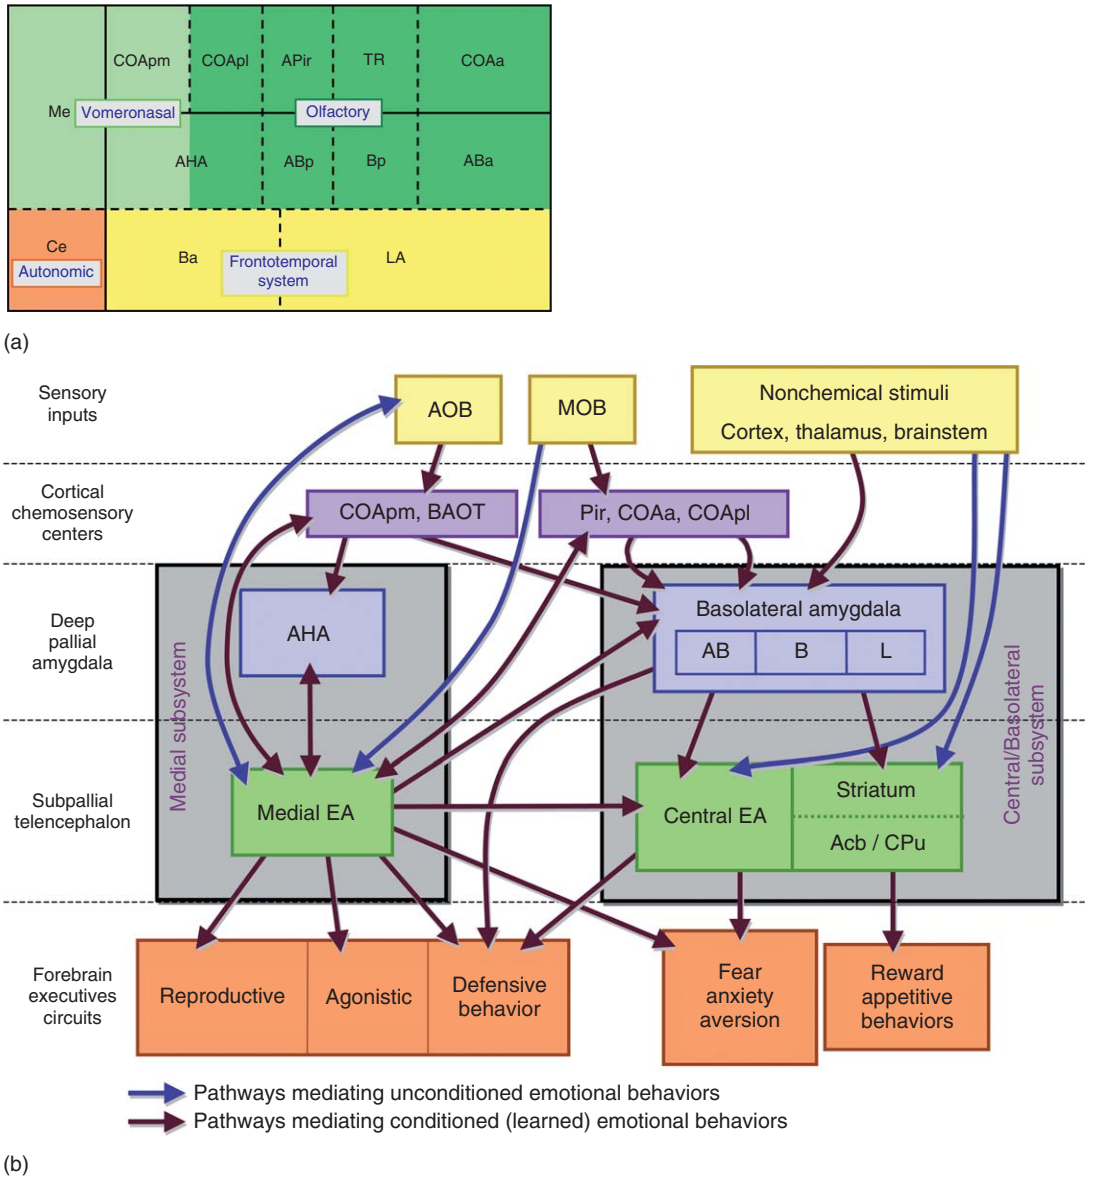

Figure 23 Is the amygdala a functional system? According to the view put forward by Swanson and Petrovich (1998) (a) the amygdala is not a functional system but is composed of structures belonging to the olfactory/vomeronasal, autonomic, and frontotemporal cortical systems. However, the available data on the anatomy and function of the amygdala suggest an alternative scheme on the functional anatomy of the amygdala (b). According to it, the different nuclei of the amygdala are interconnected to conform two functional subsystems, namely the central/basolateral subsystem and the medial subsystem. The former subsystem coordinates innate and learned reactions of fear/anxiety/aversion (through the descending projections of the central EA) or of attraction/reward-directed behaviors (through its projections to the striatum) to virtually any stimulus. The medial subsystem is primarily involved in the coordination of responses to chemosensory stimuli (olfactory and vomeronasal) that constitute species-specific emotional behaviors, such as reproductive/agonistic behaviors to conspecifics (responses to pheromones), and defensive behaviors to conspecifics (as a component of agonistic behaviors) or to predator vomeronasal organ-detected signals. Both subsystems are interconnected, in such a way that olfactory and vomeronasal stimuli can elicit fear/aversion or appetitive behaviors (medial to basolateral/central). On the other hand, nonchemosensory stimuli can modulate the response to pheromones (basolateral/central to medial), although this influence is mediated by direct projections from the basolateral amygdala to the defensive forebrain circuit, rather than through intra-amygdaloid connections.

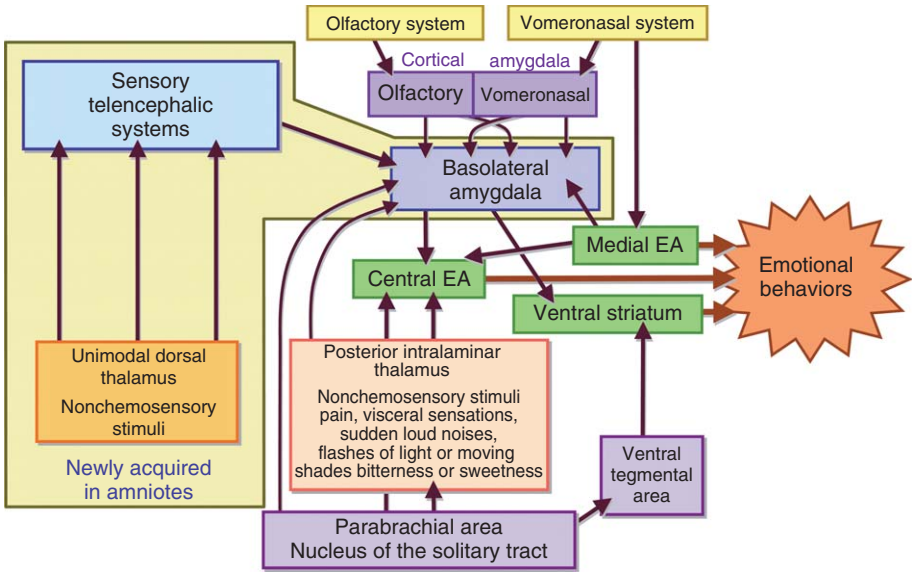

Figure 24 Evolution of the amygdala in tetrapods. The comparative study of the amygdala suggests that all tetrapods have a subpallial amygdala (composed of medial and central EA), which together with the striatum mediates unconditioned emotional behavioral responses to different stimuli (including chemical and nonchemical ones). Moreover, the ancestral amygdala of tetrapods also possesses a cortical amygdala that receives chemosensory information (mainly olfactory), and might contribute to these responses. Two new acquisitions characterize the amygdala of amniotes: (1) the existence of a deep pallial (nuclear) amygdala, namely the basolateral amygdala; and (2) the presence of unimodal nonchemosensory cortical areas in the pallium (dorsal and/or ventral depending on the class). Both have become interconnected, thus allowing processing of stimuli (recognition and identification of their spatial and/or temporal configuration) prior to their emotional evaluation. This has a great adaptive value that has potentiated these traits in all the evolutionary lines of extant amniotes.

against several fear-eliciting stimuli. Comparable functional studies are scarce in nonmammals. However, it has been shown that tonic immobility, a form of prolonged stillness and decreased responsivity induced by threatening stimulation (e.g., physical restraint), which constitutes one of the fear-related ultimate defensive behavioral resources, is reduced by lesions of the former archistriatum of birds (Maser *et al.*, 1973), or the SAT (central EA homologue) in lizards (Davies *et al.*, 2002). Tonic immobility is also part of the behavioral repertoire of some mammals, such as guinea pigs (and maybe humans, where it has been related to catatonia; Moskowitz, 2004). In guinea pigs, tonic immobility seems controlled by the central and basolateral amygdala (Ramos *et al.*, 1999; Leite-Panissi and Menescal-de-Oliveira, 2002). Some of its components, such us the profound analgesia associated with tonic immobility (Leite-Panissi *et al.*, 2001), are dependent on the integrity of the central amygdala and its projection to the periaqueductal gray (Leite-Panissi *et al.*, 2001, 2003).

The role of the descending pathways of the central amygdala in fear expression is further supported by experiments of electrical stimulation. One of the most common behaviors related to stress, discomfort, and anxiety is vocalization. For instance, rats display several kinds of ultrasonic and sonic vocalizations that convey information on their emotional state, some of which are induced by stress and anxiety and are mediated by descending projections arising from the periaqueductal gray to the vocal controlling motor nuclei (Sanchez, 2003). In this respect, electrodes implanted into the amygdala and along the trajectory of the stria terminalis in monkeys elicit different kinds of vocalization (Jurgens, 1982), including purring and chattering calls (which express a self-confident, challenging attitude) and alarm peep and groaning calls indicative of flight motivation and resentment and associated to social stress. Like in rats, the anatomical pathways responsible for these vocalizations in monkeys include periaqueductal regions that are targets for amygdaloid projections (Dujardin and Jurgens, 2005). Moreover, in guinea pigs, the central amygdala is involved in the expression of pain-related vocalization, so that vocalizations induced by noxious stimuli can be decreased by intra-amygdaloid infusions of cholinergic- and opioid-related drugs (Leite-Panissi *et al.*, 2004).

It has also been shown that electrical stimulation of the central amygdala (Rosen and Davis, 1990; Koch and Ebert, 1993) enhances acoustic startle response, one of the well-studied models of

conditioned fear in rats. In fact, it is now well established that conditioned fear to a previously neutral stimulus (conditioned stimulus) is mediated by a process of Pavlovian association between unconditioned (e.g., footshock) and conditioned stimuli (a tone, a light) that apparently takes place in the basolateral amygdala thanks to *N*-methyl-D-aspartate (NMDA)-mediated synaptic plasticity (Davis, 1994; LeDoux, 2000; Lee *et al.*, 2001; Rosen, 2004). In this respect, it has been suggested that the central EA is involved in conditioned, but not unconditioned fear responses (Choi and Brown, 2003; Rosen, 2004). However, the central EA of mammals (more specifically, its capsular and lateral divisions) receives direct nociceptive inputs from the parabrachial area and posterior intralaminar thalamus (Gauriau and Bernard, 2002), which very likely constitute powerful unconditioned fear-eliciting stimuli. These nociceptive-related afferents of the central EA are rich in the peptide CGRP (see above). In this respect, Borszcz (1993, 1995) reported that in order for a painful stimulation (tailshock) to support fear conditioning, it must generate vocalization afterdischarges (vocalizations that extend beyond the termination of the unconditioned stimulus). It is important to note that lesions of the central amygdala abolish the unconditioned vocalization afterdischarges elicited by tailshock (Borszcz and Leaton, 2003). Therefore, the central amygdala (and very likely the whole central EA) is involved in the generation of fear/anxiety or aversion responses to conditioned and, at least, to some unconditioned fear-eliciting stimuli, such as pain.

The presence of a dense CGRPergic innervation of portions of the central EA of reptiles (Martinez-Garcia *et al.*, 2002b) and birds (Lanuza *et al.*, 2000) suggests that this is a general role for the central EA of, at least, amniotes. This is strongly supported by experiments of electrical stimulation of the amygdala in crocodiles (Keating *et al.*, 1970) and iguanas (Distel, 1978), which elicit fear-related behaviors such as fleeing accompanied by vocalization, pupillary dilation, and hyperventilation. In birds, there is evidence that the descending projections arising from the former archistriatal region mediate escape responses (Phillips, 1964). In addition, Phillips and Youngren (1986) demonstrated that kainic acid lesions of the archistriatum of young domestic chicks reduced fear, as expressed by distress calls (peeps). More recently, it has been shown that the archistriatum is indeed involved in the expression of unlearned fear- or anxiety-related behaviors, such as avoidance of the center of an open field (Lowndes and Davies, 1995). It is still unknown whether these reactions are mediated by the archistriatal projections to the BSTl/SpA or by direct descending projections (like the OM). As a conclusion, despite the fact that more functional studies in nonmammals are needed to refine this view, there is ample evidence suggesting that the circuit composed of the basolateral and central amygdaloid divisions is involved in the expression of unlearned fear and anxiety elicited by unconditioned stimuli (at least pain), and in the acquisition and expression of conditioned fear and distress.

2.14.8.1.1.(ii) Amygdalostriatal pathways: The amygdala and reward In contrast to the data reviewed above, it has been reported that lesions of the basolateral amygdala or of its ventral striatal targets (Acb) in different mammalian species selectively impair learning instrumental responses that result in a delayed reinforcement, which results in impulsive choice (Baxter and Murray, 2002; Cardinal *et al.*, 2004). This indicates that the mammalian amygdalostriatal pathways, together with the prefrontal cortex and the tegmental dopaminergic cell groups, constitute the reward system of the mammalian brain (Baxter and Murray, 2002; Holland and Gallagher, 2004; Schultz, 2004). Therefore, the amygdala is involved not only in the expression of negative emotions (fear, anxiety, aversion) and related learning (conditioned fear and anxiety), but also in positive emotions (reward, attraction, and appetitive behaviors; Kelley, 2004) and related learning (goal-directed behavior through stimulus–reward associations).

In agreement with the current view of homologies between the mammalian and avian brains, lesions of the Acb in birds give rise to a mismanagement of effort economy leading to impulsive behavior when a short delay separates the instrumental response from reward acquisition (Izawa *et al.*, 2001, 2003), or to a complete inability to work for a reward when a long delay is imposed (Kalenscher *et al.*, 2003). To our knowledge there are no data on that issue in any other nonmammalian vertebrate, but the available data in birds suggest that the ventral striatal output of the amygdala of nonmammals, like its mammalian counterpart, is involved in reward expectation and in the generation of behavior using this reward as a goal. This involves not just detecting the reward but also a learning to respond to cues predicting the reward.

2.14.8.1.2 The roles of the medial extended amygdala The second system of the mammalian amygdala is mainly composed of the secondary vomeronasal centers, since it includes the vomeronasal cortex (COApm) and the medial EA, plus a

deep pallial nucleus, the AHA. Their pattern of connections with the hypothalamus and the septohippocampal system, as well as the presence of receptors to sexual steroids in most of the centers of this circuit, suggests that this system is involved in the control of reproductive and agonistic behaviors elicited by conspecific chemical signals (odorants and/or pheromones). In addition, there is compelling evidence of a role for the medial amygdala of mammals in defensive reactions to some predators. The neural basis of both functions is discussed below.

2.14.8.1.2.(i) The medial amygdala and reproductive function The medial EA of mammals, together with the COApm and AHA, are surely activated by vomeronasally detected chemical signals from conspecifics of the same or the other gender. Studies carried out in rodents reveal that these pheromones elicit neuroendocrine changes in conspecifics (e.g., Whitten, Vanderbergh, Bruce, and Lee-Boot effects: Halpern, 1987). In addition, vomeronasal organ-detected pheromones elicit behavioral responses that include agonistic/territorial ones (intermale aggression, territorial countermarking), attraction as well as facilitation of courtship and sexual behaviors, including paracopulatory (e.g., vocalizations) and mounting/lordosis (Halpern and Martinez-Marcos, 2003).

The neural mechanisms of the neuroendocrine responses to pheromones (Bronson and Whitten, 1968) or mating (mating-induced ovulation in females; Bakker *et al.*, 2001), probably involve interactions of the medial EA with gonadotropin-releasing hormone-expressing cells of the rostral medial preoptic region (Swanson, 1987). Nevertheless, the whole system of hypothalamic projections of the medial EA seems to be necessary, since lesions of the ventral premammillary nucleus block pheromone-induced ovulation (Beltramino and Taleisnik, 1985). Thus, in many mammalian species exposure of females to male pheromones induces a luteinizing hormone surge mediated by the vomeronasal organ (Beltramino and Taleisnik, 1983) that induces ovulation. A similar effect is found in males in response to female pheromones (Coquelin *et al.*, 1984; Fernandez-Fewell and Meredith, 1998), accompanied by *c-fos* activation in medial preoptic cells (Fewell and Meredith, 2002). In addition, electrical stimulation of the vomeronasal organ (probably involved in pheromone detection (Halem *et al.*, 1999; see The Evolution of the Vomeronasal System) in hamsters leads to activation of the luteinizing hormone-releasing hormone population of the preoptic area (Meredith and Fewell, 2001). In other species, such as ferrets, ovulation is not spontaneous but it is induced by mating (Carroll *et al.*, 1985). In agreement with this, in most studied mammals mating leads to *c-fos* activation in the luteinizing hormone-releasing hormone-expressing preoptic cells (Fernandez-Fewell and Meredith, 1994; Wersinger and Baum, 1996; Pfaus and Heeb, 1997; Bakker *et al.*, 2001; Meredith and Fewell, 2001), but also of the medial EA. A similar pathway may account for the acceleration or delay of puberty in prepubertal females by conspecific chemosignals. In this respect, it has been shown that vasopressinergic inputs to the gonadotropin-releasing hormone cells, most of which might arise from the medial EA (see above), are important for the modulation of luteinizing hormone surges (Dobson *et al.*, 2003).

As noted above, the medial EA is interconnected with a series of forebrain centers that are involved in reproductive behavior. These include several nuclei of the medial hypothalamus, such as the medial preoptic nucleus, the tuberal nucleus, the ventrolateral aspect of the VMH, and the PMv (Canteras, 2002). Within the cerebral hemispheres, the remaining vomeronasal amygdaloid nuclei (COApm and AHA), together with parts of the septohippocampal system, including the ventral aspect of the lateral septum, are also part of this circuit. The principal outputs of this circuit are the medial preoptic nucleus and VMH, which are involved in the control of sexual behavior of males (Hull *et al.*, 2002) and females (Blaustein and Erskine, 2002) respectively. In agreement with this, most of the nuclei conforming this circuit are sexually dimorphic and express receptors to sexual steroids that very likely mediate the modulatory effects of steroid hormones on copulation, territorial aggression, and other forms of reproductive and agonistic behavior. Therefore, the medial EA, COApm, and AHA are in a good position to facilitate innate agonistic or reproductive behavioral responses (Kollack-Walker and Newman, 1995) to pheromones and other chemical cues from conspecifics.

Functional studies of the counterparts for the medial amygdala and/or AHA of nonmammalian vertebrates are restricted to birds. Thus, lesions of the TnA in male quails (Thompson *et al.*, 1998) result in an impairment of copulatory and paracopulatory behaviors, including courtship vocalizations, thus reinforcing the view that it is homologous to parts of the medial amygdala of mammals. Similar lesions in other avian species, such as ring doves and starlings (Cheng *et al.*, 1999), lead to changes in social behavior such as increased cooing in female doves, interpreted by the

authors as an indifference to concurrent male attacks, and social detachment and lack of social inhibitions in starlings.

The connections from the medial EA to the lateral septum seem to be fundamental to modulate agonistic behavior. Using different bird species, Goodson and collaborators (Goodson, 1998a, 1998b; Goodson and Adkins-Regan, 1999; Goodson *et al.*, 2004) have shown that vasotocinergic (and vasoactive intestinal peptidergic) innervation of the lateral septum, presumably arising from the medial EA (see above), modulates mate competition, aggression, and territorial down song but not courtship. A role for vasotocin in modulating agonistic behavior has also been shown in mammals, amphibians, and fish, thus suggesting that this circuit has a long evolutionary history with a well-conserved role (Goodson and Bass, 2001).

2.14.8.1.2.(ii) The medial amygdala: Defensive behavior and predator-elicited fear Besides a role in modulating conspecific-related behaviors, the medial amygdala of mammals seems to mediate innate fear to chemical cues derived from common predators, such as cats or foxes (Dielenberg and McGregor, 2001). Confrontation of a rat to cat fur or to a chemical derived from fox feces (2,5-dihydro-2,4,5-trimethylthiazoline, TMT) innately provokes endocrine (increased corticosterone and adrenocorticotropic hormone levels), vegetative (increased arterial pressure) and behavioral components of fear (freezing in some conditions, and escape or hiding if this is allowed; Rosen, 2004).

Although the vomeronasal organ is presumed to be involved in the detection of pheromones (by definition, secreted by conspecifics), there is experimental evidence suggesting that some of the predator-related substances that elicit innate fear are also detected by the vomeronasal organ. Thus, rats do not display fear (increased hiding) if a worn cat collar is present but a mesh wire avoids direct contact with it (Dielenberg and McGregor, 1999), thus indicating that the cat-derived fear-eliciting substance is not volatile, as shown for some vomeronasal organ-detected conspecific pheromones (Moncho-Bogani *et al.*, 2002, 2005; Luo *et al.*, 2003). In agreement with this, cat-derived chemicals induce *c-fos* (Dielenberg and McGregor, 2001) in the medial EA, including the MeP (especially the MePV) and parts of the BST. In addition, the forebrain defensive circuit (Canteras, 2002) seems strongly activated: the ventral lateral septum, the anterior hypothalamus, the dorsomedial aspect of the VMH, and the dorsal premammillary nucleus. Surprisingly, despite the clear signs of fear displayed by the rats studied by Dielenberg and McGregor (2001) when confronted with cat-derived chemicals, neither their central nor their basolateral amygdala was activated by these stimuli. This led the authors to suggest that the medial amygdala is responsible for unconditioned fear, whereas the central/basolateral amygdala is just involved in the expression of conditioned fear (as discussed above; Rosen, 2004). This is partially confirmed by the effects of lesions of the medial or central amygdala on fear elicited by cat odors in rats (Li *et al.*, 2004). The results indicate that the medial but not the central amygdala is involved in generating fear of cat-derived chemicals in rats. A role of the medial amygdala in fear and stress induced by other stimuli (such as acute restraint or footshock) is also possible (Pezzone *et al.*, 1992; Rosen *et al.*, 1998; Dayas *et al.*, 1999; Kubo *et al.*, 2004), although this might be a strain-specific trait (Ma and Morilak, 2004) and the circuitry involved is unknown.

The expression of *c-fos* induced by TMT has recently been studied (Day *et al.*, 2004) and the pattern of cerebral activation differs from that of cat-derived chemicals. Thus, although in both cases the defensive forebrain circuitry is activated, TMT only activates the MeA, but not the MeP. In addition, TMT elicits a strong activation of the central amygdala. These differences can be attributed to the sensory organ used to detect TMT and the cat-related fear-eliciting chemical. Whereas the cat-derived chemical seems a vomeronasal organ-detected stimulus (Dielenberg and McGregor, 2001), TMT is a volatile chemical that displays a strong odor to the human nose, thus it is very likely detected by the main olfactory system. In agreement with this, it strongly activates the granular layer of the main olfactory bulb and those portions of the medial amygdala that show direct inputs from the main olfactory bulb, namely the MeA (see above). Since the MeA projects to the central amygdala, this depicts a circuit for odor-induced unconditioned fear that includes the main olfactory bulb, its direct (and maybe indirect) projections to the MeA and its projection to the CeA (Myers and Rinaman, 2005).

Therefore, the medial amygdala of mammals seems not only involved in coordinating agonistic and reproductive behaviors in response to conspecific pheromones, but also fear/defensive reactions to odors and vomeronasal organ-detected substances secreted by common predators. In other words, the medial amygdala seems the key center to orchestrate innate responses to biologically significant chemicals (pheromones and odorants) derived from conspecifics and predators. Similar functional studies carried out in reptiles suggest that they can also

use chemical stimuli to detect predators and generate anticipatory defensive reactions. Thus, many crotaline snakes display defensive reactions to one of its predators, the kingsnake (*Lampropeltis getula*) which are mediated by the vomeronasal organ (Miller and Gutzke, 1999). Similar functional studies are not available in birds, but since the sign stimuli for detecting predators are not chemical but visual or auditory, the neural circuitry mediating predator-elicited defensive reactions is unlikely to use the medial EA.

2.14.8.1.2.(iii) The amygdala as a functional system In their insightful review of the structure and function of the amygdala, Swanson and Petrovich (1998) proposed that the term 'amygdala' should be abandoned since it is neither a structural nor a functional unit. From a functional viewpoint, they considered the amygdala as composed of portions of the autonomic (central amygdala), chemosensory (cortical, medial, AHA, ABa, Abp, and Bp) and frontotemporal (the rest of the basolateral amygdala, L and Ba) systems of the brain (Figure 23a).

Our review of the available data in different vertebrates reveals, however, that the amygdala is composed of two functional subsystems that, together, control several aspects of behavior and physiology (Figure 23b). The subsystem that has its output through the central EA also includes portions of the basolateral amygdala that Swanson and Petrovich (1998) consider as part of the olfactory amygdala (ABa, ABp, Bp) and a frontotemporal nucleus (L). Therefore, the central/basolateral subsystem of the amniote amygdala encompasses structures belonging to the three functional divisions of the amygdala proposed by Swanson and Petrovich (1998), thus suggesting that a great part of the amygdala does act as a functional system. Concerning the medial subsystem of the amygdala, it is exclusively composed of nuclei belonging to Swanson and Petrovich's olfactory compartment of the amygdala. However, there is evidence that the medial amygdala is involved in the generation of autonomic and/or endocrine stress responses (Dayas *et al.*, 1999; Kubo *et al.*, 2004), so that it could equally be considered as part of the autonomic amygdala together with the central amygdala.

The central/basolateral and medial subsystems of the amygdala, as proposed here, are also interconnected and connected with similar forebrain centers through which they can manage, jointly, important behaviors. Thus, as we have discussed above, the MeA receives not only vomeronasal but also olfactory inputs, and projects to parts of the central EA. This connection provides a vomeronasal and/or olfactory input to the central EA that could mediate fear/anxiety reactions to this kind of stimuli (Day *et al.*, 2004; Myers and Rinaman, 2005). This does not rule out the possibility that parts of the medial EA mediate some fear/anxiety reactions, without involvement of the central EA, to either chemosensory stimuli (Dielenberg and McGregor, 2001; Li *et al.*, 2004) or nonchemosensory stressors (Dayas *et al.*, 1999; Kubo *et al.*, 2004).

In addition to the role described in mediating reproductive, agonistic, and defensive behaviors in response to chemosensory cues, the medial subsystem of the amygdala is surely involved in the appetitive behaviors due to the reinforcing value of sexual pheromones (Moncho-Bogani *et al.*, 2002, 2005). The rewarding value of these pheromones is likely to be mediated by indirect projections from the medial subsystem of the amygdala to the ventral striatum through the central/basolateral subsystem (Moncho-Bogani *et al.*, 2005) and, therefore, these behaviors are dependent on the interconnection between the two amygdaloid subsystems.

Finally, parts of the central/basolateral subsystem of the amygdala, namely the posterior AB, give rise to a strong projection to the defensive system of the hypothalamus (a portion of the pallial stria terminalis), e.g., the anterior hypothalamus and the dorsomedial (core) VMH. Canteras (2002) interprets this as a pathway mediating defensive reactions to nonchemosensory stimuli, namely visual, somatosensory, and auditory ones.

As a conclusion, the functional division proposed by Swanson and Petrovich (1998) does not seem tenable in the light of the evidence reviewed. In contrast, the amygdala is composed of two functional subsystems, named here as central/basolateral and medial, which, together with other forebrain centers, govern emotional behavioral responses to different kinds of stimuli. These include goal-directed behaviors that relay on delayed reward and involve learning (output to the striatum), fear/anxiety/aversion (central EA), and reproductive/agonistic and defensive behaviors. Interactions of both subsystems are needed to accomplish these functions.

2.14.8.2 Evolution of the Emotional Brain: The Amygdala and the Evaluation of Incoming Stimuli

Emotional behaviors can be expressed either in response to intrinsically attractive and reinforcing stimuli, such as sexual pheromones, sweet and

salty taste, or in response to intrinsically aversive/fear-eliciting ones, such as pain or disgusting visceral sensations, chemicals from predators, startling loud noises or lights (Figures 23b and 24). The presence of some direct sensory inputs to the EA and to the striatopallidal telencephalon allows quick, automatic responses to these stimuli. Thus, nociceptive stimuli reach directly parts of the central EA through the CGRP-enriched projection from the parabrachial area and intralaminar thalamus (Gauriau and Bernard, 2002), and this pathway seems to mediate unconditioned fear reactions (Borszcz and Leaton, 2003). In addition, fear/defensive reactions to predator-related chemical stimuli (cats) seem mediated by the vomeronasal/olfactory inputs to the medial amygdala (Li *et al.*, 2004). On the other hand, direct access of rewarding stimuli to the ventral striatum mediates most appetitive behaviors related to natural reinforcers, such as food and water intake, salt and sweet appetite, and sexual behavior (Pecina *et al.*, 2003; Kelley, 2004).

As we have seen, the basolateral amygdala of amniote vertebrates receives convergent afferents from all the sensory systems, but it is evident that not every stimulus reaching the amygdala elicits fear or reward. However, when a neutral stimulus coincides with an attractive or aversive stimulus (US), Pavlovian conditioning occurs and the previously neutral stimulus results in a conditioned response similar to the one provoked by the US with which it is associated. In other words, the animals acquire fear or attraction to previously neutral stimuli that become, in that way, emotionally labeled. The synaptic plasticity in the basolateral amygdala might mediate this kind of Pavlovian conditioning, and the conditioned response is mediated by the palliosubpallial projections within the amygdaloid circuit. Our review indicates that this circuit for emotional behavior and emotional learning is present in all the amniotes studied and, therefore, constitutes one of the defining features of the forebrain.

Although most of the models of emotional conditioning use somatosensory or gustatory stimuli as US and auditory or visual ones as conditioned stimuli, vomeronasal stimuli can play an important role as US. Thus, vomeronasal organ-detected chemicals apparently elicit innate fear/defensive reactions (rat defensive behavior to cat fur; Dielenberg and McGregor, 1999). Studies in several rodents reveal that the innate attraction to possible mates (Moncho-Bogani *et al.*, 2002, 2005) as well as different aspects of copulatory (Beauchamp *et al.*, 1982, 1985; Del Punta *et al.*, 2002; Leypold *et al.*, 2002; Stowers *et al.*, 2002) and paracopulatory behaviors (ultrasonic vocalizations; Wysocki *et al.*, 1982) to mates are mediated by nonvolatile pheromones apparently detected by the vomeronasal organ. In addition, similar stimuli seem to elicit agonistic behaviors such as competitive signaling (Hurst and Beynon, 2004) or intermale aggression (Clancy *et al.*, 1984; Del Punta *et al.*, 2002; Leypold *et al.*, 2002; Stowers *et al.*, 2002).

Dealing with this, it is important to stress that there is a significant olfactory–vomeronasal convergence within the basolateral amygdala of amphibians, reptiles, and mammals (see above), which can mediate olfactory–vomeronasal conditioned learning, thus providing olfactory stimuli with an attractive or aversive significance. (Indeed, neurons in the basolateral amygdala respond to a particular odor depending on whether it was previously paired with a pleasant or unpleasant taste (Schoenbaum *et al.*, 1999). A similar neural mechanism would mediate olfactory–vomeronasal associations.) This kind of associations would confer a predictive value to odors that can be detected from a distance due to their volatility. This allows the animal to anticipate its reactions to pheromones or vomeronasal organ-detected predator signals (which are usually nonvolatile; Wysocki *et al.*, 1980; Dielenberg and McGregor, 1999; Moncho-Bogani *et al.*, 2002, 2005; Luo *et al.*, 2003), thus being able to trail the source of attractive pheromones, or to avoid or flee from repulsive or fear-eliciting ones. This has a huge adaptive value and confers advantage to animals showing this ability.

In our view this kind of association might have constituted the primary role of the pallial amygdala in guiding behavior and was already present, at least, in the ancestral tetrapods. Thus, even in amphibians the medial amygdala (which receives the bulk of the projection from the accessory olfactory bulb) and the LA (which receives an important input from the main olfactory bulb) are interconnected (Moreno and Gonzalez, 2003, 2004). In addition, direct thalamic afferents to the amygdala are scarce but present in amphibians, so that they probably occurred very early in the vertebrate evolutionary history. These pathways might primarily convey information on simple but innately significant stimuli (e.g., pain, visceral sensations, sudden loud noises or lights) that would contribute to the emotional tagging of odors. In this way, the vertebrate amygdala became a neural center involved in the emotional labeling of odors by association with either attractive or fear-eliciting chemosensory (mainly vomeronasal) and nonchemosensory stimuli.

2.14.8.3 The Amygdala and the Evolution of the Pallium in Vertebrates

In all the amniotes studied, the pallial amygdala also receives important afferents from the sensory pallial areas of the telencephalon. There, specialized unimodal regions of the dorsal thalamus convey nonchemosensory stimuli to specific areas of the cortex, where these stimuli are processed by means of complex circuits that include palliopallial excitatory projections and local interneurons mediating feedback and feedforward inhibitory processes. In contrast, amphibians do not possess unimodal thalamocortical sensory pathways (Martinez-Garcia, 2003), but their dorsal thalamic sensory nuclei project to the striatum (Endepols *et al*., 2004; see Evolution of the Amphibian Nervous System). Therefore, sensory cortical areas first appeared in amniotes, where they are represented by the anterior DVR of reptiles and birds (entopallium, nucleus basorostralis of the pallium, field L of the nidopallium), the visual and somatomotor Wulst of the avian hyperpallium, and the sensory isocortex of mammals (Figure 24). The appearance of these cortical sensory areas in amniotes was accompanied by a differentiation within the pallial amygdala of superficial cortical areas receiving direct olfactory inputs, and deep nuclear territories engaged in interconnections with the nonolfactory sensory cortex, e.g., a true basolateral amygdala.

Processing information about the environment prior to conveying it to the amygdala would have been strongly selected during the evolutionary history of amniote vertebrates, since it allowed the animals to react differently to stimuli with a similar configuration but a different emotional value. This may have resulted in an increase in size and complexity of the sensory telencephalon in all the evolutionary lines of amniotes, a phenomenon that seems to have occurred independently in each line. In therapsid reptiles, leading to mammals, sensory processing mainly took place in the mediodorsal pallium, which developed into a complex isocortex with primary sensory and complex associative regions that provide highly processed sensory information to the amygdala. In sauropsids, this sensory processing occurred mainly in the ventral and lateral pallial territories, thus resulting in the development of the DVR, which, at least in birds, includes associative areas that project to the amygdala.

2.15 The Evolution of Vertebrate Eyes

R D Fernald, Stanford University, Stanford, CA, USA

Glossary

archaea	Also called archaeobacteria, these are genetically and metabolically different from all other known bacteria. They appear to be living fossils, survivors of an ancient group of organisms that bridged the gap in evolution between bacteria and eukaryotes, the multicellular organisms.
Cambrian	The first period of the Paleozoic era in geology, characterized by desert land areas, warm seas, and rapid early diversification of marine life resulting in the rise of almost all modern animal phyla.
cryptochrome	Photosensory receptors mediating light regulation of growth and development in plants; recently found in animals.
eye	An organ that can produce an image by comparing the light intensities/wavelengths coming from different directions.
metazoan	Multicellular organism.
phenotype	The observable physical or biochemical characteristics of an organism, as determined by both genetic makeup and environmental influences.
phylogeny	The evolutionary development and history of a species or higher taxonomic grouping of organs or organisms.
rhodopsin	The pigment sensitive to light in vertebrate retinal rods of the eyes, consisting of the seven transmembrane domain protein, opsin, and retinal.

2.15.1 Introduction

Light from the sun carries energy essential for all life on earth and has been a profound selective force, driving the evolution of cellular and molecular processes that harvest the sun's energy. Light is also the premier source of information for many species, and this selective pressure led to the evolution of light-sensing organs, including eyes, that harvest information carried by light. Basically, from the beginning of biological evolution on our planet over 5 billion years ago, sunlight has both fueled and informed life. Light, and the light/dark cycle from our rotating planet are arguably second only to sex as the most important selective forces ever to act on biological organisms. Energy and information are also essential inside cells in the form of DNA and mitochondria and, similar to light, they have an evolutionary history essential to life. One of the most remarkable consequences of light on earth has been the evolution of mechanisms that convert photons not only into energy but also into signals useful to organisms. The evolution of eyes and other structures that collect and use light to represent information from incoming photons has left a remarkable evolutionary trail. And in understanding the genetic, biochemical, and structural remnants of eye evolution, one must follow Ernst Mayr's dictum: "evolution is an affair of phenotypes." Nowhere is this more evident than in the varieties of eyes and the diversity of mechanisms to convert photons into energy useful to the owners of those eyes.

How did eyes evolve? Darwin, the great English naturalist who first brought the systematic

explanatory power of evolution to bear on the bewildering biological complexity of our planet, felt that eyes offered a special challenge to evolutionary thinking because they are such "... organs of extreme perfection and complication ..." (1859). He was quite explicit on this point, saying "... that the eye ... could have been formed by natural selection seems, I freely confess, absurd in the highest possible degree." Although this is most often cited in relation to Darwin's thinking on eyes, he also wrote:

> Reason tells me, that if numerous gradations from a simple and imperfect eye to one complex and perfect can be shown to exist, each grade being useful to its possessor, as is certainly the case; if further, the eye ever varies and the variations be inherited, as is likewise certainly the case; and if such variations should be useful to any animal under changing conditions of life, then the difficulty of believing that a perfect and complex eye could be formed by natural selection, though insuperable by our imagination, should not be considered as subversive of the theory.

Indeed, there are features of eye evolution that challenge the imagination, but we are coming closer to a fuller understanding of how eyes evolved.

More than a century later, new discoveries and new insights that reach from molecular to macroscopic levels of analysis reinforce Darwin's prescient writing. Although we still have much to learn from the evolution of eyes, both about the existing eyes as well as the processes of evolution that produced them, several new findings have guided our understanding about the origins of eyes (see The Role of Vision in the Origin and Evolution of Primates).

Excitement about eye evolution comes from discoveries across the spectrum of biological investigation. Molecular biologists who seek fundamental similarities among organisms have found some clusters of genes implicated in eye development that are conserved in eyes across large phylogenetic divides. We also now know that vertebrate genomes contain nearly twice as many genes encoding light-transducing opsin proteins as were once thought to be present. Moreover, physiologists have identified two fundamentally different kinds of eye phenotypes in single organisms. In fact, within the eye of at least one vertebrate, there are now known to be two fundamentally different kinds of phototransduction, each apparently serving separate but overlapping functions. Evolutionary biologists interested in understanding why organisms and their parts are so different have found new types of eyes, both in the fossil record and in living animals. What do these different approaches to the evolution of eyes tell us? Together they offer complementary views of eye evolution and possibly the beginnings of a clearer story about how and how often eyes arose during evolution.

2.15.2 Eye Variation: Structural and Functional Adaptations

2.15.2.1 Adaptations to General Constraints

In his monumental book, Walls (1942) provided remarkable insights into all aspects of the vertebrate eye. Moreover, this classic has numerous illustrations, many drawn by Walls himself, with details about the range and variety of vertebrate eye phenotypes. Indeed, the variety of eyes is astonishing, reflecting the range of adaptations produced by selective pressures for vision in different habitats. There are many features common to all eyes, however, which are a consequence of fundamental physical constraints on their construction. Since eyes collect and focus light, their structure ultimately depends on the physical properties of light, which set limits on the optical features of eyes. For example, eyes have evolved to be sensitive within a narrow range of wavelengths, relative to the broad spectrum of energy produced by sunlight (see Figure 1). This is most likely due to the fact that early evolution occurred in water, which strongly filters light (Fernald, 1988). Selection for biochemical mechanisms sensitive to this limited range of wavelengths predisposed the sensitivity that emerged during subsequent evolution. Even though many species long since moved onto land where they

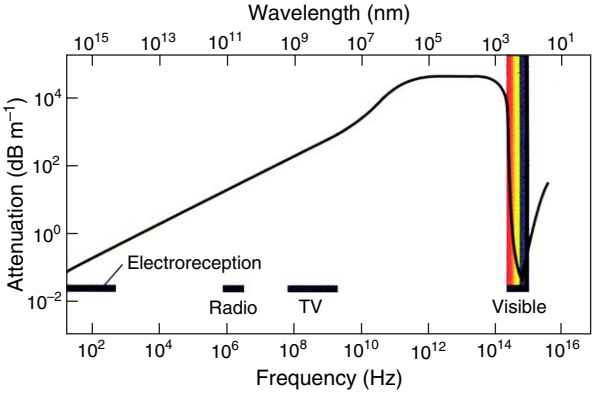

Figure 1 The attenuation (decibels/meter) of electromagnetic (EM) radiation in water as a function of wavelength (nm) and frequency (Hz). This illustrates that attenuation of EM radiation by water is generally quite high except for two ranges: under 10^3 Hz and from 10^{14} to 10^{15} Hz. This accounts for the usefulness of low-frequency signaling and electroreception to weakly electric fish and to the range of frequencies we now term visible light. The band of EM radiation we now consider visible light is transmitted through water with an attenuation six orders of magnitude lower than that of adjacent wavelengths. Redrawn from Fernald, R. D. 1988. Aquatic adaptations in fish eyes. In: Sensory Biology of Aquatic Animals (*eds.* J. Atema, R. R. Fay, A. N. Popper, and W. N. Tavolga), pp. 185–208. Springer.

are exposed to the broader spectrum of electromagnetic radiation from the sun, most animal eyes remain limited to seeing within the narrow band. However, insects and some species of fish and birds later evolved additional receptor types for ultraviolet (UV) light (e.g., Viltala *et al.*, 1995). Thus, the narrow range of wavelength sensitivity is a residual reflection of our aquatic origins and illustrates how early evolutionary solutions persist in the evolved organs.

Of the approximately 33 animal phyla, about one-third have no specialized organ for detecting light, one-third have light-sensitive organs, and the remaining third are animals with what we would consider eyes (Land and Nilsson, 2002). Image-forming eyes appeared in 6 of the 33 extant metazoan phyla (Cnidaria, Mollusca, Annelida, Onychophora, Arthropoda, and Chordata), and these 6 contribute about 96% of the known species alive today (Land and Fernald, 1992), suggesting that eyes are, indeed, useful. Existing eyes have many shapes and sizes, reflecting the diverse solutions to the problem of obtaining an image. Eyes can range in size from a fraction of a millimeter to tens of centimeters in diameter. The range of eye types, sizes, and locations suggests that they can evolve relatively easily (see below).

2.15.2.2 Optical Systems of Eyes

Eye optical systems fall into three classes based on their image-forming mechanisms: images formed via shadows, images formed via refraction (e.g., lens and/or cornea), and images formed via reflection. These different optical types were first systematically analyzed by Land (1981), who has contributed significantly to our understanding of eyes and particularly their optical function. The physical laws governing the behavior of light are well known and these fundamentally limit how an eye can be formed, whether it produces an image, records the direction of incident light, or simply the presence of light. For this reason, similar structures have arisen in distinctly unrelated animals such as fishes and cephalopods. The chambered or camera eyes in these two lineages are similar in a large number of details, even though their owners are phylogenetically distant (Packard, 1972). Both evolved spherical lenses to achieve sufficient refractive power for focusing light underwater, but the inverted retinal layers of fishes (and all vertebrates) are distinctly different from the noninverted, somewhat simpler retinas of cephalopods. Macroscopically, these eye types and the animals bearing them are not homologous, even though there are striking similarities and even homologies at the molecular and developmental levels, which are at the heart of understanding eye evolution.

The major optical types of eyes (Figure 2) consist of systems that detect shadows, refraction, and reflection. This range of eye types reveals that a limited number of optical solutions actually have persisted in organisms.

The greatest variety of eyes exists among invertebrates. These animals have both camera eyes (e.g., cephalopods) and compound eyes (e.g., *Drosophila*). Moreover, invertebrates also have the greatest variety of eyes as regards number and location on given species. Whereas vertebrates settled on paired, chambered eyes with lenses on the head, invertebrate species may have multiple, nonpaired eyes and eyes in remarkable locations. For example, certain butterflies have light detecting organs located such that darkness signals successful copulation (Arikawa *et al.*, 1996a, 1996b). In addition, Nilsson and colleagues (Nordström *et al.*, 2003) recently described a visual system in the planula of a box jellyfish *Tripedalia cystophora*, with eyecups directly connected to motor cilium. In this case, there is no nervous system to process visual information because the eyes are a complete sensorimotor system unto themselves.

While primitive eyes provide information about intensity and possibly the direction of a light source, more advanced eyes also inform their owners about wavelength and contrast and can provide high-resolution images of an illuminated scene via the concentration of cone photoreceptors in one area such as the fovea in many vertebrates.

There is great variation in the capacities of eyes depending on development and ultimately their structure. For example, resolution of an image, as measured in subtended degrees, differs by approximately 13-fold among vertebrates and even more between vertebrates and invertebrates. Eagles have the greatest acuity that is around 10 000-fold greater than that found in planaria (Land and Nilsson, 2002). Similarly, a comparison of relative sensitivities among vertebrates reveals a range of 4×10^5 between highly sensitive deep-sea animal vision and human foveal vision (Land and Nilsson, 2002).

Another remarkable adaptation is differential wavelength sensitivity of photoreceptor types resulting in the ability to distinguish colors (see The Comparative Biology of Photopigments and Color Vision in Primates, Evolution of Color Vision and Visual Pigments in Invertebrates). The selective pressures for evolution of such wavelength discrimination appear to have been quite pervasive. Very likely the added value of better

contrast discrimination, which increases the likelihood of identifying food, mates, and predators, would have been enhanced with chromatic information (e.g., Nagle and Osorio, 1993; Osorio and Vorobyev, 1996). Indeed, recent work comparing eight primate taxa suggests that trichromatic vision evolved where leaf consumption was critical (Lucas *et al.*, 2003). In support of this idea, many species of diurnal reptiles and birds have colored retinal filters, composed of oil droplets, which appear to have evolved to increase the number of colors that can be discriminated, suggesting selective pressure for improved color vision (Vorobyev, 2003).

2.15.2.3 Lenses: Multiple Protein Types and Gene Sharing

Eyes collect light through an aperture and focus it with a lens onto photoreceptor cells specialized to convert photons into neural signals. Some eyes exist without pupils and even without lenses (*Nautilus*), but eyes that evolved to give their owners a clear view of the environment on a short timescale do

have lenses. Lenses are constructed of tightly packed proteins, so could the composition of lenses yield insight into how eyes evolved?

In vertebrates, lenses are formed from modified epithelial cells and contain high concentrations of soluble proteins, known as crystallins because of their organized packing into arrays. In contrast, in most invertebrates, the lens proteins are secreted by specialized cells of the eye. Recently, lenses of mitochondrial origin have been found in the two pairs of eyes of the parasite *Neoheterocotyle rhinobatidis* (Rohde *et al.*, 1999). Despite their distinct cellular origins, for a lens to function optically, its constituent proteins must be distributed to produce a radial gradient of refractive index that is low at the edge of the lens and high in the center (see Kroeger *et al.*, 1999; Land, 2000). An exact gradient of refractive index is essential for vision in animals living in water but is also found in terrestrial vertebrates and invertebrates. Perhaps most remarkably, cephalopods assemble their spherical lens from two distinct embryological sources, yet manage to produce the required gradient of refractive index (Jagger and Sands, 1999).

Until quite recently, the 10 or so crystalline proteins found in lenses were thought to be unique to lens tissue and were also thought to have evolved for this function. Of the large number of crystallins, alpha and beta-gamma crystallins are indeed specialized lens proteins in vertebrates, related to heat shock protein and schistosome egg antigen, respectively. However, the remaining vertebrate lens proteins are not conserved, but rather comprise a diverse group, many of which are used as enzymes elsewhere in the body. Surprisingly, most of these taxon-specific lens proteins are actually products of the same genes as the enzymes; this double use has been termed gene sharing by Wistow (1993a, 1993b). For example, a crystalline protein in the duck lens was shown to be similar to a metabolic enzyme, argininosuccinate lyase, and the lens protein and metabolic enzyme are encoded by the same gene, not from duplicated genes. Such sharing might possibly have been a prelude to gene duplication. This molecular opportunism is so effective that it has also occurred both in cephalopods (Tomarev and Zinovieva, 1988) and in *Drosophila* (Janssens and Gehring, 1999). One possibility is that since lenses need the production of a relatively large amount of protein, genes that have been upregulated in other tissues might be selected as appropriate.

Perhaps the most remarkable example of a lens from an unusual source is found in the brittlestar (*Ophiocoma wendtii*). These animals form crystal lenses as a part of their skeletal armor from calcite crystals. The crystals, oriented to bring light onto the photoreceptive surfaces in the body, focus the light much as corrective lenses might and effectively concentrate the light by approximately 50 times (Aizenberg *et al.*, 2001).

The common cellular strategy of assembling lenses from diverse proteins seems to be a convergent evolutionary solution that has occurred in many vertebrates independently. The exquisite gradient of the refractive index that evolved in vertebrates and invertebrates alike resulted because it is the only way known for making an optically useful lens. What remains unknown is how such diverse protein species are assembled through folding and organization that preserves key properties of transparency and suitable refractive index gradient along the axis of the lens. The challenge for understanding lens development is to identify the mechanisms responsible for organizing diverse proteins into a functioning lens. This knowledge could provide useful insights into eye evolution from the perspective of lens assembly.

2.15.2.4 Capturing Light: The Opsin/Retinal Solution

Evolution has left its mark in the DNA sequences of the main light-capturing molecule, opsin, in the biochemistry of transduction, and in the association between the active proteins and other molecules essential for phototransduction. Vertebrate visual pigments (opsins) appeared before eyes (Land and Fernald, 1992) and evolved along at least seven lines, diverging from an ancestral type, before teleost fish diverged from other vertebrates (e.g., Hisatomi *et al.*, 1994) and indeed before deuterostomes split from the protostomes (Terakita, 2005), suggesting that a common ancestor had multiple opsin genes. This surmise has been confirmed with recent evidence (see below). That visual pigments evolved along parallel lines following an ancient divergence is widely accepted, though there are some differences in exact interpretation (Okano *et al.*, 1992).

Opsins are seven transmembrane proteins (30–50 kDa) that associate with a nonprotein moiety, the chromophore retinal. Among the approximately 1000 opsin forms that have been described to date, the phylogenetic differences among the seven major groups correspond to specific functional classifications (Figure 3). These classes differ in several ways, including their transduction via different G-proteins. For example, vertebrate and invertebrate photosensitive opsins are heterotrimeric guanine nucleotide-binding protein (G-protein) -coupled receptors that use 11-*cis*-retinal or a close variant as their chromophore. Vertebrate rod and cone opsins signal through

photoreceptor-specific G-proteins called transducins, whereas invertebrate opsins signal through the Gq family of G-proteins. Photo responses are terminated by a combination of phosphorylation of the excited opsin, the binding of arrestin proteins, which is then followed by regeneration of the active chromophore form needed for photosensitivity.

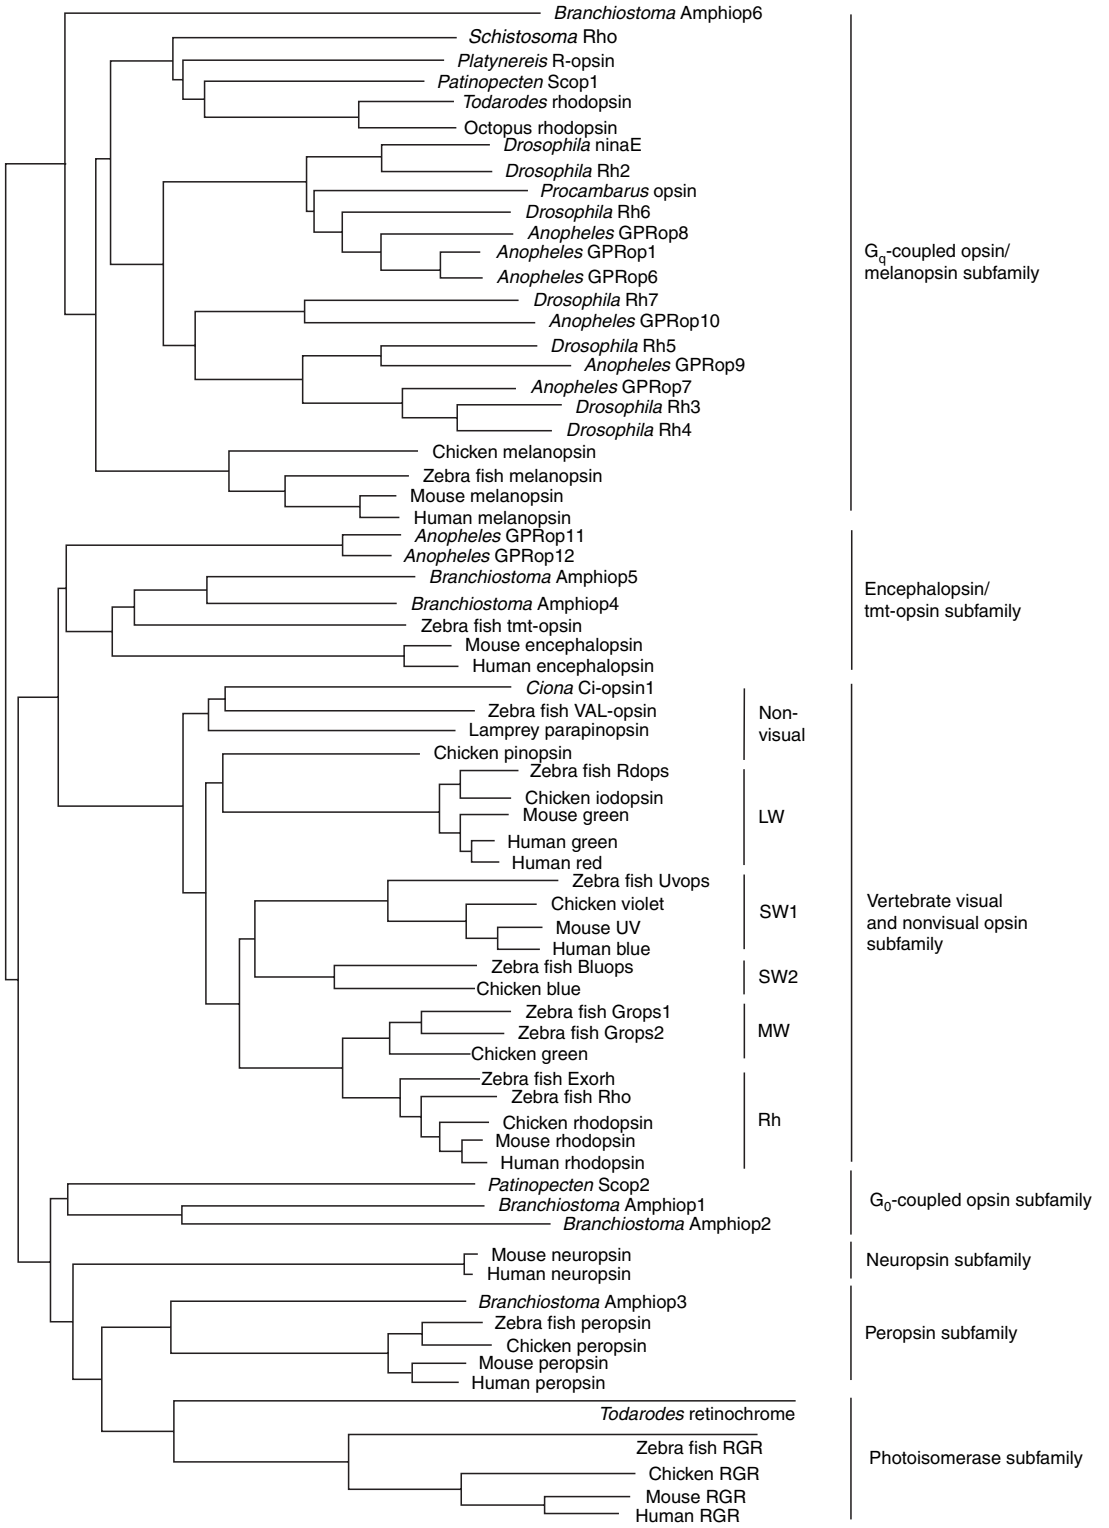

Figure 3 Phylogenetic tree of known opsins. These naturally segregate into seven families. Reprinted from Terakita, A. 2005. The opsins. *Genome Biol.* 6, 213.

A great deal is known about the detailed evolutionary relationships among rhodopsin molecules; some of this based on understanding the interaction between retinal and opsin (Marsh and Griffiths, 2005). Indeed, rhodopsin function is very well understood (e.g., Menon *et al.*, 2001) and the adaptive radiation of pigment types due to natural selection for particular wavelength responses has been described for some special cases (e.g., East African cichlids, Sugawara *et al.*, 2002; squirrelfish, Yokohama and Takenaka, 2004). However, there has been considerable variance in spectral sensitivities that likely resulted from specific selective advantages for one solution over another. Detailed comparisons between terrestrial vertebrates and insects, for example, reveal that there are not unique solutions to encoding both spatial and spectral information. Mammals and bees use long wavelength receptors for luminance and color vision, whereas flies and birds have evolved separate sets of photoreceptors for the two purposes (Orsio and Vorobyev, 2005).

Primate photopigments also offer examples of recent evolutionary change in these important molecules. For example, Old World monkeys, apes, and humans have trichromatic vision, while New World monkeys are polymorphic, having dichromatic or trichromatic color vision (Jacobs, 1996). In this context, *Homo sapiens* may be unique in the polymorphism found in our color vision system (e.g., Neitz *et al.*, 1996). This variance in the number and kinds of photopigments in the human retina might reflect the reduced selective pressure on color vision. The subtlety of selective pressures on chromatic detection can be found in many species. It is particularly evident in the variation within a single species of bluefin killifish, where the relative abundance of cone types depends on whether the animals live in springs or swamps (Fuller *et al.*, 2003). The novel differential spectral sensitivity in these populations is produced through differential expression of cone classes in the retina, rather than via modification of the spectral tuning of opsin molecules, showing that there are different ways to achieve different kinds of chromatic sensitivity.

Another mechanism for temporal modulation of wavelength sensitivity in cone photoreceptors has been described in Pacific salmon (*Oncorhynchus gorbuscha*). As salmon move from being planctivores living in surface waters where UV light is abundant to fish-eating predators in deeper waters where blue-green light prevails, they remodel their UV-sensitive cones with insertion of an opsin that is tuned to blue wavelengths (Cheng and Flamarique, 2004). A similar mechanism has been previously reported in winter flounder (*Pseudopleuronectes americanus*) in which a single opsin type in juveniles, located in hexagonally arranged single cones, is replaced by three different opsin types in photoreceptors arranged in a square array in the metamorphosed adult (Evans and Fernald, 1993; Evans *et al.*, 1993).

These examples show that animals have evolved eyes with resolution, sensitivity, and wavelength detection to match their needs, even as those needs change during their life history. The best understood aspects of visual transduction is that which is used for the main visual input in both vertebrates and invertebrates. The role of the other opsin families is beginning to be understood, although a great deal remains mysterious.

2.15.3 Evolutionary Issues

2.15.3.1 Origins of Eyes

Logically, eyes might be monophyletic, having evolved from a single progenitor, or polyphyletic, having arisen more than once during evolution. Salvini-Plawen and Mayr (1977) compared overall structure, photoreceptor types, developmental origins of eye tissue, position of receptor axons, and other anatomical markers among eyes using current fauna. Based on this analysis, they came to the conclusion that eyes evolved not once but at least 40 different times, and possibly many more (reviewed in Land and Fernald, 1992). This multiple-origins hypothesis, based on morphological evidence, has been challenged more recently by results from molecular experiments. Specifically, Gehring and Ikeo (1999) proposed that because a single, well-conserved master gene, *Pax6*, can initiate eye construction in diverse species, eyes must have arisen from a single ancestor. Did eyes appear many times in the course of evolution making them polyphyletic, as claimed by Salvini-Plawen and Mayr based on phenotype, or have all eyes descended directly from a common, primitive form, making them monophyletic, as claimed by Gehring and Ikeo (1999) based on genes controlling development? Since this original debate erupted, there have been several salient discoveries that suggest eyes arose more than once and we carry the evidence within our own eyes!

By the Cambrian period (570–500 Mya), eyes were present in the form of very simple eyecups, useful for detecting light but not for processing directional information. Although the causes are unknown, explosive speciation, or the big bang of animal evolution, happened during the Cambrian (Conway-Morris, 1998). Existing eye types improved radically, coincident with the appearance of carnivory and predation. The evolution of ocular structures

has proceeded in two stages (Figure 2; Land and Fernald, 1992). First was the production of simple eyespots, which are found in nearly all the major animal groups and contain a small number of receptors in an open cup of screening pigment (Land and Fernald, 1992). This kind of detector cannot play a role in recognizing patterns but rather in distinguishing light from dark. The second stage in eye evolution is the addition of an optical system that can produce an image. Image-forming eyes occur in 96% of known species distributed among six phyla. Among the known eye types are at least 11 distinct optical methods of producing images, the most recently described is a telephoto lens, identified in the chameleon in 1995. Indeed, six of the optical mechanisms have only been discovered in the past 25 years.

Since camera-type eyes are demonstrably superior in several respects (Nilsson, 1989), why do all animals not have them? Certainly, camera-type eyes require big heads and bodies to hold them and this likely restricted the number of animals that have followed this evolutionary path. Also, it is probable that, having evolved one eye type, conversion to another type requires intermediate stages that are much worse or useless compared with the existing design. This would make a switch essentially lethal to animals that depend on sight. Although this argument makes sense intuitively, some existing cases of novel optical combinations suggest this is probably not the whole story.

Textbooks tend to group animal eyes into two groups, the camera-type or simple eyes and the compound eyes, which may be didactically useful since such a dichotomy reflects a real and fundamental difference in optical mechanisms, but it conceals a remarkable diversity of optical systems subsumed under each heading.

For example, Nilsson and Modlin (1994) described a mysid shrimp (*Dioptromysis paucispinous*) that has a combined simple and compound eye: partly compound with multiple facets exactly like the eye of an insect, and partly simple with a single lens focusing an image on a sheet of receptors like that of a human. These shrimp are about 5 mm long with nearly spherical eyes at the ends of stalks. In addition to the facets (approximately 800–900), there is a single giant facet facing the shrimp's tail, which the shrimp frequently rotates forward, probably to get a better look at something since that facet has roughly five times the acuity (but much lower sensitivity) than the rest of the eye. It is as if the shrimp is carrying a pair of binoculars for the occasional detailed look at something ahead of it. The discovery that simple and compound eye types can be found in a single animal raises the question of how a developmental program could produce this outcome.

2.15.3.2 Developmental Evidence of Eye Evolution

Classical experimentation on ocular development focused on vertebrate eyes, a specialized extension of the brain. Experimental models were primarily limited to mice and chicks due to their extensive prior exploitation as model organisms. The beautiful images available today make the often subtle but distinctive morphological changes during eye development seem much more obvious than they were when first observed. With scanning electron microscopy and sophisticated methods of timing the state of tissue development, it is possible to watch unfolding of the production of an eye (e.g., see University of North Carolina website, 'Relevant Website').

Eyes develop from the prospective forebrain, beginning in the eyefields, which are made up of cells of the anterior neural plate. As the prosencephalon grows, this region moves forward until the optic groove forms, and the neuroectoderm of the groove locally contacts the surface ectoderm, inducing the lens placode. As the placode invaginates to form the lens vesicle, the optic vesicle forms the bilayered optic cup, which ultimately becomes the eye. The interaction between the optic vesicle and the lens placode was identified as the organizer of the lens by Spemann (1924). The presumptive lens arises from the lens placode, a thickening of the ectoderm in contact with the optic vesicle. Coincident with this change is the onset of expression of proteins that will form the lens. Other structures of the eye are formed by large- and small-scale tissue movements, caused and accompanied by the expression of tissue-specific genes at that site. The cornea arises from the surface ectoderm over the lens and from migrating mesenchyme derived from the neural crest. Many of the original observations about the role of specific tissue bits in these processes resulted from exquisite embryonic manipulations related to transplantation experiments. For example, Nieuwkoop (1963) identified, among other things, the source tissue essential for the induction of eye production.

With well-described macroscopic change in hand, the next challenge is to synthesize the phenomenological, macroscopic morphological observations with molecular explanations of eye development and understand what this tells us about evolution.

The morphological process of eye development has been viewed as a set of steps toward a final tissue arrangement. Underlying this apparently straightforward sequence of large-scale events, however, are distributions of gene expression with substantial overlap in both time and space. Gene expression is

closely regulated, and specific gene products are used repeatedly, which makes the causal relationships difficult to conceptualize. Nonetheless, progress in characterizing the genes responsible for particular steps in eye development has been reasonably rapid, as shown in several recent reviews (Harland, 2000; Chow and Lang, 2001; Graw, 2003). Functions for at least 15 transcription factors and several signaling molecules have been described in human and mice eyes, based on developmental disorders and/or molecular manipulations (e.g., Graw, 2003). As with other molecular actors, both the transcription factors and signaling molecules are expressed during ocular development and also in a wide range of other tissues. This suggests that the particular combination of expression patterns is important for the proper functioning of these genes in eye development.

As is now well known, the paired box gene 6 (*PAX6*), a member of the family of genes that encode transcription factors with a homeodomain and a paired domain, appears to be important in eye formation across many species. The remarkable demonstration that *PAX6* can induce eyes where they should not be (ectopic) in *Drosophila* (Halder *et al.*, 1995), and similar subsequent demonstration in vertebrates (Chow *et al.*, 1999), led to the suggestion that there might be master control genes responsible for development and differentiation of ocular tissue in many species. Subsequent work has suggested that the term 'master control gene' is a misnomer, however, since a suite of genes is required, collectively, to initiate eye development, and transcription factors are a necessary part of the initiation process. Moreover, as noted above, the genes in question actually have dynamic spatial and temporal expression during many stages of eye development, in addition to expression for essential purposes in other tissues. Nonetheless, it is remarkable that some of the same genes appear in the context of eye development, despite great evolutionary distance among the owners of the eyes. How this might have occurred is discussed below.

For *Drosophila* eyes, it is now known that a collection of seven genes, encoding transcription factors and two signaling molecules collaborate to make eyes (reviewed in Kumar, 2001). These nuclear factors (*eyeless* (*ey*), *twin of eyeless* (*toy*) – both of which are *PAX6* homologues – *sine oculus* (*so*), *eyes absent* (*eya*), *dachshund* (*dac*), *eye gone* (*eyg*), and *optix*), and signaling systems, including the Notch and receptor tyrosine kinase pathways, act via a complex regulatory network that is reasonably well understood (see Kumar, 2001, figure 1). The master gene hypothesis is not supported, because deletion of any of these genes causes loss or radical reduction in the *Drosophila* compound eye and, surprisingly, any gene except *sine oculus*, in collaboration with certain signaling molecules, can cause ectopic expression of an eye in a limited set of imaginal disks. This means that the whole troupe is needed to produce a reasonable eye. Why this might be so is suggested by recent work showing that the *eya* gene products are phosphatases, the first case in which a transcription factor can itself dephosphorylate other proteins to fine-tune gene expression (Li *et al.*, 2003). This elegant work demonstrated the details of interactions among *Six1*, *Dach*, and *Eya* in the formation of the kidney, muscle, and inner ear, as well as eyes, suggesting that this suite of genetically interacting proteins has been recruited repeatedly during evolution for organogenesis of different structures.

It is difficult to abandon the heuristic of hierarchical regulatory processes in development originally proposed by Lewis to characterize homeotic properties of bithorax and antennapedia genes, but molecular analysis of eye development shows that this concept may not be useful in this case. Instead, eye development appears to need new ways of thinking about how complex tissues are made and how such organs arose in evolution. The widespread and redundant activities of specific genes during ocular development (e.g., Chauhan *et al.*, 2002; Baumer *et al.*, 2003) suggest that hierarchies, if they exist, are unknown and the more likely scenario is the orchestrated activity of a suite of molecular actors.

As described above, the diversity of eyes confirms their dynamic evolutionary past. Explosive speciation, or the big bang of animal evolution, occurred during the Cambrian (Conway-Morris, 1998), when existing eye types appear to have improved radically, coincident with the onset of carnivory and predation. Many selective forces were likely at work (Fernald, 2000), including perhaps the first instances where light enabled behavioral signals (Parker, 1998), so no predominant selective force can be claimed. The rapidity of eye evolution has always been a question, but, using a simulation, Nilsson and Pelger (1994) suggested that about 2000 sequential changes could produce a typical image-forming eye from a light-sensitive patch. With reasonable estimates, this suggests that an eye could evolve in less than half a million years, making the virtual explosion of eyes during the Cambrian seem reasonable (Land and Nilsson, 2002). After the Cambrian, three phyla emerged: arthropods, mollusks, and chordates. Although these groups all use the opsin molecule to capture

light, details of the structure and function of their eyes differ considerably.

One of the most interesting developmental differences among extant eyes is the embryonic origin of the different structures in vertebrate and cephalopod eyes (summarized in Nilsson, 1996). Cephalopod eyes form from an epidermal placode through successive infoldings, whereas vertebrate eyes emerge from the neural plate and induce the overlying epidermis to form the lens as described above. It is also noteworthy that the cephalopod eyes lack a cornea, which is present in all vertebrates whether aquatic or not.

In addition to the differences in embryonic origin, photoreceptor cells divide into either ciliary or microvillar structures to provide the membrane surface for the opsin molecule (Salvini-Plawen and Mayr, 1977). Microvilli predominate in invertebrates, whereas vertebrate photoreceptors are ciliary. Physiological responses are also quite different, with the microvillous receptors of arthropods and mollusks depolarizing to light, and the ciliary receptors of vertebrates hyperpolarizing to light. In phototransduction, vertebrate photoreceptors exploit cyclic guanosine 5′-monophosphate (GMP) as a second messenger system, while invertebrates use inositol trisphosphate (Fernald, 2000). And, even though opsin is the key molecule for detecting light, mechanisms for regeneration (e.g., reisomerization) of the chromophore/opsin system are dramatically different among phyla (Gonzalez-Fernandez, 2003).

2.15.3.3 Functional Evidence about Eye Evolution

Until recently, the photodetection systems we understood well were localized primarily to eyes and pineal glands and a few other sites in the body such as the skin. For each of these, a canonical opsin and related transduction cascade were known. Specifically, ciliary structures associated with specific G-proteins are known from vertebrate eyes and microvilli associated with inositol phosphate signaling cascades are known from invertebrate eyes (see above). Then, in several laboratories, each of these phototransduction cascades was found in unexpected organisms. Arendt *et al.* (2004) found that the polychete ragworm (*Platynereis dumerilii*), in addition to the rhadomeric photoreceptors in its eyes, had ciliary photoreceptors in the brain. They also showed that the typical types of opsins associated with each photoreceptor type were both expressed in the ragworm and localized only with that type (e.g., vertebrate c-opsin in the brain and invertebrate r-opsin in the eye). This means that the two main types of eyes exist in a worm.

The idea that two kinds of photoreceptors might exist in a single organism was first suggested by the pioneering work of Gorman, who with colleagues showed physiological and morphological data suggesting that both types of photoreceptors exist in a scallop, *Pecten irradians* (Gorman and McReynolds, 1969, 1971). These investigators found depolarizing and hyperpolarizing responses to light stimuli from cells located in different layers of the scallop retina, with depolarizing potentials arising from the proximal layer and hyperpolarizing potentials form the distal layer. The investigators interpreted their data solely with respect to the various kinds of selective advantages each response type might have but did not consider the evolutionary implications, though their data support the existence of the two canonical receptor types in one organism.

Meanwhile, in vertebrates, a parallel set of results has been appearing. A small population of intrinsically photosensitive retinal ganglion cells have been discovered that play key roles in the regulation of nonvisual photic responses. These rely on melanopsin (see Figure 3), an opsin first identified in vertebrate melanophores, brain, and eyes by Provencio *et al.* (1998). The melanopsin in the retina was soon shown to be in the form of photosensitive ganglion cells (Berson *et al.*, 2002), required for normal light-induced circadian phase shifting (Panda *et al.*, 2002), and yet could not function without normal rods and cones (Ruby *et al.*, 2002), meaning that its signals are combined with those from rods and cones somewhere in the visual system. Photosensitive ganglion cells comprise a non-image-forming system that can detect the presence or absence of light but not much more. Subsequent functional analyses showed that retinal melanopsin functions via a phototransduction cascade that resembles invertebrate opsins and, in another similarity to invertebrates, has intrinsic photoisomerase activity (Panda *et al.*, 2005; Qiu *et al.*, 2005). Adding to the remarkable set of discoveries, melanopsin-expressing ganglion cells in the primate retina have been shown to signal color and radiance levels to the lateral geniculate nucleus (Dacey *et al.*, 2005). So, not only do vertebrates carry a version of the invertebrate visual transduction system with them, but it is used in a variety of ways, including to provide information to the image-forming visual system.

Taken together, these findings show that at least two kinds of photoreception existed in the urbilateria, before the split into three Bilateria branches at the Cambrian (Figure 4), and, importantly, each of these branches still carry versions of

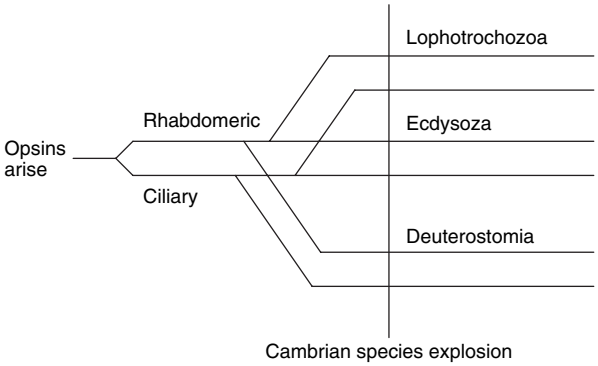

Figure 4 Schematic phylogeny of the Bilateria showing that the distinct rhabdomeric and ciliary organization of opsins preceded the splitting of the urbilateria. Based on Nilsson, D. E. 2005. Photoreceptor evolution: Ancient siblings serve different tasks. *Curr. Biol.* 15, R94–R96.

these two systems. In addition, cryptochromes, also discovered very recently (Cashmore *et al.*, 1999), are another photoreceptive system that is not based on opsin, has no molecular amplification, and is found in both plants and animals. To date, cryptochromes have been shown to play a role in circadian rhythms (Green, 2004) and control of the iris muscle in birds (Tu *et al.*, 2004) as well as many functions in plants. Considering that seven families of opsin have been described in humans (see Figure 3), we can expect more surprises in the detection of light. The additional opsins discovered recently have not yet been functionally characterized, but the evidence suggests that there are no more opsins to be discovered (Kumbalasiri and Provencio, 2005). Even so, figuring out how all the existing opsins work together is a daunting challenge.

2.15.3.4 Parallel Evolutionary Universe?

One of the persistent issues in the evolution of eyes, as noted above, is whether eyes evolved once or many times. Though it seems quite clear that there were at least two kinds of phototransduction (e.g., ciliary and rhabdomeric) before the urbilateria split into three families (see Figure 2), energy and information are harvested in archaea and eukaryotic microbes using a system that clearly arose independently, via convergent evolution. Microbial, or type 1 rhodopsins, named to distinguish them from the visual pigments or type 2 rhodopsins, function to harvest light for energy, to guide phototaxis, and probably many yet undiscovered functions (Spudich *et al.*, 2000). While the number of known type 2 (visual) rhodopsins has increased dramatically over the past several years (see above), the number of known type 1 rhodopsins has rapidly increased with the harvesting and genetic sequencing of ocean samples from a handful to over 800 (Spudich and Jung, 2005). These type 1 rhodopsins are widely dispersed on the planet, found in organisms living in both freshwater and seawater, salt flats, and glacial seas, among others.

There are several fundamental differences between types 1 and 2 rhodopsins. First, there is no evident phylogenetic relationship between the genetic sequences of type 1 and type 2 rhodopsins. As more type 1 opsins are discovered, a connection may become apparent, but given the current state of knowledge, this seems unlikely. Second, the type 1 rhodopsins reveal convergent solutions to the mechanisms for converting photon energy. Both rhodopsin types consist of seven transmembrane domain proteins and, in each, retinal is attached in a Schiff base linkage via a lysine residue in the seventh helix (Spudich *et al.*, 2000). However, type 1 rhodopsin (25–30 kDa) has a different organization of its intramembrane domains from type 2 rhodopsin (35 kDa), which reflects the fundamental difference in their signaling cascades. Whereas type 1 rhodopsins function within the membrane to pump ions or signal to other integral membrane proteins, type 2 rhodopsins signal via G-proteins, receptor kinases via the cytoplasmic loops (see above and Spudich *et al.*, 2000). Retinal is used in association with both apoproteins, but these are photoisomerized quite differently. In the familiar, type 2 rhodopsins, 11-*cis* retinal is transformed to all *trans* upon absorbing light, whereas in type 1 rhodopsins, all *trans* retinal is transformed to 13-*cis* when absorbing light.

Taken together, the remarkable convergence of type 1 and 2 rhodopsins suggests that in the course of evolution, an opsin apoprotein associated with retinal has been discovered and exploited twice. Clearly, when the seven transmembrane protein is appropriately solvated with retinal, it is useful for transforming the energy of photons into more useful forms. This also suggests that progenitors of the type 1 opsins may have existed in earliest evolution before the divergence of archaea, eubacteria, and eukaryotes. This means that the light-driven ion transport mechanism for deriving energy used in association with retinal 1 preceded the evolution of photosynthesis as a means for using the sun's energy (Spudich and Jung, 2005). We can now wonder whether a proto eye-like structure using rhodopsin 1 remains to be found that would allow a comparison of an additional independent solution to extracting information from light.

2.15.4 How Did Eyes Evolve?

Eyes exist in a variety of shapes, sizes, optical designs, and locations on the body, but they all

provide similar information about wavelength and intensity of light to their owners. Different tissues have been recruited to build lenses and retinas across the phyla. In contrast, all eyes share the same mechanism of absorbing photons, i.e., the opsin–chromophore combination has been conserved across phylogeny. Despite new findings yielded by powerful molecular techniques, all evidence still suggests that eyes have a polyphyletic origin, particularly since the discovery that two photodetection systems had evolved prior to the split of the urbilateria into three families. Clearly, eyes as we know them contain homologous molecules responsible for many structural, functional, and even developmental features. Given a growing list of homologous gene sequences among molecules in the eye across vast phylogenetic distances, the challenge is now to discover what makes the eyes of *Drosophila*, squid, and mouse so different. Understanding what makes eyes different may be a bigger challenge than finding what they have in common.

It seems increasingly evident that as eyes evolved, different functional mechanisms have been generated by recruiting existing gene programs. From genome sequencing, we know that there are far fewer genes in organisms than previously thought, so the use and reuse of genes and their products in combinatorial assemblies as reported for known genomes make sense. In the development of eyes, this seems to be the rule not the exception. Specifically, in the evolution of eyes, it seems likely that light sensitivity evolved early in the Cambrian in the form of a proto-opsin molecule in association with the chromophore, retinal. This molecular combination, sensitive to light, became associated with the genes *pax6* (Sheng *et al.*, 1997), and possibly *eya* (based on its phosphatase activity (Li *et al.*, 2003)). One can imagine that this combination was recruited and worked well in early evolved eyespots and other light-sensing organs. It would not be surprising, for example, to find these genetic players in the recently described eye without a nervous system (Nordström *et al.*, 2003). As different eye types evolved over time, there was probably repeated recruitment of particular gene groups, not unlike improvisational groups of actors, interacting to produce candidates for selection. The evolutionary fiddling through which various combinations or routines were tried could have led to numerous parallel evolutionary paths for eyes as we now envisage.

From this, two different mechanisms for transmitting the photic information to surrounding cells were selected for, one in ciliary and one in rhabdomeric photoreceptors. These two systems are likely present in all organisms, as described above for worms and mice. The big surprise is that both of these transduction systems persisted, with each selected as the primary visual system for a major branch of animals. So the answer to the question of whether eyes evolved from a single prototypical eye (monophyletic), or whether they evolved repeatedly (polyphyletic), appears to be that quite evidently eyes arose at least twice and probably many times. And, as described above, given the vast number of organisms using rhodopsin 1, we should not be surprised if additional eyes appear in the biological world in the future.

2.16 The Evolution of Ultraviolet Vision in Vertebrates

S Yokoyama and T Tada, Emory University, Atlanta, GA, USA

Glossary

in vitro assay	Visual pigments are constructed by expressing opsins in cultured COS 1 cells, regenerated with 11-*cis*-retinal, and purified by immunoaffinity chromatography. Ultraviolet–visible spectrophotography was used to determine the wavelength of maximum absorption of the resulting visual pigments.
λ_{max}	Wavelength of maximal absorption of a visual pigment.
SWS1 pigments	Short wavelength-sensitive type 1 pigment group; one of the five evolutionarily distinct groups of visual pigments found in the retina that contain UV and violet pigments.
UV pigments	Visual pigments with λ_{max} values of ~360 nm.
violet pigments	Visual pigments with λ_{max} values of ~390–440 nm.
visual pigments	Photo-sensitive molecules, each of which consists of a transmembrane protein, opsin, and the chromophore, either 11-*cis*-retinal or 11-*cis*-3,4-dehydroretinal.

2.16.1 UV Vision and Violet Vision

We receive a broad spectral irradiance from the sun. Most organisms have developed vision systems to utilize energies in the narrow spectral range between 400 and 700 nm (Yokoyama, 2000). By the early 1930s, it was already well recognized that the behavior of a variety of insects was strongly influenced by their ultraviolet (UV) vision, detecting the wavelengths at ~360 nm (Jacobs, 1992). In contrast, a serious survey of UV vision in vertebrates did not start until the late 1980s. Through behavioral analyses, vertebrate species such as swordtail (*Xiphophorus nigrensis*), rainbow trout (*Oncorhynchus mykiss*), anolis species (*Anolis krugi*, *A. cristatellus*, *A. pulchellus*, *A. gundlachi*, *A. evermanni*, *A. cooki*, and *A. cristatellus*), zebra finch (*Taeniopygia guttata*), starling (*Sturnus vulgaris*), blue tits (*Parus caeruleus*), kestrels (*Falco tinnunculus*), hummingbirds (*Archilochus alexandri*, *Lampornis clemenciae*, and *Eugenes fulgens*), cuckoo (*Cuculus solitarius*), and bat (*Glossophaga soricina*) have been shown to use UV vision for foraging, mating, and communication. From these studies and the characterization of UV pigments (see below), it became clear that many fish, amphibian, reptilian, and avian species, as well as some mammalian species, use UV vision (Bennett *et al*., 1996, 1997; Browman and Hawryshyn, 1994; Burkhardt, 1982, 1989; Cherry and Bennett, 2001; Church *et al*., 1998; Cummings *et al*., 2003; Fleishman *et al*., 1993; Goldsmith, 1980; Hunt *et al*., 1999; Koyanagi *et al*., 2004; Leal and Fleishman, 2002; Ma *et al*., 2001; Viitala *et al*., 1995; Winter *et al*., 2003).

UV vision and violet (or blue) vision are mediated by UV- and violet- (or blue-) sensitive visual pigments, which absorb light maximally (λ_{max}) at ~360 and 390–440 nm, respectively (Jacobs, 1992). The UV and violet pigments belong to an evolutionarily distinct short wavelength-sensitive type 1 (SWS1) pigment group (Yokoyama, 2000). The evolution of UV and violet vision in various vertebrates can be studied in two steps; we first examine how UV and violet pigments diverged from each other and then relate the evolution of SWS1 pigments to the ecological and behavioral characteristics of organisms. These analyses will reveal why and how these organisms have acquired, or abandoned, their UV vision.

2.16.2 Visual Pigments

Visual pigments represent a group of G-protein-coupled receptors that are responsible for the

capture of photons and the initiation of visual excitation. The crystal structure of the bovine rhodopsin demonstrates the existence of seven transmembrane (TM) motifs (Palczewski *et al*., 2000; Okada *et al*., 2002). Each visual pigment consists of an apoprotein, opsin, covalently linked to a conjugated polyene chromophore, either 11-*cis*-retinal or 11-*cis*-3,4-dehydroretinal. A visual pigment with 11-*cis*-3,4-dehydroretinal often absorbs longer wavelengths than a pigment with 11-*cis*-retinal. For UV pigments, however, the two chromophores do not cause any appreciable difference in the λ_{max} value. Therefore, the variable λ_{max} values among different SWS1 pigments are generated by the direct and indirect interactions between the chromophore and various types of opsins, which is referred to as the spectral tuning of visual pigments. In many amphibians, birds, and reptiles, the light sensitivity of visual pigments can also be modified by a colored oil droplet in a photoreceptor cell. In this respect, UV pigments are unique because if there are associated oil droplets, they are transparent and UV pigments mediate UV vision (Yokoyama, 2000).

To determine the λ_{max} values of visual pigments experimentally, we first isolated total RNAs from a retina or whole eye. From this RNA, the opsin cDNAs were obtained by reverse transcription-polymerase chain reaction using appropriate primers, subcloned into an expression vector, and expressed in cultured cells. These opsins were incubated with 11-*cis*-retinal in the dark, and the absorption spectra of the resulting visual pigments were recorded using a spectrophotometer. Using this *in vitro* assay, we could also evaluate the effects of virtually any single and multiple amino acid changes on the λ_{max} shift (Yokoyama *et al*., 1998; Wilkie *et al*., 1998).

2.16.3 Ancestral SWS1 Pigments

The evolutionary changes in UV and violet vision in vertebrates can be studied directly by constructing SWS1 pigments of ancestral organisms and tracing their λ_{max} values through time. For this purpose, the phylogenetic tree of 10 representative SWS1 pigments from a wide range of vertebrate species was examined. Based on this tree topology, the amino acid sequences of visual pigments at all ancestral nodes have been inferred by using statistical methods. Then, eight ancestral pigments were engineered by introducing all necessary amino acid changes into selected contemporary pigments and their λ_{max} values were determined using an *in vitro* assay (Shi and Yokoyama, 2003).

The results show that most SWS1 pigments had λ_{max} values of ~360 nm and were UV sensitive; i.e., most ancestral vertebrate species used UV vision (e.g., Figure 1). In Figure 1, the evolutionary changes in the avian lineage are of particular interest; the avian ancestor developed violet vision, but some descendants regained UV vision. Thus, with the exception of the avian UV pigments, contemporary UV pigments inherited their UV sensitivities directly from the vertebrate ancestor, whereas violet pigments evolved from the ancestral UV pigment (Shi and Yokoyama, 2003).

2.16.4 Molecular Bases of UV and Violet Vision

The genetic analyses of UV vision began only in approximately the year 2000 by comparing the SWS1 pigments of zebra finch, budgerigar, canary, chicken, pigeon, and a wide range of other vertebrates. The comparative analysis of their amino acid sequences revealed that the cysteine at site 90 (C90) is restricted to the UV pigments of zebra finch, budgerigar, and canary, whereas all other SWS1 pigments, including those of pigeon and chicken, have serine at the same position (S90). Thus, it was hypothesized that this amino acid difference was responsible for the differentiation of UV and violet pigments. Such hypotheses can be tested rather easily by introducing specific amino acid changes in the visual pigments and evaluating whether or not the mutant pigments cause any λ_{max} shifts. Indeed, the amino acid change S90C in the pigeon pigment shifted the λ_{max} value from 393 to 359 nm and in the chicken pigment it shifted the value from 415 to 369 nm, decreasing the λ_{max} values by some 35–45 nm, whereas the reverse change, C90S, in the zebra finch and budgerigar pigments increased the λ_{max} values by ~40 nm (Yokoyama *et al*., 2000; Wilkie *et al*., 2000; Dukkipati *et al*., 2001; Table 1). Therefore, UV and violet sensitivities in birds can be interchanged by one amino acid change.

When these analyses were extended to mammalian pigments, things suddenly became complicated. For example, the mouse and human pigments have λ_{max} values of 359 and 414 nm, respectively (Figure 1). By constructing a series of chimeric pigments between these two pigments, the cause of their λ_{max} difference was traced to 19 amino acid sites in TM helices I–III. Surprisingly, none of these mutations caused any λ_{max} shift individually (Yokoyama and Shi, 2000; Shi *et al*., 2001; Table 1). By constructing additional chimeric pigments and conducting extensive mutagenesis analyses, it was shown that seven amino acid replacements, F46T/F49L/T52F/F86L/T93P/A114G/S118T, were responsible for the functional differentiation of

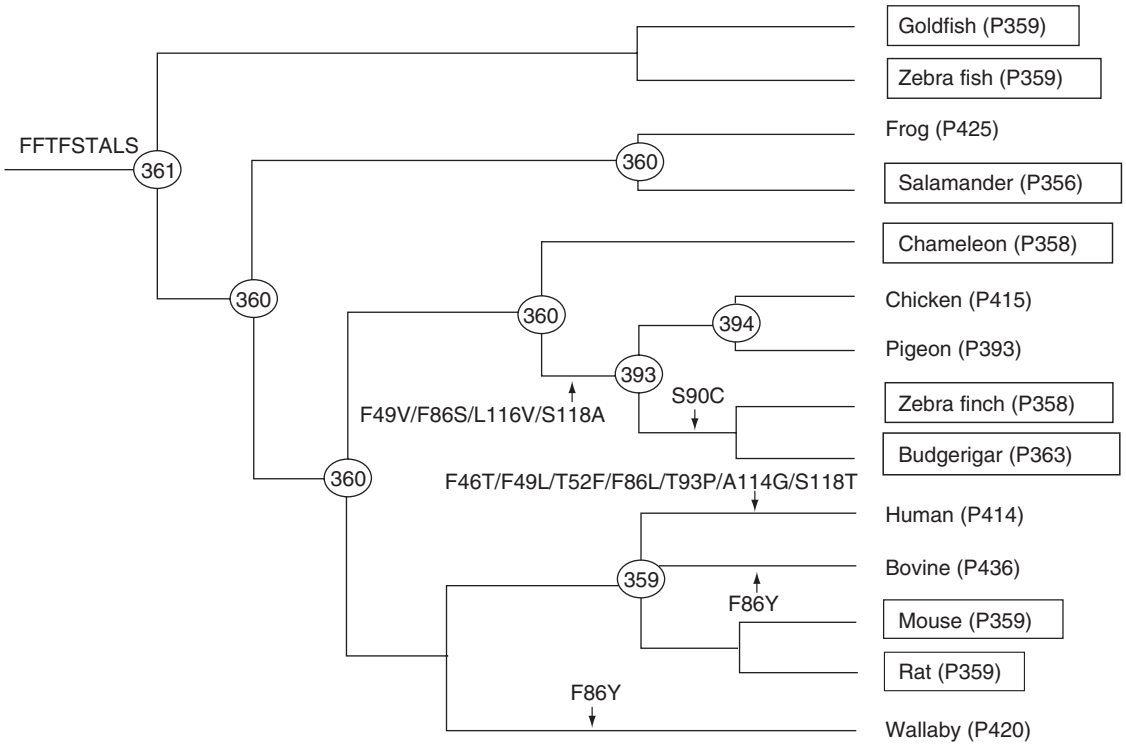

Figure 1 An evolutionary tree of 14 SWS1 pigments. FFTFSTALS are the amino acids at the critical sites 46, 49, 52, 86, 90, 93, 114, 116, and 118 for the ancestral pigment. The UV pigments are shown in rectangles. The numbers after P refer to λ_{max} values. Species considered are goldfish (*Carassius auratus*), zebra fish (*Danio rerio*), frog (*Xenopus laevis*), salamander (*Ambystoma triginum*), chameleon (*Anolis carolinensis*), chicken (*Gallus gallus*), pigeon (*Columba livia*), zebra finch (*Taeniopygia guttata*), budgerigar (*Melopsittacus undulates*), human (*Homo sapiens*), bovine (*Bos taurus*), mouse (*Mus musculus*), rat (*Rattus norvegicus*), and wallaby (*Macropus eugenii*).

Table 1 Representative amino acid changes that cause significant spectral shifts

Pigment	*Mutation*	λ_{max} *shift* (nm)
Mouse (P359)	F46T, F49L, T52F, F86L, T93P, A114G, S118T	0
Mouse (P359)	F46T/F49L/T52F/F86L/T93P/A114G/S118T	+51
Mouse (P359)	F86S	+17
Mouse (P359)	F86Y	+66
Wallaby (P420)	Y86F	−59
Mouse (P359)	S90C	−3
Pigeon (P393)	S90C	−34

Zebra fish (P359)	C90S	+38

the human pigment (Yokoyama and Shi, 2000; Shi *et al*., 2001; Table 1). For the bovine SWS1 pigment, however, F86Y explained the majority of its λ_{max} shift (Fasick *et al*., 2002; see also Cowing *et al*., 2002; Table 1). Curiously, the wallaby pigment also achieved its present λ_{max} by F86Y independently; the reverse mutation, Y86F, in the wallaby pigment decreased the λ_{max} value by 59nm (Figure 2). The effect of F86Y exhibited a stark contrast to that of F86L at the same site in the human pigment (Table 1). Despite the significant contribution of F86Y in the differentiation of these violet pigments, the total λ_{max} shift must be explained by complex amino acid interactions at several critical sites. The details of such interactions remain to be elucidated.

We have seen that S90C decreased the λ_{max} values of the avian pigment by ~50nm. However, when the same mutation was introduced into the mouse pigment, the mutant pigment caused virtually no λ_{max} shift (Shi *et al*., 2001; Table 1), again showing strong synergistic interactions among different amino acids in the UV pigment. To understand such interactions at the critical sites, extensive mutagenesis experiments were required. Furthermore, additional mutagenesis analyses of the engineered ancestral avian pigments showed that L116V is

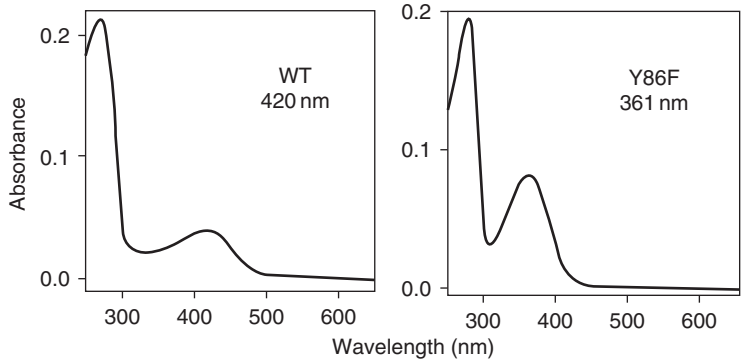

Figure 2 Absorption spectra of wallaby SWS1 pigment. WT, wild-type pigment; Y86F, mutant pigment with Y86F.

also involved in the evolution of the violet pigment. Thus far, therefore, a total of nine amino acid sites have been shown to be involved in the spectral tuning of SWS1 pigments. As more SWS1 pigments are analyzed, this number is expected to increase.

2.16.5 Ecology and Physiology of UV Vision

UV vision is useful for organisms only when they are exposed to UV light. Thus, knowing that many diurnal animals, living under ample UV exposure, abandoned their UV vision, it is not immediately clear why nocturnal rodents, such as mouse and rat, have maintained their UV vision. For example, voles (*Microtus agrestis*) mark their runaways with urine and feces, which can be detected more easily under UV light than under visible light (Viitala *et al.*, 1995). To understand the maintenance of UV vision in these rodents, it seems important to realize that a high proportion of light available at approximately dawn and dusk is of short wavelength. Therefore, these and other nocturnal animals that are active at these times of the day can perform a wide range of tasks better using UV vision. Similarly, the restoration of UV vision in some avian species might have occurred because they migrate and use UV vision as the 'sun compass'.

Since many species have switched from UV vision to violet vision, the advantage of organisms having UV vision must be limited to certain circumstances. We can identify at least three major reasons why so many species abandoned UV vision. First, UV vision is not useful when organisms do not receive UV light in their habitats. Under such conditions, organisms will probably abandon UV vision. For example, living at the depth of 200 m, coelacanths (*Latimeria chalumnae*) receive only a narrow range of light at approximately 480 nm (Yokoyama, 2000). In this species, both UV pigments and longer wavelength-sensitive pigments have become nonfunctional. It should also be noted that many fish species have UV vision, but this does not mean that they use UV vision throughout their entire lives. In fact, UV vision in many fishes declines as they grow older. This change in gene expression makes sense because young fishes may live in shallow water and feed on plankton, where UV light is essential, whereas adults live in deeper water and do not receive much UV light (e.g., Browman and Hawryshyn, 1994). Second, UV light can damage retinal tissues. To prevent such injuries, yellow pigments in the lenses or corneas in human and many other species are devised to absorb most UV light before it reaches the retina. This makes UV vision unattainable even with UV pigments. Third, by abandoning UV vision, organisms can improve their visual acuity and subtle contrast detection (see The Evolution of Vertebrate Eyes).

2.16.6 Perspectives

The use of UV vision is strongly associated with the photic environment and behavior of organisms. Compared with organisms with violet vision, those with UV vision have the advantage of recognizing certain UV-reflecting objects much more quickly, but they lack acuity in viewing their surroundings and are also subjected to a higher chance of developing retinal damage from UV light. Thus, whether organisms use UV vision or violet vision depends on the relative importance of these and other conflicting characteristics associated with UV vision (see The Evolution of Vertebrate Eyes). To appreciate the evolution of UV vision, it is necessary to study the roles of the UV and violet pigments of many species in different photic environments. The molecular basis of the functional differentiation of SWS1 pigments is unique, showing strong synergistic interactions among critical amino acids (Babu *et al.*, 2001; Dukkipati *et al.*, 2002; Fasick *et al.*, 2002; Kusnetzow *et al.*, 2001, 2004; Shi *et al.*, 2001). The nature of these interactions is still poorly understood and remains to be elucidated.

2.17 Evolution of Vertebrate Olfactory Subsystems

H L Eisthen and G Polese, Michigan State University, East Lansing, MI, USA

Glossary

olfactory system	The olfactory system in any animal is the primary sensory system that responds to chemical stimuli emanating from a distant source.
pheromone	A chemical cue that, when released by an individual, elicits specific behavioral or physiological responses from conspecifics.
terminal nerve	The most anterior cranial nerve in vertebrates. The terminal nerve releases compounds into the nasal epithelia, modulating activity of sensory receptor cells.
vomeronasal system	A discrete olfactory subsystem present in tetrapods that differs morphologically from the olfactory system. Its function is unclear.

2.17.1 Introduction

2.17.1.1 What is Olfaction?

The term olfaction is commonly applied to chemosensory systems that detect chemicals emanating from a distant source. Other chemosensory systems generally require physical contact with the source for detection, and this sensory modality is called gustation. The vertebrate olfactory and gustatory systems are anatomically distinct; the latter is discussed in a separate article (Evolution of Taste). Fibers of the trigeminal nerve also detect chemical stimuli, as dochemosensors in the respiratory, circulatory, and digestive systems that detect gasses, ions, and nutrients. In general, these chemosensory systems consist of isolated sensory cells that project to the spinal cord or hindbrain. These systems will not be discussed here.

In this article, we will consider three interrelated olfactory subsystems: the main olfactory system, or olfactory system proper; the vomeronasal system; and the terminal nerve. The main olfactory system comprises receptor neurons located in a specialized sensory epithelium in the nasal cavity, as well as the central projections of these neurons. The receptor cells of the olfactory epithelium develop from the nasal placode, and the ingrowing fibers of the developing sensory neurons are involved in development of the olfactory bulb at the rostral pole of the prospective telencephalon (Gong and Shipley, 1995; Graziadei and Monti-Graziadei, 1992; Long *et al.*, 2003).

The vomeronasal system, or accessory olfactory system, also develops from the nasal placode, and is present as a discrete sensory system only in tetrapods (see The Evolution of the Vomeronasal System). The vomeronasal epithelium is sequestered in the vomeronasal organ, also known as Jacobson's organ (Figure 1). The sensory epithelium contains some what different cell types than does the main olfactory epithelium, and the vomeronasal receptor neurons terminate in microvilli, whereas olfactory receptor neurons can terminate in cilia or microvilli or both. In some vertebrates,

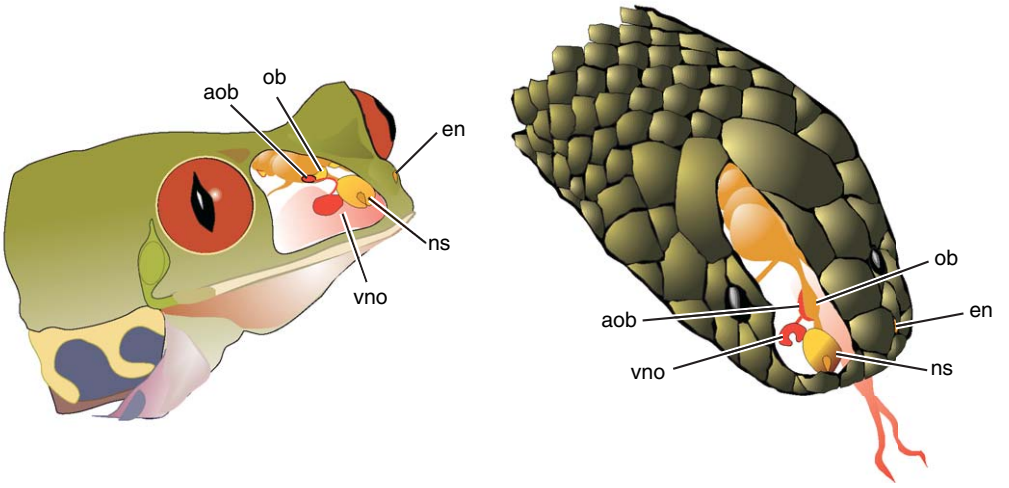

Figure 1 Illustration of the locations of the olfactory epithelium, inside the nasal sac (ns), and of the vomeronasal organ (vno) in a frog and a snake. The nasal sac opens to an external nostril (en) on the dorsal surface of the snout, whereas the vomeronasal organ opens to the nasal sac in frogs and oral cavity in snakes. The axons of the olfactory receptor neurons project to the olfactory bulb (ob), and those of the vomeronasal receptor neurons project to the accessory olfactory bulb (aob).

the axons of the vomeronasal receptor neurons form a separate cranial nerve, the vomeronasal nerve, but in others these axons run alongside the olfactory nerve and the two cannot be distinguished using conventional light microscopy. Vomeronasal receptor cell axons project to the accessory olfactory bulb, a structure that is histologically distinct from the main olfactory bulb (Figure 1). The secondary projections of the olfactory and accessory olfactory bulbs differ. The molecular, physiological, and anatomical differences between the vomeronasal and olfactory system suggest that the two subsystems serve different behavioral functions, but the nature of this difference is unclear. Although the vomeronasal system is often presumed to be specialized for detecting pheromones, it responds to a variety of odorants with differing behavioral significance in all groups of tetrapods, and this presumption is unwarranted (see The Evolution of the Vomeronasal System; Baxi *et al.*, 2006; Halpern and Martínez-Marcos, 2003; Restrepo *et al.*, 2004; Shepherd, 2006). A different hypothesis posits that the vomeronasal system is specialized for detecting nonvolatile molecules. Although better supported than the pheromone hypothesis, this hypothesis is still problematic (Baxi *et al.*, 2006).

Throughout this article, we will refer to the nasal chemosensory system present in all vertebrates as the 'olfactory system' rather than the 'main olfactory system'. Similarly, although it is common to use the term 'main olfactory bulb' to refer to the primary target of the olfactory receptor cells in animals that possess a separate vomeronasal system, we will refer to this structure simply as the 'olfactory bulb' to facilitate comparisons across vertebrates.

The terminal nerve, or nervus terminalis, is the most anterior of the cranial nerves. It extends between the nasal cavity and basal forebrain, and, because of its anatomy, has been thought to serve sensory function (e.g., Demski and Northcutt, 1983; Rossi *et al.*, 1972). Nevertheless, recordings from the terminal nerve have failed to detect sensory activity (Bullock and Northcutt, 1984; White and Meredith, 1995), and the terminal nerve is now thought to function in modulating activity in the olfactory epithelium (reviewed in Oka, 1992; Wirsig-Wiechmann *et al.*, 2002a). The terminal nerve usually contains a ganglion, the location of which varies across groups of vertebrates. The neurites extending outward from these bipolar neurons sometimes comprise a separate nerve, but the fibers of the terminal nerve can also run within the olfactory or vomeronasal nerve, as illustrated in Figure 2. The cells and fibers of the terminal nerve contain neuromodulatory compounds, including gonadotropin releasing hormone (GnRH) and acetylcholine (reviewed in Wirsig-Wiechmann *et al.*, 2002a). The nerve can also be immunohistochemically labeled with antisera directed against neuropeptide Y (NPY) and the molluscan cardioexcitatory neuropeptide FMRFamide, but the two antisera may cross-react with a single peptide (Chiba, 2000). We include the terminal nerve in this article not only because of its role as a centrifugal portion of the olfactory system, but also because the primary neurons of the terminal nerve develop from the

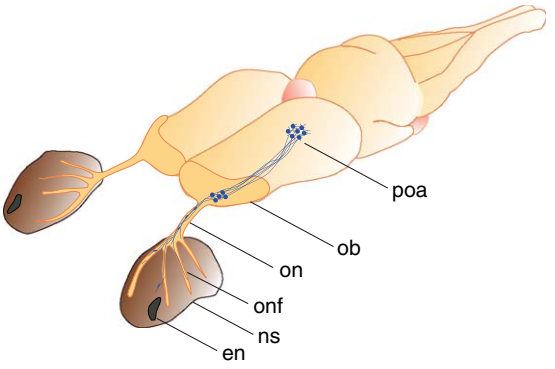

Figure 2 Location of the terminal nerve around the nasal cavities and in the brain of a salamander. Anterior is down and to the left. The fibers of the terminal nerve extend between the preoptic area and nasal cavities, wrapping around the outside of the olfactory epithelium (lower left). en, external nostril; ns, nasal sac; ob, olfactory bulb; onf, olfactory nerve fascicles; on, olfactory nerve; poa, preoptic area.

nasal placode (Schwanzel-Fukuda and Pfaff, 1989), as do the olfactory and vomeronasal receptor neurons.

2.17.1.2 Components of the Vertebrate Olfactory System

Elements of the olfactory system have been described from an evolutionary or comparative perspective in several reviews (Ache and Young, 2005; Eisthen, 1992, 1997, 2002; Hildebrand and Shepherd, 1997; Nieuwenhuys, 1967). Here, we will describe the general features of the olfactory system in nonmammalian vertebrates, illustrated in Figure 3, to provide a context for understanding the changes that have occurred over the course of vertebrate evolution, as well as variations that occur within specific lineages. In the sections that follow, we will survey the structure and function of the olfactory system in each class of vertebrates, noting features that are new, unusual, or taxon-specific. We will not describe the results of neurobiological studies designed to investigate general features of olfactory system function in vertebrates unless the results have interesting implications for understanding olfaction in the group under investigation. At the end of the article, we will discuss innovations and variations, and their possible functional implications.

In all vertebrates, the olfactory epithelium is sequestered inside the nasal cavity. Because adaptation occurs fairly quickly, the odorant-containing medium must be kept moving over the surface of the sensory epithelium. A variety of mechanisms are employed to achieve this end, including nasal cavities that allow water or air to flow through when the animal is locomoting or breathing, specialized pumping mechanisms, and nonsensory cells with motile cilia that create constant movement. Within the nasal cavity, the pseudostratified sensory epithelium contains three basic cell types (Figure 3b): olfactory receptor cells; sustentacular cells, a class of supporting cells; and basal cells, the progenitor cells that give rise to new receptor and sustentacular cells throughout life. The olfactory receptor cells are bipolar neurons with a dendrite that terminates in cilia or microvilli or both. The membrane-bound odorant receptors are localized to these processes, which are therefore presumed to be the site of transduction (Menco, 1997). The odorant receptors are part of the large superfamily of G-protein-coupled receptors (GPCRs) that have seven membrane-spanning domains (reviewed in Gaillard *et al.*, 2004; Mombaerts, 2004). The large family of odorant receptor genes has been suggested to contain two fundamentally different classes that differ in the size of the third extracellular loop (Freitag *et al.*, 1995, 1998), although others have suggested that a larger number of groupings better describes the evolutionary history of the gene family (Niimura and Nei, 2005). As depicted schematically in Figure 3c, the odorant receptor is coupled to an olfactory-specific G-protein ($G\alpha_{olf}$), with alpha subunits that are expressed in few other tissues; when stimulated, the G-protein activates type III adenylyl cyclase (Nakamura, 2000; Ronnett and Moon, 2002). The details of olfactory transduction are well understood for only a small number of vertebrate species, and involve myriad mechanisms (Firestein, 2001; Schild and Restrepo, 1998). One interesting feature of olfactory transduction is that it often involves several steps, in which ions entering through one channel gate another (Eisthen, 2002).

Even before odorants contact receptors, they interact with other molecules in the nasal cavity. The dendrites of the receptor neurons protrude into a specialized mucus produced by a combination of glands and secretory cells, including goblet and sustentacular cells as well as Bowman's glands. This mucus contains a variety of compounds, including mucopolysaccharides, peptides, and amines (Getchell and Getchell, 1992; Getchell *et al.*, 1993; Zancanaro *et al.*, 1997). In some vertebrates, it also contains specialized odorant binding proteins, soluble lipocalins produced in the lateral nasal glands. The role of odorant binding proteins in olfactory processing is unresolved (Pelosi, 2001; Tegoni *et al.*, 2000).

At the opposite pole of the olfactory receptor neuron, the unmyelinated axon projects to the

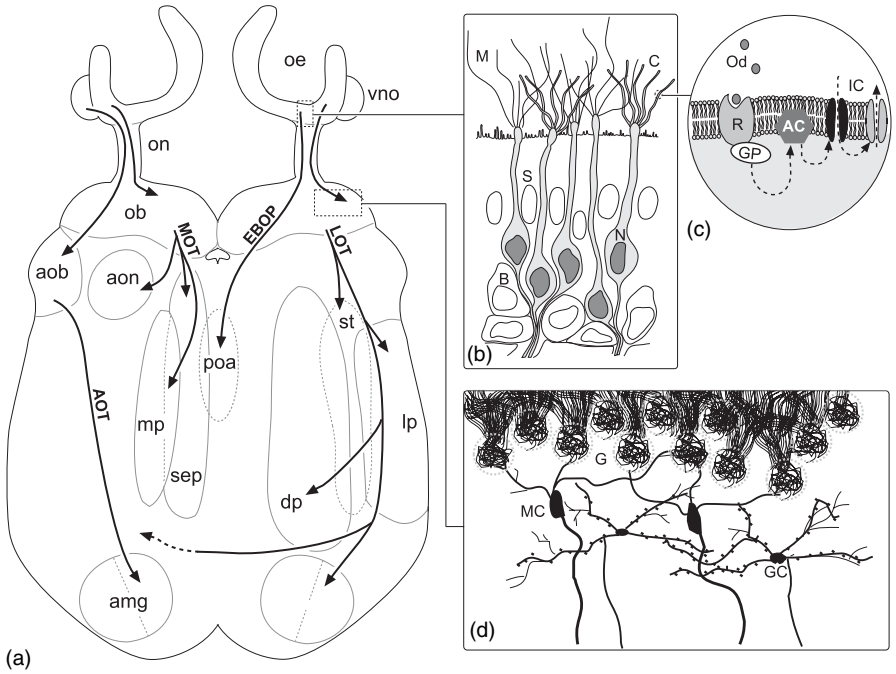

Figure 3 Diagram illustrating the basic elements of the olfactory system in nonmammalian vertebrates. a, Schematic dorsal view of the forebrain and nasal sensory epithelia of a generalized nonmammalian vertebrate. The olfactory epithelium (oe) and vomeronasal organ (vno) lie rostral to the brain, and the axons of the receptor neurons project through the olfactory nerves (on) to the olfactory bulb (ob) and accessory olfactory bulb (aob), respectively. In general, four tracts project centrally. The accessory olfactory tract (AOT) projects from the accessory olfactory bulb to the amygdala (amg). The medial olfactory tract (MOT) projects to the anterior olfactory nucleus (aon), septum (sep), and medial pallium (mp). The extrabulbar olfactory pathway (EBOP) contains axons of primary olfactory receptor neurons that bypass the olfactory bulbs, projecting directly to the preoptic area (poa). The lateral olfactory tract (LOT) projects bilaterally to the striatum (st), lateral pallium (lp), dorsal pallium (dp), and the amygdala. b, The olfactory sensory epithelium consists of three types of cells: receptor neurons (N), sustentacular cells (S), and basal cells (B). The receptor neurons in vertebrates terminate in either cilia (C) or microvilli (M). c, Transduction occurs on ciliary or microvillar membranes. The receptor protein (R) has seven membrane-spanning regions and is coupled to a G-protein (GP). Odorant (Od) binding activates adenylyl cyclase (AC), gating an ion channel (IC). Often, ions entering through this channel gate another ion channel. d, Organization of the olfactory bulb. The axons of olfactory receptor neurons enter glomeruli (G), where they interact with dendrites from mitral cells (MC), the large output neurons of the olfactory bulb. Granule cells (GC) are also present in a deeper layer of the olfactory bulb.

olfactory bulb in the rostral telencephalon. In the olfactory bulb, each unbranching axon forms synapses with many other cells in tangles of fibers known as glomeruli, which are characteristic of olfactory systems in a variety of animals (Eisthen, 2002). The olfactory bulb has a laminar organization. In many vertebrates these layers are not clearly differentiated, but in almost all the layers form concentric rings around the ventricular region in the center of the olfactory bulb. The outermost layer consists of the axons of the olfactory receptor cells, which course over the surface of the bulb before terminating in a single glomerulus in the subjacent layer (Figure 3d). This glomerular layer may contain periglomerular interneurons. Below this, an external plexiform layer is sometimes present, overlying a layer containing the cell bodies of the mitral cells, the output cells of the olfactory bulb. The mitre-shaped cell body that gives these cells their name is only obvious in tetrapods, leading to some confusion concerning the number of classes of output cells in nontetrapods. Mitral cells are large, and generally possess several dendrites that project into different glomeruli. Within a glomerulus, each mitral cell dendrite arborizes extensively, making large numbers of synapses with the axons of the olfactory receptor neurons. The granule cell layer lies between the mitral cell layer and the layer of ependymal cells surrounding the ventricle. The mitral and granule cell layers may be separated by an internal plexiform layer. In some vertebrates, the granule cell layer contains two classes of cells: the granule and stellate cells. Both types of cells generally have axons. Stellate cells possess multiple dendrites that arborize in the glomeruli. In contrast, the granule cells have an oval-shaped soma, and the dendrites interact with neurites of other cells below the glomerular layer or outside glomeruli. In some animals, granule cell dendrites bear spiny processes, whereas those of stellate cells do not. In the

following discussion, we will use these definitions in describing cell types present in diverse animals, regardless of the labels used by the authors of the papers cited.

The fibers projecting centrally from the olfactory bulb consist of the axons of mitral cells. In some groups of vertebrates, axons of other classes of cells, such as the granule and stellate cells, may contribute to these tracts. In most vertebrates, two tracts extend from the olfactory bulb (Figure 3a). The medial tract generally projects to ipsilateral ventral forebrain areas such as the septum and, in tetrapods, to the anterior olfactory nucleus and medial pallium/hippocampus. The lateral olfactory tract projects bilaterally to lateral and dorsolateral pallial areas and to the amygdala, and ipsilaterally to the striatum. Thus, unlike other sensory systems, olfactory projections to the cortex are not routed through the thalamus, contributing to Edinger's (1904) famous hypothesis that the telencephalon was originally an olfactory structure that was invaded by other sensory systems over the course of vertebrate evolution. In addition to the fiber tracts that arise from output cells of the olfactory bulbs, many vertebrates possess a small extrabulbar olfactory pathway that consists of axons of primary olfactory receptor neurons that bypass the olfactory bulb and project directly to the preoptic area (Hofmann and Meyer, 1989; Szabo *et al.*, 1991). Because of their similar projections, many older papers appear to confound the terminal nerve and extrabulbar olfactory pathway (Eisthen and Northcutt, 1996). In the following discussion, we will refer the projection that arises from olfactory receptor neurons as the extrabulbar olfactory pathway, regardless of the name the authors ascribed to it.

The olfactory system does not seem to contain simple maps or even one-to-one functional relationships. Olfactory receptor neurons tend to be broadly tuned, and a given cell will respond to many different odorants, sometimes in different ways; similarly, a given odorant can evoke different responses from different receptor neurons (e.g., Dionne, 1992; Dionne and Dubin, 1994). In mammals, olfactory receptor neurons expressing the same receptor genes project to the same glomeruli, which are located in relatively stable positions within the olfactory bulb (Mombaerts *et al.*, 1996; Schaefer *et al.*, 2001). The neurons that project to a given glomerulus tend to respond to the same sets of odorant stimuli (e.g., Bozza and Kauer, 1998), but a given odorant can activate many glomeruli across the olfactory bulb (e.g., Wachowiak *et al.*, 2002). The effect of changing odorant concentration on spread of activation among glomeruli is unclear, probably in part due to differences in recording methods, odorants used, and species examined in different studies (e.g., Wachowiak and Cohen, 2003; Wachowiak *et al.*, 2002). Nevertheless, the olfactory bulb does not appear to contain a simple map in which an odorant can be identified by the location of the glomeruli that are stimulated; instead, temporal features of the response also play an important role in odorant recognition (e.g., Friedrich and Laurent, 2001; Laurent, 2002).

The vomeronasal epithelium contains the same basic cell types found in the main olfactory epithelium, but lacks Bowman's glands (Parsons, 1967). Vomeronasal receptor neurons express GPCR genes, but the two families of GPCRs found in the vomeronasal organ do not share strong sequence similarity with those expressed in the olfactory epithelium (Dulac and Axel, 1995; Herrada and Dulac, 1997; Matsunami and Buck, 1997; Ryba and Tirindelli, 1997). Transduction in vomeronasal receptor neurons seems to involve different G-proteins, second messengers, and ion channels than in olfactory receptor neurons, although only a handful of species have been examined to date (reviewed in Halpern and Martínez-Marcos, 2003). The axons of vomeronasal receptor neurons project to the accessory olfactory bulb, caudal to the olfactory bulb. In general, the accessory olfactory bulb contains only mitral, granule, and periglomerular cells, and the layers are less distinct than are those in the olfactory bulb (reviewed in Lohman and Lammers, 1967; Nieuwenhuys, 1967). The accessory olfactory tract projects from the accessory olfactory bulb primarily to portions of the amygdala that differ from those receiving olfactory input via the lateral olfactory tract.

Although there are theoretical reasons for envisioning that the receptors in a chemosensory system should differ in their breadth of tuning (Hildebrand and Shepherd, 1997), it is not clear that vertebrates possess any narrowly tuned receptor neurons. To illustrate this point, we will briefly discuss two examples: ciliated versus microvillar olfactory receptor neurons in teleost fishes, and olfactory versus vomeronasal receptor neurons in mammals. Researchers studying teleost fishes have used electro-olfactogram (EOG) recordings to examine odorant responses in patches of epithelium that are dominated by one receptor cell type. The results indicate that ciliated cells respond to bile acids, which can serve as pheromones in fishes, and that microvillar cells respond to amino acids (salmonids; Thommesen, 1983); or that ciliated cells respond to

amino acids, and that bile acids, steroids, and prostaglandin pheromones are preferentially detected by microvillar cells (goldfish; Zippel *et al.*, 1997). A similar study with channel catfish indicated that both ciliated and microvillar cells respond well to both amino acids and bile acids (Erickson and Caprio, 1984), but a later study in the same species using pharmacological agents to disrupt signaling in different cell types demonstrated that ciliated olfactory receptor neurons respond to bile acids and amino acids, and that microvillar receptor neurons respond to nucleotides and amino acids (Hansen *et al.*, 2003). Whole-cell recordings from olfactory receptor neurons in rainbow trout indicate that microvillar neurons respond selectively to amino acids, and that ciliated neurons respond more broadly to amino acids, a steroid, and conspecific urine (Sato and Suzuki, 2001). Agmatine labeling suggests that a greater proportion of microvillar than ciliated olfactory receptor neurons respond to amino acids in zebra fish (Lipschitz and Michel, 2002). Thus, the relationship between cell morphology and odorant responses is unclear, and may be species-specific. To consider a different comparison for a moment, researchers often assume that vomeronasal receptor neurons in tetrapods are much more narrowly tuned than are olfactory receptor neurons. Because of this bias, few studies have investigated the breadth of tuning of vomeronasal receptor neurons (Baxi *et al.*, 2006). Nevertheless, a few studies that have examined the issue conclude that vomeronasal receptor neurons respond to a broad array of chemicals, both naturally occurring and artificial (e.g., Sam *et al.*, 2001; Tucker, 1971).

The olfactory system, broadly defined, plays an important role in the behavior of most vertebrates. Olfactory cues may be involved in orientation and homing, habitat selection, territoriality, species recognition, kin recognition, individual recognition, parent–offspring interactions, mate choice, courtship and mating behavior, predator avoidance, foraging, and food choice. A thorough review of the behavioral functions of the olfactory system in each class of vertebrates is far beyond the scope of this article. Instead, for each group, we will provide a brief overview in which we illustrate the behavioral significance of olfactory input.

2.17.2 Evolutionary Changes in the Vertebrate Olfactory System

2.17.2.1 Chordates and Basal Craniates

Animals in many phyla possess a sensory system for detecting chemicals at a distance, and these sensory systems are generally labeled 'olfactory'. Nevertheless, there is no evidence that the vertebrate olfactory system is homologous with those present in other phyla; instead, it appears that similar features have evolved independently several times for use in sensing odorants (Eisthen, 2002). The nearest relatives to vertebrates are the urochordates (ascidians or tunicates), cephalochordates (lancelets), and hagfishes, which are considered craniates but not vertebrates. Ascidian larvae possess unpaired anterior sense organs, including a photosensitive system and a balance sensor, but no candidate homologue of the vertebrate olfactory system (Lacalli, 2001; Nieuwenhuys, 2002). Thus, the vertebrate olfactory system may not have arisen from a system shared with the common ancestor with urochordates.

Lancelets may or may not possess an olfactory system that is homologous with that of vertebrates. Lancelets respond to various classes of sensory stimuli, including chemical cues (Parker, 1908). They lack a discrete olfactory organ, but a class of potentially chemosensory cells that occurs in the rostral epithelium has been described (Lacalli and Hou, 1999). A GPCR gene that bears some sequence similarity to vertebrate olfactory receptor genes is expressed in bipolar rostral sensory cells in *Branchiostoma belcheri* (Satoh, 2005). Given that these cells bear axons, they appear to be one of the classes of type I sensory cells described by Lacalli and Hou (1999), who argued on morphological grounds that these cells are likely mechanosensory. In addition, the sequence was not subjected to rigorous phylogenetic analysis nor compared with those of many other GPCRs. Given that the use of GPCRs in chemosensory receptor cells appears to be a trait that has evolved several times independently (Eisthen, 2002), it is difficult to accept this observation as strong support for the presence of a vertebrate-like olfactory system in lancelets.

The lancelet *Branchiostoma floridae* possesses paired anterior nerves that, based on consideration of their external topography, have been suggested to be homologues of the vertebrate olfactory nerves (Lacalli, 2002). Although the author interprets the central target of these nerves as a possible homologue of the telencephalon, this region can also be interpreted as the equivalent of the vertebrate mesencephalon or rostral rhombencephalon; if so, these fibers are probably not homologues of the olfactory nerves (Northcutt, 2005). If Northcutt and Gans's 'new head' hypothesis is correct, then many rostral structures are evolutionarily new in craniates; among these structures are the ectodermal

placodes, including the nasal placode, and portions of the forebrain, including the olfactory system (Gans and Northcutt, 1983; Northcutt, 2005; Northcutt and Gans, 1983).

The condition in hagfishes should be instructive, as features shared by hagfish and vertebrates may have been present in earliest vertebrates. Hagfish are scavengers as well as opportunistic predators (Shelton, 1978). They respond vigorously to odorants from dead fish, and can use chemical cues to find carrion (Greene, 1925; Tamburri and Barry, 1999). In addition to their olfactory system, hagfish possess Schreiner organs, unusual chemosensory organs that are distributed across the body surface (Braun, 1995; see Evolution of Taste). The relative contributions of the olfactory and Schreiner organ system to behavior have not been determined, but odorants such as L-amino acids, GABA, and hydroxyproline evoke strong physiological responses from the olfactory epithelium (Døving and Holmberg, 1974).

Hagfish possess a single midline olfactory organ, with the sensory epithelium folded across a radial array of lamellae (e.g., Døving and Holmberg, 1974). The olfactory epithelium of the Atlantic hagfish *Myxine glutinosa* contains both ciliated and microvillar receptor neurons. Instead of the 9+2 microtubule arrangement that is typical of many cilia, including those on vertebrate olfactory receptor neurons, the cilia have a 9+0 arrangement (Theisen, 1973).

In *Myxine glutinosa* and *Eptatretus burgeri*, the olfactory bulb contains mitral, stellate, and granule cells, but the layers are indistinct, with somata of each cell type occurring in several different layers (Iwahori *et al.*, 1998; Jansen, 1930; Holmgren, 1919, in Nieuwenhuys, 1967). All three cell types have axons, and the dendrites of the mitral cells extend into several glomeruli. Periglomerular cells do not seem to be present, but all authors describe intraglomerular mitral cells with a single dendrite that arborizes in one glomerulus, and an axon that presumably exits the olfactory bulb (Holmgren, 1919; Iwahori *et al.*, 1998; Jansen, 1930).

Projections of the olfactory bulb have been investigated in the Pacific hagfish, *Eptatretus stouti* (Wicht and Northcutt, 1993). A short fiber tract projects from the medial olfactory bulb to the ipsilateral septum and through a dorsal commissure to the contralateral olfactory bulb. Fibers extend from the lateral olfactory bulb project bilaterally and widely in the forebrain, with targets that include the striatum, all layers of the pallium, and the central prosencephalic nucleus. An additional group of fibers extends from the ventrolateral portion of the olfactory bulb to terminate diffusely along a path extending into the diencephalon, including the hypothalamus and dorsal thalamus (Wicht and Northcutt, 1993). Given its location and targets, this tract may constitute the extrabulbar olfactory pathway. Immunocytochemical data suggest that hagfish lack a terminal nerve (Braun *et al.*, 1995; Crim *et al.*, 1979b; Jirikowski *et al.*, 1984; Wicht and Northcutt, 1992).

2.17.2.2 Lampreys

Lampreys have a biphasic lifecycle. The ammocoete larvae hatch in streams and rivers, then live buried in sediment for years, filter feeding, before metamorphosing and swimming downstream to live in larger bodies of water. Juvenile lampreys are generally parasitic, attaching to other fish to consume their blood and flesh. When sexually mature, adult lampreys stop feeding and migrate upstream in streams and rivers to spawn, after which they usually die.

In both *Ichthyomyzon fossor* and *Petromyzon marinus*, the complexity and relative size of the nasal cavity increases greatly during metamorphosis from ammocoete to the juvenile form, suggesting that olfaction may be important for free-swimming lampreys than for larvae (Leach, 1951; VanDenbossche *et al.*, 1995, 1997). Metamorphosed *P. marinus* increase activity in response to odorants from trout and fish-derived amines, but not amino acids (Kleerekoper and Mogensen, 1960).

Adult male *P. marinus* migrate and build nests in the spawning area before females arrive. The males emit a unique bile acid that is attractive to females, and to which females are highly sensitive (Li *et al.*, 2002; Siefkes and Li, 2004). Migratory lampreys do not home to particular streams; rather, they appear to simply seek suitable habitat for spawning (Bergstedt and Seelye, 1995). The means by which they do this is wonderful in its simplicity, for adult lampreys are attracted to odorants produced by healthy ammocoetes. Specifically, adults of several species have been shown to be extremely sensitive to bile acids produced by ammocoetes (Fine *et al.*, 2004; Li and Sorensen, 1997; Li *et al.*, 1995), as well as to two unique steroids that are released by ammocoetes (Sorensen *et al.*, 2005b). Adults are highly sensitive to these compounds, and both types of cues are released in sufficient quantities to attract them (Polkinghorne *et al.*, 2001; Sorensen *et al.*, 2005b). Interestingly, the bile acids are not released by nonfeeding ammocoetes, suggesting that these cues serve as a good indicator of habitat suitability (Polkinghorne *et al.*, 2001).

Lampreys possess a single midline nostril and nasal cavity that develops from a single nasal placode. Although earlier authors suggested that monorhiny is the ancestral condition for vertebrates, the presence of paired olfactory organs during development in *P. marinus* suggests that monorhiny may be a derived condition (Kleerekoper and Van Erkel, 1960). If so, it arose independently in hagfishes and lampreys. Within the nasal cavity, the olfactory epithelia of *Lampetra fluviatilis* and *P. marinus* contain only ciliated receptor cells, indicating that lampreys lack microvillar receptor neurons (Bronshtein and Ivanov, 1965; Thornhill, 1967; VanDenbossche *et al.*, 1995).

In contrast with the numerous and large families of odorant receptor genes described in other groups of vertebrates, lampreys (*L. fluviatilis*) appear to possess only a few small families of odorant receptors (Berghard and Dryer, 1998; Freitag *et al.*, 1999). Of course, it is difficult to rule out the possibility that lampreys possess many additional receptor genes that have not yet been identified. Although the sequences possess features that are characteristic of vertebrate odorant receptor genes, including a large third extracellular loop (Berghard and Dryer, 1998; Freitag *et al.*, 1999), phylogenetic analysis indicates that the lamprey odorant receptor gene family diverged before the origin of the two main classes of odorant receptor genes present in other vertebrates (Freitag *et al.*, 1999). The odorant receptor genes from lampreys also share strong similarity with histamine receptors, indicating that the odorant receptor genes in lampreys and other vertebrates may have been independently co-opted out of the larger GPCR superfamily (Berghard and Dryer, 1998; Niimura and Nei, 2005). The genes are expressed in the olfactory epithelium of both ammocoetes and adults, suggesting that the quantitative differences in the size of the olfactory system in the two forms do not necessarily indicate qualitative differences in the odorants detected (Berghard and Dryer, 1998).

In *Petromyzon* larvae, the olfactory bulb glomeruli are histochemically heterogeneous and form six distinct territories, suggesting a rough functional specialization (Frontini *et al.*, 2003). Whether this organization is particular to ammocoetes or remains throughout the lifecycle is not known. A single layer of glomeruli encircles the bulb (Heier, 1948; Iwahori *et al.*, 1987). As in hagfish, the layers are indistinct, and the somata of some mitral cells can be found in the glomerular layer. The olfactory bulb of *L. fluviatilis* contains mitral, stellate, and granule cells, all of which have axons that exit the olfactory bulb (Heier, 1948; Nieuwenhuys, 1967). Two classes of mitral cells appear to be present: those with cell bodies in the mitral cell layer, which extend a single dendrite to arborize in one glomerulus; and those with cell bodies in the glomerular layer, which have dendrites that arborize in more than one glomerulus (Heier, 1948; Iwahori *et al.*, 1987; Nieuwenhuys, 1967). The latter class of cells may function more like periglomerular cells than like mitral cells. A more recent description of the olfactory bulb of *L. japonica* suggests that either granule or stellate cells are absent in this species (Iwahori *et al.*, 1987). The cells that Iwahori *et al.* call 'granule' approximate our description of stellate cells, above. These cells lack axons, but possess several dendrites that arborize in glomeruli, often spanning the width of the bulb (Iwahori *et al.*, 1987). It is difficult to reconcile these different descriptions of bulbar organization, particularly for two species of *Lampetra*, but perhaps the discrepancies are due to developmental or methodological differences.

The olfactory bulb gives rise to four major centripetal pathways in silver lampreys, *Ichthyomyzon unicuspis*, illustrated in Figure 4 (Northcutt and Puzdrowski, 1988). A group of fibers that may comprise a homologue of the medial olfactory tract originates from the ventrolateral olfactory bulb and projects to the ipsilateral septum, preoptic area, and possibly to the rostral portion of the striatum (Figure 4a). A lateral olfactory tract projects ipsilaterally throughout the lateral pallium and either to or through the dorsal and medial pallia, as well as to the posterior tuberculum and hypothalamus; some fibers project contralaterally to a dorsal portion of the lateral pallium, septum, striatum, and the posterior tuberculum and hypothalamus (Figure 4b). A third group of fibers extends through the ventromedial olfactory bulb to the striatum and preoptic regions, as well as to the hypothalamus and throughout the posterior tuberculum (Figure 4c; Northcutt and Puzdrowski, 1988). This tract has been interpreted as an extrabulbar olfactory pathway (Eisthen and Northcutt, 1996). Finally, silver lampreys possess an olfactory pathway through a dorsal commissure to the adjacent dorsomedial neuropil, a fibrous region that spans the length of the olfactory bulb, and to glomeruli in the contralateral olfactory bulb (Figure 4d; Northcutt and Puzdrowski, 1988). Fibers projecting to the contralateral olfactory bulb have also been described in *L. fluviatilis* (Heier, 1948) and in hagfish (Wicht and Northcutt, 1992), suggesting that a dorsal commissure carrying secondary olfactory fibers to the contralateral olfactory bulb may have been present in the earliest vertebrates.

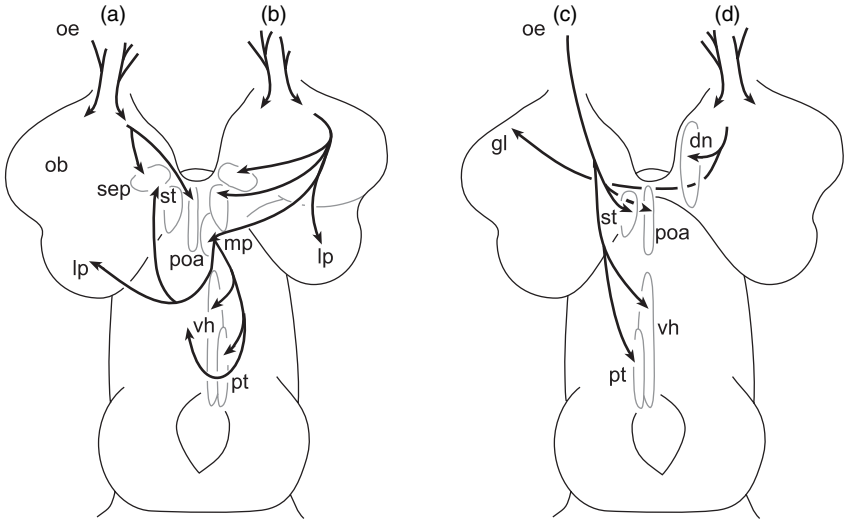

Figure 4 Schematic dorsal view of the forebrain in the silver lamprey (*Ichthyomyzon unicuspis*), illustrating the major olfactory projections. a, Projections of the medial olfactory tract. b, Projections of the lateral olfactory tract. c, Projections of the extrabulbar olfactory pathway. d, Projections through the dorsal commissure to the contralateral olfactory bulb. dn, dorsomedial neuropil; gl, glomerular layer; lp, lateral pallium; mp, medial pallium; ob, olfactory bulb; oe, olfactory epithelium; poa, preoptic area; pt, posterior tubercle; sep, septum; st, striatum; vh, ventral hypothalamus. Based on Northcutt, R. G. and Puzdrowski, R. L. 1988. Projections of the olfactory bulb and nervus terminalis in the silver lamprey. *Brain Behav. Evol.* 32, 96–107.

Heier (1948) first suggested that lampreys lack a terminal nerve, and since that time its presence in lampreys has been questionable. In other vertebrates, the terminal nerve can be labeled with antisera directed against GnRH, NPY, or FMRFamide (Wirsig-Wiechmann *et al.*, 2002a). These antisera fail to label any structures reminiscent of the terminal nerve in larval or adult *I. unicuspis*, *Lampetra japonica*, *L. planeri*, *L. richardsoni*, *Lethenteron japonica*, or *Petromyzon marinus* (Chiba, 1999; Crim *et al.*, 1979b, 1979a; Eisthen and Northcutt, 1996; King *et al.*, 1988; Meyer *et al.*, 1987; Ohtomi *et al.*, 1989; Tobet *et al.*, 1995; Wright *et al.*, 1994). Fibers that project from the nasal sac through olfactory bulb to the ventral forebrain have been labeled with injections of horseradish peroxidase or cobalt lysine into the nasal sac of larval or adult lampreys (*L. planeri*, Meyer *et al.*, 1987; *I. unicuspis*, Northcutt and Puzdrowski, 1988; von Bartheld *et al.*, 1987; von Bartheld and Meyer, 1988). Although this projection was originally interpreted as a terminal nerve, it may instead be the extrabulbar olfactory pathway, which was unknown at the time these studies were conducted (Eisthen and Northcutt, 1996).

2.17.2.3 Cartilaginous Fishes: Sharks, Skates and Rays, and Chimaeras

The class chondrichthyes consists of cartilaginous fishes (sharks, ratfish or chimaeras, and skates and rays) that are widely distributed in the world's oceans. Some species enter freshwater, and a few, like the rays *Paratrygon motoro* and *Himantura signifer*, live exclusively in freshwater (Compagno and Roberts, 1982; Müller and Henle, 1841).

Olfaction plays a major role in the life of cartilaginous fishes. Their olfactory ability is legendary, and olfaction is important for prey detection (Kleerekoper, 1978; Sheldon, 1911). Nevertheless, the popular notion that sharks can detect even a small amount of blood diluted in the ocean over many miles is an exaggeration. Electrophysiological experiments demonstrate that sharks are able to detect components of human and bovine blood, as well as other stimuli like amino acids and crab or squid extract, but responses to blood are no stronger than the responses to other stimuli (Hodgson and Mathewson, 1978; Kajiura *et al.*, 2004b; Silver, 1979; Zeiske *et al.*, 1986).

The role of olfaction in prey localization in sharks has been the subject of much study. Some species approach prey from downstream by swimming into the current (rheotaxis). Tests in the open sea indicate that lemon sharks (*Negaprion brevirostris*) use rheotaxis to find odorants from prey, but will continue to swim against the current past the stimulus source, suggesting that additional sensory cues are involved in short-range localization (Hodgson and Mathewson, 1971). Other species use a strategy called klinotaxis in which they turn in the direction of the nostril that is more strongly stimulated. Early

naris-occlusion experiments with smooth dogfish (*Mustelus canis*) demonstrated that the animals turn persistently toward the open nostril when activated by an olfactory stimulus (Sheldon, 1911). Subsequent experiments with other sharks and rays indicate that klinotaxis is common in cartilaginous fishes (reviewed in Kleerekoper, 1978).

Prey localization through klinotaxis has been suggested to constitute an important pressure driving evolution of increasing head width in hammerhead sharks (Sphyrnidae). Recent work by Kajiura *et al.* (2004a) demonstrates that the ability to localize odorants increases with increasing head width in sphyrnid sharks, although their olfactory sensitivity does not differ significantly from that of other families of sharks (Kajiura *et al.*, 2004b). In addition to its role in foraging, olfaction has also been implicated in reproductive behavior in sharks (e.g., Bleckmann and Hofmann, 1999; De Martini, 1978; Forlano *et al.*, 2000). Nevertheless, this area of research remains largely unexplored.

The olfactory organ of cartilaginous fishes consists of a chamber inside a cartilaginous capsule. Incurrent and excurrent nostrils on the ventral snout allow water to flow over the olfactory mucosa. The anterior margin of the nasal flap is sufficiently diverse that it was used in species identification until researchers learned that within-species variability is also high (Tester, 1963). In chimaeras, the two olfactory chambers are adjacent, with a cartilaginous septum that separates them down the midline. The incurrent nostrils are located medially above the mouth, and the excurrent nostrils open laterally near the edge of the mouth (Zeiske *et al.*, 1992). In pelagic sharks, water is driven over the olfactory epithelium by swimming movements, as illustrated in Figure 5. In sedentary animals, flow is driven by respiratory movements. Some species, such as spiny dogfish (*Squalus acanthias*) and the small-spotted catshark (*Scyliorhinus canicula*), use specialized valve mechanisms to regulate flow over the olfactory epithelium (Theisen *et al.*, 1986).

Inside the nasal cavity, the olfactory organ consists of a rosette composed of two rows of olfactory lamellae situated on each side of a transverse raphe. In some species, such as Oman sharks (*Iago omanensis*), secondary lamellae greatly increase the surface area of the sensory epithelium (Fishelson and Baranes, 1997). In addition to the usual receptor neurons, supporting cells, and basal cells present in all vertebrates, the olfactory epithelium of some cartilaginous fishes also contains goblet cells (Zeiske *et al.*, 1986). In sharks, the ancestral condition appears to be the presence of only microvillar olfactory receptor neurons (Reese and Brightman, 1970; Theisen *et al.*, 1986; Zeiske *et al.*, 1986, 1987). The spiny dogfish *Squalus acanthias* was originally reported to possess both ciliated and microvillar receptor cells (Bakhtin, 1976, 1977), but a later study concluded that only microvillar receptor neurons are present (Theisen *et al.*, 1986). Similarly, the olfactory epithelium of the ratfish *Chimaera monstrosa* and those of skates and rays contain only microvillar receptor cells (Holl, 1973; Meng and Yin, 1981). Nevertheless, one study with Oman sharks demonstrates the presence of unusual olfactory receptor neurons that resemble the crypt-type olfactory receptor neurons present in ray-finned fishes (Fishelson and Baranes, 1997; see discussion in Hansen and Finger, 2000).

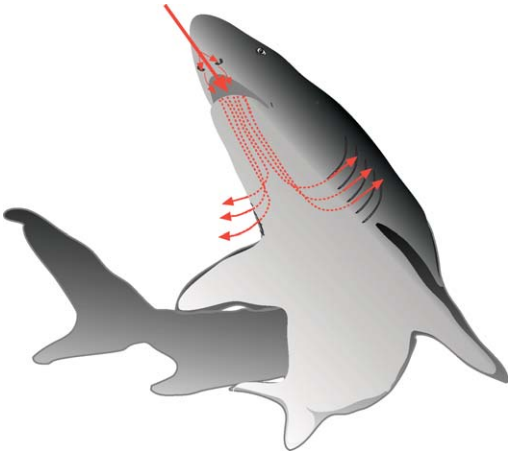

Figure 5 Schematic ventral view of a shark, showing the characteristic nostrils with prominent nasal flap, and the direction of water flow (arrows).

In cartilaginous fishes, the olfactory bulb is adjacent to the olfactory sac, and is connected by short olfactory nerves; thus, the tracts are much longer than the nerves. The length of these tracts varies across species, and in all cases they are formed by mitral cell axons with a characteristic black myelin sheath (Dryer and Graziadei, 1996). The olfactory bulb is somewhat laminated, but no plexiform layers separate the cell layers (Dryer and Graziadei, 1993; Franceschini and Ciani, 1993; Nieuwenhuys, 1967). Periglomerular cells appear to be lacking. Sterzi (1909, in Nieuwenhuys, 1967) described the olfactory bulb of spiny dogfish (*Squalus acanthias*) as containing a clear layer of mitral cells with primary dendrites that arborize in multiple glomeruli as well as secondary dendrites that interact with fibers of other cells outside the glomeruli. Granule cells have both axons and smooth dendrites, and stellate cells also appear to be present; Sterzi referred to the latter as 'triangular cells'. In contrast, a more recent study of sharks

(*Sphyrna tiburo* and *Rhizoprionodon terranovae*) and rays (*Dasyatis sabina*) found two types of mitral cells present, one with a loose dendritic arborization and the other with a more dense one (Dryer and Graziadei, 1993, 1994, 1996). The dendrites of both types arborize in a single glomerulus. Given the irregular laminar borders described by Dryer and Graziadei, it seems possible that their mitral cells with loose dendritic arbors are actually stellate cells.

The central projections of the olfactory bulb have not been examined in detail in cartilaginous fishes. The lateral olfactory tract in sharks and rays projects ipsilaterally to the area retrobulbaris, striatum, lateral pallium, and area superficialis basalis (Ebbesson and Heimer, 1970; Smeets, 1983). The existence of a medial olfactory tract is uncertain, and an earlier description of a widely projecting pathway (Smeets, 1983) has been reinterpreted as an artifact of the degeneration technique used (Northcutt, 1995). An extrabulbar olfactory pathway has not been described in this group (Hofmann and Meyer, 1995).

The terminal nerve was originally discovered in a small shark (*Mustelus asterias*) by Fritsch (1878), who referred to it as a 'supernumerary nerve'. Locy (1905) later described this structure in a variety of sharks and rays, and named it the *nervus terminalis* because the nerve enters the brain through the lamina terminalis. The exact point of entry in the brain varies somewhat among species; for example, in *Squalus acanthias* the terminal nerve enters the telencephalon dorsally (Locy, 1905). In most cartilaginous fishes, the terminal nerve is completely separate from the olfactory nerve, and includes a visible ganglion located medial and external to the nasal cavity. In some species, additional ganglia occur along the nerve (Locy, 1905).

Electron microscopic examination of the terminal nerve in sharks and rays demonstrates that the cells are heterogeneous. Most fibers are unmyelinated, but a few fibers in the proximal part of the nerve are myelinated (Demski and Schwanzel-Fukuda, 1987; White and Meredith, 1987). The ganglion consists largely of unipolar cells, with a few bipolar and multipolar cells present (White and Meredith, 1995; Wu *et al.*, 1992). Cells and fibers of the terminal nerve display GnRH-like immunoreactivity in many species of sharks and rays (Chiba, 2000; Chiba *et al.*, 1991; Demski and Schwanzel-Fukuda, 1987; Stell, 1984; White and Meredith, 1995). Data from two species of sharks (*Sphyrna tiburo* and *Scyliorhinus torazame*) suggest that in cartilaginous fishes, separate populations of terminal nerve neurons contain GnRH and FMRFamide-like compounds (Chiba, 2000; White and Meredith, 1995). Additional FMRFamide immunoreactive fibers have been described within the olfactory nerve in sharks and rays (Wu *et al.*, 1992), but it is not yet clear whether these fibers constitute part of the terminal nerve pathway.

Electrical stimulation of the terminal nerve ganglion in Atlantic stingrays (*Dasyatis sabina*) leads to an increase in GnRH levels in the brain (Moeller and Meredith, 1998), but electrical stimulation of the terminal nerve does not significantly alter activity in the olfactory bulb (Meredith and White, 1987). Recordings from the terminal nerve in sharks and rays have failed to detect sensory activity, although efferent activity from the brain has been recorded (Bullock and Northcutt, 1984; Demski and Schwanzel-Fukuda, 1987; White and Meredith, 1995). Further, activity of terminal nerve ganglion cells can be modulated by application of acetylcholine or norepinephrine, suggesting that centrifugal fibers may regulate activity of these cells (White and Meredith, 1993, 1995). Overall, the available data indicate that the terminal nerve in cartilaginous fishes is not sensory, although it has not yet been demonstrated to serve a modulatory function.

2.17.2.4 Ray-Finned Fishes

Actinopterygii, the ray-finned fishes, is the largest class of vertebrates, comprising nearly 25 000 species. One division of ray-finned fishes, the teleost fishes, contains over 23 000 species (Nelson, 1994). In addition to teleosts, the class Actinopterygii contains paddlefish and sturgeons, gars, bowfins, and bichirs or reed fishes. Ray-finned fishes occupy an enormous diversity of aquatic ecological niches and possess many specialized adaptations. We will describe here the main features of the olfactory system that are shared by the species that have been examined to date.

Olfactory cues are critical for foraging in some species of ray-finned fishes (Atema, 1980; Bateson, 1890), and electrophysiological recordings from goldfish and carp (*Carassius*) reveal a high sensitivity to food-related odorants, with thresholds for amino acids generally in the range of 10^{-6}–10^{-9} M (Goh and Tamura, 1978; Zippel *et al.*, 1993). This sensitivity is greater than that typically measured in other aquatic vertebrates (Hamdani *et al.*, 2001). In addition to locating food by following trails of extremely dilute odorants, many salmonid species return to their natal streams to spawn after spending years developing in oceans, homing in part based on olfactory cues. In anadromous species, the developing fish undergo behavioral, anatomical, and physiological changes necessary to survive the marine environment as they migrate downstream.

During this period, olfactory sensitivity increases, allowing the animals to imprint on odorants that will guide their homing behavior when they are reproductively mature (reviewed in Nevitt and Dittman, 2004).

The complex nature of pheromonal signaling during courtship is understood better in goldfish (*Carassius auratus*) than in any other vertebrate. Vitellogenic females release 17β-estradiol, which attracts males (Kobayashi *et al.*, 2002). As the female approaches ovulation, it begins to release sex steroids. During the 12 h period leading up to ovulation, the ratio of the three released steroids changes, allowing males to assess the female's reproductive state with great temporal precision (Scott and Sorensen, 1994). The steroid that dominates the mixture early in this process inhibits male responses to one of the steroids that dominates later, perhaps as a mechanism to prevent inappropriate responses to a signal that is present in small quantities throughout the ovulatory period (Stacey and Sorensen, 2002). At ovulation, the female begins to release prostaglandins, attracting males, which are extremely sensitive to this mixture (Sorensen *et al.*, 1988). Males also release a pheromone that attracts females, which has been suggested to function in sex recognition during competition for mates (Sorensen *et al.*, 2005a).

The mechanisms underlying olfactory transduction of prostaglandins and sex steroids are substantially similar in goldfish, and differ from those used to transduce amino acid odorants (Sorensen and Sato, 2005). In zebra fish (*Danio rerio*), pheromonal cues stimulate a different region of the olfactory bulb than do other odorants (Friedrich and Korsching, 1998), and processing of these two types of information may be segregated in goldfish as well (Hanson *et al.*, 1998). In addition, in goldfish and its congener the Crucian carp (*C. carassius*), the lateral olfactory tract carries information related to foraging behavior, whereas the medial tract is involved in pheromonal mediation of courtship and spawning behavior (Dulka, 1993; Hamdani *et al.*, 2001; Kyle *et al.*, 1987; Sorensen *et al.*, 1991).

Many teleost pheromones also function as hormones, or are metabolites of hormones, and may be passively released through diffusion from the blood in gills during respiration (e.g., Vermeirssen and Scott, 1996). In contrast to the common conception of pheromones as cues specifically produced as communication signals, such observations have led to the hypothesis that pheromonal communication in fishes originally evolved as a mechanism by which animals could assess the reproductive status of conspecifics through detection of cues that the releaser cannot control (e.g., Sorensen and Scott, 1994). In addition to sex pheromones, teleost fishes appear to produce alarm pheromones, which also raise interesting evolutionary issues. The phenomenon of alarm cues was first described by von Frisch (1938, 1941), who noted that a minnow, *Phoxinus phoxinus*, releases a chemical ('Schreckstoff') when injured; the release of the chemical results in a behavioral alarm response by conspecifics. This phenomenon has since been documented in many teleost species, particularly in Ostariophysi (reviewed in Døving *et al.*, 2005). Nevertheless, because its adaptive value is difficult to understand, some have questioned the very existence of the phenomenon (e.g., Magurran *et al.*, 1996). The problem is that production of alarm substances is energetically costly (Wisenden, 2000), but of questionable benefit to the animal that produces them while being consumed by a predator, even if kin are nearby (Williams, 1992). A resolution to this apparent paradox may be that release of alarm substances may attract secondary predators that will chase or consume the initial predator, allowing the injured individual to escape (Mathis *et al.*, 1995). This hypothesis has received some empirical support (Chivers *et al.*, 1996a; but see Cashner, 2004).

An interesting adaptation in some teleosts is the use of the olfactory system for detecting changes in external salinity; for example, Atlantic salmon (*Salmo salar*) have polyvalent cation-sensing receptors in the olfactory epithelium (Nearing *et al.*, 2002). Other species can compensate for changes in salinity. In sea bream (*Sparus auratus*), a euryhaline marine species, olfactory receptor neurons increase their firing rate to compensate for reduction in extracellular calcium levels (Hubbard *et al.*, 2000). Olfactory responses to odorants are similar in freshwater and seawater in rainbow trout (*Oncorhynchus mykiss*), suggesting that the compensatory mechanism resides within the olfactory epithelium (Shoji *et al.*, 1996).

Ray-finned fishes usually have two pairs of nostrils on the dorsal surface of the snout, with the anterior and posterior nares separated by a strip of skin. Water flows into the anterior (incurrent) nares, passes over the olfactory epithelium in the nasal sac, and then exits through the posterior (excurrent) nares. Water flow can be generated by swimming movements. In teleosts with an accessory nasal sac, opercular movements during respiration alternately compress and expand the accessory nasal sacs, pumping water through the nasal sac (Døving *et al.*, 1977; Nevitt, 1991).

As in other fishes, the olfactory epithelium in ray-finned fishes is organized into a rosette of lamellae

radiating outward from a central raphe. Both the shape and complexity of lamellar organization differs among species (Yamamoto, 1982; Zeiske *et al.*, 1992). The number of lamellae is also variable, increasing during development to a species-typical level, such as the 168 lamellae present in adult undulated moray eels (*Gymnothorax undulatus*) or the 230 lamellae in adult barred snappers (*Hoplopagrus guenteri*) (Fishelson, 1995; Pfeiffer, 1964). Some groups, such as salmonids, have secondary lamellae that greatly increase the size of the epithelial surface (Yamamoto and Ueda, 1977).

As illustrated in Figures 6a and 6c, the olfactory epithelium of teleost fishes contains both ciliated and microvillar receptor cells (extensively reviewed in Eisthen, 1992). Within these two broad categories, many subtypes can be distinguished; these subtypes differ morphologically and project to distinct regions of the olfactory bulb (Morita and Finger, 1998).

Ray-finned fish are the only group of vertebrates in which the olfactory epithelium clearly contains receptor neurons that do not fit into the preceding categories. Hansen *et al.* have described 'crypt' receptor neurons with a dendritic surface that bears apical microvilli as well as a large concave section that is filled with cilia (Figure 6b; Hansen and Zeiske, 1998). Another unusual feature of crypt cells is that they express two types of G-proteins (Hansen *et al.*, 2004). A recent study of the electrophysiological properties of crypt cells in the Pacific jack mackerel (*Trachurus symmetricus*) found that, among the relatively small number of neurons examined, some responded to amino acid odorants, but that none responded to polyamines or bile acids (Schmachtenberg, 2006). The axons of crypt cells terminate in the olfactory bulb, indicating that they are true olfactory receptor neurons (Hansen *et al.*, 2003). Crypt cells are present in the olfactory epithelium of many, but not all, species of teleosts that have been examined to date, and are present in a polypteriform fish, *Polypterus senegalus*, but not in shortnose gars, *Lepisosteus plastostomus* (Hansen and Finger, 2000). Like teleosts, sturgeons, and paddlefish possess ciliated, microvillar, and crypt olfactory receptor neuron (Bakhtin, 1976; Hansen and Finger, 2000; Pyatkina, 1976; Zeiske *et al.*, 2003). Overall, these data suggest that ciliated, microvillar, and crypt-type olfactory receptor neurons are broadly present in ray-finned fishes, but that the distribution of each cell type is somewhat variable.

In addition to these receptor cell types, both 'rod' and 'rodlet' cells have been proposed to function as olfactory receptor neurons in teleosts. Instead, the former are probably unhealthy or degenerating cells (Muller and Marc, 1984; Zeiske and Hansen, 2005), and the latter may be migrating secretory cells, a type of white blood cell, or even parasites (Bielek, 2005).

Both olfactory-type and vomeronasal-type odorant receptor genes are expressed in the olfactory epithelium of teleosts, although the size of the gene families appears to be smaller than in mammals. In channel catfish (*Ictalurus punctatus*) fewer than 100 members of the olfactory receptor gene family have been found (Ngai *et al.*, 1993b, 1993a). In zebra fish, the entire odorant receptor gene repertoire appears to consist of 143 genes, with even smaller numbers found in pufferfish (44 genes in *Takifugu rubripes* and 42 in *Tetraodon nigroviridis*) (Alioto and Ngai, 2005). Members of the V2R gene family have been sequenced from both pufferfish (*Takifugu*

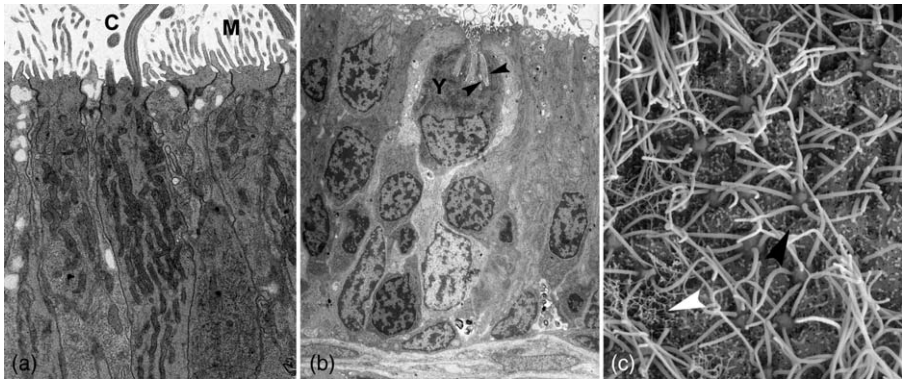

Figure 6 Electron micrographs of the three classes of olfactory receptor neurons in ray-finned fishes. a, Transmission electron micrograph of dendrites of ciliated (C) and microvillar (M) olfactory receptor neurons in goldfish, *Carassius auratus*. b, Transmission electron micrograph of a crypt cell (Y) in zebra fish, *Danio rerio*. Crypt cells are characterized by cilia sunken within the cell (arrowheads), as well as microvilli on the surface. c, Scanning electron micrograph of the dendritic surface of ciliated (black arrowhead) and microvillar (white arrowhead) olfactory receptor neurons in a fathead minnow (*Pimephales promela*). rubripes) and goldfish (Cao *et al.*, 1998; Naito *et al.*, 1998). A single member of the V1R gene family has been sequenced in zebra fish and found to be expressed in the olfactory epithelium, and V1R-like genes with high sequence variability are also present in the genomes of several other teleost species (*Oryzias latipes*, *Danio malabaricus*, *Takifugu rubripes*, and *Tetraodon nigroviridis*) (Pfister and Rodriguez, 2005). In goldfish, the olfactory sensory neurons that bear cilia express olfactory receptor genes and $G\alpha_{olf}$, and those with microvilli express V2R genes and $G\alpha_o$, although some are immunoreactive for $G\alpha_{i\text{-}3}$ or $G\alpha_q$ instead (Hansen *et al.*, 2004). V2Rs are also expressed in crypt cells (Hansen *et al.*, 2004). In zebra fish, ciliated olfactory receptor neurons express the olfactory-type receptor genes also express olfactory marker protein and the cyclic nucleotide-gated channel A2 subunit that is typical of mammalian olfactory receptor neurons; microvillar neurons express V2R-type receptors and the TRPC2 channel that are typical of mammalian vomeronasal receptor neurons (Sato *et al.*, 2005). Taken together, these data suggest that a vomeronasal-type system is present in teleosts, but that the receptor neurons are mixed together with olfactory receptor neurons in the epithelium (discussed in Alioto and Ngai, 2005; Eisthen, 2004).

The organization of the olfactory bulb is moderately laminar. As in other fishes, distinct plexiform layers are lacking, and the cell bodies are somewhat intermingled across layers (Nieuwenhuys, 1967). Periglomerular cells may be lacking. Each mitral cell has from one to five primary dendrites, and each dendrite ends in one or more glomeruli (Nieuwenhuys, 1967). Another class of output cell is called the 'ruffed' cell, due the presence of a ruff of processes at the base of the axon (Kosaka and Hama, 1979a, 1979b). This type of cell may be broadly present in teleosts, but has not been described in other classes of vertebrates (Alonso *et al.*, 1987; Fuller and Byrd, 2005; Kosaka and Hama, 1980). In his study of the olfactory bulb of teleosts, Catois (1902) referred to an additional class of large output cells with an elongated, horizontally oriented cell body as 'fusiform' cells. Morphologically similar cells are apparent in illustrations of the olfactory bulb of sturgeons (Johnston, 1898), and may be present in other ray-finned fishes as well. Granule cells and stellate cells appear to be present in both teleosts and sturgeons (Johnston, 1898; Nieuwenhuys, 1967).

The forebrain of ray-finned fish is everted and contains many discrete cell groups, the homologies of which are difficult to establish. Because connectivity is often used by comparative neuroanatomists as a key criterion for homology, any attempt to compare the similarity of olfactory projection patterns between teleosts and other vertebrates can become circular; therefore, independent evidence, such as histochemical data, is necessary to corroborate hypotheses of homology. The central projections of the olfactory bulb have been examined in some detail in goldfish, *Carassius auratus* (Levine and Dethier, 1985; Northcutt, 2006; von Bartheld *et al.*, 1984). As depicted in Figure 7a, the medial olfactory tract projects bilaterally to the ventral forebrain areas Vs, Vl, and Vv, which may be equivalent to part of the septum (Northcutt and Braford, 1980); to Vd, which may be the equivalent of part of the striatum (Northcutt and Braford, 1980); to Dm, which may be the equivalent of the amygdala (Northcutt, 2006); and to the preoptic area, with some fibers terminating as far caudally as the hypothalamus. The lateral olfactory tract of goldfish projects mainly to dorsolateral pallial areas, as well as projecting bilaterally to the hypothalamic region and nucleus tuberis (Figure 7b). One of the targets of the lateral olfactory tract is Dl, which may be the equivalent of the medial pallium/hippocampus (Northcutt, 2006). Topographically similar projections have been described in a salmonid, *Oncorhyncus mykiss* (Folgueira *et al.*, 2004). The presence of an extra-bulbar olfactory pathway is well-established in teleosts (Anadón *et al.*, 1995; Bazer *et al.*, 1987; Hofmann and Meyer, 1995; Szabo *et al.*, 1991) as well as in *Amia*, sturgeons, and polypteriform species (Hofmann and Meyer, 1995; Huesa *et al.*, 2000). The details of the targets differ among species, but the fibers generally project to ventral forebrain areas (Figure 7c).

Among nonteleost ray-finned fishes, the olfactory projections have been most carefully examined in the bichir, *Polypterus palmas* (Braford and Northcutt, 1974; von Bartheld and Meyer, 1986). In *Polypterus*, a lateral olfactory tract projects largely to the pallial area P3 and may contain some contralaterally projecting fibers, and a medial tract projects ipsilaterally to the pallial areas P1 and bilaterally to ventral telencephalic regions, with some fibers extending as far caudal as the hypothalamus. Similar projections have been described in the sturgeon *Acipenser baeri* (Huesa *et al.*, 2000). Based on its position and its massive input from the olfactory bulb, P1 is generally considered to be the homologue of the lateral pallium (Northcutt and Davis, 1983; von Bartheld and Meyer, 1986), and topological considerations have led to the suggestion that P3 is the homologue of the medial pallium / hippocampus (Braford, 1995; Northcutt and Davis, 1983; von Bartheld and Meyer, 1986). If these interpretations

are correct, then the lateral olfactory tract of the bichir *Polypterus palmas* projects to the homologue of the medial pallium/hippocampus and the medial tract projects to the homologue of the lateral pallium, which is the reverse of the general vertebrate pattern. Perhaps the apparent medial and lateral tracts have been reversed in *Polypterus*, in conjunction with eversion of the telencephalon. If this were the case, then we would expect that the tracts in other ray-finned fish, such as goldfish, would be similarly reversed. Unfortunately, the data from goldfish are ambiguous: the lateral olfactory tract projects to a lateral pallial area, as is typical of the lateral tract, but also to a region that may be the equivalent of the septum, as is typical of the medial olfactory tract in tetrapods. Further, the medial olfactory tract of goldfish projects to ventral areas that are suspected homologues of portions of the septum and medial pallium, which is typical of the medial tract of other vertebrates, but also to a potential homologue of the amygdala, as it is typical of the lateral olfactory tract of other vertebrates. Thus, the relationships between the medial and lateral olfactory tracts in ray-finned fishes and other vertebrates are unresolved, and may bear no one-to-one correspondence with those in other vertebrates.

Unlike in cartilaginous fishes, the terminal nerve in ray-finned fishes projects alongside the primary olfactory fibers in the olfactory nerve, and is not visible externally. The ganglion cells of the terminal nerve develop from the nasal placode (Parhar, 2002; Whitlock and Westerfield, 2000). In most teleosts the terminal nerve ganglion consists of a cluster of cells located between the olfactory bulb and the ventral telencephalon, with fibers that extend centrally to the ventral forebrain and peripherally to both the olfactory epithelium and retina (Brookover and Jackson, 1911; Kim *et al.*, 1995; Oka *et al.*, 1986; Parhar *et al.*, 1996; Rossi *et al.*, 1972; Yamamoto *et al.*, 1995). Because of this association with both the olfactory system and retina, the terminal nerve ganglion in teleosts is also

frequently called the nucleus olfacto-retinalis (Münz *et al.*, 1981). The exact location and the morphology of the ganglion cells varies somewhat among species (reviewed in Münz and Claas, 1987). In some teleosts, such as the dwarf gourami (*Colisa lalia*), the fibers of the terminal nerve project to many disparate regions of the brain (Oka, 1992; Oka and Matsushima, 1993).

The teleost terminal nerve contains at least one form of GnRH (Yamamoto *et al.*, 1995), and many of the cells and fibers of the terminal nerve are GnRH-immunoreactive (e.g., Oka and Ichikawa, 1990; Schreibman *et al.*, 1979). Some of these cells also display immunoreactivity to NPY or to FMRFamide (Ekström *et al.*, 1988; Mathieu *et al.*, 2002; Östholm *et al.*, 1990; Pinelli *et al.*, 2000; Rama Krishna and Subhedar, 1992; Walker and Stell, 1986). The terminal nerve displays similar immunoreactivity in polypteriform fishes (*Polypterus palmas*, *P. senegalus*, and *Calamoichthys calabaricus*), sturgeons (*Acipenser ruthenus*), and gars (*Lepisosteus oculatus*) (Chiba, 1997, 2005; Pinelli *et al.*, 2000; Wright and Demski, 1996). Curiously, GnRH immunoreactivity has also been described in primary olfactory receptor neurons in the carp *Cirrhinus mrigala*; expression is seasonal, and occurs only in adult females (Biju *et al.*, 2003, 2005). Perhaps these cells are evolutionarily derived from terminal nerve cells that did not migrate properly during development, and differentiated into olfactory receptor neurons under the influence of local cues. Nevertheless, given that the neurons involved are not ganglion cells, they do not appear to be part of the terminal nerve system.

The function of the terminal nerve has been the subject of much study in teleosts, particularly in the dwarf gourami, *Colisa lalia*. Electrophysiological experiments demonstrate that the majority of the ganglion cells fire spontaneous action potentials brought about by the interaction of a tetrodotoxin-resistant, persistent sodium current that depolarizes the cell and a persistent potassium current that repolarizes the cell (Abe and Oka, 1999; Oka, 1992, 1996). The firing frequency of the cells is modulated by the same form of GnRH that is present in the nerve, causing an initial decrease in firing rate, followed by a later increase (Abe and Oka, 2000, 2002). This modulation of firing rate by GnRH may function to synchronize firing (Abe and Oka, 2000). Studies such as these were the first to suggest that the terminal nerve may function as a neuromodulatory system, rather than as a sensory system, as originally thought. Additional evidence for this hypothesis comes from studies showing that exposure to odorants does not alter the firing rate of terminal nerve ganglion cells (Fujita *et al.*, 1991), and that lesions of the terminal nerve impair initiation of nest-building behavior, but do not abolish reproduction, in dwarf gouramis (Yamamoto *et al.*, 1997). In addition, compounds present in the terminal nerve alter the activity of retinal ganglion cells, suggesting that the retinopetal branch of the terminal nerve in teleost fishes is neuromodulatory (Huang *et al.*, 2005; Maaswinkel and Li, 2003; Walker and Stell, 1986). Interestingly, a tract-tracing study with dwarf gouramis and tilapia (*Oreochromis niloticus*) indicates that the terminal nerve receives input from olfactory areas in the forebrain, as well as from the nucleus tegmento-olfactorius, a midbrain region that receives input from the reticular formation as well as areas involved in visual and somatosensory processing (Yamamoto and Ito, 2000). Taken together, the results of these studies suggest that the teleost terminal nerve functions to modulate activity in the olfactory epithelium and retina, in part in response to visual and olfactory input.

2.17.2.5 Lobe-Finned Fishes: Lungfishes and Coelacanths

Three genera of lungfishes and one of coelacanths are alive today. Although they are dispersed around the globe, each species lives in a relatively restricted area. Lungfishes live in freshwater in Africa (*Protopterus*), South America (*Lepidosiren*), and Australia (*Neoceratodus*), and the two known extant species coelacanths (*Latimeria*) live in the deep ocean near Madagascar and Indonesia. In addition to their wide geographical separation, the living lobe-finned fishes share only distant common ancestors, and each group possesses unique features that are poorly understood. *Protopterus*, for example, has a reduced olfactory system that is thought to be the result of adaptation to drought and starvation (Derivot, 1984).

In lungfish, the olfactory organ is located ventrally. The incurrent nostril opens on the dorsal surface of the snout, but, unlike other fishes the excurrent nostril opens inside the mouth (Huxley, 1876). This internal naris functionally connects the nasal cavity and respiratory system, causing water to flow across the surface of the olfactory epithelium during breathing (Huxley, 1876). The degree to which the gills and lungs are involved in respiration varies among groups.

As in other fishes, the nasal cavity of lungfishes contains a series of lamellae, on the surface of which lies the olfactory epithelium (Derivot, 1984; Pfeiffer, 1969; Theisen, 1972). The morphology of

olfactory receptor neurons varies among taxa. The African lungfish (*Protopterus annectans*) has both ciliated and microvillar olfactory receptor neurons, but the Australian lungfish (*Neoceratodus forsteri*) lacks ciliated olfactory receptor neurons (Derivot *et al.*, 1979; Theisen, 1972). The microvillar olfactory receptor neurons in these animals are unusual: the cells lack centrioles, and the microvilli contain microtubules, which have not been described in the microvilli on olfactory receptor cells in other vertebrates (Theisen, 1972). Both species lack the crypt-type olfactory receptor neurons characteristic of ray-finned fishes (Hansen and Finger, 2000).

The olfactory bulbs are located adjacent to the telencephalon in *Protoperus* and *Lepidosiren*, but those in *Neoceratodus* are connected to the telencephalon by short, hollow peduncles (Holmgren and van der Horst, 1925). The structure of the olfactory bulb in *Protoperus* has been described by Rudebeck (1945). Clear laminae are present, including plexiform layers, although the internal plexiform layer is not as robust as in *Neoceratodus* (Holmgren and van der Horst, 1925). Periglomerular cells are scattered among the glomeruli, and their morphology is unlike those in other vertebrates: each cell has a single dendrite that arborizes in a glomerulus, and the axons of most periglomerular cells form a distinct tract that passes over the dorsal surface of the olfactory bulb and extends to the anterior pallium (Rudebeck, 1945). The mitral cells have primary dendrites that arborize in the glomerular layer as well as secondary dendrites that extend through the external plexiform layer. The granule cells have spiny dendrites and unmyelinated axons. Stellate cells may not be present.

Although *Protopterus* has been suggested to possess a vomeronasal nerve and accessory olfactory bulb (Schnitzlein and Crosby, 1967), more recent studies have demonstrated that this is not the case (Derivot, 1984; Reiner and Northcutt, 1987). Thus, a discrete vomeronasal system is lacking in lobe-finned fishes.

The central projections of the olfactory system in lungfishes have not been examined using modern methods, but were described by Holmgren and van der Horst (1925) and Rudebeck (1945) based on normal material (reviewed in Nieuwenhuys, 1967). A central olfactory tract consisting of axons from both mitral and granule cells passes through the telencephalic hemisphere in the pallium and subpallium, forming internal and external fiber layers. The internal fiber layer is confined to the pallium whereas the external fiber layer extends to the striatum and the lateral parts of the olfactory tubercle, continuing posteriorly to the stria medullaris. A medial olfactory tract projects to the septum. A contralateral projection is present, but the terminations of decussating fibers has not been determined. The presence of primary olfactory fibers that project bilaterally to the di- and mesencephalon has been detected in *Protopterus* using horseradish peroxidase injections into the nasal cavity (von Bartheld and Meyer, 1988), and a similar projection has been described in *Neoceratodus* (Schober *et al.*, 1994). Thus, lungfishes appear to possess an extrabulbar olfactory pathway.

Initial studies of the anatomy of the terminal nerve in lungfish (*Protopterus annectans*; Pinkus, 1894 and *Neoceratodus forsteri*; Sewertzoff, 1902) described a discrete ganglion close to the olfactory sac with a nerve that runs independent of the olfactory nerve, entering the brain at the level of the preoptic area. Because of this topology, it was named 'nervus praeopticus' (Sewertzoff, 1902). The terminal nerve has now been examined in all three genera of lungfish, and in each it has two roots: an anterior root that runs within the olfactory nerve, consisting of a fascicle of fibers and bipolar cells, and a posterior root that corresponds to Sewertzoff's 'nervus praeopticus' (Holmgren and van der Horst, 1925; Rudebeck, 1945). In *Neoceratodus*, the two roots are joined at the level of the ganglion (Fiorentino *et al.*, 2002; Holmgren and van der Horst, 1925; Rudebeck, 1945). Experimental embryological work with larval *Neoceratodus* demonstrates that the terminal nerve ganglion and both roots originate within the olfactory placode (Fiorentino *et al.*, 2002). In *Neoceratodus* and *Protopterus*, only the posterior root displays GnRH immunoreactivity (Schober *et al.*, 1994), but in *Neoceratodus*, both roots display FMRFamide-like immunoreactivity (Fiorentino *et al.*, 2002). Perhaps the anterior root is homologous with the bundle of FMRFamide-immunoreactive fibers that run within the olfactory nerve of some sharks, described by Wu *et al.* (1992).

Two species of coelacanths are known, and because of the rarity of material the olfactory system has been examined only superficially in *Latimeria chalumnae*. This species has an incurrent nostril on the dorsal side of the snout, and a valvular excurrent nostril that opens just in front of the eye. The olfactory epithelium is radially organized around a central axis where the three dorsal and two ventral lamellar lobes converge (reviewed in Zeiske *et al.*, 1992). Although the fine structure of the olfactory epithelium has not been examined, odorant receptor genes have been sequenced from coelacanths (Freitag *et al.*, 1998). Both classes of receptor genes described by Freitag *et al.* (1995, 1998),

purportedly for odorant detection in air and in water, are present.

A bundle of receptor cell axons emerges from each lobe, and the bundles merge to become a short olfactory nerve that projects into the nearby olfactory bulb (Northcutt and Bemis, 1993). The olfactory bulb is located adjacent to the nasal cavity, and is connected to the telencephalon by a long olfactory peduncle (Nieuwenhuys, 1965). The organization of the olfactory bulb resembles that of other fishes, but clear plexiform layers are lacking (Nieuwenhuys, 1965). The olfactory tracts run through the peduncle. Some tracts terminate within the olfactory bulb (corpus rostrale), whereas the others form a central olfactory tract that becomes thinner as it proceeds caudally through the pallium. The termination sites of these fibers are unclear (Nieuwenhuys, 1965). Neither an extrabulbar olfactory pathway nor a terminal nerve has been identified in *Latimeria* (Northcutt and Bemis, 1993).

2.17.2.6 Tetrapods: Amphibians, Reptiles, and Mammals

The tetrapods include all extant amphibians, reptiles (including birds), and mammals. Early tetrapods were aquatic, and the last common ancestor of tetrapods is now generally accepted to have been fully aquatic (Lebedev and Coates, 1995; Panchen, 1991). Thus, many features in amphibians and amniotes (reptiles and mammals) that represent adaptations to terrestrial life arose independently.

In early tetrapods, the external nostril shifted position to lie low on the snout, and became enlarged (Clack, 2002). In addition, olfaction became coupled to respiration, and remains so in many extant tetrapods (Clack, 2002). The olfactory system of tetrapods is dramatically reorganized compared with that of other vertebrates, as the vomeronasal system now forms a discrete sensory system. The olfactory system of terrestrial tetrapods must contain features that facilitate functioning to detect odorants in air, instead of in water, yet few concrete examples have been identified. For example, the vomeronasal system was once thought to have arisen as an adaptation to terrestrial life (Bertmar, 1981), but this idea has since been discarded (Eisthen, 1992, 1997).

2.17.2.6.1 Amphibians Amphibians comprise three distinct groups: anurans, or frogs and toads; urodeles, or salamanders, including newts; and apodans or caecilians, legless neotropical animals that are relatively poorly understood. Amphibians lack a diaphragm, and as they draw air into and out of the lungs by expanding and contracting the buccopharyngeal cavity, air passes across the sensory epithelium in the nasal cavity (Jørgensen, 2000). Salamanders have been observed to do the same underwater, allowing for olfactory sampling of the aqueous environment (Jørgensen, 2000).

The vomeronasal system is generally present throughout life in amphibians. Among salamanders, the system is present in both aquatic and terrestrial species, including those that never metamorphose. The vomeronasal system has been described in cryptobranchids, sirenids, ambystomatids, salamandrids, amphiumids, and plethodontids, but is absent in members of the proteid family (Anton, 1908, 1911; Eisthen, 2000; Eisthen *et al.*, 1994; Saito *et al.*, 2003; Schmidt and Roth, 1990; Seydel, 1895; Stuelpnagel and Reiss, 2005). Given the phylogenetic relationships among salamander families (Frost *et al.*, 2006), either a vomeronasal-like system arose independently at least four times in salamanders, or it was present in the last common ancestor of extant salamanders and lost in proteids. Clearly, the latter is the most parsimonious hypothesis. The vomeronasal system is also present throughout life in both metamorphosing and direct-developing frogs, including those that are fully aquatic as adults (Cooper, 1943; Hansen *et al.*, 1998; Jermakowicz *et al.*, 2004; Nezlin and Schild, 2000; Reiss and Burd, 1997b, 1997a; Scalia, 1976; Zwilling, 1940), as well as in caecilians (Billo and Wake, 1987; Schmidt and Wake, 1990).

Although anurans are often considered to rely almost entirely on visual and acoustic cues, olfaction plays an important role in the lives of some species (Waldman and Bishop, 2004). For example, tadpoles reduce their activity or seek refuge when exposed to odorants from sympatric predators, injured conspecifics, or predators that have consumed conspecifics (e.g., Laurila *et al.*, 1997; Marquis *et al.*, 2004). Sustained exposure to such cues can also lead to more dramatic changes in morphology and life history (Chivers *et al.*, 2001). Juvenile toads (*Bufo cognatus* and *B. microscaphus*) avoid chemical cues from predatory garter snakes, *Thamnophis* (Flowers and Graves, 1997). Wood frog tadpoles (*Rana sylvatica*) prefer to school with kin (Waldman, 1982, 1984), and kin recognition is mediated by olfactory cues (Waldman, 1985). Some tree frogs that lay eggs in small pools of water in plants provide additional trophic eggs to ensure adequate food supplies for tadpoles. In one such species, *Chirixalus eiffingeri*, tadpoles become highly active when exposed to water conditioned by

adult females (Kam and Yang, 2002), suggesting that tadpoles associate odorants from females with food.

Olfactory cues are also used by adult frogs, particularly in relation to reproductive behavior. Olfaction is involved in orientation to breeding ponds (Ishii *et al.*, 1995), and some frogs prefer their own odorants to those from conspecifics (Waldman and Bishop, 2004). Male magnificent tree frogs, *Litoria splendida,* produce a pheromone that attracts females (Wabnitz *et al.*, 1999). Males of some other *Litoria* species have a rostrally directed spike on the tip of the snout, and the surface epithelium is rich in secretory glands (Menzies, 1993). Although the function of this spike is unknown, its sexually dimorphic distribution and glandular surface suggest that it is involved in chemical communication related to reproduction (Menzies, 1993). Adult *Xenopus* can also use odorant cues in air to find food (Shinn and Dole, 1978).

The role of olfaction in salamander behavior has been examined much more extensively than that in frogs. Like tadpoles, salamanders respond to odorants from injured conspecifics (Chivers *et al.*, 1996b, 1997). Larval tiger salamanders (*Ambystoma tigrinum*) are facultative cannibals, and larvae are more likely to become cannibals in mixed-sibship groups than when surrounded by siblings (Pfennig and Collins, 1993). Cannibals prefer to consume conspecifics that are not kin, but this discrimination disappears when the nostrils are plugged, implicating olfaction in the kin recognition process (Pfennig *et al.*, 1994).

Chemical cues are involved in social behavior in salamanders, and odorants from conspecifics are involved in aggregation (Secondi *et al.*, 2005), individual recognition (Jaeger, 1981; Ovaska, 1988), and marking territories (Chivers *et al.*, 1996b; Jaeger, 1986; Ovaska and Davis, 1992; Simons *et al.*, 1994). Salamanders also use chemical cues to discriminate the sex and reproductive condition of conspecifics (Marco *et al.*, 1998; Park *et al.*, 2004; Verrell, 1985), and the use of pheromones in courtship behavior appears to be widespread. For example, in two species of fire-belly newts (*Cynops*), males produce a species-specific peptide that attracts females (Kikuyama *et al.*, 1995; Yamamoto *et al.*, 2000). In plethodontid salamanders, (*Desmognathus ochrophaeus* and *Plethodon jordani*), male pheromones can increase female receptivity, and in red-spotted newts (*Notophthalmus viridescens*) unreceptive females can become receptive when exposed to chemical cues from a male (Houck and Reagan, 1990; Rogoff, 1927; Rollmann *et al.*, 1999). Interestingly, in red-spotted newts, males are less attracted to odorants from females engaged in courtship behavior than females that are not, even when male odorants are present in both situations (Park and Propper, 2001; Park *et al.*, 2005). Nevertheless, not all pheromone effects in salamanders are mediated by nasal chemosensory systems: in many plethodontid salamanders, males use their teeth to inject pheromones through the skin of females, thereby increasing their receptivity (Houck and Arnold, 2003).

The behavior of caecilians has not been examined in detail. Nevertheless, Himstedt and Simon (1995) showed that plugging the nostrils in *Ichthyophis kohtaoensis* disrupts foraging, suggesting that olfaction plays an important role in this behavior. Chemical cues have been shown to play a role in both aggregation and individual recognition in *Typhlonectes natans* (Warbeck and Parzefall, 2001).

The relative contributions of the olfactory and vomeronasal systems to amphibian behavior are unclear. The vomeronasal organ plays a role in predation in the red-backed salamander, *Plethodon cinereus* (Placyk and Graves, 2002). In both salamanders and caecilians, the relative size of the vomeronasal organ is larger in aquatic or semiaquatic species than in terrestrial species (Dawley, 1998; Schmidt and Wake, 1990), suggesting that aquatic amphibians may rely more on vomeronasal input than do terrestrial species. The vomeronasal organ tends to be larger in male than female plethodontid salamanders, and organ size increases during the breeding season, suggesting a role in reproductive behavior (Dawley, 1998; Dawley *et al.*, 2000). Indeed, in female salamanders (*Cynops pyrrhogaster* and *Plethodon jordani*), male-produced attraction pheromones elicit physiological responses from the vomeronasal organ, but not from the olfactory epithelium (Kikuyama and Toyoda, 1999; Wirsig-Wiechmann *et al.*, 2002b). Nevertheless, EOG recordings demonstrate that both the olfactory and vomeronasal epithelia respond to pheromones in female red-bellied newts (*C. pyrrhogaster*) and male red-spotted newts (*N. viridescens*), and that both epithelia respond more strongly to odorants from the opposite sex than the same sex in male and female axolotls, *Ambystoma mexicanum* (Park *et al.*, 2004; Park and Propper, 2002; Toyoda *et al.*, 1999).

The morphology of the nasal cavity varies considerably among amphibian groups, and often changes during metamorphosis. Many of the anatomical differences associated with life in water and on land have recently been reviewed by Reiss and Eisthen (2006). Perhaps the most dramatic changes occur during metamorphosis in frogs. For example, larval African clawed frogs, *Xenopus laevis*, possess

only one olfactory chamber, which is used for olfaction in water. This chamber contains both ciliated and microvillar receptor neurons (Hansen *et al.*, 1998). During metamorphosis, this chamber is transformed into the principal cavity, which functions for detecting odorants in air, and a new middle chamber develops (reviewed in Hansen *et al.*, 1998; Reiss and Eisthen, 2006). In other frogs, this middle cavity is nonsensory, but in *Xenopus* the middle cavity is lined with sensory epithelium and functions in olfaction underwater (Altner, 1962; Paterson, 1951). Adult *Xenopus* are almost entirely aquatic, and sample odorants in both at the surface and in water. A muscular valve shunts the medium into one chamber or the other (Altner, 1962). In all frogs studied to date, including *Xenopus*, the adult principal cavity contains only ciliated receptor neurons, but the middle cavity of *Xenopus* contains both ciliated and microvillar receptor neurons (Bloom, 1954; Hansen *et al.*, 1998; Mair *et al.*, 1982; Menco, 1980; Oikawa *et al.*, 1998; Reese, 1965; Taniguchi *et al.*, 1996). Because the principal cavity that detects waterborne odorants in larvae is transformed into the principal cavity that detect airborne odorants in adult, a clear correlation emerges: in *Xenopus*, ciliated receptor neurons are used for olfaction in air, and both ciliated and microvillar receptor neurons are used for olfaction in water (Hansen *et al.*, 1998).

In addition to these morphological differences, the sensory epithelia in the principal and middle cavities of *Xenopus* differ at the molecular level. Freitag *et al.* (1995, 1998) divide the odorant receptor genes in frogs into two classes: class I genes, with a large loop in the third extracellular domain and sequences similar to those found in teleosts, and class II genes, similar to those found in mammals. In *Xenopus*, class II genes are expressed in principal cavity and are proposed to function for detecting odorants in air, and class II are expressed in middle cavity and are proposed to function for detecting odorants in water (Freitag *et al.*, 1995; Mezler *et al.*, 2001). The principal cavity also contains a novel form of $G\alpha_s$ that is more closely related to the mammalian $G\alpha_{olf}$ than to other forms of $G\alpha_s$ in frogs, and that induces cAMP formation. In contrast, the epithelium in the middle cavity contains $G\alpha_{o1}$, which stimulates formation of IP_3 (Mezler *et al.*, 2001). Two different homologues of mammalian olfactory marker protein have been found in *Xenopus*, and they are differentially expressed in the two olfactory cavities (Rössler *et al.*, 1998).

Odorant binding proteins, suggested to be a mammalian adaptation, have been found in *Rana pipiens*, *Xenopus laevis*, and *Xenopus tropicalis* (Lee *et al.*, 1987; Millery *et al.*, 2005). As in mammals, odorant binding proteins in frogs appear to be lipocalins. Interestingly, in both species of *Xenopus*, the protein is expressed in principal cavity but not middle cavity (Millery *et al.*, 2005). This observation lends support to the hypothesis that the function of odorant binding proteins is related to physical constraints imposed by the problem of detecting odorants in air; for example, odorant binding proteins may function to transport hydrophobic molecules through aqueous lymph or mucus to the odorant receptors (Bignetti *et al.*, 1987; Vogt, 1987).

The nasal sac of salamanders is essentially a simple oval-shaped tube that is almost completely lined with sensory epithelium, which is one of the reasons why some electrophysiologists favor salamanders as model animals for olfactory research (e.g., Kauer, 2002). The olfactory epithelium of most adult salamanders, even those that are fully terrestrial, appears to contains both ciliated and microvillar receptor cells (Breipohl *et al.*, 1982; Eisthen, 2000; Eisthen *et al.*, 1994; Farbman and Gesteland, 1974; Jones *et al.*, 1994). In contrast, four types of olfactory receptor neurons have been described in *Dicamptodon tenebrosus*: those with cilia, with long microvilli, with unusual short microvilli, and those with both cilia and extremely short (<0.5 μm) microvilli (Stuelpnagel and Reiss, 2005). This finding suggests that other salamanders may possess additional types of neurons that have not been distinguished. Thirty-five putative odorant receptor genes have been sequenced from tiger salamanders (*A. tigrinum*), and all appear to be class II genes (Marchand *et al.*, 2004). Because terrestrial tiger salamanders were used, this result appears to support the Freitag *et al.* (1998) hypothesis that odorant receptors in the class II gene family function to detect odorants in air. Nevertheless, mudpuppies (*Necturus maculosus*), which are members of the fully aquatic proteid family, possess both class I and class II odorant receptor genes (Zhou *et al.*, 1996), casting doubt on the distinction. Olfactory transduction in mudpuppies also involves a novel cyclic nucleotide-dependent chloride current (Delay *et al.*, 1997). The existence of this current in mudpuppies may represent an environmental adaptation to life in freshwater, in which the ionic concentrations of the olfactory mucus may be difficult to regulate. If so, the external calcium required to gate the chloride channels widely involved in olfactory transduction may not reliably be present, leading to the use of a different gating mechanism in these animals (Delay *et al.*, 1997).

Caecilians have paired nares that open into the nasal cavity, which contains the olfactory

epithelium. Adult caecilians also have short tentacles between the naris and eye that are both chemosensory and somatosensory (Badenhorst, 1978). Caecilians are blind, and the tentacles are derived from modified eye structures (Billo and Wake, 1987). The lumen of the tentacle carries secretions from the Harderian gland and communicates with the vomeronasal organ (Badenhorst, 1978; Schmidt and Wake, 1990), an arrangement that allows the animal to detect chemicals with the vomeronasal organ even while burrowing or swimming, when the external nares are closed (Prabha *et al.*, 2000). The nasal cavity of *Typhlonectes compressicaudum* contains two morphologically distinct types of olfactory epithelium. The dorsocaudal portion of the nasal cavity contains an epithelium with only ciliated olfactory receptors neurons, whereas the anterior ventral epithelium contains both ciliated and microvillar receptor neurons (Saint Girons and Zylberberg, 1992). Given their relative locations, these observations suggest that, as in *Xenopus*, caecilians use morphologically different receptor neurons for detecting odorants in water and air (Reiss and Eisthen, 2006).

As in other tetrapods, the vomeronasal receptor neurons in frogs, salamanders, and caecilians terminate in microvilli (Eisthen, 2000; Eisthen *et al.*, 1994; Franceschini *et al.*, 1991; Kolnberger, 1971; Kolnberger and Altner, 1971; Oikawa *et al.*, 1998; Saint Girons and Zylberberg, 1992). In addition to the receptor neurons, sustentacular cells, and basal cells that are generally present in the vertebrate olfactory and vomeronasal epithelia, the vomeronasal epithelium of frogs and salamanders contains large ciliated supporting cells that may function to move fluid across the surface of the epithelium (Eisthen, 1992). The vomeronasal epithelium in *Xenopus* has been shown to express members of the V2R family of vomeronasal receptor genes as well as $G\alpha_o$, the G-protein that is co-expressed with V2Rs in mammals (Hagino-Yamagishi *et al.*, 2004). Although a portion of the principal cavity containing olfactory epithelium was reported to express V2R genes (Hagino-Yamagishi *et al.*, 2004), the authors appear to have misidentified the posterior portion of the vomeronasal organ, which is longer in *Xenopus* than in other frogs (Reiss and Eisthen, 2006).

The olfactory bulbs of amphibians display a moderate degree of lamination, and include both internal and external plexiform layers in all groups (Herrick, 1948; Hoffman, 1963; Nieuwenhuys, 1967). Unlike in any other group of vertebrates, the olfactory bulb of salamanders does not consist of concentric layers; rather, the olfactory nerve enters from the rostrolateral pole, and the layers progress in wide bands from rostral to caudal (e.g., Herrick, 1948). In frogs, the layers are not completely concentric (Scalia *et al.*, 1991b).

In addition, in frogs the two olfactory bulbs are fused across the midline (Hoffman, 1963), a condition also observed in some teleost fishes and bird species (Nieuwenhuys, 1967). Morphologically, the two bulbs in frogs appear to be organized almost as a single unit. For example, the axons of some olfactory receptor neurons cross the midline to project to the contralateral bulb (Hoffman, 1963). The laminae within the bulb are continuous across the midline (Hoffman, 1963; Scalia *et al.*, 1991b), and the processes of both mitral and granule cells cross the midline to interact with elements in the contralateral olfactory bulb (Herrick, 1921; Ramón y Cajal, 1922; Scalia *et al.*, 1991b). Field potential recordings demonstrate that the responses to unilateral stimulation of the olfactory nerve are similar in both olfactory bulbs, suggesting that signal transmission is fully bilateral (Andriason and Leveteau, 1989). However, recordings from mitral cells indicate that unilateral nerve stimulation leads to an inhibition of evoked responses on the contralateral side (Leveteau *et al.*, 1993). The authors of this study suggest that the contralateral inhibition is a mechanism for enhancing contrast between the two sides, facilitating odorant localization. If so, perhaps the joint olfactory bulbs of frogs allow them to better localize odorants than salamanders, which have separate olfactory bulbs.

In both salamanders and frogs, the axons of olfactory receptor neurons have been shown to branch upon entering the outer fiber layer of the bulb and innervate glomeruli that are widely spaced (Herrick, 1924, 1931; Nezlin and Schild, 2005). Periglomerular cells are present, although they do not surround and isolate individual glomeruli to the same extent observed in mammals (Herrick, 1924, 1931; Nezlin *et al.*, 2003; Nezlin and Schild, 2000; Ramón y Cajal, 1890). The primary dendrites of the mitral cells arborize in multiple glomeruli (Herrick, 1948; Hoffman, 1963). Mitral cells also bear secondary dendrites that do not terminate in glomeruli and appear to make synapses with processes of granule cells; these neurites are more prominent in frogs than in salamanders (Scalia *et al.*, 1991b). Herrick (1924) describes 'atypical mitral cells' in the external plexiform layer in tiger salamanders that could be homologous with the tufted cells found in mammals, and Scalia *et al.* (1991b) described candidate tufted cells in a similar location in northern leopard frogs (*Rana pipiens*). Axonless granule cells are present. The dendrites of these cells are spiny in

frogs and tiger salamanders, but smooth in mudpuppies (Herrick, 1924, 1931; Hoffman, 1963; Scalia *et al.*, 1991b). Amphibians appear to lack stellate cells. The structure of the accessory olfactory bulb is similar to that of the olfactory bulb, but plexiform layers are absent and the boundaries of the layers are less distinct (Herrick, 1924, 1931; Nieuwenhuys, 1967). In salamanders, some mitral cells have dendrites that project to glomeruli in both the olfactory and accessory olfactory bulbs (Herrick, 1924).

Central olfactory projections have been examined in several anurans, including *Xenopus* and ranid and hylid frogs, as well as in tiger salamanders, *Ambystoma tigrinum* (Kemali and Guglielmotti, 1987; Kokoros and Northcutt, 1977; Northcutt and Royce, 1975; Roden *et al.*, 2005; Scalia, 1972; Scalia *et al.*, 1991a). As shown in Figure 8a, the medial olfactory tract projects to the postolfactory eminence and medial pallium as well as to the lateral and medial septal nuclei (Northcutt and Royce, 1975; Roden *et al.*, 2005; Scalia *et al.*, 1991a). The lateral olfactory tract projects ipsilaterally to the lateral pallium, dorsal striatum, lateral amygdala, and a region interpreted as either the dorsal pallium or the dorsal portion of the lateral pallium (Figure 8b; Moreno *et al.*, 2005; Northcutt and Royce, 1975; Scalia *et al.*, 1991a). Fibers of the medial and lateral olfactory tracts project in combination to the contralateral amygdala and lateral pallium. The accessory olfactory tract projects bilaterally to the medial amygdala (Figure 8d), the rostral portion of which also receives olfactory input (Kemali and Guglielmotti, 1987; Moreno and Gonzalez, 2003; Moreno *et al.*, 2005; Scalia *et al.*, 1991a). The extrabulbar olfactory pathway of *Xenopus* has been examined in detail by Hofmann and Meyer, who have found that fibers originating in the olfactory epithelium bypass the olfactory bulb and terminate in the ipsilateral preoptic area and bilaterally in the hypothalamus (Figure 8c; Hofmann and Meyer, 1991a, 1991b; 1992). The pathway that Schmidt and colleagues (Schmidt *et al.*, 1988; Schmidt and Wake, 1990) described as the terminal nerve in salamanders and caecilians is more likely the extrabulbar olfactory

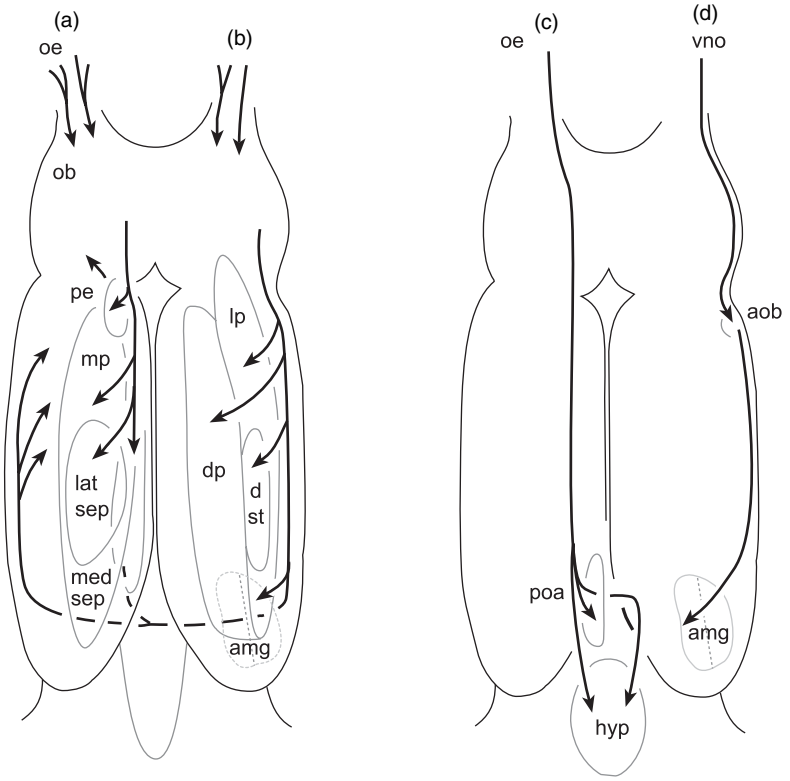

Figure 8 Schematic dorsal view of the forebrain in ranid frogs. a, Projections of the medial olfactory tract. b, Projections of the lateral olfactory tract. c, Projections of the extrabulbar olfactory pathway. d, Projections of the accessory olfactory tract. amg, amygdala; aob, accessory olfactory bulb; dp, dorsal pallium; d st, dorsal striatum; hyp, hypothalamus; lat sep, lateral septum; lp, lateral pallium; med sep, medium septum; mp, medial pallium; ob, olfactory bulb; oe, olfactory epithelium; pe, postolfactory eminence; poa, preoptic area; vno, vomeronasal organ. Based on Kemali and Guglielmotti (1987), Northcutt and Royce (1975), Scalia (1972), and Scalia *et al.* (1991a).

pathway, as it was labeled by injection of tracer into the nasal cavity but not vomeronasal organ, and ganglion cells were not found. If this interpretation is correct, the extrabulbar pathway may be more extensive in both salamanders and caecilians than in frogs (Hofmann and Meyer, 1989).

The terminal nerve of both frogs and salamanders has been examined in detail. The cells and fibers of the nerve are immunoreactive for a variety of compounds, including GnRH (D'Aniello *et al.*, 1994b, 1995; Muske and Moore, 1988; Northcutt and Muske, 1994; Sherwood *et al.*, 1986), NPY (D'Aniello *et al.*, 1996a; Lázár *et al.*, 1993; Mousley *et al.*, 2006; Tuinhof *et al.*, 1994), and FMRFamide (D'Aniello *et al.*, 1996b; Muske and Moore, 1988; Northcutt and Muske, 1994). In tiger salamanders (*Ambystoma tigrinum*), the terminal nerve also displays acetylcholinesterase activity, indicating that acetylcholine is present (Wirsig and Getchell, 1986). In frogs, the terminal nerve may send an additional projection to the retina (Uchiyama *et al.*, 1988; Wirsig-Wiechmann and Basinger, 1988).

In salamanders, terminal nerve-derived peptides alter both the odorant sensitivity and excitability of olfactory receptor neurons. The olfactory epithelium appears to contain GnRH receptors (Wirsig-Wiechmann and Jennes, 1993), and GnRH modulates both odorant responses and the voltage-dependent, tetrodotoxin-sensitive sodium current in olfactory receptor neurons (Eisthen *et al.*, 2000; Park and Eisthen, 2003). Interestingly, olfactory receptor neurons are more responsive to GnRH during the breeding season, suggesting that GnRH may play a role in regulating responses to odorants in a way that promotes reproduction (Eisthen *et al.*, 2000). Other studies show that estrogen affects GnRH concentrations in the terminal nerve in *Xenopus* (Wirsig-Wiechmann and Lee, 1999) and that concentrations are higher in courted female salamanders than in uncourted conspecifics (Propper and Moore, 1991), lending further support to the idea that the GnRH-containing fibers of the terminal nerve play a role in reproductive behavior. In addition, FMRFamide modulates both odorant responses and the sodium current in olfactory receptor neurons (Park *et al.*, 2003). Recently, we have also shown that the terminal nerve in axolotls (*Ambystoma mexicanum*) is NPY-immunoreactive, and that application of synthetic axolotl NPY modulates both odorant responses and the sodium current, but only in hungry animals (Mousley *et al.*, 2006). Taken together, these data suggest that terminal nerve modulates responsivity in the olfactory epithelium in concert with changes in internal state, perhaps to maximize sensitivity to odorants most relevant to the animal's condition.

2.17.2.6.2 Reptiles The class Reptilia includes rhynchocephalians, or tuatara; squamates, a group that consists of lizards, snakes, and amphisbaenians; crocodilians; and turtles. Because birds (Aves) form the sister group to extant crocodilians, we include birds in this group.

2.17.2.6.2.(i) Tuatara The rhynchocephalians, or tuatara, constitute a separate order of reptiles. The two living species of tuatara, *Sphenodon punctatus* and *S. guntheri*, are found only on small islands off the coast of New Zealand. Because of their phylogenetic importance as a sister group to squamate reptiles, their chemosensory systems have been studied to a limited extent.

Unlike snakes and some lizards, tuatara do not have a forked tongue (Schwenk, 1986), and they do not tongue-flick (Walls, 1981). The role of the olfactory and vomeronasal systems in tuatara feeding has been reviewed by Schwenk (2000). Much of the available evidence is anecdotal (e.g., Walls, 1981), but suggests that visual cues predominate and that chemoreception plays a secondary role in foraging and food choice (Schwenk, 2000). Tuatara will bite cotton that has been swabbed on prey, demonstrating that the animals will respond to chemical cues related to feeding (Cooper *et al.*, 2001). The role of chemical signals in social and reproductive behavior is unknown.

The nasal cavity of *Sphenodon* is fairly simple in organization, although some conchae are present. A long choana connects the ventral nasal cavity to the oral cavity. Olfactory epithelium lines the posterior portion of the dorsal half of the nasal cavity, and the vomeronasal sensory epithelium is confined to the dorsal portion of the small vomeronasal organ, which lies along the septum. The vomeronasal organ opens into the ventromedial portion of the nasal cavity, anterior to the choana. Unlike that of snakes and lizards, the vomeronasal organ has no direct connection to the oral cavity. The ultrastructure of the olfactory and vomeronasal epithelia has not been described. The axons of the vomeronasal receptor neurons join the olfactory nerve to project to a small accessory olfactory bulb dorsomedial to the much larger main olfactory bulb (Hoppe, 1934, in Parsons, 1959a; Parsons, 1967). Cairney (1926) described the olfactory projections in normal material without distinguishing among the tracts, deducing that the olfactory bulbs project to the medial pallium, septum, olfactory tubercle, olfactostriatum, lateral pallium (piriform cortex),

anterior nucleus of the amygdala, and a region he called the 'hypopallium posterius'. The nucleus sphericus of squamates has a roughly similar position and appearance, and receives a large projection from the accessory olfactory bulb. The nucleus sphericus has been thought to be present only in squamates (Northcutt, 1978), but without studying projections in tuatara using modern tract-tracing techniques, the uniqueness of this structure cannot be determined.

2.17.2.6.2.(ii) Squamates: Amphisbaenians, lizards, and snakes Squamate reptiles are diverse and widespread, and many species rely heavily on chemosensory input to mediate all aspects of their behavior. In many snakes and lizards the vomeronasal system is behaviorally more important than the olfactory system and, in some species, the neural structures that comprise the vomeronasal system are hypertrophied relative to those of the olfactory system. Although squamates are favored model animals for neurobiologists seeking to understand the structure and function of the vomeronasal system, this endeavor is paradoxically complicated by the dominance of the vomeronasal system: in many squamates, the behavioral relevance of olfactory information is not clear. This broad generalization does not apply to all squamates, however. For example, in geckos the olfactory system appears to be the dominant chemosensory system (Schwenk, 1993b).

The nasal chemosensory systems play a critical role in foraging and feeding in many squamates. For example, pygmy rattlesnakes (*Sistrurus miliarius*), which are sit-and-wait predators, aggregate in areas containing chemical cues from potential prey animals (Roth *et al.*, 1999). Snakes are well-known to follow chemical trails left by prey (Schwenk, 1994), as can some lizards, like Gould's monitor lizards, *Varanus gouldii*, and Gila monsters, *Heloderma suspectum* (Garrett *et al.*, 1996). Rattlesnakes, which strike and release their prey, use chemical cues to follow and identify envenomated animals. These cues derive from the venom itself as well as recognition of the envenomated individual (Chiszar *et al.*, 1999; Furry *et al.*, 1991; Lavin-Murcio and Kardong, 1995). Both snakes and lizards with experimentally impaired vomeronasal systems will attack but not consume prey, and garter snakes (*Thamnophis sirtalis*) with sectioned vomeronasal nerves stop following prey trails and eventually cease eating (Alving and Kardong, 1996; Graves and Halpern, 1990; Halpern *et al.*, 1997; Haverly and Kardong, 1996).

Chemical cues can facilitate predator avoidance. The Texas banded gecko, *Coleonyx brevis*, displays defensive behavior when presented with odorants from a predatory snake; changes in the rate of buccal pulsing in response to these cues suggest that the discrimination is based on input to the olfactory system (Dial and Schwenk, 1996). The ability to discriminate harmful from harmless species based solely on chemical cues has been demonstrated in lizards (Lacertidae, Iguanidae, and Anguidae) and in amphisbaenians, *Blanus cinereus* (Amo *et al.*, 2004; Bealor and Krekorian, 2002; Cabido *et al.*, 2004; Lopez and Martin, 1994, 2001; Van Damme and Quick, 2001). Vomeronasal input is critical to the ability of crotaline snakes to recognize predatory kingsnakes, *Lampropeltis getula* (Miller and Gutzke, 1999). Responsiveness to chemical cues from predators has been shown to increase the probability of surviving an encounter with a predator in garden skinks, *Lampropholis guichenoti* (Downes, 2002).

Chemical cues play a role in discrimination of the sex of conspecifics in amphisbaenians, *Blanus cinereus* (Cooper *et al.*, 1994), in recognition of familiar and unfamiliar conspecifics in lacertid lizards (Aragon *et al.*, 2003; Font and Desfilis, 2002), and in recognition of mates in snow skinks, *Niveoscincus microlepidotus* (Olsson and Shine, 1998). Male skinks (*Eulamprus heatwolei*) use chemosensory cues to assess female receptivity (Head *et al.*, 2005). Mate choice is influenced by chemical cues in snakes (*Thamnophis sirtalis*) and lizards (*Lacerta monticola*) (Lopez *et al.*, 2003; Shine *et al.*, 2003), and female Swedish sand lizards (*Lacerta agilis*) prefer odorants from males that differ from themselves at the MHC class 1 loci (Olsson *et al.*, 2003). Taken together, these observations indicate that squamates can use chemosensory information to discriminate sex, receptivity, quality as a potential mate, genotype, and individual identity of conspecifics. In squamates, pheromonal cues are not always attractants: female brown tree snakes, *Boiga irregularis*, produce a cloacal secretion that decreases courtship intensity and duration in males (Greene and Mason, 2003).

In general, squamates sniff to draw odorants across the olfactory epithelium and use their tongues to physically pick up chemical stimuli that will be deposited in the vomeronasal organ. Geckos, which depend more on olfactory than on vomeronasal input, appear to sniff via oscillations of the throat (Dial and Schwenk, 1996). Garter snakes (*Thamnophis sirtalis*) can detect prey odorants in air, without physical contact with the tongue, using the olfactory system (Halpern *et al.*, 1997).

Olfactory input appears to be important for elevating the rate of tongue-flicking, which then allows the animal to sample with the vomeronasal organ (Halpern *et al.*, 1997; Zuri and Halpern, 2003). Although tongue-flicking is widespread among squamates, not all have forked tongues (Schwenk, 1993a, 1994). Forked tongues have evolved repeatedly among squamates, particularly in groups that forage widely (Schwenk, 1994). This arrangement may be used to enhance two-point comparisons, for example to facilitate trail following by improving edge detection (Schwenk, 1994).

The vomeronasal organ of squamate reptiles opens directly into the oral cavity and has no connection with the nasal cavity, a condition that is different than in any other tetrapod (Schwenk, 1993a). Tongue-flicking brings molecules into the vomeronasal organ (reviewed in Schwenk, 1995; see also Graves and Halpern, 1989; Halpern and Kubie, 1980). Although the tongue tips are essential for vomeronasal sampling, the mechanism by which compounds move from the tongue to the vomeronasal ducts and into the organ is not understood (reviewed in Schwenk, 1994). The sublingual plicae have been suggested to play a key role, perhaps by creating suction within the vomeronasal organ or duct (Young, 1993), but snakes with cauterized plicae are able to find and consume food, and transport of molecules into the vomeronasal organs does not differ between lesioned and control animals (Halpern and Borghjid, 1997). Instead, the heavily vascularized vomeronasal organ may use a pumping mechanism to create suction, similar to a mechanism used by some mammals (Halpern and Martínez-Marcos, 2003).

The squamate nasal cavity has a relatively simple organization, and in most species is essentially an elongated sac, the posterior dorsal portion of which is lined with olfactory epithelium (Parsons, 1959b, 1967). The dorsal wall of the spherical vomeronasal organ is lined with sensory epithelium, and the lumen is made narrow by a ventral protruding structure called the mushroom body. In garter snakes (*Thamnophis sirtalis*), as in other squamates, fluid from Harderian glands flows into vomeronasal organ (Rehorek, 1997; Rehorek *et al.*, 2000a, 2000b). The products of the gland play a critical role in solubilizing a lipophilic pheromone in this species, allowing the pheromone to be detected by vomeronasal receptor neurons (Huang *et al.*, 2006). Animals from which the gland has been removed display impaired courtship behavior and prey capture, demonstrating the essential role of Harderian gland secretions in signal detection in the vomeronasal system in snakes (Mason *et al.*, 2006).

Both cilia and short microvilli are present together on the olfactory receptor cells of the blue-tongued lizard, *Tiliqua scincoides* (Kratzing, 1975), although only ciliated receptor cells were found in a scanning electron microscopic investigation of the olfactory epithelium in the garter snakes *Thamnophis sirtalis* and *T. radix* (Wang and Halpern, 1980b). The morphology of receptor neurons may vary between species, but it also seems possible that short microvilli could have been overlooked or difficult to see in the preparations from snakes. Both lizards and snakes possess only microvillar vomeronasal receptor neurons (Altner and Brachner, 1970; Altner and Müller, 1968; Bannister, 1968; Kratzing, 1975; Takami and Hirosawa, 1990; Wang and Halpern, 1980a, 1980b). The olfactory and vomeronasal receptor genes from squamates have not yet been sequenced. In snakes and lizards, the vomeronasal epithelium expresses $G\alpha_o$ and $G\alpha_{i2}$, which are also found in the vomeronasal epithelium of mammals, but lack $G\alpha_{olf}$, $G\alpha_{11}$, and $G\alpha_q$, which are found in the mammalian olfactory epithelium (Labra *et al.*, 2005; Luo *et al.*, 1994). The vomeronasal epithelium in garter snakes expresses type IV adenylyl cyclase (Liu *et al.*, 1998), as does that of rats (Rössler *et al.*, 2000).

The olfactory bulb of squamates is distinctly laminated, with both external and internal plexiform layers present. In adult lizards (*Podarcis hispanica*), periglomerular cells have a single dendrite, oriented parallel to the bulbar surface (García-Verdugo *et al.*, 1986). Each mitral cell has one primary dendrite that arborizes in a single glomerulus, as well as secondary dendrites that travel through the external plexiform layer. In contrast, in embryonic snakes (*Elaphe quadrivirgata*), the primary dendrites of mitral cells arborize in many glomeruli (Iwahori *et al.*, 1989a). In both animals, the spiny dendrites of the axonless granule cells extend into the plexiform layer, but do not arborize in the glomeruli (García-Verdugo *et al.*, 1986; Iwahori *et al.*, 1989a).

The accessory olfactory bulb lacks the clear laminar organization of the olfactory bulb, and plexiform layers are absent (Iwahori *et al.*, 1989b; Llahi and García-Verdugo, 1989). In *Podarcis*, incoming axons of vomeronasal receptor neurons branch and enter more than one glomerulus, which does not appear to be the case for olfactory receptor cell axons entering the main olfactory bulb (García-Verdugo *et al.*, 1986; Llahi and García-Verdugo, 1989). The dendrites of periglomerular cells arborize in more than glomerulus, as do those of the mitral cells (Iwahori *et al.*, 1989b; Llahi and

García-Verdugo, 1989). Mitral cells also possess secondary dendrites that extend through the external and internal plexiform layers (Iwahori *et al.*, 1989b; Llahi and García-Verdugo, 1989). A class of cells that Llahi and García-Verdugo call 'small mitral cells' have a soma in the outer mitral cell layer or external plexiform layer and a single dendrite that arborizes sparsely in the glomerular layers; these cells might be equivalent to the tufted cells present in the mammalian olfactory bulb (Llahi and García-Verdugo, 1989). The granule cells resemble those in the main olfactory bulb (Iwahori *et al.*, 1989b; Llahi and García-Verdugo, 1989). Stellate cells do not seem to be present in the main or accessory olfactory bulbs in either species.

Among squamates, the central olfactory projections have been described in most detail in garter snakes, *Thamnophis sirtalis* and *T. radix* (Halpern, 1976; Lanuza and Halpern, 1997, 1998). Three central olfactory projections are present in these animals, comprising the lateral, intermediate, and medial olfactory tracts, illustrated in Figure 9. The medial olfactory tract projects ipsilaterally to the anterior olfactory nucleus (Figure 9a). The lateral olfactory tract projects bilaterally to the lateral cortex, as well as to the external and ventral anterior amygdala (Figure 9b). The intermediate olfactory tract projects to the olfactory tubercle and olfactory gray, and joins the lateral olfactory tract in a projection to the contralateral hemisphere (Figure 9c). The accessory olfactory tract, carrying information from the vomeronasal organ, projects to three portions of the amygdala: the nucleus sphericus, medial amygdala, and nucleus of the accessory olfactory tract (Figure 9d). The homology of the nucleus sphericus with regions of the amygdala in other tetrapods is unclear, because it has been suggested to be the only amygdalar target of the accessory olfactory bulb that does not project to the hypothalamus (Bruce and Neary, 1995; Lanuza and Halpern, 1997). This interpretation is complicated by newer data demonstrating a small projection from the nucleus sphericus to the hypothalamus, and a much larger projection to the olfactostriatum (Martínez-Marcos *et al.*, 1999, 2002). The latter structure in turn projects to the lateral posterior hypothalamic nucleus, and may be homologous with the nucleus accumbens (Martínez-Marcos *et al.*, 2005a, 2005b). Thus, the nucleus sphericus may be unique to squamates, may be unique to lepidosaurs (squamates and tuatara), or may be homologous with amygdalar regions in other vertebrates but have reorganized connections in squamates.

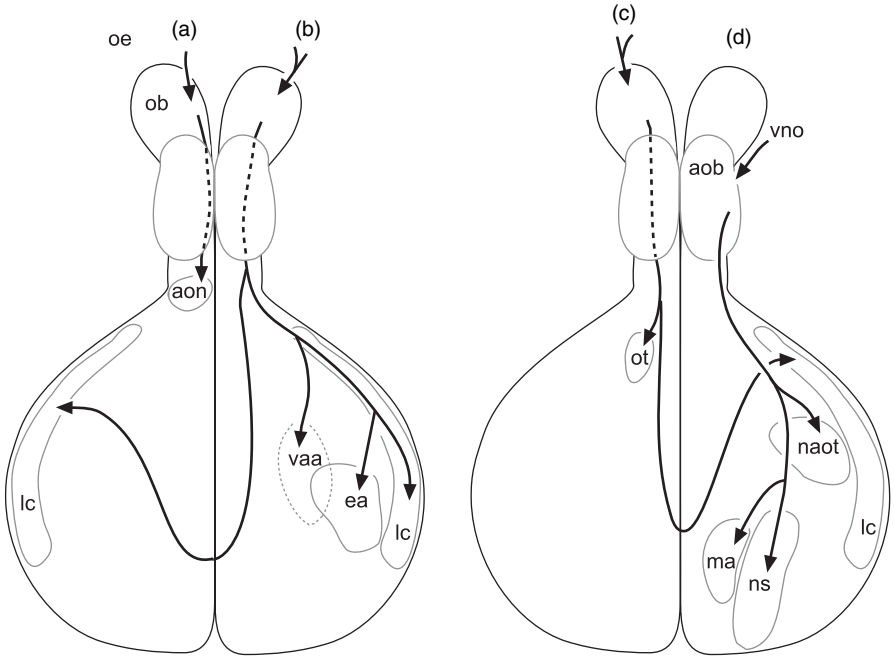

Figure 9 Schematic dorsal view of the forebrain in garter snakes, *Thamnophis sirtalis*. a, Projections of the medial olfactory tract. b, Projections of the lateral olfactory tract. c, Projections of the intermediate olfactory pathway. d, Projections of the accessory olfactory tract. aob, accessory olfactory bulb; aon, anterior olfactory nucleus; ea, external amygdala; lc, lateral cortex; ma, medial amygdala; naot, nucleus of the accessory olfactory tract; ns, nucleus sphericus; ob, olfactory bulb; oe, olfactory epithelium; ot, olfactory tubercle; vaa, ventral anterior amygdala. Based on Halpern (1976), Lanuza and Halpern (1997, 1998), and Lohman and Smeets (1993).

The medial amydala in garter snakes receives a direct projection from the accessory olfactory bulb, as well as indirect vomeronasal input via the nucleus sphericus. The olfactory bulb has an indirect projection as well, via the external and ventral anterior amygdaloid nuclei (Lanuza and Halpern, 1997, 1998; Martínez-Marcos *et al.*, 1999). Because the medial amygdala projects to the lateral posterior hypothalamic nucleus, which in turn projects to the hypoglossal nucleus, this pathway has been suggested to function in control of tongue-flicking in response to chemosensory input in snakes (Martínez-Marcos *et al.*, 2001).

Olfactory projections have also been examined in several lizards, including *Gekko gecko*. The lateral olfactory tract projects bilaterally to the entire length of the lateral cortex, as well as to the anterior olfactory nucleus, external amygdaloid nucleus, and perhaps the central amygdaloid nucleus. An intermediate olfactory tract projects to the olfactory tubercle and joins the lateral olfactory tract to project to the contralateral hemisphere. A short medial olfactory tract is present. Finally, an accessory olfactory tract projects ipsilaterally to the nucleus sphericus, external and central amygdaloid nuclei, and bed nucleus of the stria terminalis (Lohman and Smeets, 1993; Lohman *et al.*, 1988). In *Tupinambis teguixin*, the projections are similar, although the projections to the contralateral hemisphere differ somewhat between the two species (Lohman and Smeets, 1993). To our knowledge, an extrabulbar olfactory pathway has not been described in squamates.

The anti-peptide antisera often used to identify the terminal nerve in other vertebrates produce mixed results with squamates. In adult garter snakes (*Thamnophis sirtalis*), a GnRH-immunoreactive terminal nerve is present, with a discrete ganglion at the ventral border between the olfactory bulb and rostral telencephalon (Smith *et al.*, 1997). Intraventricular administration of a GnRH antagonist interferes with courtship behavior in these animals, although the relative contributions of the terminal nerve and central GnRH neurons to this effect cannot be determined (Smith and Mason, 1997). Among lizards, GnRH-immunoreactive cells and fibers are also present in the terminal nerve of adult *Eumeces laticeps* and *Sceloporus undulatus*, but not in adult *Anolis carolinensis* (Rosen *et al.*, 1997). In *Podarcis sicula*, GnRH-immunoreactive cells and fibers cannot be detected in a terminal nerve, nor in the olfactory epithelium and bulb, in either embryos or adults (D'Aniello *et al.*, 1994a; Masucci *et al.*, 1992). FMRFamide-immunoreactive cells and fibers are present in the terminal nerve during development in *Chalcides chalcides*, but not in adults (D'Aniello *et al.*, 2001). Overall, the available data indicate either that the immunoreactive characteristics of the terminal nerve in some squamate species differ from those in other jawed vertebrates, perhaps a way that varies with developmental stage, or that the nerve is not present at all developmental stages in all squamate species.

2.17.2.6.2.(iii) Crocodilians Crocodiles, alligators, caimans, and gharials are a relatively small group, comprising only 20–25 species. The nasal chemosensory systems have not been extensively studied in this group, and much of the information available concerning the role of chemoreception in behavior is reviewed by Weldon and Ferguson (1993).

The nares of crocodilians are closely situated on the dorsal portion of the snout and can protrude even while most of the animal is submerged under water, suggesting that olfactory cues may serve important functions in crocodilians. Crocodilians draw air through the nasal cavity through buccal oscillations that do not contribute to respiration (Gans and Clark, 1976). Electroencephalograph recordings from the olfactory bulb demonstrate activity coincident with buccal oscillations, demonstrating that this behavior is equivalent to sniffing in crocodilians (Huggins *et al.*, 1968; Naifeh *et al.*, 1970). Because of this demonstrated correlation, buccal pumping is used as a metric of olfactory sampling in some studies. For example, analysis of buccal pumping demonstrates that juvenile alligators (*Alligator mississippiensis*) respond to odorants from food (Weldon *et al.*, 1992). Other studies further demonstrate that olfactory cues play a role in localization of food (Scott and Weldon, 1990; Weldon *et al.*, 1990).

Crocodilians have prominent paracloacal and gular glands, which are suspected to play a role in territorial and sexual behavior (Weldon and Ferguson, 1993). Recent work has described the chemistry of the secretions from these glands (e.g., Garcia-Rubio *et al.*, 2002; Ibrahim *et al.*, 1998; Wheeler *et al.*, 1999; Yang *et al.*, 1999), but the behavioral significance of these compounds has not yet been elucidated. Behavioral observations suggest that crocodilians rub scent glands during courtship and nesting (Weldon and Ferguson (1993) and references therein), suggesting that pheromonal cues may play a role in crocodilian reproductive behavior.

The vomeronasal system has been lost in crocodilians. The vomeronasal organ begins to develop in the embryos of some alligators and crocodiles, but

regresses by the time of hatching (Parsons, 1959a). The accessory olfactory bulb is similarly present in crocodilian embryos but not adults (Parsons, 1967, 1970).

To our knowledge, the ultrastructure of the olfactory epithelium in crocodilians has not been described. The detailed anatomy of the olfactory bulb and tracts has been examined in young *A. mississippiensis* (Crosby, 1917). In these animals, clear laminae, including external and internal plexiform layers, are present. The glomeruli are surrounded by somata of periglomerular cells, which are clearly present. The mitral cells project primary dendrites into two or more glomeruli, but also possess secondary dendrites that extend laterally through the external plexiform layer. Somata in the external plexiform layer may belong to tufted cells, but could also belong to displaced mitral cells. The granule cell layer contains three classes of cells. The first are anaxonal intrinsic cells, with spiny dendrites that extend in all directions within the layer. The second are granule cells with spiny dendrites that project to the glomerular layer but do not seem to arborize inside glomeruli; Crosby (1917) called these 'stellate' cells. The axons of these cells enter the olfactory tracts and may project out of the olfactory bulb. The stellate cells have the smooth dendrites that arborize in glomeruli, and axons that project out of the olfactory bulb; Crosby (1917) called these cells "goblet" cells.

The central projections of the olfactory bulb have been described in *A. mississippiensis* based on Golgi-stained material (Crosby, 1917) and in *Caiman sklerops* based on a degenerating fiber stain (Scalia *et al.*, 1969). In *Alligator*, as in garter snakes, three centripetal tracts emerge from the olfactory bulb. The individual tracts could not be visualized in *Caiman*, but where the same target was noted in both species we will assume that the same tract carries the fibers to it. The lateral tract projects bilaterally to the lateral cortex, amygdala, and lateral portion of the olfactory peduncle. The medial tract projects to the anterior hippocampus and medial septum. The intermediate tract projects to the nucleus of the diagonal band of Broca and bilaterally to the olfactory tubercle. An additional small projection to the internal plexiform layer of the contralateral olfactory bulb was observed in *Caiman*.

Medina *et al.* (2005) report that Nile crocodiles (*Crocodylus niloticus*) possess a GnRH-immunoreactive terminal nerve, but a detailed description of the pathway has not been published. The terminal nerve of the spectacled caiman (*Caiman crocodilus*) displays FMRFamide-like immunoreactivity in embryos, but not adults (D'Aniello *et al.*, 1999, 2001).

2.17.2.6.2.(iv) Birds Although olfaction used to be considered unimportant or even absent in birds, birds possess a robust olfactory system that mediates many types of behavior. Notably, olfaction has been shown to play a role in food finding in brown kiwis (*Apteryx australis*; Wenzel, 1968, 1971), and in some, but not all, species of vultures (Graves, 1992; Houston, 1984), as well as in ravens (*Corvus corax*; Harriman and Berger, 1986), parrots (*Strigops habroptilus*; Hagelin, 2004), and procellariiforms, the group of Antarctic seabirds that includes shearwaters, petrels, and albatrosses (Hutchison and Wenzel, 1980). Some procellariid species are highly sensitive to specific odorants such as dimethyl sulfide and 3-methyl pyrazine that are associated with krill, an important and patchily distributed food source (Nevitt, 2000; Nevitt and Haberman, 2003; Nevitt *et al.*, 1995, 2004). Olfaction plays a role in both feeding and predator avoidance in chickens (reviewed in Jones and Roper, 1997).

Olfaction has also been implicated in homing and navigation by passerines, which may use stable features such as the presence of airborne hydrocarbons to orient within landscapes (reviewed in Wallraff, 2003, 2004). Nevitt and Bonadonna (2005) suggest that Procellariiforms may use dimethyl sulfide in a similar fashion for navigating to small islands in large open ocean areas.

The role of olfaction in reproduction has been examined in only a handful of species. Crested auklets (*Aethia cristatella*) produce a scent that is attractive to conspecifics, which humans perceive as resembling tangerine odor (Hagelin *et al.*, 2003). Antarctic prions, *Pachiptila desolata*, can discriminate between chemical cues from their partners and from other birds in the breeding colony, demonstrating that this species is capable of individual recognition based on odorant cues (Bonadonna and Nevitt, 2004).

Many vertebrates show learned preferences for odorants experienced before birth or hatching, as do chicks, *G. domesticus*, which could use such cues to recognize and orient to the nest (Sneddon *et al.*, 1998). Prions and petrels (Procellariidae), that nest in burrows and return to them at night, use olfactory cues to find their own burrow, but olfaction appears to be unimportant for nest recognition in diurnal and surface-nesting species (Bonadonna and Bretagnolle, 2002; Bonadonna *et al.*, 2001, 2003a, 2003b, 2004). The use of acoustic cues to recognize partners and chicks might attract avian

predators; thus, the use of chemical cues by some species may represent an adaptation for avoiding predation by other birds (Bonadonna *et al.*, 2003a). In some species, olfactory cues play an additional role in nesting: both European starlings (*Sturnus vulgaris*) and blue tits (*Parus caeruleus*) use olfactory cues to select plant leaves that are used as nest fumigants (Clark, 1991; Clark and Mason, 1985, 1987; Petit *et al.*, 2002).

Physiological studies demonstrate that the components of the olfactory system function similarly in birds and other groups of vertebrates. At the level of the olfactory epithelium and nerve, both excitatory and inhibitory responses can be observed in a wide range of odorants (Jung *et al.*, 2005; Shibuya and Tucker, 1967; Tucker, 1965). Similarly, single-unit recordings from the olfactory bulb demonstrate both excitatory and inhibitory responses to odorants (McKeegan, 2002; and references therein), and an electroencephalography study with chickens found no significant differences in responses to odorants relative to those recorded in mammals using the same technique (Oosawa *et al.*, 2000).

Birds lack a vomeronasal organ and accessory olfactory bulb (Huffman, 1963; Parsons, 1959b). The olfactory epithelium is located on a single spiral-shaped turbinate bone inside the nasal cavity, and air is drawn across it as the animal breathes in and out (Bang and Wenzel, 1985). The anatomy of the olfactory epithelium has been examined in members of five orders of birds (Anseriformes, Charadriiformes, Ciconiiformes, Columbiformes, and Galliformes), and all possess unusual olfactory receptor neurons that are capped with cilia surrounded by short microvilli (Bedini *et al.*, 1976; Brown and Beidler, 1966; Drenckhahn, 1970; Graziadei and Bannister, 1967; Matsuzaki *et al.*, 1982; Müller *et al.*, 1979; Okano and Kasuga, 1980).

Of the 20 000–23 000 genes in the genome of jungle fowl (*Gallus gallus*), 283 odorant receptor genes and ~100 odorant receptor pseudogenes have been identified (Hillier *et al.*, 2004); however, a study of domesticated chickens (*Gallus domesticus*) reported only 12 odorant receptor genes (Nef and Nef, 1997). It is not clear whether this large discrepancy is due to methodological differences, or to loss of genes as a result of domestication. The odorant receptor genes in galliforms are evolutionarily more closely related to those found in mammals than to those found in aquatic vertebrates, like teleost fishes (Niimura and Nei, 2005).

The size of the olfactory bulb relative to the brain varies considerably across birds (Bang and Cobb, 1968), and some species have small, conjoined bulbs whereas others have large, obvious olfactory bulbs (Nieuwenhuys, 1967). Lamination appears to be highly variable across taxa, with small, indistinct layers in species that have tiny olfactory bulbs (Nieuwenhuys, 1967) but clear cellular laminae with internal and external plexiform layers visible even in species with moderately sized olfactory bulbs, such as chickens and pigeons (McKeegan, 2002; Rieke and Wenzel, 1978). We are unaware of any Golgi studies of the olfactory bulbs in birds; thus, the cell types present and the details of cellular morphology are largely unknown. Rieke and Wenzel (1978) speculate that somata visible in the external plexiform layer of pigeons may belong to tufted cells.

An early study with pigeons (*Columba livia*) using a combination of electrophysiology and degenerating fiber stains demonstrated ipsilateral projections to the piriform cortex, hyperstriatum ventrale and the medial striatum, as well as projections to the contralateral globus pallidus and caudal portion of the medial striatum (Rieke and Wenzel, 1978; terminology after Reiner *et al.*, 2004). The authors of this study did not distinguish among the different olfactory tracts. The results of later study with the same species indicate that the medial olfactory tract projects ipsilaterally to the septum and to a region dorsal to this, that an intermediate tract projects to the olfactory tubercle and medial striatum, and that the lateral olfactory tract projects bilaterally to the piriform cortex and nucleus taeniae of the amygdala (Reiner and Karten, 1985; terminology after Reiner *et al.*, 2004). The authors note that the projection to the amygdala in birds is more restricted than in some other groups, including turtles, which could be related to the lack of a vomeronasal system in birds. The differences in results obtained in the two studies are difficult to understand, as they do not appear to be attributable to simple differences in nomenclature or mistaken identification of cell groups. In young ducks (*Anas platyrhynchos*), the medial olfactory tract projects to the dorsomedial hippocampus and superior frontal lamina, whereas the lateral tract terminates in the pallial–subpallial lamina, medial striatum, dorsomedial telencephalic wall, and posterior pallial amygdala (Teuchert *et al.*, 1986; terminology after Reiner *et al.*, 2004). An intermediate olfactory tract has not been described in this species.

The existence of an extrabulbar olfactory pathway in birds has not been directly demonstrated, but a study in which horseradish peroxidase was injected into the nasal cavity in ducks (*Anas platyrhynchos*) labeled a pathway that proceeded through the ventral olfactory bulb (Meyer *et al.*, 1987; von

Bartheld *et al.*, 1987). The terminations of these fibers were not observed, but ganglion cell bodies were not found and the injection is likely to have labeled primary olfactory receptor neurons.

As in other jawed vertebrates, the terminal nerve in birds arises from the nasal placode and, during development, demonstrates immunoreactivity to both GnRH and FMRFamide (Norgren and Lehman, 1991; Norgren *et al.*, 1992; Wirsig-Wiechmann, 1990; Yamamoto *et al.*, 1996). A FMRFamide-immunoreactive terminal nerve has been described in adult Japanese quail (*Coturnix japonica*), but the anatomy and chemical characteristics of the terminal nerve have not been studied in detail in adult birds (Fujii and Kobayashi, 1992).

2.17.2.6.2.(v) Turtles Turtles live in diverse habitats, ranging from completely terrestrial tortoises to fully aquatic sea turtles. Many freshwater species are semi-aquatic. Turtles sample the olfactory environment both on land and under water, and in both cases, sniffing involves throat movements that resemble those used by crocodilians and amphibians (Belkin, 1968; McCutcheon, 1943; Root, 1949). As an adaptation for prolonged diving, many species are remarkably tolerant of anoxia (Lutz and Milton, 2004). This trait makes turtles well suited for electrophysiological experiments, and many studies have used turtles as model animals for understanding general principles of olfactory system function in vertebrates. These studies will not be comprehensively reviewed here.

Sea turtles can swim thousands of miles to particular nesting beaches, and olfactory cues have been suggested to play a key role in this behavior. The available data indicate that olfactory-based homing cannot account for long-distance migration in turtles (reviewed in Lohmann *et al.*, 1999). However, some studies indicate that hatchlings may imprint on odorants specific to their local environment, suggesting that such cues could play a role in short-range orientation or selection of nesting sites (Grassman, 1993; Grassman and Owens, 1987; Grassman *et al.*, 1984). In addition, freshwater turtles (*Chrysemys picta*) can use chemical cues to discriminate water from home ponds versus that from ponds with and without conspecifics (Quinn and Graves, 1998).

The importance of chemical cues in foraging and feeding has not the subject of extensive study in turtles. Nevertheless, Honigmann (1921) showed that both aquatic and semi-aquatic species will bite at a bag filled with fish, but not at one filled with sand. Olfaction has also been shown to play a role in foraging in leatherback turtles, *Dermochelys coriacea*, in a laboratory setting (Constantino and Salmon, 2003).

Olfactory cues play a role in courtship and reproduction in turtles. Many turtles are endowed with secretory glands (Ehrenfeld and Ehrenfeld, 1973), although the behavioral significance of these secretions has not been thoroughly studied. Males of many species sniff or bob their heads when stimulated by odorants from female scent glands (e.g., Auffenberg, 1978; Kaufmann, 1992; Rose, 1970). Some species, such as the musk turtle *Sternotherus odoratus*, produce chemicals that probably serve as a deterrent or aposematic signal to predators, but could also function in intraspecific communication (Eisner *et al.*, 1977). The size of chin glands in male desert tortoises (*Gopherus agassizii*) is testosterone dependent, varying seasonally and with dominance status (Alberts *et al.*, 1994). Both males and females can discriminate individuals based on secretions from these glands (Alberts *et al.*, 1994). In male Berlandier's tortoise, *Gopherus berlandieri*, fatty acids from chin glands elicit aggressive behavior in males and cause females to approach and bob their heads at a model painted with these compounds (Rose, 1970; Rose *et al.*, 1969). In contrast, in desert tortoises (*Gopherus agassizii*), males prefer to use burrows scented with chin gland rubbings from conspecific males compared with untreated burrows (Bulova, 1997). Male stripe-necked terrapin (*Mauremys leprosa*) have been shown to avoid water conditioned by other males and prefer water conditioned by conspecific females, but only during the breeding season (Muñoz, 2004). The results of these studies clearly indicate that chemical signals play a role in social and reproductive behavior in some turtles.

The organization of the nasal cavity and vomeronasal organ varies considerably among species. In some, such as *Testudo* or *Emys*, the vomeronasal epithelium is not contained in a separate organ, but lies along the ventromedial wall or in grooves in the floor of the nasal cavity; the olfactory and vomeronasal regions of the nasal cavity are separated only by a slight horizontal ridge (Parsons, 1959b, 1959a). In loggerhead turtles, *Caretta caretta*, the vomeronasal epithelium is more widely distributed in the nasal cavity than is the olfactory epithelium (Saito *et al.*, 2000). On the other hand, in *Dipsochelys* and *Dermochelys coriacea*, the vomeronasal organ is a discrete structure that is encapsulated in bone and opens into the oral cavity (Gerlach, 2005). A comparison of axon counts indicates that olfactory receptor neurons outnumber vomeronasal receptor neurons in the Russian tortoise (*Testudo horsfieldii*), which is terrestrial, but

that two semi-aquatic species (*Chinemys reevesii* and *Mauremys japonica*) have more vomeronasal than olfactory receptor neurons (Hatanaka and Matsuzaki, 1993).

As in some other reptiles, the dendrites of the olfactory receptor neurons in Hermann's tortoise, *Testudo hermanni*, bear both cilia and numerous short microvilli (Delfino *et al.*, 1990). Like other tetrapods, turtles possess only microvillar vomeronasal receptor neurons (Graziadei and Tucker, 1970; Hatanaka *et al.*, 1982). Electrophysiological recordings from both the vomeronasal epithelium and accessory olfactory bulb in *Geoclemys reevesii* demonstrate that the vomeronasal system in turtles responds to general odorants with no inherent behavioral significance, such as amyl acetate, geraniol, cineole, and citral (Hatanaka and Matsuzaki, 1993; Hatanaka and Shibuya, 1989; Shoji *et al.*, 1993; Shoji and Kurihara, 1991). Recordings from dissociated vomeronasal receptor neurons in stinkpot turtles, *Sternotherus odoratus*, demonstrate that turtle vomeronasal cells also respond to a variety of complex natural odorants, including urine and musk from both males and females, as well as odorants derived from food pellets (Fadool *et al.*, 2001). $G\alpha_o$ is expressed in different vomeronasal receptor neurons than is $G\alpha_{i1-3}$, although the zonal segregation of expression seen in mammals does not occur in *Sternotherus* (Murphy *et al.*, 2001). In the same species, females show higher levels of $G\alpha_{i1-3}$ expression and lower levels of TRP2 immunoreactivity than do males (Murphy *et al.*, 2001), and odorant responses recorded from vomeronasal receptor neurons from females are larger than those from males (Fadool *et al.*, 2001). Taken together, these data demonstrate that the vomeronasal system in turtles responds to a wide range of chemicals, including cues that may be involved in intraspecific communication, and that the functioning of the system may be sexually dimorphic.

The turtle olfactory bulb is highly laminar, with both external and internal plexiform layers separating the cell layers (Johnston, 1915; Orrego, 1961). The glomeruli are surrounded by periglomerular cells (Orrego, 1961). Mitral cells usually extend primary dendrites into two glomeruli, and possess long secondary dendrites that project through the external plexiform layer (Mori *et al.*, 1981; Orrego, 1961). Tufted cells may be present; Johnston (1915) called these 'brush cells'. Two classes of granule cells are present, one of which has processes that arborize in glomeruli (Johnston, 1915; Orrego, 1961). As in frogs, the olfactory bulbs are fused in some species, with continuous layers and some neurites interacting across the midline (Skeen and Rolon, 1982).

As in other reptiles, three central olfactory tracts have been described in turtles. The medial olfactory tract projects ipsilaterally to the septum and to a medial cortical area that may be the homologue of the medial pallium/hippocampus of other vertebrates (Johnston, 1915; Reiner and Karten, 1985). The lateral olfactory tract has a massive bilateral projection to a lateral cortical area, and an intermediate olfactory tract that may be a subdivision of the lateral tract projects to the olfactory tubercle and the basal amygdaloid nucleus (Gamble, 1956; Reiner and Karten, 1985). In addition, a large olfactory projection to the entire pial surface of the amygdala was described in *Trachemys scripta* (Reiner and Karten, 1985). Given that the accessory olfactory bulb in turtles is sometimes included in injections or lesions of the main olfactory bulbs (Chkheidze and Belekhova, 2005; Gamble, 1956), the description of the large amygdalar projection in *Trachemys* may be due in part to inclusion of projections from the accessory olfactory bulb (see discussion in Eisthen, 1997). Because the separate projections of the accessory olfactory bulb in turtles have not been described, it is not clear whether the main and accessory olfactory systems project to different portions of the amygdala, as in other tetrapods (Chkheidze and Belekhova, 2005).

The development of the terminal nerve in turtles has been described by Johnston (1913) and Larsell (1917), who were able to visualize the nerve as it courses over the surface of the olfactory nerve due to its several conspicuous ganglia. To our knowledge, the histochemical characteristics of the nerve have not been examined in detail in turtles, although FMRFamide-immunoreactive cells and fibers do not appear to be present in or around peripheral olfactory structures in adult *Trachemys scripta* (D'Aniello *et al.*, 2001, 1999).

2.17.2.6.3 Mammals The comparative neurobiology of the olfactory system in mammals will not be described in detail here. Nevertheless, the textbook view of the organization of the vertebrate olfactory system typically includes many features that are unique to mammals, which should be noted by those interested in understanding the structure and function of the olfactory system in vertebrates in general. For example, the olfactory epithelium in mammals contains only ciliated olfactory receptor neurons (reviewed in Eisthen, 1992), whereas in other vertebrates, the morphology of olfactory receptor neurons varies considerably. As in other tetrapods, the vomeronasal receptor neurons in mammals are microvillar (Eisthen, 1992).

The organization of the olfactory bulb of mammals is similar to that of other tetrapods, with a distinct laminar organization that includes large plexiform layers. In mammals, the mitral cells possess a single primary dendrite that arborizes in one glomerulus, and prominent secondary dendrites that extend orthogonal to the primary dendrite through the external plexiform layer (reviewed in Eisthen, 1997; Nieuwenhuys, 1967). In addition to mitral cells, mammals possess tufted cells, a second class of output cell (Nieuwenhuys, 1967; Pinching and Powell, 1971). Although the somata of most tufted cells are found in the external plexiform layers, another group, the external tufted cells, have cell bodies in the glomerular layer; the glomerular layer also contains short-axon cells with no clear counterpart among nonmammalian vertebrates (Pinching and Powell, 1971). The lateral olfactory tract projects ipsilaterally, and not bilaterally as in other vertebrates (Skeen *et al.*, 1984). Mammals may lack a true medial olfactory tract that arises from the olfactory bulb; instead, the tract of the same name in mammals appears to arise from the anterior olfactory nucleus (Lohman and Lammers, 1967; Nieuwenhuys, 1967). The vomeronasal system is generally present in mammals, but has been lost in cetaceans as well as in some bats and primates (reviewed in The Vomeronasal Organ and Its Evolutionary Loss in Catarrhine Primates).

2.17.3 Conclusions

In this section, we integrate the preceding information, both to describe patterns of change and to consider the functional implications of these changes. In general, we will not cite references for information presented earlier, as details are provided in the sections pertaining to each taxonomic group.

2.17.3.1 Evolutionary Changes in the Organization of the Olfactory Epithelium

Before odorants contact the sensory receptor cells, they pass through a mucous layer. This mucus contains odorant binding proteins, which are known to be present in terrestrial mammals and in frogs. Interestingly, in *Xenopus*, the binding proteins are expressed in the principal cavity, which is used for detecting odorants in air, but not in the middle cavity, which is used for detecting odorants in water. Odorant binding proteins have been suggested to represent an adaptation for detecting odorants in air, to transport hydrophobic molecules through the mucous layer to the receptor neurons. Another possibility is that odorant binding proteins are too energetically expensive for use by aquatic vertebrates, as the hydrophilic proteins could easily dissolve in the water flowing over through the nasal sac (discussed in Eisthen, 2002). Although their presence in *Xenopus* and mammals suggests that odorant binding proteins should be broadly present in terrestrial tetrapods, Baldaccini *et al.* (1986) were unable to find binding proteins in birds (*Columba livia* and *Cairina moschata*) and turtles (*Testudo hermanni*), despite being able to sequence them from several mammalian species. Given that the odorant binding proteins in both *Xenopus* and mammals are lipocalins, it is surprising that these proteins have not been found in other classes of vertebrates. Perhaps different types of molecules are used as binding proteins in other groups of vertebrates, or perhaps the presence of these molecules in both *Xenopus* and mammals is convergent and not informative about tetrapods generally.

Although vomeronasal receptor neurons invariably terminate in microvilli, vertebrate olfactory receptor neurons are morphologically diverse; their phylogenetic distribution is shown in Figure 10. Researchers have long considered the possibility that the microvillar olfactory receptor

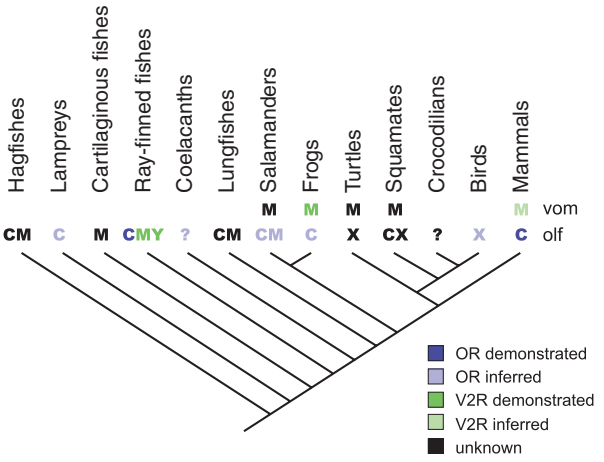

Figure 10 Phylogenetic distribution of receptor cell types and correlation with expression of olfactory (OR) and vomeronasal (V2R) receptor genes in the olfactory (olf) and vomeronasal (vom) epithelia. The expression of genes is demonstrated with electron microscopy; otherwise, it is inferred. Boldface letters indicate cell types: C, ciliated receptor neuron; M, microvillar receptor neuron; X, receptor neuron with both cilia and microvilli; Y, crypt-type receptor neuron. ? indicates that the morphology of the receptor neurons is unknown. Salamanders possess both ciliated and microvillar receptor neurons, but we do not yet know whether one or both express olfactory-type odorant receptor genes. Crocodilians, birds, and all fishes lack a vomeronasal organ. This diagram is simplified, as it assumes homogeneity within large taxonomic groups, such as teleost fishes. See text for references.

neurons in teleosts could be homologous with mammalian vomeronasal receptor neurons (discussed in Dulka, 1993; Eisthen, 1992). Recent data demonstrating that the olfactory epithelium of teleost fishes contains ciliated receptor neurons that express genes typical of olfactory receptor neurons, and microvillar neurons that express genes typical of vomeronasal receptor neurons may bolster this impression. Nevertheless, the expression of olfactory- or vomeronasal-typical genes may not correlate tightly with cell morphology (Figure 10). Further, if one assumes that the correlation applies to all craniates, then unlikely patterns are predicted to emerge. For example, although hagfish have both ciliated and microvillar olfactory receptor neurons, lampreys possess only ciliated olfactory receptor neurons, and those of sharks and skates terminate in microvilli. If the association between receptor cell morphology and gene expression arose with the earliest craniates, we would expect to see only olfactory-type genes expressed in lampreys, and only vomeronasal-type genes expressed in sharks and skates. Thus, the apparent correlation between receptor cell morphology and gene expression observed in teleosts and mammals may be a coincidence, may represent examples of convergent evolution, or may represent a derived condition that pertains only to bony vertebrates.

Alternatively, the morphological categories we are using may be too crude. For example, distinct subsets of microvillar and ciliated olfactory receptor neurons project to different regions of the olfactory bulb in channel catfish, *Ictalurus punctatus* (Morita and Finger, 1998). Similarly, in goldfish (*Carassius auratus*), the microvillar receptor neurons that are immunoreactive for $G\alpha_q$ are shorter and have more stiff microvilli than other microvillar receptor neurons (Hansen *et al.*, 2004). If 'ciliated' and 'microvillar' receptor neurons in vertebrates actually comprise several subclasses of cells, cell morphology and receptor gene expression may be tightly correlated within specific subclasses of receptor neurons. If so, some of the vomeronasal-type microvillar receptor neurons in goldfish could be homologous with vomeronasal receptor neurons in mammals. On the other hand, microvillar olfactory and vomeronasal receptor neurons often contain centrioles and basal bodies, suggesting that they derive evolutionarily from ciliated cells (Delfino *et al.*, 1990). If ciliogenesis is suppressed in microvillar cells (Kolnberger and Altner, 1971; Pyatkina, 1976), then receptor cell morphology might be evolutionarily labile, with no fixed relationship between receptor cell morphology and receptor gene expression.

2.17.3.2 Evolutionary Changes in the Organization of the Olfactory Bulbs

The organization of olfactory bulb circuits differs among vertebrate groups. Figure 11 illustrates the phylogenetic distribution of the cellular elements of the olfactory bulb. In interpreting the significance of these patterns, it is important to note that we assigned names to the different cell types based on their morphology alone, and did so independently of the names used by the authors of the source material. Thus, we use the term 'stellate cell' for any cells

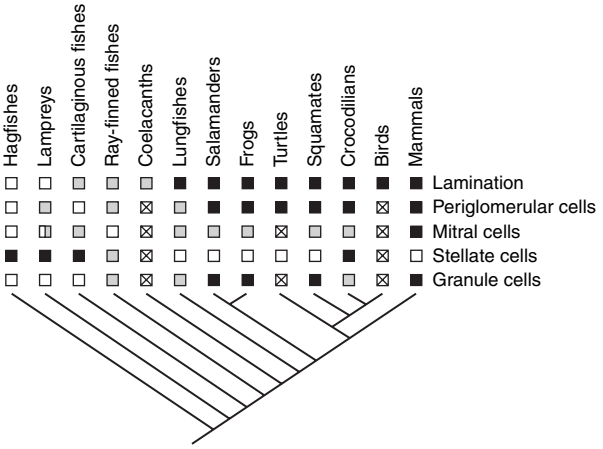

Figure 11 Phylogenetic distribution of cellular elements of olfactory bulb circuitry. The hypothesized ancestral condition, illustrated by hagfish, includes a low degree of lamination, with cell bodies frequently located across laminar boundaries and a lack of plexiform layers; periglomerular cells absent; mitral cells with primary dendrites that arborize in more than one glomerulus and no secondary (basal) dendrites; stellate cells present, with smooth dendrites that arborize in glomeruli; and granule cells bearing smooth dendrites, with an axon present. Boxes with crosses indicate cases for which information is unavailable. Lamination: white box = low degree of lamination, with cell bodies frequently located across laminar boundaries and a lack of plexiform layers; gray = moderate degree of lamination, with cell bodies confined to clear layers, and a lack of plexiform layers; black = high degree of lamination, with cell bodies confined to clear layers, separated by one or more plexiform layers. Periglomerular cells: white = absent; gray = ambiguous condition, in which candidate periglomerular cells have been described by some authors; black = periglomerular cells present. Mitral cells: white = primary dendrites arborize in more than one glomerulus, with no secondary dendrites; white/gray = primary dendrites arborize in only one glomerulus, with no secondary dendrites; gray = primary dendrites arborize in more than one glomerulus, with secondary dendrites that extend laterally; black = primary dendrites arborize in only one glomerulus, with secondary dendrites that extend laterally. Stellate cells: white = absent; gray = stellate cells present, with spiny dendrites that arborize in glomeruli; black = stellate cells present, with smooth dendrites that arborize in glomeruli. Granule cells: white = smooth dendrites, with an axon present; gray = -spiny dendrites, with axon present; black = spiny dendrites, with no axon. See text for references.

with a soma in the deep layers of the bulb, and with multiple dendrites that arborize in glomeruli. The somata of stellate cells are generally star-shaped, as the name implies. A 'granule cell' is a cell with an oval-shaped soma located in a deep layer of the bulb, and with dendrites that project upward but that do not enter or arborize in glomeruli. The dendrites of granule cells generally bear spines, whereas those of stellate cells are generally smooth. In many groups, both types of cells have a long axon. 'Periglomerular' cells have a soma in the glomerular layer, with dendrites that arborize in several glomeruli. In many groups, these cells have an axon that projects at least to deeper layers of the bulb. Ideally, additional criteria would be used to recognize cell types, such as data concerning the neurotransmitter characteristics of the cells. Unfortunately, such data are available for an extremely limited set of species, and cannot be used for broad phylogenetic comparisons. Thus, the categories we are using are quite broad, and in at least some groups probably encompass several recognizably different types of cells; for example, Golgi data indicate that multiple classes of mitral cells are present in some animals, and histochemical data indicate that several types of periglomerular cells are present in some species.

With these caveats in mind, the pattern depicted in Figure 11 indicates that the organization of the olfactory bulb did not undergo any sudden, dramatic shifts over the course of vertebrate evolution. Rather, changes in organization occurred as a series of steps. Laminar organization of brain structures is generally regarded as indicative of multiple stages of integration, with cells in one layer receiving processed input from cells in other layers and then processing these signals in more extensive ways. What are the functional consequences of the almost complete lack of lamination observed in hagfish or lampreys, or the high degree found in squamates or mammals? It is difficult to make predictions based on this feature alone, particularly because the numbers of cell types with axons that project to secondary processing areas differs considerably among these groups. Perhaps more processing occurs in the olfactory bulbs in some animals, and in secondary olfactory regions in others.

The textbook view of a mitral cell is one with a single primary dendrite that extends to one glomerulus, and prominent secondary dendrites that extend laterally to interact with dendrites of granule cells as well as secondary dendrites of other mitral cells. Nevertheless, this type of mitral cell is present only in mammals, and in most vertebrates, mitral cells have multiple primary and secondary dendrites. The breadth of inputs to mitral cells therefore differs considerably among groups. In mammals, each olfactory receptor neuron is believed to express only one odorant receptor gene, and receptor neurons that express the same gene project to the same glomerulus (reviewed in Mombaerts, 2004). Thus, mitral cells with dendrites in a single glomerulus receive inputs from a homogeneous population of receptor neurons. In contrast, olfactory receptor neurons in teleost fishes may express more than one receptor gene (Ngai *et al.*, 1993a; Speca *et al.*, 1999), and mitral cells in these animals extend dendrites to several glomeruli. Perhaps these glomeruli receive inputs from receptor neurons that express one receptor gene in common, in which case the type of coding occurring in the olfactory bulbs of teleosts and mammals may be similar. If not, the nature or location of odorant information processing in teleosts may differ considerably from that in mammals, which seems quite possible given that teleosts possess stellate cells, which mammals lack, and that the stellate and granule cells in teleosts have long axons that may project to secondary olfactory regions in the telencephalon.

Other aspects of bulbar circuitry differ among groups, although the functional consequences are not easy to predict. For example, morphologically distinct periglomerular cells are present only in tetrapods, but other cells, such as the displaced mitral cells in the glomerular layer of hagfish and lampreys, or even stellate cells, may serve similar functions. Similarly, a dorsal commissure connecting the two olfactory bulbs is unique to hagfish and lampreys, but other types of connections between the bulbs exist in other groups. For example, in frogs and some turtles and birds, the two olfactory bulbs are fused across the midline, with mitral and granule cell dendrites apparently integrating inputs from both sides. In other animals, such as the hedgehog *Erinaceus europaeus*, the olfactory bulb projects ipsilaterally to the anterior olfactory nucleus, which sends fibers to the mitral cell layer of the contralateral olfactory bulb (De Carlos *et al.*, 1989). These different anatomical arrangements may facilitate integration of inputs to the two nares, or perhaps bilateral comparison of inputs to enhance localization of odorant sources.

Granule cells lack dendritic spines in hagfish, lampreys, and cartilaginous fishes, and functionally equivalent circuitry is probably lacking. The presence of spines varies even within groups: for example, although granule cell dendrites are spiny in most amphibians, Herrick's (1931) studies indicate that the dendrites are smooth in mudpuppies

(*Necturus*). What are the functional consequences of this diversity? Given that dendritic spines are often involved in plasticity in other regions of the central nervous system, does this suggest that olfactory bulb circuits in animals lacking spines are more hard-wired? Alternatively, or in addition, perhaps less compartmentalization of processing occurs in the olfactory bulbs of animals with granule cells that lack dendritic spines (e.g., Woolf *et al.*, 1991). Finally, additional types of output cells have been described in some animals, such as the ruffed cells present in teleost olfactory bulbs, or the tufted cells present in reptiles and mammals. Without intensive electrophysiological and neurochemical studies of the olfactory bulb circuits in diverse vertebrates, the functional significance of these differences in organization are likely to remain mysterious. Given that we also lack detailed psychophysical data concerning the relative capabilities of the olfactory system in diverse vertebrates, the behavioral consequences of differences in circuitry cannot be predicted.

2.17.3.3 Evolutionary Changes in the Organization of Central Olfactory Projections

Broad patterns of change in the organization of central olfactory pathways are illustrated in Figure 12. Most vertebrates possess a medial olfactory tract that projects to the septum. The tract has been lost in mammals and may also be lost in cartilaginous fishes, although the central projections in this group must be examined using modern tract-tract methods before strong conclusions can be drawn. In tetrapods, the tract may acquire a projection to the medial pallium/hippocampus. Such a projection may also be present in ray-finned fishes, but given the confusion concerning pallial homologies in this group, we cannot reach a conclusion concerning this matter at present. Nevertheless, the medial pallium/hippocampus is generally involved in memory and spatial perception, and one might expect that olfactory input to this region would be behaviorally important for many vertebrates.

In general, a lateral olfactory tract is present and projects bilaterally to lateral and dorsal pallial or cortical areas. Although it is tempting to interpret this connectivity as a conserved feature that must be critical for processing olfactory information in all vertebrates, in many animals the homologies of pallial areas are based largely on their receipt of olfactory input. Thus, it would be circular to argue that this projection is conserved or that the lateral olfactory tract projects to homologous areas in diverse vertebrates. One clear trend is that the

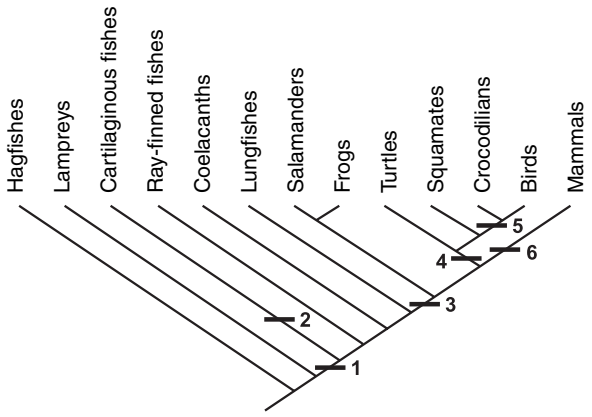

Figure 12 Evolutionary changes in the central projections of the olfactory bulbs. The hypothesized ancestral condition includes the presence of a lateral olfactory tract that projects bilaterally to lateral pallial/cortical areas and the striatum; the presence of a medial olfactory tract that projects ipsilaterally to the septum; and an extrabulbar olfactory pathway. Numbers indicate hypothesized changes in connectivity. 1, Reduction in the extent of projections of the lateral olfactory tracts. 2, Possible loss of the medial olfactory tract and bilateral projections of the lateral tract. 3, Origin of a distinct vomeronasal system, including an accessory olfactory tract that projects to the amygdala. Origin of an olfactory projection to separate portions of the amygdala via the lateral olfactory tract. Origin of an olfactory projection to the medial pallium / hippocampus via the medial olfactory tract. 4, Origin of an intermediate olfactory tract that projects to the olfactory tubercle, and loss of olfactory projection to the striatum via the lateral olfactory tract. 5, Loss of the vomeronasal system. 6, Loss of the medial olfactory tract and the contralateral projection of the lateral olfactory tract. See text for references.

lateral olfactory tract has extensive bilateral projections to both dorsal and ventral telencephalic regions in hagfish and lampreys, and that these projections are more restricted in jawed vertebrates. In addition, the lateral olfactory tract projects to the striatum in most groups discussed in this review, but not in reptiles; instead, an intermediate olfactory tract projects to the olfactory tubercle in the ventral striatum. This shift in connectivity suggests that the intermediate olfactory tract may be a branch of the lateral olfactory tract, or may have arisen from it evolutionarily. Some support for this idea comes from data demonstrating that the intermediate and lateral olfactory tracts project together to the contralateral hemisphere in snakes (Lanuza and Halpern, 1998), and that the two tracts run in partial continuity with each other through the rostral forebrain in turtles (Reiner and Karten, 1985).

A discrete vomeronasal system, including an accessory olfactory bulb and tract, is present only in tetrapods. The main central target of the accessory olfactory tract is the amygdala. The lateral

olfactory tract also projects to the amygdala, but the specific regions of the amygdala that receive input from the lateral and accessory olfactory tracts show little or no overlap in the species studied to date. Clear olfactory projections to the amygdala have been recognized only in tetrapods; thus, the origin of an olfactory bulb projection to the amygdala correlates roughly with the origin of the vomeronasal system. Given that the portions of the amygdala that receive olfactory and vomeronasal input are interconnected (reviewed in Halpern and Martínez-Marcos, 2003), perhaps this olfactory projection arose to facilitate integration of information from the two systems. If so, integration of chemosensory inputs cannot be the only current function of the olfactory projection to the amygdala, as this projection is retained in crocodilians and birds, which have lost the vomeronasal system. An olfactory projection to the amygdala may also exist in ray-finned fishes, but the homologies of possible amygdala-equivalent areas in ray-finned fishes are controversial (reviewed in Northcutt, 2006). Given that the vomeronasal-like and olfactory-like receptor neurons in teleosts project to different portions of the olfactory bulb, perhaps tracing the central projections of these two regions would provide new insight into the organization of the amygdala in teleosts.

2.17.3.4 Evolution of Vertebrate Olfactory Subsystems

A common assertion is that the olfactory system is phylogenetically ancient, or that olfaction is the oldest sensory system. The basis of such statements is unclear. Olfactory systems in animals in several phyla, including nematodes, mollusks, arthropods, and vertebrates, possess olfactory systems with similar features, but these features probably arose independently in each group, in response to similar constraints and as adaptations for similar tasks (Eisthen, 2002). Perhaps such statements simply indicate that the ability to sense chemicals in the external environment is widespread among animals, although this ability is by no means restricted to metazoans. A third possibility is that such statements are an oblique reference to a long-standing idea that among vertebrates, the forebrain was originally an olfactory structure, and that inputs from other sensory systems 'invaded' the telencephalon via thalamus over the course of vertebrate evolution (Ariëns-Kappers *et al.*, 1936; Edinger, 1904; Herrick, 1948). As described above, the olfactory projections in hagfish and lampreys distribute to larger portions of the telencephalon than do those in jawed vertebrates (Northcutt and Puzdrowski, 1988; Wicht and Northcutt, 1993). Overall, however, the available data clearly demonstrate that the invasion scenario is incorrect (reviewed in Northcutt, 1981).

Two large-scale changes in the organization of the olfactory system have occurred over the course of vertebrate evolution: the origin of the terminal nerve, and the origin of the vomeronasal system. Both hagfish and lampreys appear to lack a terminal nerve, as no projection has been described that comprises a peripheral ganglion and fibers that display the types of immunoreactivity that characterize the terminal nerve (reviewed in Wirsig-Wiechmann *et al.*, 2002a). If so, then the terminal nerve arose in jawed vertebrates. As described above, studies of the terminal nerve ganglion and retina in teleost fishes strongly indicate that the terminal nerve serves a modulatory function, and studies with salamanders demonstrate that terminal nerve-derived peptides modulate activity in the olfactory epithelium. In teleost fishes, the terminal nerve ganglion receives input from the olfactory, visual, and somatosensory systems. In amphibians, the extent to which terminal nerve peptides modulate olfactory epithelial activity depends on the animal's physiological or behavioral state, as both hunger and reproductive condition appear to play a role. Similar centrifugal modulation occurs in the retina and cochlea of many vertebrates (reviewed in Akopian, 2000; Manley, 2000, 2001). Do hagfish and lampreys lack this modulation, or do they possess alternate mechanisms for regulating olfactory responses with regard to their physiological needs? What are the overall functional consequences for animals that possess or lack such mechanisms? Perhaps the more active foraging and courting behaviors of jawed vertebrates benefit from more central control of olfactory epithelial function, which is unnecessary in hagfishes and lampreys.

A discrete vomeronasal system is present only in tetrapods, but recent work, described above, clearly indicates that the elements of the vomeronasal system are present in teleost fishes: the olfactory and vomeronasal receptor genes, as well as their associated G-proteins and ion channels, are expressed in different receptor neurons in the olfactory epithelium. In goldfish (*Carassius auratus*), the vomeronasal-type elements are expressed in microvillar olfactory receptor neurons, whereas the olfactory-type elements are expressed in ciliated receptor neurons (Hansen *et al.*, 2004). Although these morphological cell types are superficially similar to the vomeronasal and olfactory receptor neurons in mammals, as discussed above, it appears

unlikely that the two cell types in teleosts simply segregated into two epithelia to give rise to a separate vomeronasal organ (Eisthen, 2004). In zebra fish (*Danio rerio*), the two classes of receptor neurons send their axons to different portions of the olfactory bulb (Sato *et al.*, 2005), an arrangement similar to that in tetrapods, in which the olfactory and vomeronasal receptor neurons send axons to distinct olfactory and accessory olfactory bulbs. In tetrapods, the projections of the olfactory and accessory olfactory bulb differ, and the next step is to determine whether the portions of the olfactory bulb that receive input from the two cell types in teleosts also have distinct projections. If so, it would appear that teleost fishes have a complete vomeronasal system intermingled with the olfactory system. It would be interesting to know whether the same is true of other classes of fishes; perhaps the vomeronasal system has been present since the origin of vertebrates, and only became separate from the olfactory system in tetrapods. Because the functional differences between the olfactory and vomeronasal systems are unclear (reviewed in Baxi *et al.*, 2006; Halpern and Martínez-Marcos, 2003), it is difficult to speculate about the causes or consequences of the origin of a separate vomeronasal system in tetrapods.

Acknowledgments

The authors thank Anne Hansen for providing them with the lovely electron micrographs in Figure 6. Their research is supported by a grant from the National Institutes of Health (DC05366).
